Answer: B This patient likely has undiagnosed HIV infection and *Pneumocystis* pneumonia based on the symptoms and presence of thrush. Patients presenting with *Pneumocystis* pneumonia can have a normal chest x-ray (CXR) and normal pulse oximetry or arterial oxygenation at rest. Even in patients with a normal CXR, a CT scan of the chest will invariably show infiltrates, as illustrated in Figure 341-2. PCR-based assays have a high sensitivity but the specificity does not approach 100% as it can also be positive in individuals who are colonized or subclinically infected with *Pneumocystis*, but do not have *Pneumocystis* pneumonia and do not require specific anti-*Pneumocystis* therapy. Pneumocystis cannot be cultured, so definitive diagnosis depends on direct detection of the organism in a clinical sample, usually an induced sputum or bronchoalveolar lavage sample. Bronchoscopy with bronchoalveolar lavage has a >90% sensitivity for *Pneumocystis* pneumonia and is usually the definitive diagnostic procedure for *Pneumocystis* pneumonia. Prior to the AIDS epidemic and the demonstration of the utility of bronchoscopy, open lung biopsy was often required to make the diagnosis, but currently it is rarely necessary; negative results by bronchoscopy with BAL is sufficient to rule out *Pneumocystis* pneumonia in most circumstances.

2. A 25 year old female with a history of prior intravenous drug use comes in with a 1 week history of fever and a non-productive cough. CXR shows diffuse bilateral infiltrates. Resting PaO_2 at presentation is 96 mm Hg with an A-a gradient of 15 mm Hg. A rapid HIV test is positive. An induced sputum stain for *Pneumocystis* is positive, and the patient is started on trimethoprim-sulfamethoxazole, 2 double strength tables 3 times a day. She is sent home to be followed in clinic. Three days later she returns complaining of increasing shortness of breath with walking. Resting PaO_2 has decreased to 86 mm Hg, with an A-a gradient of 30 mm Hg. What is the most appropriate management course for this patient?

A. Discontinue the trimethoprim-sulfamethoxazole and begin pentamidine.
B. Discontinue the trimethoprim-sulfamethoxazole and begin clindamycin-primaquine.
C. Bronchoscope the patient to rule out other infections, and evaluate the patient for pulmonary emboli.
D. Begin prednisone 40 mg/day in addition to the trimethoprim-sulfamethoxazole.
E. Continue the trimethoprim-sulfamethoxazole; no change in therapy is needed.

Answer: E Deterioration in oxygenation at day 3 to 4 after start of therapy is common and expected in patients with PCP and does not signify clinical failure. Thus there is no reason to change therapy to an alternative regimen, or to search for alternative diagnoses at this point. While prednisone has been shown to decrease the frequency of deterioration in oxygenation in patients with PCP, a large randomized trial found that clinical benefit in terms of respiratory failure and survival outcome was limited to patients with moderate to severe disease, defined as a $PaO_2 < 70$ mm Hg or an A-a gradient >35 mm Hg. Moreover, addition of prednisone after 3 days of specific anti-*Pneumocystis* therapy has not been shown to be beneficial.

3. A 38 year old male with a recent history of thrush is admitted with a fever and non-productive cough. He is diagnosed with HIV infection and *Pneumocystis* pneumonia, and is started on trimethoprim-sulfamethoxazole. He would like to start anti-HIV medications soon. How should his antiretroviral therapy be managed?

A. Initiate HAART 2 months after discontinuation of anti-*Pneumocystis* therapy.
B. Initiate HAART immediately if HIV plasma viral load is >100,000 copies/ml, and 2 months after discontinuation of anti-*Pneumocystis* therapy if HIV plasma viral load is ≤100,000 copies/ml.
C. Timing of HAART should be based on the CD4 count. If the CD4 count is ≤350 cells/mm^3, HAART should be initiated within 1 month of completion of therapy. If the CD4 count is >350 cells/mm^3, therapy can be deferred until the cell count drops below that level.
D. Initiate HAART within 2 weeks of starting anti-*Pneumocystis* therapy if possible.
E. Don't initiate HAART until the CXR has normalized to minimize the risk of developing immune reconstitution inflammatory syndrome (IRIS).

Answer: D A randomized trial in patients with an opportunistic infection, 63% of whom had *Pneumocystis* pneumonia, found that initiation of HAART early (~12 days) vs. late (~45 days) after the start of therapy for the opportunistic infection was associated with a lower risk of AIDS progression or death. Patients with *Pneumocystis* pneumonia should be started on HAART regardless of the CD4 count or viral load, since they have already shown that their immune systems are severely compromised; without HAART or anti-*Pneumocystis* prophylaxis they are at high risk for recurrence of *Pneumocystis* pneumonia. Of note, most patients diagnosed with *Pneumocystis* pneumonia will have a CD4 count under 200 cells/mm^3. While cases of IRIS in the setting of *Pneumocystis* pneumonia have been reported, the incidence appears to be relatively low and rarely appears to be life-threatening; in the randomized trial noted above, the incidence of IRIS in patients with *Pneumocystis* pneumonia was 7.3%.

4. A patient who received a renal transplant 6 months ago and is receiving mycophenolate mofetil, cyclosporine, and prednisone for chronic immunosuppression is diagnosed with *Pneumocystis* pneumonia. This is the fourth renal transplant patient diagnosed with *Pneumocystis* pneumonia during the past year. Renal transplant patients at this center do not routinely receive anti-*Pneumocystis* prophylaxis because no cases of *Pneumocystis* pneumonia were seen in the prior ten years. What is the best management strategy for stopping this outbreak of *Pneumocystis* pneumonia?

A. Place the patient on respiratory isolation to prevent spread of the organism to other transplant patients.
B. Clean the walls, floors, and ceilings of the patient rooms in the clinic and inpatient service with bleach to eliminate the source of *Pneumocystis*.
C. Have the patients at risk for infection wash daily with a povidone-iodine antiseptic solution to minimize colonization with *Pneumocystis*.
D. Begin prophylaxis with trimethoprim-sulfamethoxazole in all transplant patients for at least 6 months, and longer for high risk patients (e.g. those requiring additional immunosuppression for graft rejection).
E. Begin prophylaxis with clindamycin-pyrimethamine in all transplant patients for at least 4 months, and longer for high risk patients (e.g. those requiring additional immunosuppression for graft rejection).

Answer: D Outbreaks of *Pneumocystis* pneumonia have been reported from multiple renal transplant centers over the past 10 years. As demonstrated in molecular typing studies, these outbreaks are caused by a single or a limited number of strains of *Pneumocystis* at each center. This strongly implies recent transmission of the infection, and potential acquisition as a nosocomial infection. Current data suggest that *Pneumocystis* is acquired from other humans via transmission by the respiratory route. There is no evidence for an environmental reservoir, thus cleaning a room will not eliminate the sources of infection. Although colonization or subclinical infection of the respiratory tract with *Pneumocystis* has been documented by sensitive PCR-based methods, there is no evidence that the skin is colonized, and thus washing with povidone-iodine antiseptic solution will not eliminate potential reservoirs for this specific organism. While it is logical to utilize respiratory isolation to prevent the spread of *Pneumocystis*, there are no data to demonstrate that this is an effective strategy to halt an outbreak. Infection may be spread during the incubation period, which in animal models, can be 8-12 weeks before the development of severe pneumonia. Clindamycin-pyrimethamine has not been demonstrated to have activity in either treatment or prophylaxis of *Pneumocystis* pneumonia. Trimethoprim-sulfamethoxazole is a highly effective prophylactic regimen and institution of prophylaxis with trimethoprim-sulfamethoxazole has been successful in halting the outbreaks of *Pneumocystis* pneumonia reported to date.

5. A 35 year-old female comes in with a headache and weakness in her right arm. An MRI scan shows multiple ring-enhancing lesions. Her anti-toxoplasma IgG antibody test is positive, but her IgM is negative. Cerebrospinal fluid is positive for *Toxoplasma* by PCR. Her HIV test is positive, and her baseline labs include a CD4 count of 27 cells/mm^3 and an HIV viral load of 42,500 copies/ml. The patient noted that she had received trimethoprim-sulfamethoxazole many years ago for a urinary tract infection and said she thought she developed a rash around her elbows but did complete her therapy. She is started on pyrimethamine-sulfadiazine-leucovorin for treatment of CNS toxoplasmosis. How should anti-*Pneumocystis* prophylaxis be managed in this patient?

A. No specific anti-*Pneumocystis* prophylaxis is required.
B. Begin dapsone 100 mg/day since she may have an allergy to trimethoprim-sulfamethoxazole.
C. Begin atovaquone 1,500 mg per day since she may have an allergy to trimethoprim-sulfamethoxazole and patients with sulfa allergies are frequently allergic to dapsone.
D. Begin azithromycin, 1,200 mg per week, to provide prophylaxis for both *Pneumocystis* and *Mycobacterium avium* complex.
E. Begin trimethoprim-sulfamethoxazole, one double-strength daily; change to dapsone if the patient develops a rash.

Answer: A This severely immunocompromised patient with HIV infection and toxoplasmosis is at high risk for *Pneumocystis* pneumonia based on her CD4 count. Although she describes a possible rash during prior treatment with trimethoprim-sulfamethoxazole, a rash limited to the elbows would be unusual for a drug reaction, and reactions to sulfamethoxazole, the component that appears to be most commonly responsible for reactions to trimethoprim-sulfamethoxazole, are rarely immediate or life-threatening. Thus therapy with a sulfa drug is not contraindicated, and the patient was started on pyrimethamine-sulfadiazine-leucovorin for treatment of toxoplasmosis. Pyrimethamine and sulfadiazine target the same enzymes as trimethoprim and sulfamethoxazole (dihydrofolate reductase and dihydropteroate synthase, respectively), and studies have shown that patients receiving pyrimethamine-sulfadiazine-leucovorin are at low risk for developing *Pneumocystis* pneumonia and thus do not require additional prophylaxis. While azithromycin prophylaxis should be started in this patient due to the low CD4 count, it has not been studied as an anti-*Pneumocystis* agent and thus additional prophylaxis for *Pneumocystis* would be required if it were indicated.

342

MYCETOMA

D. P. KONTOYIANNIS

DEFINITION

Mycetoma (a tumor produced by fungi) was first described in 1842 in the Madura district of India, hence the terms "Madura foot," "maduromycosis," and "maduromycetoma." However, there is evidence of its existence from as far back as the Byzantine era and ancient India.

Mycetoma is a chronic, slowly progressive infection that starts in the subcutaneous tissue and spreads across tissue planes to contiguous structures. The disease has diverse etiology; also, the offending organism is inoculated into the subcutaneous tissues by trauma typically associated with soil contamination. The hallmarks of mycetoma are the presence of "grains" that consist of colonies of the infectious organism and chronically draining sinus tracts. There is some confusion in the literature, however, because the term pulmonary mycetoma is used inappropriately to describe fungus balls typically caused by *Aspergillus* species that colonize a preexisting lung cavity; the term *aspergilloma* is more appropriate for this entity, the pathogenesis of which is distinctly different from that of true mycetoma.

The Pathogen

Two groups of soil-inhabiting pathogens, each of which accounts for approximately 50% of the cases, cause mycetoma: (1) the filamentous aerobic actinomycetes, hence the term actinomycetoma, and (2) a wide range of saprophytic soil and woody plant fungi, hence the term eumycetoma. Eumycetoma accounts for approximately 50% of cases of mycetoma.[1,2]

A variety of *Nocardia* species (e.g., *Nocardia brasiliensis, Nocardia asteroides*), *Actinomadura* species (e.g., *Actinomadura pelletierii, Actinomadura madurae*), and *Streptomyces* species (e.g., *Streptomyces somaliensis*) have been reported to cause actinomycetoma. Even more numerous are the agents that cause eumycetoma, such as *Madurella* species (e.g., *Madurella mycetomatis* causes 70% of all cases of eumycetoma,), which are probably the most prevalent mycetoma-causative fungal species worldwide. Other eumycetoma include *Fusarium* species, *Acremonium* species, *Pseudallescheria boydii, Exophiala* species, and *Curvularia* species. There is controversy about whether the various dermatophytes and *Aspergillus* species can cause mycetoma. Eumycetoma is often further characterized on the basis of the color of the grains; specifically, white- to yellow-grain mycetomas (white piedra) are typically caused by hyalohyphomycetes (e.g., *P. boydii*, *Fusarium* species, *Acremonium* species), and black-grain eumycetomas (black piedra) are caused by *Madurella* species and other less common fungi. However, the geographic distribution of the fungi that cause black grain eumycetoma is variable.

EPIDEMIOLOGY

Although mycetoma has a global distribution, it occurs primarily in the tropical and, to a lesser extent, the temperate zones. More specifically, the infection is quite prevalent in India, Mexico, Central America, South America, the Middle East, and especially sub-Saharan Africa (the "mycetoma belt"); Sudan has a particularly high burden of mycetoma. Indigenously acquired mycetoma is sporadic in North America and Europe. However, the globalization of tourism and the increase in immigration from countries of high endemicity of mycetoma to the western countries necessitates awareness of this entity, even in the developed word.

The relative frequency of actinomycetoma and eumycetoma differs among geographic areas. Hence, eumycetoma is more common in India and Africa, and actinomycetoma is more common in Central and South America. Furthermore, the causative agents of mycetoma differ in their geographic distribution. For example, *Scedosporium apiospermum* (*P. boydii*) is the most common agent of mycetoma in North America, and *Actinomadura* and *Nocardia* species are predominant in Central and South America. Finally, *Luidia senegalensis* and *M. mycetomatis* are predominant in sub-Saharan Africa and India (Fig. 342-1). The recent development of molecular typing procedures such as polymerase chain reaction restriction fragment length polymorphism holds promise in expanding our knowledge on the environmental sources and the pathogenesis of some agents of eumycetoma such as *M. mycetomatis*.

PATHOGENESIS

Local trauma (e.g., wood splinters) introduces a mycetoma-causative organism into the skin and subcutaneous tissues and initiates a chain of events that leads to chronic, suppurative granulomatous inflammation, tumefaction, formation of multiple fistulous tracts and sinuses, deep abscesses, fibrosis and scar formation, and extension to adjacent connective tissue across the lines of least resistance (fascia) and ultimately to bones, muscles, nerves, and tendon sheaths, leading to gross anatomic distortion of the affected site. In addition, a chronic suppurative granuloma featuring reactive fibrosis and grains (sclerotia), which is a matrix consisting of vegetative aggregates of the etiologic agents and host-derived inflammatory response, is characteristic of mycetoma in histologic sections. This infection is not contagious, however. Even though the genetics and immunopathogenesis of mycetoma are not well defined, it appears that there are differences in host susceptibility because some affected persons have impaired or delayed hypersensitivity reactions or polymorphisms in genes encoding for chemokines (e.g., CCL50) and cytokines (e.g., IL-10).[3] However, mycetoma does not appear to be more common in immunocompromised hosts. The lack of appropriate animal models that simulate the macroscopic features of subcutaneous human infection limits our understanding of the pathogenesis of mycetoma.

CLINICAL MANIFESTATIONS

The clinical manifestations and natural history of mycetoma are variable and, to some degree, related to the pathogenic agent involved.[4] For example, the progression of eumycetoma tends to be slower than that of actinomycetoma. In addition, eumycetoma lesions tend to be more confined and have less inflammation and fewer granulomas and fistulas but more fibrosis compared with actinomycetoma lesions. Furthermore, male mycetoma patients predominate (5 : 1 over female patients), and the disease is typically seen in rural areas and in persons susceptible to local trauma and contamination from soil (e.g., thorns). Hence, farmers, gardeners, woodcutters, herders, and people who work outside while barefoot are more susceptible to this infection. Not surprisingly, the foot is the most common site involved in mycetoma (Fig. 342-2), but any other part of the body, such as the hands, thighs, torso, and back of the head, may become involved. Location is typically solitary. Painless

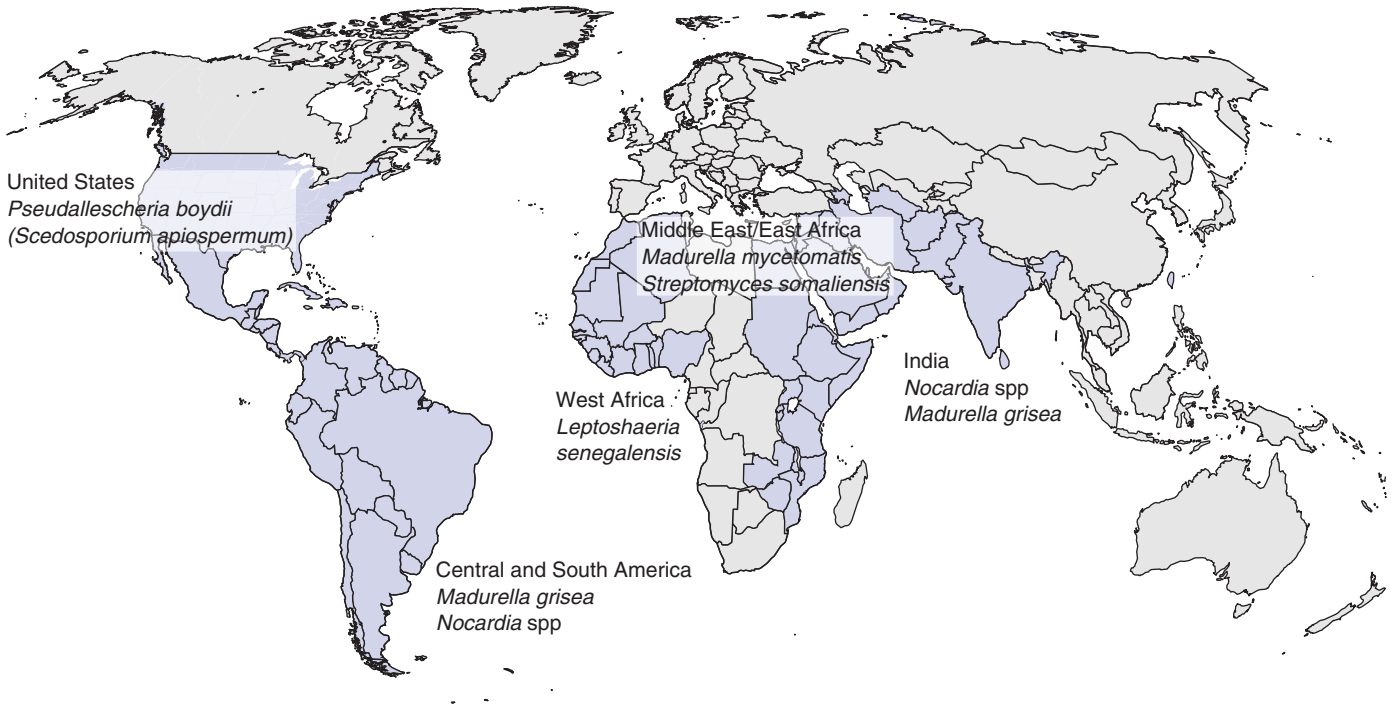

FIGURE 342-1. **Predominant agents of mycetoma according to region.**

FIGURE 342-2. **Madura foot.** A 40-year-old farmer from rural Venezuela with a 10-year history of foot edema and slowly progressive deformity following an injury caused by being struck by a hammer presented with chronic crusted plaques, multiple confluent tender abscesses with fistulization, and release of black grains. The range of motion of the patient's ankle and foot joints was limited, but the joints were not painful. A deep skin biopsy with hematoxylin and eosin staining, periodic acid–Schiff staining, foot radiography, sampling of black grain smears, and a mycology culture were performed. The foot radiograph showed osteofibrosis, destruction of articular surfaces, osteoporosis, and ankylosis, and *Madurella* species grew in the culture. (Courtesy Dr. M. Mendoza, Instituto De Biomedicina, Laboratorio de Micología, San Jose Caracas, Venezuela.)

nodular and/or papular swelling is the most common early manifestation of mycetoma, which is followed by a slow evolution to painless, fixed woody induration. This infection typically runs a chronic, relentless course, sometimes spanning several decades. It is characterized by recurring, vicious cycles of suppuration, draining sinuses, bacterial superinfection, and scar formation. Old sinuses may close up, but new ones may occur, and satellite lesions may be seen. Constitutional symptoms are surprisingly rare. In particular, the presence of fever indicates bacterial superinfection. Bone involvement mimicking clinically chronic osteomyelitis with osteolytic cavitary bone lesions, periosteal reaction or sclerosis (seen with radiography, computed tomography [CT], or magnetic resonance imaging [MRI] studies), osteoporosis, and reactive periosteal bone formation may occur; such involvement can be substantial. However, pathologic fractures are rare. In addition, because nerves are relatively spared from involvement, neuropathic manifestations are uncommon. Inexorable limb deformity and misuse because of destruction of deeper tissues may be seen in chronic, refractory, and advanced cases. Finally, because mycetoma does not spread hematogenously, visceral dissemination is not seen. However, because lymphatic spread may occur (typical incidence of 1 to 3% but more common with actinomycetoma and especially after surgery), regional lymphadenitis may develop.

DIAGNOSIS

Mycetoma, especially in its advanced forms, has a rather characteristic presentation. The classic triad of painless soft tissue swelling, draining sinus tracts, and extrusion of grains facilitates diagnosis with a high degree of accuracy, especially in endemic areas. For instance, the macroscopic and microscopic appearance of grains in pus-filled draining sinuses frequently allows presumptive diagnosis of the offending pathogen. However, basing the diagnosis on the presence of grains in tissue may be difficult because these grains might be composed of dead organisms. Furthermore, grains may be contaminated by surface bacteria or fungi. Therefore, a deep-tissue biopsy specimen is ideal for staining with hematoxylin and eosin, and appropriate selective bacterial (e.g., Löwenstein-Jensen culture medium) and fungal (e.g., blood agar and modified Sabouraud dextrose agar with antibiotics) cultures and stains (Gram stain, modified Ziehl-Neelsen stain, Gomori methenamine silver, periodic acid–Schiff stain) are preferable for primary detection. Alternatively, aspiration of grains from unopened sinus tracts might provide material for culture.

The culture should be maintained for several weeks because some of the causative agents of mycetoma (e.g., *Nocardia* and *Streptomyces* species) are slowly growing and can take 4 to 6 weeks to grow. Histopathology differentiates eumycetoma from actinomycetoma; however, the multitude of fungi causing eumycetoma necessitates culture identification because agents of eumycetoma might respond differently to antifungal agents. Similarly, cross-reactivity, lack of standardization, and the multitude of agents causing eumycetoma limit the practical value of serology. Finally, there are no studies correlating in vitro susceptibility testing with outcome in either actinomycetoma or eumycetoma.

Differential Diagnosis

The specific manifestations of mycetoma are sometimes confused with other entities.[5] For example, early lesions could be confused with soft tissue neoplasms or foreign body granulomas. In addition, mycetoma without fistulas must occasionally be distinguished from chronic cutaneous fungal infections such as sporotrichosis (mycetomatous lymphatic sporotrichosis) and dermatophytic mycetoma. The latter infection, which is typically seen in Africans and sometimes called pseudomycetoma, is a painless granulomatous

induration of the skin and subcutaneous tissues caused by ringworm that may be associated with grains consisting of fungi. However, unlike mycetoma, dermatophytic mycetoma is confined to the skin and subcutaneous tissue and does not spread to fasciae or bone. Similarly, chronic severe botryomycosis (typically caused by gram-positive cocci) with purulent exudates, grains, and draining sinus tracts may be confused with mycetoma; however, the presence of visceral dissemination supports a diagnosis of (severe) botryomycosis. Actinomycosis (Chapter 329), which is caused by endogenous microaerophilic actinomycetes (part of normal mucosa flora), also has a propensity for grains and formation of draining sinus tracts, but unlike mycetoma, its location (e.g., neck, chest, pelvis) is rather characteristic. In addition, differentiation between mycetomas with bone involvement and chronic osteomyelitis or osseous tumors may be difficult. Ultrasonography has been used to reliably differentiate mycetoma from either tumor or osteomyelitis. The dot-in-circles sign seen at MRI (tiny hypodense foci, believed to be grains, within high-hyperintensity spherical lesions, believed to be granulomas scattered by areas of fibrosis) might provide an early and specific diagnostic clue for mycetoma, Finally, in cases of mycetoma without draining sinus tracts, benign or malignant skin tumors, chronic granulomatous lesions (e.g., thorn granuloma, cutaneous tuberculosis), chromomycosis, and verrucous leishmaniasis are diagnoses that should be excluded. Unfortunately, delays of specific diagnosis by many months or even years is not uncommon, even in areas of high endemicity.

TREATMENT

Rx

Therapy for mycetoma should be individualized.[6] Optimal management has not been well defined, however, because the literature consists of rather heterogeneous and uncontrolled small studies. There is no "gold standard" approach for therapy, and no single agent is effective against all causative agents of mycetoma. Hence, successful treatment necessitates a reliable diagnosis, differentiation between actinomycetoma and eumycetoma, assessment of the extent of the lesion, and identification of the causative agent. Specifically, the degree of tissue invasion, especially bone involvement (as determined by radiology studies), site affected, and specific etiologic diagnosis determine the type and intensity of therapy. Recent studies indicate that MRI and CT (more sensitive especially for mycetoma involving bone) are especially useful in "staging" the disease.

In general, considering the refractoriness of eumycetoma to medical therapy, surgery plays a more prominent role.[7] In contrast, considering the satisfactory response of actinomycetoma to medical therapy (success rate of up to 90%) and recognized risk for lymphatic spread following surgery, chronic antibiotic administration is the mainstay of actinomycetoma management.

For actinomycetoma, treatment consists primarily of chronic antibiotic therapy (for at least 9 to 12 months) in conjunction with limited debulking surgery in selected cases; combination therapy designed for potential synergy is preferred. A variety of drugs (trimethoprim-sulfamethoxazole, tetracyclines, dapsone, streptomycin) have been used in different sequences and combinations according to the specific cause of actinomycetoma (e.g., trimethoprim-sulfamethoxazole with or without dapsone for *Nocardia* species, streptomycin with dapsone for *A. madurae*). Parenteral streptomycin is usually reserved for cases that do not respond to oral therapy. Responses to these drugs tend to occur slowly (within at least 1 month). Also, relapse is not uncommon, and multiple cycles of therapy may be needed for chronically recurrent disease. Side effects and compliance issues after prolonged administration of antibiotics are common problems.

For eumycetoma, however, medical therapy has produced mixed results. The best results were obtained with prolonged (9 to 12 months) use of oral imidazoles (e.g., ketoconazole 200 to 400 mg/day or itraconazole 200 to 400 mg/day). The experience using newer triazoles (e.g., voriconazole or posaconazole) or the allylamine terbinafine (with or without concomitant itraconazole), although encouraging, is not as extensive, however.[8] Posaconazole or voriconazole might prove to be especially useful for treatment of eumycetoma due to *S. apiospermum (P. boydii),* a fungus that is not susceptible to either ketoconazole or itraconazole. Also, intravenous amphotericin B and its lipid formulations have been used for refractory cases with rather disappointing results. This is not surprising because most eumycetoma-causative agents (e.g., *P. boydii*) are resistant to amphotericin B in vitro.

The need for and extent of surgery for mycetoma depend on the etiologic agent and, more important, extent of the lesion. Early wide-margin surgery for early localized lesions is curative. Although it is potentially curative, major disfiguring or mutilating surgery (e.g., amputation) is reserved for very advanced or refractory cases. Furthermore, primary reliance on surgery could result in recurrence or even spreading of the disease because of incomplete excision.

The prognosis for mycetoma depends on the site and degree of tissue involvement (e.g., worse with involvement of the back because of poor healing or in the presence of bone destruction) and, more important, the timeliness of the diagnosis and monitoring of recurrence and extension to other tissues, especially bone. CT and MRI are important modalities for early detection of bone involvement.

Finally, since mycetoma represents a significant, yet frequently ignored, socioeconomic burden for tropical and subtropical countries,[1] every effort for its prevention should be made. There is vaccine for that entity, and education of persons at risk in endemic areas is crucial (e.g., avoidance of walking barefoot). Finally, prompt recognition for early curative chemotherapy and/or surgery could lead to a better outcome of this difficult-to-manage, chronic infection.

REVIEW QUESTIONS

1. All is true for eumycetoma *except* which one of the following?

A. The condition is most commonly found in tropical and subtropical regions.
B. Dissemination of subcutaneous lesion is common.
C. Examination of grains from draining sinuses can aid in identification of the offending fungus.
D. Local trauma and exposure to soil are typical initiating factors.

Answer: B Local trauma (e.g., wood splinters) introduces a mycetoma-causative fungus into the skin and subcutaneous tissues and initiates a chain of events that leads to chronic, suppurative granulomatous inflammation, tumefaction, and formation of multiple fistulous draining tracts in which fungal colonies in the form of grains are found. The color and morphologic characteristics of these grains could contribute to the identification of the offending fungal pathogen. Eumycetoma has a global distribution, but it is more common in areas with tropical or subtropical climate. Although extensive soft tissue involvement and adjacent bone involvement can be seen in advanced cases, visceral dissemination is typically absent (Estrada R, Chavez-Lopez G, Estrada-Chavez G, Lopez-Martinez R, Welsh O. Eumycetoma. *Clin Dermatol.* 2012;30:389-396).

2. Which antifungal has in vitro activity against *Scedosporium apiospermum (Pseudallescheria boydii)*?

A. Terbinafine
B. Fluconazole
C. Amphotericin B
D. Posaconazole
E. Ketoconazole

Answer: D *S. apiospermum (P. boydii)* is a cause of eumycetoma for which therapeutic options are limited because the fungus is resistant to most antifungals with the exception of the new triazoles, posaconazole and voriconazole (Negroni R, Tobon A, Bustamante B, et al. Posaconazole treatment of refractory eumycetoma and chromoblastomycosis. *Rev Inst Med Trop Sao Paulo.* 2005;47:339-346).

343 DEMATIACEOUS FUNGAL INFECTIONS

PETER G. PAPPAS

DEFINITION

Dematiaceous fungi represent a large group of fungal organisms characterized by the presence of abundant melanin in the cell wall, which gives rise to a brown-black coloration on artificial culture media and which can be seen on histopathologic specimens. A related term, *phaeohyphomycosis,* refers broadly to infection by these pigmented fungi. The two terms are often used interchangeably, but when dematiaceous fungi are reviewed, three distinct clinical conditions are encountered: eumycetoma (e.g., Madura foot), chromomycosis (also known as chromoblastomycosis), and phaeohyphomycosis. Eumycetoma are covered in Chapter 342. This chapter focuses on the latter two entities.

The Pathogens

More than 100 dematiaceous fungi have been identified as causes of colonization or disease in humans. The most common organisms and their related conditions are listed in Table 343-1. The taxonomy of the dematiaceous fungi is somewhat confusing because these agents belong to different classes, including Hyphomycetes, Ascomycetes, Basidiomycetes, Coelomycetes, and Zygomycetes. The most common agents of phaeohyphomycosis include species in the following genera: *Bipolaris, Curvularia, Exophiala, Cladosporium, Cladophialophora, Alternaria, Exserohilum, Ochroconis, Wangiella, Phialophora, Scedosporium, Phaeoacromonium,* and *Chaetomium.* These agents are ubiquitous saprophytes of soil and decaying matter, and some are important plant pathogens. In tissue, these organisms exist as yeastlike cells, septated hyphae, or a combination of yeast and hyphae. Many have a histologic appearance similar to *Aspergillus* and *Fusarium* species, but they can be easily distinguished on the basis of positive melanin staining with the Fontana-Masson procedure.

Chromomycosis (formerly known as chromoblastomycosis) is a chronic skin and subcutaneous infection that is observed most frequently in the tropics. Virtually all cases of chromomycosis are caused by three species: *Fonsecaea pedrosoi, Cladosproium carrionii,* and *Phialophora verrucosa.* The distinctive histologic appearance is characterized by the presence of thick-walled, dark brown bodies known as *sclerotic cells* or *copper pennies,* which represent individual organisms and may be seen in clusters or as single cells. The etiologic fungi causing chromomycosis are indistinguishable on histologic examination of tissue.

EPIDEMIOLOGY AND PATHOBIOLOGY

The agents of chromomycosis and phaeohyphomycosis are found worldwide. Although there is no unique endemic area for most of these infections, some

TABLE 343-1 DEMATIACEOUS FUNGI AND ASSOCIATED DISEASES

Chromomycosis	*Fonsecaea pedrosoi* *Cladophialophora carrionii* *Phialophora verrucosa*
Cutaneous or subcutaneous disease	*Exophiala jeanselmei* *Wangiella dermatitidis* *Phialophora* spp *Bipolaris* spp *Alternaria* spp
Sinusitis	*Bipolaris* spp *Curvularia* spp *Exserohilum* spp *Alternaria* spp
Central nervous system	*Cladophialophora bantiana* *Ochroconis gallopavum* *Rhinocladiella mackenziei* *Chaetomium altrobrunnium*
Healthcare-associated	*Exserohilum rostratum* *Exophilia* spp
Disseminated	*Wangiella dermatitidis* *Exophiala jeanselmei* *Bipolaris* spp *Ochroconis gallopavum* *Phialophora* spp *Scedosporium prolificans*

observations are relevant. Allergic fungal sinusitis associated with dematiaceous fungi appears to be more common in the southern United States. Chronic infections of the lower extremities are more commonly seen in men and in tropical areas. Chromomycosis is more prevalent in rural populations in the tropics and is hyperendemic in certain geographic areas such as Madagascar, Brazil, and other Latin American countries, where most infections are caused by *Fonsecaea pedrosoi* and *Cladosporium carrionii.*[1]

Most cutaneous infections occur as a result of minor skin trauma and direct inoculation of the organism. Other risk factors include intravenous drug abuse, chronic sinusitis, freshwater immersion, and chronic corticosteroid therapy.

In the developed world, phaeohyphomycosis is an important emerging fungal infection, particularly among immunocompromised patients such as solid organ and hematopoietic stem cell transplant recipients, patients with prolonged neutropenia, and other chronically immunocompromised individuals. Phaeohyphomycosis is reported in HIV-infected patients but is far less common than other opportunistic fungi. Extracutaneous invasive disease occurs in otherwise normal patients but is much less common.

The recent U.S. epidemic of fungal meningitis, epidural abscess, sacroiliitis, vertebral osteomyelitis, discitis, and peripheral arthritis caused by *Exserohilum rostratum* following injection of contaminated methylprednisolone acetate from a single compounding pharmacy is a striking example of the risk for dematiaceous fungal infections following invasive procedures in the health care setting.[2-4] In this epidemic, more than 750 persons with injection associated infection were identified, of whom almost 10% died as a direct result of the infection. Previous reports of infection due to *Exophiala* species following contaminated steroid injections, infected breast implants, other prosthetic materials, and, rarely, contaminated intravascular catheters and intravenous fluids further underscore the importance of these pathogens as potential health care–associated infections.

CLINICAL MANIFESTATIONS

Chromomycosis is manifested as a cutaneous or subcutaneous lesion that may range in size from a small papule to a large confluent plaque involving a major portion of an extremity. Single or multiple lesions may be seen, and ulceration may occur. Lesions may remain unchanged in size and consistency for months or years, although most tend to progress in the absence of specific therapy. Chronic lesions may become dry and crusted with a raised border, which may be smooth or irregular. Multiple lesions can coalesce to form larger plaques in which central scarring may develop. Occasionally, lesions assume a verrucous, warty appearance. The differential diagnosis includes other fungal infections such as blastomycosis, coccidioidomycosis, sporotrichosis, histoplasmosis, and paracoccidioidomycosis. Nocardiosis and cutaneous mycobacteriosis can also mimic the lesions of chromomycosis. Cutaneous lesions usually remain confined to one anatomic site, although nodular lymphangitis and autoinoculation resulting in multifocal cutaneous disease may occur. Common complications include local disfigurement due to scarring and extensive tissue involvement. Disseminated disease involving visceral organs may occur, but this is rare.

Phaeohyphomycosis is associated with several well-described clinical syndromes. *Superficial* infection is characterized by tinea nigra and black piedra. Tinea nigra is a darkening of the skin caused by growth of *Phaeoannellomyces werneckii* in the stratum corneum. Black piedra is associated with the development of focal thickening on the hair shaft and results from colonization of the shaft by *Piedraia hortae. Cutaneous* phaeohyphomycosis involves deeper skin structures and results in dermatomycosis and onychomycosis; this is frequently due to agents such as *Scytalidium* and *Phyllosticta* species.

Subcutaneous phaeohyphomycosis is relatively common and may be confused with chromomycosis. Patients have discrete subcutaneous nodules or cysts that result from direct inoculation or penetrating trauma. The most common organisms are *Exophiala jeanselmei, Wangiella dermatitidis, and Phialophora* species. *Mycotic keratitis* as a result of infection with *Curvularia, Exophiala,* and *Exserohilum* species may occur after corneal trauma or surgery.

Foreign body–related infections are seen in patients undergoing chronic ambulatory peritoneal dialysis in whom fungal peritonitis develops, in patients with indwelling intravenous catheters, and rarely in other devices such as breast implants.

Fungal sinusitis is commonly associated with dematiaceous fungi and can be manifested as allergic fungal sinusitis, a fungus ball (eumycetoma) in a sinus cavity, and invasive fungal sinusitis associated with extension into bone, soft tissue, and the central nervous system.[5] This latter manifestation is indistinguishable from rhinocerebral zygomycosis or invasive *Aspergillus* sinusitis. *Bipolaris, Curvularia,* and *Alternaria* species are the most common organisms causing invasive fungal sinusitis.

Systemic phaeohyphomycosis may result from direct extension from a colonized area or dissemination from a distant source. Most patients with systemic disease have significant underlying immunosuppression, and the organisms have a proclivity for involvement of the brain, lungs, endocardium, and other visceral organs. Among patients with primary central nervous system disease, *Cladophialophora bantiana, Ochroconis gallopavum, Rhinocladiella mackenziei,* and *Chaetomium altrobrunnium* are the most common etiologic agents, and the majority of these are otherwise healthy patients with no known underlying immunodeficiency. Among immunocompromised patients, *Ochroconis gallopavum*, *Bipolaris* species, and *Exophiala* species are seen more commonly.

A unique form of systemic phaeohyphomycosis has been seen recently in the fungal meningitis epidemic due to *Exserohilum rostratum* from contaminated methylprednisolone acetate injections as mentioned earlier. Patients with the meningeal form of this infection presented with symptoms ranging from local symptoms due to epidural abscess to devastating complications such as severe meningitis and basilar infarctions. Persons with extraneural involvement included those with focal sacroiliitis and peripheral joint arthritis.[6]

DIAGNOSIS

The diagnosis of phaeohyphomycosis is suggested by direct examination of a clinical specimen with a 10% potassium hydroxide preparation or special stains to demonstrate pigmentation in the cell walls of these organisms. For patients with chromomycosis, the finding of sclerotic cells or copper pennies on skin biopsy is characteristic, and special stains are usually unnecessary. For patients with other forms of phaeohyphomycosis, the Fontana-Masson stain is useful in distinguishing organisms with significant melanin content. Culture remains the "gold standard" by which a specific etiologic diagnosis is established, and the identity of the organism is largely based on colony and microscopic morphology. A polymerase chain reaction–based diagnostic assay for *Exserohilum rostratum* was developed in the context of the fungal meningitis outbreak, and it has served as a reliable marker of infection in patients who were exposed to contaminated steroid injections.[7] Serologic studies and molecular diagnostics for other organisms are not generally available.

TREATMENT

Rx

For chromomycosis, surgical excision of a cutaneous or subcutaneous lesion is often curative, although antifungal therapy is usually given in conjunction with surgery.[8] There are limited clinical studies and no large randomized trials that have assessed the efficacy of antifungal therapy for this condition. Historically, 5-flucytosine (5-FC, 150 mg/kg/day) has been advocated for the oral treatment of chromomycosis based on moderate in vitro activity and clinical experience. Because of limited availability, the need for prolonged therapy, and the necessity of monitoring serum levels, 5-FC is uncommonly used for this purpose. The triazoles, including itraconazole (200 mg orally twice daily), voriconazole (200 mg twice daily), and posaconazole (300 mg daily), demonstrate the best in vitro activity, although clinical studies with these agents are very limited. Terbinafine (500 mg orally twice daily) has also been used successfully for the treatment of chromomycosis and is an effective alternative to azole therapy.

Amphotericin B has modest in vitro activity against most of the dematiaceous fungi and is most often reserved for patients with life-threatening or disseminated disease. Among the triazoles, posaconazole offers the most potential in the clinical setting based on scattered reports from patients with central nervous system infection, but comparative clinical data are not available because of the relative rarity of these infections. Most patients with epidemic *Exserohilum rostratum* infections have been treated with voriconazole (intravenous, then oral) with or without a lipid formulation of amphotericin B for severe central nervous system involvement, and anecdotal reports suggest that this approach has been generally successful. The length of antifungal therapy for any of the systemic dematiaceous fungal infections is unclear but should probably be continued for at least 6 months or until 1 month after resolution of all signs and symptoms of disease.

REVIEW QUESTIONS

1. Which of the following organisms is most commonly associated with central nervous system infections?

A. *Exserohilum rostratum*
B. *Alternaria alternans*
C. *Scedosporium prolificans*
D. *Cladophialophora bantiana*
E. *Exophiala* spp

Answer: D *Cladophialophora bantiana* is commonly associated with central nervous system infections, especially brain abscess, in normal hosts and in immunocompromised hosts. The other organisms frequently associated with central nervous system infections include *Ochroconis gallopavum* and *Rhinocladiella mackenziei*.

2. Which of the following organisms was associated with the U.S. epidemic involving injectable methylprednisolone acetate, leading to hundreds of cases of meningitis, parameningeal infections, and peripheral joint infections?

A. *Exserohilum* spp
B. *Alternaria* spp
C. *Curvularia* spp
D. *Bipolaris* spp
E. *Fonsecaea* spp

Answer: A The major cause of the recently reported U.S. epidemic of contaminated methylprednisolone injections was *Exserohilum rostratum*. This organism was isolated by culture and/or polymerase chain reaction in the majority of patients in for whom positive tests results were available. The epidemic led to 751 proven and probable cases, of which approximately 8% died as a direct result of the infection.

3. Which of the following statement is *not* true concerning dematiaceous fungi?

A. These organisms contain high concentrations of melanin in the cell wall.
B. These organisms belong to the same class.
C. These organisms are unusual causes of invasive human infection.
D. These organisms are commonly found in the environment.
E. More than 100 of these organisms have been associated with invasive human disease or colonization.

Answer: B These organisms belong to several classes of fungi. More than 100 dematiaceous fungi have been associated with human disease or colonization. These organisms are ubiquitous in the environment, and most have the capability to cause invasive disease in the appropriate clinical setting.

4. Which of the following features of chromomycosis is true?

A. This disorder is characterized by discreet nodular skin and/or subcutaneous lesions.
B. The infection often follows cutaneous inoculation through minor trauma.
C. Most disease is caused by three organisms: *Fonsecaea*, *Cladosporium,* and *Phialophora*.
D. The characteristic histologic findings are sclerotic cells or "copper pennies."
E. All of the above are true.

Answer: E Chromomycosis is a disease largely seen in the tropics and follows minor skin trauma. The lesion is usually unilateral and is typically confined to an extremity. The lesions have a characteristic nodular, cutaneous, or subcutaneous appearance, and a histologic finding of sclerotic cells or copper pennies is characteristic of this condition. Chromomycosis is usually caused by one of the three organisms listed.

5. Which of the following is the best choice for therapy for chromomycosis?

A. Fluconazole
B. Amphotericin B
C. Flucytosine
D. Miconazole topical cream
E. Itraconazole

Answer: E Among the choices given, itraconazole is the most effective agent. Among the azoles, posaconazole and voriconazole have excellent in vitro activity against most of the dematiaceous fungi, including those that cause chromomycosis. Small clinical trials evaluating these azoles and terbinafine suggest that each of these agents is effective when administered for an appropriate duration of treatment, usually months or even years.

ANTIPARASITIC THERAPY

RICHARD D. PEARSON

International travel, widespread immigration, and a growing number of persons with compromised immunity due to HIV/AIDS, organ transplants, corticosteroids and other conditions have resulted in increased attention to parasitic diseases worldwide. A number of drugs are available to treat them, but physicians practicing in industrialized countries often are not familiar with their use. The focus of this chapter is on their therapeutic indications, pharmacology, and major side effects. Generalizations emerge that help in organizing an otherwise vast amount of information.

In considering the chemotherapy of parasitic diseases, it is helpful to classify infections into those caused by helminths, multicellular worms with complex internal structures, and protozoa, single-celled organisms that multiply by cell division. Helminths are further divided into nematodes, or roundworms, which can be grouped into those that live in the gastrointestinal tract and those found elsewhere in the body, and platyhelminths, or flat worms, which are subdivided into cestodes, or tapeworms, and trematodes, or flukes.

The protozoa can be grouped into those that reside under anaerobic conditions in the gastrointestinal tract or vagina and those that live aerobically in the body. The most prevalent systemic protozoan infections are attributable to members of the Apicomplexa, which cause malaria, babesiosis, and toxoplasmosis, and the Kinetoplastida, which are responsible for Chagas disease, human African trypanosomiasis (sleeping sickness), and leishmaniasis.

The Centers for Disease Control and Prevention (CDC) provide detailed information about the diagnosis and treatment of parasitic diseases through their website (www.cdc.gov). An excellent compilation of therapeutic recommendations is available in tabular form in *The Medical Letter on Drugs and Therapeutics*, "Drugs for Parasitic Infections" (available at www.medicalletter.org). Many antiparasitic drugs are commercially available in the United States, whereas others can only be obtained from the manufacturer, special pharmacies, or the CDC Drug Service. Some are available through investigational new drug protocols. Several drugs that are used for the treatment of parasitic diseases are also active against common bacterial or fungal pathogens. They are discussed elsewhere (Chapters 287 and 331).

TREATMENT OF HELMINTHS

Intestinal Roundworms (Nematodes)

Soil-transmitted intestinal roundworms (Chapter 357) are among the world's most prevalent parasites, and there are good therapeutic options for them. *Ascaris lumbricoides*, the hookworms *Ancylostoma duodenale* and *Necator americanus*, and *Trichuris trichiura* each infect on the order of 1 billion people worldwide. Many residents of impoverished areas harbor more than one soil-transmitted pathogen.

Albendazole has a broad spectrum of activity against intestinal roundworms. It is active against *A. lumbricoides*, the hookworms, and *T. trichiura*. Administered as a single 400-mg dose, it has been used successfully in mass treatment programs for children living in high prevalence areas. However, reinfection is common, and treatment is often repeated at 3- to 4-month intervals. The CDC recommends presumptive treatment of refugees from endemic regions with a single dose of albendazole (600 mg), administered overseas before departure for the United States. It has been highly effective and well tolerated in refugees from Africa and Southeast Asia.[1] Daily doses of albendazole for 3 days are recommended for persons with heavy *T. trichiura* infection. Twice-daily doses of albendazole, 600 mg for 7 days, are used as an alternative to ivermectin for the treatment of *Strongyloides stercoralis* infection. Failures can occur with either drug, and they are often used together for longer periods to treat those with disseminated hyperinfection. Albendazole is effective against pinworms in a single dose that is repeated in 2 weeks. It can be used for cutaneous larva migrans, which is caused by migrating stages of *Ancylostoma braziliense* and other intestinal helminths of animals. It is the drug of choice for trichinosis, and it is an alternative for the treatment of *Trichostrongylus* species and *Capillaria philippinensis*.

Mebendazole, administered twice daily at a dosage of 100 mg orally for 3 days, has a similar spectrum of activity as albendazole against *A. lumbricoides*, hookworms, and *T. trichiura*. In this regimen, it is more effective than a single dose of albendazole and is considered the treatment of choice for *T. trichiura*. A single 500-mg dose of mebendazole has been used in mass treatment programs. Mebendazole is effective in treating pinworm when given at 100 mg orally in one dose followed by a second dose after 2 weeks. It is an alternative to albendazole for the treatment of trichinosis. Mebendazole is poorly absorbed and not effective against *S. stercoralis*.

Pyrantel pamoate is a relatively safe, poorly absorbed, over-the-counter drug with activity against *A. lumbricoides*, hookworms, and pinworms, but it is not effective against *T. trichiura* or *S. stercoralis*. When used for pinworms, it is administered as an oral suspension at a dose of 11 mg/kg (to a maximum of 1 g), which is repeated after 2 weeks. The combination of ***oxantel pamoate***, 20 mg/kg, and ***albendazole***, 400 mg, taken on consecutive days, has been recently found to result in higher cure and egg-reduction rates for *T. trichiura* infection then the rates with standard therapy.

Ivermectin at an oral dose of 200 µg/kg daily for 2 days is considered the treatment of choice for *S. stercoralis*.[2] It is also effective against cutaneous larva migrans and *A. lumbricoides*, but not hookworms. It is considered an alternative to mebendazole for the treatment of *T. trichiura*. Albendazole, mebendazole, pyrantel pamoate, and ivermectin replaced a number of older anthelmintics that were more toxic, such as piperazine and thiabendazole, or less effective.

Systemic Roundworms (Nematodes)

Diethylcarbamazine is the drug of choice for lymphatic filarial infections (Chapter 358) caused by *Wuchereria bancrofti*, *Brugia malayi,* and *Brugia timori,* as well as for tropical pulmonary eosinophilia. It promotes the host's killing of microfilariae of these species and also damages or kills the adult worms. Inflammatory side effects are common and due in part to the release of lipopolysaccharide from endosymbiotic *Wolbachia* bacteria within dying filaria. *Wolbachia* are necessary for filarial development and are a potential drug target. Long-term therapy with doxycycline has been shown to result in their elimination and has been used for therapy. Diethylcarbamazine is also used for *Loa loa* infections in persons with acceptably low microfilaremia (<8000/mL). Encephalopathy may result from treatment of those with

higher levels. In that case, apheresis or treatment with albendazole is used first to reduce the number of microfilaria. Diethylcarbamazine can also be used prophylactically for *L. loa*. Ivermectin has activity against the microfilariae of *W. bancrofti*, *Brugia* species, and *L. loa*, but it does not kill adult worms and is not recommended for treatment of these organisms.

Ivermectin is the treatment of choice for onchocerciasis. It is administered as a single dose of 150 μg/kg. It does not kill adult *Onchocerca volvulus*, but it decreases ova production and reduces microfilariae in the skin and eyes. Retreatment is usually necessary at 6- to 12-month intervals until the patient is free of symptoms. Profits from the use of ivermectin for treatment of the dog heartworm *Dirofilaria immitis* have permitted the manufacturer to provide the drug free to persons with onchocerciasis in developing areas. Diethylcarbamazine should not be used for onchocerciasis. It kills the microfilariae of *O. volvulus* rapidly, but the release of parasite and *Wolbachia* antigens can result in severe ocular and systemic inflammatory responses. The latter is known as the Mazzotti reaction. Ivermectin is associated with less rapid killing of microfilariae and less severe reactions.

Tapeworms (Cestodes)

Praziquantel has a broad spectrum of activity against tapeworms (Chapter 354) and flukes. It is the drug of choice for adult tapeworms in the human intestinal tract. It is effective against *Taenia solium* (pork tapeworm), *Taenia saginata* (beef), *Diphyllobothrium latum* (fish), and *Hymenolepis nana* (dwarf tapeworm) when administered as a single dose. Niclosamide, which is not absorbed, is an effective alternative for the treatment of *T. saginata* and *D. latum*. It also kills adult *T. solium*, but disintegration of the worm and release of viable ova into the intestinal lumen raise the theoretical possibility of autoinfection. In the case of *H. nana*, a dose of nitazoxanide, 500 mg twice daily for 3 days, provides an alternative to praziquantel. It also has activity against *T. saginata* and potentially other tapeworm species.

Neurocysticercosis caused by the larval or tissue phase of *T. solium* is a major cause of seizures and other central nervous system (CNS) abnormalities in residents of and immigrants from endemic areas in Latin America and elsewhere. Symptoms can result from the physical presence of cysticerci, but the inflammation elicited by the release of antigens from dying cysticerci is often more important. Both albendazole and praziquantel are capable of killing cysticerci in the brain; albendazole is the drug of choice for pharmacokinetic reasons. Their use depends on the clinical syndrome. Corticosteroids are administered concurrently—and sometimes alone—to reduce the inflammatory response and the increase in intracranial pressure associated with it. Albendazole is administered for 15 to 30 days at 400 mg twice a day. Praziquantel is administered at 100 mg/kg in three divided doses the first day and then at 50 mg/kg in three divided doses for 29 days. The concurrent use of corticosteroids increases the serum level of albendazole but decreases that of praziquantel. Neither albendazole nor praziquantel should be used in persons with cysticerci in the eye or spinal cord because the release of antigens can trigger a locally destructive inflammatory reaction.

Surgery or PAIR (*p*ercutaneous *a*spiration, *i*njection of chemicals, and *r*easpiration) is the preferred approach for *Echinococcus granulosus* cysts. Albendazole is used for inoperable *E. granulosus* and *Echinococcus multilocularis* disease and in persons in whom medical treatment is preferred for other reasons. Administered at a dose of 400 mg twice daily for adults, generally for 1 to 6 months, albendazole may cure one third of uncomplicated *Echinococcus granulosus* liver cysts. Albendazole is also administered before ultrasound-guided PAIR or surgery to prevent seeding of the peritoneum should the cyst's contents spill. Potentially fatal bone marrow suppression and hepatitis are concerns in persons receiving high-dose, prolonged albendazole therapy.

Flukes (Trematodes)

Praziquantel is the drug of choice for the treatment of all forms of schistosomiasis (Chapter 355), as well as intestinal, lung, and liver flukes (Chapter 356), with the exception of the liver fluke *Fasciola hepatica*. For schistosomiasis, two or three doses are given in 1 day depending on the species. The flukes are treated with three doses on 1 or 2 days, depending on the species. Oxamniquine is an alternative for *Schistosoma mansoni*, but it is more toxic and less effective. Higher doses of oxamniquine are recommended for *S. mansoni* infections acquired in areas of Egypt or equatorial Africa where the parasite is less susceptible. Either praziquantel or albendazole can be used to treat the liver fluke *Clonorchis sinensis*. *F. hepatica* responds to the veterinary agent triclabendazole. Bithionol, which is more toxic, and nitazoxanide are alternatives.

Drugs Used for Helminthic Infections

Albendazole is poorly soluble in water, but it is well absorbed when administered with a fatty meal. It undergoes rapid first-pass metabolism in the liver to albendazole sulfoxide, which has excellent anthelmintic activity. The serum half-life of albendazole sulfoxide is 8 to 9 hours. Elimination of albendazole sulfoxide and other metabolites is achieved primarily through the kidney. Albendazole binds to tubulin in susceptible parasites, inhibits microtubule assembly, and decreases glucose absorption. It does not affect human tubulin. It also inhibits fumarate reductase in helminths. Concurrent administration of dexamethasone, which is frequently given to prevent cerebral edema in persons with neurocysticercosis, increases serum levels by approximately 50%. The cerebrospinal fluid (CSF) concentration of albendazole is approximately 40% of that in serum.

Albendazole is generally well tolerated when given as a single dose for the treatment of intestinal nematode infections, although gastrointestinal discomfort may develop or patients may experience migration of adult *A. lumbricoides* from the nose or mouth or see them in their stools. Albendazole at higher doses and for longer duration is also used for persons with neurocysticercosis. Corticosteroids are administered concurrently to reduce intracranial inflammation and resulting increased pressure. Albendazole is contraindicated in those with cysticerci in the eye or spinal cord. High-dose, prolonged therapy with albendazole, such as that recommended for echinococcal disease, can be complicated by alopecia, hepatitis, or bone marrow suppression, which is not always reversible after discontinuation of the drug. Albendazole is embryotoxic in animals and contraindicated during pregnancy.

Mebendazole is only slightly soluble in water and is relatively poorly absorbed from the gastrointestinal tract. This is advantageous for the treatment of intestinal parasites but limits its effectiveness against tissue-dwelling helminths. Absorbed drug is metabolized in the liver and excreted in urine. Mebendazole selectively binds to helminthic tubulin, blocks its assembly into microtubules, and inhibits glucose uptake, thereby leading to depletion of glycogen stores and ultimately death of the parasite. It is relatively well tolerated in the doses used to treat intestinal helminths. Transient abdominal pain and diarrhea occur in a small number of recipients. Mebendazole is contraindicated during pregnancy.

Ivermectin is a macrocyclic lactone produced by *Streptomyces avermitilis*. It has a broad spectrum of activity against helminths and arthropods, including *Sarcoptes scabiei*, the cause of scabies. It is well absorbed after oral administration. Ivermectin is highly protein bound, has a serum half-life of 12 hours, and accumulates in adipose tissue and the liver. It is subject to enterohepatic recirculation and ultimately eliminated in stool. Ivermectin activates the opening of gated chloride channels in susceptible helminths and arthropods. The result is an influx of chloride ions and paralysis of the pharyngeal pumping mechanism of helminths. Ivermectin is generally well tolerated in humans, although inflammatory reactions can result in response to antigens released from dying parasites.

Diethylcarbamazine, a piperazine derivative, is well absorbed orally and has a half-life of 8 hours. The parent drug and its metabolites are excreted through the kidney. Although the mechanism of action is uncertain, the piperazine moiety may result in paralysis of sensitive helminths. Diethylcarbamazine also alters the surface membranes of susceptible microfilariae, thereby resulting in destruction by the host's immune system. Side effects include those caused by the drug and those that result from release of the parasite antigens and lipopolysaccharide from filaria-harbored, endosymbiotic *Wolbachia*. Adverse effects include nausea, vomiting, anorexia, headache, malaise, weakness, arthralgias, and rarely, acute psychotic reactions. In patients with lymphatic filariasis, localized swelling or nodules may develop along the lymphatics during treatment, or transient lymphedema or hydrocele formation may occur.

Praziquantel is well absorbed after oral administration. It undergoes extensive first-pass metabolism, and the metabolites, which are inactive, are excreted in urine. Praziquantel is approximately 80% protein bound, with a serum half-life of 4 to 6 hours. It is rapidly taken up by susceptible cestodes and trematodes. In the case of schistosomes, praziquantel damages the tegument, which results in intense vacuolation and increased permeability to calcium. Adult schistosomes are paralyzed and translocated to the liver through the portal circulation. Sequestered antigens are exposed on their surface, permitting binding of antibodies and phagocytes and resulting in immune destruction. Praziquantel is an alternative to albendazole for the treatment of neurocysticercosis. The concurrent administration of

corticosteroids, which are necessary to decrease inflammation and edema in the brain, reduces the serum concentration of praziquantel. The concentration in CSF is approximately 15 to 20% that of serum.

Praziquantel is frequently associated with mild, transient side effects, including headaches, lassitude, dizziness, nausea, vomiting, and abdominal discomfort, but they are seldom severe enough to interrupt therapy. Untoward reactions attributed to release of parasite antigens have been reported in patients treated for schistosomiasis and pulmonary paragonimiasis. Increased intracranial pressure resulting from release of cysticercal antigens is a potentially life-threatening consequence in patients receiving praziquantel for neurocysticercosis. Corticosteroids should be administered concurrently. Praziquantel is contraindicated in persons with cysticerci in the eye or spinal cord.

TREATMENT OF PROTOZOAL DISEASES

Intestinal and Vaginal Protozoa

Several major luminal pathogens, including *Entamoeba histolytica* (Chapter 352), *Giardia lamblia* (Chapter 351), and *Trichomonas vaginalis* (Chapter 353), live in anaerobic conditions in the intestine or vagina and are susceptible to metronidazole and tinidazole. The latter has favorable pharmacodynamics and is generally better tolerated. Because neither metronidazole nor tinidazole reliably eradicates cysts of *E. histolytica*, either paromomycin or iodoquinol, which are active in the lumen of the bowel, is administered as well. Either one of these drugs or diloxanide furoate can be used alone to treat persons with asymptomatic cyst excretion.

Giardiasis can also be treated with nitazoxanide. It is well tolerated, and an oral formulation is available for children. Nitazoxanide is the only drug available for the treatment of cryptosporidiosis (Chapter 350). It is effective in immunocompetent persons, but not in those with AIDS. Trimethoprim-sulfamethoxazole, which inhibits successive steps in the folic acid pathway, is the drug of choice for *Cystoisospora* (*Isospora*) *belli* and *Cyclospora cayetanensis*. Ciprofloxacin, a fluoroquinolone antibiotic, is an alternative. Tetracycline is the treatment of choice for *Balantidium coli*; metronidazole and iodoquinol are alternatives. Finally, albendazole is effective in the treatment of intestinal and disseminated microsporidiosis caused by *Encephalitozoon* (*Septata*) *intestinalis* and for some other microsporidial species that cause disease in persons with AIDS.

Metronidazole, a nitroimidazole, is rapidly absorbed after oral administration and has a half-life of 8 hours. More than half of each dose is metabolized in the liver. The metabolites and remaining parent drug are excreted in urine. Metronidazole is activated by reduction of its 5-nitro group through a sequence of intermediate steps involving microbial electron transport proteins of low redox potential. It is concentrated in susceptible anaerobic organisms and serves as an electron sink. Nausea, vomiting, diarrhea, and a metallic taste are often associated with the use of metronidazole. They are less common with the lower doses recommended for the treatment of giardiasis than with the higher doses used for amebiasis. Other untoward effects include headache, dizziness, vertigo, and numbness. Potentially severe disulfiram-like reactions occur in patients who ingest alcohol while taking metronidazole.

Tinidazole, another 5-nitroimidazole, has a similar mechanism of action and spectrum of activity as metronidazole but more favorable pharmacodynamics, and it is generally better tolerated. It has been used widely around the world for the treatment of giardiasis, intestinal amebiasis, and trichomoniasis. In comparison with metronidazole, it has a longer half-life, a shorter and less complicated dosing regimen, and fewer gastrointestinal side effects. It, too, can cause severe disulfiram-like reactions after alcohol ingestion.

Nitazoxanide, a 5-nitrothiazole salicylamide derivative, has a broad spectrum of activity against protozoa and helminths. It is formulated as a liquid for use in children. Nitazoxanide is well absorbed orally and hydrolyzed to its active metabolite tizoxanide, which undergoes conjugation to tizoxanide glucuronide. The parent compound is not detectable in serum. Maximum concentrations of the metabolites are observed in 1 to 4 hours. They are excreted in urine and bile. Tizoxanide is highly protein bound. Although its antiparasitic mechanism of action is uncertain, tizoxanide inhibits pyruvate : ferredoxin oxidoreductase–dependent electron transport reactions essential for the metabolism of susceptible anaerobic organisms. It is very well tolerated in children and adults.

Malaria: Prophylaxis and Treatment

As discussed in this section, a number of drugs are available for the prophylaxis and treatment of malaria. Most act against *Plasmodium* stages within erythrocytes. Only primaquine kills *Plasmodium vivax* and *Plasmodium ovale* hypnozoites in the liver. The antimalarial drug of choice depends on the geographic site visited and the *Plasmodium* species encountered (Chapter 345). Antimicrobial resistance is now widespread among *Plasmodium falciparum* isolates and well documented in *P. vivax* from some regions. Country-specific recommendations for prophylaxis and treatment are provided by the CDC at www.cdc.gov/travel/ and in "CDC Health Information for International Travel 2014."[3,4] Major additions to the therapeutic armamentarium in the United States include the fixed drug combination of artemether and lumefantrine (Coartem), which is used for the oral treatment of acute malaria acquired in areas with chloroquine-resistant *P. falciparum*, and artesunate for intravenous administration in those with severe malaria who cannot take oral medications and for whom quinidine is contraindicated or not available. Artesunate can be obtained from the CDC on an emergency basis as an investigational new drug.

Atovaquone plus ***proguanil*** (adult tablets contain 250 mg of atovaquone and 100 mg of proguanil) is used for prophylaxis and treatment of chloroquine-resistant and sensitive malaria. Atovaquone is a highly lipophilic compound with low aqueous solubility. Administration with food enhances its absorption two-fold. Plasma concentrations do not increase proportionately with dose. Atovaquone is highly protein bound with a half-life exceeding 60 hours. It undergoes extensive enterohepatic cycling and is eventually excreted unchanged in feces. Atovaquone selectively inhibits electron transport in the mitochondria of susceptible *Plasmodium* species at the level of the cytochrome bc_1 complex, which results in collapse of mitochondrial membrane potential. It also affects pyrimidine biosynthesis, which is obligatorily coupled to electron transport in *Plasmodium*. Resistance develops rapidly when atovaquone is used alone to treat malaria. Atovaquone is generally well tolerated but can cause nausea, vomiting, diarrhea, rash, and pruritus.

Proguanil is absorbed slowly after oral administration. Its serum level falls to zero within 24 hours, so it must be administered daily. Its triazine metabolite, cycloguanil, inhibits dihydrofolate reductase in susceptible *Plasmodium* species. Resistance is well documented when proguanil is used alone. Proguanil also acts synergistically with atovaquone to collapse mitochondrial membrane potential in susceptible *Plasmodium* species.

The combination of atovaquone and proguanil is considered the best tolerated of the options for prevention of chloroquine-resistant malaria. It is begun 1 to 2 days before departure and continued during the time of exposure and for 7 days thereafter. Higher doses are administered over a period of 3 days to treat acute, uncomplicated malaria. Potential side effects include abdominal pain, nausea, vomiting, diarrhea, headache, pruritus, and rash. Asymptomatic, transient elevations in liver enzymes have been observed with treatment doses.

Doxycycline 100 mg taken daily by adults provides effective prophylaxis against all *Plasmodium* species. It is begun 1 to 2 days before departure and continued during the time of exposure and for 4 weeks after leaving the malaria-endemic area. Doxycycline or tetracycline is also often administered with quinine for the treatment of acute chloroquine-resistant malaria, but neither drug acts rapidly enough to be used alone for treatment. Doxycycline is generally well tolerated, although it can cause gastrointestinal symptoms and "pill" esophagitis. To avoid the latter, it should be taken with a full glass of water, and the recipient should remain upright for an hour or more after ingestion. Other potential side effects include photosensitivity dermatitis, *Candida albicans* vaginitis, and antibiotic-associated colitis. Finally, doxycycline and tetracycline should not be used in children younger than 8 years or in women who are pregnant or breastfeeding.

Mefloquine, a quinoline methanol compound derived from quinine, was once used widely for the prophylaxis and occasionally treatment of chloroquine-resistant *P. falciparum* malaria. Mefloquine is available for oral administration only. Slowly and incompletely absorbed, it is 99% protein bound. It has a variable half-life ranging from 6 to 23 days with a mean of approximately 14 days. It is metabolized and excreted slowly through bile and feces.

Concern about neuropsychiatric and other toxicities and the availability of better-tolerated alternatives have limited its use in recent years. It is associated with nausea, dizziness, vivid dreams, fatigue, and lassitude. Less common but of greater concern are anxiety, depression, acute psychosis, and seizures. Mefloquine is contraindicated in persons with a history of epilepsy or psychiatric disorders. It now carries a U.S. Food and Drug Administration (FDA) black-box warning. It also depresses atrioventricular conduction and should not be used in persons taking β-blockers for cardiac indications.

Although not approved for use during pregnancy or in children weighing less than 15 kg, mefloquine has been used in situations in which its potential benefits were judged to outweigh the risks.

Chloroquine, a 4-aminoquinoline, has a bitter taste but is well absorbed from the gastrointestinal tract. Its half-life, which varies among persons, averages 4 days, thus permitting once-weekly administration for prophylaxis. Chloroquine is concentrated in the hemoglobin-containing digestive vesicles of asexual intraerythrocytic parasites. It inhibits the parasite's heme polymerase that incorporates ferriprotoporphyrin type IX complexes, which are potentially toxic to the parasite, into insoluble, nontoxic, crystalline hemozoin. Chloroquine-resistant strains of *P. falciparum* actively transport chloroquine out of the intraparasitic compartment. Although this action can be blocked by calcium-channel inhibitors in vitro, chloroquine resistance has not been effectively reversed in humans. Hydroxychloroquine (Plaquenil), which is used for rheumatologic diseases, is also effective against chloroquine-sensitive *Plasmodium* species.

Chloroquine is generally well tolerated when used at the doses recommended for the prophylaxis and treatment of malaria. Side effects include headache, nausea, vomiting, blurred vision, dizziness, and fatigue. Some Africans and African Americans experience pruritus, which responds to antihistamines. Rare side effects include depigmentation of hair, exacerbation of psoriasis, blood dyscrasias, seizures, neuropsychiatric effects, and reactions in persons with porphyria. Retinal damage has occurred in persons receiving chloroquine at high doses for the treatment of rheumatologic disorders, but it has not been documented as a problem in those taking it weekly over a period of many years for malaria prophylaxis. Cardiopulmonary collapse and death have occurred after accidental overdose and in adults attempting suicide. As little as 5 g of chloroquine can be fatal unless treatment is initiated with mechanical respiration, medications to control seizures, and blood pressure support.

Primaquine, an 8-aminoquinoline, eradicates the hepatic hypnozoite stage of *P. vivax* and *P. ovale* and is used as a 14-day course at the end of treatment or prophylaxis to prevent late relapses in persons who are or may be infected with these *Plasmodium* species. It is also an alternative for daily prophylaxis for *Plasmodium vivax* and other species. In that case, it is begun 1 or 2 days before exposure and continued during and for 7 days after the traveler leaves the endemic area.

Primaquine is well absorbed orally and rapidly converted to carboxyprimaquine, which has a half-life of approximately 7 days. It is generally well tolerated, although some recipients experience abdominal cramps, epigastric distress, and nausea. The major concern is hemolysis in persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 161). The G6PD status of the recipient should be determined before it is administered. Rarely, primaquine causes neutropenia, methemoglobinemia, hypertension, or arrhythmias. Primaquine is contraindicated during pregnancy and in breast-feeding mothers because life-threatening hemolysis may occur if the fetus or baby is deficient in G6PD. Travelers should be warned not to give the drug to fellow travelers who have not been screened for G6PD deficiency.

Quinine sulfate, a cinchona alkaloid, is the oldest of the antimalarials. It has a very bitter taste. It is rapidly absorbed after oral administration and has a half-life of 16 to 18 hours in persons with malaria. Quinine has the poorest therapeutic-to-toxicity ratio of any antimalarial drug. The side effects, known collectively as cinchonism, include tinnitus, decreased hearing, headache, nausea, vomiting, dysphoria, and visual disturbances. They are dose related and reversible. Quinine has also been associated with severe hypoglycemia in persons with heavy *P. falciparum* infection as a result of the utilization of glucose by the parasites and release of insulin from the pancreas. Hypoglycemia can be prevented or treated by the intravenous administration of glucose. Rare complications with quinine include massive hemolysis in patients with heavy *P. falciparum* infection resulting in hemoglobinuria and renal failure (blackwater fever), cutaneous hypersensitivity reactions, agranulocytosis, and hepatitis. Quinine can cause respiratory paralysis in persons with myasthenia gravis. It stimulates uterine contractions and can produce abortions, but it has saved the lives of many pregnant women with *P. falciparum* malaria. Quinine dihydrochloride given intravenously can cause myocardial depression, peripheral vascular collapse, respiratory depression, and potentially death.

Quinidine gluconate, the stereoisomer of quinine, is recommended for the intravenous treatment of patients with severe malaria and in those who cannot take antimalarials orally. Quinidine gluconate was once widely used for the treatment of ventricular ectopy, but it has been replaced by newer antiarrhythmic agents, which has decreased its availability in many hospitals. Side effects include prolongation of the QT interval, arrhythmias, and hypotension, particularly if it is infused too rapidly. Persons receiving intravenous quinidine should be monitored in an intensive care setting, and therapy should be switched to an oral antimalarial medication as soon as possible.

Artemether,[5] ***artesunate***,[6] and other artemisinins are sesquiterpene lactone derivatives of the wormwood plant *Artemisia annua*, from which qinghaosu, the Chinese herbal medication for fever, is derived. They are endoperoxide-containing compounds. In the presence of intraparasitic iron, they are converted into free radicals and other intermediates that alkylate specific malarial proteins and act rapidly to kill intraerythrocytic parasites. The artemisinins have been used widely around the world for the treatment of acute malaria caused by chloroquine-resistant *P. falciparum*, as well as other *Plasmodium* species. They are usually administered with a second antimalarial drug that has a different mechanism of action and longer half-life to prevent the development of resistance. The route of administration with artemisinins varies; some are well absorbed orally, whereas others are administered intravenously, intramuscularly, or by suppository. Their short half-lives preclude their use for prophylaxis. Side effects in humans are common but seldom result in discontinuation of the drug. Neurologic toxicity and cerebellar dysfunction have been observed in dogs receiving chronic, high-dose therapy.

Artemether plus lumefantrine (Coartem), a fixed drug combination, is available in the United States and has been widely used around the world to treat chloroquine-resistant malaria. It should be taken with food, but grapefruit juice should be avoided. Common adverse reactions in adults are headache, anorexia, dizziness, asthenia, arthralgia, and myalgia. The most common in children are fever, cough, vomiting, anorexia, and headache. They do not usually require discontinuation of therapy. Of greater concern, artemether-lumefantrine can result in prolongation of the QT interval and is contraindicated in persons with abnormal QT. It also inhibits CYP206 and can hereby reduce the metabolism of other medications that prolong the QT interval. It can also decrease the effectiveness of birth control pills. Care must be taken in reviewing the recipient's medication list for potential interactions before artemether-lumefantrine is prescribed.

Artesunate is available from the CDC as an investigational new drug for the intravenous treatment of severe malaria in persons who cannot take quinidine gluconate, in those who have failed quinidine, or when it is not available (contact the CDC Malaria Hot Line for information). Artesunate is rapidly hydrolyzed to dihydroartemisinin, which is responsible for the antimalarial effect. Studies in malaria endemic regions suggest that parenteral artesunate has a higher success rate and lower adverse event rate than quinidine. In addition to the side effects with Coartem described previously, artesunate has been associated with delayed hemolysis approximately 2 weeks after completion of therapy.

Toxoplasmosis, Babesiosis, and Amoebic Encephalitis

Toxoplasma gondii (Chapter 349) and *Babesia* species (Chapter 353) are other important pathogens of the phylum Apicomplexa. Pyrimethamine and sulfadiazine are recommended for the treatment of toxoplasmosis. They inhibit sequential steps in the folic acid metabolic pathway. Pyrimethamine preferentially inhibits dihydrofolate reductase in susceptible parasites. It is well absorbed orally. The major side effect is macrocytic anemia, which can be prevented by the concurrent administration of leucovorin. Sulfonamides reduce the activity of dihydropteroate synthetase and the binding of *p*-aminobenzoic acid to it. In ocular toxoplasmosis with macular involvement, corticosteroids are used along with anti-*Toxoplasma* therapy to minimize the local inflammatory response. Clindamycin plus pyrimethamine and atovaquone plus pyrimethamine are therapeutic options in sulfonamide-intolerant patients. Persons with AIDS, $CD4^+$ counts less than $100/mm^3$, and serologic evidence of *T. gondii* infection should receive prophylaxis with one of the following regimens: daily trimethoprim-sulfamethoxazole, pyrimethamine plus dapsone, pyrimethamine plus atovaquone, or atovaquone alone. Spiramycin, a macrolide, is used for the treatment of toxoplasmosis during pregnancy. Two therapeutic regimens are available for babesiosis. The greatest experience has been with the combination of clindamycin plus quinine, but side effects are common. Atovaquone plus azithromycin is effective and better tolerated (Chapter 353). Finally, the addition of miltefosine, an antileishmanial drug (see later), to multidrug regimens has improved the outcome of persons with encephalitis due to the free-living *Acanthamoeba* and *Balamuthia*. It is now recommended as part of regimens to treat them as well as *Naegleria* infections. It is available from the CDC for these infections.

CHAGAS' DISEASE, AFRICAN TRYPANOSOMIASIS, AND LEISHMANIASIS

The *Leishmania* species that cause cutaneous, mucosal, and visceral leishmaniasis; *Trypanosoma cruzi*, the etiology of Chagas' disease; and *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense,* which are responsible for human African trypanosomiasis (sleeping sickness); pose difficult therapeutic challenges.

Nifurtimox and benznidazole orally are the only drugs available to treat *T. cruzi* (Chapter 347).[7] Benznidazole has been used widely in endemic areas in Latin America and nifurtimox in the United States. They lower mortality and shorten the duration of acute Chagas' disease. Treatment is also recommended for persons with recent infection as well as asymptomatic children and adults through middle age with indeterminate-stage *T. cruzi* infection. The percentage of those who are parasitologically cured by treatment has been debated. Neither benznidazole nor nifurtimox can reverse the manifestations of chronic Chagas' disease after they have developed. Side effects are common with both drugs and increase in frequency and severity with age. Benznidazole is associated with allergic dermatitis, peripheral neuropathy, insomnia, and gastrointestinal symptoms, including anorexia and weight loss. Nifurtimox causes anorexia, nausea, vomiting, weight loss, headache, dizziness or vertigo, paresthesias, weakness, and polyneuropathy.

Suramin, pentamidine, eflornithine, and melarsoprol are used for the treatment of human African trypanosomiasis (Chapter 346). Suramin is recommended for the hemolymphatic stage of *T. brucei rhodesiense* infection, and melarsoprol is used in those with CNS involvement. Both drugs are associated with potentially severe side effects. Eflornithine, which is much better tolerated, is effective against both the hemolymphatic and CNS stages of *T. brucei gambiense* infection. It does not have activity against *T. brucei rhodesiense*. Unfortunately, eflornithine is costly and not available in many endemic areas, and supplies are limited. When eflornithine is not available, pentamidine, which has substantial untoward effects, is used for the hemolymphatic stage of *T. brucei gambiense* infection, with suramin being used as an alternative. Melarsoprol is used for CNS disease.

Liposomal amphotericin B (AmBisome) and miltefosine are the only drugs approved by the FDA for treatment of visceral leishmaniasis (Chapter 348) in the United States. Amphotericin B deoxycholate is also effective. Liposomes deliver amphotericin to macrophages and are theoretically attractive because leishmania reside within them. Liposomal amphotericin B is also better tolerated than amphotericin B. Other lipid-associated amphotericin B preparations appear to be effective, but they have been less extensively studied and are not FDA approved for this indication.

For many years, two pentavalent antimony drugs, stibogluconate sodium and meglumine antimoniate, were used to treat visceral leishmaniasis, but resistance is now common among *Leishmania donovani* isolates in India, and therapeutic failures occur in other areas. In addition, pentavalent antimonials require parenteral administration. Side effects increase with age and include gastrointestinal complaints, pancreatitis, myalgias, headache, malaise, elevated liver enzyme levels, and occasionally, bone marrow suppression. Nonspecific ST-T wave changes are common. Sudden death has been reported in persons receiving more than the recommended dose.

Miltefosine,[8] an alkylphospholipid and phosphocholine analogue, that was initially developed as an antineoplastic drug, has proved effective for the treatment of antimony-resistant visceral leishmaniasis in the Indian subcontinent and for cutaneous leishmaniasis in a number of other geographic locations. A major advantage is oral administration. The pharmacokinetics are characterized by a long elimination half-life and extensive drug accumulation. The mechanism of action is uncertain, but it induces apoptosis-like changes in the parasite and has immune modulatory effects in the host. Side effects are frequent but typically are mild to moderate. Dose-dependent gastrointestinal toxicity can result in nausea, vomiting, and diarrhea. They tend to decrease with continued administration of the drug. Elevations in liver enzymes and creatinine are common but usually transient. Miltefosine is embryotoxic and is thus contraindicated during pregnancy. Contraceptive cover is mandatory in females of childbearing years during and for 4 months after therapy. Although miltefosine has proved effective in the treatment of visceral leishmaniasis on the Indian subcontinent, relapses have been reported in 10 to 20% of cases and are even more frequent in persons coinfected with HIV/AIDS. Resistance has also been reported.

Treatment of cutaneous leishmaniasis depends on the size, number, complexity, and location of the skin lesions, their cosmetic impact, the infecting *Leishmania* species, and its propensity to cause mucosal disease. Simple lesions acquired in Europe, Africa, and Asia where mucosal dissemination is rare are often treated topically, or if they are spontaneously healing, followed without therapy. Lesion-directed treatment options include cryotherapy; heat therapy, which requires a specialized delivery system; or intralesional injection of pentostam, which is not available in the United States. Topical therapy with direct application of paromomycin is another option. An ointment containing 15% paromomycin and 12% methylbenzethonium chloride in white paraffin developed in Israel has been the most widely used. Recent results with a U.S. Army formulation of topical paromomycin appear very promising.[9]

Parenteral or oral antileishmanial therapy is used for persons with complicated cutaneous disease and those who are or may be infected with a New World *Leishmania* species potentially associated with mucosal leishmaniasis. Stibogluconate sodium and meglumine antimoniate have been used widely over the years, but toxicity and the requirement for parenteral administration are problematic. Miltefosine has also been used in the treatment of cutaneous and mucosal leishmaniasis. The efficacy has varied with the *Leishmania* species and geographic location. The imidazole antifungals vary in their activity against different *Leishmania* species. Recent clinical experience in Brazil suggests that higher doses of fluconazole are more effective than the 200-mg/day dose used in earlier trials. Liposomal amphotericin B and amphotericin B deoxycholate are effective but more toxic and expensive parenteral alternatives.

Mucosal leishmaniasis is less responsive than cutaneous leishmaniasis to treatment, and relapses are common. Therapeutic options include stibogluconate sodium, meglumine antimoniate, liposomal amphotericin B, amphotericin B deoxycholate, and miltefosine.

REVIEW QUESTIONS

1. A regional health district in a resource limited area in rural Africa desires to treat school children empirically for intestinal helminthes to enhance their growth and intellectual development. Which of the following would be the best choice?

A. Albendazole 400 mg once
B. Ivermectin 150 µg/kg once
C. Diethylcarbamazine 50 mg once
E. Pyrantel pamoate 100 mg once
F. Praziquantel 50 mg/kg once

Answer: A The most likely intestinal helminthes in areas of poor sanitation are *Ascaris lumbricoides*, hookworms, and *Trichuris trichiura*. A single dose of albendazole 400 mg is active against all of them. Ivermectin can be used against *Ascaris* and *Trichuris* but lacks activity against hook worms. Pyrantel pamoate has activity against *Ascaris* and hookworms, but not *Trichuris*. Diethylcarbamazine is used for the treatment of lymphatic filariasis. Praziquantel is used for the treatment of intestinal tapeworms (cestode) and most fluke (trematode) infections.

2. Plans are underway to start a new hospital in Southeast Asia where *Schistosoma japonicum*, *Fasciolopsis buski,* and *Clonorchis sinensis* are endemic. Which of the following antihelminthic medications should be available to treat these diseases?

A. Nitazoxanide
B. Praziquantel
C. Albendazole
D. Atovaquone/proguanil
E. Tinidazole

Answer: B Praziquantel is the treatment of choice for these three pathogens and other flukes (trematodes) with the exception of *Fasciola hepatica*, the liver fluke. Nitazoxanide is indicated for intestinal protozoa, including *Giardia lamblia* and *Cryptosporidium,* and has activity against some intestinal nematodes and cestodes. Albendazole is used primarily for intestinal round worms and neurocysticercosis. Atovaquone/proguanil is effective for the prophylaxis and treatment of malaria. Tinidazole is used for the treatment of anaerobic luminal pathogens including *Entamoeba histolytica, Giardia lamblia,* and *Trichomonas vaginalis*.

3. A 24-year-old man is planning a 7-day trip to a game park in Tanzania, East Africa. He has a history of depression, which is well controlled with daily fluoxetine (Prozac). Which of the following would be the best choice for malaria prophylaxis?

A. Mefloquine (Lariam) weekly
B. Artemether/lumefantrine (Coartem) daily
C. Chloroquine weekly
D. Pyrimethamine daily
E. Atovaquone/proguanil (Malarone) daily

Answer: E The options for prevention of chloroquine-resistant malaria include atovaquone/proguanil, doxycycline, mefloquine, and primaquine. They are of comparable efficacy. In respect to side effects, atovaquone/proguanil is the best tolerated. Artemether/lumefantrine and other artemisinin derivates have short half-lives and cannot be used for prophylaxis. Chloroquine cannot be used in sub-Saharan Africa where chloroquine-resistant *Plasmodium falciparum* is endemic. Likewise, resistance to pyrimethamine is widespread in Africa. Mefloquine is effective against chloroquine-resistant malaria but is associated with serious neuropsychiatric and other effects, including depression, psychosis, and seizures.

4. A 55-year-old woman presented in May with fever and headache of 1 day's duration. She returned 7 days earlier from a 3-week trip to game parks in Tanzania, East Africa. She is otherwise in good health and taking no medications. She denies cough, sputum production, nausea, vomiting, diarrhea, dysuria, and skin rash. On examination, her temperature is 40° C, blood pressure is 120/85 mm Hg, heart rate is 120 beats per minute, and respiratory rate is 18 breaths per minute. She has no rash, her neck is supple, chest is clear to auscultation and percussion, and abdomen is soft and nontender with normal bowel sounds. The laboratory technician on call has never done a malaria smear, and the hospital does not offer rapid diagnostic tests. Results from a reference laboratory will be available in 24 hours. Which of the following would be the best course of action?

A. Treat with mefloquine
B. Treat if parasites are identified at the reference laboratory
C. Treat with chloroquine
D. Treat with artemether/lumefantrine (Coartem)
E. Treat with doxycycline

Answer: D Fever in a returning traveler from Africa is malaria until proved otherwise! A delay in treatment can result in death, and therapy should not be delayed. The fastest acting drug for acute malaria is the fixed combination artemether/lumefantrine. Chloroquine cannot be used because of widespread chloroquine-resistant *Plasmodium falciparum* in East Africa. High-dose mefloquine has the risk for neurologic toxicity and would be used only if other antimalarial drugs were not available. Doxycycline does not act rapidly enough to be used alone for the treatment of acute malaria.

5. A 27-year-old woman presents with diarrhea of 3 weeks' duration. She recently returned after a 6-week visit to the Amazon Basin of South America. She stayed in local houses, drank tap water, and was an adventurous eater. She has had four to six loose stools a day, bloating, and intermittent abdominal crampy pain. On physical examination, her temperature is 37.0° C, blood pressure is 120/62 mm Hg, heart rate is 70 beats per minute, and respiratory rate is 12 breaths per minute. She is in no distress. The bowel sounds are normal. Her abdomen is soft, nontender, and without mass or hepatosplenomegaly. The rectal examination is normal. She is HIV negative. Stool tests are positive for cryptosporidial antigen and giardia antigen. What is the best choice for treatment?

A. Nitazoxanide
B. Tinidazole
C. Metronidazole
D. Albendazole
E. Praziquantel

Answer: A Nitazoxanide is the only drug with activity against *Cryptosporidium* species, and it is also effective against *Giardia*. Tinidazole and metronidazole are active against luminal protozoa, including *Entamoeba histolytica*, *Giardia lamblia,* and some others, but not *Cryptosporidium*. Albendazole is active against most intestinal nematodes. Although it has some activity against *Giardia*, albendazole is not the drug of choice for giardiasis and is not effective for *Cryptosporidium*. Praziquantel has activity against tapeworms (cestodes) and most flukes (trematodes), with the exception of *Fasciola hepatica.*

345

MALARIA

PHILIP J. ROSENTHAL AND MOSES R. KAMYA

DEFINITION

Malaria is caused by infection with protozoan parasites of the genus *Plasmodium,* all of which are transmitted by bites of infected anopheline mosquitoes.[1] Malaria is typically characterized by an acute febrile illness, with parasites infecting large numbers of erythrocytes, and classically entails recurrent episodes of fever and chills. It was first described thousands of years ago and is named on the basis of the belief that it was caused by the bad air of the marshes surrounding Rome. Malaria is common, causing hundreds of millions of illnesses each year throughout most of the tropics. Severe disease can occur, primarily with *Plasmodium falciparum* infection, with the acute development of serious organ dysfunction or when chronic and repeated infection leads to severe anemia. *P. falciparum* malaria kills an estimated 660,000 people each year, mostly children in sub-Saharan Africa.

The Pathogen

P. falciparum is responsible for most episodes of severe malaria. It is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P. falciparum,* except in Africa, but causes severe disease much less commonly. However, studies suggest that severe illness associated with *P. vivax* infection is more common than had previously been appreciated.[2] *Plasmodium ovale* and *Plasmodium malariae* are

much less common causes of disease and generally do not cause severe illness. A fifth parasite causing human infections is *Plasmodium knowlesi*, a parasite of macaque monkeys that is a fairly common zoonosis in parts of Southeast Asia and has been responsible for malarial illnesses, including severe disease, in individuals exposed to macaque-biting vectors in forested areas.

EPIDEMIOLOGY

Malaria in Endemic Countries

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and hundreds of thousands of deaths each year. The disease is endemic in most of the tropics, including many parts of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where infection with *P. falciparum* predominates. In most other endemic areas, disease caused by both *P. falciparum* and *P. vivax* is common. In highly endemic areas, the group at greatest risk is young children, who experience most episodes of disease and the most deaths. A second high-risk group is pregnant women, with high risks of maternal and fetal morbidity from *P. falciparum* malaria, including many deaths secondary to low birthweight. In highly endemic areas, in addition to extensive mortality, malaria exerts a massive toll through adverse effects on child development; contributions to school and work absenteeism; and, overall, billions of dollars in lost income among the poorest citizens of the poorest countries of the world. In areas of developing countries with lower levels of malaria transmission, malaria can be epidemic, with intermittent increases in transmission that cause major morbidity in relatively nonimmune populations.

Malaria in Travelers

Malaria is also common in travelers of any age from nonendemic areas to the tropics and may be manifested in those who have returned to nonendemic areas up to many months after travel. Indeed, malaria is the most common documented cause of febrile illness in travelers returning from the tropics to developed countries. Malaria is also rarely transmitted in areas considered nonendemic, including the United States, when imported parasites are transmitted by local anopheline mosquitoes, by blood products, or through congenital spread of infection.

Malaria Transmission

Malaria is transmitted by multiple species of mosquitoes of the genus *Anopheles,* which vary in geographic distribution, ecologic preferences, and susceptibility to mosquito control measures. Anopheline mosquitoes bite at night, so personal mosquito control measures focus on avoidance of mosquito bites overnight. Levels of malaria transmission in endemic areas vary greatly, from areas where residents experience only rare infectious bites to regions of Africa where individuals may receive hundreds of infectious bites each year.

Recent Changes in the Epidemiology of Malaria

A major effort to eradicate malaria after World War II led to elimination of the disease in many areas, including the United States and Europe, but eventually failed to control the disease in most of the tropics. During the ensuing decades, improvements in malaria control were few, and malarial morbidity worsened in many areas, driven by the loss of enthusiasm for vector control; increasing resistance of mosquitoes to insecticides; and, in particular, resistance of parasites to commonly used antimalarial drugs. More than 50 years later, a new large effort to control and eventually to eradicate malaria has been initiated.[3] Key control measures include indoor residual spraying of insecticides, distribution of insecticide-impregnated bed nets, prompt provision of effective drugs to those with malaria, and targeted administration of drugs to prevent infection in high-risk groups. Recent efforts have led to documented decreases in levels of malarial morbidity and mortality in some areas, notably parts of Africa,[4] Asia, and Oceania with relatively low levels of transmission intensity. It is of great interest to learn whether recent advances due to intensified control efforts can bring significant improvements to those parts of the world most affected with malaria, in particular, highly endemic regions of Africa and Asia.

Malaria and Human Immunodeficiency Virus Infection

Malaria does not differ as markedly between those with human immunodeficiency virus (HIV) infection and others as is the case with typical opportunistic infections. However, several interactions between malaria and HIV infection have been established. First, HIV infection appears to disrupt the acquired immune response to malaria and thereby increases the incidence and severity of malaria. Second, acute malaria elevates HIV viral load and so may increase the risk of HIV transmission. Third, HIV infection may be associated with reduced efficacy of antimalarial treatment, especially in the setting of severe immune suppression. Fourth, therapies for each infection may have an impact on the other, leading to unanticipated effects on drug efficacy or toxicity. Fifth, routine interventions for HIV infection may affect the incidence of malaria; notably, daily trimethoprim–sulfamethoxazole, a routine regimen in HIV-infected patients, offers partial protection against malaria. Because both HIV infection and malaria are common in many areas, in particular sub-Saharan Africa, even modest associations are important. Thus, malaria coinfection in HIV-infected individuals may be an important factor in promoting the spread of HIV infection in Africa. However, increasing implementation of insecticide treated bed nets, prophylaxis against opportunistic infections with trimethoprim–sulfamethoxazole, and antiretroviral therapy will likely substantially lessen malaria risk in HIV-infected patients, such that the risk in those receiving optimal management will not be substantially greater than that in the general population.

PATHOBIOLOGY

Parasite Life Cycle

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver and infect hepatocytes, causing asymptomatic liver infection (Fig. 345-1). Merozoites are subsequently released from the liver, and they rapidly infect

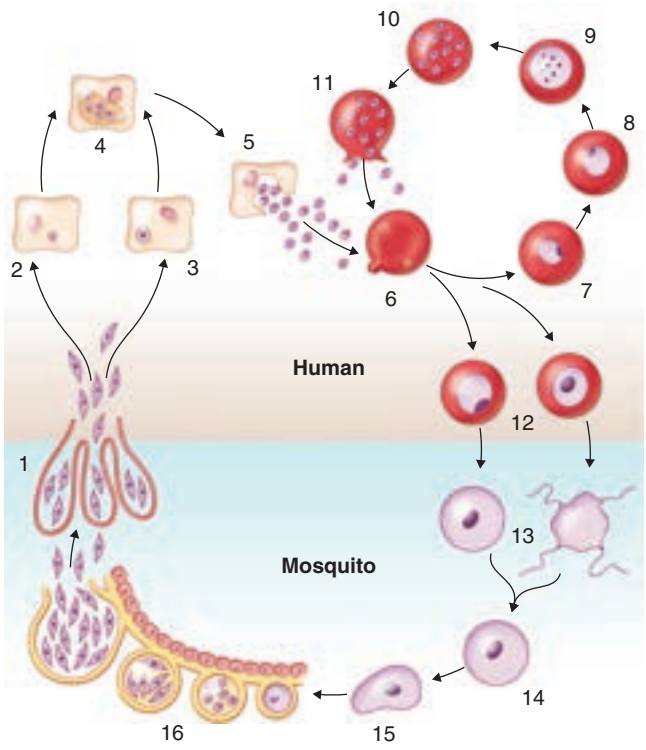

FIGURE 345-1. Life cycle of the malaria parasite. The *upper* and *lower halves* of the diagram indicate the human and anopheline mosquito parts of the cycle, respectively. Sporozoites from the salivary gland of a female *Anopheles* mosquito are injected under the skin (1). They then travel through the blood stream to the liver (2) and mature within hepatocytes to become tissue schizonts (4). Up to 30,000 parasites are then released into the blood stream as merozoites (5) and produce symptomatic infection as they invade and destroy red blood cells. However, in *Plasmodium vivax* and *Plasmodium ovale* infection, some parasites remain dormant in the liver as hypnozoites (3), which can later develop to tissue schizonts and merozoites, leading to relapse. Within the blood stream, merozoites (5) invade erythrocytes (6) and mature to the ring (7, 8), trophozoite (9), and schizont (10) asexual stages. Mature schizonts lyse their host erythrocytes and release the next generation of merozoites (11), which invade previously uninfected cells. Some erythrocytic parasites differentiate to sexual forms (male and female gametocytes) (12). When taken up by a mosquito, the gametocytes mature to male and female gametes (13), fuse to form zygotes (14), and then develop into ookinetes that invade the gut of the mosquito (15) and develop into oocysts (16). Mature oocysts produce sporozoites, which migrate to the salivary gland of the mosquito (1) to allow another human infection. (From Krogstad DJ: Blood and tissue protozoa. In: Schaechter M, Medoff G, Eisenstein BI, eds. *Mechanisms of Microbial Diseases.* 2nd ed. Baltimore: Williams & Wilkins; 1993:600.)

erythrocytes[5] to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Each erythrocytic cycle lasts approximately 24 hours for *P. knowlesi*; 48 hours for *P. falciparum*, *P. vivax*, and *P. ovale;* and 72 hours for *P. malariae*. Some erythrocytic parasites also develop into sexual gametocytes, which are taken up by mosquitoes. In the mosquito, gametocytes mature to gametes, and after fusion of male and female gametes to produce zygotes, parasites develop into ookinetes, oocysts, and then salivary gland sporozoites that are infectious for humans, allowing completion of the life cycle and infection of others. *P. vivax* and *P. ovale* also cause a chronic liver infection, in which hypnozoites persist in hepatocytes in a dormant state not eradicated by most therapies for acute disease and subsequently can progress to erythrocytic infection and a relapse of clinical illness.

Pathogenic Features of Malaria Parasites

The most common clinical feature of malaria is fever. Fever coincides with rupture of large numbers of schizont-infected erythrocytes at the completion of the erythrocytic cycle and with high circulating levels of tumor necrosis factor-α (TNF-α). Severe falciparum malaria is associated with very high levels of TNF-α and other inflammatory cytokines, but the specific roles of cytokines in pathogenesis are not well understood. *P. falciparum* infects erythrocytes of all ages, so it is capable of routinely causing high parasitemias, with infection of more than 1% of erythrocytes and more than 10^5 infected erythrocytes per microliter of blood. Non–*P. falciparum* parasites infect smaller numbers of erythrocytes, limiting the extent of infection and morbidity. Non–*P. falciparum* parasites are more likely to cause highly synchronous infections, leading if untreated to regular cycles of fever every 48 (*P. vivax* and *P. ovale*) or 72 (*P. malariae*) hours, often with minimal symptoms between fever episodes.

The contribution of parasite virulence determinants to the severity of malaria is poorly understood. A key biologic feature of *P. falciparum* infection is the ability of parasites to mediate the adherence of infected erythrocytes to a number of ligands on endothelial cells. By this mechanism, erythrocytes infected with the more mature stages of erythrocytic parasites do not circulate but rather adhere within small blood vessels in the brain and other organs. This phenomenon, termed cytoadherence, allows parasites to avoid passing through the spleen, where abnormal erythrocytes would be cleared. Cytoadherence is also likely to play a major role in mediating severe manifestations of *P. falciparum* malaria, with local inflammatory changes mediated by large numbers of adherent parasites leading to organ dysfunction. In particular, *P. falciparum* malaria can progress to cerebral malaria, including coma; noncardiogenic pulmonary edema, including severe respiratory compromise; and renal failure, severe anemia, acidosis, hypoglycemia, and other syndromes of organ dysfunction. Pregnancy selects for a subset of *P. falciparum* strains that specifically bind to ligands in the placenta. Pregnant women in endemic areas, in particular those in their first pregnancy who lack antibodies specific for placenta-binding parasites, are at high risk of morbidity, including anemia, from high parasite loads in the placenta and of poor fetal outcomes, including intrauterine growth retardation, spontaneous abortion, and low birthweight.

A common cause of death from *P. falciparum* malaria, in particular in children in endemic areas, is severe anemia. Anemia is caused by destruction of infected and uninfected erythrocytes, decreased hematopoiesis, and bleeding. In many endemic areas, most asymptomatic young children are infected with *P. falciparum,* with chronic infection contributing to chronic anemia. Other factors contributing to anemia are nutritional deficits and intestinal roundworm infections. With frequent malarial infections and chronic anemia, children are ill equipped to manage acute worsening of the anemia caused by acute malarial illness. With limited access to health care, children often present for medical care late in the course of illness if at all, and many deaths result.

P. falciparum parasites use antigenic variation to evade the host immune response. The principal protein that mediates the cytoadherence of infected erythrocytes to endothelial cells, *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), is transported to the erythrocyte surface and is a target of host immune responses that limit infection. The PfEMP-1 family comprises about 60 proteins, but only one PfEMP-1 variant is expressed on the surface of infected erythrocytes at a time. During the course of an infection, parasites frequently vary the expression of PfEMP-1s to stymie host responses. This factor and the high variability in sequence of many PfEMP-1 molecules present a broad repertoire of antigens and probably help explain the slow acquisition of protective antimalarial immunity. Antigenic variation and other aspects of immunologic diversity are poorly understood for non–*P. falciparum* malaria parasites, but each species appears capable of repeated infections.

Plasmodial parasites other than *P. falciparum* do not cause cytoadherence of infected erythrocytes, infect lower numbers of erythrocytes, and are much less commonly responsible for complicated and severe disease. However, recent reports suggest that *P. vivax* can cause severe disease, in particular respiratory compromise, more commonly than has previously been appreciated. *P. vivax* is also particularly prone to cause splenic rupture, although this complication can be seen with all malarial species. *P. malariae* most commonly causes a mild febrile illness, but chronic or repeated infection has been associated with an immune complex–mediated glomerulonephritis with nephrotic syndrome (Chapter 121). Recent reports indicate that *P. knowlesi* can cause severe illness, including deaths. The short (24-hour) erythrocytic cycle of *P. knowlesi,* which allows more rapid replication of these parasites compared with others, may partly explain the propensity of this zoonotic parasite to cause severe illness.

Host Immunity and Genetics

The nature of human immune responses to malaria remains poorly characterized, but protective responses require multiple infections and apparently humoral and cell-mediated responses. Where *P. falciparum* malaria is common, disease occurs primarily in children. After some protection during the first few months of life, probably because of protective effects of maternal antiplasmodial antibodies and fetal hemoglobin, young children are infected frequently, experience repeated febrile malaria illnesses, and are at high risk of severe disease. With repeated episodes of malaria, children develop partial immunity. Immunity develops gradually, with some protection against severe malaria after only a few infections, increasing protection against symptomatic illness in children, and eventually strong protection against infection. Thus, in highly endemic areas, young children experience frequent episodes of malaria, especially at about age 6 months to 5 years; older children are frequently infected but uncommonly symptomatic; and adults experience identifiable malarial parasitemia only uncommonly. However, antimalarial immunity is not complete; malaria can occur in individuals of any age. In addition, immunity requires boosting by repeated infections, so adults are at increased risk of disease if they return to a highly endemic site after an extended stay in a nonendemic area.

A number of human genetic polymorphisms offer protection against malaria.[6] The best characterized is sickle hemoglobin (Chapter 163). Hemoglobin S heterozygotes are partially protected against severe *P. falciparum* malaria, leading to a balanced polymorphism in which the survival advantage of the polymorphism allows persistence of sickle cell disease in homozygotes. Other erythrocyte polymorphisms that also are likely to offer protection against malaria include hemoglobin C and E, thalassemias (Chapter 162), glucose-6-phosphate dehydrogenase deficiency (Chapter 161), and ovalocytosis (Chapter 161). The Duffy antigen, an erythrocyte chemokine receptor of uncertain function, is the principal receptor on human erythrocytes for attachment and subsequent invasion of *P. vivax*. Most Africans lack the erythrocyte Duffy antigen, explaining the nearly complete absence of *P. vivax* malaria in most of Africa.

CLINICAL MANIFESTATIONS

Uncomplicated Malaria

Most malarial episodes, even with *P. falciparum* infection, are uncomplicated. The incubation period after an infectious bite is usually 10 to 14 days for *P. falciparum* and about 2 weeks for other species, but this can be much longer, especially in non–*P. falciparum* malaria and in individuals with prior immunity. The hallmark of malaria is fever, often with a nonspecific influenza-like prodrome including headache and fatigue followed by a classic malarial paroxysm including chills, high fever, and then sweats. Patients may be remarkably well between febrile episodes. Fevers are typically irregular early in the illness but without therapy may become regular, with 48-hour (*P. vivax* and *P. ovale*) or 72-hour (*P. malariae*) cycles, especially with non–*P. falciparum* disease. Headache, malaise, myalgias, arthralgias, rigors, confusion, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures are often simple febrile convulsions, especially in young children, but they also may represent evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical

in malaria and thus are suggestive of another cause of fever. Laboratory studies commonly show anemia, thrombocytopenia, and liver and renal function abnormalities.

Severe *P. falciparum* Malaria

Severe malaria can be defined as presentation with signs of severe illness or organ dysfunction (including prostration, impaired consciousness, convulsions, respiratory distress, shock, acidosis, severe anemia, excessive bleeding, hypoglycemia, jaundice, hemoglobinuria, and renal impairment) or a high parasite load (generally peripheral parasitemia >5% or >200,000 parasites/μL). Cerebral malaria, the most common severe complication in children, is generally defined as altered consciousness in the setting of *P. falciparum* malaria. Seizures are common, and deep coma, abnormal posturing, focal neurologic findings, and abnormal respiratory patterns can be seen. The mortality rate is 15% to 25%, with about 10% with persistence of neurologic sequelae, but many patients do remarkably well with appropriate therapy.

Severe anemia is a common presentation, particularly in young children. Transfusions are avoided when possible but play a key role in management of those with severe compromise. Respiratory failure is caused by noncardiogenic pulmonary edema and is more common in adults than in children. Mechanical ventilation can be life saving, if available. Acute renal failure is also more common in adults and generally due to hypoperfusion and acute tubular necrosis; hemofiltration and hemodialysis are valuable, if available. Blackwater fever, including intravascular hemolysis and hemoglobinuria, has an uncertain etiology but can be caused by quinine. Hepatic dysfunction, including jaundice, can be seen; jaundice may also be caused by hemolysis. Splenic enlargement is common, and splenic rupture can be seen. Hypoglycemia is common because of glucose consumption by parasites, increased demand, impaired gluconeogenesis, and quinine-induced insulin secretion; blood glucose levels should be observed closely, with glucose replacement as needed. Metabolic acidosis caused by lactic acidosis and other factors is common; the value of specific therapies for acidosis or aggressive fluid resuscitation is uncertain. Electrolyte derangements can be seen. Coagulopathy, caused by consumption of clotting factors, and marked thrombocytopenia, caused by increased platelet turnover, can lead to significant bleeding. Bacterial infection and sepsis can coexist with malaria; presumptive use of antibiotics is warranted when signs of sepsis are seen.

Complications of Non–*P. falciparum* Malaria

The large majority of infections with non–*P. falciparum* parasites are uncomplicated both in endemic areas and in nonimmune travelers. Nonetheless, *P. vivax* infection is common in many areas, and studies from a number of sites in Asia and Oceania have shown that it makes up about a quarter of children hospitalized with severe malaria, with a mortality rate of about 1%. Important features of severe *P. vivax* malaria include severe anemia and respiratory distress. All malarias, but in particular *P. vivax* infection, can be complicated by splenic rupture. Chronic malaria infections can be complicated by hyperreactive malarial splenomegaly, with massive splenomegaly and findings of hypersplenism. Chronic infections can also lead to the nephrotic syndrome, particularly with *P. malariae* infection.

DIAGNOSIS

Clinical Features

In individuals with febrile illness and malaria risk, it is essential to make a diagnosis promptly and important to distinguish the different species that infect humans because management differs according to the infecting species. Malaria is the most common cause of febrile illness in many areas, and with limited diagnostic capabilities, it is frequently diagnosed based only on presentation with a febrile illness. However, formal diagnosis is preferred. In travelers returning from endemic areas with fever, historical details can aid in the diagnosis. Malaria is most likely in individuals who failed to use measures to prevent infection and in travelers to the most highly endemic areas, such as rural sub-Saharan Africa. *P. falciparum* malaria generally has a fairly short incubation period in nonimmune individuals, so it presents within 1 to 2 months of return in more than 90% of travelers. Infection with the other malarial species can present a number of months and uncommonly more than 1 year after exposure.

Blood Smears

The standard means of diagnosis in malaria-endemic areas is by thick blood smear. In this procedure, 1 drop of blood is allowed to dry on a slide, erythrocytes are lysed, and parasites are then stained with Giemsa. Parasites are easily identified by trained microscopists, and parasite density can be estimated on the basis of counts relative to those of leukocytes. However, thick blood smears do not allow identification of erythrocyte morphology, which is helpful in species diagnosis, and are difficult for those with limited training. Giemsa-stained thin blood smears offer an improved means of characterizing parasite morphology, but the process is much less efficient than for thick smears. Thus, thick smears are the standard means of diagnosis in highly endemic areas, and thin smears are preferred where malaria is uncommon and where laboratory personnel have ample time to examine multiple microscopic fields. It is important to distinguish infecting species of malaria parasites. In *P. falciparum* infection, generally only ring-form asexual parasites are seen. Trophozoites of *P. vivax* and *P. ovale* are present in enlarged (and ovoid in the case of *P. ovale*) erythrocytes that contain inclusions known as Schüffner's dots. Intraerythrocytic *P. malariae* and *P. knowlesi* trophozoites are often elongate in shape. Sexual stage gametocytes (which have a characteristic oblong shape in *P. falciparum*) are also seen on blood smears; most treatments do not eradicate gametocytes, so persistence of these forms for a few weeks is not a sign of treatment failure.

Antigen Detection

An important new means of malaria diagnosis is antigen detection. Multiple simple tests are now available, incorporating colorimetric detection of one or two antigens in an assay that requires limited training and only a few minutes.[7] The most used assays in Africa use histidine-rich protein-2, a protein that is abundant and long-lived but expressed only by *P. falciparum*. Other assays identify plasmodial lactate dehydrogenase and aldolase, which are produced by all human malarial species. Some tests use two antigens to separately identify *P. falciparum* and all-species plasmodial infection. Rapid diagnostic tests have recently become a standard component of many malaria control programs. One test is approved in the United States. However, with many different tests available around the world, standardization is not optimal, and the specific role of rapid antigen tests for the diagnosis of malaria in different epidemiologic settings is not yet established.

Other Diagnostic Tests

Serologic tests are available to identify prior malaria infection, but responses develop slowly and persist for an extended period, so these tests have limited clinical value unless it is helpful to diagnose the cause of a febrile illness retrospectively in an individual without prior history of malaria. Malaria parasites can be identified readily with polymerase chain reaction (PCR) using primers encoding genus- and species-specific sequences. These tests are convenient for research purposes because they can be conducted on DNA extracted from blood spotted onto filter paper in field settings. PCR is more sensitive than other diagnostic modalities. It is not practical for routine diagnosis because of the time required to complete an assay, the uncertain significance of a positive test result in endemic areas where low-level parasitemia may be common and clinically insignificant, and the cost and logistical requirements of the procedure in developing countries.

TREATMENT Rx

The treatment of falciparum malaria has been challenged by drug resistance for many years[8,9] and has changed dramatically recently, with recommendations for artemisinin-based combination therapy (ACT) in nearly all countries endemic for *P. falciparum* malaria (Table 345-1). Non–*P. falciparum* malaria is still generally treated with chloroquine, although chloroquine resistance is increasing in *P. vivax*; resistant vivax malaria can be treated with other drugs that are standard to treat falciparum malaria.

Chloroquine and Other Aminoquinolines

Chloroquine has been widely used to treat malaria for more than 60 years. It remains the treatment of choice for non–*P. falciparum* malaria and *P. falciparum* malaria in the few areas where resistance has not been seen (primarily Central America and the Caribbean) and is generally rapidly effective and well tolerated. For *P. vivax* and *P. ovale* infections, primaquine must also be given to eradicate dormant liver forms and thereby prevent subsequent relapse. Chloroquine remains effective as weekly chemoprophylaxis to prevent malaria in areas without resistance. Amodiaquine and piperaquine probably share mechanisms of action with chloroquine, but they are routinely active against chloroquine-resistant parasites because of increased potency compared with chloroquine and some differences in mechanisms of resistance. Monotherapy with either drug is discouraged, but each is now a component of a leading ACT (Table 345-2). Amodiaquine is somewhat less well tolerated than other

TABLE 345-1 TREATMENT OF MALARIA*

CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*, RESISTANT *PLASMODIUM VIVAX*, OR SPECIES UNIDENTIFIED	
UNCOMPLICATED DISEASE	
Coartem (artemether 20 mg, lumefantrine 120 mg)	4 tablets orally twice daily for 3 days
or	
Malarone (atovaquone 250 mg, proguanil 100 mg)	4 tablets daily for 3 days
or	
Quinine	650 mg quinine sulfate 3 times daily for 3-7 days
plus	
Doxycycline	100 mg twice daily for 7 days
or plus	
Clindamycin	600 mg twice daily for 7 days
or	
Mefloquine	750 mg followed by 500 mg in 6-8 hours; can also be given as a single 1250-mg dose, although this is less well tolerated than the divided dose
COMPLICATED *P. FALCIPARUM* MALARIA OR UNABLE TO TOLERATE ORAL MEDICATIONS†	
IV artesunate‡	2.4 mg/kg every 12 hr on day 1; then daily for 2 additional days
or	
IV quinidine gluconate§	10 mg/kg over 1 to 2 hr; then 0.02 mg/kg/min *or* 15 mg/kg over 4 hr; then 7.5 mg/kg over 4 hr every 8 hr
or	
IV quinine dihydrochloride§,‖	20 mg/kg over 4 hr; then 10 mg/kg every 8 hr
or	
IM artemether‖	3.2 mg/kg IM; then 1.6 mg/kg/day
CHLOROQUINE-SUSCEPTIBLE *P. FALCIPARUM* AND OTHER SPECIES	
Chloroquine phosphate	1 g, followed by 500 mg at 6, 24, and 48 hr *or* 1 g at 0 and 24 hr; then 0.5 g at 48 hr
plus (for *P. vivax* and *P. ovale* only)	
Primaquine¶	30-mg base (52.6 mg primaquine phosphate) daily for 14 days

*Dosages refer to salts unless indicated and are for adults. For pediatric dosing and full Centers for Disease Control and Prevention (CDC) recommendations, see http://www.cdc.gov/malaria/pdf/treatmenttable.pdf.
†IV regimens should be given until the patient can tolerate oral agents and then followed by a course of oral therapy (doxycycline, clindamycin, or full treatment courses of other drugs, as listed) when patients can tolerate this.
‡Available in the United States on an investigational basis through the CDC.
§Cardiac monitoring should be in place during IV administration of quinidine or quinine.
‖Not available in the United States.
¶Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.
IM, Intramuscular; *IV,* intravenous.

TABLE 345-2 RECOMMENDATIONS FOR THE TREATMENT OF *PLASMODIUM FALCIPARUM* MALARIA IN DEVELOPING COUNTRIES*

REGIMEN	NOTES
Artemether–lumefantrine (Coartem, Riamet)	First-line therapy in many countries; FDA approved
Artesunate–amodiaquine (ASAQ)	First-line therapy in many African countries; efficacy limited by resistance to amodiaquine in many areas
Artesunate–mefloquine	Standard therapy in parts of Southeast Asia
Artesunate–sulfadoxine–pyrimethamine	Efficacy low compared with other regimens in most areas
Dihydroartemisinin–piperaquine	Newer regimen; highly effective in studies in Asia and Africa

*Recommendations modified from World Health Organization. *Guidelines for the Treatment of Malaria.* Geneva: World Health Organization; 2010.
FDA, Food and Drug Administration.

aminoquinolines. It is generally safe with short-term use but can cause rare serious toxicities, including hepatic and bone marrow toxicity, especially with chronic use, and so it is not recommended for chemoprophylaxis. Piperaquine was well tolerated during extensive use in China a few decades ago; although resistance was reportedly common in China, it does not appear to be a problem at present.

Mefloquine, Halofantrine, and Lumefantrine

Mefloquine offers effective therapy and chemoprophylaxis for most chloroquine-resistant strains of *P. falciparum* and for other species. Resistance to mefloquine is uncommon but has been seen in parts of Southeast Asia. Mefloquine is now used to treat *P. falciparum* malaria in combination with artesunate and is one of three drugs recommended for chemoprophylaxis against *P. falciparum* by the Centers for Disease Control and Prevention (CDC). Tolerability of chemoprophylactic and especially treatment doses of mefloquine is often limited by neurologic and gastrointestinal (GI) toxicity. Halofantrine is an effective drug; however, its use is limited by uncommon but dangerous cardiac rhythm disturbances. Lumefantrine is a related drug that does not share this toxicity and offers effective therapy in combination with artemether as Coartem.

Quinine and Quinidine

Quinine has been used to treat malaria for hundreds of years. It offers rapid action against all species, with limited known resistance except in Southeast Asia, where failures against *P. falciparum* malaria are fairly common. Quinine can be used to treat uncomplicated malaria, but GI and other nonspecific toxicities lead to difficulty in tolerating a full 7-day treatment course. This problem is circumvented by combining a 3-day course of quinine with other agents. For severe disease, intravenous (IV) quinine or, in the United States, IV quinidine has been standard therapy for many years; therapy should be accompanied by cardiac monitoring because of cardiac toxicities of the drugs.

Primaquine

Primaquine is the only available drug to eradicate dormant liver forms of *P. vivax* and *P. ovale* that are not cleared by other drugs and can lead to relapses after therapy with chloroquine and other agents. Primaquine is also an alternative agent for chemoprophylaxis against *P. falciparum* and other species. Primaquine use is limited principally by hemolysis or methemoglobinemia (Chapter 158) in individuals with deficiency in glucose-6-phosphate dehydrogenase (Chapter 161). Testing for deficiency should be performed before use of the drug.

Inhibitors of Folate Metabolism

Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase and dihydropteroate synthase, are used in fixed-dose combination regimens for the treatment and prevention of malaria. For treatment, sulfadoxine–pyrimethamine (Fansidar) was heavily used to treat uncomplicated *P. falciparum* malaria, but resistance has increased markedly in most endemic areas. The dihydrofolate reductase inhibitor proguanil is combined with atovaquone in Malarone (see later). For chemoprophylaxis, sulfadoxine–pyrimethamine is no longer recommended because of drug resistance and rare life-threatening dermatologic toxicities. However, less frequent dosing in intermittent preventive therapy regimens has been well tolerated and has decreased malaria in high-risk African groups, particularly pregnant women and young children. Seasonal malaria chemoprevention with monthly combined sulfadoxine–pyrimethamine and amodiaquine during the transmission season is now recommended for malaria control in areas of Africa with highly seasonal transmission and limited drug resistance. Daily trimethoprim–sulfamethoxazole, a common prophylactic to prevent opportunistic infections in individuals with HIV infection, has offered some protection against malaria in Africa.

Artemisinins

Artemisinin, the active component of an herbal medicine from China, and a number of its analogues offer rapid elimination of circulating malaria parasites and activity against gametocytes to limit disease transmission. The drugs are all short-acting, leading to frequent recrudescences of infection after short-course monotherapy. For this reason and to limit selection of resistance, artemisinins are now used in combination with longer acting drugs to treat malaria in 3-day regimens. A number of these combinations have become the standard therapies for *P. falciparum* malaria in most endemic

countries (see Table 345-2). Leading regimens are fixed-dose combinations of artemether–lumefantrine, artesunate–amodiaquine, artesunate–mefloquine, and dihydroartemisinin–piperaquine, and artesunate–pyronaridine will soon be available.[A1] In some settings rank orders of efficacy are seen for leading ACTs, typically with optimal efficacy for artemether–lumefantrine or dihydroartemisinin–piperaquine, although results have varied based on study details and geography. Of these, artemether–lumefantrine is most widely advocated, is now approved in the United States, and includes a partner drug that has never been available as monotherapy, but it requires twice-daily therapy. The other regimens offer once-daily therapy but have potential problems with resistance to partner drugs. Resistance to artemisinins is a recent concern, with evidence for prolonged times to parasite clearance in Southeast Asia suggestive of diminished drug responsiveness of *P. falciparum*.[9-11] Artemisinins also have an increasing role for the treatment of severe malaria. IV artesunate has been shown to be superior to quinine for the treatment of severe malaria in a mostly adult population in Asia[A2] and in African children,[A3] notably with survival advantages over quinine in both populations. For settings with limited infrastructure, intramuscular artemether and intrarectal artesunate have also shown good efficacy. IV artesunate should now be considered the first-line therapy for severe malaria in the United States, where it is available from the CDC. Artemisinins are generally very well tolerated, with minimal toxicity.

Atovaquone–Proguanil (Malarone)

This fixed-dose combination of a dihydrofolate reductase inhibitor and atovaquone, which has a unique antimalarial mechanism, has excellent efficacy against most *P. falciparum* infections. It is approved for both treatment and chemoprophylaxis of *P. falciparum* malaria and other species in the United States, where it is now widely used for both indications. Malarone offers excellent efficacy with minimal toxicity. Adverse effects may include GI symptoms, elevations in liver enzymes, headache, and rash. Widespread use in developing countries is limited by high cost and concerns about resistance because resistance to each component drug is readily selected.

Antibiotics

A number of antibacterials are slow-acting antimalarials. Tetracyclines and clindamycin should not be used alone to treat malaria but are combined with quinine to allow a shorter duration of therapy with that drug. In addition, doxycycline is effective in chemoprophylaxis of most *P. falciparum* malaria and is recommended for this purpose by the CDC, in particular for travelers to regions of Southeast Asia with high-level resistance to other drugs. Macrolides also have antimalarial activity and are currently under study for use against malaria.

Treatment of Severe Malaria

Severe malaria is a medical emergency and requires parenteral therapy. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals. As noted before, standard therapy for severe malaria has been IV quinine or quinidine, with continuous cardiac monitoring if possible. However, as noted above, IV artesunate showed superior efficacy and decreased toxicity. Although it is not yet available in all endemic areas, it has become the worldwide standard to treat severe malaria. In the United States, IV quinidine is not available in all hospitals and IV artesunate must be obtained from the CDC; initial treatment should be with whichever drug is most rapidly available. Appropriate care of severe malaria includes close nursing care; maintenance of fluids, electrolytes, and glucose; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and hemodialysis or hemofiltration. Aggressive fluid resuscitation, blood transfusion for moderate anemia, exchange transfusion, and specific treatment of acidosis are of uncertain value. After the acute illness, parenteral quinine, quinidine, or artesunate should be followed with oral longer acting drugs, typically a full course of an oral ACT, Malarone, mefloquine, or quinine plus doxycycline or clindamycin.

PREVENTION

Recent years have been marked by a dramatic increase in interest and investment in the control of malaria. Key malaria control interventions in malaria-endemic regions are control of mosquito vectors by indoor residual spraying of insecticides; personal protection against mosquito bites with insecticide-impregnated bed nets; routine use of artemisinin-based combination therapies, which offer prompt control of malaria infections and activity against gametocytes to limit transmission to mosquitoes; and selected use of intermittent preventive therapies to decrease malarial incidence in high-risk groups. No vaccine to prevent malaria is yet available, but extensive research on potential vaccines is under way. RTS,S, which is based on an immunogenic sporozoite antigen, is the most advanced vaccine candidate. Recent clinical trials have consistently shown protection in children immunized with RTS,S, with protection against malaria of about 30% to 60% in the year after immunization, but lower levels of protection in very young children, in areas of highest malaria exposure, and when assessed over longer periods of time after immunization.[A1]

TABLE 345-3 CHEMOPROPHYLAXIS OF MALARIA*

AREAS WITH CHLOROQUINE-RESISTANT *PLASMODIUM FALCIPARUM*	
Malarone	1 tablet (250 mg artesunate/100 mg proguanil) daily
Mefloquine	250 mg weekly
Doxycycline	100 mg daily
Primaquine†	30 mg daily during exposure (chemoprophylaxis) or 30 mg daily for 14 days (terminal prophylaxis against *P. vivax* and *P. ovale*)
AREAS WITHOUT CHLOROQUINE-RESISTANT *P. FALCIPARUM*	
Chloroquine phosphate	500 mg weekly

*Recommendations may change on the basis of drug resistance patterns. For additional details and pediatric dosing, see Centers for Disease Control and Prevention guidelines (http://www.cdc.gov). Begin 1 to 2 weeks before travel for mefloquine and 2 days before for doxycycline, Malarone, and primaquine; continue for 4 weeks after leaving the endemic area (1 week for Malarone; 2 weeks for primaquine). All doses refer to salts unless indicated.
†Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.

Preventive Measures for Travelers to Malaria-Endemic Regions

It is important for nonimmune travelers (Chapter 286) to endemic areas to be protected against potentially lethal malaria. Travelers should decrease exposure to night-biting anopheline mosquitoes by use of insecticide repellants and sleeping in rooms that are screened or equipped with insecticide-impregnated bed nets. Standard advice for travelers to endemic areas is also to use low doses of preventive drugs chosen on the basis of the resistance profile of the particular region. Chloroquine is still recommended for malaria-endemic regions of Central America and the Caribbean. For nearly all other areas, the CDC recommends use of daily Malarone, weekly mefloquine, or daily doxycycline; details of dosing vary, but it is important to continue therapy after return from travel to eliminate parasites as they emerge from the liver (Table 345-3). For areas with high risk of *P. vivax* malaria, some authorities recommend a full treatment course of primaquine after travel to eliminate dormant liver stages. For all chemoprophylaxis, it is important to appreciate that no mosquito avoidance methods or drug regimens are fully protective, so consideration of malaria as a cause of fever in returned travelers is essential (Chapter 286).

PROGNOSIS

Patients with malaria caused by *P. vivax, P. ovale,* or *P. malariae* generally respond well to chloroquine and make an uneventful recovery. Chloroquine-resistance is increasing with *P. vivax* from many areas; failures of initial treatment are usually not dangerous but should be followed by treatment with another regimen, such as an ACT, Malarone, or mefloquine. Patients with *P. falciparum* malaria also generally respond well to prompt therapy as long as the disease is not overly advanced at presentation. The mortality rate in those with uncomplicated *P. falciparum* malaria is about 0.1%. Key contributing factors to most deaths from *P. falciparum* malaria are probably a delay between the appearance of symptoms and presentation for definitive therapy and the use of suboptimal therapies. Presentation with high-level parasitemia (>200,000 parasites/μL or >5% parasitemia) or signs of severe malaria are predictive of a poor outcome. However, with aggressive support, even individuals with severe disease can often experience complete recoveries.

REVIEW QUESTIONS

1. A young American adult consults with you before travel to Kenya. Appropriate regimens for the prevention of malaria in travelers from a developed country to areas with chloroquine-resistant *P. falciparum* malaria include

A. Malarone, mefloquine, or artemisinin.
B. Malarone, mefloquine, or doxycycline.
C. Coartem, Malarone, or doxycycline.
D. quinine, artemisinin, or Fansidar.

Answer: B These three drugs are all listed as first-line regimens for the prevention of malaria in travelers. Artemisinin and artemisinin-based combination therapy (Coartem) are not appropriate because of the short half-lives of artemisinins. Quinine is not appropriate because of a short half-life and poor tolerability.

2. Reasons for the predilection for *P. falciparum* to cause severe malaria include all of the following except

A. cytoadherence of *P. falciparum*–infected erythrocytes to vascular endothelium.
B. infection of erythrocytes of all ages.
C. a high prevalence of resistance to available antimalarial drugs.
D. increasing pathogenicity with increasing age of the patient.

Answer: D Major contributors to the pathogenesis of *P. falciparum* malaria include cytoadherence of P. falciparum–infected erythrocytes to vascular endothelium, infection of erythrocytes of all ages, and high prevalence of resistance to available antimalarial drugs. *P. falciparum* malaria does not generally show increasing pathogenicity with increasing age. Rather, the disease is typically most severe in young children because of their lack of prior exposure to the pathogen and thus lack of antimalarial immunity and possibly other factors.

3. The region with the greatest morbidity and mortality from malaria in the world is

A. Africa.
B. Southeast Asia.
C. South America.
D. Oceania.
E. the Middle East.

Answer: A The greatest morbidity and mortality from malaria is in Africa, likely because of many factors, including a preponderance of *P. falciparum* malaria, particularly competent anopheline mosquito vectors, and limited medical infrastructure.

4. The region with the most highly resistant malaria parasites in the world is:

A. Africa
B. Southeast Asia
C. South America
D. Oceania
E. Middle East

Answer: B Explanation. The greatest prevalence of parasites resistant to available antimalarial drugs is in Southeast Asia. Resistance to chloroquine, antifolates, mefloquine, and quinine is seen in this area, and new data demonstrate decreasing efficacy of artemisinins, manifested as delayed clearance of parasites after treatment with artesunate or artemisinin-based combination therapies.

5. A child from Ghana is admitted with fever, altered consciousness, acute renal failure, and 7% parasitemia with *P. falciparum*. Severe malaria should be treated with:

A. Oral artemisinin-based combination therapy
B. Malarone or mefloquine
C. Quinine or quinidine
D. Intravenous artesunate, if available, and as a back-up intravenous quinine or quinidine

Answer: D The new international standard-of-care for the treatment of severe malaria is intravenous artesunate. Oral therapy should be avoided in very ill individuals. Intravenous quinine or quinidine is highly effective, but intravenous artesunate was superior to intravenous quinine in randomized trials of Asians and Africans with severe malaria.

AFRICAN SLEEPING SICKNESS

WILLIAM A. PETRI, JR.

DEFINITION

Human African trypanosomiasis (HAT), commonly known as sleeping sickness, is a vector-borne parasitic disease transmitted to humans and animals by the bite of the tsetse fly (genus *Glossina*). Infection is caused by protozoa of the genus *Trypanosoma* and species *brucei*. In humans, there are two forms of illness caused by two distinct subspecies that are morphologically identical but differ in their geographic range and clinical presentations. *Trypanosoma brucei gambiense* is typically found in west and central Africa and *Trypanosoma brucei rhodesiense* in east Africa. *T. b. gambiense* has a more chronic course, and *T. b. rhodesiense* causes a rapid disease course; both have late stages marked by meningoencephalitis, resulting in coma and death if untreated. There is a third subspecies, *Trypanosoma brucei brucei,* known to cause chronic infection called nagana in cattle; however, humans are not susceptible to this organism.

The Pathogen

As an extracellular microbe, the parasite must evade immune clearance to establish a persistent infection. The surface of the blood stream form of the trypanosome is covered by a dense, homogeneous coat of variant surface glycoproteins (VSGs), which are immunodominant. Each individual trypanosome expresses only one VSG at a time but possesses more than 1000 different silent copies of the VSG gene, and switching to a new VSG occurs at a frequency of about 1×10^{-6} parasites. Hence, the trypanosomes expressing a given VSG will eventually be cleared by the host antibody response, but any individual trypanosome that has switched to a new VSG will evade immune clearance, resulting in a new peak of parasitemia. Recombination between VSG alleles ensures a virtually limitless repertoire of new VSGs; therefore, antibody-mediated parasite eradication is impossible.

EPIDEMIOLOGY

Human African trypanosomiasis is relatively less of a problem now than it has been in the prior century, partly because of cyclic epidemics in the past as well as recent increases in public health efforts for control. However, it remains a looming threat to an estimated 60 million people living in tsetse fly–inhabited areas among 36 countries of sub-Saharan Africa and causes significant morbidity, accounting for 1.5 million disability-adjusted life years in Africa as a whole.

The causative organism was first identified during the latter half of the 19th century, roughly corresponding to the first of three epidemics occurring during the past century. The first epidemic occurred in the Congo basin and Uganda between 1896 and 1906, driven in part by various natural disasters that decimated populations of livestock and regional droughts as well as changes in population distribution influenced by colonialism. The second epidemic occurred in numerous endemic countries in the 1920s; control was achieved after major efforts to systematically screen and treat individuals followed by extensive vector control programs, including bush clearing and insecticide spraying. These acts were nearly successful in halting transmission by the 1960s; however, the independence of many African nations around this time hindered the sustainability of prevention and control programs. The incidence began to rise by the 1970s and surged a decade later, leading to the third epidemic of the 20th century. However, in the past 15 years, increased access to at-risk populations for diagnosis and treatment has led to a 68% reduction in the incidence of reported cases.

Despite increased surveillance efforts during the past 15 years, there are still at-risk areas that lack active monitoring programs, and many people are thought to die of HAT without an accurate diagnosis. The World Health Organization reported an annual incidence of 12,000 cases in 2007, a dramatic decrease from the estimated incidence of 300,000 cases a decade earlier. It is estimated that 300,000 to 500,000 people are infected, contributing to approximately 100,000 deaths each year. More than 90% of reported cases are due to *T. b. gambiense,* the majority being from the Democratic Republic of the Congo.

The geographic distribution includes areas where the vector, parasite, reservoir hosts, and human hosts cohabit (Fig. 346-1). In general, these include focal areas on the African continent within 15 degrees North and 15 degrees South latitude, with a predilection for rural areas. Humans at greatest risk for infection are those who rely on animal husbandry, agriculture, fishing, and hunting for their livelihoods. Often, disease is concentrated among foci of rural areas, having significant socioeconomic impact on affected villages. With a few exceptions, this infection is never found in urban areas. There have

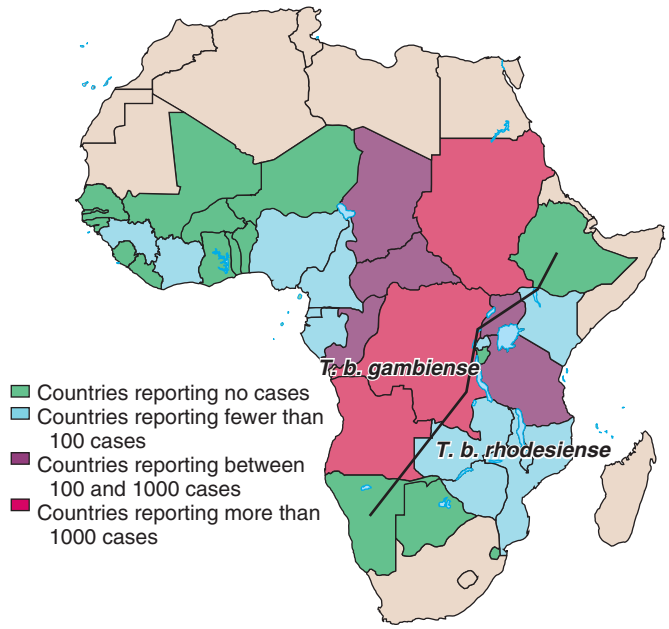

FIGURE 346-1. Map of human African trypanosomiasis (HAT). These 36 sub-Saharan African countries are considered endemic for HAT. *Shaded areas* represent the reported incidence from 1997 to 2006. The *black line* roughly represents the dividing line for the two parasites, although some overlap may already occur.

been fewer than 50 cases reported annually outside of Africa, usually the result of travel by North Americans or Europeans to African game reserves.[1]

T. b. gambiense is transmitted by tsetse flies from the *Glossina palpalis* group, the annotated genome sequence of which was recently reported. Teste flies are typically found along riverbanks among wooded areas in the more tropical regions of central and West Africa. The reservoir hosts for *T. b. gambiense* and the focus of public health campaigns are mainly humans. Because of this, *T. b. gambiense* is not generally considered a zoonotic disease; the role of the animal reservoir for this organism remains undetermined, although natural infections have been reported in domestic animals such as dogs, sheep, cattle, and pigs.

T. b. rhodesiense is transmitted by tsetse flies belonging to the *Glossina morsitans* group,[2] which are commonly found among woodland and savannah areas of east and central Africa. *T. b. rhodesiense* is a zoonotic disease with numerous wild and domestic species of animals acting as reservoirs. With this infection, the animal reservoir serves an important role in the cycle, sustaining parasite transmission and human infections. Domestic species, especially cattle, have the potential to drive outbreaks and, not surprisingly, have served as the focus of successful prevention campaigns.

PATHOBIOLOGY

After the bite of a tsetse fly carrying metacyclic trypomastigotes, a local reaction (chancre) may form at the inoculation site. This symptom is seen with *T. b. rhodesiense* infection and is more frequently observed in travelers but is rarely seen with *T. b. gambiense* infection. Parasites subsequently disseminate into the blood and lymphatic systems in what is considered stage I of the disease. Spread of the parasites into the central nervous system (CNS) defines stage II of the disease, which is invariably fatal if untreated. The parasite appears to remain extracellular throughout the course of infection.

Peaks and waves of parasitemia occur during stage I disease and result in the classic symptom of intermittent fever. These bouts of fever correspond to a type 1 inflammatory response (Chapter 48), in which classically activated macrophages produce high levels of tumor necrosis factor (TNF) and nitric oxide. This helps in the control of parasitemia but also contributes to tissue damage. Type 2 inflammatory responses with high interleukin-10 production may subsequently occur, which limit TNF and nitric oxide production after initial parasitemia has been controlled. Antibody responses are directed to VSGs and other trypanosome antigens (e.g., antigens from lysed parasites), but autoantibodies are also produced. Generalized febrile episodes are observed together with lymphadenopathy and myocardial and pericardial inflammation. Cardiac involvement is typically more severe with *T. b. rhodesiense* infection. Anemia, thrombocytopenia, disseminated intravascular coagulation, and renal disease may also be observed.

In stage II of the disease, parasites cross the blood-brain barrier and invade the CNS. Acute meningoencephalitis develops, with a variety of inflammatory cells infiltrating the brain, including macrophages, lymphocytes, plasma cells, Mott cells, and morular cells. These inflammatory cells are found in the meninges, which become thickened, as well as in the perivascular spaces and neuropil. Edema, hemorrhage, and granulomatous lesions are often present; thrombosis and neuronal degeneration may also be observed.

CLINICAL MANIFESTATIONS

The clinical manifestations of HAT differ on the basis of the infecting organism.[3] *T. b. gambiense* is more of a chronic disease, with an estimated average duration of 3 years; infection with *T. b. rhodesiense* progresses much more rapidly, leading to coma and death within weeks to months. However, infection with *T. b. gambiense* has been known to cause a rapid decline. Other similarities exist, including an early hemolymphatic stage (stage I) and a late stage characterized by prominent CNS disease including meningoencephalitis (stage II).[4,5]

West African Sleeping Sickness

Infection starts after the bite of a fly infected with *T. b. gambiense*. At the site of inoculation, a painful, indurated, and erythematous trypanosomal chancre may develop 1 to 2 weeks after the bite and resolves spontaneously after several weeks. On occasion, the chancre may ulcerate. However, these features are rarely seen at the time of clinical presentation and sometimes are not known to have occurred on history; thus, many develop disseminated disease without awareness of a localized infection.

The hemolymphatic stage, when parasites disseminate throughout the body, may not be manifested clinically until weeks or months after the initial bite. Typical symptoms include intermittent spiking fevers, occasionally accompanied by headaches and malaise. These features may persist for weeks or months because of the cyclic nature of parasitemia and antibody production against the various antigens sequentially expressed by the parasite.

Lymphadenopathy (Chapter 168) is a common finding in West African sleeping sickness. Whereas regional lymphadenopathy may develop after the initial bite, generalized lymphadenopathy around the head and neck is often found as chronic illness develops. Enlargement of nodes in the posterior cervical triangle, commonly known as Winterbottom's sign, is the classic finding, but other cervical and supraclavicular nodes may also be involved. Affected nodes are discrete, movable, rubbery nodes that are nontender to palpation; over time, they may become more indurated because of fibrosis.

Other symptoms reported include pruritus, occasionally accompanied by rash, arthralgias, and periarticular swelling as well as by transient edema of the extremities and face. Less common symptoms include features consistent with neuroendocrine dysfunction, including loss of libido and impotence, amenorrhea and infertility, alopecia, and gynecomastia. Signs of disease include hepatomegaly and splenomegaly; cardiac dysfunction, including tachycardia; electrocardiographic abnormalities such as prolonged QTc intervals and repolarization changes; and, less commonly, pericarditis or myocarditis. Hemolytic anemia and derangements in liver function test results may occur.

Months or even years after the initial infection, stage II disease develops and is characterized by headaches, daytime somnolence, and neuropsychiatric features. Behavioral changes, including irritability, confusion, inability to concentrate, and lassitude, are among the first signs of CNS disease; psychosis has also been described. Neurologic findings are numerous and include a variety of motor and sensory disturbances, including extrapyramidal features, dysesthesias, and visual impairment. These symptoms have given the infections its common name of sleeping sickness and are manifested by daytime somnolence and nocturnal irritability. Late-stage disease is marked by cerebral edema and meningoencephalitis. Progressively, a loss of neurologic function can lead to paralysis, and many may succumb to aspiration pneumonias or malnutrition; otherwise, coma leads to death in the absence of treatment.

East African Sleeping Sickness

Compared with Gambian sleeping sickness, East African sleeping sickness is more rapidly progressive. The infective bite is more frequently associated with the development of a chancre, although some studies report this in only 20% of patients. An incubation period lasting days to weeks is needed before symptoms are demonstrated. Initial symptoms include severe intermittent fevers that may resemble those found with malaria. Lymphadenopathy is not as common with this infecting organism; Winterbottom's sign is typically absent. Skin changes are more prominent, and rashes in the early stage of infection are particularly common in expatriates with the infection. In addition, cardiac manifestations are more commonly and clinically relevant; tachycardia, arrhythmias, myocarditis, and congestive heart failure have been documented and may be severe enough to cause death before the development of severe CNS disease. CNS disease mirrors that of West African sleeping sickness, but the onset occurs earlier, and the rate of deterioration is more rapid. Hematologic abnormalities include anemia, thrombocytopenia, and disseminated intravascular coagulation. Death may ensue after weeks or months without treatment.

DIAGNOSIS

Epidemiologic clues and clinical findings may together suggest the diagnosis of HAT, but definitive diagnosis relies on demonstration of the parasite. In the early stage of disease, light microscopy and Giemsa stain may be used to visualize the highly motile parasites directly from fresh specimens of fluid expressed from chancres or lymph node aspirates. Peripheral blood smears, including Giemsa-stained thick and thin smears and bone marrow aspirates, have been successful. Blood smears have increased sensitivity when they are performed during stage I disease, when parasitemia is high (Fig. 346-2); the threshold for visualization of parasites by thick smear is approximately 5000 parasites/mL. Performance is superior with *T. b. rhodesiense* infection, given the higher parasite load. If the initial smear analysis is negative, subsequent examinations should be pursued. Concentration techniques, including buffy coat examination, should be used when technically feasible. Culture of any of these fluids may yield higher sensitivity than smear preparations.

Cerebrospinal fluid (CSF) must also be analyzed to determine the most appropriate treatment. Abnormalities in CSF analysis often start with increased cell counts and progress to include an elevated opening pressure

and total protein levels with an increased polyclonal IgM. Stage II disease is defined by the presence of more than 5 white blood cells/μL, the presence of trypanosomes, or an elevated total protein count (>370 mg/L) in the CSF. Newer diagnostic methods, including polymerase chain reaction analysis of CSF and a latex-agglutination test for CSF IgM, hold promise but require validation to determine outcomes after treatment of patients with positive test results.

Allocation of resources to this neglected tropical disease in recent years has allowed slow but exciting progress in the field of HAT diagnostics. The genomes of *T. brucei* species have been mapped, and molecular assays have been developed that can distinguish among species of HAT with a single polymerase chain reaction test. Novel uses of mass spectrometry have been developed that use proteomic signature analysis to identify specific fingerprints of HAT with the host.

In contrast to these highly technical and expensive methods, other tests suitable for the field are being validated, including the dot-ELISA test, which would be able to provide information on stage of disease. Serology tests are also available for diagnosis of *T. b. gambiense* infection. The card agglutination test for trypanosomiasis with *T. b. gambiense* (CATT) is commonly used by screening programs; the sensitivity ranges from 87% to 98%, depending on the population under study, and the specificity may be as high as 95%. No serology tests are available for *T. b. rhodesiense* infection. Rapid diagnostic tests for infection with *T. b. gambiense* include HAT Sero-Strop (which uses a dipstick method) and the HAT Sero + K SeT test (which uses a lateral flow device) for testing blood or plasma, respectively, with results available in 15 minutes at an estimated price of $2.50 each.[6]

TREATMENT

Rx

There are very few drugs for treatment of HAT, and those that are commonly used are quite toxic (Table 346-1).[7] Treatment depends on the infecting organism and the stage of disease. For stage I disease with *T. b. gambiense* infection, pentamidine is the drug of choice. The standard regimen consists of daily parenteral administration for 1 week; however, studies are ongoing to determine the efficacy of shortening therapy to three doses.

Suramin is also used for stage I disease with *T. b. rhodesiense*. This medication is complex to mix and to administer. The drug must be administered in a slow intravenous infusion periodically during 3 weeks. Although anaphylaxis is rare (approximately one in 20,000 patients), a test dose is recommended before full treatment is initiated. A number of side effects require close monitoring, the most important being nephrotoxicity. Urinalysis is recommended before each dose, and the drug should be discontinued if proteinuria persists and casts are seen in the urine sediment.

Melarsoprol is a highly effective but impressively toxic drug used for stage II disease with either organism. The side effects are numerous, but the most important is the life-threatening encephalopathy that may develop from the arsenic (highly fatal) or as an inflammatory reaction. Concomitant steroid use is helpful in reducing the risk of encephalopathy and death without compromising the efficacy of melarsoprol. Gradual increase in the first round of treatment between 2 and 3.6 mg/kg in divided doses three times daily during 3 days has also been shown to reduce the risks of encephalopathy. Melarsoprol has been replaced by eflornithine for *T. b. gambiense* infection but remains the only agent available for the treatment of stage II *T. b. rhodesiense* infection.

Developed more than 20 years ago, eflornithine is the newest agent and drug of choice for treatment of stage II disease with *T. b. gambiense*. Unfortunately, it is not effective as monotherapy for *T. b. rhodesiense* because of reduced susceptibility of this organism to the drug. Eflornithine requires frequent intravenous administration, and up to 40% of patients may report some adverse effects. The drug is much more tolerable than its predecessor melarsoprol and is associated with a comparatively reduced mortality rate.

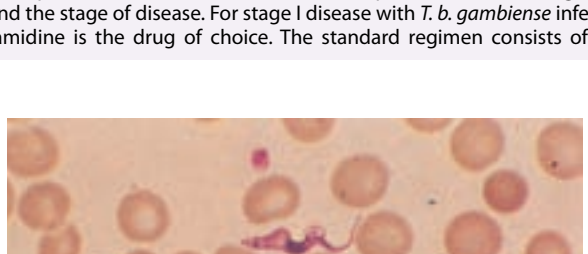

FIGURE 346-2. *Trypanosoma rhodesiense* in peripheral blood. It has a nucleus, posterior kinetoplast, undulating membrane, and flagellum (×1500).

PREVENTION

To date, there is no vaccine against HAT. The mainstays of prevention include active case finding with early treatment and vector control. Given the nature of each infection, active case surveillance is more suitable for infection with *T. b. gambiense*, but vector control is more effective for prevention of infection with *T. b. rhodesiense.* The goal of active case finding is to identify infected individuals who may still be in the asymptomatic stage or early stage. This approach, which is more suited for disease from *T. b. gambiense*, typically consists of a screening examination for lymphadenopathy followed by a CATT test. If results are positive for both, the patient should undergo further evaluation with lymph node aspirate and blood testing. If trypanosomes are found, the patient should be treated. Vector control measures include tsetse fly traps and insecticide-impregnated screens; the traps are easily maintained by locals, but the screens require regular retreatment and thus are more labor intensive and costly to maintain. Mass spraying, once a successful method until the 1960s, is no longer practiced. However, if an epidemic does occur, ground or aerial spraying combined with disruption of the animal reservoir's habitat may be the most effective method of achieving rapid vector control.

Travelers to endemic areas should be aware of this disease and should use basic protective measures. Protective clothing of at least medium weight should be worn; neutral colors are most effective because flies are attracted

TABLE 346-1 DRUGS USED TO TREAT HUMAN AFRICAN TRYPANOSOMIASIS

DRUG	CLASS	STAGE	ROUTE	ADULT DOSE	ADVERSE EFFECTS
TRYPANOSOMA BRUCEI GAMBIENSE					
Pentamidine	Aromatic diamidine	I	IM or IV	4 mg/kg daily for 7 days	Pain, GI symptoms, hypoglycemia or hyperglycemia, electrolyte abnormalities, leukopenia, thrombocytopenia
Eflornithine	Ornithine carboxylase inhibitor	II	IV	100 mg/kg every 6 hr for 14 days	GI symptoms, bone marrow toxicity, seizures
Melarsoprol (alternative option)	Trivalent arsenical	II	IV	2.2 mg/kg daily for 10 days (maximum daily dose, 180 mg)	Encephalopathic syndromes, peripheral neuropathy, paralysis, cardiac dysrhythmias, GI symptoms, rash, pruritus, thrombophlebitis
TRYPANOSOMA BRUCEI RHODESIENSE					
Suramin	Polysulfonated naphthylamine derivative of urea	I	IV	1 g IV on days 1, 3, 7, 14, and 21 (after test dose of 100-200 mg)	Anaphylaxis, nephrotoxicity, fever, rash, pruritus, arthralgias, reversible peripheral neuropathy, and bone marrow toxicity
Melarsoprol	Trivalent arsenical	II	IV	1.2 mg/kg every 8 hr for 3 consecutive days each week for 3 weeks (maximum daily dose, 180 mg)	Encephalopathic syndromes, peripheral neuropathy, paralysis, cardiac dysrhythmias, GI symptoms, rash, pruritus, thrombophlebitis

GI, Gastrointestinal; IM, intramuscular; IV, intravenous.

to bright and dark colors. Tsetse flies are attracted to moving vehicles but rest in the shade or bushes. Although use of insect repellant is prudent for other vector-borne illnesses that may be endemic in these areas, it has not been proven to substantially reduce the risk of tsetse fly bites. There is no recommended chemoprophylaxis for travelers.

REVIEW QUESTIONS

1. Risk factors for sleeping sickness is/are

a. tsetse fly bite.
b. residence in urban areas of North Africa.
c. rural areas of sub-Saharan Africa.
d. a and c.
e. a and b.

Answer: D African sleeping sickness is rare in urban areas or in North Africa. This vector-borne parasitic disease is transmitted to humans and animals by the bite of the tsetse fly.

2. Clinical presentation of sleeping sickness is/are

a. chancre at site of bite.
b. fever and headache.
c. lymphadenopathy.
d. a and c.
e. a, b, and c.

Answer: E Sleeping sickness can present acutely with a chancre at the site of the bite, fever, headache, and lymphadenopathy.

3. Diagnostic test(s) of sleeping sickness is/are

a. visualize parasite in chancre, node, or blood.
b. polymerase chain reaction (PCR) on cerebrospinal fluid.
c. serology.
d. a and c.
e. a, b, and c.

Answer: E Diagnosis of African sleeping sickness can be accomplished by visualizing the parasite by PCR and serology.

4. What drug is used to treat patients with stage 1 sleeping sickness caused by *T. b. gambiense*?

a. Pentamidine
b. Melarsoprol
c. Eflornithine
d. a and b
e. a, b, and c

Answer: A Therapies with demonstrated effectiveness include melarsoprol, pentamidine, and eflornithine. For stage I disease, pentamidine is the treatment of choice.

5. East African sleeping sickness is

a. more rapidly progressive than West African.
b. characterized by severe fevers.
c. commonly associated with lymphadenopathy.
d. a and b.
e. a, b, and c.

Answer: D East African sleeping sickness tends to be more severe and rapidly progressive, with intermittent fevers that resemble those seen in malaria. Unlike West African sleeping sickness, in which lymphadenopathy (often generalized) is common, lymphadenopathy is not typically associated with lymphadenopathy in East African sleeping sickness.

CHAGAS DISEASE

LOUIS V. KIRCHHOFF

DEFINITION

Chagas disease, or American trypanosomiasis, is caused by the protozoan parasite *Trypanosoma cruzi*. The terms *Chagas disease*, *American trypanosomiasis*, and *T. cruzi infection* are synonyms.

The Pathogen

Several dozen species are included in the genus *Trypanosoma*, but only the African trypanosome *Trypanosoma brucei* (subspecies *T. b. gambiense* [West African] and *T. b. rhodesiense* [East African]) (Chapter 346) and the American trypanosome *T. cruzi* cause disease in humans. Many species of triatomine insects, also called kissing bugs, act as vectors for *T. cruzi*, and many species of wild and domestic mammals, as well as humans, are involved in the complex life cycle of this fascinating organism. The vectors become infected by ingesting blood from mammals that have parasites in their blood stream. The parasites then multiply in the gut of the insects and are ultimately discharged in the feces of the vector. Transmission to a new mammalian host occurs when parasite-laden vector feces contact vulnerable surfaces such as the mucosae of the mouth or nose, the conjunctivae, or breaks in the skin. When in contact with tissues of the new host, the contaminating parasites enter local cells and multiply intracellularly, and as parasitized cells rupture, are released into the lymphatics and blood stream. The circulating organisms enter new cells at distant sites and in this manner maintain an endless process of asynchronous multiplication. The life cycle is completed as parasites are swept up in blood meals taken by vectors. In addition to vector-borne transmission, *T. cruzi* can be transmitted by blood or organs donated by infected persons, from mother to unborn child, by the ingestion of contaminated food or drink,[1] and in laboratory accidents.

EPIDEMIOLOGY

Epizootiology of *T. cruzi*

The triatomine vectors that transmit *T. cruzi* are found in the Americas from southern Argentina through the southern half of the United States. The parasite has been isolated from more than 100 species of domestic and wild mammals, which for the most part probably become infected when they eat infected vectors. Armadillos, wood rats, raccoons, and opossums are typical wild mammalian reservoirs, and these and other species that harbor *T. cruzi* can be found in large numbers in the southern and western parts of the United States.

Typically, humans acquire *T. cruzi* infection when they live in houses in enzootic areas where the sylvatic cycle of transmission is active. The process begins when vector species adaptable to living in human dwellings take up residence in niches in the primitive wood, mud, and stone houses that are typical in many regions of Latin America. These vectors become domiciliary and they then take blood meals, mostly at night, from the humans who occupy the dwellings that they have invaded, as well as from domestic animals that sleep there, particularly dogs. Thus, Chagas disease is primarily a public health problem among poor people who live in rural areas.

Epidemiology of Chagas Disease in Latin America

Chagas disease is a zoonosis that is endemic in Mexico and all countries of Central and South America. None of the Caribbean islands are endemic. In 2006, the Pan American Health Organization estimated that 8 million people are chronically infected with *T. cruzi* and that up to 12,000 deaths result from Chagas disease annually.[2] Since 1991 a major international vector control program in the southern cone countries of South America (Chile, Argentina, Paraguay, Brazil, Bolivia, and Uruguay) has achieved a marked reduction in transmission of *T. cruzi* through housing improvement, education of people at risk for acquiring the infection, and spraying of residual insecticides. Substantial reductions in prevalence rates in school-aged children and in blood donors constitute clear evidence of the success of the program. Uruguay, Chile, and Brazil were certified as being free of vector transmission in 1997, 1999, and 2006, respectively. Marked reduction in transmission has been achieved in Argentina as well. Similar programs have been initiated in Central America and the Andean countries. In parallel with the vector control programs, donor screening has been implemented throughout almost the entire endemic range, and with the notable exception of Mexico, transmission of *T. cruzi* by transfusion has largely been eliminated.

Epidemiology of Chagas Disease in the United States

As noted, the sylvatic cycle of *T. cruzi* exists in much of the southern and western regions of the United States, but only six cases of autochthonous transmission have been reported: three in Texas and one each in Tennessee, Louisiana, and California. Moreover, the nationwide blood donor screening that started in January 2007, in which more than 50 million units have been tested, has uncovered only 17 *T. cruzi*–infected donors, who appear to have acquired the infection autochthonously.[3] In the past 30 years, only about 15 laboratory-acquired and imported cases of acute Chagas disease have been reported to the Centers for Disease Control and Prevention (CDC). Only one of the latter infections occurred in a tourist returning to the United States, but three such instances have been reported in Europe as well as one in Canada. Thus, acute Chagas disease is extremely rare in the United States.

Census data indicate that including illegal and legal immigrants, 23 million persons born in countries endemic for Chagas disease currently live in the United States. Roughly 17 million of these individuals are from Mexico, where the overall prevalence of *T. cruzi* infection is thought to range from 0.5% to 1.0%. Moreover, more than half of the non-Mexican immigrants have come from Central America, a region where the prevalence of *T. cruzi* infection is relatively high. A recent estimate puts the number of *T. cruzi*–infected persons currently living in the United States at 300,000. Several studies done before blood donor screening began in 2007 identified *T. cruzi*–infected persons in the donor pool, and nine instances of transmission by transfusion in the United States and Canada were described. Since screening began in 2007, more than 50 million units have been screened, and nearly 3000 *T. cruzi*–infected donors have been identified and permanently deferred from donation. The confirmed rate of *T. cruzi* infection in donors is about 1 in 13,300.[4] With the goal of reducing the enormous cost of universal screening ($100 to $200 million per year), a selective screening protocol based on previous negative test results has been implemented.

The transplantation in the United States of organs from three persons with undiagnosed chronic *T. cruzi* infection resulted in acute Chagas disease in five recipients, one of whom died of the infection. To date, only one instance of congenital transmission of *T. cruzi* here has been reported. A reasonable estimate of the number of babies born in the United States each year with congenital Chagas disease puts it in the range of 63,000. The fact that most babies with congenital Chagas disease are asymptomatic[5] and the low level of knowledge about Chagas disease among caregivers likely underlie the dearth of reported cases.

PATHOBIOLOGY

In acute Chagas disease, an inflammatory lesion, called a chagoma, may appear at the site of entry of the parasites. Local histologic changes include intracellular parasitism of muscle and other subcutaneous tissues, lymphocytic infiltration, interstitial edema, and hyperplasia of lymph nodes that drain the area. As the parasites spread systemically through the lymphatics and blood stream, muscles, including the myocardium, are the most heavily parasitized tissues, but the organisms can invade essentially any tissue. Myocarditis may develop in association with focal areas of infected cardiomyocytes, inflammation, and necrosis. The characteristic pseudocysts seen in sections of *T. cruzi*–infected tissues are actually host cells filled with

multiplying forms of the parasite (Fig. 347-1). In some patients, parasites can be seen in cerebrospinal fluid (CSF).

In persons with chronic Chagas disease, the heart is the organ most commonly affected. Hearts obtained at autopsy from patients who died of Chagas cardiomyopathy usually have a global appearance reflecting biventricular enlargement and thinning of ventricular walls (Fig. 347-2). Mural thrombi are frequently present, and an apical aneurysm of the left ventricle is typical in patients with advanced disease. At the cellular level, the process that underlies these gross pathologic abnormalities is a chronic inflammation with mononuclear cell infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells. The chronic inflammation affects the conduction system as well and causes a variety of rhythm disturbances, including atrial bradyarrhythmias and fibrillation; premature ventricular contractions; bundle branch blocks, often of the right bundle; ventricular tachycardia; and third-degree atrioventricular block. Parasites are rarely seen in diseased tissues by conventional histologic methods, but several studies using polymerase chain reaction (PCR) assays found a correlation between the intensity of inflammation and the presence of parasites. Evidence accumulated to date implicates the persistence of parasites and the resulting chronic inflammation in affected tissues—rather than autoimmune mechanisms—as the basis for the pathogenesis in patients with chronic *T. cruzi* infection.

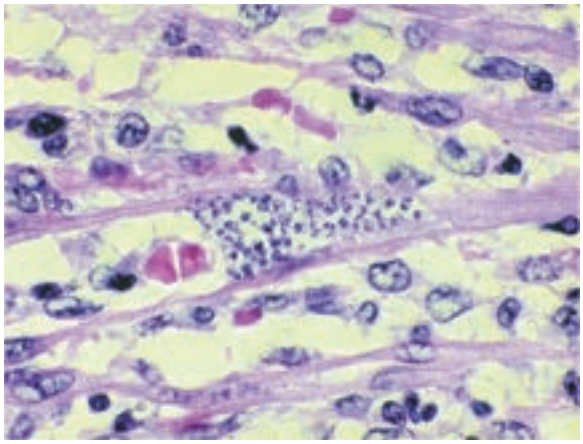

FIGURE 347-1. ***Trypanosoma cruzi*** **in cardiac muscle of a child who died of acute Chagas myocarditis.** An infected myocyte containing several dozen *T. cruzi* amastigotes is in the center of the field (hematoxylin-eosin staining, ×900).

FIGURE 347-2. Chest radiograph of a patient from Bolivia with chronic *Trypanosoma cruzi* infection, rhythm disturbances, and cardiomyopathy. Pacemaker wires can be seen in the area of the left ventricle.

The dilation and hypertrophy observed on gross examination of the esophagus or colon of a patient with chronic Chagas disease of the digestive tract (megadisease) is striking. Focal inflammatory lesions with lymphocytic infiltration are seen on microscopic examination of affected tissues. In addition, the number of neurons in the myenteric plexus is reduced, and periganglion and intraganglion fibrosis with Schwann cell proliferation and lymphocytosis is present. In most patients, the clinical consequences of this parasympathetic denervation are limited to the esophagus or colon (or to both), but the ureters, biliary tree, and other hollow viscera can be affected as well.

CLINICAL MANIFESTATIONS

Acute Chagas Disease

Acute Chagas disease is usually an illness of children but can occur at any age.[6] Symptoms are typically mild and nonspecific. When the parasite has entered through a break in the skin or the site of a vector's puncture, as noted, a chagoma may appear with local lymphadenopathy. The Romaña sign, the classic finding in acute Chagas disease, consists of painless edema of the palpebrae and periocular tissues and may appear when the conjunctiva is the portal of entry. These initial local signs can be followed by fever, malaise, anorexia, and edema of the face and lower extremities. Generalized lymphadenopathy and hepatosplenomegaly may also be present. Severe myocarditis may develop as well, and most deaths are caused by the resulting congestive heart failure. Meningoencephalitis is a rare complication. In untreated patients the acute illness resolves spontaneously over a period of 6 to 8 weeks as the patient enters the indeterminate phase of Chagas disease, which is characterized by subpatent parasitemia, absence of associated signs and symptoms, and easily detectable antibodies to *T. cruzi*.

Chronic Chagas Cardiopathy

In only 10% to 30% of persons chronically infected with *T. cruzi* does clinically manifested disease develop. It most often involves rhythm disturbances or cardiomyopathy.[7,8] Symptoms of cardiac Chagas disease can develop insidiously over years and often decades after the initial infection. Clinical findings reflect the rhythm disturbances, congestive heart failure, and thromboembolism that characterize the illness. Dizziness, syncope, and even seizures can result from a wide variety of arrhythmias. The cardiomyopathy often leads to biventricular failure, and right-sided heart failure can predominate in patients with advanced disease. A validated risk score assessment tool has been developed to gauge prognosis. Chronic Chagas disease is an independent risk factor for stroke.

Chronic Gastrointestinal Chagas Disease (Megadisease)

The esophagus and colon are the segments of the gastrointestinal (GI) tract most commonly affected in persons with chronic *T. cruzi* infection. In patients with megaesophagus, the symptoms are similar to those of idiopathic achalasia (Chapter 138) and may include cough, dysphagia, odynophagia, and regurgitation. Hypersalivation and consequent salivary gland hypertrophy develop in some patients with advanced esophageal dysfunction. Aspiration can occur, especially during sleep, and in untreated patients, repeated episodes of aspiration pneumonitis are common. Weight loss and even cachexia in patients with severe megaesophagus can combine with pneumonitis to cause death. Patients with chagasic megacolon have intermittent abdominal pain and chronic constipation and in advanced cases can go for several weeks between bowel movements. Rarely, acute obstruction, occasionally with volvulus, can lead to perforation, sepsis, and death.

IMMUNOSUPPRESSION AND TRANSPLANTATION IN PATIENTS INFECTED WITH *T. CRUZI*

When persons with chronic carriage of *T. cruzi* become immunosuppressed, reactivation of the infection can occur, sometimes with an intensity that is atypical of acute Chagas disease in immunocompetent persons.[9] The overall incidence of reactivation in immunosuppressed persons who harbor the parasite chronically is not known. Reactivation after renal transplantation has been reported, and in rare instances central nervous system abscesses and skin lesions were involved. The consensus view is that Chagas disease should not be a contraindication to kidney transplantation. In *T. cruzi*–infected patients who do undergo the procedure, periodic monitoring for signs and symptoms of acute Chagas disease should nonetheless be carried out, including careful neurologic evaluation, and parasitologic testing should be performed when acute illnesses occur postoperatively.

Reactivation of *T. cruzi* infection can also occur in persons coinfected with the parasite and human immunodeficiency virus (HIV). Dozens of such

patients have been described. It is striking that in many of these patients *T. cruzi* brain abscesses developed, which do not occur in immunocompetent patients with chronic Chagas disease. It has been shown that HIV viral loads increase in the context of reactivated acute Chagas disease. Calculations based on the overlapping epidemiologies of HIV and *T. cruzi* infections in the endemic countries suggest that the incidence of reactivation of the latter in coinfected persons is low.

DIAGNOSIS

Acute Chagas Disease

The first step in considering the diagnosis of acute Chagas disease is establishing that a person is at risk for *T. cruzi* infection. Risk factors include recent residence or blood transfusion in an endemic area, birth to a mother with geographic- or transfusion-associated risk in the case of a newborn, or a laboratory accident involving the parasite. Definitive diagnosis of acute Chagas disease can be made only by detecting parasites. Serologic assays for *T. cruzi*–specific IgM are not accurate enough to justify their use. In immunocompetent persons suspected of having acute Chagas disease, the most productive approach is examination of wet preparations of anticoagulated blood or buffy coat for the highly motile blood stream parasites. They can be seen in Giemsa-stained smears as well. In infected immunocompromised patients, moreover, parasites can sometimes be found in other specimens such as lymph node aspirates, biopsy specimens of skin lesions, bone marrow, endomyocardial tissue, CSF, and pericardial fluid.

When these direct methods fail to detect organisms in an at-risk person, samples should be tested with a PCR assay (see later).[10] PCR assays have been shown to be more sensitive than the direct methods described earlier for detecting *T. cruzi*. Another method is to culture blood or other samples in specialized liquid medium, but the usefulness of this approach is limited by low sensitivity (50%-70% for hemoculture) and by the fact that cultures take a minimum of 2 weeks before turning positive. In newborns whose blood is negative both by direct examination and in a PCR assay right after birth, serologic evaluation for *T. cruzi*–specific IgG should be performed 6 to 9 months later, by which time maternal antibodies will have disappeared.

Chronic Chagas Disease

Chronic *T. cruzi* infection is usually diagnosed by detecting IgG antibodies that specifically bind to parasite antigens, and in almost all instances isolation of the organism is not necessary. More than 30 serologic assays for diagnosing Chagas disease are currently available commercially in endemic countries, where they are used widely for testing clinical specimens and screening blood donors. Even though these tests usually have good sensitivity and reasonable specificity, false-positive reactions do occur, typically with specimens from people who have other infectious diseases or autoimmune conditions. The World Health Organization has recommended that testing be done with two assays based on different formats. In the United States, the Ortho *T. cruzi* ELISA Test System (Ortho-Clinical Diagnostics, Raritan, NJ) and the Abbott Prism Chagas Assay (Abbott Laboratories, Abbott Park, IL) are used to screen donated blood. The Abbott ESA Chagas and the Chagas RIPA[11] are used for confirmatory testing of donor samples that are positive in the screening tests.

Since the publication in 1989 of two reports describing the use of PCR tests to detect *T. cruzi*, well over 100 articles dealing with this approach have appeared. In human studies, the sensitivity of the PCR assays ranged from 44.7% to 100%, with most being higher than 90%. It is generally accepted that the level of sensitivity of these assays is not high enough to justify their use for confirmatory testing of serologically positive donor samples. In contrast, PCR assays may be useful in persons who have borderline serologic results, in patients suspected of having congenital or acute Chagas disease in whom parasites are not detected microscopically, and in infected patients who have received specific treatment. In all such persons, because of the sensitivity issue, only positive PCR results can be taken as being truly indicative of infection status.

TREATMENT Rx

Antiparasitic Drugs (also see Chapter 344)

The two drugs currently available for treating Chagas disease are unsatisfactory, and the need for a parasitologically curative drug regimen is the most important current challenge in Chagas disease research.[12] Nifurtimox (Lampit, Bayer 2502, Leverkusen, Germany) is a nitrofuran derivative that has been used for more than 3 decades. Nifurtimox reduces symptoms and decreases mortality rates in patients with acute Chagas disease, approximately 70% of whom are cured parasitologically. Nifurtimox also can cure a substantial portion of children in the indeterminate phase, but unfortunately, cure rates may be less than 10% in adults with long-standing chronic *T. cruzi* infection.

Disadvantages of nifurtimox include its long course of treatment and occasionally bothersome side effects, including GI complaints such as anorexia, nausea, vomiting, weight loss, and abdominal pain. Patients taking the drug may also have neurologic symptoms such as insomnia, restlessness, paresthesias, twitching, polyneuritis, and even seizures.[13] For adults, the recommended oral dosage is 8 to 10 mg/kg body weight per day. For adolescents, the dose is 12.5 to 15 mg/kg/day, and for children 1 to 10 years of age, it is 15 to 20 mg/kg/day. The drug should be given each day in four divided doses, and treatment should be continued for 90 to 120 days. In the United States, nifurtimox can only be obtained from the CDC Drug Service (404-639-3670).

The second drug for treating *T. cruzi* infection is the nitroimidazole derivative benznidazole (Rochagan, Radinil, Roche 7-1051; LAFEPE, Pernambuco, Brazil). Cure rates are similar or perhaps a bit higher than those achieved with nifurtimox. A cure rate higher than 90% in babies with congenital infection has been observed with benznidazole. Side effects can include rash, peripheral neuropathy, and granulocytopenia.[14] Benznidazole is considered the drug of choice by most Latin American experts. The recommended oral dosage of benznidazole is 5 to 10 mg/kg body weight per day for children and 5 mg/kg body weight per day for adults, in both cases for 60 days.

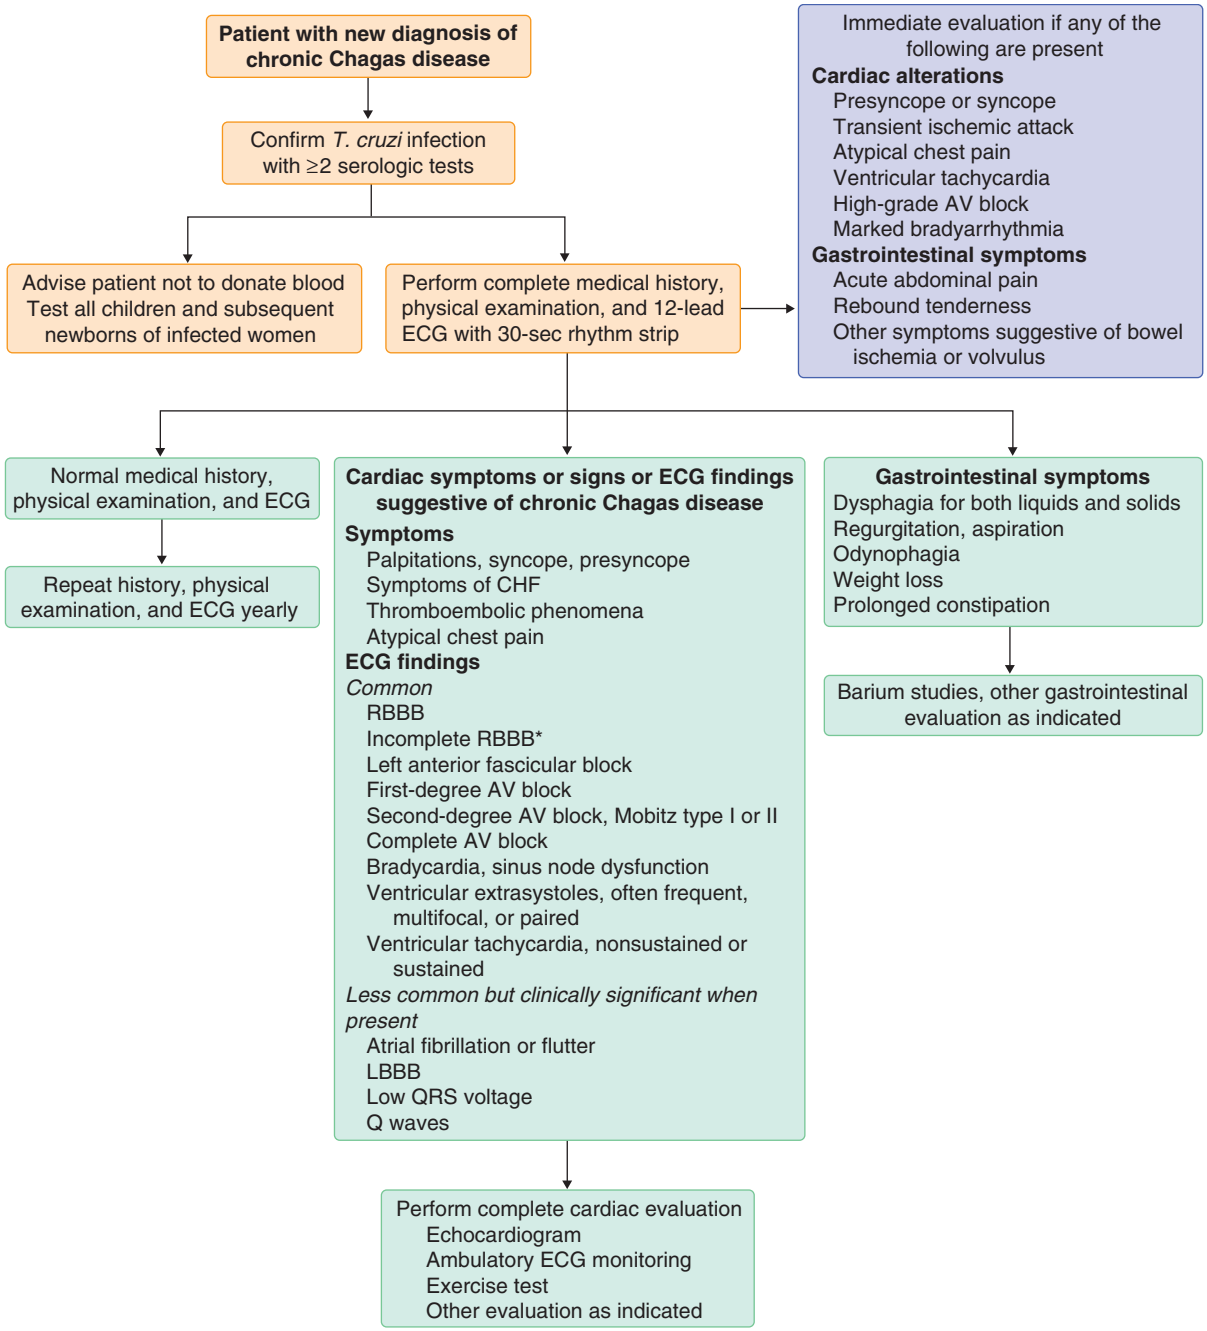
There is broad agreement among experts that treatment is indicated in all patients with acute or congenital infections, as well as in chronically infected children up to 18 years old. This recommendation is supported by several studies showing that a majority of such patients can be cured parasitologically. By extension, it would be reasonable to treat anyone 18 years or older known to have acquired *T. cruzi* infection within the past 17 years. There is also broad agreement that persons with advanced symptomatic *T. cruzi* infection should not be given specific treatment. The remaining question, then, is whether adults with long-standing indeterminate-phase infections, who by far constitute the largest group of *T. cruzi*–infected persons, should be treated. This is a thorny question because the burden of taking a full course of either drug can be substantial and because parasitologic cure rates are so low. Importantly, there is no clear evidence from randomized controlled trials that therapy with either drug delays the onset of symptoms or the progression of pathology or reduces mortality rates in adults with chronic *T. cruzi* infection. In 2006, a panel of experts convened at the CDC recommended that adults 19 to 50 years old in the indeterminate phase or with mild symptoms be offered treatment. A large randomized trial (the BENEFIT multicenter trial) designed to assess the clinical and parasitologic efficacy of benznidazole in patients with Chagas disease 18 to 75 years old without advanced disease is being conducted in Colombia, Bolivia, Brazil, and Argentina. Initial findings will be available in 2015. A recently reported randomized trial comparing benznidazole (150 mg twice daily) with posaconazole, which had shown trypanocidal activity in mouse models, given at two doses (400 mg twice daily or 100 mg twice daily) all for 60 days for chronic Chagas disease showed that benznidazole had a significantly smaller percentage of treatment failures than did either treatment dose of posaconazole.■ A recently reported study from Argentina showed that treatment with either benznidazole or nifurtimox before pregnancy can reduce the probability of subsequent congenital transmission of the parasite.[15]

Management of Symptomatic Chagas Disease

An algorithm for the evaluation of persons with newly diagnosed Chagas disease has been developed (Fig. 347-3). *T. cruzi*–infected patients in whom symptomatic cardiac or GI disease develops should be referred to appropriate subspecialists. Beyond the possible use of nifurtimox or benznidazole, treatment of acute and chronic Chagas disease is symptomatic. In patients with symptomatic chronic Chagas cardiac disease, treatment should be directed at managing symptoms with the anticoagulants and cardiotropic drugs used in patients with cardiomyopathy of other causes. Pacemakers are useful in patients with ominous arrhythmias. The usefulness of implantable cardioverter-defibrillators in patients with Chagas heart disease has not been established and needs further investigation in prospective randomized trials.

Heart transplantation (Chapter 82) is an option in patients with end-stage Chagas cardiac disease, and more than 150 such patients have undergone the procedure in Brazil and the United States.[16] As is the case with other *T. cruzi*–infected patients who are immunosuppressed, reactivation is a risk but it is manageable. The usefulness and side effects of long-term prophylaxis for reactivation with either benznidazole or nifurtimox in *T. cruzi*–infected patients after heart transplantation have not been evaluated. The long-term survival of Chagas patients with heart transplants appears to be longer than that in patients undergoing cardiac transplantation for other reasons, probably because the lesions of *T. cruzi*–associated pathology affect mostly the heart.

Chagas megaesophagus should be treated as normally done for idiopathic achalasia (Chapter 138), which usually responds to balloon dilation of the lower esophageal sphincter when symptoms are mild. Surgical treatment may



*QRS interval of 0.10 to 0.11 seconds in adults. Criteria based on the *Minnesota Code Manual of Electrocardiographic Findings* with modifications from Maguire et al. Different criteria may be required for ECGs in children.

FIGURE 347-3. **Algorithm for baseline evaluation of a patient with newly diagnosed chronic *Trypanosoma cruzi* infection. *AV,* Atrioventricular; *CHF,* congestive heart failure; *ECG,* electrocardiogram; *LBBB,* left bundle branch block; *RBBB,* right bundle branch block. (From Bern C, Montgomery SP, Herwaldt BL, et al. Evaluation and treatment of Chagas disease in the United States: a systematic review. *JAMA*. 2007;298:2171-2181.)**

be required in patients who do not respond to repeated attempts at balloon dilation. Laparoscopic myotomy is being used with increasing frequency to treat Chagas megaesophagus, as is the case with achalasia.

Chagas megacolon in its early stage can be treated with a high-fiber diet and occasional laxatives or enemas. Fecal impaction requiring manual disimpaction can occur, and toxic megacolon requires surgery. In patients with advanced megacolon, volvulus (Chapter 142) can develop when an enlarged and lengthened sigmoid colon twists and folds on itself; volvulus causes a constellation of symptoms and in many cases requires immediate surgery. Even if the symptoms associated with volvulus are resolved without operative intervention, however, surgical treatment is usually ultimately necessary because the volvulus tends to recur. Several surgical procedures are used to treat advanced Chagas megacolon, all of which include resection of the sigmoid and removal of part of the rectum.

PREVENTION

Reducing human contact with triatomine vectors through education of at-risk persons, housing improvement, and spraying of residual insecticides in endemic countries has resulted in reduction or elimination of vector transmission of *T. cruzi* in a major part of the endemic range, and progress in this regard is expected to continue. Serologic screening of donated blood has essentially eliminated transfusion-related transmission of the parasite in most endemic areas. Outbreaks of acute Chagas disease through oral transmission can be avoided by the implementation of better food safety standards. Drug treatment of *T. cruzi*–infected women before pregnancy reduces the likelihood of congenital transmission. No protocols have been defined and validated for preventing reactivation of *T. cruzi* infection in chronically infected persons who are immunosuppressed iatrogenically or by HIV. A treatment regimen that reliably results in parasitologic cure is

needed to prevent the onset or progression of chronic symptomatic Chagas disease.

PROGNOSIS

The prognosis for patients with acute Chagas disease is generally excellent because most acutely infected persons have only mild symptoms that resolve spontaneously, even without specific treatment. The occasional patient who has symptomatic acute Chagas myocarditis should generally do well if treated early. In persons with chronic *T. cruzi* infection, the lifetime risk for the development of related cardiac or GI dysfunction is only 10% to 30%.[17] A validated risk score assessment tool has been developed to gauge prognosis.[18] It has not been determined in randomized controlled trials whether this rate of progression to clinical disease or overall mortality is significantly affected by treatment with nifurtimox or benznidazole.

REVIEW QUESTIONS

1. Which of the following measures have been important over the past few decades in reducing the transmission of *Trypanosoma cruzi* (Chagas disease) in endemic countries?

A. Improvement of housing conditions
B. Identification and treatment of babies with congenital Chagas disease
C. Spraying of insecticides in at-risk houses to eliminate insect vectors
D. All of the above
E. A and C

Answer: E Improvement of housing conditions and insecticide spraying, along with education of at-risk populations, all of which reduce contact with infected vectors, have been at the core of the successful programs that reduce transmission of *T. cruzi*. Programs focused on identifying and treating babies with congenital *T. cruzi*-infection have not been implemented widely and in any event would have relatively little effect on reducing transmission of the parasite.

2. In which of the following patients is chronic Chagas disease (*Trypanosoma cruzi* infection) likely to be the cause of the patient's signs and symptoms?

A. A 56-year-old man from rural Brazil with early-onset dementia
B. A 58-year-old Bolivian woman with abdominal pain caused by a small bowel obstruction
C. A 62-year-old man with weight loss, hemoptysis, and anemia
D. A 20-year-old Bolivian man with recurrent syncope and third-degree heart block and an ectopic ventricular pacer on ECG
E. A 7-year-old child with intermittent diarrhea and eosinophilia

Answer: D In the endemic countries, particularly in Bolivia, where the overall prevalence is about 7%, chronic Chagas disease is a major cause of serious rhythm disturbances, heart block and sudden death among young people. The other options are unlikely because a link between Chagas disease and dementia has not been established; chronic Chagas disease is sometimes manifest as obstructive megacolon but not small bowel obstruction; weight loss, hemoptysis, and anemia are more suggestive of tuberculosis than Chagas disease; and intermittent diarrhea and eosinophilia are not associated with chronic Chagas disease in patients of any age.

3. Which of the following Latin American countries has the lowest prevalence of Chagas disease?

A. Bolivia
B. Dominican Republic
C. Colombia
D. Argentina
E. Ecuador

Answer: B Chagas disease is endemic in all the countries of Central and South America, as well as in Mexico. None of the Caribbean islands are endemic for Chagas disease. The only persons with Chagas disease in the Dominican Republic would be immigrants from the endemic countries, and thus the prevalence there would be quite low and far less than in the other countries listed where vector-borne transmission continues.

4. Which of the following statements is false?

A. Of all the countries in which Chagas disease is endemic, Bolivia has the highest prevalence.
B. Several hundred cases of transfusion transmission of Chagas disease were reported in the United States and Canada before the implementation of donor screening in 2007.
C. Transfusion transmission of *Trypanosoma cruzi* (Chagas disease) has been largely eliminated in the endemic countries by serologic screening of blood donors.
D. Highly accurate assays for diagnosing Chagas disease are available in the United States, Canada, and the endemic countries.
E. *Trypanosoma cruzi* is widely distributed among wild mammals and insect vectors in the southern and southwestern United States.

Answer: B Before the implementation of blood donor screening for Chagas disease in the United States and Canada in 2007, only nine instances of transfusion transmission of the infection had been reported. The other statements are all true: Bolivia's Chagas disease prevalence of about 7% is the highest of all the endemic countries; To the credit of politicians and public health authorities in the endemic countries, and because of the availability of accurate serologic assays, transfusion transmission of Chagas disease is largely a thing of the past. Mexico is a notable exception to this achievement, however, because universal donor testing for Chagas disease has not been implemented there yet. To the surprise of many, in the southern third of the United States *T. cruzi* is widely enzootic in many species of wild mammals and insect vectors, as well as in domestic dogs.

5. The current consensus of experts in Chagas disease holds that the following groups of persons with *T. cruzi* infection should be given specific treatment (benznidazole or nifurtimox) except

A. babies with congenital Chagas disease.
B. patients older than 50 years of age with advanced symptomatic Chagas heart disease.
C. children and adolescents up to age 18 years.
D. patients with AIDS and reactivated acute *T. cruzi* infection.
E. adults with acute Chagas disease and mild symptoms.

Answer: B A panel of experts in Chagas disease from the endemic countries as well as the United States and Canada, convened by the Centers for Disease Control and Prevention in 2006 with the goal of developing evidence-based guidance on diagnosis and treatment, concluded that all groups of patients listed above should be treated, with the exception of patients older than 50 years of age or those with advanced symptomatic Chagas cardiac disease (Bern C, Montgomery SP, Herwaldt BL, et al. Evaluation and treatment of Chagas disease in the United States: a systematic review. *JAMA*. 2007;298: 2171-2181).

LEISHMANIASIS

SIMON L. CROFT AND PIERRE A. BUFFET

DEFINITION

Leishmaniasis is caused by protozoan parasites of the genus *Leishmania* that are generally transmitted between mammalian hosts by female phlebotomine sandflies. The disease in humans has a number of clinical manifestations ranging in severity from self-curing, limited cutaneous lesions to disseminated, potentially fatal visceral disease. The parasite exists in the sandfly gut as an extracellular flagellated form, the promastigote, and as an intracellular form, the amastigote, that survives and multiplies in a phagolysosomal compartment of macrophages in the mammalian host.

This disease complex is caused by 17 species of *Leishmania*, which are widely distributed in Europe, Asia, Africa, and South and Central America, with limited foci in Southeast Asia.[1] The characteristics of the main *Leishmania* species are summarized in Table 348-1. There are an estimated 1.5 to 2.0 million new cases each year, with up to 70,000 deaths, although this is probably an underestimate as leishmaniasis is not a reportable disease in many of the 101 countries and territories in which it is known to occur. Many *Leishmania* infections are either asymptomatic or misdiagnosed.

Because leishmaniasis is a disease complex, clinical aspects are considered under separate sections for visceral leishmaniasis (VL) and cutaneous leishmaniasis (CL).

EPIDEMIOLOGY

Infection is established in the mammalian host following a bite of the female sandfly belonging to either *Phlebotomus* spp in Europe, Asia, and Africa or *Lutzomyia* spp in the Americas. Different species of sandfly are associated with transmission of different *Leishmania* species. Most species that cause CL have a zoonotic (acquired from another mammal) transmission cycle, with the exception of *Leishmania tropica*, which is sometimes anthroponotic (transmitted between human beings). VL is either normally anthroponotic (in the case of *Leishmania donovani*) or zoonotic (in the case of *Leishmania infantum*). The predominant mammalian hosts (the reservoirs) are associated with different *Leishmania* species in diverse ecosystems (Fig. 348-1).

VL is caused by either *L. donovani* or *L. infantum* (which is identical to *Leishmania chagasi* in South America). These species have different geographic distributions, with the highest incidence found in the poorest communities in six countries (Bangladesh, Nepal, India, Sudan, Ethiopia, Brazil), and infection is potentially fatal if it is untreated. An estimated 1 in 5 to 1 in 50 infections are asymptomatic, depending on the parasite species and host immunity. Since 2005, there has been a regional program to eliminate VL (aiming to reduce annual incidence to <1 per 10,000) in the Indian subcontinent.[2]

CL, which undergoes self-cure in more than 90% of patients within 3 to 18 months, is widely distributed, but its prevalence is difficult to estimate because of underreporting. Prevalence is associated with age, possibly related to the acquisition of immunity and risk factors, including the presence of domestic animals, rodents, or other mammalian hosts.[3] Ecologic conditions for sandflies, including shaded and humid habitats in crevices and mammal burrows, have been identified. The disease also must be considered in travelers returning from endemic areas.[4]

Urbanization, deforestation, and migration have resulted in changing patterns of disease, with transmission occurring in peridomestic cycles.[5] Other forms of transmission, such as through intravenous needles shared by drug users, have been reported in Spain.

PATHOBIOLOGY

The infection is initially established in the skin after the inoculation of infective metacyclic promastigotes by the sandfly. These infective forms have a glycoprotein coat (a lipophosphoglycan) that enables them to resist complement and to attach to and invade host cells. Peptides in sandfly saliva (e.g., maxadilan) cause vasodilation and erythema and help establish infection in the dermal layer of the skin. Early responses to infection involve neutrophil infiltration and invasion of resident macrophages. Progress of the disease depends on the parasite species and host responses. For both VL and CL, disease progression depends on the maintenance of a parasite-specific immunosuppressive state. Host cell macrophages are in a deactivated state, but cure follows when macrophages become activated and kill the parasites, which are sensitive to nitric oxide and oxygen radicals, in the phagolysosomal compartment. Resolution of disease, after the activation of macrophages, is mediated by a T-helper cell T_H1 response after interaction of antigen-presenting cells (e.g., dendritic cells) with $CD4^+$ and $CD8^+$ T cells and subsequent secretion of pro-inflammatory cytokines (e.g., interleukin 2, interferon-γ, tumor necrosis factor-α). However, in clinical forms such as active VL or diffuse CL, a T_H2 cell response predominates whereby downregulation of macrophage activity follows the production of cytokines such as interleukins 4, 10, and 13 and transforming growth factor-β. This profile has been defined in experimental models, mainly inbred mice, and ongoing clinical studies support the notion of a similar profile in human infection.

In patients with VL, the absence of a T cell–specific immune response to leishmanial antigens is associated with uncontrolled progression of infection. This is linked to elevated levels of interleukin 10 and decreased production of interferon-γ. Genetic susceptibility to *L. donovani* in Sudan has been associated with a solute carrier family (formerly NRAMP1) that regulates macrophage activation and with a polymorphism in the interleukin 4 gene. In localized simple CL, patients show a T_H1-type response and a delayed-type hypersensitivity (DTH) response. DTH is frequently measured by a Montenegro skin test, which can also be used in epidemiologic prevalence studies. Chronic infections show a T_H2-type response, most predominantly in patients with diffuse CL, in whom there is complete anergy to leishmania antigen and no DTH response. Patients with mucosal leishmaniasis (ML) have both T_H1 and T_H2 cell responses and a strong DTH response. Post–kala-azar dermal leishmaniasis (PKDL), a rare sequela to cure from VL, is poorly understood. The roles of $CD4^+$ and $CD25^+$ T cells appear to be different in Indian and Sudanese forms of PKDL.[6]

VISCERAL LEISHMANIASIS

CLINICAL MANIFESTATIONS

The onset of VL, often referred to as kala-azar when it is caused by *L. donovani*, occurs weeks to months after the initial infection. Clinical signs and symptoms do not distinguish VL from hyperreactive malarial splenomegaly or other infectious or hematologic conditions. Anemia, leukopenia, thrombocytopenia, systemic inflammation, or polyclonal hypergammaglobulinemia, either isolated or combined, suggests but does not confirm the diagnosis. Parasitologic tests are therefore indispensable before a therapeutic decision is made.[7]

TABLE 348-1 CHARACTERISTICS OF THE MAIN *LEISHMANIA* SPECIES

LEISHMANIA SPP	*LEISHMANIA* SUBGENUS	DISTRIBUTION: OLD WORLD	DISTRIBUTION: NEW WORLD	PRIMARY FORM	SECONDARY FORMS	ANTHROPONOTIC: AREAS OF TRANSMISSION	ZOONOTIC: RESERVOIR	ALTERNATIVE NAME
L. donovani	*Leishmania*	Indian subcontinent E. Africa		VL	PKDL CL, ML OIVL	Indian subcontinent E. Africa		Kala-azar
L. infantum (*L. chagasi*)	*Leishmania*	Europe Asia	S. & C. America	VL	CL, ML OIVL		Canid	
L. major	*Leishmania*	Asia N. & E. Africa Europe		CL			Rodent	
L. tropica	*Leishmania*	Asia Europe		CL	Recidivans	Syria Afghanistan	Rodent	Aleppo boil
L. aethiopica	*Leishmania*	Ethiopia		CL	DCL		Hyrax	
L. mexicana	*Leishmania*		C. America	CL			Rodent	Chiclero's ulcer
L. amazonensis	*Leishmania*	C. & S. America		CL	DCL		Rodent	
L. braziliensis	*Viannia*	S. America		CL ML	DissCL Lymph		Rodent, marsupial	ML-espundia
L. panamensis	*Viannia*	C. & S. America		CL	ML Lymph		Edentate rodent	Ulcera de bejuco
L. guyanensis	*Viannia*	S. America		CL	ML Lymph		Rodent, edentates	Pian bois
L. peruviana	*Viannia*	S. America		CL			Canids	Uta
L. siamensis		Southeast Asia		CL VL				

CL = cutaneous leishmaniasis; DCL = diffuse cutaneous leishmaniasis; DissCL = disseminated cutaneous leishmaniasis; Lymph = nodular lymphangitis; ML = mucosal leishmaniasis; OIVL = opportunistic infection with VL in HIV-infected patients; PKDL = post–kala-azar dermal leishmaniasis; VL = visceral leishmaniasis.

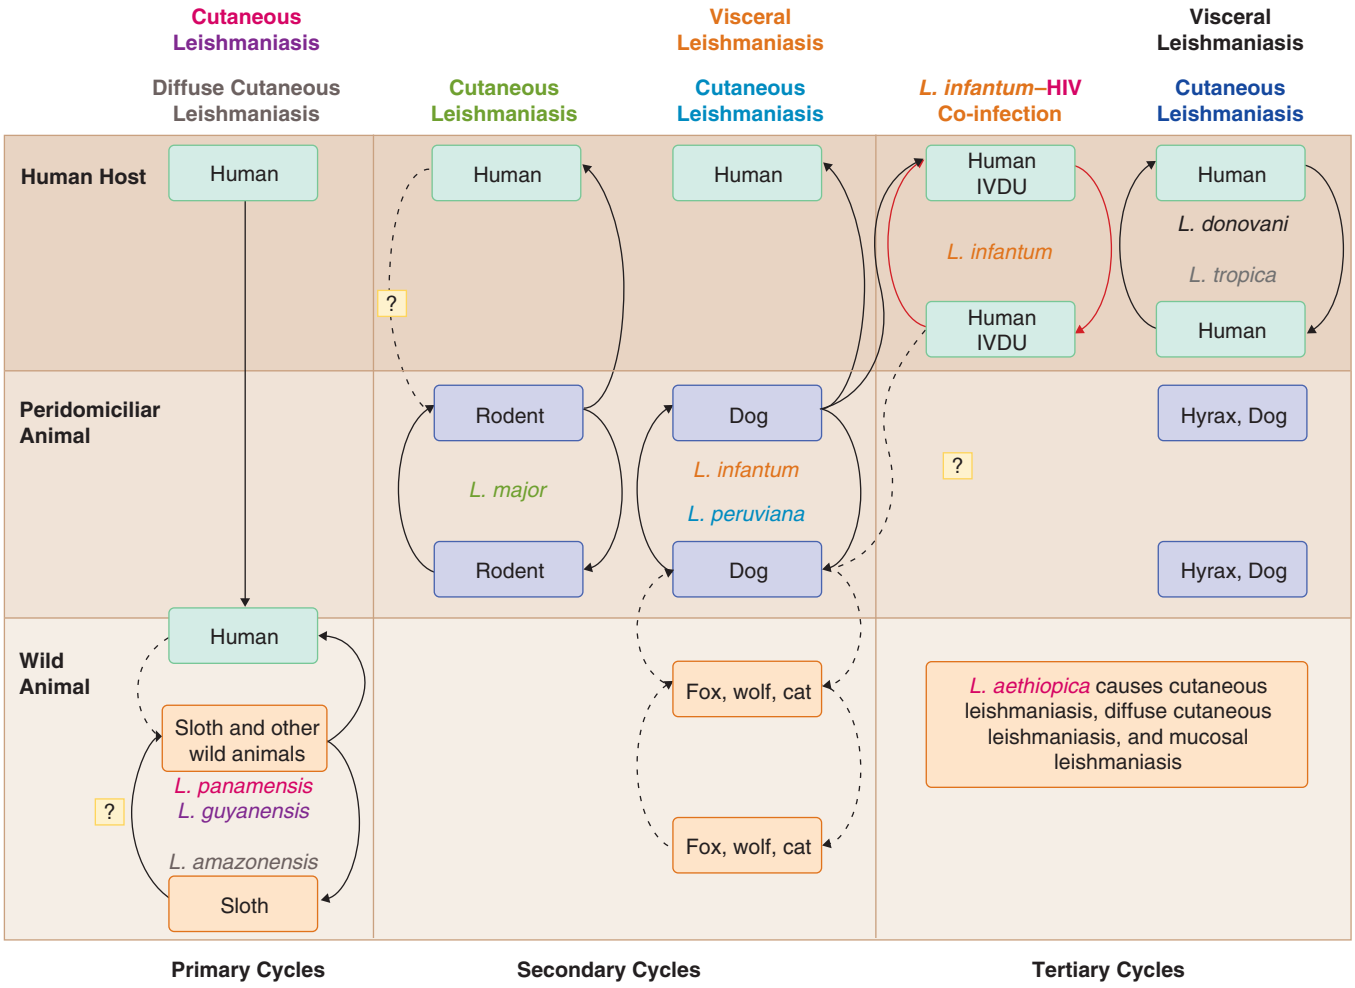

FIGURE 348-1. Old World and New World zoonotic and anthroponotic life cycles of the main species of *Leishmania*. Leishmaniasis is often referred to as a disease complex because different forms of disease can be caused by the same parasite species and similar forms of disease can be caused by different parasite species. IVDU = intravenous drug use.

DIAGNOSIS

Parasitology

Microscopic visualization of amastigotes in samples from the lymph nodes, bone marrow, liver, spleen, or other organs was usually the first step. Because spleen aspiration causes life-threatening complications in approximately 0.1% of patients, it should be performed only in trained facilities and only if other, lower-risk methods cannot be used. It is still used in the field because of the higher cost, logistic constraints, and lower sensitivity of bone marrow aspiration. Polymerase chain reaction (PCR) is more sensitive than microscopic examination and has become the first-line test in several referral hospitals and research centers.[8] Quantitative PCR with validated thresholds allows accurate diagnosis with venous blood samples, thereby avoiding bone marrow aspiration.

Serology

Serologic tests based on indirect fluorescent antibody, enzyme-linked immunosorbent assay, or Western blot display high performance but require equipment that is poorly adapted to field settings. The field-friendly direct agglutination test and immunochromatography (dipstick) with the rK39 antigen have high diagnostic accuracy and can be used in peripheral health centers.[9] Whatever the serologic test used, specific antibodies remain detectable for several years after cure or asymptomatic infection.

Antigen Detection Tests

A latex agglutination test that detects a heat-stable, low-molecular-weight carbohydrate antigen in the urine of patients with VL showed good specificity but low to moderate sensitivity in East Africa and the Indian subcontinent. Further optimization is required.

Complex Manifestations of Visceral Leishmaniasis

VISCERAL LEISHMANIASIS–HUMAN IMMUNODEFICIENCY VIRUS COINFECTION

Although the clinical manifestations in VL patients infected with human immunodeficiency virus (HIV) without severe immunosuppression are similar to those in immunocompetent patients, atypical clinical features can be found in patients with low $CD4^+$ T-cell counts (<200/μL). In the latter group, physicians may order investigations for VL even in the absence of classic signs (e.g., lack of splenomegaly). A substantial proportion of HIV-VL–coinfected patients may have other opportunistic infections that complicate the clinical diagnosis. The parasitic load is usually higher and parasites may be found in tissues other than spleen, liver, bone marrow, or lymph nodes (e.g., in the gut or lung), especially in severely immunosuppressed patients. Therefore, the sensitivity of microscopic examination, culture, or PCR of blood (plain blood or buffy coat) or bone marrow aspirates is generally higher than that in immunocompetent VL patients. Limited data have also shown high sensitivity of the latex agglutination test in the urine of HIV-VL–coinfected patients. In contrast, the sensitivity of serologic tests is decreased in coinfected patients, although study results are equivocal and depend on several factors, such as the test's format, region of endemicity, and level of immunosuppression. For example, the direct agglutination test has shown high sensitivity in Ethiopia. Increased sensitivity can be achieved by using a sequential combination of different serologic tests.

POST–KALA-AZAR DERMAL LEISHMANIASIS (PKDL)

After successful treatment of visceral disease due to *L. donovani*, a proportion of patients progress to disseminated cutaneous disease. In a small proportion of patients with PKDL, uveitis occurs with poor prognosis for preservation of eyesight. This is reported in up to 20% of patients in Sudan and 0.5% in India and Bangladesh. Studies in India have shown that smears are more likely to show amastigotes if specimens are taken from nodular lesions rather than from papular or macular lesions. Serologic tests such as the direct agglutination test, enzyme-linked immunosorbent assay, and rK39 immunochromatography are of limited value because a positive finding may be the result of persistent antibodies after the past episode of VL. Nevertheless, serology can be helpful when a previous history of VL is uncertain.

TREATMENT Rx

General Principles

The therapeutic management of patients with VL requires renutrition; broad-spectrum antibiotics if bacterial superinfection is suspected; transfusion in case of severe anemia; and proper hydration, especially when amphotericin B is used as the specific antileishmanial treatment.

The clinical response to antileishmanial agents depends on the clinical form and the infecting species or even the subspecies (zymodeme). Many antileishmanial agents are toxic, expensive, or difficult to administer in field conditions. No single satisfactory option for treating most of the clinical forms or species has been validated. Although therapeutic decisions and follow-up have become relatively simple for the treatment of VL in nonendemic and some endemic countries based on the powerful, well-tolerated agent liposomal amphotericin B,[10] more complexity persists for the treatment of VL in East Africa and in endemic countries where liposomal amphotericin B is not available.[11] The treatment decision for CL or ML often requires expert advice.[12]

Visceral Leishmaniasis in Immunocompetent Patients

Single-Agent Therapies

Pentamidine is efficient in treating VL only when high doses (more than seven injections of 4 mg/kg) are used. These are toxic, and pentamidine is no longer used for the treatment of VL. Lower doses (fewer than four injections of 4 mg/kg) induce much less severe adverse events and are still used for the secondary prophylaxis of VL in HIV-infected patients (fortnightly to monthly injections) and in those with CL caused by *Leishmania guyanensis* or *Leishmania panamensis* (one to three injections).

Pentavalent antimonials (sodium stibogluconate, meglumine antimoniate) are still prescribed as first-intention drugs in many areas. In the Indian subcontinent (mainly in northern Bihar), *L. donovani* is resistant to pentavalent antimonials.[13] Their efficacy has decreased from 90% to less than 40% during the past 40 years. In other VL foci, failure rates of initial treatment do not exceed 10% as long as the dosage is respected (20 mg of pentavalent antimony per kilogram per day for 28 days). In an endemic country, mortality in treated patients may exceed 10%, with toxicity positively correlating with age. Pentavalent antimonials are contraindicated in patients with heart, kidney, or liver disease or advanced age and in pregnant women. Generic formulations have generally but not constantly demonstrated activity and tolerance identical to those of sodium stibogluconate.

Miltefosine is an alkyl phosphocholine. The oral form (2.5 mg/kg/day for 28 days) is effective for VL in India. In Ethiopian patients with VL (28% with HIV infection), there was significantly higher mortality with sodium stibogluconate (generic) than with miltefosine (9.7% vs. 2.1%) despite the lower parasitologic efficacy of miltefosine (92.1% vs. 99.3%). Miltefosine is contraindicated in pregnant women or those who may become pregnant. Because of persistent levels of the drug, contraceptive measures must be observed for 3 months after therapy. Compared with a decade ago, substantial increase in the failure rate of oral miltefosine has been noted in the treatment of visceral leishmaniases in India and Nepal since 2012.

Paromomycin (aminosidine sulfate) (15 mg/kg in sulfate form equivalent to 11 mg of base per kilogram intramuscularly for 21 days) is highly effective in India, where it was registered in 2006. In East Africa, its efficacy is significantly lower. Similar to the situation with miltefosine, the longevity of the product would probably be better preserved in combination than as a single-agent therapy.

Amphotericin B (cumulative dose of 7 to 15 mg/kg) cures more than 98% of patients in India, whereas treatment of visceral infection with *L. infantum/chagasi* requires at least 14 mg/kg.

Liposomal amphotericin B achieves very high cure rates in India with lower cumulative doses than are needed with the deoxycholate formulation. In preliminary studies in East Africa, the doses of liposomal amphotericin B required to cure VL (about 30 mg/kg cumulatively) are markedly higher than those used in India. Liposomal amphotericin B is associated with less infusion-related fever and chills, less renal toxicity, and a reduction in the number of infusions and length of hospitalization. The better renal tolerance of liposomal amphotericin B is especially beneficial in patients with renal failure or a kidney graft and in those with an increase in serum creatinine concentration during amphotericin B deoxycholate therapy. Liposomal amphotericin B is the antileishmanial agent with the best benefit-risk ratio. It is now the first-line option in most nonendemic countries, both in children and in adults. The very high cost of liposomal amphotericin B has been reduced for use in endemic countries, but wider implementation would be greatly facilitated by donation. A single infusion of liposomal amphotericin B at a dose of 10 mg/kg of body weight was reported in 2010 not to be inferior to and less expensive than conventional treatment with amphotericin B deoxycholate. In this study, conducted in India, 304 of 304 patients (100%) with VL in the liposomal therapy group and 106 of 108 (98%) in the conventional therapy group had apparent cure responses at day 30. Cure rates at 6 months were similar: 95.7% with liposomal therapy and 96.3% with conventional therapy.

Combinations and Coadministration

To limit extension of the resistance to pentavalent antimonials and to prevent the emergence of resistance to paromomycin or miltefosine, shorter courses of therapy are being investigated. Because only miltefosine may be administered orally, this approach is based at least partly on products administered parenterally. As high cure rates have been reported, the combination of antimony and paromomycin is approved for use in East Africa but still

requires many injections. Combinations of amphotericin with oral miltefosine (sequential) and of intramuscular paromomycin with miltefosine can achieve cure rates of up to 98% with 7- to 10-day courses of therapy. A single infusion of liposomal amphotericin B followed by oral miltefosine has been highly effective in India, but confirmation studies are required here and elsewhere.

Visceral Leishmaniasis in Immunodeficient Patients

Leishmania infantum–HIV Coinfection

As with other major opportunistic infections during HIV infection, treatment may be subdivided into initial course and secondary prophylaxis. With initial treatment, the efficacy of meglumine antimoniate and that of amphotericin B are similar. The severe adverse effects of antimony derivatives are more common in this context. Doses of liposomal amphotericin B administered to immunodeficient patients are higher (30 to 40 mg/kg in cumulative dose) than those administered to immunocompetent patients. When therapeutic immunosuppression may not be reduced or optimization of highly active antiretroviral therapy is not possible, secondary prophylaxis is often proposed. Amphotericin B lipid complex moderately reduces the frequency of recurrences. Discontinuous administration of liposomal amphotericin B is generally used, but a progressive reduction in its efficacy has been reported, although apparently not associated with decreased parasitic sensitivity in vitro. Miltefosine is another option, especially if the reduction in parasitic load is backed up by quantitative PCR with a validated threshold (low residual load probably being associated with a lower risk for resistance). Administration of pentamidine once or twice a month is another potentially interesting option because drug levels persist for weeks or months after a single administration. Pancreatic tolerance should be monitored closely.

Leishmania donovani–HIV Coinfection

Patients should benefit from effective antiretroviral treatment. The experience with *L. infantum*–HIV coinfection is in part transposable. The potential risk for the emergence of resistance to antileishmanial agents is still more significant in this context because *L. donovani* (but not *L. infantum*) can be transmitted from human to human. Important clinical research is ongoing in East Africa.

CUTANEOUS LEISHMANIASIS

CLINICAL MANIFESTATIONS

Although the signs and symptoms of CL vary considerably (Fig. 348-2)—from pure nodular lesions to developing ulceration through dry crusty lesions and squamous plaques—there are some fairly constant features. First, firm infiltration is almost constant (the exception being the initial macule of PKDL). Second, the evolution is subacute, which is a useful criterion in practice. A lesion reaching its maximum size in less than a week is most likely not due to CL. Finally, except in patients with numerous satellite papulopustules, the lesion or lesions are sharply defined. Colonization of the CL ulceration with bacteria may give the lesion a purulent appearance, whereas patent superinfection adds an erythematous ring distinctly overflowing the infiltrated edge of the ulceration and making a usually cold and painless lesion feel hot and painful. Several dermatologic conditions, such as staphylococcal or streptococcal infection, mycobacterial ulcer, leprosy, fungal infection, cancer, sarcoidosis, and tropical ulcer, can mimic CL or ML lesions (see Fig. 348-2). Because treatment is costly and potentially toxic, diagnostic confirmation is necessary.

DIAGNOSIS

Parasitology

Scraping, fine-needle aspiration, or biopsy of lesions provides appropriate samples in which amastigotes can be identified (Fig. 348-3). Scraping should be performed at both the center and edges of the lesion with a curved scalpel blade. Local anesthesia considerably reduces patients' discomfort and increases sensitivity. Use of an epinephrine-containing local anesthetic (contraindicated for lesions on extremities) or pinching of the lesion between the thumb and finger until blanching appears helps obtain a bloodless scraping, thus optimizing microscopic examination. The 2- to 4-mm skin fragment obtained by punch biopsy provides abundant material, which facilitates the search for scarce parasites and for an alternative diagnosis by culture (e.g., mycobacteria, fungi) as well as by histopathologic examination. Culture of a biopsy sample requires homogenization in saline or culture medium under sterile conditions.

The material obtained by any of these methods can be used for microscopic examination, culture, and PCR. Microscopic examination of Giemsa-stained material is the most widely available method. Culture of the parasite in specific media (such as fetal calf serum–supplemented Schneider's or Novy-Nicolle-McNeal media) allows identification, characterization, and storage of the isolate. Detection of parasitic nucleic acids by molecular diagnosis (mainly PCR) increases sensitivity and allows identification of the *Leishmania* species (see Table 348-1). This is particularly useful in regions (e.g., New World) where several *Leishmania* species—with various clinical outcomes and responses to treatment—coexist. Both culture and molecular-based diagnosis require substantial laboratory infrastructure and technical expertise.

Serology

Serologic diagnosis is of limited use for CL because of low sensitivity and variable specificity. The leishmanin (or Montenegro) skin test (LST) evaluates the cell-mediated response against *Leishmania* spp. The LST requires culture and preferentially fixation of local species of *Leishmania* and therefore lacks standardization. The production of commercial formulations of the LST lacks sustainability. Like serologic tests, the LST does not distinguish between past and present infections.

Complex Manifestations of Cutaneous Leishmaniasis

MUCOSAL LEISHMANIASIS

A proportion of CL infections (about 1 to 10% in Brazil, Bolivia, and Peru) caused by *Leishmania braziliensis* or *L. guyanensis* progress to a metastatic infection of the mucosa of the oral or nasal cavity or larynx, often 1 to 5 years after healing of the initial simple cutaneous lesion. An immunopathologic response results in extensive destruction of local tissue. Allergic rhinitis, paracoccidioidomycosis or other deep mycosis, cancrum oris, leprosy, and sarcoidosis may mimic the lesions of ML. Positive serology (e.g., indirect fluorescent antibody, enzyme-linked immunosorbent assay) or LST indicates possible ML. Parasites are scarce in mucosal lesions. Therefore, a search for parasites in mucosal samples—obtained by scraping or biopsy—by microscopic examination or by culture lacks sensitivity. PCR has proved to be the most sensitive approach to confirm ML.

DIFFUSE CUTANEOUS LEISHMANIASIS

Patients with diffuse CL have an anergic response to *Leishmania* antigens, and nonulcerative nodules, loaded with parasites, disseminate from the initial site of infection to multiple sites on the patient's body. There is no self-cure, and treatment is difficult. This form of the disease is found in South America and East Africa, often associated with *Leishmania amazonensis* and *Leishmania aethiopica* infection.

RECIDIVANS CUTANEOUS LEISHMANIASIS

Recidivans CL is characterized by the development of lesions containing granulomatous tissue. The lesions often take many years to heal and may arise years after healing of a simple localized lesion. New ulcers and papules may form over the edge of the old scar. Infections are normally associated with *L. tropica* infection and are difficult to treat.

TREATMENT Rx

The clinical consequences of CL are dermatologic; concomitant visceral impairment is exceptional. The intensity of the discomfort, related to one or several oozing or unsightly lesions, and the impact of atrophic, hypopigmented or hyperpigmented scars depend on the lesions' topography. In the New World, mucosal impairment may affect up to 1 to 15% of patients (higher in Bolivia). The risk for metastasis (initially nasal and then affecting the entire otorhinolaryngeal zone) has strongly influenced therapeutic decisions. Systemic treatment of any New World CL has been recommended, but recent data indicate that a different strategy should probably be considered.[14] Inadequate surgical excision and pentavalent antimonials or systemic pentamidine administered in excessive doses or without sufficient follow-up may paradoxically be a major risk for patients with CL. Analysis of the number and size of the lesions and their topography, the clinical signs of spread (cutaneous, mucous, or lymphatic), and the predictable cosmetic or functional impact helps in estimating the benefit-risk ratio.[15]

Oral therapy with relatively nontoxic drugs (ketoconazole, fluconazole, itraconazole, miltefosine) would be the simplest option, and oral miltefosine monotherapy has been successful in Brazil.■ Local therapy with intralesional injections of pentavalent antimonials (with or without cryotherapy), photodynamic therapy, and thermotherapy are therefore attractive options to avoid potentially toxic, expensive, or impractical systemic schedules. However, implementation of these methods is hampered by logistic constraints and requires skilled health care providers. An efficient topical ointment would

FIGURE 348-2. Clinical features of cutaneous leishmaniasis (CL). FIGURE 348-3. **Amastigotes of *Leishmania major* in scrapings from a skin ulcer.**

resolve most of these issues, but no efficient formulation is widely available. Several formulations of topical paromomycin have been tested with variable results. Recently, an ointment containing paromomycin and gentamicin has shown efficacy with acceptable local tolerance in patients with CL caused by *L. major* and *L. panamensis*.[A3,A4] An algorithm for accurate therapeutic decisions recently validated in travelers is proposed in E-Figure 348-1.

PREVENTION

There are no modern vaccines for human disease and no prophylactic drug regimens. Leishmanization, or inoculation of people with live virulent parasites to cause a local limited lesion and provide protection, was used for CL (e.g., in Iran) but is not recommended by the World Health Organization. Sandflies are sensitive to most insecticides, and transmission has been controlled with malaria eradication campaigns and residual spraying in houses. Insecticide-impregnated bed nets and dog collars (to prevent transmission of zoonotic CL) have been investigated. The high incidence of vertical and venereal transmission in dogs may cause elimination programs to fail in *L. infantum* foci.

PROGNOSIS

Most untreated patients with established disease ultimately die of the disease. VL has an excellent prognosis with less than a 2% death rate in patients treated soon enough with liposomal amphotericin B. Mortality increases when bleeding (mainly from the digestive tract or lung) or secondary bacterial infection occurs, usually after prolonged untreated evolution or unresponsiveness of VL to first-line agents. Post-therapeutic relapse is frequent in HIV-coinfected patients with low initial or persistently low $CD4^+$ counts. In immunosuppressed patients, VL is rarely the direct cause of death but may give rise to complex therapeutic situations. A proportion of *L. donovani*–infected patients experience PKDL weeks to years after the initial episode, which may rarely lead to severe ocular involvement. CL caused by *L. braziliensis* may metastasize to the nose and other mucous membranes with variable frequency in different areas. CL caused by *L. tropica* often relapses (recidivans CL). A small proportion of patients infected with *L. amazonensis* and *L. aethiopica* experience diffuse CL. Even when treated, most CL lesions leave disfiguring, hypotrophic, hypopigmented, or hyperpigmented scars.

E-FIGURE 348-1. Algorithm of treatment options for cutaneous leishmaniasis (CL)—an example of decision making. (1) Abstention can probably be proposed to patients with scarring lesions. The healing rate in *L. major*–infected patients is 50 to 75% after 3 to 6 months of evolution. (2) Many patients do not understand that no therapy is proposed and will therefore search for a physician ready to recommend immediate therapy, thus raising the risk for an inadequate therapeutic choice (e.g., surgical excision, toxic overdosed systemic course of the reference antileishmanial agent). Genuine adherence of the patient to abstention is therefore essential. As time passes, lack of cure makes abstention more difficult to maintain. Close follow-up is thus important. (3) Most local therapies require injections either for intralesional injection or for local anesthesia. Pain is therefore a strong limiting factor, which makes treatment of more than three lesions in one session almost impracticable in most patients. The crude number of lesions is, however, a poor determinant of treatment choice because most patients with numerous lesions have only two or three large exposed lesions requiring immediate therapy, the other lesions being small, nodular, or unexposed and therefore amenable to abstention or expectant therapy. The number of lesions that can be treated with a topical ointment is much higher. (4) Most lesions on the face (cheek, over the zygomatic bone) can easily be injected. Lesions on nose, lips, eyelids, and ears are, however, in general difficult to inject. Lesions on joints cannot usually be injected but are in general easily treated by applying ointment. (5) Most local methods require heavy or expensive equipment and trained health care providers; they are therefore resource limited. L-AmB = liposomal amphotericin B; Sb = pentavalent antimony. (From Morizot G, Kendjo E, Mouri O, et al. Travelers with cutaneous leishmaniasis cured without systemic therapy. *Clin Infect Dis*. 2013;57:370-380.)

*Self-curing lesions show flattening or reduction in the surface of the ulceration or induration.

†Washing of the lesion, wound dressing, and follow-up were performed in all situations.

‡Lymphatic dissemination did not influence treatment decision. However, because it increased the number of lesions requiring therapy, it sometimes justified the use of systemic therapy.

§Most lesions of limbs, trunk, check, upper cheek, chin, and front were injected, including those close to large joints. Ears, fingers, or toes were not injected. In children, premedication facilitated the injection.

¶Systemic pentamidine for *L. guyanensis/panamensis.*

REVIEW QUESTIONS

1. A 60-year-old woman has been experiencing fever without chills for 10 days, starting 1 month after a 6-month travel from China to Europe. Clinical examination shows splenomegaly and liver enlargement. Laboratory parameters show anemia, leukopenia, and thrombocytopenia. Which of the following statements is correct?

A. The most likely diagnostic possibilities are a hematologic condition and visceral leishmaniasis.
B. The most likely diagnostic possibilities are bacterial infection and Chagas' disease.
C. The most likely diagnostic possibilities are viral infection and histoplasmosis.
D. None of the above is accurate.

Answer: A The association of fever and splenomegaly with pancytopenia is highly suggestive of but not specific for visceral leishmaniasis. Several hematologic conditions (myeloproliferative neoplasms, splenic lymphoma, Castleman's syndrome) are manifested with the same association of signs and laboratory abnormalities. Bacterial conditions and acute Chagas' disease are infrequently associated with pancytopenia, so this option is possible but less frequent. Viral infections (human immunodeficiency virus, human herpesvirus 8, cytomegalovirus) and histoplasmosis may be manifested with splenomegaly and pancytopenia, but these presentations are less prevalent in series of fever of unknown origin (at least in the European context), so this option is possible but less likely.

2. A 3-year-old child has fever, splenomegaly, anemia, leukopenia, and thrombocytopenia. Direct examination of a bone marrow aspirate (Giemsa-stained smear) for *Leishmania* amastigotes is negative. The most sensitive and specific, safest laboratory test to confirm the diagnosis of visceral leishmaniasis is

A. Wait for *Leishmania* culture on the bone marrow aspirate to become positive
B. Test for antileishmanial antibody
C. Quantitative polymerase chain reaction (PCR) for *Leishmania* on a blood sample
D. Direct examination of a splenic aspirate (Giemsa-stained smear)
E. Direct examination of the bone marrow aspirate

Answer: C Quantitative PCR is a highly sensitive and specific test as soon as thresholds for symptomatic disease have been defined (low-grade positivity is frequent in endemic areas). Antileishmanial antibody can be positive because of past infection. Culture is also a sensitive test although generally less so than an optimized PCR based on the amplification of kinetoplastic DNA. Splenic aspiration is not a safe procedure.

3. A 22-year-old HIV-seropositive man with fever, splenomegaly, and pancytopenia has visceral leishmaniasis confirmed by quantitative PCR on a peripheral blood sample. The following items suggest a complicated form.

A. Mucosal hemorrhages
B. Presence of splenomegaly 5 cm below the costal margin
C. Cough
D. Moderate thrombocytopenia

Answer: A Hemorrhage and bacterial superinfection are the two main complications of advanced visceral leishmaniasis. Splenomegaly and mild to moderate thrombocytopenia are present in a majority of patients with uncomplicated visceral leishmaniasis. Dry cough is present in 10 to 15% of patients with visceral leishmaniasis (but will justify diagnostic study to rule out a bacterial superinfection in the lung).

4. A 2-year-old child has parasitologically confirmed, uncomplicated visceral leishmaniasis. The treatment option with the most favorable therapeutic window is

A. Miltefosine 2.5 mg/kg for 28 days orally
B. Pentamidine mesylate 4 mg/kg for 10 days by slow IV infusion
C. Amphotericin B deoxycholate 0.5 mg/kg/day for 14 days by slow IV infusion
D. Meglumine antimoniate (pentavalent antimony) 20 mg SbV/kg/day for 28 days by slow IV infusion
E. Liposomal amphotericin B 10 mg/kg D1 and D2 by slow IV infusion

Answer: E All these options have been used in the therapy of visceral leishmaniasis. The 2-day schedule of liposomal amphotericin B has been validated in children.

5. A 35-year-old woman has a subacute, painless, crusted ulceration of the forearm that appeared 1 month after travel to Israel. Which of the following findings makes the diagnosis of cutaneous leishmaniasis unlikely?

A. The lesion has an oval shape.
B. The lesion is infiltrated.
C. The lesion had a red, painful border for the last 4 days.
D. The lesion reached its maximum size in less than a week.
E. The lesion has small peripheral papules.

Answer: D Cutaneous leishmaniasis evolves subacutely, and therefore a lesion that reaches its maximum size within a week of its appearance makes the diagnosis unlikely. Firm, sharply defined lesions are characteristic, and numerous satellite papulopustules can occur. Although the uncomplicated lesions are "cold and painless," superinfection can make them "hot and painful" with surrounding erythema.

TOXOPLASMOSIS

JOSE G. MONTOYA

DEFINITION

The ubiquitous parasite *Toxoplasma gondii* is the etiologic agent of toxoplasmosis. The term *toxoplasmosis* is reserved for the disease process in which clinical manifestations are present, whereas *Toxoplasma infection* best describes the asymptomatic presence of the parasite. Toxoplasmosis may result in significant morbidity and mortality of the fetus, newborn, and immunocompromised patient. However, *T. gondii* can also be responsible for chorioretinitis, lymphadenopathy, pneumonia, brain abscesses, myositis, myocarditis, and hepatitis in immunocompetent patients.

A more aggressive form of congenital and adult toxoplasmosis appears to occur in certain geographic locales in Latin America, where pneumonia, fever of unknown origin, brain abscesses, and death have been reported in HIV-negative and otherwise immunocompetent individuals. Recent epidemiologic studies have established the role of novel risk factors for the acquisition of the acute infection, including the ingestion of untreated water, oysters, mussels, or clams.

The Pathogen

T. gondii is an intracellular parasite with a high capacity for host cell invasion due to a motile invasive form (tachyzoite or trophozoite) characterized by an evolutionarily unique apical complex and a mechanism of actin-based motility.

T. gondii maintains a highly clonal population structure in North America and Europe that consists of three main lineages: types I, II, and III. This relatively low genetic diversity comes as a surprise, given the fact that the parasite has the capacity to infect any warm-blooded animal. It has a sexual life cycle that takes place in the small intestine of cats. In Europe, type II strains predominate and are most commonly associated with human toxoplasmosis, both in congenital infections and in immunocompromised patients. In North America, types II and I appear to be equally common. In Latin America, type I strains are common, but *Toxoplasma* strains appear to be genetically more diverse, with many different genotypes described mainly in Brazil and French Guiana. These atypical Latin American strains, initially called exotic strains, belong to several haplogroups that are endemic to Latin America and have been found to be associated with more severe clinical manifestations; physicians need to entertain the diagnosis of toxoplasmosis in their patients presenting with pneumonia, fever of unknown origin, brain abscesses, lymphadenopathy, or chorioretinitis who are from or were traveling in these endemic areas.

In nature, the parasite exists in several forms, including the tachyzoite (Fig. 349-1A), the oocyst that contains sporozoites (Fig. 349-1B), the tissue cyst that contains bradyzoites (Fig. 349-1C), and the sexual forms (macrogametes and microgametes). The tachyzoite is the rapidly proliferating form of the parasite responsible for the clinical manifestations of toxoplasmosis observed in the setting of the acute infection or reactivation of a latent infection. The tissue cyst is the slower metabolic form of the parasite responsible for chronic infection and for its transmission through meat consumption in humans and animals. Tissue cysts persist in tissues for the life of the host and cannot be eradicated by drugs. Tissue cysts vary in shape and size from younger ones that contain only a few bradyzoites to older tissue cysts that may contain several thousand bradyzoites and may reach more than 100 μm in size. The central nervous system (CNS), eye, and skeletal, smooth, and heart muscles appear to be the most common sites of tissue cyst formation (i.e., latent infection). Oocysts are primarily responsible for the worldwide and large-scale spread of the parasite among different populations of other animals and humans. Domestic and feral animals belonging to the Felidae family shed

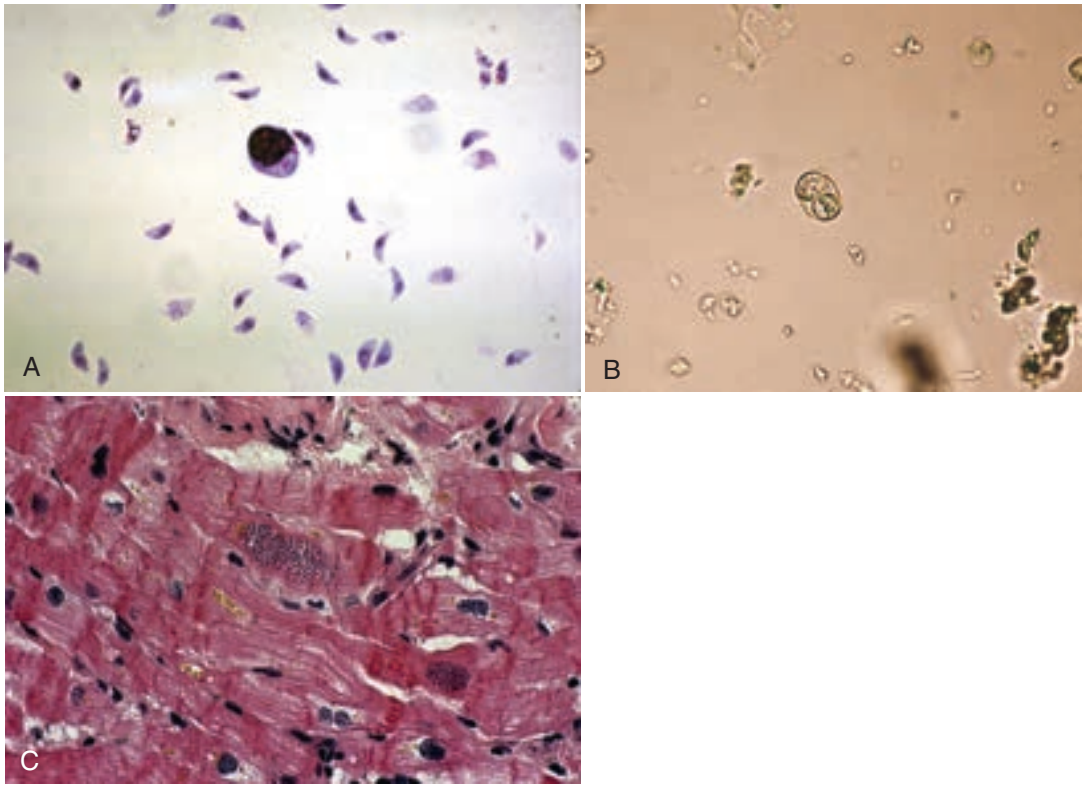

FIGURE 349-1. ***Toxoplasma gondii*** **exists in nature primarily in three forms. A,** Tachyzoites are bow or banana shaped, measure 2 to 3 µm wide and 5 to 7 µm long, and can be stained with Wright-Giemsa stain. **B,** Oocysts isolated from cat's feces are subspherical to spherical and measure 10 × 12 µm in diameter. **C,** Tissue cyst observed in human myocardial tissue stained with hematoxylin and eosin. Tissue cysts vary in shape and size and may reach more than 100 µm.

oocysts after they ingest any of the infectious forms of the parasite: tachyzoites, tissue cysts, and oocysts. As many as 10 million oocysts may be shed in the feces of an infected animal in a single day for periods varying from 7 to 20 days. Oocysts may remain viable for as long as 18 months in moist soil; this results in an environmental reservoir from which incidental hosts may be infected.

EPIDEMIOLOGY

The prevalence of *T. gondii* infection varies significantly according to geographic locale and the socioeconomic status of the population. It can be as low as 7% in England and as high as 80% in the Central African Republic. Seroprevalence increases with age because of increasing length of exposure with age, and it is inversely associated with socioeconomic status because of the strong influence of hygienic and alimentary habits in the transmission of the parasite. The overall age-adjusted seroprevalence of *T. gondii* infection in the United States has been recently reported at 11%, but it may be higher in certain geographic areas or socioeconomic groups. The seroprevalence of the parasite has declined during the past 30 years in the United States[1] and several other countries but appears to be stable or increasing in certain geographic locales, such as in the tropics (e.g., Latin America).

Humans and non-felid animals are incidental hosts and become infected primarily by the ingestion of infected meat containing tissue cysts or of contaminated food, water, or soil material containing oocysts. They can also become infected during gestation by vertical transmission of the parasite from the mother to her offspring. In addition, humans can become infected through organ transplantation and, more rarely, in the setting of laboratory accidents. Ingestion of raw or undercooked meat contaminated with tissue cysts is probably one of the major routes of transmission in humans. Ingestion of untreated water, food, or soil contaminated with oocysts is another significant route of infection with the parasite. Untreated water has been found to be the source of large epidemics of toxoplasmosis in Canada and Brazil.

The main risk factors for *T. gondii* infection in the United States include eating raw ground beef; eating rare lamb; eating locally produced cured, dried, or smoked meat; working with meat; drinking unpasteurized goat's milk; having three or more kittens. In this study, eating raw oysters, clams, or mussels was also identified as a novel risk factor. Untreated water as a potential vehicle for the transmission of *T. gondii* has been established in several large epidemiologic studies and was found to have a trend toward increased risk for acute infection in the United States.

In up to 50% of individuals acutely infected with *T. gondii*, it is not possible to identify the presence of a known risk factor for their acute infection. Thus, attempting to establish whether a patient is at risk for toxoplasmosis solely on the basis of the epidemiologic history is a futile task. Patients may have been infected with *T. gondii* even if they have not owned or been in contact with cats, have not eaten undercooked meat or shellfish, and have not ingested untreated water.

The seroprevalence of *T. gondii* infection in immunocompromised patients reflects the seroprevalence of the particular population from which they come. Latent *T. gondii* infection can reactivate in these patients, particularly in those with the acquired immunodeficiency syndrome (AIDS) and in hematopoietic stem cell transplant (HSCT, including bone marrow transplant) and liver transplant patients. In these patients, it is important to establish whether they have been infected with the parasite before severe immunosuppression ensues or their transplant procedure because serologic testing in severe immunosuppression or after transplantation may be unreliable. Approximately 30% of AIDS patients who are infected with *T. gondii* will develop toxoplasmosis by reactivation of their chronic infection if their CD4 count falls below 200 cells/µL and they are not taking anti-*Toxoplasma* primary prophylaxis. The advent of highly active antiretroviral therapy, in addition to the use of primary anti-*Toxoplasma* prophylaxis, has clearly contributed to the decline in the incidence of toxoplasmosis in AIDS patients. Among HSCT (including bone marrow transplant) patients, those recipients who are *Toxoplasma* seropositive before transplantation, receive an allogeneic graft, and develop graft-versus-host disease have the highest risk of reactivation.

For solid organ transplants, the highest risk for toxoplasmosis is observed when an allograft from a *Toxoplasma*-seropositive donor (D^+) is transplanted into a seronegative recipient (R^-). In D^+/R^- patients, there is a 25% risk for development of potentially life-threatening toxoplasmosis if effective anti-*Toxoplasma* prophylaxis is not instituted. It is highly advised that the *Toxoplasma* serologic status of the donor and the recipient be established before transplantation. Serologic test results are less reliable in the post-transplantation period, and they may significantly vary without any clinical relevance.

Transmission of *T. gondii* to the fetus can occur during pregnancy when a woman acquires her primary infection during gestation. The incidence of seroconversion for pregnant women in the United States has been estimated at 0.27%. The overall rate of transmission of the parasite (prevalence of congenital toxoplasmosis) in seroconverting women has been estimated between 50 and 60% before spiramycin was instituted as an attempt to decrease vertical transmission and 25 to 30% thereafter. The transmission rate increases with the gestational age at which maternal infection is acquired. In women who have been treated for toxoplasmosis during gestation, it can be as low as 4.5% during the first trimester, 31.7% during the second trimester, and as high as 63% during the third trimester. The likelihood of severe disease is inversely proportional to the gestational age at which maternal infection was acquired. Although objective data are lacking on the prevalence of congenital toxoplasmosis in the United States, it has been estimated that among the approximately 4.2 million live births per year, congenital *T. gondii* infection occurs in 500 to 5000 newborns. The global annual incidence of congenital toxoplasmosis has been estimated to be 190,100 cases. This is equivalent to a burden of 1.2 million disability-adjusted life years. Particularly high burdens are seen in South America and in some Middle Eastern and low-income countries.[2]

Congenital transmission in women who were infected before conception has only rarely been reported in immunosuppressed patients, in those who were acutely infected shortly before conception (i.e., within 3 months of conception), and in those who have been reinfected with a more virulent strain.

PATHOBIOLOGY

Pathogenesis

After oral infection with tissue cysts (e.g., contaminated meat) or oocysts (e.g., contaminated soil, water, or food), the wall of both infectious forms is disrupted by the digestive juices of the gastrointestinal tract. Bradyzoites (from cysts) and sporozoites (from oocysts) are released and converted to the tachyzoite form. Tachyzoites have the capacity to infect contiguous cells or distant tissues by hematogenous or lymphatic spread. Tachyzoites appear to actively and rapidly migrate across epithelial cells and may traffic to distant sites while they are extracellular (acute infection).[3] Their histologic hallmark is necrosis surrounded by inflammation.

In immunocompetent individuals, the immune system controls the proliferation of the tachyzoite and induces its conversion to bradyzoites, facilitating the final formation of tissue cysts (chronic infection). Tissue cysts persist for the life of the host, and *T. gondii* can be isolated from tissues of individuals who have died from causes other than toxoplasmosis.

It appears that the activation of well-orchestrated immune responses is required for the successful resistance against *T. gondii*. Innate, humoral, and cellular immune responses likely to be involved in preventing the uncontrolled proliferation of tachyzoites include activation of the monocyte-macrophage system, dendritic cells, natural killer cells, and αβ and γδ T cells; *T. gondii*–specific and cytotoxic $CD4^+$ and $CD8^+$ T cells; and interferon-γ, interleukin 12, tumor necrosis factor-α, interleukin 10 and other cytokines, transforming growth factor-β, costimulatory molecules (e.g., CD28, CD40 ligand), and, to some degree, immunoglobulins. Recent studies have shown that innate type 1 immune responses that involve interferon-γ–producing natural killer cells and neutrophils, rather than interferon-γ–producing T cells, predetermine host resistance to *T. gondii*.[4]

In immunocompromised patients previously infected with *T. gondii*, decreased T cell–mediated or severe impairment in B cell–mediated immune responses can facilitate the reactivation of their infection (i.e., conversion of bradyzoites in their tissue cysts into rapidly proliferating tachyzoites). Toxoplasmosis in this setting is 100% lethal if untreated.

Pathology

Most of the data on the pathology of toxoplasmosis come from studies of congenitally infected babies and immunosuppressed patients. CNS lesions of patients with toxoplasmosis are characterized by significant necrosis and surrounding inflammation. In congenitally infected cases, necrotic areas may calcify and lead to typical radiographic findings suggestive but not diagnostic of toxoplasmosis. Hydrocephalus may result from obstruction of the aqueduct of Sylvius or foramen of Monro. Tachyzoites and tissue cysts may be visualized near necrotic foci, near or in glial nodules, in perivascular regions, and in cerebral tissue uninvolved by inflammatory changes.

Formation of multiple brain abscesses is relatively common in patients with AIDS. In the areas around the abscesses, edema, vasculitis, hemorrhage, and cerebral infarction secondary to vascular involvement may also be present. Important associated features in toxoplasmic encephalitis are arteritis, perivascular cuffing, and astrocytosis. A "diffuse form" of toxoplasmic encephalitis has been described with histopathologic findings of widespread microglial nodules without abscess formation in the gray matter of the cerebrum, cerebellum, and brain stem.

Pulmonary involvement by *T. gondii* in the immunodeficient patient can lead to interstitial pneumonitis, necrotizing pneumonitis, consolidation, pleural effusion or empyema, or all of these. Chorioretinitis in AIDS patients is characterized by segmental panophthalmitis and areas of coagulative necrosis associated with tissue cysts and tachyzoites.

Toxoplasmic lymphadenitis in immunocompetent individuals may result in patterns of findings that are often diagnostic of the disease: a reactive follicular hyperplasia; irregular clusters of epithelioid histiocytes encroaching on and blurring the margins of the germinal centers; and focal distention of sinuses with monocytoid cells.

CLINICAL MANIFESTATIONS

Toxoplasmosis should be entertained in the differential diagnosis of several clinical syndromes in immunocompetent, unborn, newborn, infant, pediatric, adult, and immunocompromised patients (Table 349-1). Symptoms result from the primary infection or reactivation of the parasite due to T cell–mediated or severe B cell–mediated immunodeficiency. Primary infection can be asymptomatic in a significant number of individuals, and conventional risk factors for the acute infection may not be present in a particular patient. Thus, the possibility of acute toxoplasmosis or *T. gondii* infection should not be ruled out because of the absence of epidemiologic risk factors (e.g., exposure to cats or undercooked meat) or symptoms in a given patient. For this reason, if the goal is to detect each case of primary *T. gondii* infection in a population of patients (e.g., pregnant women), only systematic and universal screening methods can achieve such an objective; testing of only symptomatic patients or those with conventional epidemiologic risk factors will miss a significant number of acute cases.

Severity of toxoplasmosis due to primary infection or reactivation in a given patient or population may be influenced by the infecting strain (e.g., type I strain), size of the inoculum, infectious form (e.g., oocyst vs. cyst), or genetics of the host (e.g., presence of HLA-DQ3). During the past decade, it has become clear that patients infected in certain geographic locales (e.g., South America) have more aggressive clinical presentations, including a more severe primary infection and disease due to reactivation. These observations need to be kept in mind on seeing ill travelers returning from the endemic areas or patients who were born in these areas and in whom toxoplasmosis by reactivation has been included in their differential diagnosis.

Lymphadenopathy due to toxoplasmosis may be completely asymptomatic or be accompanied by other symptoms, such as fever (temperature as high as 104° F), headache, general malaise, and fatigue. It can be localized or generalized. A solitary, occipital, and painlessly enlarged lymph node can be the sole manifestation of toxoplasmosis in a child, pregnant woman, or adult. However, more generalized cervical, axillary, and abdominal lymphadenopathy has also been reported. Lymph nodes are usually 1 to 3 cm in size, nonsuppurative, and nontender on palpation. They usually regress within 12 weeks, but a mild relapse of the lymphadenopathy has been observed between months 3 and 6. Recurrence of toxoplasmic lymphadenopathy beyond the sixth month is extremely rare.

Ocular disease due to *T. gondii* can be asymptomatic or symptomatic and can be the result of congenital or postnatally acquired infection. In both settings (congenitally and postnatally acquired), toxoplasmic chorioretinitis can be discovered at the time of the diagnosis of the infection or as a reactivation of the subsequent latent infection months to years later.[5] Up to 17% of patients acutely infected with the parasite in Brazil and in a Canadian outbreak of toxoplasmosis presented with concurrent symptomatic toxoplasmic chorioretinitis at the time their acute infection was diagnosed. Similar cases have been described in Europe and the United States. *T. gondii* strain type appears to be a contributing factor determining severity and recurrence of ocular toxoplasmosis.[6] Symptomatic ocular disease primarily consists of a retinochoroiditis that can result in blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora. The morphology of the retinal lesions on funduscopic examination is thought to be characteristic of toxoplasmosis. An active whitish infiltrate is usually attached to the darkly pigmented border of an older scar (Fig. 349-2). However, retinal lesions tend to be less typical in older or immunocompromised patients.

TABLE 349-1 CLINICAL MANIFESTATIONS OF TOXOPLASMOSIS IN HUMANS

CLINICAL CATEGORIES	CLINICAL MANIFESTATIONS AND SYNDROMES
Primary infection	
Immunocompetent individuals and pregnant women	Most patients are asymptomatic. However, in ≈10% of patients, the following symptoms or syndromes, alone or in various combinations, have been reported: fever, lymphadenopathy, headache, myalgias, arthralgias, sore throat, stiff neck, nausea, abdominal pain, anorexia, rash, confusion, earache, eye pain, general malaise, fatigue. Chorioretinitis resulting in blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora Hepatitis; myositis; myocarditis Disseminated disease, pneumonia, brain abscesses, and even death have been observed in immunocompetent individuals infected with atypical strains of *T. gondii* (e.g. in Latin America).
Congenital toxoplasmosis	
Fetus	Ultrasound study can be normal or reveal hydrocephalus, brain or hepatic calcifications, splenomegaly, ascites, pericarditis. Fetal death can also result from overwhelming infection.
Newborn	Newborn can be entirely normal, have a nonspecific illness, or have abnormal findings on physical examination including chorioretinitis, strabismus, blindness, seizures, encephalitis, abnormal cephalic perimeter (microcephaly or hydrocephalus), psychomotor or mental retardation, hepatosplenomegaly, pneumonitis, diarrhea, hypothermia, jaundice, petechiae, rash. Intracranial calcifications can be present in brain imaging studies. Newborns can also die as a result of overwhelming infection.
Children and adults	Children can continue to suffer the chronic sequelae of the congenital disease. However, children may be born apparently normal and become symptomatic for the first time during childhood, adolescence, or adulthood, primarily in the form of reactivation of congenitally acquired chorioretinitis.
Chronic infection	Asymptomatic. However, some investigators have proposed a role of chronic infection in individuals with schizophrenia, bipolar disease, and behavioral issues including a higher incidence of motor vehicle accidents. Chorioretinitis can occur as a reactivation of congenital or postnatally acquired disease in otherwise immunocompetent individuals.
Reactivation of chronic infection in immunocompromised patients	Multiple brain abscesses, diffuse encephalitis, seizures, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, rash

Other less common but well-documented syndromes have been associated with the acute infection, including hepatitis, myositis, myocarditis, and skin lesions. More aggressive disease, including pneumonia, brain abscesses, and death, has been observed in immunocompetent patients in Latin America.

Primary infection can be observed in solid transplant patients when an allograft from a seropositive donor is transplanted into a seronegative recipient (D^+/R^-). Disseminated and localized toxoplasmosis has been reported in this setting, including myocarditis, pneumonia, fever of unknown origin, and encephalitis.

Congenital disease can be asymptomatic in the fetus, newborn, child, or adult. However, most of the infected offspring will eventually develop signs and symptoms of toxoplasmosis (see Table 349-1). The classic triad of chorioretinitis, hydrocephalus (Fig. 349-3A and B), and brain calcifications is highly suggestive of toxoplasmosis and is primarily seen in babies whose mothers have not been treated against the parasite during gestation. Eye examination by an experienced pediatric ophthalmologist may reveal active or inactive toxoplasmic chorioretinitis. New lesions have been reported in up to 30% of congenitally infected children observed up until 11 years of age when their mothers have been treated but in up to 70% when their mothers have not.

FIGURE 349-2. The morphology of the retinal lesions on funduscopic examination believed to be characteristic of toxoplasmic retinochoroiditis. An active whitish infiltrate is usually attached to the darkly pigmented border of an older scar.

Chronic infection is believed to be asymptomatic. However, several investigators have recently suggested the possibility that chronic infection may play a role in the predisposition of infected individuals to have a higher frequency of traffic accidents, mental illness (e.g. schizophrenia, bipolar disease), and behavioral abnormalities.

Reactivation of the chronic infection is usually observed in patients with significant impairment of T cell–mediated immunity or severe impairment of B cell–mediated immunity. Toxoplasmosis by reactivation can cause brain abscesses, diffuse encephalitis, seizures, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, and rash. Although multiple brain abscesses (Fig. 349-3C) are commonly described in patients with toxoplasmic encephalitis, diffuse encephalitis without space-occupying lesions by magnetic resonance imaging has been reported with a very high mortality. Fever with pneumonia can be the sole manifestation of toxoplasmosis in immunocompromised patients, including HSCT and solid organ transplant recipients. Toxoplasmic pneumonitis can be manifested with cough, dyspnea, hypoxia, and diffuse bilateral or localized infiltrates. Most patients with pneumonia have been reported to have bilateral ground-glass opacities that can be confused with *Pneumocystis* pneumonia or viral etiologies. Fever alone has frequently been described in patients with allogeneic HSCT and liver transplant patients. Reactivation in heart tissue causing congestive heart failure, arrhythmias, and pericarditis has been described.

DIAGNOSIS

Laboratory methods for the diagnosis of *T. gondii* infection and toxoplasmosis include serologic tests, polymerase chain reaction (PCR), microscopy examination of tissue and body fluids, and attempts to isolate the parasite (Table 349-2).

The first step is to establish whether the patient has never been infected with *Toxoplasma* or has an acute or latent *T. gondii* infection; this can be accomplished by serologic testing. Serologic tests can establish whether a patient has never been infected or is acutely or chronically infected regardless of the presence or absence of symptoms. Available serologic tools include methods to detect *T. gondii*–specific IgG-, IgM-, IgA-, IgE-, and IgG-based avidity and differential agglutination (AC/HS).

With the use of commercial kits for the detection of IgG and IgM, most hospital-based or commercial laboratories can reliably diagnose the absence of *T. gondii* infection (negative IgG/negative IgM) and the presence of chronic infection (positive IgG/negative IgM). However, the diagnosis of acute infection is more challenging. A positive IgM test result is observed during the acute infection, but it may remain positive for months to years in

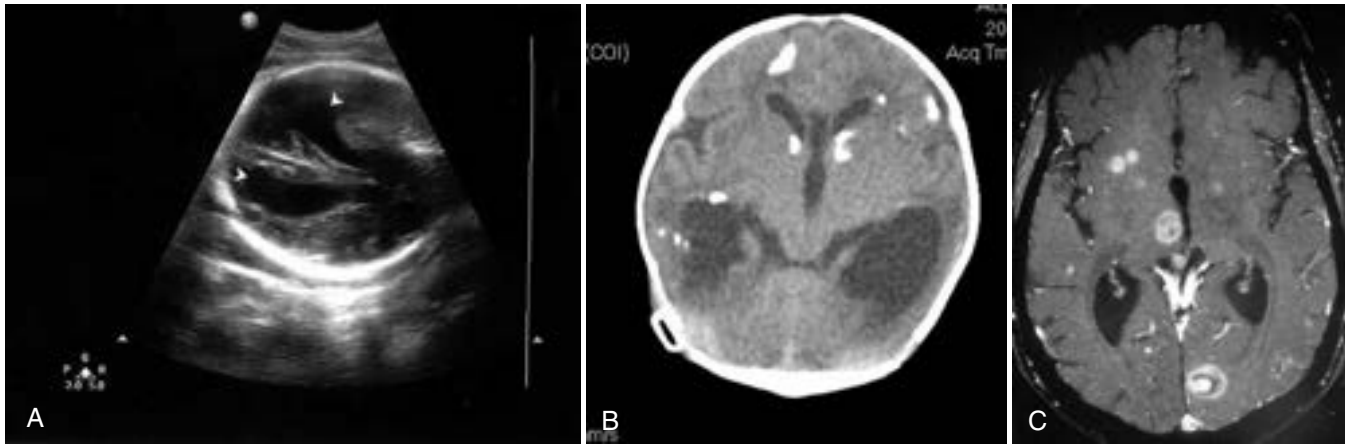

FIGURE 349-3. Radiologic manifestations of central nervous system toxoplasmosis. A, Fetal ultrasound of a fetus congenitally infected with *T. gondii* in the United States reveals hydrocephalus. **B,** Computed tomography scan of the brain of a newborn congenitally infected with *T. gondii* in the United States reveals hydrocephalus and calcifications. **C,** Magnetic resonance image of the brain of an AIDS patient revealing multiple ring-enhancing brain lesions.

TABLE 349-2 LABORATORY METHODS FOR THE DIAGNOSIS OF *T. GONDII* INFECTION AND TOXOPLASMOSIS* IN HUMANS

METHOD	CLINICAL INTERPRETATION
Serologic tests	
IgG	A positive test result establishes that the patient has been infected with *T. gondii*. However, a negative test result can be seen in patients infected within 4 weeks before serum sampling or in patients unable to produce IgG (e.g., immunocompromised hosts).
IgM	A positive test result suggests but is not necessarily diagnostic of an acute infection. Sera with positive IgM test results should be sent to a reference laboratory for confirmatory testing that includes a more specific IgM assay and additional tests, including avidity, acetone (AC)–fixed versus formalin (HS)–fixed (AC/HS) differential agglutination test of tachyzoites, and IgA and IgE.† Positive IgM test results can be seen in chronically infected patients because of persistence of the IgM response or false-positive results observed in certain commercial kits.
Confirmatory testing for positive IgM test results	IgG avidity test; differential agglutination (AC/HS); IgA, IgE performed at a reference laboratory.† At PAMF, a high IgG avidity test result‡ or a nonacute AC/HS test result indicates that the patient has been infected for more than 4 months (avidity) or 12 months (AC/HS).
Polymerase chain reaction (PCR)	B1 and AF487550 genes are the most commonly used targets for amplification. PCR test can be performed in any body fluid, including amniotic fluid, peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, peritoneal fluid, pleural fluid, ascitic fluid, and urine. PCR can also be performed in any tissue. A positive test result in any body fluid establishes that the patient has either acute or reactivated toxoplasmosis. However, a positive PCR test result in tissue is more difficult to interpret because it does not differentiate symptomatic toxoplasmosis from a latent infection. Although DNA extraction is more cumbersome, it can be attempted in paraffin-embedded tissue.
Direct visualization of the parasite	Identification of tachyzoites in any body fluid or tissue is diagnostic of toxoplasmosis due to acute infection or reactivation of a chronic infection. Tachyzoites can be identified by hematoxylin and eosin or cytologic studies but are better visualized with Wright-Giemsa and immunoperoxidase stains. Identification of cysts by hematoxylin and eosin or immunoperoxidase stains confirms the presence of *T. gondii* in the host but does not necessarily establish that the patient has toxoplasmosis. However, a strong inflammatory response surrounding the cysts is highly suggestive of toxoplasmosis, possibly explaining the patient's symptoms.
Attempts to isolate the parasite	A positive isolation study in any body fluid establishes the diagnosis of toxoplasmosis. Isolation of *T. gondii* in cell cultures or peritoneal cavity of mice can be attempted at reference laboratories. These studies can be important in trying to establish a correlation between the genetics of the parasite and its clinical manifestations.
Histology of the lymph node	Classic histologic triad is considered diagnostic: follicular hyperplasia, epithelioid histiocytes impinging on the margins of the germinal centers, and monocytoid cells focally distending sinus walls.

**T. gondii* infection = asymptomatic presence of the parasite. Toxoplasmosis = active symptoms and signs are present.
†For example, Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL), Palo Alto, Calif; *www.pamf.org/serology*; 650-853-4828; *toxolab@pamf.org*.
‡The window of exclusion for acute infection varies for different avidity kits (usually between 3 and 5 months).

certain individuals without any apparent clinical relevance. In addition, commercial IgM kits have been designed to be extremely sensitive so that an acute infection will be rarely missed; as a consequence, their specificity is somewhat sacrificed. Of patients who are found to be IgM positive at hospital-based or commercial laboratories, 60% are found to be chronically infected when their serum is tested at the national reference laboratory for the study and diagnosis of toxoplasmosis in the United States (Palo Alto Medical Foundation Toxoplasma Serology Laboratory [PAMF-TSL], Palo Alto, Calif; www.pamf.org/serology; 650-853-4828; toxolab@pamf.org). At PAMF-TSL, a battery of confirmatory tests (avidity, differential agglutination, IgA, IgE) are performed in addition to the "gold standard" dye test for IgG and the "double" sandwich capture enzyme-linked immunosorbent assay for IgM for confirmatory testing of positive IgM test results obtained at hospital-based or commercial laboratories. These tests are used in various combinations, depending on the clinical scenario of each patient and the questions of the treating physician. For an appropriate interpretation of the serologic test results obtained at PAMF-TSL, it is also crucial to have relevant clinical information available for the medical consultants (for instance, low positive IgG and positive IgM test results with a high IgG avidity test result will mean no risk of congenital toxoplasmosis for a 16-week pregnant woman, but the same results can be highly supportive of the diagnosis of toxoplasmic encephalitis for an AIDS patient with multiple brain lesions). At PAMF-TSL, three interpretations can be given to final serologic test results: (1) acute, results are consistent with a recently acquired infection; (2) chronic, consistent with an infection acquired in the distant past; and (3) equivocal, cannot exclude a recently acquired infection; an earlier or subsequent sample is required to attempt to establish whether the infection is acute or chronic. For serologic test results consistent with an acute infection, an attempt is made by the

medical consultants at PAMF-TSL to establish the approximate date that the infection was acquired.

The definitive diagnosis of toxoplasmosis (due to primary infection or reactivation of a chronic infection) requires the identification of tachyzoites in tissues or body fluids or the amplification of parasite DNA in any body fluid (see Table 349-2). Tachyzoites can be visualized in histologic sections stained with hematoxylin and eosin or in cytologic preparations without any specific staining, but they are better visualized with Wright-Giemsa (see Fig. 349-1A) and *T. gondii*–specific immunoperoxidase stains. Real-time PCR has become a useful method for the diagnosis of toxoplasmosis in the cerebrospinal fluid (CSF), and it is the diagnostic tool of choice for toxoplasmic encephalitis in immunocompromised patients (in CSF, assuming the lumbar puncture is deemed safe and feasible) and for the prenatal diagnosis of congenital toxoplasmosis (in amniotic fluid). Isolation of the parasite in any body fluid is also diagnostic of toxoplasmosis and can be attempted at reference laboratories. The diagnosis of toxoplasmosis can be indirectly supported by the use of serologic tools, demonstration of cysts in tissues (see Fig. 349-1C) surrounded by an inflammatory response, and attempts to isolate the parasite (see Table 349-2); in cases of toxoplasmic lymphadenitis, histologic features can be diagnostic.

Immunocompetent Patients, Pregnant Women, and Patients with Lymphadenopathy

The first diagnostic goal in these patients is to establish whether they have ever been infected with *T. gondii*. If *T. gondii*–specific IgG and IgM test results are negative, the possibility that the patient's symptoms are due to the parasite can be ruled out. During pregnancy, these results confirm that the mother has not been exposed to *T. gondii* but that she is at risk, if exposed, to acquire the primary infection during pregnancy and therefore can potentially transmit *T. gondii* to her offspring.[7] In attempting to determine whether the patient is infected with *T. gondii*, it is important to perform both IgG and IgM tests because during the first 4 weeks of the acute infection, the IgG can still be negative while the IgM will be positive. In these cases, seroconversion can be diagnosed by having a new positive IgG test result in a subsequent serum sample. In rare instances, infected patients may be IgG negative because of their incapacity to produce IgG.

If the patient is found to be IgG positive, the next goal is to determine whether the patient is having an acute infection or has been chronically infected (e.g., >6 months). If the IgG titer is low (e.g., a dye test at PAMF-TSL ≤512) and the IgM test result is negative, the patient has essentially been infected for more than 6 months. With these results, a patient whose symptoms or lymphadenopathy had a date of onset within 6 months of serum sampling will be considered unlikely to have toxoplasmosis. For a pregnant woman whose serum was obtained within 6 months of gestation, these results will mean that her infection was acquired before conception and that the risk for congenital toxoplasmosis is essentially zero.

If the patient is found to have a positive IgM test result confirmed to be indicative of a recently acquired infection at a reference laboratory and the onset of symptoms or lymphadenopathy falls within the time predicted by the serologic test results for the acquisition of *T. gondii*, the patient will be diagnosed as having acute toxoplasmosis. For a pregnant woman, if the predicted time for when the infection was acquired falls within her gestational age, she will be diagnosed with toxoplasmosis during pregnancy and at risk for transmitting the parasite to her baby.

In patients with lymphadenopathy, the histologic examination of the lymph node tissue obtained by excisional biopsy can be diagnostic or pathognomonic of toxoplasmic lymphadenitis (see earlier under Pathology).

Prenatal and Postnatal Diagnosis of Congenital Toxoplasmosis

Once the diagnosis of acute toxoplasmosis or *T. gondii* infection has been confirmed or is highly suspected in the mother, the next step is to attempt to establish whether her offspring has been infected. Consultation with reference centers for the study and diagnosis of congenital toxoplasmosis is highly recommended.

Ultrasound abnormalities can be consistent with or suggestive of congenital toxoplasmosis (see Fig. 349-3A), but they are not diagnostic. The method of choice for the prenatal diagnosis of congenital toxoplasmosis is a PCR in amniotic fluid obtained at 18 weeks of gestation. Attempts to diagnose congenital toxoplasmosis from amniotic fluid obtained before 18 weeks of gestation should be avoided because the studies reported to date have included only pregnant women whose gestational age was 18 weeks or more. In addition, false-negative results have been reported in women whose amniocentesis was performed before 18 weeks of gestation. The overall sensitivity of the amniotic fluid PCR has been reported between 64 and 92% and is highly dependent of the gestational age at which the mother acquired the infection.

In the newborn, congenital toxoplasmosis can be confirmed by positive *T. gondii*–specific serologic test results or PCR.[8] Samples for serology should be obtained in the peripheral blood of the baby. Cord blood should be avoided because of the high rate of maternal blood contamination. However, there is still a small degree of maternal blood contamination in newborn blood obtained by peripheral venipuncture, during the first 5 days of life for IgM antibodies and the first 10 days of life for IgA antibodies. A positive IgM immunosorbent agglutination assay (after 5 days of life) or IgA enzyme-linked immunosorbent assay (after 10 days) is diagnostic of congenital disease. Congenitally infected babies can be positive for both; positive for either one, but negative for the other test; or negative for both. A positive *T. gondii*–specific IgM in CSF is diagnostic of congenital disease, but testing of the CSF by PCR rather than for IgM is strongly recommended because of the higher sensitivity of the PCR test. The diagnosis can also be made by a positive PCR in peripheral blood, CSF, or urine. The CSF of infected infants may exhibit very high levels of protein (e.g., 1000 mg/dL). Cellular response in CSF is characterized by lymphocytosis, and eosinophilia may be present. Brain imaging studies may reveal calcifications or hydrocephalus; computed tomography scan is superior to ultrasound examination in the detection of these CNS abnormalities (see Fig. 349-3B).

Ocular Disease

Serologic and PCR testing can be helpful in the diagnosis of toxoplasmic chorioretinitis. An IgG-negative/IgM-negative patient is unlikely to have ocular disease due to toxoplasmosis. However, patients should be tested at reference laboratories (e.g., PAMF-TSL) because their *T. gondii*–specific IgG can be present but at very low levels such that only a gold standard method like the dye test can detect it. In patients with eye lesions typical of toxoplasmic chorioretinitis (see Fig. 349-2), a positive IgG test result at a relatively low titer (e.g., a dye test at PAMF-TSL ≤512) and a negative IgM test result are diagnostic of ocular disease due to the parasite reactivation. If the serologic test reveals a positive IgM result and confirmatory testing at PAMF-TSL establishes the diagnosis of an acute infection in patients 1 year of age or older, the eye disease is most likely the result of eye involvement in the setting of a recent and postnatally acquired infection.

In patients with atypically appearing lesions or in whom the response to anti-*Toxoplasma* drugs is atypical or absent, a *T. gondii*–specific immune load (aqueous humor) or PCR in ocular fluids (vitreous fluid is preferable to aqueous humor because of probable higher sensitivity, but it is riskier to obtain) should be considered.

Immunocompromised Patients

It appears that acute infection rarely occurs in immunocompromised patients. However, life-threatening disease can occur when the patient's latent infection is reactivated by AIDS, HSCT, liver transplantation, or other diseases characterized by severe T-cell deficiency.

Toxoplasmosis can also develop when *T. gondii* is transmitted from a seropositive donor to a seronegative recipient through an infected allograft (e.g., heart, liver, kidney).[9] Therefore, to establish the risk for toxoplasmosis and to have a high index of suspicion when patients develop illnesses suggestive of toxoplasmosis, all immunocompromised patients should be tested for *T. gondii*–specific IgG as soon as they have been diagnosed with the underlying disease or it has been established that they will be subsequently immunosuppressed. In addition, serologic testing may not be reliable when immunosuppression is advanced or severe. Post-transplantation serologic test results for IgG antibodies may remain positive or may rise, decrease, or even become negative. Thus, pretransplantation *Toxoplasma* serologic studies are critical for interpretation of subsequent test results and clinical evaluation. Solid organ donors should also be tested for *T. gondii*–specific IgG as their allograft has the potential to transmit the parasite to the transplanted patient (e.g., heart, heart-lung, kidney, kidney-pancreas, liver, liver-pancreas). Toxoplasmosis in solid organ transplant recipients causes substantial morbidity, including disseminated disease, and mortality.

In AIDS patients suspected of having toxoplasmic encephalitis with the presence of multiple brain-occupying and ring-enhancing lesions (see Fig. 349-3C), a CD4 count below 200 cells/μL, and a positive *T. gondii*–specific IgG, the response to anti–*Toxoplasma*-specific treatment is considered an

additional "diagnostic" indicator of toxoplasmic encephalitis. In these patients, invasive diagnostic tests (e.g., lumbar puncture, brain biopsy) are considered unnecessary unless they do not respond to treatment within a 7- to 10-day period. This diagnostic paradigm should not be applied to other populations of immunosuppressed patients (e.g., transplant patients) because their differential diagnosis often includes other pathogens, such as invasive mold infections. In those patients, examination of the CSF by PCR or brain biopsy should be attempted at the outset of the illness.

The definitive diagnosis of toxoplasmosis in immunosuppressed patients relies on PCR, direct visualization of the parasite, and attempts for isolation of the organism (see Table 349-2). PCR testing in body fluids is the diagnostic method of choice for immunosuppressed patients at risk for toxoplasmosis who develop unexplained fever (e.g., in whole blood), pneumonia (e.g., in bronchoalveolar lavage fluid), brain lesions (e.g., in CSF), or other compatible syndromes. Theoretically, PCR can be performed in any body fluid or tissue, and laboratories have validated its use in most fluids and some tissues. Attempts to identify the tachyzoite or tissue cyst in tissues by microscopy can be enhanced with the use of the *T. gondii*–specific immunoperoxidase stain. CSF examination by PCR or brain biopsy should be initially considered in AIDS patients who have a low likelihood of having toxoplasmic encephalitis, such as those who have a single lesion by magnetic resonance imaging examination, have tested seronegative for *T. gondii* infection, have a CD4 count of more than 200 cells/μL, or who are not responding to an appropriate anti-*Toxoplasma* regimen.

TREATMENT

Rx

Principles of antiparasitic therapy are discussed in Chapter 344. Treatment of toxoplasmosis is indicated for immunocompetent patients with acute infection in the setting of ongoing fever, myocarditis, myositis, hepatitis, pneumonia, brain lesions or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Treatment is indicated as well for patients with active chorioretinitis due to primary infection or reactivation of a latent infection (Table 349-3).[10] In immunocompetent patients, treatment is prescribed for 3 to 4 weeks or until symptoms have subsided, whichever is longer. For toxoplasmic lymphadenitis, trimethoprim-sulfamethoxazole (TMP-SMZ) (8 mg TMP/40 mg SMZ per kilogram per day divided into two doses for 1 month) increased the cure rate to 65% compared with a 13% resolution rate with placebo.[11] Treatment is also often recommended for all pregnant women suspected of having or diagnosed with primary infection during gestation (Table 349-4) in an attempt to prevent transmission of the parasite to the fetus (spiramycin) or, if congenital infection has occurred, to start treatment of the fetus in utero (pyrimethamine, sulfadiazine, and folinic acid). During pregnancy, treatment regimens are prescribed for the duration of the gestation. There was a worldwide controversy about the efficacy of spiramycin to decrease the incidence of congenital toxoplasmosis and of pyrimethamine, sulfadiazine, and folinic acid to decrease the frequency of clinical signs in infected offspring. Although no definitive studies ever disproved their efficacy, several epidemiologic studies erroneously concluded that there was no evidence of benefit. However, since 2006, several studies have reported a strong association between prenatal treatment of women infected during gestation (with spiramycin or pyrimethamine, sulfadiazine, and folinic acid) and decreases in the incidence of congenital toxoplasmosis and frequency of clinical signs in infected offspring. Spiramycin is recommended for pregnant women who have been definitively diagnosed to have or are highly suspected of having an acute infection during pregnancy and acquired before 18 weeks of gestation. Spiramycin should be given throughout pregnancy unless fetal infection is suspected or documented. Fetal infection should be investigated with amniotic fluid PCR at 18 weeks of gestation to see whether *Toxoplasma* DNA is amplified and with monthly follow-up ultrasound examinations. Therapy with pyrimethamine, sulfadiazine, and folinic acid is recommended for pregnant women who have been definitively diagnosed to have or are highly suspected of having an acute infection during pregnancy and acquired after18 weeks of gestation, whose amniotic fluid PCR is positive for the presence of *Toxoplasma* DNA, or whose follow-up ultrasound examinations are suggestive of congenital toxoplasmosis in the setting of acute *Toxoplasma* infection during gestation. In addition, newborns and infants diagnosed with or suspected of having congenital toxoplasmosis should also be treated during their first year of life (see Table 349-4).

Treatment at higher doses is urgently indicated for all immunocompromised patients with toxoplasmosis due to reactivation of their latent infection or primary infection acquired by natural exposure to the parasite or by solid organ transplantation (see Table 349-3). If untreated, toxoplasmosis in these patients has a very high rate of morbidity and mortality.

TABLE 349-3 TREATMENT REGIMENS FOR PATIENTS WITH ACUTE OR PRIMARY TOXOPLASMOSIS AND IMMUNOCOMPROMISED PATIENTS WITH TOXOPLASMOSIS DUE TO REACTIVATION*

	IMMUNOCOMPETENT PATIENTS WITH ACUTE INFECTION†	IMMUNOCOMPROMISED PATIENTS
Pyrimethamine (PO)	50 mg every 12 hr for 2 days, followed by 25 to 50 mg daily	200 mg loading dose, followed by 50 mg/day (<60 kg) to 75 mg/day (>60 kg)
plus		
Folinic acid‡	10-20 mg daily (during and 1 week after therapy with pyrimethamine)	10-20 mg daily (up to 50 mg/day)
	plus either sulfadiazine or clindamycin or atovaquone as follows:	*plus either sulfadiazine or clindamycin or atovaquone as follows*:
Sulfadiazine (PO)	75 mg/kg (first dose), followed by 50 mg/kg every 12 hr (maximum 4 g/day)	1000 mg (<60 kg) to 1500 mg (>60 kg) every 6 hr
or		
Clindamycin (PO or IV)	300 mg every 6 hr	600 mg every 6 hr (up to 1200 mg every 6 hr)
or		
Atovaquone (PO)	1500 mg orally twice daily	1500 mg orally twice daily
Trimethoprim-sulfamethoxazole (PO or IV)	10 mg/kg/day (trimethoprim component) in two or three doses	10 mg/kg/day (trimethoprim component) in two or three doses (doses as high as 15-20 mg/kg/day have been used)
Pyrimethamine and folinic acid	Same doses as above	Same doses as above
plus		
Clarithromycin (PO)	500 mg every 12 hr	500 mg every 12 hr
or		
Dapsone (PO)	100 mg/day	100 mg/day
or		
Azithromycin (PO)	900 to 1200 mg/day	900 to 1200 mg/day

After the successful use of a combination regimen during the acute or primary therapy phase, the same agents at half-dose are usually used for maintenance or secondary prophylaxis.
*Preferred regimens: pyrimethamine, sulfadiazine, and folinic acid or trimethoprim-sulfamethoxazole. Assistance is available for the diagnosis and management of patients with toxoplasmosis at the Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL), Palo Alto, Calif; *www.pamf.org/serology*; 650-853-4828; *toxolab@pamf.org*.
†Particularly in the setting of myocarditis, myositis, hepatitis, pneumonia, brain or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Also indicated for those with active ocular disease due to primary infection or reactivation.
‡Folinic acid = leucovorin; folic acid must not be used as a substitute for folinic acid.

PREVENTION

Primary Infection

Because approximately 50% of patients may inadvertently become infected with the parasite without having a recognized risk factor for acute infection, only systematic serologic testing can establish whether a patient has been exposed to *T. gondii*. Thus, each pregnant woman and immunocompromised patient should be screened for *T. gondii*–specific IgG and IgM regardless of their epidemiologic history. Seronegative pregnant women and immunocompromised individuals should be counseled on how to maximize their prevention efforts to avoid infection with *T. gondii*. In addition, seronegative pregnant women should be tested serially during gestation in an attempt to diagnose seroconversion at the earliest time possible. In some countries, such as France, seronegative pregnant women are mandated by law to be tested every month for *T. gondii*–specific IgG and IgM. Women who seroconvert are offered spiramycin (if infected before 18 weeks of gestation) or pyrimethamine, sulfadiazine, and folinic acid (if infected after 18 weeks). Mothers whose amniotic fluid is found to be positive by PCR or those in whom fetal ultrasound study is highly suggestive of congenital toxoplasmosis are offered pyrimethamine, sulfadiazine, and folinic acid. Although infection often occurs in the absence of known risk factors for the acute infection, educational interventions to avoid exposure to the parasite have been shown to be effective in decreasing the incidence of seroconversion during gestation.

The majority of epidemiologic studies worldwide have recognized contaminated and undercooked meat as one of the main risk factors for the

TABLE 349-4 TREATMENT REGIMENS FOR PREGNANT WOMEN WHO HAVE LIKELY ACQUIRED *T. GONDII* INFECTION DURING GESTATION AND INFANTS SUSPECTED OF HAVING OR CONFIRMED TO HAVE CONGENITAL TOXOPLASMOSIS

	DURING PREGNANCY	IN CONGENITAL DISEASE
Spiramycin (oral)	Recommended for pregnant women suspected of having or confirmed to have acquired the infection during gestation and before 18 weeks of gestation. Spiramycin should be administered until delivery in those with negative amniotic fluid PCR test results and normal follow-up ultrasound studies or low suspicion of fetal infection. Spiramycin is not teratogenic, and it is available in the United States only through the Investigational New Drug (IND) process at the Food and Drug Administration (301-796-1600). Prior medical consultation is required.* Dosage: 1 g (3 million units) every 8 hr (for a total of 3 g or 9 million units per day)	Not recommended during pregnancy if the fetus has been documented to be or suspected to have been infected. In the setting of fetal infection, pyrimethamine, sulfadiazine, and folinic acid should be instituted (see below)
Pyrimethamine (oral) plus sulfadiazine (oral) plus folinic acid† (oral)	Recommended for women ≥18 weeks of gestation in whom it is suspected or confirmed that the acute infection has been acquired at or after 18 weeks of gestation or who have a positive amniotic fluid PCR test result or an abnormal ultrasound study suggestive of congenital toxoplasmosis. Pyrimethamine is teratogenic and should not be used during pregnancy before week 18 (in some centers in Europe, it is used as early as week 14). Sulfadiazine should not be used alone. Dosages: Pyrimethamine: 50 mg every 12 hr for 2 days followed by 50 mg daily Sulfadiazine: 75 mg/kg (first dose) followed by 50 mg/kg every 12 hr (maximum 4 g/day) Folinic acid† (leucovorin): 10-20 mg daily (during and for 1 week after pyrimethamine therapy)	**Infant** (treatment regimen is usually recommended for 1 year): Pyrimethamine: 1 mg/kg every 12 hr for 2 days; followed by 1 mg/kg/day for 2 or 6 months; followed by 1 mg/kg/day every Monday, Wednesday, Friday Sulfadiazine: 50 mg/kg every 12 hr Folinic acid† (leucovorin): 10 mg three times weekly Prednisone (if CSF protein ≥1 g/dL or severe chorioretinitis): 0.5 mg/kg every 12 hr (until CSF protein <1 g/dL or resolution of severe chorioretinitis) **Older children with active disease** (usually 1-2 weeks beyond resolution of clinical manifestations): Pyrimethamine: 1 mg/kg every 12 hr (maximum 50 mg) for 2 days followed by 1 mg/kg/day (maximum 25 mg) Sulfadiazine: 75 mg/kg (first dose) followed by 50 mg/kg every 12 hr Folinic acid† (leucovorin): 10-20 mg three times weekly Prednisone (severe chorioretinitis): 1 mg/kg/day, divided bid, maximum 40 mg/day, rapid taper

†Folic acid should not be used as a substitute for folinic acid.
CSF = cerebrospinal fluid; PCR = polymerase chain reaction.

transmission of the parasite. This appears to be the case in Europe, North America, and Latin America. Tissue cysts in meat are rendered nonviable by γ-irradiation (0.4 kGy), heating throughout to 67° C, or freezing to −20° C for 48 hours and then thawing. Cured, dried, or smoked meat has been associated with the acute infection and should not be considered *Toxoplasma* free. Soil exposure and soil-related activities have been reported to play a more prominent role in transmission in certain geographic areas, such as Latin America.

In seronegative recipients of a solid organ from a seropositive donor, TMP-SMZ for at least 6 months or pyrimethamine for at least 6 weeks has been reported to be effective in the prevention of primary infection in the newly immunosuppressed patient.

Reactivation of Latent Infection in Immunocompromised Patients and Those with Ocular Disease

Drugs used to prevent reactivation of the latent infection in immunosuppressed hosts include TMP-SMZ (e.g., single strength or 80 mg TMP and 400 mg SMZ, 1 tablet per day) and atovaquone (1500 mg/day). Dapsone-pyrimethamine and sulfadoxine-pyrimethamine have been also reported to be effective, but their use appears to be limited because of potential hematologic toxicity.

Prophylaxis against reactivation of latent infection has been successful in AIDS patients dually infected with HIV and *T. gondii* (*Toxoplasma* IgG seropositive) and whose $CD4^+$ T-cell counts are below 200 cells/μL. For prophylactic purposes, TMP-SMZ should probably not be used below a minimum dose of 160 mg TMP/800 mg SMZ orally twice a day on a thrice-weekly regimen or 80 mg TMP/400 mg SMZ once a day. In AIDS patients, 100 mg of dapsone plus 50 mg of pyrimethamine orally twice weekly or atovaquone (1500 mg/day) has also been effective in preventing toxoplasmic encephalitis. Findings in these studies have been extrapolated to non-AIDS immunosuppressed patients because of the absence of data in this population of patients.

Toxoplasma-seropositive recipients of an allogeneic HSCT (Chapter 178) who develop graft-versus-host disease represent a unique challenge. Reactivation of toxoplasmosis can be manifested by a nonspecific illness (e.g., fever or pneumonia) and be life-threatening. The disease is often not recognized. Atovaquone prophylaxis has been proposed as an alternative regimen in these patients, given the potential bone marrow toxicity of TMP-SMZ. Some investigators have proposed a preemptive strategy in which *Toxoplasma*-seropositive patients who receive an allogeneic HSCT are monitored on a routine basis (e.g., weekly for the first 100 days) with *T. gondii* PCR. Those found positive would receive preemptive prophylaxis with TMP-SMZ or atovaquone.

Discontinuation of prophylaxis against toxoplasmic encephalitis has proved safe in AIDS patients receiving highly active antiretroviral therapy who demonstrate an increase in their $CD4^+$ T-cell counts to at least 200 cells/μL and whose viral load has been undetectable for at least 6 months.

In patients with ocular toxoplasmosis who experience frequent relapses (e.g., more than two episodes per year), 80 mg TMP/400 mg SMZ daily for at least 1 year has been shown to be effective in the prevention of their recurrences.

PROGNOSIS

The primary infection has a wide spectrum of manifestations in humans, from asymptomatic in most individuals to pneumonia or life-threatening disease if it is acquired in certain areas of the world. Primary infection can also be fatal in the fetus and in immunocompromised individuals. Early diagnosis and treatment can make a significant difference in the prognosis of these patients.

It is not clear at this time whether chronic infection in immunocompetent individuals is clinically irrelevant. Several investigators have proposed that latent infection with the parasite may play a significant role in mental illness (e.g., schizophrenia) or in the propensity of the infected individual to incur motor vehicle accidents. Immunocompetent patients can reactivate chronic infection in their retina, and the prognosis is influenced by the proximity of the lesions to the macula, involvement of one or both eyes, and number of relapses. It is believed that treatment can slow the progression of these lesions and expedite their healing.

Reactivation of latent infection in immunosuppressed individuals with significant defects in their T cell–mediated or B cell–mediated immunity, if untreated, is 100% fatal. Even when treated in an intensive care unit, disseminated toxoplasmosis in immunocompromised patients has a mortality rate of about 80%.[11]

REVIEW QUESTIONS

1. Toxoplasmosis should be suspected in the following groups of patients.

A. Only those who own cats
B. Only those who eat undercooked or raw meat
C. Those with clinical syndromes suggestive of toxoplasmosis regardless of their epidemiologic history
D. Those who own cats or eat undercooked or raw meat

Answer: C One of the greatest misconceptions in the care of patients in whom the diagnosis of toxoplasmosis should be entertained is the belief among clinicians that *Toxoplasma* infection should be suspected only in patients with epidemiologic risk factors. In all epidemiologic studies addressing risk factors for *Toxoplasma* infection, a risk factor could not be established in up to 50% of individuals with toxoplasmosis. Toxoplasmosis should be suspected on the basis of clinical manifestations and should not be excluded solely by the absence of epidemiologic risk factors. (See Epidemiology section.)

2. The diagnosis of lymphadenitis due to toxoplasmosis can be established by

A. Amplification of *Toxoplasma* DNA from the affected lymph node tissue by the polymerase chain reaction (PCR)
B. Isolation of the *Toxoplasma* strain by inoculation of macerated lymph node tissue in the peritoneal cavity of mice in reference laboratories
C. Presence in lymph node biopsy specimen of a classic histologic triad: reactive follicular hyperplasia, irregular clusters of epithelioid histiocytes encroaching on the margins of the germinal centers, and focal distention of sinuses with monocytoid cells.
D. Presence in lymph node biopsy specimen of caseating and necrotizing granulomas
E. Microscopic examination of lymph node tissue with Wright-Giemsa stain to identify presence of tachyzoites or tissue cysts

Answer: C Toxoplasmic lymphadenitis can be diagnosed by the identification of this classic inflammatory response in the microscopic examination of lymph node tissue. This classic histologic triad (reactive follicular hyperplasia, irregular clusters of epithelioid histiocytes encroaching on or blurring the margins of the germinal centers, and focal distention of sinuses with monocytoid cells) has not been observed in other diseases causing lymphadenitis. The diagnosis requires intact lymph node tissue (e.g., excisional lymph node biopsy) and cannot be made with the fine-needle aspiration of a lymph node. Toxoplasmic lymphadenitis typically does not result in formation of caseating or necrotizing granulomas. Attempts at identifying the presence of tachyzoites or tissue cysts by various stain methods, amplifying the parasite's DNA by PCR, or isolating the parasite in reference laboratories from lymph node tissue have all yielded negative results or have been successful in only a handful of case reports. The most effective approach to diagnosis of toxoplasmic lymphadenitis is by performing *Toxoplasma* serologic tests at a reference laboratory and, if indicated, lymph node excisional biopsy.

3. The definitive diagnosis of toxoplasmosis in hematopoietic cell, stem cell, or bone marrow transplant recipients can be made by the following methods, *except*

A. Amplification of *Toxoplasma* DNA in cerebrospinal fluid by PCR in patients with encephalitis
B. Amplification of *Toxoplasma* DNA in bronchoalveolar lavage fluid by PCR in patients with pneumonia
C. Amplification of *Toxoplasma* DNA in vitreous fluid by PCR in patients with atypical retinal lesions
D. Amplification of *Toxoplasma* DNA in peripheral blood by PCR in patients with fever of unknown origin
E. Amplification of *Toxoplasma* DNA in brain tissue by PCR in patients with encephalitis

Answer: E PCR is the primary method for the diagnosis of toxoplasmosis in immunocompromised patients. A positive *Toxoplasma* PCR test result in cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, and peripheral blood and other body fluids is diagnostic of toxoplasmic encephalitis, pneumonia, chorioretinitis, and dissemination, respectively, in these patients. Ideally, all immunocompromised patients should be tested for *Toxoplasma* IgG and IgM before they become immunosuppressed or as soon as the diagnosis of the underlying immunosuppressive disorder has been made because serologic testing is less reliable or not at all reliable once the patient is in a more advanced immunosuppressive state. The identification of patients at risk of toxoplasmosis is facilitated by the identification of those who are *Toxoplasma* IgG positive and should not be solely based on epidemiologic history because up to 50% of at-risk patients may be missed. (See Diagnosis section, Immunocompromised Patients, and Table 349-2.)

4. All pregnant women should be tested for *Toxoplasma* IgG and IgM as early as possible during gestation to determine whether they have an acute infection (positive *Toxoplasma* IgG/IgM confirmed with additional tests at a reference laboratory) or are at risk of acquiring an acute infection during gestation (negative *Toxoplasma* IgG/IgM). Those identified as having acute *Toxoplasma* infection or toxoplasmosis during pregnancy acquired before 18 weeks of gestation should be treated with the following drug.

A. Spiramycin
B. Pyrimethamine
C. Sulfadiazine
D. Folinic acid
E. Clindamycin

Answer: A Spiramycin is the drug of choice during pregnancy in an attempt to prevent transmission of the parasite to the fetus. Spiramycin is not teratogenic and can be obtained at no cost in the United States through the Investigational New Drug (IND) process at the Food and Drug Administration (301-796-1600). Medical consultation with the Palo Alto Medical Foundation Toxoplasma Serology Laboratory ([PAMF-TSL], Palo Alto, Calif; *www.pamf.org/serology*; 650-853-4828; *toxolab@pamf.org*) is required. If *Toxoplasma* infection was acquired after 18 weeks of gestation (when vertical transmission rates become significantly higher) or fetal infection is highly suspected (e.g., ultrasound abnormalities suggestive of congenital toxoplasmosis) or established (positive *Toxoplasma* PCR test result in amniotic fluid), the combination of pyrimethamine, sulfadiazine, and folinic acid is the treatment of choice. None of these drugs should be used alone. Clindamycin could theoretically replace sulfadiazine in patients with significant sulfa drug allergy. (See Treatment section and Table 349-3.)

350 CRYPTOSPORIDIOSIS

ALDO A. M. LIMA AND RICHARD L. GUERRANT

DEFINITION

Cryptosporidiosis is the clinical disease in humans and animals caused by protozoal parasites of the genus *Cryptosporidium* (Apicomplexa). *Cryptosporidium* spp are recognized as major waterborne parasites worldwide, and 14 species of 30 to date have been documented to infect humans. Two named species, *C. hominis* and *C. pestis*, are considered of major public health significance. Four (*C. cuniculus, C. meleagridis, C. viatorum,* and *C. felis*) and eight (*C. parvum, C. fayeri, C. canis, C. suis, C. ubiquitum, C. scrofarum, C. muris,* and *C. andersoni*) of 14 named species are considered of moderate and minor public health significance, respectively. There are nine species of 30 that are shared between humans and cattle.

The Pathogen

The family Cryptosporidiidae has a hidden sporocyst and undergoes monoxenous completion of its cycle in one host, where it can cause predominantly intestinal, cloacal, and gastric infections.

EPIDEMIOLOGY

The life cycle begins with ingestion of *Cryptosporidium* oocysts (2 to 5 μm) by the vertebrate host, with subsequent excystation within the lumen of the small intestine to release four sporozoites (Fig. 350-1). The sporozoites attach to and enter the host's epithelial cells to form intracellular but extracytoplasmic parasitophorous vacuoles, where they develop into trophozoites and subsequently type 1 meronts (schizonts). By asexual nuclear division, they multiply and release six to eight type 1 merozoites that invade neighboring host cells and develop into type 2 meronts, or trophozoites, to complete the asexual reproductive cycle. Type 2 meronts undergo two nuclear divisions and release four type 2 merozoites that can infect the host's cells and further develop into male (microgamont) or female (macrogamete) forms. Microgametes released from the microgamont can penetrate the macrogametes to form zygotes. Approximately 20% of the zygotes develop into thin-walled autoinfectious oocysts; some 80% become thick-walled oocysts, which are excreted in stool.

Cryptosporidium oocysts have at least five characteristics that make this organism a common problem and that help define the potential risk for person-to-person spread and for waterborne and food-borne disease outbreaks. First, *Cryptosporidium* oocysts are resistant to many chemical disinfectants, such as chlorine. Second, the organism is highly infectious, with the median *C. parvum* infectious dose being 132 or fewer oocysts. Third, the size of the oocysts, 2 to 5 μm, allows them to pass through many conventional filters. Fourth, the monoxenous life cycle allows infectious oocysts to be excreted in large numbers in feces, which can easily spread. Fifth, the organism is associated with geographic, seasonal, and socioeconomic differences in the distribution of *Cryptosporidium* spp.

Cryptosporidiosis is seasonal and related to precipitation and temperature fluctuations worldwide.[1] Excystation of *C. parvum* increases in water temperatures up to 46° C (natural sunlight for 12 hours). Two waterborne outbreaks brought cryptosporidiosis to public health attention. In January 1989, an increased number of cases of cryptosporidiosis were reported in Swindon and Oxfordshire, United Kingdom, with a peak reached in March. Mapping of the addresses of early cases showed associations with water supplies. In late February, the water authority detected *Cryptosporidium* oocysts in samples from the water that supplied the affected areas and in the treated water. Contamination of the raw Thames River water used at three water treatment plants was found, with evidence of pollution by farm effluent. This outbreak resulted in 516 cases and thus ignited public interest and led to an official inquiry. The second outbreak occurred in early spring 1993 in Milwaukee, Wisconsin, and was the largest documented outbreak of waterborne disease ever in the United States, with an estimated 403,000 people having acute watery diarrhea and potentially 112 deaths. Findings from this outbreak indicated that *Cryptosporidium* oocysts passed through the filtration system of one of the city's water treatment plants. Again, this suggested that the water quality standards and detection methods for *Cryptosporidium* were inadequate. Swimming pool contamination, especially of bigger pools, pools with more heterogeneous mixing such as municipal pools, and pools catering to young children (wading pools), is associated with more cases.[2] Food-borne outbreaks have also been reported in association with contaminated apple cider, unpasteurized milk, chicken salad, vegetables, raw produce, and shellfish.[3]

The prevalence of cryptosporidiosis varies by geographic region, with the highest rates seen in developing countries. Most cases of cryptosporidiosis occur in young children, thus suggesting that the host's immune response plays a role in susceptibility. Furthermore, cryptosporidiosis in individuals infected with human immunodeficiency virus (HIV) and in those with acquired immunodeficiency syndrome (AIDS) is persistent and occasionally life-threatening and may involve infections of the hepatobiliary and respiratory tracts in addition to the entire gastrointestinal tract. Only effective antiretroviral therapy with restoration of immune function controls this devastating disease. The prevalence of cryptosporidiosis in patients with AIDS varies from 31% in those with $CD4^+$ cell counts equal or higher than 200/μL to 38% in those with $CD4^+$ cell counts lower than 100/μL.

PATHOBIOLOGY

Cryptosporidium oocysts and sporozoites interact with host cells, including the processes of excystation, gliding motility, attachment, invasion, parasitophorous vacuole formation, intracellular maintenance, and host cell damage.[4] Oocysts of *Cryptosporidium* spp use their cysteine and serine proteases and aminopeptidase for excystation in the upper part of the small bowel and release infective sporozoites that invade the mucosal epithelium and occasionally Peyer's patch M cells, often extending to the terminal ileum and colon. The sporozoites secrete proteins from the apical organelles for locomotion and attachment. In immunocompromised patients, the organisms can be found throughout the gut, biliary tract, pancreas, and respiratory tract. As noted earlier, trophozoites undergo asexual reproduction by merogony to form type 1 and then type 2 meronts. Sporozoites and merozoites are internalized by similar invasion machinery and actin reorganization. Two classes of proteins, mucin-like glycoproteins and thrombospondin-related adhesive proteins, mediate adhesion of the parasite. The parasite uses proteases for the proteolytic processing of surface and apical complex proteins for invasion and for egress from the host cells. Entry into the host's cell occurs within 30 seconds and is dependent on the parasite's actinomyosin cytoskeleton to enter host-derived bimembrane parasitophorous vacuoles in a unique intracellular but extracytoplasmic niche.[5] Dense polymerized actin forms at the base fusion of the host-parasite bimembranes. Invasion of cells of the host leads to displacement of the microvillous border, villous atrophy, blunting and crypt cell hyperplasia, and marked infiltration by lymphocytes, plasma cells, and some neutrophils into the lamina propria, with apoptosis of infected cells and significant alteration in intestinal permeability, as measured by mannitol and lactulose markers. This noninvasive functional test shows both reduced absorptive area and disrupted barrier function, which is even more severe in patients with HIV/AIDS. Upregulation of nuclear factor κB and the pro-inflammatory cascade causes secretory and mildly inflammatory diarrhea. Pro-inflammatory cytokines and potential biomarkers, such as tumor necrosis factor-α, interleukins 1β and 8, and lactoferrin, are significantly increased in murine and human infections. Interleukins 1β and 8 both upregulate cyclooxygenase 2, which results in prostaglandin synthesis in the epithelial cells and production of substance P by the inflammatory cells; these products together decrease net sodium absorption and increase net chloride secretion, which causes the secretory diarrhea often seen with this infection.

Both innate and adaptive immune responses are associated with immunity to cryptosporidiosis. Two chemokines, CXCL-10 and perhaps CXCL-8, are initially implicated in the attraction of pro-inflammatory cells. Activation of

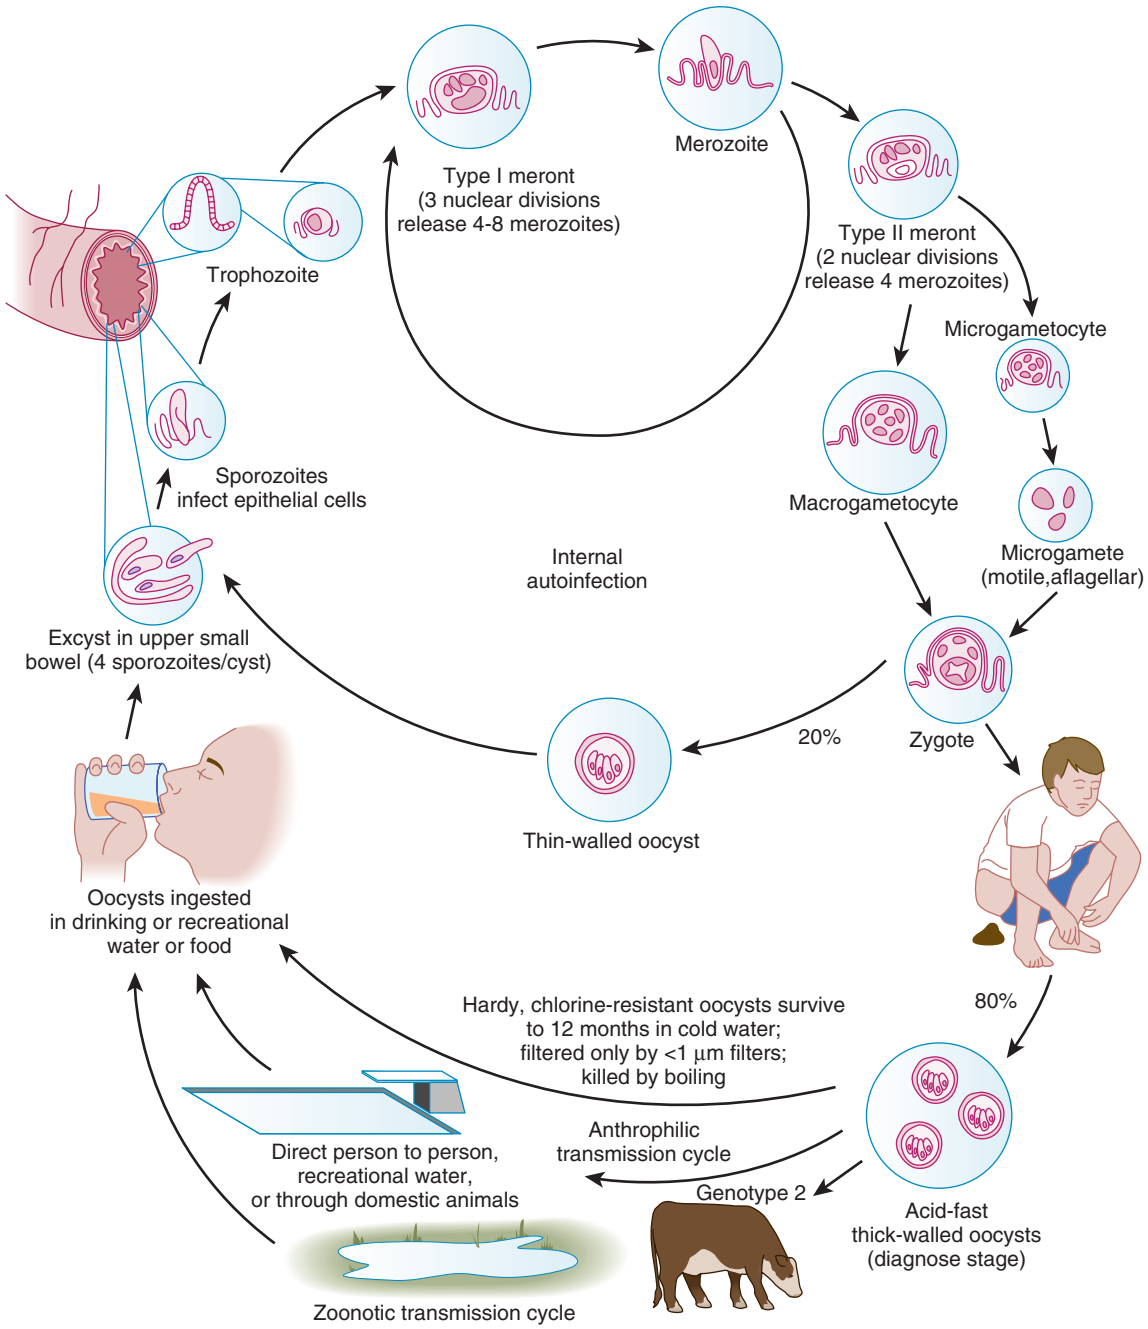

FIGURE 350-1. **Life cycle of *Cryptosporidium* spp. (Redrawn with permission from Kosek M, Alcantara C, Lima AAM, et al. Cryptosporidiosis: an update. *Lancet Infect Dis.* 2001;1:262-269.)**

the immune system involves early stimulation by interleukin 15, which may be important for initial clearance of the parasite. $CD4^+$ T cells and interferon-γ play important roles in the eventual immune defense against this infection, probably more so than B cells or $CD8^+$ cells.

CLINICAL MANIFESTATIONS

Cryptosporidiosis is a cosmopolitan, self-limited infection in immunocompetent hosts that affects all age groups and both sexes. In developing countries, the disease occurs most frequently in children younger than 5 years because of high rates of fecal-oral exposure and the development of partial immunity in older children and adults. In developed countries, the disease occurs at all ages, and most cases are associated with small waterborne outbreaks, frequently with contamination of recreational water. Patients from developed countries are more often adults. The incubation period is approximately 1 week, with a range of 1 to 30 days.[6] The diarrhea can have a sudden onset, frequently with voluminous watery stools, abdominal pain, nausea or vomiting, bloating, malaise, fatigue, weight loss, and occasional fever. In young children at risk in developing countries, it may have a long-term impact on physical activity, school performance, and development of cognitive function. Rarely, respiratory infection and cough have been reported. In normal hosts, the disease usually lasts 1 to 3 weeks but sometimes for more than a month. Oocyst shedding typically lasts 1 to 2 weeks but can occur for up to 2 months. Patients with T-cell immune deficiency, such as those with hematologic malignant neoplasms (particularly children), primary T-cell deficiencies (severe combined immunodeficiency and CD40 ligand deficiency), and HIV/AIDS, are at high risk for the development of more severe disease and have an increased risk for death.

Immunocompetent Host

Data on the natural history of cryptosporidiosis in immunocompetent hosts have been obtained mostly from developed countries, and such data are derived from waterborne outbreaks, patients seeking medical assistance, travelers, animal workers, children in daycare, and their contacts. Most patients in outbreaks and travelers are adults and usually have diarrhea with a median duration of 14 days and a range of 1 to 100 days. The duration and severity of diarrhea appear to be similar for *C. parvum* and *C. hominis* infections. Recurrence of diarrhea is common and occurs in 30 to 41% of patients. Reports from the United Kingdom describe abdominal pain (96%), vomiting (65%), fever (59%), and bloody diarrhea (11%). The clinical manifestations in 285 people surveyed with a confirmed laboratory diagnosis of *Cryptosporidium* infection in the massive outbreak in Milwaukee showed a median duration of 9 days (range, 1 to 55 days), with watery diarrhea in 93%,

abdominal cramps in 84%, fever in 57%, and vomiting in 48%. Patients may continue to shed oocysts for seven months despite being asymptomatic.[7]

Childhood Cryptosporidiosis in Developing Countries

In developing countries, cryptosporidiosis is associated with prolonged (7 to 13 days) or persistent (≥14 days) diarrhea, increased overall burden of diarrhea, risk for malnutrition, and infant mortality. A nested case-control study from a cohort of children in Brazil has shown that children younger than 1 year with cryptosporidiosis have subsequent increased diarrheal burdens and growth shortfalls. These findings have been extended in a shantytown in Peru, where cryptosporidiosis has been associated with growth faltering and stunting. This was also true for children with asymptomatic infections, which are even more common in endemic areas. The long-term impact of childhood diarrhea and cryptosporidiosis has also been evaluated in a cohort study in Brazil, in which it was shown that children with more diarrhea morbidity or cryptosporidiosis early in life (0 to 2 years) have reduced fitness and impaired cognitive function at 6 to 9 years of age. Several studies have now shown that oocysts are shed longer and the number of oocysts is higher with *C. hominis* than with *C. parvum* infection. In Brazil, a birth cohort study demonstrated that children with *C. hominis* infection have higher fecal lactoferrin and delayed growth in comparison to those with *C. parvum* infections. Diarrhea, nausea, vomiting, and general malaise are more frequently associated with *C. hominis* infection. Subtype family analysis of *C. hominis* (Ia, Ib, Id, and Ie) has indicated that Ib is more commonly associated with nausea, vomiting, and general malaise.

Immunocompromised Hosts

Low $CD4^+$ lymphocyte counts in HIV-infected patients are associated with severe cryptosporidial diarrhea. For example, patients with $CD4^+$ counts higher than $180/mm^3$ usually have transient or self-limited disease, whereas those with $CD4^+$ counts lower than $50/mm^3$ often have severe disease with more than 2 L of stool per day. The introduction of highly active antiretroviral therapy (HAART) heralded reduced rates of cryptosporidiosis in patients with HIV/AIDS. HAART may also directly inhibit sporozoite development and invasion in the host's cells. Patients with other immune disorders, such as T-cell immune deficiency (severe combined immunodeficiency and CD40 ligand deficiency) or hematologic malignant neoplasms, particularly children, are at higher risk for more severe, prolonged, or extensive disease, with infection occasionally extending to the gallbladder, the pancreatic duct, and even the bronchial tree. Several complications in these patients have been described, including pancreatitis, cholecystitis, sclerosing cholangitis, papillitis, and terminal bile duct stenosis with subsequent biliary cirrhosis.

DIAGNOSIS

The clinical manifestations and physical examination findings in patients with cryptosporidiosis are not unique, and the differential diagnosis should include other causes of infectious gastroenteritis, such as *Giardia*, *Cyclospora*, *Isospora*, microsporidia, *Escherichia coli* pathotypes (enteropathogenic [EPEC], enteroaggregative [EAEC], diffusely adherent [DAEC], enterohemorrhagic [EHEC], enteroinvasive [EIEC], and enterotoxigenic [ETEC]), *Campylobacter*, *Salmonella*, *Shigella*, rotavirus, norovirus, and others. Definitive diagnosis of *Cryptosporidium* enteric infection is made by stool examination. Up to three fecal samples with fixation and concentration before permanent staining or polymerase chain reaction analysis[8,9] may increase detection rates. Oocysts are stained with the acid-fast stain, modified Ziehl-Nielsen stain, fluorescence staining with auramine-phenol, or immunofluorescent stains. Acid-fast staining requires around 500,000 oocysts per gram for detection in formed stools, whereas immunofluorescence is at least 10 times more sensitive, and commercially available enzyme-linked immunoassays have a sensitivity and specificity approaching 100% for *Cryptosporidium*. Polymerase chain reaction testing can detect as few as 50 to 500 oocysts per milliliter of liquid stool and can be used to differentiate or even to quantify *Cryptosporidium* species and genotypes.

TREATMENT Rx

Nitazoxanide has emerged as the only promising candidate for treatment of cryptosporidiosis. It is licensed in the United States for treatment of cryptosporidiosis in nonimmunodeficient children and adults and has reportedly reduced the duration of diarrhea and oocyst shedding in several double-blind, placebo-controlled clinical trials. A clinical trial in Egypt in adults (500 mg twice daily for 3 days) and children (200 mg for 4- to 11-year-olds and 100 mg for 1- to 3-year-olds, twice daily for 3 days) with cryptosporidiosis showed that 80% exhibited resolution of diarrhea versus 41% of the placebo group.[A1] A second clinical trial of a 3-day course of treatment showed resolution of symptoms at 4 days in 96% of the patients receiving nitazoxanide tablets (500 mg twice daily for 3 days) versus only 41% of those receiving placebo tablets.[A2]

Prevention and treatment of cryptosporidiosis in immunocompromised patients have been reviewed; there has been no evidence of a reduction in the duration or frequency of diarrhea with nitazoxanide. However, nitazoxanide has resulted in significantly greater oocyst clearance than has placebo in all children.[A3] In patients with HIV/AIDS, HAART has emerged as the most important therapy to prevent and to reduce the severity and frequency of cryptosporidiosis. Oral rehydration therapy or intravenous fluid replacement for more severe disease is key to preventing dehydration and risk for immediate death.

PREVENTION

Prevention of person-to-person spread should be achieved with personal hygiene guidelines such as frequent handwashing after using or cleaning the toilet, changing diapers, and caring for a person with diarrhea. It is recommended that people with cryptosporidiosis be excluded from the workplace setting until 48 hours after the last diarrheal episode. Handwashing facilities should be available and used at farms to facilitate personal hygiene. Because most outbreaks of cryptosporidiosis are linked to oocysts in source water, routine survey of treated water for this parasite is key to preventing major spread of this disease. Optimization of multibarrier approaches, including chemical treatment and water filtration and treatment systems, is highly recommended. Ultraviolet irradiation and ozone are effective in inactivating *Cryptosporidium* and *Giardia* cysts in water and may prove useful in controlling the transmission of waterborne protozoa.

REVIEW QUESTIONS

1. *Cryptosporidium* infection

A. May be asymptomatic but still impair a child's growth
B. Produces solid protective immunity
C. Is readily treated with broad-spectrum antimicrobial agents
D. Is primarily a food-borne pathogen
E. Can be diagnosed with an iodine stain for parasites

Answer: A Asymptomatic infections can impair growth, even without causing overt diarrheal symptoms. In fact, because they are more common, the total stunting impact of asymptomatic infections can exceed that of the symptomatic ones. Furthermore, recurrent infection is common, especially where water and environmental fecal contamination is often seen, and it is difficult to treat, especially in the immunocompromised host. Finally, diagnosis requires special acid-fast or fluorescence antibody staining, enzyme-linked immunosorbent assay, or polymerase chain reaction analysis as routine iodine stains for ova and parasites typically do not identify this protozoan parasite.

2. Cryptosporidiosis

A. Usually causes bloody diarrhea in immunocompromised patients
B. Cannot be spread by direct contact because it requires maturation outside the host
C. Is a major cause of moderate to severe diarrhea in developing countries
D. Does not cause relapsing disease
E. Is an acute disease

Answer: C *Cryptosporidium* can cause severe, watery, cholera-like diarrhea in immunocompromised patients, such as patients with AIDS. Because the infectious dose is low and sporozoites develop into the mature oocysts in the infected host, they are infectious when shed in the feces (unlike *Cyclospora*, which do require maturation outside the host). In the recent GEMS study in seven sites in Africa and Asia, *Cryptosporidium* was second only to rotaviruses as an attributable cause of moderate to severe diarrhea that can often recur. (Kotloff KL, Nataro JP, Blackwelder WC, et al. Burden and aetiology of diarrhoeal disease in infants and young children in developing countries [the Global Enteric Multicenter Study, GEMS]: a prospective, case-control study. *Lancet*. 2013;382:209-222.)

3. The risk of acquiring *Cryptosporidium* infections is

A. Reduced by chlorination of water
B. Greater in immunocompromised patients
C. Reduced by filters that remove particles larger than 6 μm
D. Requires ingestion of more than 10^5 parasite oocysts
E. Greater in adults

Answer: B *Cryptosporidium* is a hardy, chlorine-resistant oocyst that can be infectious with doses as low as 150 or fewer oocysts and probably even lower doses in immunocompromised individuals. It is also able to pass through common filters unless they are definitely smaller than 1-μm filter size.

4. The major outbreaks of cryptosporidiosis were associated with

A. Ingestion of contaminated drinking water
B. Ingestion of contaminated recreational water
C. Exposure to infected animals
D. Ingestion of contaminated food
E. Contact with infected persons or animals

Answer: A *Cryptosporidium* infection is transmitted by the fecal-oral route and results from the ingestion of *Cryptosporidium* oocysts through the consumption of fecally contaminated food or water (drinking and recreational water) or through direct person-to-person or animal-to-person contact. The major outbreaks of cryptosporidiosis were associated with fecally contaminated drinking water.

5. Which of the following is true regarding the treatment or prevention of cryptosporidiosis?

A. Nitazoxanide reduces the shedding of oocysts in immunocompetent hosts.
B. Disinfection by chlorination prevents cryptosporidiosis.
C. Nitazoxanide cures cryptosporidiosis in immunocompromised patients.
D. Filtration is an efficient method to prevent cryptosporidiosis.
E. Ozone and ultraviolet irradiation are not adequate to prevent cryptosporidiosis.

Answer: A Nitazoxanide has emerged as the drug of choice for treatment of cryptosporidiosis in immunocompetent children and adults. In immunocompromised patients, treatment or prevention with nitazoxanide shows no evidence of a reduction in the duration or frequency of diarrhea. Chlorination alone is ineffective against *Cryptosporidium* oocysts. Ultraviolet irradiation and ozone are effective in inactivating *Cryptosporidium* and *Giardia* cysts in water and can be used to prevent transmission of waterborne protozoa.

GIARDIASIS

THEODORE E. NASH AND DAVID R. HILL

DEFINITION

Giardia lamblia (Giardia duodenalis, Giardia intestinalis) is a ubiquitous, small intestinal protozoan parasite of humans and other mammals. It is the most common parasitic infection of the gastrointestinal tract in the United States as well as worldwide and is responsible for outbreaks of diarrhea and sporadic endemic disease.[1,2]

The Pathogen

Giardia has a simple life cycle. The trophozoite, which is 9 to 21 µm long, 5 to 15 µm wide, and 2 to 4 µm thick (Fig. 351-1), resides in the small intestine and is responsible for manifestations of disease. It has four pairs of flagella, two nuclei, and a ventral sucking disc by which it may adhere to intestinal epithelial cells. The dorsal surface is pear shaped and bilaterally symmetrical, with the two highly characteristic nuclei best visualized after staining. In the lower small intestine, the trophozoite develops into an environmentally resistant cyst. Detection of soluble cyst wall proteins in the feces forms the basis of many stool antigen assays.

FIGURE 351-1. ***Giardia lamblia*.** This scanning electron micrograph reveals some of the external ultrastructural details displayed by a flagellated *G. lamblia* protozoan parasite.

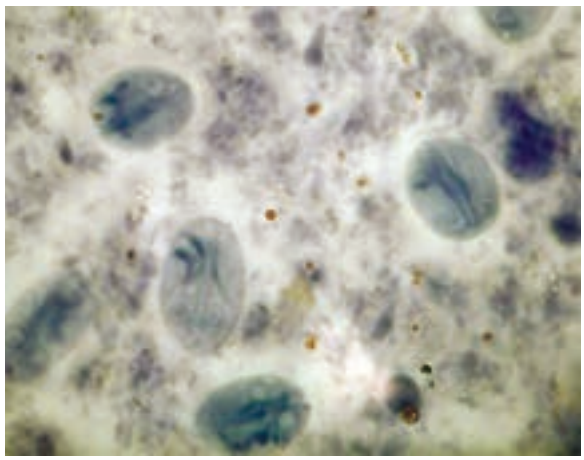

FIGURE 351-2. **Iron hematoxylin stain of *Giardia lamblia* cysts from stool.**

Excreted cysts are mature and infectious. They are oval and about 8 to 12 µm in length and 7 to 10 µm in width (Fig. 351-2). After ingestion and exposure to acid and proteases in the stomach and intestines, they excyst in the small intestine, yielding two trophozoites from each cyst, which quickly divide again. In vitro trophozoites double in number every 6 hours for the fastest growing isolates.

A number of morphologically identical but genetically distinct *Giardia* infect humans and animals that are now divided into eight assemblages. Humans and some animals are infected with either assemblage A or B. These two assemblages are genetically and biologically diverse and appear to be two separate species.[3]

Giardia is well adapted to its existence as a parasite. It has two equal functioning nuclei and lacks mitochondria and peroxisomes. It has a simplified metabolism and is dependent on the host for nutrients such as purines, pyrimidines, cysteine, and cholesterol. The WB isolate, assemblage A, has a compact genome (11.7 Mb) with unusually short promoters. The parasite's rigid cytoskeleton is composed of unique families of structural proteins and carbohydrates.

Giardia is the only bowel-dwelling parasite that undergoes antigenic variation. Only one of a family of about 250 variant-specific proteins (VSPs) is expressed on the surface of the trophozoite at a time.[4] Both immune and biologic selection of trophozoites that express specific VSPs occurs in humans and animals with giardiasis. Expressed VSPs must be compatible with the host's intestinal environment and are probably not recognized by the host's immune system because antibodies to VSPs are inhibitory or cytotoxic. Whereas all VSPs are transcribed, all but one of the transcripts are eliminated by RNA interference–based mechanisms, resulting in expression of a single VSP surface protein.[5] Exactly how selection and switching occur is unclear.

EPIDEMIOLOGY

Giardia is among the most common parasitic infections of humans; it is highly infectious, and cysts are frequently excreted in large numbers (as high as 10^7 cysts per gram of feces), especially in young children. Cysts can survive for months in cold water, are relatively resistant to chlorination, but are intolerant of desiccation and heat in comparison to the relatively resistant ova of cryptosporidia and helminths. Experimentally, between 10 and 100 cysts is sufficient to establish infection 100% of the time. Consequently, ingestion of water or food that contains small levels of contamination can result in infection. Approximately 20,000 infections are reported annually in the United States, but because of underreporting, actual infections are estimated at more than 100,000 cases per year.

Infections are most common in young children and are more frequent in summer and fall months. Giardiasis is acquired after ingestion of contaminated water or food or through person-to-person contact. In past decades, large outbreaks in high-income countries such as the United States occurred after ingestion of contaminated drinking water obtained from surface sources such as reservoirs, lakes, and mountain streams. However, with improved water treatment measures, ingestion of contaminated recreational water from pools or lakes is now a more common source of outbreaks. Backpackers who ingest untreated surface water remain at risk of infection.

Although outbreaks from contaminated food or infected food handlers are well described, they are not often documented. Worldwide, person-to-person transmission may be the most frequent mode of infection and is the primary way children are infected in daycare centers, where infection can be common. Person-to-person spread occurs among family members with infected children and following sexual practices that lead to fecal-oral contact.[6] In low-income, highly endemic regions, almost all children are infected by 2 to 3 years of age. Although partial immunity can develop in previously exposed adults, reinfection of children after treatment is common in highly endemic regions. Longer-term travel, particularly to south Asia, increases the risk of giardiasis. For the returned traveler with persistent diarrhea, giardiasis should be ruled out.

The understanding of immunity in humans is based mostly on animal models that have limited applicability to human infection and disease. In addition, some of the findings are conflicting. In the classic human experimental infections reported by Rendtorff and colleagues in the 1950s, self-cure occurred in about 84% of the persons. In a more recent experimental human challenge study, in which the infecting parasite was well characterized and the inoculum known, rechallenge with the same isolate after treatment resulted in brief, asymptomatic infections in two persons, suggesting development of partial immunity. Humans with hypogammaglobulinemia are susceptible to *Giardia* and have more severe disease that is resistant to treatment. Studies in animals support a major role of intestinal antibodies (particularly IgA) in protective immunity and an essential role of T-cell immunity in the control of *G. lamblia* infection.

Giardia infections are neither more severe nor more common in most other immunosuppressed states and in persons with selective IgA deficiency. Even though most human immunodeficiency virus–infected patients respond to usual treatment, a subset develop recurrent or repeated infections that are difficult to treat.

PATHOBIOLOGY

Giardia infections involve complex interactions between host and parasite. The two assemblages (A and B) that infect humans are composed of genetically distinguishable isolates, which may vary in infectivity, antigenicity, and virulence. In addition, human hosts vary in susceptibility to infection and disease and in the response or tolerance to infection. Pathogenic mechanisms need to explain the varied clinical manifestations as well as the contrasting situation in which there are high rates of infection and disease seen in waterborne outbreaks of giardiasis in regions where infections are sporadic, like in the United States, compared with the large number of asymptomatic infections in children in low-income regions. In addition, infection with *Giardia* can lead to malabsorption, weight loss, and nutritional deficiencies in some settings and little effect on nutritional parameters in other settings.

Giardia is strictly an intraluminal parasite that adheres to the epithelium by way of an adhesive or sucking disc. Invasion of the epithelium either does

not occur or is rare. The number of trophozoites in the intestine can be so large that adherent organisms cover much of the epithelial surface. This could disrupt the epithelial brush border and contribute to disaccharidase deficiency seen in some patients. A number of studies demonstrate direct epithelial cell barrier dysfunction in vitro and in vivo in humans. Exactly how this occurs is not known. There is no evidence of production of a classic enterotoxin, although it is possible that secreted or surface proteins may be injurious to cells. Of patients with persistent giardiasis after treatment, nearly half exhibited inflammation on small bowel biopsy specimens, supporting the view that chronic inflammatory responses contribute to disease at least in this subset.

CLINICAL MANIFESTATIONS

The clinical manifestations, course, and duration of *Giardia* infections are variable. Infections may be self-limited or persistent, asymptomatic or symptomatic. In general, patients are not as sick as those with bacterial diarrheas. Acute disease manifestations occur commonly in travelers and in outbreaks and are characterized by diarrhea, nausea, anorexia, dehydration, flatulence, eructation, foul-smelling stools, distention, abdominal cramping, and weight loss. Malabsorption is more commonly seen in chronic infection. Fever and vomiting are uncommon. Blood, mucus, and polymorphonuclear cells in the stool, which are not usual features of small bowel infections, should suggest an alternative or additional diagnosis. Dehydration, although uncommon, may be severe and require hospitalization; hospitalization for giardiasis has occurred in the United States with a frequency similar to that for shigellosis. On occasion, nausea and vomiting will predominate and suggest other causes.

In experimental infections using inoculated cysts, presence of cysts in the stool occurred 6 to 15 days (mean, 9 days) after inoculation. In more recent experimental infections, *Giardia* antigen was detected 1 day before cyst excretion. In one well-documented food-borne outbreak, 74% became ill, with an incubation period of 2 to 19 days and peak symptoms at 5 to 6 days. Symptoms continued for a median of 18 days.

Acute symptoms can resolve, wax and wane, or settle into a chronic phase, which can be prolonged and last weeks to months. Long-lasting symptoms should indicate a search for the parasite. Lactose deficiency is common and can persist for some weeks after treatment, and it needs to be distinguished in symptomatic patients from relapse or reinfection. In extreme cases, malabsorption and weight loss are severe and mimic sprue. Infants and children are particularly susceptible to infection and disease, which can result in growth failure that is reversed on successful treatment.

A typical scenario is a mildly to moderately ill person who complains of an increased number of urgent loose stools, with flatus, cramping, anorexia, and weight loss. There may be periods when the person feels better only to relapse and become noticeably worse. After days to several weeks, the individual will seek medical help. Similar to other causes of infectious diarrheas, symptoms can continue after successful treatment and evolve into irritable bowel syndrome (Chapter 136).[7] Uncommonly, *Giardia* is found in biliary and pancreatic ducts and can cause cholecystitis and pancreatitis. Extraintestinal manifestations and long-term consequences are usually uncommon, but a series of sporadic cases documented them in a third of the patients.[8] The manifestations can include rash, reactive arthritis, eye complaints, and cognitive deficiencies.[9]

Disease and symptoms caused by *Giardia* in children in low-income regions are variably present despite almost universal infection by the age of 3 years and frequent reinfection with prevalence rates that are commonly above 20%. Although there are convincing studies showing detrimental growth and nutritional effects in some populations, other studies show little or no effects. An analysis of published studies indicated that persistent diarrhea as a result of infection with *Giardia* is a cause of malnutrition.[10] The reasons for these disparate results may be due to differences in the populations, such as prior exposures, maternal factors, nutritional status, and diet, or variability in the organism, including the genetics of the isolate (e.g., assemblage type) and properties of the expressed VSP. In contrast, *Giardia*-naïve visitors frequently develop symptomatic giardiasis while visiting or working in highly endemic regions, in contrast to a mostly asymptomatic population, suggesting that the endemic population has developed an accommodation to the disease. Some studies suggest giardiasis protects against other acute diarrhea episodes.[11]

DIAGNOSIS

The diagnosis of giardiasis is based on detection of cysts, trophozoites, or, more recently, parasite-specific antigens in fecal samples. Polymerase chain reaction has been largely experimental but is being increasingly used in field and laboratory settings. Polymerase chain reaction is sensitive and specific and can determine the infecting assemblages.[12] Because excretion of cysts may be variable or in low concentrations, a single examination for ova and parasites is only 50 to 80% sensitive, and two or three examinations may be necessary. Stool antigen tests are standard in most laboratories and are highly sensitive (>90%), specific (close to 100%), and relatively inexpensive and do not require a trained microscopist. Examination of small intestine biopsy specimens or intestinal contents for trophozoites was the previous "gold standard" for diagnosis but is now uncommonly needed to establish or to confirm the diagnosis. In low-intensity infections, all testing methods can be falsely negative and require repeated testing.

The laboratory findings are nonspecific. The white blood cell count and liver function test results are usually normal. Electrolyte disturbances can be present if diarrhea and vomiting are severe. White blood cells, lactoferrin, blood, and mucus are not found in the stool. Immunoglobulin levels are usually normal but abnormally low or absent in susceptible hypogammaglobulinemic individuals.

TREATMENT

Rx

Details of antiparasitic therapy in general are provided in Chapter 344. Tinidazole (Tindamax), a Food and Drug Administration (FDA)–approved nitroimidazole drug similar to metronidazole (Flagyl), has been the treatment of choice; other nitroimidazoles (e.g., ornidazole and secnidazole) that are not approved in the United States are also effective. Tinidazole is given as a single dose, and compared with metronidazole, it has fewer side effects and greater efficacy. In adults, the dose is 2 g orally; in children, the dose is 50 mg/kg as a single dose with a maximum of 2 g. Metronidazole has been used to treat giardiasis for decades but has never been approved by the FDA for this indication; it requires multiple dosing at 250 mg orally three times a day for 5 to 7 days for adults and 15 mg/kg/day in three divided doses for 5 to 7 days for children. Gastrointestinal side effects of metronidazole are relatively common, and alcohol should not be taken concomitantly because of the possibility of a disulfiram reaction with both drugs. A meta-analysis indicated that albendazole (400 mg/day for 5 days), not presently approved by the FDA for treatment of giardiasis, has efficacy similar to that of metronidazole and fewer side effects. However, many studies test for efficacy shortly after therapy is stopped, so recurrent infection cannot be adequately determined, and there is only limited experience with albendazole. Nitazoxanide is a drug with broad activity against protozoa, helminths, and bacteria and is FDA approved for the treatment of giardiasis. It is given at a dose of 100 mg orally every 12 hours for 3 days for children aged 12 months to 3 years, 200 mg orally every 12 hours for 3 days for children 4 to 11 years of age, and 500 mg orally every 12 hours for 3 days for persons older than 12 years. Because it is available in a liquid suspension as well as in a 500-mg tablet, it may be easier to give to young children. It should be given with food. Most of the side effects are gastrointestinal symptoms and headache.

Paromomycin, a nonabsorbable aminoglycoside, has activity against *Giardia* and has been used in pregnant women to avoid the theoretical fetal adverse events of nitroimidazoles, particularly during the first trimester. It is given to adults at 500 mg three times a day for 5 to 10 days and to children at 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days. Quinacrine and furazolidone (FDA approved but not usually available) are also active against *Giardia* but should be reserved for use in particular situations.

Patients usually experience relief of symptoms on treatment. Failure of treatment is frequently heralded by a return of symptoms days to weeks after cessation of therapy and requires either re-treatment with an alternative class of drug or an increased dosing of the initial therapy. Clinically resistant cases usually respond to combination treatment; quinacrine and metronidazole have been most effective, with metronidazole plus albendazole also showing efficacy.[13]

PREVENTION

Infection is prevented by scrupulous personal hygiene, proper disposal of sewage, removal or killing of cysts from water supplies, and preventing contamination of food and water. Cysts are relatively labile and are susceptible to heating and filtration with small water volume filters of 0.2 to 1 μm. Heating (bringing water to a boil) is preferred because other pathogens found in feces are also inactivated. Cysts are not reliably susceptible to chlorination because the concentrations of chlorine, water temperatures, turbidity, and pH present when treating commercial water supplies are subopitmal. Four drops of 5.25% bleach to 1 liter for 1 hour at room temperature is sufficient for killing. At lower temperatures, inactivation may not be complete.

REVIEW QUESTIONS

1. A 24-year-old woman spends 4 days in Cancun and within 2 days of return to the United States develops diarrhea consisting of multiple episodes per day of unformed stool. The patient is normally well but 2 years ago was diagnosed with giardiasis. As her symptoms are now similar, she seeks evaluation for it again. The health care provider orders a stool examination for ova and parasites. Which is the correct answer?

A. Giardiasis is the likely diagnosis because the symptoms are similar.
B. Ordering a stool examination for ova and parasites is the best way to establish the diagnosis for her symptoms.
C. The diagnosis of giardiasis is unlikely.
D. Amebiasis is more common than giardiasis in travelers to Mexico.
E. None of the above

Answer: C Giardiasis is unlikely. First, the incubation period is too short for giardiasis, amebiasis, and other gastrointestinal parasites. Second, most diarrhea episodes of travelers to Mexico are due to bacterial infections (e.g., *Escherichia coli*, *Campylobacter*, and *Salmonella*). If she is sufficiently unwell, evaluation should also be directed at these causes or empirical antibiotic treatment considered. Unless giardiasis is confirmed, treatment should not be initiated for this.

2. A 25-year-old man developed diarrhea and weight loss. He was diagnosed with giardiasis after an evaluation for diarrhea that also included stool culture and testing for *Clostridium difficile*, as he has a history of chronic sinusitis that has been intermittently treated with antibiotics. He was treated for *Giardia* with metronidazole and initially responded. However, his symptoms have returned, and he has again been diagnosed with giardiasis. What is the most appropriate step in his evaluation?

A. Repeat evaluation for *C. difficile*.
B. Re-treat with a second course of metronidazole.
C. The *Giardia* is resistant and should be tested for drug sensitivities.
D. Order quantitative immunoglobulin levels.
E. None of the above.

Answer: D The patient has recurrent giardiasis, weight loss, and chronic sinusitis, which is consistent with a diagnosis of common variable immunoglobulin deficiency. Giardiasis in these patients is difficult to treat and recurrent. Although his diarrhea could be due to several causes, *C. difficile* is not likely because it was not diagnosed initially and would not have occurred while the patient was taking metronidazole. Another course of treatment is not unreasonable, but in general, re-treatment with the same drug fails in this situation.

3. A mother of 2- and 7-year-old children develops severe diarrhea. Five weeks earlier, the family stayed at a campground over the weekend. There was supplied faucet water from a deep well that is protected from surface contamination. Three weeks before becoming ill, both children began attending a new daycare school for the summer. She has had two episodes of dehydration requiring fluid resuscitation. On evaluation, she is found to be infected with *Giardia*. The most likely source of her infection is

A. The camping trip
B. The faucet water
C. Her children
D. The water in the home
E. None of the above

Answer: C In addition to the patient, both of her children were subsequently diagnosed with giardiasis. Frequently, the parents of young children are diagnosed, and infection is then traced to a child who is a carrier or only mildly symptomatic. The entire family may become infected. Surface water from lakes or streams during camping can be a source of exposure compared with a relatively secure water source, such as a faucet at park destinations. Given the possible sources for her infection, the daycare center is most likely.

4. A 45-year-old woman who was diagnosed with and treated successfully for symptomatic giardiasis 6 months ago now returns to your office complaining of listlessness, intermittent abdominal pains, and occasional loose stools. Which is the most likely diagnosis?

A. Lactose intolerance
B. Recurrent giardiasis
C. Bacterial diarrhea
D. Post-giardiasis irritable bowel syndrome

Answer: D Although the symptoms are vague and could be due to recurrent giardiasis, the more likely diagnosis is irritable bowel syndrome secondary to prior symptomatic giardiasis. Irritable bowel syndrome and fatigue were found to occur more frequently than in controls after a large epidemic of giardiasis in Bergen, Norway. Prior giardiasis does not preclude other causes of her symptoms, such as depression. Symptoms and findings of lactose intolerance due to shortening of villi is commonly found during and shortly after giardiasis but would not be expected to be present 6 months after infection.

5. A 10-year-old Filipino child who lives in a rural area of the Philippines is taking part in a study surveying children for enteric parasites. He is found to have *Giardia* in his stool but is asymptomatic and is well nourished. Which of the following is a reason for not treating this child?

A. The child is likely to be reinfected in his home setting.
B. Treatment of giardiasis in children is associated with severe adverse drug events.
C. Treatment is usually unsuccessful in endemic settings.
D. The child is too old for treatment to be helpful.

Answer: A Prevalence of *Giardia* infection can be 20% or more in cross-sectional studies from highly endemic regions. Many of these persons are asymptomatic, and reinfection after treatment can be common, particularly in young children. Although he could be treated, there is debate in the literature about the benefits of treatment of asymptomatic children who are likely to be reinfected.

352

AMEBIASIS

WILLIAM A. PETRI, JR. AND ALDO A.M. LIMA

DEFINITION

Amebiasis is due to infection with the enteric protozoan parasite *Entamoeba histolytica*. Amebiasis can cause asymptomatic colonization, diarrhea, dysentery, and colitis as well as spread extraintestinally to cause liver and rarely brain abscess (Fig. 352-1).

The Pathogen

E. histolytica has a low infectious dose (<100 organisms), is resistant to chlorine, and is environmentally stable. These properties make it a threat to food and water supplies, as the 1998 municipal water outbreak of amebic liver abscess in Tbilisi, Georgia, demonstrated. Its tissue-destructive properties are the reason for the parasite's being named *histolytica*.

EPIDEMIOLOGY

Most *E. histolytica* infections occur in the developing world, including the Indian subcontinent, Southeast Asia, sub-Saharan Africa, and Central and South America, as a result of fecal-oral transmission. A national serologic survey in Mexico demonstrated antibody to *E. histolytica* in 8.4% of the population. In an urban slum of Fortaleza, Brazil, 25% of the population tested carried antibody to *E. histolytica*, and the prevalence in children 6 to 14 years of age was 40%. In Dhaka, Bangladesh, where diarrheal diseases are the leading cause of childhood death, the annual incidence of *E. histolytica* infection in a cohort of preschool children was 40%. The annual incidence of amebic liver abscess was 21 cases per 100,000 inhabitants in Hue City, Vietnam. The best current estimate by the World Health Organization is that *E. histolytica* infection results in 34 to 50 million symptomatic cases each year worldwide and as many as 100,000 deaths.

In the United States, amebiasis is the third most common parasitic infection after giardiasis and cryptosporidiosis (1.2 cases/100,000 U.S. population). Most cases in industrialized countries occur in travelers to and immigrants from endemic regions as well as in institutionalized individuals. In returning travelers, diarrhea is the predominant reason for a patient to visit a physician, and amebiasis is the second most common cause of diarrhea in returning travelers. Previously reported high rates of *E. histolytica* infection in homosexual men in the United States actually reflect a high prevalence of *Entamoeba dispar* infection in this population. In contrast, in Asia, amebiasis is more frequently an initial symptom of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome because of the common risk for acquisition of both HIV infection and amebiasis through the sexual practices of men who have sex with men. The typical patient with an amebic liver abscess in the United States is a 20- to 40-year-old Hispanic male immigrant. Several groups are at increased risk for severe amebiasis, including the very young or old, malnourished persons, pregnant women, and patients treated with corticosteroids.

PATHOBIOLOGY

Killing of host cells is required for invasion of the intestine by the parasite. The process of host cell destruction has been experimentally separated into sequential steps of adherence, contact-dependent cytotoxicity, followed finally by phagocytosis of the host cell corpse. The initial contact of parasite to host is mediated by the parasite's galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, which binds to carbohydrate determinants on the host's intestinal epithelium. Human cells die by apoptosis induced by *E. histolytica*, a process that requires attachment of the Gal/GalNAc lectin to a host cell's receptor, as well as the parasite's acid intracellular vesicles, which may serve as delivery vehicles for an amebic pore-forming protein. *E. histolytica* initiates apoptosis in host cells by directly activating the host cell's distal apoptotic machinery; caspase 3 is activated within minutes of *E. histolytica* adherence, a caspase 3 inhibitor blocks *E. histolytica* killing, and caspase 3–deficient or bcl-2–overexpressing mice are resistant to amebic infection. Recognition and ingestion of the apoptotic host cell's corpse are required for colonic infection by the parasite, and multiple ligands and receptors are involved, including the Gal/GalNAc lectin, a phosphatidylserine receptor, serine-rich *E. histolytica* protein, and collectins. After ingestion of the corpse of the host cell, additional parasitic factors participate in invasion into the intestinal mucosa. For example, *E. histolytica* encodes at least 44 cysteine proteinase genes that have been implicated in degradation of colonic mucin glycoproteins; digestion of extracellular matrix, hemoglobin, and villin; and inactivation of interleukin-18 (IL-18).

The innate immune response to amebic infection includes activation of the alternative complement pathway, with C3a and C5a recruiting neutrophils to the site of infection but with amebae resisting killing by the membrane attack complex through the Gal/GalNAc lectin. In the murine model of intestinal amebiasis, innate resistance is conferred by nonhematopoietic cells, thus suggesting importance of the epithelial production of cytokines such as tumor necrosis factor-α (TNF-α), IL-1α, IL-6, IL-8, growth-related oncogene-α (GROα), and granulocyte-macrophage colony-stimulating factor. Neutrophils are the earliest innate cellular immune response (within 1 to 2 days) for both intestinal and hepatic amebiasis. Depletion of neutrophils with anti–Gr-1 neutralizing antibody in a murine model results in exacerbated amebic hepatic and intestinal disease. Macrophages and T lymphocytes are also recruited by day 3 of an infection. Macrophages acquire amebicidal activity after in vitro stimulation with interferon-γ (IFN-γ), TNF-α, or colony-stimulating factor 1. Natural killer cells may be important in part as a source of IFN-γ, as well as infiltrating mast cells for their ability to contribute to the innate immune response by the production of IL-6 and TNF-α.

The acquired immune response reflects the opposing roles of IL-4 and IFN-γ in persistence and clearance of amebic infection, respectively. Inbred mice of the CBA strain are susceptible to intestinal amebiasis and develop a rapid T_H2 phenotypic immune response, and this response is deleterious insofar as inhibition of IL-4 can convert the response to a healing IFN-γ response. Effective acquired immunity in humans is associated with both a systemic IFN-γ and a mucosal IgA response directed at the Gal/GalNAc lectin. Children with mucosal IgA against the Gal/GalNAc lectin were found to have 86% fewer new *E. histolytica* infections in the following year. Similarly, the risk for amebiasis was 50% lower in children who were in the 50th percentile and above for the production of IFN-γ by peripheral blood mononuclear cells stimulated with soluble amebic antigen. In contrast, there is an association between higher TNF-α production and *E. histolytica* diarrhea,[1] thus indicating that there is a fine line between a pro-inflammatory cellular immune response that is protective and one that is disease enhancing.

CLINICAL MANIFESTATIONS

Asymptomatic Intraluminal Amebiasis

The asymptomatic cyst-passing carrier state is the most common type of amebic infection. All *Entamoeba moshkovskii* and *E. dispar* infections and as many as 80% of *E. histolytica* infections are asymptomatic. Asymptomatically infected individuals represent a risk to the community because they are a source of new infections and a risk to themselves because 1 in 10 to 20 colonized individuals progress to symptomatic infection. The host has a bearing on whether infection is asymptomatic in that children heterozygous for the HLA class II DQB1*0601/DRB1*1501 haplotype have been found to be protected from symptomatic infection with amebiasis. In addition, certain genotypes of *E. histolytica* appear to be associated with the propensity for colonization as opposed to invasion.

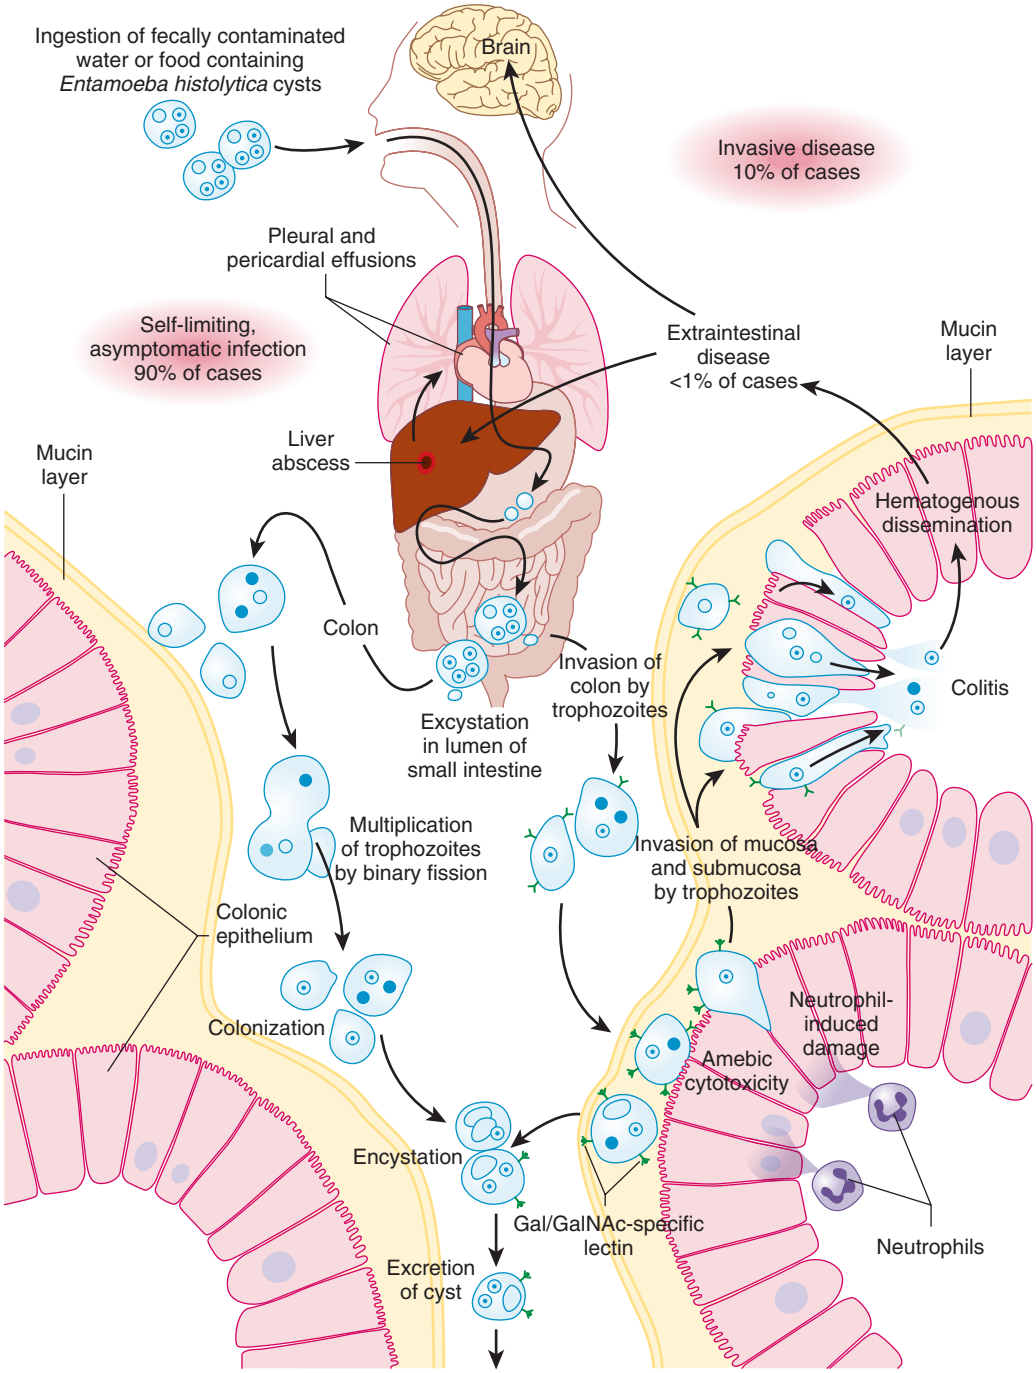

FIGURE 352-1. Life cycle of *Entamoeba histolytica*. Infection is normally initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, which results in a self-limited and asymptomatic infection. In some cases, however, adherence to and lysis of the colonic epithelium, mediated by the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular protection at the site of invasion. Once the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, probably include parasitic "quorum sensing" signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (Redrawn with permission from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med.* 2003;348:1565-1573.)

Amebic Diarrhea

Amebic diarrhea without dysentery is the most common amebic disease. It is defined as diarrhea in an *E. histolytica*–infected individual. There is no requirement for the presence of mucus or visible or microscopic blood in stool for the diagnosis of amebic diarrhea. In one community-based study of a cohort of preschool children in Bangladesh, the annual incidence of amebic infection, diarrhea, and dysentery was 45%, 9%, and 3%, respectively. The mean duration of amebic diarrhea was 3 days in one study. It causes approximately 2% of cases of diarrhea severe enough to warrant hospital evaluation in developing countries such as Bangladesh.

Amebic Dysentery or Colitis

Diarrhea with mucus or visible or microscopic blood in a patient with *E. histolytica* infection is the definition of amebic dysentery or colitis. Approximately 15 to 33% of patients with *E. histolytica* diarrhea also have amebic dysentery. The onset of symptoms is typically gradual during a period of 3 or 4 weeks after infection, with abdominal tenderness and increasingly severe diarrhea being the primary complaints. Patients with bacterial causes of dysentery usually have only 1 or 2 days of symptoms. Surprisingly, fever is present in only a minority of patients with amebic colitis. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop

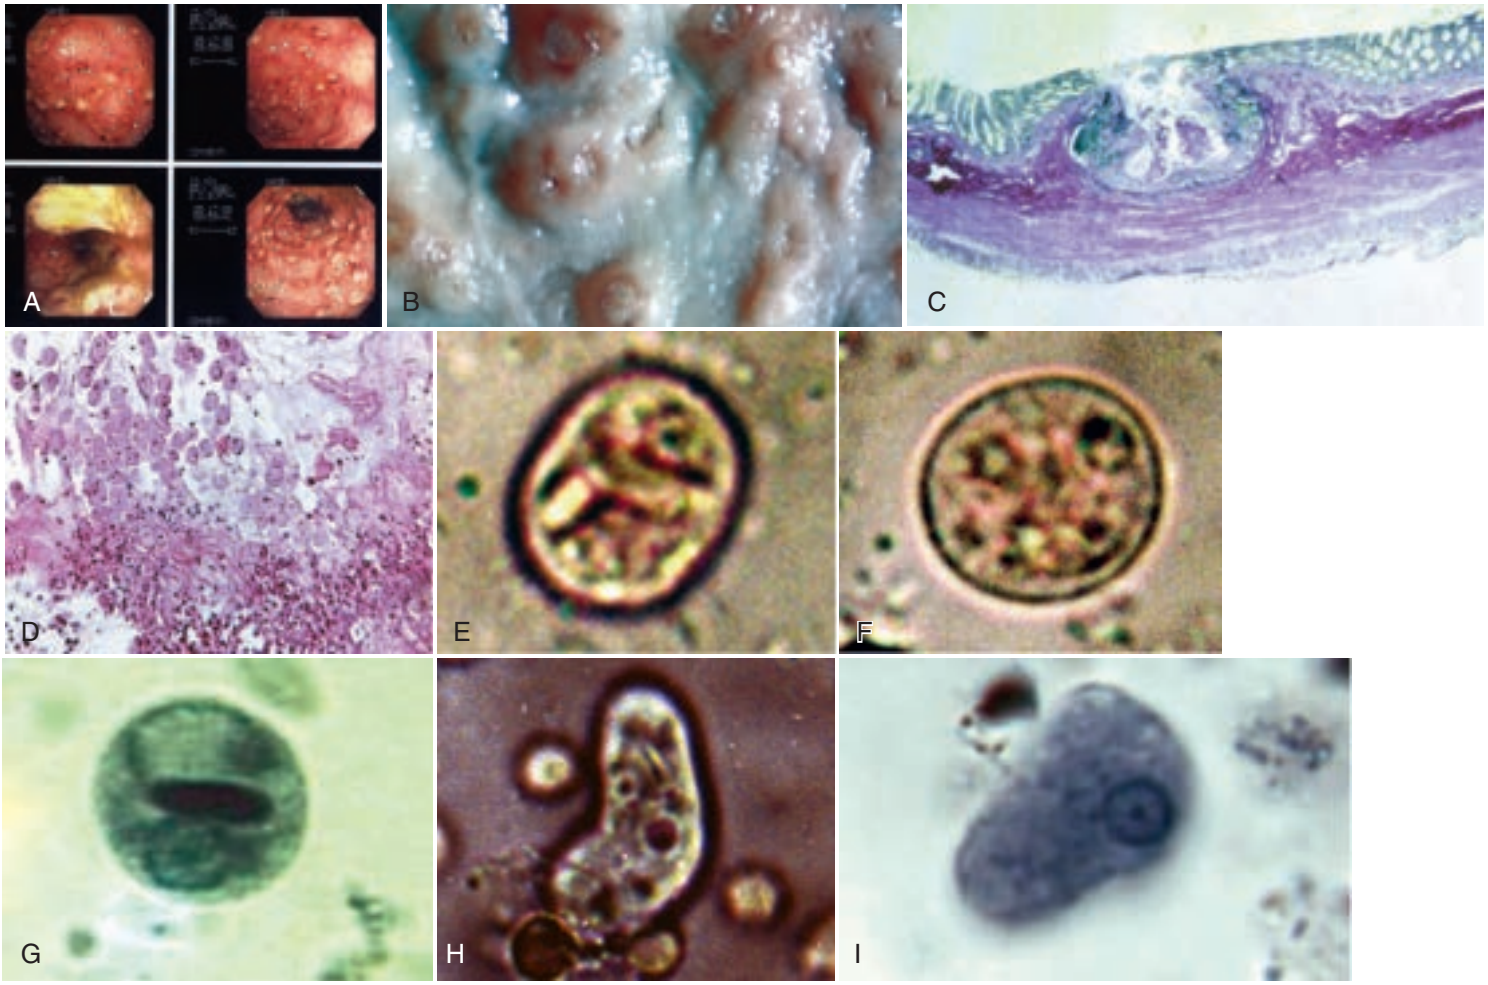

FIGURE 352-2. **Endoscopic and pathologic features of intestinal amebiasis. rapidly (Fig. 352-2). Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requiring surgical intervention) and ameboma (granulation tissue in the colonic lumen mimicking colon cancer in appearance).[2]

Amebic Liver Abscess

Amebic liver abscess is 10 times as common in men as in women and is unusual in children. The typical patient with an amebic liver abscess in the United States is an immigrant from an endemic area, a man aged 20 to 40 years with fever, right upper quadrant pain, leukocytosis, abnormal serum transaminase and alkaline phosphatase levels, and a defect seen on hepatic imaging studies.[3] Most patients have 2 to 4 weeks of prior fever, cough, and abdominal pain in the right upper quadrant or epigastrium. Involvement of the diaphragmatic surface of the liver may lead to right-sided pleural pain or referred shoulder pain and an elevated right hemidiaphragm seen on chest radiography (Fig. 352-3). Hepatomegaly with point tenderness over the liver, below the ribs, or in the intercostal spaces is a typical finding.

If a space-filling defect in the liver is observed, the differential diagnosis includes (1) amebiasis (most common in men with a history of travel to or residence in a developing country), (2) pyogenic or bacterial abscess (particularly suspected in women, patients with cholecystitis, the elderly, individuals with diabetes, and patients with jaundice), (3) echinococcal abscess (which would be an incidental finding because echinococcal abscess should not cause pain or fever), and (4) cancer. Most patients with amebic liver abscess will have detectable circulating antigen in serum as well as serum antiamebic antibodies.

In children, abdominal pain is reported infrequently with amebic liver abscess. More commonly, high fever, abdominal distention, irritability, and tachypnea are noted. Some of these children are admitted to the hospital with fever of unknown origin. Hepatomegaly occurs frequently, but elicitation of hepatic tenderness is not well documented. In one report, four of five children younger than 5 years died of amebic liver abscess because the diagnosis was not suspected.

Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to the pleura or pericardium and brain abscess. Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium, but it may also be caused by extensive hepatic damage and liver failure.

Other Extraintestinal Infections

Thoracic amebiasis is the most common type of extra-abdominal amebiasis after liver abscess and occurs in about 10% of patients with amebic liver abscess. It develops by direct extension from the liver. Pericardial amebiasis is the next most common form of extraintestinal involvement and may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or from extension of the right-sided pleural amebiasis. Cerebral amebic abscesses have been found in about 0.5 to 5% of patients with amebic liver abscess. In one series of 18 patients with proven cerebral amebiasis, findings on the initial neurologic examination were normal in 13. Other foci of infection are rare, but amebic rectovesical fistula formation and involvement of the pharynx, heart, aorta, and scapula have been reported. Cutaneous infection may arise from trophozoites emerging from the rectum.

DIAGNOSIS

Diagnosis of amebiasis is best accomplished by the combination of serology and identification of the parasite in feces or at extraintestinal sites of invasion

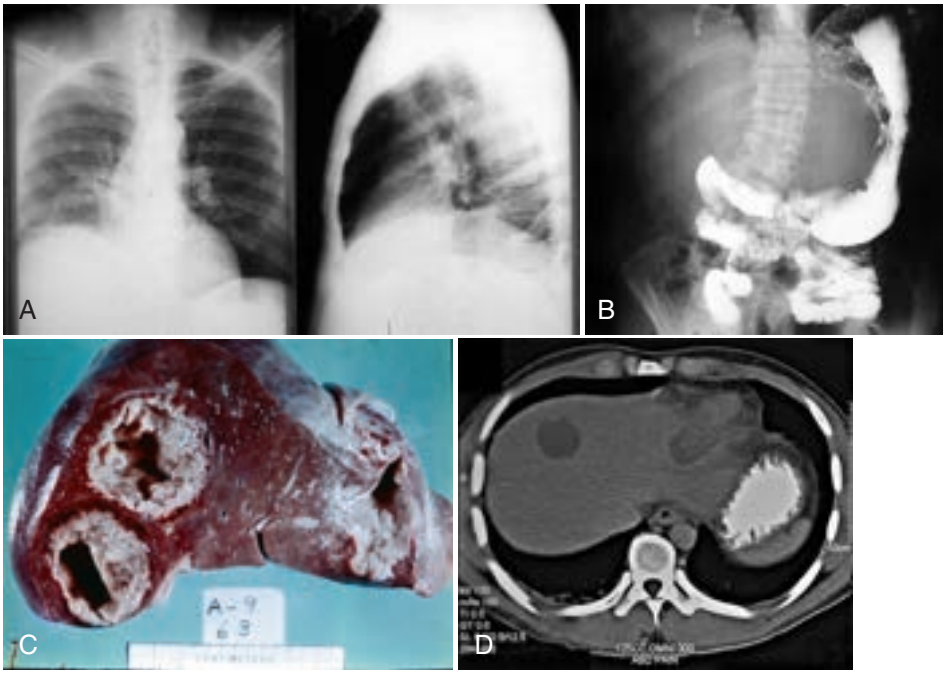

FIGURE 352-3. Radiographic and pathologic features of extraintestinal amebiasis. A, Left posteroanterior and right lateral chest radiographs in a patient with amebic liver abscess. The findings include an elevated right hemidiaphragm and evidence of atelectasis. **B,** Luminal narrowing revealed by barium enema examination in a patient with an ameboma. **C,** Two abscesses in the right lobe and one abscess in the left lobe of a patient with amebic liver abscess. **D,** Abdominal computed tomography showing one abscess in the right lobe and one abscess in the left lobe in a patient with amebic liver abscess. TABLE 352-1 SENSITIVITY OF TESTS FOR DIAGNOSIS OF AMEBIASIS

TEST	COLITIS	LIVER ABSCESS
Microscopy: stool	25-60%	10-40%
Stool antigen detection	80%	≈40%
Serum antigen detection	65%	>95%
Microscopy: abscess fluid	N/A	≤20%
Real-time PCR	>95%	>95%
Serologic testing (indirect hemagglutination)		
Acute	70%	70-80%
Convalescent	>90%	>90%

N/A = not available; PCR = polymerase chain reaction.
Modified from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med.* 2003;348:1565-1573.

(such as pus obtained by fine needle aspiration of a liver abscess).[4] Examination of stool for ova and parasites should *not* be used to diagnose amebiasis (Table 352-1). The most sensitive diagnostic approach is the combined use of *E. histolytica*–specific antigen detection or polymerase chain reaction plus serology.

TREATMENT (also see Chapter 344)

Rx

Therapy for invasive infection differs from that for noninvasive infection, which may be treated with paromomycin (Table 352-2). Invasive infections require treatment with nitroimidazoles, particularly metronidazole, tinidazole, secnidazole, or ornidazole. For amebic colitis, tinidazole reduces treatment failure rates and adverse effects compared with metronidazole. In the rare case of fulminant amebic colitis, it is prudent to add broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum. Parasites persist in up to half of the patients who are treated with a nitroimidazole, so treatment should be followed with paromomycin or the second-line agent

TABLE 352-2 DRUG THERAPY FOR TREATMENT OF AMEBIASIS

DRUG	ADULT DOSAGE	SIDE EFFECTS
AMEBIC LIVER ABSCESS		
Metronidazole	750 mg PO tid × 10 days	Primarily GI side effects: anorexia, nausea, vomiting, diarrhea, abdominal discomfort, or unpleasant metallic taste Disulfiram-like intolerance reaction to alcoholic beverages Neurotoxicity, including seizures, peripheral neuropathy, dizziness, confusion, irritability
or		
Tinidazole	2 g PO once daily × 5 days	Primarily GI side effects and disulfiram-like intolerance reaction to alcoholic beverages as for metronidazole
Followed by a luminal agent		
Paromomycin	30 mg/kg/day PO in 3 divided doses per day × 5-10 days	Primarily GI side effects: diarrhea, GI upset
or		
Diloxanide furoate	500 mg PO tid × 10 days	Primarily GI side effects: flatulence, nausea, vomiting Pruritus, urticaria
AMEBIC COLITIS		
Metronidazole	750 mg PO tid × 5-10 days	Same as for amebic liver abscess
Plus a luminal agent (same as for amebic liver abscess)		
ASYMPTOMATIC INTESTINAL COLONIZATION		
Treatment with a luminal agent as for amebic liver abscess		

GI = gastrointestinal.
Modified from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med.* 2003;348:1565-1573.

TABLE 352-3 FREE-LIVING AMEBAE

ORGANISM	DISEASE	EPIDEMIOLOGY	DIAGNOSIS	CLINICAL COURSE	THERAPY
Naegleria fowleri	Primary amebic encephalitis	Warm freshwater exposure	CSF wet mount for ameba, PCR	Death within 1-2 weeks of onset	Amphotericin B
Acanthamoeba spp	Keratitis	Corneal trauma, usually from contact lens	Corneal scraping for amebae and cysts	Subacute	Polyhexamethylene biguanide, chlorhexidine, propamidine, hexamidine
Acanthamoeba spp	Granulomatous amebic encephalitis	Immunodeficient (organ transplants, HIV/AIDS)	Biopsy of brain or skin abscess—IFA or PCR	Subacute	Combination therapy with pentamidine, an azole (fluconazole or itraconazole), flucytosine, and sulfadiazine
Balamuthia mandrillaris	Granulomatous amebic encephalitis	Immunodeficient but also immunocompetent	Biopsy of brain	Subacute	Combination therapy with flucytosine, pentamidine, fluconazole, and sulfadiazine plus either azithromycin or clarithromycin
Sappinia	Amebic encephalitis	Single patient was not immunodeficient			Azithromycin, pentamidine, itraconazole, flucytosine

AIDS = acquired immunodeficiency syndrome; CSF = cerebrospinal fluid; HIV = human immunodeficiency virus; IFA = indirect fluorescent antibody; PCR = polymerase chain reaction.
Modified from Visvesvara GS, Moura H, Schuster FL. Pathogenic and opportunistic free-living amoebae: *Acanthamoeba* spp, *Balamuthia mandrillaris*, *Naegleria fowleri*, and *Sappinia diploidea*. *FEMS Immunol Med Microbiol*. 2007;50:1-26.

diloxanide furoate to cure luminal infection. High-throughput drug screening has identified auranofin, a Food and Drug Administration–approved drug used for treatment of rheumatoid arthritis, as a potentially active agent against *E. histolytica*. Drainage of a liver abscess should be considered in patients who do not show a clinical response to drug therapy within 5 to 7 days or in those with a high risk for rupture of the abscess, as defined by a cavity with a diameter of greater than 5 cm or by the presence of lesions in the left lobe. Percutaneous needle aspiration or catheter drainage is the procedure of choice for drainage of a liver abscess. Surgical intervention is occasionally required for drainage of a liver abscess, acute abdomen, gastrointestinal bleeding, or toxic megacolon.

PREVENTION

The feasibility of prevention by vaccination with the parasite's Gal/GalNAc lectin is supported by substantial data from human, animal model, and in vitro studies.[5] This vaccine is in the late stages of preclinical development for the prevention of amebiasis in infants and children in the developing world. Provision of sanitation and clean water and safe sexual practices to prevent fecal-oral transmission are of great importance but not universally effective because of the low infectious dose and chlorine resistance of the cyst.

PROGNOSIS

Therapy for amebiasis is highly effective. Drug resistance is not reported.

FREE-LIVING AMEBAE

Rare infections of the central nervous system can be seen with infection by free-living amebae of the genera *Naegleria*, *Balamuthia*, *Acanthamoeba*, and *Sappinia*. *Naegleria fowleri* is the agent of primary amebic meningoencephalitis, which occurs in previously healthy children and young adults who have swum in fresh water 2 to 5 days before the onset of meningoencephalitis. Cerebrospinal fluid has a polymorphonuclear predominance, and motile amebae can be seen in a wet mount of cerebrospinal fluid. The disease is relentlessly progressive to death in most patients. In one case of successful treatment, a combination of intrathecal and intravenous amphotericin B and miconazole and oral rifampin was used. *Acanthamoeba* can cause keratitis[6] in individuals with corneal injuries (usually from contact lens use) as well as granulomatous amebic encephalitis in the immunocompromised. Granulomatous amebic encephalitis can also be caused by *Balamuthia* and *Sappinia*; it is usually associated with focal neurologic findings and has a subacute course (Table 352-3).

REVIEW QUESTIONS

1. Individuals at increased risk for amebiasis include all *but*

A. Diabetics
B. Pacific Islanders
C. Men who have sex with men
D. Residents of institutions for the mentally retarded
E. Children in the developing world

Answer: A All of the other answers are risk factors for amebiasis, with children in low-income settings in the developing world at highest risk.

2. Which statement is *false* for the parasite *Entamoeba dispar*?

A. It is as prevalent as *Entamoeba histolytica* worldwide.
B. It is a cause of amebic colitis and liver abscess.
C. It is more common than *E. histolytica* in North America.
D. It is identical in appearance to *E. histolytica* on stool ova and parasite examination.
E. It is fecal-orally transmitted.

Answer: B *E. dispar* is not known to cause disease and is more common in temperate climates than the identical-appearing *E. histolytica*.

3. Which statement is true for the diagnosis of intestinal amebiasis?

A. Serology is positive acutely in more than 90% of cases.
B. Test results for occult blood in stool are positive in most.
C. Stool ova and parasite examination is sensitive and specific.
D. *E. histolytica*–specific stool antigen detection test is more than 80% sensitive for the diagnosis.

Answer: D Stool ova and parasite examination is sensitive and specific. Serologic testing by indirect hemagglutination is positive during acute illness in no more than 70% of cases (but >90% in convalescence). Blood in the stool occurs in virtually all patients with amebic colitis, but stools do not have to be positive for occult blood in amebic diarrhea. The stool ova and parasite examination is neither sensitive nor specific for amebiasis.

4. Which statement is false about extraintestinal amebiasis?

A. Amebic liver abscess is much more common in men than in women and rare in children.
B. Amebic brain abscess is seen only in patients with amebic liver abscess.
C. Amebic liver abscess can be treated without drainage in many cases.
D. Bacterial superinfection of amebic liver abscess is common.

Answer: D For unclear reasons, bacterial superinfection of an amebic liver abscess is rare.

353

BABESIOSIS AND OTHER PROTOZOAN DISEASES

SAM R. TELFORD III AND PETER J. KRAUSE

BABESIOSIS

Babesiosis is a tick-borne malaria-like disease caused by sporozoan parasites of the genus *Babesia*.

EPIDEMIOLOGY

Three worldwide epidemiologic patterns are apparent. The first involves the rodent-maintained *Babesia microti*, which is a species complex distributed across the Holarctic. On average, more than 1000 cases of *B. microti* babesiosis have been reported from the northeastern United States and upper Midwestern states from 2011 through 2013, the first 3 years that human babesiosis has been designated as a notifiable infectious disease by the Centers for Disease Control and Prevention (CDC). By comparison, about 30,000 Lyme disease cases are reported each year in the United States. The vector for *B. microti* is the same as that for Lyme disease (Chapter 321), the deer tick, *Ixodes dammini*, also known as northern populations of *I. scapularis*. Indeed, concurrent babesiosis and Lyme disease is common. Immune-intact as well as immunocompromised individuals are at risk. Within the last decade, *B. microti* has been increasingly reported in an expanded distribution from the original foci in coastal New England and the Upper Midwest, and it is now possible that babesiosis cases may be found wherever Lyme disease is intensely zoonotic. In addition, cases of *B. microti* or *B. microti*–like babesiosis have been reported from Australia, China, Germany, Japan, and Taiwan; the vectors have not been definitively identified.[1] The second pattern is represented by fewer than 50 cases of babesiosis due to *Babesia divergens*, *B. divergens*–like, or closely related species (e.g., *Babesia venatorum* or EU1) that have been reported from Europe. Almost all have been in splenectomized patients residing in sites where European castor bean ticks (*Ixodes ricinus*) and deer are common.[2] A few cases have been described in the United States and the Canary Islands. The third pattern of babesiosis involves sporadic cases due to diverse *Babesia* spp. These include a *Babesia duncani* (WA-1) and CA-type parasites of the western United States; a *B. divergens*–like species (MO-1); a *Babesia motasi*–like infection (KO-1) in Korea; and unidentified

Babesia spp from Colombia, Egypt, India, Mexico, and South Africa. There are at least 100 described *Babesia* spp from mammals and birds, and these hemoparasites are common animal infections on all continents. With few exceptions, *Babesia* spp are transmitted by ixodid ticks. Thus, wherever humans are intensely exposed to hard-bodied ticks, babesiosis should be part of a differential diagnosis for a patient presenting with fever and hematologic abnormalities.

Although the known zoonotic tick vectors (*I. dammini, I. ricinus*) have marked seasonal periods of activity (May to August) and the majority of reported cases are acquired during these times, babesiosis may be diagnosed at any time of the year. More than 150 cases of transfusion-acquired babesiosis due to *B. microti* and three due to *B. duncani* have been reported. The actual number of cases is thought to be much greater. *B. microti* is currently the most commonly reported transfusion-transmitted pathogen in the United States, and the number of such cases is increasing, including those ending in death.[3] Cases occur throughout the year, and about 10% of cases occur in nonendemic areas because *Babesia*-infected blood is exported to nonendemic areas or persons become infected in endemic areas and subsequently donate blood in nonendemic areas. A few cases of transplacentally transmitted babesiosis have been reported.

PATHOBIOLOGY

The pathophysiology of *Babesia* infection is directly related to the development of parasitemia. Peripheral blood parasitemias of 70% or greater have been reported, although most cases sustain parasitemias on the order of 0.5 to 5%. In hamsters infected by inoculation of a human-derived *B. microti* strain, intravascular hemolysis develops as the parasitemia rises and results in profound anemia. The hematocrit may fall to less than 20%. During this acute phase of disease, there is extramedullary hematopoiesis and hyperplasia of the splenic red pulp. Livers of infected hamsters contain hypertrophied Kupffer cells, many with ingested parasitized erythrocytes but little hemoglobin breakdown products. The proximal convoluted tubules of the kidneys contain abundant hemosiderin, an observation consistent with the occurrence of marked intravascular hemolysis.

Excessive production of pro-inflammatory cytokines seems to best explain the most common clinical manifestations, which include fever, sweats, chills, headache, myalgia, nausea, vomiting, diarrhea, and pallor. Administration of recombinant tumor necrosis factor (TNF) to human volunteers induces most of the symptoms of babesiosis and malaria. Such findings are not seen when erythrocyte lysis is due to noninfectious causes, which suggests that the release of merozoites serves as a trigger for the pro-inflammatory cascade. Elevated serum concentrations of TNF as well as of interferon-γ, interleukins 2 and 6, E-selectin, vascular cell adhesion molecule 1, and intracellular cell adhesion molecule 1 are detected during the acute phase of human *B. microti* infection and return to baseline within 3 months after resolution of infection.

Severe illness caused by infection with *Babesia* includes a complex array of metabolic abnormalities and organ dysfunction. Pulmonary disease is the most common complication in people experiencing severe *Babesia* infection, with up to 20% of patients suffering from noncardiogenic pulmonary edema. Pro-inflammatory cytokines appear to mediate the pulmonary complications of *Babesia* infection, at least in part. TNF and interferon-γ mRNA are upregulated in the lungs of *B. duncani*–infected mice, whereas TNF-knockout mice are less likely to die of fulminating *B. duncani* infection than are those with an intact TNF response. It is also likely that lung and other end-organ disease is mediated, at least in part, by vascular stasis, which has been described in the lungs of hamsters and mice infected with *B. duncani*.

CLINICAL MANIFESTATIONS

About a quarter of *B. microti* infections in adults and half of those in children are subclinical. This estimate is derived from an epidemiologic study that determined the frequency of people who seroconverted during the course of the summer transmission season but reported no illness, coupled with a careful accounting of symptomatic cases. Most people experience a mild to moderate illness lasting about a week. There is a gradual onset of malaise, anorexia, fatigue, fever (temperature as high as 40° C), sweats, and myalgia. Nausea, vomiting, headache, shaking chills, emotional lability, depression, hemoglobinuria, and hyperesthesia also have been reported. Findings on physical examination consist of fever, pallor, splenomegaly, and hepatomegaly. Laboratory abnormalities include anemia, thrombocytopenia, and leukopenia. Parasitemia generally ranges from barely detectable on blood smear to 5% in previously healthy people but may reach 85% in asplenic and other immunocompromised patients. Lactate dehydrogenase, bilirubin, and transaminase levels may be elevated in more severe cases. Persistent relapsing illness may occur in highly immunocompromised people who fail to clear the infection for months or more than a year despite multiple courses of antibiotics. The case-fatality rate for *B. microti* babesiosis has been estimated to be 6 to 9% in hospitalized patients but may be as high as 20% in immunocompromised hosts, including those who acquire the infection through blood transfusion. Severe babesiosis usually occurs only in people with asplenia, malignant disease, coinfection with human immunodeficiency virus (HIV), immunosuppressive treatment, or age younger than 2 months or older than 50 years.

Cases of babesiosis caused by species other than *B. microti* tend to be severe, at least in part because they are primarily reported in immunocompromised patients. Virtually all European patients experiencing *B. divergens* infection have been splenectomized, and about a third of the patients died. In these patients, there was an acute onset of illness with hemoglobinuria, a persistent nonperiodic high fever (temperature of 40° to 41° C), shaking chills, intense sweats, headaches, and myalgia as well as lumbar and abdominal pain. Vomiting and diarrhea may occur. Pulmonary, renal, or liver failure may develop rapidly. In fatal cases, patients become comatose with multiorgan failure. *B. duncani*, *B. venatorum*, and *B. divergens*–like infections also have often been reported in immunocompromised hosts with a similarly severe course of illness.

DIAGNOSIS

The diagnosis of babesiosis is based on epidemiologic and clinical findings and confirmed by laboratory testing. Given clinical findings consistent with babesiosis, the diagnosis may be confirmed by examination of a Giemsa-stained thin blood smear for the presence of parasites within erythrocytes. In an immunocompromised patient, parasitemias are likely to exceed one infected cell per oil immersion field and thus are quickly detected. For *B. microti* babesiosis (Fig. 353-1), examination of a slide for 10 minutes or as many fields as needed to tally 200 leukocytes (that are not infected but serve as a marker for effort) and repeated smears performed twice a day may be required. Standard Romanowsky stains (Giemsa, Wright) with malaria protocols are optimal. Artifactual inclusions are limited mainly to stain precipitates (which can be determined by their presence in the plasma spaces between cells), Howell-Jolly or Heinz bodies (Chapter 157), or platelets superimposed on erythrocytes, which always have a light colored halo when visualized this way. *Babesia* spp have clearly defined chromatin with a lighter-colored cytoplasm (Fig. 353-2A). They may be mistaken for early malarial trophozoites. Neither malarial nor babesial rings have hemozoin (malarial pigment), so this is not a good feature to distinguish between the two. Paired piriform parasites, arranged in a *v*, are suggestive of *B. divergens* or *B. divergens*–like infection (Fig. 353-2B). Rings of all sizes may be seen in all species. Multiple parasites may frequently be seen in single erythrocytes, as well as clumps of extracellular parasites. Tetrad forms (Fig. 353-2C) and Maltese cross forms (Fig. 353-2D) are diagnostic but are rarely seen in *B. microti* babesiosis. They seem to be more common with *B. duncani* or CA-type infections.

Polymerase chain reaction (PCR) assays are an important adjunct to blood smears. PCR is usually more sensitive than blood smears in cases in which parasitemias are sparse. Real-time PCR assays performed in-house would

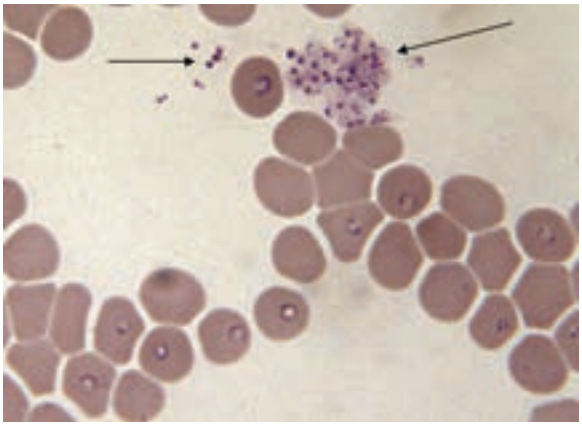

FIGURE 353-1 ***Babesia microti*.** Human infection, Nantucket Island. Predominance of ring forms with a cluster of extraerythrocytic parasites (*arrow*) free in the plasma.

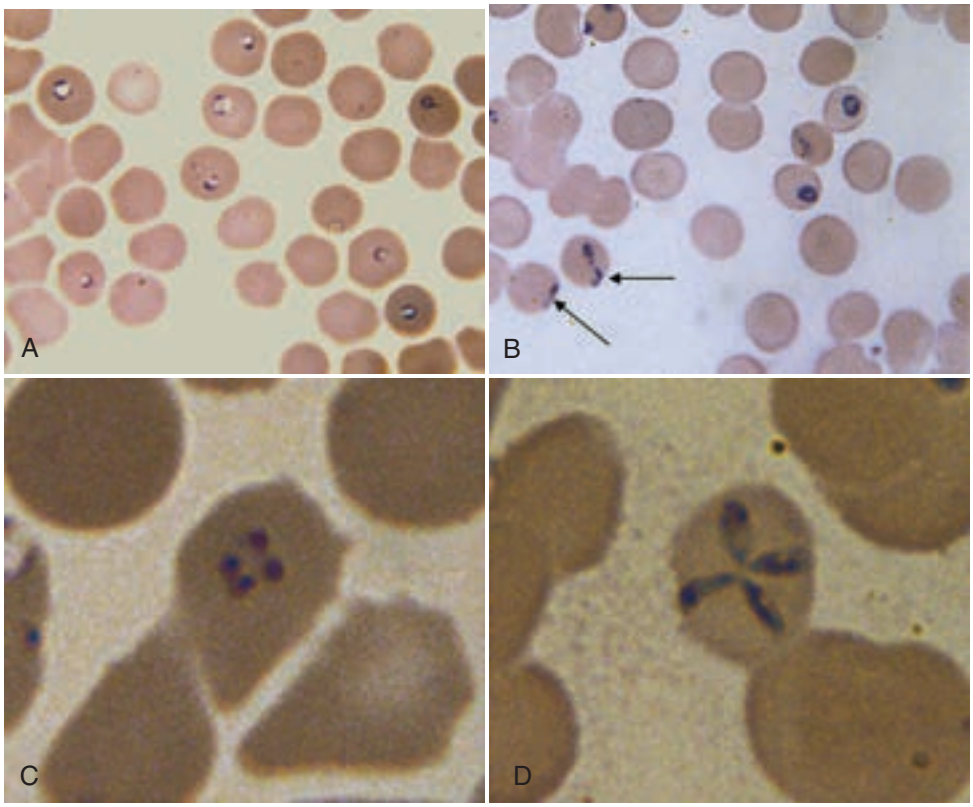

FIGURE 353-2. Diagnosis of *Babesia* infection. A, Typical thin-film field demonstrating ring forms of *B. microti* with vacuole or "whitish" cytoplasm demarcated by a dark-staining, defined chromatin. **B,** *B. Divergens*–like (MO-1) with robust rings; accolé form and paired piriform parasites are marked by *arrows*. **C,** Tetrad forms of *B. microti*. **D,** MO-1, classic Maltese cross. (Microscope slide from human case of MO-1 kindly provided by Dr. J. F. Beattie, Department of Pathology, The Medical Center, Bowling Green, Ky).

provide confirmation nearly as quickly as microscopy with the added advantage of increased sensitivity.[4] As with many molecular diagnostic assays, use of PCR for babesia (either conventional or real-time quantitative) is limited by false positives, validation of experimental assays, and insurance reimbursement. PCR sequencing, performed by collaborating research laboratories, is extremely valuable in retrospectively identifying the species of *Babesia* when the identity is not clear.

Serologic testing is useful for confirming *B. microti* infection. The indirect immunofluorescence test, using antigen from infected hamster red cells, is sensitive and specific and is currently the serologic method of choice. Analysis of paired acute and convalescent serum samples is most useful for a confirmation of *B. microti* infection. The presence of parasite-specific IgM may indicate that the patient has an acute infection even in the absence of readily demonstrable parasitemia. Serology is not generally useful for *B. divergens* babesiosis, given its fulminant natural history. Because parasitemia occurs before an antibody response and the doubling time of *B. divergens* can be as short as 8 hours, treatment needs to be initiated immediately on the basis of clinical suspicion and initial laboratory results.

The known vectors for human babesiosis are ticks that also transmit the agents of Lyme disease, human granulocytic anaplasmosis, *Borrelia miyamotoi* infection, *Ehrlichia muris*–like infection, and tick-borne encephalitis virus. Thus, coinfections should be considered in all patients with babesiosis. Acute illness in patients coinfected with Lyme disease and babesiosis is more severe and more persistent than in patients experiencing Lyme disease alone.

TREATMENT

Rx

Therapy for mild to moderate *B. microti* cases should consist of the combination of atovaquone (750 mg orally twice daily for 7 to 10 days) and azithromycin (500 to 1000 mg initial dose followed by 250 mg orally daily for 7 to 10 days; for immunocompromised hosts, 600 to 1000 mg orally daily for 7 to 10 days). A prospective randomized trial demonstrated that patients treated with atovaquone and azithromycin cleared parasitemia as effectively as did those receiving clindamycin and quinine and with fewer side effects. For severe babesiosis, a 7- to 10-day course of the combination of clindamycin (either 300 to 600 mg every 6 hours intravenously or 600 mg orally every 8 hours) and quinine (650 mg orally every 8 hours) should be used. The pediatric regimen is clindamycin, 7 to 10 mg/kg given every 6 to 8 hours (maximum of 600 mg/dose) and quinine 8 mg/kg given every 8 hours orally (maximum of 650 mg per dose).

Treatment may occasionally fail in high-risk patients or in those who must discontinue quinine because of side effects, such as severe tinnitus and gastrointestinal distress. Multiple courses of treatment for a prolonged duration may be required to clear parasitemia in immunocompromised patients; combination therapy should be used that may include two or more of the following antimicrobials: artemisinin, atovaquone, azithromycin, clindamycin, doxycycline, atovaquone-proguanil (Malarone), pentamidine, quinine, and trimethoprim-sulfamethoxazole. Once an effective combination is identified, it should be continued for at least 6 weeks and 2 weeks beyond the time when *Babesia* can no longer be visualized on blood smear or blood samples become PCR negative.

Exchange transfusion should be considered in severely ill patients with parasitemias in excess of 10%, evidence of severe hemolysis, or organ compromise. In particularly severe babesiosis cases, partial or complete blood exchange transfusion (1 to 3 blood volumes) should be undertaken, in addition to treatment with clindamycin and quinine.

PREVENTION

Prevention depends on reducing the risk for tick bites. Immunocompromised individuals should be especially careful to use personal protection and may even consider avoiding highly endemic sites such as coastal New England and Long Island during May through July, when risk is the greatest.[5] Use of repellants such as DEET or application of permethrin to clothing will greatly reduce tick attachment. Such products should be applied to shoes, socks, and trouser cuffs. Wearing light-colored long pants and tucking the cuffs into socks will also help prevent ticks from gaining access to attachment sites. Daily examination for attached ticks should be performed; the best way to do this is to feel for new bumps on a soapy body in the shower. Any attached

ticks should be promptly removed by simple traction, which is best accomplished with the use of tweezers. As with the agent of Lyme disease, ticks must be attached at least 36 to 48 hours before a sufficient inoculum of *Babesia* sporozoites is delivered. Community-level prevention should focus on public education about the risks of tick-borne infection, reducing habitat for ticks (brush removal and landscaping around yards), or reducing the reproductive hosts for the tick. Deer reduction will reduce the abundance of the deer tick vector for *B. microti* babesiosis. Currently, screening of blood donations for *Babesia* spp consists only of targeted questions about a history of previous *Babesia* infection, but laboratory screening methods are being developed.

PROGNOSIS

Death may occur in patients with severe babesiosis, but other long-term sequelae have not been reported for patients who have been adequately treated. In most patients who complete a full treatment regimen, *B. microti* DNA becomes undetectable by PCR within 3 months. Infection does not imply protective immunity based on laboratory rodent models, although subsequent infections are limited in duration and intensity. Recrudescent infections have been reported, mainly in immunocompromised individuals.

MISCELLANEOUS ENTERIC PROTOZOA

The gastrointestinal and urogenital tracts may contain representatives of the four major groupings of protozoa (amebae, sporozoa, flagellates, and ciliates). Diarrhea and other lower gastrointestinal signs and symptoms may be caused by diverse protozoa. Specific clinical diagnosis is not possible; expert clinical parasitology support is required to determine whether an agent that has been detected in a stool sample is a pathogenic species.[6] Identification is necessary because treatment options differ by the agent. With the exception of *Trichomonas vaginalis* infection (sexually transmitted), all of the enteric protozoa are acquired by the ingestion of food or materials contaminated by human feces; a small subset may have extraintestinal manifestations. Given a shared mode of transmission (fecal-oral), demonstrating the presence of any one of these protozoa within a stool sample from a patient is justification for an intensified search for those that are recognized as clinically significant pathogens (*Entamoeba histolytica*, *Giardia lamblia/intestinalis*, *Cyclospora cayetanensis*, *Cystoisospora belli*, and *Cryptosporidium parvum/hominis*). Other protozoa, many of which morphologically resemble true pathogens, are commonly detected within stools of patients with lower gastrointestinal disturbances, but support for their role as etiologic agents is weak.

Cryptosporidiosis (Chapter 350), giardiasis (Chapter 351), and amebiasis (Chapter 352) are discussed in separate chapters. Trichomoniasis and coccidian enteritis are discussed here because they are relatively common infections.

Trichomoniasis

EPIDEMIOLOGY

Trichomonas vaginalis is among the most prevalent of all pathogenic protozoa and is one of the most common sexually transmitted infections in the United States and likely worldwide.[7] As many as 30% of female college students and 40% of pregnant Nigerian women were found to be infected. The highest incidence of infection occurs in women with multiple sexual partners and those with other sexually transmitted diseases (Chapter 285). *T. vaginalis* can also be passed from infected mothers to their newborn daughters, but it is seldom symptomatic in girls before menarche. The parasite is able to survive for some time in moist environments, and nonvenereal transmission, although uncommon, can occur. Trichomoniasis, like other sexually transmitted diseases, may increase the likelihood of transmission of HIV.

PATHOBIOLOGY

T. vaginalis, known colloquially as a flagellate, is classified in the phylum Metamonada and class Parabasalia along with another human pathogen, *Dientamoeba fragilis* (previously thought to be an ameba). The 10- to 15-µm-long trophozoites multiply by longitudinal binary fission on the epithelial surface of the vagina or urethra as well as in vaginal or urethral secretions and are thereby transmitted by sexual intercourse. No cyst form is known, and the trophozoites are easily killed by drying.

The parabasalids are a phylogenetic sister group to the class Eopharingia, which includes *Giardia* spp. The parabasalids lack mitochondria and are anaerobic; they all have a unique cellular organelle, the hydrogenosome, which is a relic of the mitochondrion and serves as the site of anaerobic pyruvate metabolism. A hemolysin is produced and may cause epithelial damage.

CLINICAL MANIFESTATIONS

Trichomoniasis is one of three common causes of vaginitis or vaginosis (along with bacterial vaginosis and vulvovaginal candidiasis). It is characterized by a thin gray to yellowish green frothy discharge; vulvovaginal erythema; ectocervical erythema or "strawberry cervix," observable mainly by colposcopy; pH higher than 4.5; increased presence of polymorphonuclear leukocytes; and a positive result of the whiff test, in which a foul fishy odor is intensified on addition of potassium hydroxide. The incubation period for trichomoniasis is 5 to 28 days. In addition to a frothy discharge, vaginitis can be accompanied by vulvovaginal irritation, dyspareunia, abdominal pain, and dysuria. Symptoms may worsen during menstruation. Population-based studies indicate that as many as half of *T. vaginalis* infections in women and the majority in men are asymptomatic. *T. vaginalis* can frequently be isolated from the male partners of infected women and can produce symptomatic urethritis. Urethral discharge is generally scant in these cases. Rarely, *T. vaginalis* is associated with epididymitis, superficial penile ulcerations that are usually located under the prepuce, or prostatitis.

DIAGNOSIS

The CDC guidelines (http://www.cdc.gov/std/treatment/2010/vaginal-discharge.htm#a2) state that all women with a sexually transmitted infection should be specifically tested for evidence of *T. vaginalis* infection, and HIV-positive women should be tested annually. In women, vaginal and urethral secretions should be examined. *T. vaginalis* is seen in wet mounts of vaginal secretions in approximately 60% of infected women, thus confirming the diagnosis. Live *T. vaginalis* have a twitching or tumbling motion in wet mounts, and polymorphonuclear leukocytes are usually present. Direct immunofluorescent antibody staining is more sensitive than wet mounts but technically more difficult. Culture is an even more sensitive method of diagnosis; commercial kits for culture are available, but the results are not available for 3 to 7 days. *T. vaginalis* is occasionally identified in Papanicolaou-stained smears; Giemsa stain may also be used (Fig. 353-3). For men, a wet mount of material from a platinum loop scraping of the anterior urethra reveals the organism in approximately half the cases. Prostatic massage before collection of urine for *Trichomonas* culture is a more sensitive diagnostic approach. *T. vaginalis* is not found in the gastrointestinal tract, and the presence of trichomonads in wet fecal mounts or stained fixed fecal smears (iron hematoxylin or trichrome) most likely represents the commensal *Pentatrichomonas* (formerly *Trichomonas*) *hominis*. Serology has limited clinical use because of issues of sensitivity and specificity and because evidence of exposure does not imply current disease. New modes of testing are becoming available and will eventually supplant microscopy. One Food and Drug Administration (FDA)–approved (and CLIA waived) point-of-care antigen assay (OSOM Trichomonas Rapid Test; Sekisui Diagnostics, Framingham, Mass) has

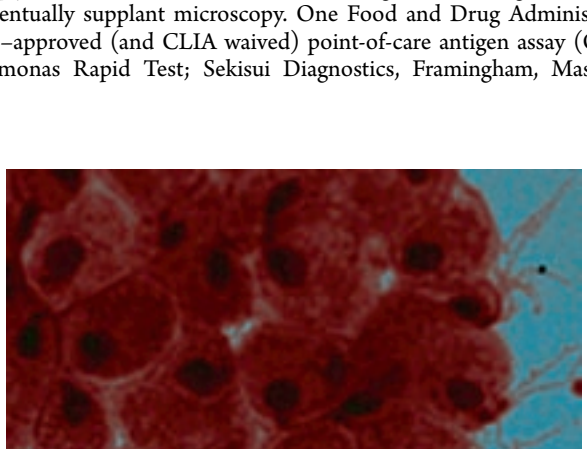

FIGURE 353-3. ***Trichomonas vaginalis*, Giemsa-stained smear of cultivated trophozoites.** (Bright-field microscopy, ×630. Scale bar is 15 µm.)

greater sensitivity and specificity in comparison with microscopy. The FDA has also cleared a single PCR-based assay (APTIMA *Trichomonas vaginalis* Assay; Hologic GenProbe, San Diego, Calif) with excellent sensitivity and specificity, but the assay requires specimens (swab samples) fixed in a proprietary solution.

TREATMENT (also see Chapter 344)

Rx

Tinidazole, a single 2-g oral dose in adults, or metronidazole, either as a single 2-g oral dose or 500 mg twice daily for 7 days, is the treatment of choice. Tinidazole is the better tolerated of the two. Single-dose therapy (metronidazole or tinidazole) ensures compliance of the patient but can produce nausea and a metallic taste, particularly with metronidazole. Both tinidazole and metronidazole have a disulfiram-like effect, and patients who consume alcohol within 24 hours of metronidazole or 72 hours of tinidazole may experience severe nausea, vomiting, and flushing. The use of tinidazole and metronidazole is relatively contraindicated during pregnancy, given the lack of well-controlled studies. Treatment failures with metronidazole are uncommon but well documented. HIV-positive women should be treated for 7 days with 500 mg of metronidazole because of frequent recrudescence with the single-dose therapy. Some instances of treatment failure in immune-intact women result from reinfection, others from poor compliance, but some are caused by metronidazole-resistant parasites. A repeated course of metronidazole (2 g orally daily for 5 days) may be tried. If patients remain refractory to appropriate treatment, metronidazole sensitivity can be tested by the CDC (available at www.dpd.cdc.gov/dpdx/HTML/DiagnosticProcedures.htm).

PREVENTION

Condoms (male or female) reduce risk of acquiring trichomoniasis. Sexual partners should be treated concurrently to prevent reinfection because nearly 20% of male partners are coinfected.

PROGNOSIS

Rare complications include pelvic inflammatory disease. Infection during gestation may lead to fetal growth retardation. There is no natural or acquired immunity, so reinfection may be common.

Coccidian Enteritis

EPIDEMIOLOGY

The coccidia, with 43 genera and more than 1700 recognized species, are well-known veterinary pathogens.[8] At least two of the coccidia, *Cyclospora cayetanensis* (an eimeriid) and *Cystoisospora belli* (a sarcocystid), are causative agents of enteritis in humans. Despite their ubiquity (nearly 100 species have been described), *Sarcocystis* spp have been rare causes of enteritis in humans and an even less common cause of myositis, although *Sarcocystis nesbitti* caused a disease comprising fever, myalgia, headache, and myositis in 89 college students who had traveled to Malaysia.[9] *C. cayetanensis* may have both an animal and human reservoir, but *C. belli* is thought to be an anthroponosis. Cyclosporiasis is a cause of gastroenteritis in tropical and subtropical areas, with Peru, Mexico, Haiti, Caribbean countries, and Nepal commonly reporting such cases. Since 1990, at least 11 food-borne outbreaks affecting approximately 3600 persons have been documented in the United States and Canada among persons who have eaten contaminated raspberries, fresh basil, snow peas, or mesclun. Cyclosporiasis is not uncommonly diagnosed in international travelers, and large outbreaks have been reported from cruise ships.[10]

PATHOBIOLOGY

Oocysts are passed in feces and must sporulate for at least a day (*C. belli*) or 5 to 11 days (*C. cayetanensis*) before attaining infectivity. Sporozoites are liberated in the small bowel, penetrating enterocytes (for *C. cayetanensis*, mainly in the jejunum). *C. cayetanensis* appears to have a complicated developmental cycle with at least two merogonic cycles in the bowel, leading to the formation of gametes. The gametes fuse within the enterocyte cytoplasm, and an oocyst wall is deposited around the zygote. The sexual cycle begins about a week after infection, with oocysts sloughing into the bowel lumen and subsequently out of the body through feces. Biopsy specimens from infected patients demonstrate mononuclear and eosinophilic infiltrates in the lamina propria as well as alterations to the morphology of villi. Humans appear to be intermediate hosts for *S. nesbitti*, with sporozoites liberated in the small bowel, entering the vasculature, and forming cysts in muscle.

CLINICAL MANIFESTATIONS

After an incubation period of approximately 1 week, either organism produces watery diarrhea, nausea, vomiting, abdominal pain, myalgias, anorexia, and fatigue. Illness is usually self-limited, but symptoms can be prolonged (10 to 12 weeks) and associated with steatorrhea, flatulence, and substantial weight loss in persons who are immunocompromised, especially those with AIDS. Infections may also be asymptomatic. With *S. nesbitti*, fever and prominent myalgias are the dominant presentation.

DIAGNOSIS

The diagnosis is confirmed by identifying coccidia in stool samples stained with modified acid-fast or modified safranin preparations or by phase contrast microscopy or bright-field microscopy (using iodine as a contrast medium) of wet mounts (Fig. 353-4). *C. cayetanensis* and *C. belli* may be sensitively detected by fluorescent microscopy of wet mounts. PCR is specific and can be sensitive, depending on the mode of DNA extraction, but there are no FDA-approved assays available; PCR support may be requested from the CDC through state public health departments. *S. nesbitti* appears to undergo an aberrant asexual cycle only within humans and may not produce oocysts to be liberated into the bowel; therefore, diagnosis has required muscle biopsy and demonstration of sarcocysts by histology or detection of the agent's DNA by PCR.

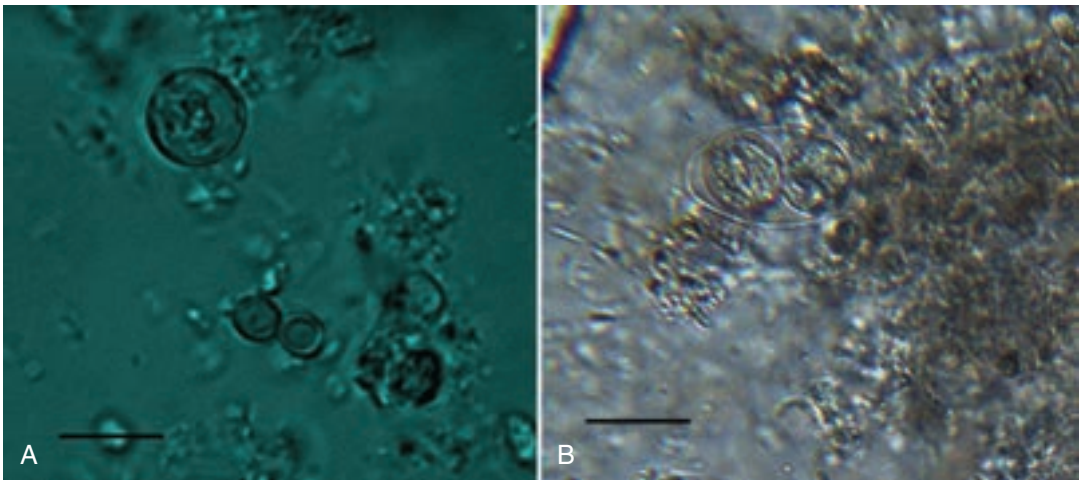

FIGURE 353-4. Diagnosis of coccidian enteritis. A, *Cyclospora cayetanensis*, seen on formalin-fixed human feces, unsporulated. (Bright-field microscopy, ×1000 with green contrast filter. Scale bar is 10 µm.) Note the doublet of yeast cells in lower right of the photomicrograph. **B,** *Cystoisospora belli*, seen on formalin-fixed human feces, partially sporulated. (Bright-field microscopy, ×400. Scale bar is 15 µm.)

TABLE 353-1 OTHER ENTERIC PROTOZOA

ORGANISM	EPIDEMIOLOGY	MANIFESTATIONS	THERAPY*
Balantidium coli	Primarily an infection of animals, especially pigs, but also affects humans	Asymptomatic or mild and self-resolving; occasionally more severe with abdominal pain, blood, and mucus in stool	Tetracycline (500 mg qid for 10 days) Alternative: metronidazole (750 mg tid for 5 days) or iodoquinol (650 mg tid for 20 days)
Blastocystis hominis	Probably worldwide, including North America; often found concomitantly with *Giardia lamblia*	Pathogenicity is debated	The need for treatment is debated, but symptomatic improvement has been reported with metronidazole (750 mg tid for10 days), or trimethoprim-sulfamethoxazole (160 mg TMP/800 mg SMX bid for 7 days)
Dientamoeba fragilis	Worldwide distribution; frequently found concomitantly with the pinworm *Enterobius*	Often asymptomatic; diarrhea reported	Paromomycin (25-35 mg/kg body weight per day in 3 doses for 7 days), tetracycline (500 mg qid for 10 days), metronidazole (500-750 mg tid for 10 days), or iodoquinol (650 mg tid for 20 days)
Microsporidia† (*Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*)	Apparent worldwide distribution	AIDS patients with persistent diarrhea and wasting; self-limited cases in immunocompetent persons	Oral fumagillin (20 mg tid) has been effective for *E. bieneusi*, but it has been associated with thrombocytopenia. Albendazole (400 mg bid) has been effective for *E. intestinalis*. Treatment with HAART may lead to clinical response in HIV-infected patients with microsporidial diarrhea.
Sarcocystis species	Common pathogens of animals; rare in humans; acquired by ingesting contaminated beef or pork	Often asymptomatic; nausea, vomiting, abdominal pain, and diarrhea may occur; eosinophilic necrotizing enteritis has been reported	No specific therapy

*Based on CDC recommendations, www.cdc.gov/parasites/az/index.html. Accessed March 9, 2015. The dosages and durations are for adults.
†Associated with persistent, severe diarrhea in persons with AIDS.
AIDS = acquired immunodeficiency syndrome; HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus.

TREATMENT

Rx

Rehydration is important, as it is for any severe diarrheal disease. Both infections may respond to treatment with 160 mg trimethoprim and 800 mg sulfamethoxazole taken twice daily for 7 to 10 days. HIV-infected patients may require a longer course of therapy. The widespread use of trimethoprim-sulfamethoxazole (Bactrim) prophylaxis for *Pneumocystis* has reduced the incidence of coccidial diarrhea in patients with HIV infection. No specific treatment has been recommended for sarcocystosis.

PREVENTION

At the community level, preventing the contamination of water and food (mainly vegetables and fruits) by animal or human feces reduces the risk of transmission. Washing vegetables and fruits in water will reduce the potential inoculum but does not eliminate all risk. Sarcocystosis may be prevented by ensuring that meat is well cooked.

PROGNOSIS

Reactive arthritis, Guillain-Barré syndrome, Reiter's syndrome, cholecystitis, and cholangitis have been reported as complications of either coccidian enteritis, mainly in patients with AIDS. Otherwise, treatment appears to eradicate the organism. Whether reinfection may occur is not known. Reports of extraintestinal development of *C. belli* and *C. cayetanensis* suggest the possibility of reinvasion of the bowel with ensuing recrudescence of signs and symptoms.

Other Enteric Protozoans

A number of other protozoa transmitted by fecal-oral contamination have been associated with enteric disease (Table 353-1). Some reside in the lumen of the bowel, and others invade and multiply within enterocytes. Enteric protozoa should be considered in the differential diagnosis of patients with persistent diarrhea and abdominal symptoms, particularly those with a history of recent international travel. A clinical diagnosis is rarely possible; laboratory tests, mainly for ova and parasites in stools, establish the diagnosis. Expert microscopists are required because these parasites may be confused with fecal debris. Pathogenic protozoa must also be differentiated from commensals such as *Entamoeba coli, Endolimax nana, Iodamoeba bütschlii, Pentatrichomonas hominis,* and *Chilomastix mesnili.* Therapy includes administration of the appropriate antiprotozoal drug and rehydration, as listed in Table 353-1[11] (also see Chapter 344).

REVIEW QUESTIONS

1. A 35-year-old woman presented to the emergency department in Toronto with a 2-day history of fever, headache, and malaise. She had just returned from spending 2 weeks during June on Nantucket Island. A 3-inch expanding circular rash was noted on one of her extremities, and she was diagnosed with acute Lyme disease and provided with a prescription for 100 mg of doxycycline, to be taken twice a day for 21 days. A month later, she presents again with fever, headache, chills, myalgia, and fatigue. She had not traveled again and works as a law clerk. Complete blood count demonstrates a hematocrit of 35, hemoglobin of 12, white blood cell count of 3000 (60% neutrophils, 35% lymphocytes, and 5% monocytes), and platelet count of 120,000; a blood smear is normal. What is the most likely cause of the recurrent symptoms?

A. Epstein-Barr virus infection
B. Human anaplasmosis
C. Myelodysplastic syndrome
D. Human ehrlichiosis
E. Babesiosis

Answer: E Symptomatic Epstein-Barr virus infection is unlikely in a 35-year-old patient and usually is accompanied by lymphocytosis with atypical lymphocytes. Although thrombocytopenia or leukopenia may be seen with anaplasmosis and ehrlichiosis, these infections are susceptible to doxycycline and would have been adequately treated with the course prescribed for the Lyme disease. Myelodysplastic syndrome typically is manifested with anemia and without fever. Treatment failure may rarely occur with acute Lyme disease, mostly as a result of poor compliance of the patient with therapy, but later manifestations of Lyme disease are more likely to be a monarticular arthritis or radiculopathy. Babesiosis may be coacquired with Lyme disease, but babesia are not susceptible to the tetracyclines. The negative blood smear is not unusual, and the severity of illness is not necessarily related to parasitemia. Thrombocytopenia and leukopenia may be evident in the absence of hematologic signs of anemia, particularly in early infection. Polymerase chain reaction will often be positive when blood smears are negative, given its greater sensitivity. Serology with a high anti-*Babesia* titer would provide evidence of infection if polymerase chain reaction is not performed, given that the patient was likely infected 6 weeks previously.

2. A 30-year-old biologist presented with a 3-week history of watery, nonbloody diarrhea with nausea and low-grade fever. He had previously been in good health and had returned 6 weeks ago from a field trip to Panama, where he had stayed for 1 month. He had several episodes of diarrhea in Panama that had responded quickly to Pepto-Bismol. He had remained hydrated and thus his activity was not curtailed. He now seeks medical attention because the diarrhea fails to respond to Pepto-Bismol or Imodium. Physical examination findings are normal, as is a complete blood count with the exception of slight eosinophilia. The patient admits to eating local foods and failing to always drink bottled water. Leukocytes are not noted in a stool examination, but Charcot-Leyden crystals are present. Stool analysis for ova and parasites demonstrates 30 × 15-µm oocysts with a sharply defined cell wall and a single sporoblast. Rare *Entamoeba* spp cysts with eight nuclei are also found. Which of the following would provide the most critical information for case management?

A. Testing for *Clostridium difficile* toxin
B. Human immunodeficiency virus (HIV) infection status
C. Testing for norovirus
D. Specific identification of the *Entamoeba* sp
E. Whether the Pepto-Bismol–treatable diarrhea was similar in quality to that experienced now

Answer: B The oocyst that was detected is likely *Cystoisospora belli*, which typically causes a self-limited diarrhea in immunocompetent younger patients. Norovirus and *C. difficile* disease should also terminate within a few days in a younger, healthy individual. The presence of eight nuclei identifies *Entamoeba coli*. Amebic infection reflects fecal-oral contamination, although the nonpathogenic *Escherichia coli* may also be found as a gut commensal. It is possible that the diarrhea episodes in Panama were an uncomplicated traveler's diarrhea and that the current disease is not related. Persistent enteritis due to *C. belli* is commonly seen in HIV-infected patients, who may develop life-threatening persistent diarrhea, malabsorption, and dehydration and require lifelong suppression of *C. belli* with trimethoprim-sulfamethoxazole (Bactrim).

3. A 40-year-old married woman presents with a foul-smelling vaginal discharge of 3 days' duration. She is sexually active with her husband and complains of a recurring history of discharge during the last 6 months, typically a week after intercourse, but not with every instance of intercourse. The discharge would resolve within 2 weeks if she was abstinent. A wet mount of the discharge demonstrates flagellated cells moving with a tumbling motion, and a diagnosis of trichomoniasis is made. Metronidazole 250 mg orally three times a day is prescribed for 7 days. She returns 2 months later with the same discharge, stating that she had improved after the treatment course but that the discharge returned within the last week. Which of the following is the most likely explanation for the recurrence of symptoms?

A. The patient's husband has *Trichomonas* infection and is reinfecting the patient.
B. The patient has antibiotic-resistant trichomoniasis.
C. The original diagnosis based on the web mount examination alone was incorrect.
D. The patient has been noncompliant with treatment.

Answer: A Patients may be reinfected by their untreated sexual partners, and thus a diagnosis of trichomoniasis should imply presumptive treatment of the partner. The majority of infected men are asymptomatic. The current Centers for Disease Control and Prevention recommendations for treatment failure are to re-treat with tinidazole. Metronidazole susceptibility may be established, but there is no guidance on minimum inhibitory concentration thresholds to define resistant strains. Although *Trichomonas vaginalis* is detected on wet mount examination of vaginal secretions in only about 60% of infected women, it confirms the diagnosis when it is seen in the appropriate clinical setting.

CESTODES

A. CLINTON WHITE AND ENRICO BRUNETTI

DEFINITION

The Pathogens

Cestode parasites are members of the animal kingdom, subphylum Cestoda. The organisms are characterized by several life cycle stages, which typically develop in distinct hosts. The adult stage is the tapeworm, which is acquired by ingestion of uncooked tissues harboring larval forms. After ingestion, the larvae excyst and the scolex attaches to the intestines. Segments, termed *proglottids*, develop at the base of the scolex and are displaced from the scolex by new proglottids to form a chain or tapeworm. The host in which the tapeworm develops is termed the *definitive host*. The proglottids contain male and female sexual organs and produce large numbers of ova. The proglottids or their ova are shed in stools. Humans are the definitive hosts for a number of different tapeworms, including the *Taenia* species, *Diphyllobothrium* species, and *Hymenolepis nana*. Humans can also be an accidental host for the dog and cat tapeworms of the genus *Dipylidium* (Table 354-1).

The intermediate hosts harbor the larval form of the parasite. Infection follows ingestion of the ova. Under the influence of gastric and intestinal fluids, the ova hatch, releasing the invasive larvae (oncospheres), which migrate to tissues, forming tissue forms. The forms in tissue vary between

TABLE 354-1 COMMON HUMAN TAPEWORM INFECTIONS

ORGANISM	INTERMEDIATE HOST	COMMON NAME	CLINICAL PRESENTATION	TREATMENT
Diphyllobothrium spp	Fish	Fish tapeworm	Passing segments, pernicious anemia	Praziquantel, niclosamide
Hymenolepis nana	Humans	Dwarf tapeworm	Asymptomatic, diarrhea	Praziquantel, niclosamide
Taenia saginata	Cattle	Beef tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Taenia asiatica	Pigs	Asian tapeworm	Asymptomatic, passing worms	Praziquantel, niclosamide
Taenia solium	Pigs	Pork tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Dipylidium caninum	Fleas	Dog tapeworm	Passing segments	Praziquantel, niclosamide

TABLE 354-2 HUMAN LARVAL CESTODE INFECTIONS

ORGANISM	COMMON NAME	ORGANS INVOLVED
Taenia solium	Cysticercosis	Brain, spinal fluid, eye, muscle
Echinococcus granulosus group	Cystic hydatid disease	Liver, lung, other
Echinococcus multilocularis	Alveolar hydatid disease	Liver
Taenia multiceps, *Taenia* spp	Coenurosis	Brain, eyes
Spirometra species	Sparganosis	Subcutaneous tissue, viscera

TABLE 354-3 THERAPY FOR INTESTINAL TAPEWORM INFECTIONS

	PRAZIQUANTEL	NICLOSAMIDE	NITAZOXANIDE
Dosage			
Adults	5-10 mg/kg for all age groups (25 mg/kg for *Hymenolepis nana*)	2 g (4 tablets)	500 mg
Children >34 kg		1.5 g (3 tablets)	200 mg
Children 11-34 kg		1 g (2 tablets)	100 mg
Administration	Taken as a single dose	Taken as a single dose; tablets must be chewed and swallowed	Taken twice a day for 3 days
Side effects	Mild but frequent, including dizziness, myalgias, nausea, vomiting, diarrhea, abdominal pain	Nausea, vomiting, abdominal pain, diarrhea, drowsiness, dizziness, headache, pruritus	
Pregnancy		No known mutagenic effects; considered safe if indicated	

organisms and may include the cysticercus (a bladder containing a single invaginated scolex), the coenurus (a bladder with multiple scolices), the hydatid (a cystic structure with a germinal layer, which forms numerous protoscolices), or the plerocercoid (a solid form seen in *Spirometra* species). Humans can harbor the intermediate forms of *Taenia solium* (cysticercosis), *Echinococcus granulosus* group (cystic hydatid disease), *Echinococcus multilocularis* (alveolar hydatid disease), and rarely other organisms (Table 354-2). Humans can serve as both the definitive host and an intermediate host for two species, *T. solium* and *H. nana*. In the case of *T. solium*, humans are the obligate host for the tapeworm stage (pork tapeworm) but can also harbor the cystic form (cysticercosis). In the case of *H. nana*, both stages typically develop in a single person, with the cysticercoid form in the intestinal wall and the tapeworm in the lumen.

INTESTINAL TAPEWORM INFECTIONS

Diphyllobothrium Species (Fish Tapeworm)

Diphyllobothrium tapeworms are large segmented parasites that are acquired by ingestion of undercooked or pickled freshwater fish dishes (sushi, sashimi, ceviche, carpaccio, gefilte fish). The tapeworms develop within a few weeks and can live for more than 10 years.

EPIDEMIOLOGY AND PATHOBIOLOGY

Diphyllobothrium species are found worldwide, including foci in Europe, North and South America, and Asia. Perhaps 20 million people are thought to be infected worldwide. Major foci include Russia, Japan, and South America. Disease was formerly highly endemic in Scandinavia, where it is now rarely diagnosed.

In most cases, infection has little impact on the host. However, one species, *Diphyllobothrium latum*, contains vitamin B_{12} receptors on the surface of the tapeworm, which can out-compete the host, leading to vitamin B_{12} deficiency (Chapter 164). This manifestation has been described only in Scandinavia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In most of those infected, *Diphyllobothrium* species produce few or no symptoms. Some may complain of gastrointestinal symptoms (abdominal discomfort, nausea, weight loss). The main clinical manifestation is the observation of proglottids being passed in stool. Pernicious anemia with symptoms of anemia or peripheral neuropathy may develop with *D. latum* infection. The diagnosis depends on observation of the characteristic operculated eggs in stool.

TREATMENT AND PREVENTION

Rx

A single oral dose of praziquantel (5 to 10 mg/kg) is usually adequate for therapy (Table 354-3). Niclosamide can be used as an alternative (2 g [adults] or 50 mg/kg [children] in a single dose chewed and swallowed), but it is not available in the United States. Parasites in fish can be killed by cooking (>56°C, >5 minutes) or freezing (–20°C, 24 hours). Infected fish may also be identified by inspection.

Hymenolepis nana

Hymenolepis nana is the human dwarf tapeworm. *Hymenolepis diminuta*, a rat tapeworm, can also cause human infection.

EPIDEMIOLOGY AND PATHOBIOLOGY

H. nana is widely prevalent worldwide, with estimates of 50 to 75 million people infected. Infection follows ingestion of ova. The larvae are released, invade, and develop into cysticercoid forms in the intestinal villi. After a few days, the cysticercoids mature, invade the lumen, and are transformed into a scolex, forming small tapeworms (up to 5 cm long), which begin producing eggs within 2 to 3 weeks. Autoinfection either in the intestines or by the fecal-oral route can lead to heavy infection.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most infections are asymptomatic. However, some children may be infected by hundreds or thousands of worms, which can cause abdominal pain, loose stools, diarrhea, and malabsorption. Diagnosis depends on observation of the characteristic eggs in stool. More than one specimen may be required.

TREATMENT AND PREVENTION

Rx

Praziquantel (15 to 25 mg/kg as a single oral dose) is usually effective in treating *H. nana* infection,[1] but it may need to be repeated in heavy infection (see Table 354-3). Nitazoxanide (100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children) is a reasonable alternative therapy; efficacy is about 75 to 82%. Niclosamide can be used as an alternative. Transmission is by the fecal-oral route and could be prevented by improved hygiene. Mass chemotherapy has been used to control infection in some populations.

Dipylidium caninum

Dipylidium caninum is a common tapeworm of dogs and cats. Dogs are infected by ingestion of fleas, which carry the cysticercoid form in their body cavities. The tapeworms can also develop in children who have ingested the fleas. It is widespread worldwide, but human infections are unusual.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Infection may be asymptomatic. In some cases, the motile proglottids may be noted in stool. The proglottids are similar in size and shape to rice grains. Diagnosis depends on identification of the ova in stool or identification of the proglottids.

TREATMENT AND PREVENTION

Rx

There are no controlled trials of treatment for *Dipylidium* infection, but infection is likely to respond to regimens used for other tapeworms (see Table 354-3). The main measure for prevention is treatment of pets for fleas and tapeworms.

Taenia saginata

Taeniasis refers to infection with the tapeworm form of one of three *Taenia* species. *Taenia solium* and *Taenia asiatica* are acquired from ingestion of undercooked pork. *Taenia saginata*, called the beef tapeworm, is a common intestinal infection worldwide. Cattle are the intermediate hosts, harboring the tissue cysticerci in their muscle. Humans are the obligate definitive host, harboring the tapeworm form.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. saginata is common worldwide in areas where cattle are raised and human fecal material contaminates the pastures. Approximately 45 to 60 million people are thought to be infected. It is found on most continents. Very high rates (>20% of the population) have been noted in east Africa, Bali, and Tibet. It is likewise endemic in the Middle East, the Americas, and Europe. *T. saginata* is also common in other parts of Asia, but many of the epidemiologic studies did not differentiate *T. saginata* from *T. asiatica*.

T. saginata tapeworms are acquired by ingestion of undercooked beef. The scolex attaches to the intestinal wall, and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The chain of proglottids can reach a length of up to 30 feet. The terminal proglottids are shed periodically in the stool. Terminal proglottids are typically off-white, 2 to 3 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The motile proglottids may cause discomfort as they exit the anus or may be noted in stool.

Ova may be noted in stool. The ova are 40 µm in diameter, surrounded by brown radial striations, and the embryos have six hooks. However, the ova of the three *Taenia* species are morphologically indistinguishable. The proglottids can be distinguished from those of *T. solium* by counting the number of uterine branches (≥14 branches suggests *T. saginata*). However, the proglottids of *T. saginata* cannot be readily distinguished from *T. asiatica*.

TREATMENT, PREVENTION, AND PROGNOSIS

Rx

Taeniasis can be treated with praziquantel in a single dose (see Table 354-3). Single doses of niclosamide are also effective. Nitazoxanide has also been used for *T. saginata*. Taeniasis can be prevented by inspection of beef. Also, cooking to 56°C for 5 minutes or freezing at –20°C for 7 to 10 days destroys the infective larvae. Only minor symptoms are noted and are eventually self-limited with or without treatment.

Taenia asiatica

T. asiatica is a cause of taeniasis in Asia, termed *Asian taeniasis*. Infection is acquired by ingestion of undercooked pork. Pigs are infected by ingestion of the ova from tapeworm carriers. *T. asiatica* has been widely described in China, Taiwan, Korea, Indonesia, and Southeast Asia. The clinical manifestations, diagnosis, treatment, and prevention of *T. asiatica* infection are similar to those noted for *T. saginata* infection.

Taenia solium

T. solium, also known as the pork tapeworm, can cause both tapeworm infection and larval infection termed *cysticercosis*. *T. solium* tapeworm infections are caused by ingestion of infected undercooked pork. The scolex evaginates and attaches to the intestines, forming proglottids. The proglottids gradually mature as they are separated from the scolex by new proglottids. The adult worms are often 10 to 20 feet long. Within the mature proglottids, thousands of microscopic ova develop. The ova are either excreted into the stool or shed with the proglottids. By contrast, ingestion of the ova results in development of larval infection, termed cysticercosis (see later). Thus, the tapeworm carrier poses risk of self-infection as well as infection to other people.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. solium is common worldwide in areas where pigs are raised and where pigs have access to human fecal material. Only a few million people are thought to harbor the tapeworm form. Pork tapeworm infection is highly endemic in Latin America, sub-Saharan Africa, south Asia, and Southeast Asia.

T. solium tapeworms are acquired by ingestion of undercooked pork. The scolex attaches to the intestinal wall and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The terminal proglottids are shed periodically in the stool. Terminal proglottids are typically off-white, 2 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The proglottids may be noted in stool. Diagnosis is made by the finding of ova in stool. The ova are 40 µm in diameter, surrounded by brown radial striations, and embryos have six hooks and are morphologically indistinguishable from the other *Taenia* species. The proglottids can be distinguished from those of *T. saginata* and *T. asiatica* by counting the number of uterine branches (<14 branches suggests *T. solium*).

TREATMENT AND PREVENTION

Rx

Taeniasis can be treated with praziquantel in a single dose. Single doses of niclosamide are also effective. Taeniasis can be prevented by inspection of pork. Also, cooking to 56°C for 5 minutes or freezing at –20°C for 7 to 10 days destroys the infective larvae. Current control measures include mass chemotherapy for entire populations with praziquantel. Comprehensive control programs include mass chemotherapy to eliminate tapeworm carriers, treatment of porcine cysticercosis with drugs such as oxfendazole, and improved hygiene to limit access of pigs to human fecal material.

TISSUE CESTODE (CYST) INFECTION

Taenia solium (Cysticercosis)

DEFINITION

T. solium is the cause of human larval infection termed cysticercosis. The normal hosts for the larval (cysticercus) forms are pigs. When ingested by

pigs, the ova hatch, releasing the invasive larvae (termed *oncospheres*), which invade the intestines, migrate to tissues (especially muscle), and mature into cysticercus forms within the tissues. The cysticercus consists of a thin translucent bladder containing an invaginated scolex, which is poised to form a tapeworm after being ingested by a human host. The ova are also infectious to people, including the tapeworm carrier. The sticky ova attach to the hands of the tapeworm carrier and are transmitted by the oral route to the carrier or close contacts. After ingestion, the ova can migrate to tissues and form cysts (cysticercosis). The presence of cysticerci in the central nervous system is termed *neurocysticercosis*.[2] Neurocysticercosis includes cysticerci in the brain parenchyma (parenchymal neurocysticercosis) and cysticerci in the ventricles, subarachnoid space, spine, and eye (extraparenchymal neurocysticercosis).

EPIDEMIOLOGY

Cysticercosis is found in all regions of the world where pigs are raised with access to human fecal material. Some estimate that 60 million people are infected with *T. solium* cysticerci. However, exact data on incidence and prevalence are available from only a limited number of studies because of the requirement for neuroimaging studies to make a diagnosis. In the 19th century, infection was highly endemic in Europe. However, with improving standards of living, local transmission is now limited to a few rural areas in southern and eastern Europe. Cysticercosis is widespread in rural areas of Latin America. High prevalence rates have been documented in parts of Mexico, Guatemala, Honduras, Ecuador, Peru, Brazil, and Bolivia. In endemic villages, more than 10% of the population may have abnormalities on neuroimaging studies consistent with neurocysticercosis. Studies have highlighted the importance of cysticercosis in sub-Saharan Africa. Cysticercosis is widespread in India, Nepal, Southeast Asia, and parts of China. In India, neurocysticercosis most commonly is manifested with single enhancing lesions, which are the main lesion associated with seizure disorders in that country. In the United States, approximately 2000 cases are diagnosed each year. Most cases are in immigrants from pig-raising villages in Mexico and Latin America. However, there are also imported cases from Asia and a few locally acquired infections.

PATHOBIOLOGY

For cysticercosis, the pathogenesis and pathophysiology vary with the location of the cysticerci and the host inflammatory response. Cysticerci in the brain parenchyma initially suppress the host inflammatory response. After a silent period, estimated to be several years, the cysticerci lose the ability to suppress the host inflammatory response, leading to parenchymal inflammation, which typically is manifested by seizures. The cysticerci induce a granulomatous response, which gradually degrades the parasites. In some cases, the lesions resolve. However, in others, degradation leads to formation of calcified granulomas. These calcified lesions may intermittently become inflamed (as evidenced by edema or contrast enhancement on magnetic resonance imaging [MRI] scan) and may cause recurrent seizures during a period of years. In some cases, cysticerci develop within the ventricles of the brain and can mechanically cause obstructive hydrocephalus. Cysticerci in the subarachnoid space may cause a chronic arachnoiditis, which can be manifested by vasculitis and stroke, communicating hydrocephalus, basilar meningitis, and, in some cases, mass effect. Cysticerci can also develop in the spine (manifested as radiculitis), eye, subcutaneous tissue, and muscle.

CLINICAL MANIFESTATIONS

The clinical manifestations vary with the location of the cysticerci and the associated host response (Fig. 354-1).[3,4] Neurocysticercosis can lead to a spectrum of cognitive abnormalities, ranging from impairment in a single domain, to cognitive impairment, and occasionally to dementia. All forms of disease may be associated with headaches. In general, parenchymal cysticerci are associated with seizures,[5] whereas ventricular and subarachnoid cysticercosis are associated with hydrocephalus.

Single Enhancing Lesion

A single enhancing lesion is the most common manifestation of cysticercosis in India and the United States. Patients typically present with seizures, which can be focal or focal with secondary generalization. Many will have a single seizure or a few seizures during the period when the cysticercus is degenerating, but the duration of seizures is eventually self-limited in most cases. However, a few go on to develop calcified lesions, which are a risk factor for recurrent seizures.

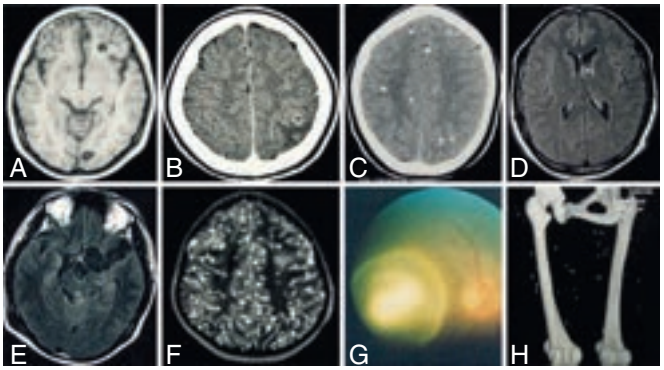

FIGURE 354-1. Human neurocysticercosis can be classified on the basis of neuroimaging studies. A, Multiple cystic lesions. **B,** Single enhancing lesion. **C,** Multiple calcifications. **D,** Intraventricular cysticerci. **E,** Subarachnoid cysticerci. **F,** Diffuse infection with cerebral edema, termed cysticercal encephalitis. **G,** Ocular cysticerci. **H,** Diffuse muscle calcifications. (Reprinted from Garcia HH, Del Brutto OH. Neurocysticercosis: updated concepts about an old disease. *Lancet Neurol.* 2005;4:653-661.)

Multiple Parenchymal Cysticerci

In patients with multiple lesions, the main presentation is with seizures, associated with parenchymal inflammation. In contrast to those with single lesions, seizures are more likely to recur.

Calcified Lesions

Many patients do not present until after they have calcified lesions. Patients with calcified lesions may develop recurrent seizures during a period of years.

Ventricular Cysticerci

The cysticerci typically are manifested by obstructive hydrocephalus. The patient may present with headache, nausea and vomiting, dizziness, altered mental status, or papilledema with altered vision. This is a medical emergency and can be fatal if it is not treated.

Subarachnoid Cysticerci

Cysticerci in the basilar cisterns are often accompanied by cysticerci in other locations, including parenchymal cysticerci or calcifications, ventricular cysticerci, and spinal or ocular cysticerci; patients may present with disease attributable to cysticerci at these sites. Cysticerci in the basilar cisterns are particularly prone to cause arachnoiditis. Manifestations of arachnoiditis may include vascular involvement (large- or small-vessel strokes), meningeal signs, or communicating hydrocephalus (headaches, nausea, vomiting, dizziness, and altered mental status).

DIAGNOSIS

The major clinical manifestations of neurocysticercosis (e.g., seizures and hydrocephalus) are not specific, and it is difficult to identify the parasites. The main tools used to diagnose neurocysticercosis are neuroimaging studies. Computed tomography (CT) scans are sensitive for identification of parenchymal calcifications, which appear as 2- to 5-mm nodules. CT may also reveal parenchymal cysticerci or obstructive hydrocephalus. MRI scans are more sensitive for identification of the cysticerci, especially in the subarachnoid space and ventricles. Three-dimensional fast imaging employing steady-state acquisition (FIESTA) sequences are particularly effective for ventricular cysticerci. The cysticerci are typically round, 1 to 2 cm in diameter. The cyst fluid is usually isodense with spinal fluid. In uninflamed cysticerci, the walls may not be visible. However, most cases demonstrate enhancement of the cyst walls or surrounding tissues and associated edema. In some cases, the scolex may be visible as a 1- to 2-mm solid nodule, cylinder, or spiral on the side of the cystic lesions. Serologic tests are useful to confirm the diagnosis. Assays using crude antigen, including enzyme-linked immunosorbent assay, are associated with poor sensitivity and specificity and are not reliable. An immunoblot assay using semipurified membrane glycoproteins is highly specific for the diagnosis. The sensitivity is excellent in cases with extraparenchymal or multiple parenchymal cysticerci. However, the sensitivity is poor in those with single enhancing lesions or just calcifications. Antigen detection assays are sensitive and more specific for viable cases and are increasingly available in the United States.

TREATMENT

Rx

Treatment varies with the clinical manifestations and form of infection. Seizures should be treated with antiepileptic drugs (Chapter 403). Phenytoin and carbamazepine are typically used and can control the seizures. Newer antiepileptic drugs may be more effective. There are no viable parasites in those with just calcified lesions, so the main measure is to control symptoms (e.g., antiepileptic drugs for those with seizures). In patients presenting with hydrocephalus, surgery to reestablish cerebrospinal fluid flow is the critical initial step in management. The role of antiparasitic drugs (Chapter 344) varies with the form of infection. Randomized controlled trials have demonstrated more rapid resolution of parenchymal cystic lesions with fewer generalized seizures in those treated with corticosteroids and albendazole (15 mg/kg/day in two daily doses) compared with those treated with placebo. Praziquantel (50 to 100 mg/kg/day in three daily doses) can be used as an alternative. There are emerging data on the use of the two drugs in combination, which may have greater cysticidal activity. A number of clinical trials in subjects with single enhancing lesions have demonstrated a slightly more rapid radiologic resolution and fewer seizures in those treated with steroids or antiparasitic drugs. However, the benefits of even high-dose steroids are not dramatic. For patients with cysticerci in the ventricles, management usually involves removal of the cysticerci, which can be best achieved by neuroendoscopy.[6] However, the main alternative approach is placement of a ventriculoperitoneal shunt. Chronic steroids or antiparasitic drugs may decrease the rate of shunt failure, which usually results from clogging of the shunts by the cysticerci or proteinaceous debris. There are no controlled trials on the management of subarachnoid cysticercosis. However, expert opinion supports treatment of subarachnoid cysticercosis with prolonged courses of antiparasitic drugs (e.g., albendazole for months), higher doses of albendazole, or combinations of albendazole and praziquantel. Chronic anti-inflammatory medications (e.g., prednisone 1 mg/kg/day, or 24 mg/day of dexamethasone) are also critically important. Patients who will be treated with chronic steroids should be screened for *Mycobacterium tuberculosis* and *Strongyloides* infections before initiation of steroid therapy. Methotrexate is increasingly recommended as a steroid-sparing agent. Patients with hydrocephalus should be treated by cerebrospinal fluid diversion (e.g., ventriculoperitoneal shunting). Before treatment with antiparasitic drugs, patients should undergo a funduscopic examination. Intraocular parasites may develop brisk inflammatory responses after treatment with antiparasitic drugs. Because this inflammation could lead to blindness, most authorities recommend extraction of the parasites before antiparasitic therapy. However, there are also reports of treatment of intraocular parasites with antiparasitic drugs.

PROGNOSIS

The prognosis varies significantly between the different forms of neurocysticercosis. Parenchymal enhancing lesions and parenchymal cystic lesions will eventually resolve, but this may take months to years. Patients who have or develop calcifications are at lifelong risk for recurrent seizures. Patients with ventricular or subarachnoid disease are at high risk for morbidity and mortality. However, a recent case series noted no deaths with optimal management.

Cystic Hydatid Disease (*Echinococcus granulosus* group)

DEFINITION

Cystic echinococcosis (CE), also called cystic hydatidosis, is caused by the larval stage of cestodes of the *Echinococcus granulosus* complex. All of these parasites were initially thought to be a single species, *E. granulosus*. However, molecular studies demonstrate that *E. granulosus* comprises a number of different species and genotypes. In humans, the clinical manifestations range from asymptomatic infection to severe, potentially fatal disease.

Echinococcal cysts consist of a periparasitic host tissue (pericyst or adventitia), which encompasses the larval endocyst, and the endocyst itself. The endocyst has an outer, acellular laminated layer and an inner, or germinative, layer that gives rise to brood capsules and protoscolices. The cyst is filled with clear fluid, numerous brood capsules, and protoscolices. Some cysts may also harbor daughter cysts of variable size. The protoscolices convert to tapeworms in the canine definitive hosts but can also form new cysts when released in mammalian tissues.

EPIDEMIOLOGY

E. granulosus species occur on all continents and in circumpolar, temperate, subtropical, and tropical zones. The highest prevalence of the parasite is found in parts of Eurasia, Africa, Australia, and South America. Within the endemic zones, the prevalence of the parasites varies from sporadic to high, but only a few countries can be regarded as being free of *E. granulosus*.

It is difficult to determine the true incidence of CE because of the slow rate of growth and variable clinical presentation. Most epidemiologic reports are based on hospital- and surgery-based surveys that greatly underestimate the actual rates of infection, especially in low socioeconomic groups with limited access to diagnosis and treatment.

Since the mid-1980s, however, mass community-based surveys using portable ultrasound scanners have been conducted in many remote, rural areas of the world. The sensitivity and specificity of ultrasound have been shown to be superior to those of serology in prevalence surveys. These studies showed the real burden of disease, uncovering population infection rates of up to 6.6%.

E. granulosus exists as a complex of species and strains that differ in a variety of criteria that may have an impact on the epidemiology, pathology, and control of CE. To date, 10 distinct genotypes (G1 to G10) have been identified. Some distinct species have been identified (*Echinococcus equinus*, *Echinococcus ortleppi*). The great majority of *E. granulosus* isolates from human patients thus far have been of the sheep genotype (G1).

CLINICAL MANIFESTATIONS

The presentation of human CE is protean.[6] Patients seek medical attention when a large cyst has some mechanical effect on organ function or rupture of a cyst causes acute hypersensitivity reactions. The cyst is often diagnosed incidentally during ultrasound examination, chest radiography, or body scanning performed for other clinical reasons. The liver is the most frequent location of echinococcal cysts, representing approximately 70% of cases.[7,8] The lungs are the second most common location. However, CE can occasionally occur in virtually any other organ.

Common symptoms are upper abdominal discomfort and pain, poor appetite, and a mass in the abdomen. Physical findings are hepatomegaly, a palpable mass on the surface of the liver or other organs, and abdominal distention. Other manifestations include jaundice, colic-like pains, portal hypertension, ascites, and compression of the inferior vena cava. If cysts in the lung rupture into the bronchi, symptoms may include intense cough, a salty taste in the mouth, or vomiting of hydatid material and cystic membranes. Patients may present with a chest mass, chest pain, chronic cough, pneumothorax, eosinophilic pneumonitis, pleural effusion, parasitic lung embolism, hemoptysis, or biliptysis. Cysts in the heart can cause a cardiac mass, pericardial effusion, and embolism. Cysts in the breast must be differentiated from neoplasms. Cysts located in the spine and in the brain can cause serious neurologic symptoms, including paralysis and seizures.

DIAGNOSIS

The diagnosis of CE is based on imaging methods and on serology, but serology has only a confirmatory role. Routine laboratory tests are nonspecific. Cyst rupture into the biliary tree may cause elevation of alkaline phosphatase, sometimes in association with hyperamylasemia and eosinophilia (up to 60%). Unless the cyst has ruptured, eosinophilia is low grade or absent.

Imaging

Modern imaging tools (ultrasound, CT, and, to a lesser extent, MRI) are central to the diagnosis and clinical management of CE. Ultrasound is the procedure of choice for diagnosis of asymptomatic CE. Ultrasound is also useful for longitudinal studies, such as monitoring the response of cysts to treatment and recording cyst growth rate. In 2003, the World Health Organization (WHO) Informal Working Group on Echinococcosis proposed a standardized ultrasound classification (Fig. 354-2). This classification defines six cyst stages that are assigned to three clinical groups. The active group comprises developing cysts, which may be unilocular (CE1) or multivesicular with daughter cysts (class CE2) and are usually found to be viable. The transitional group (class CE3) contains cysts that are usually starting to degenerate. There are two types of CE3: the "water lily sign" for floating membranes, which is now known as subclass CE3a; and predominantly solid cysts with daughter cysts, or subclass CE3b. This subdivision is based on their different response to percutaneous treatment (see later) and albendazole, which is generally good for CE3a and poor for CE3b. A study using nuclear magnetic resonance spectroscopy has found that CE3a and CE3b may have different metabolic characteristics. The inactive group (classes CE4 and CE5) exhibits involution and signs of solidification of cyst content with increasing degrees of calcification and is nearly always found to be nonviable.

CT scanning has the advantage of inspecting any organ, detecting smaller cysts located outside the liver, locating cysts precisely, and sometimes differentiating parasitic from nonparasitic cysts. MRI may have some advantages

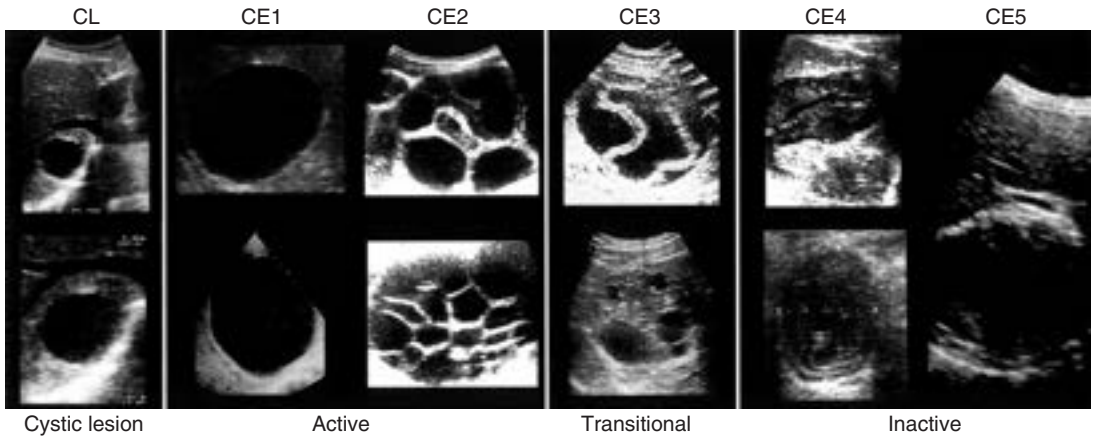

FIGURE 354-2. WHO Informal Working Group on Echinococcosis standardized ultrasound classification of cystic echinococcosis. CL lesions are cystic lesions lacking a distinct wall and may have other diagnoses. CE1 lesions are cystic lesions with a visible wall that may demonstrate protoscolices ("hydatid sand"). CE2 lesions include internal septation. CE3 lesions may be detached from the wall (CE3a, top row) or have daughter cysts with internal thickening (CE3b, bottom row). CE4 lesions are heterogeneous lesions with degeneration. CE5 lesions show thick calcification.

over CT scanning in the evaluation of postsurgical residual lesions, recurrences, and selected extrahepatic infections, such as cardiac infections. Furthermore, a study has shown that MRI reproduces the ultrasound-defined features of CE better than CT does. If ultrasound cannot be performed because of cyst location or patient-specific reasons, MRI with heavily T2-weighted series is preferable to CT. Plain radiographs are used for cysts in the lungs, bone, and muscle and for detection of calcified cysts.

Serology

Serologic tests are useful for confirmation of presumptive imaging diagnoses. However, many tests are available, and they are not standardized. Their sensitivity varies with the location of the cysts. Hepatic cysts are more likely to elicit an immune response than are pulmonary, brain, or splenic cysts. Serologic test results are usually positive when the endocyst is detached (CE3a) and in active (CE2) and transitional (CE3b) stages. Serologic test results are generally negative in patients with inactive cysts (CE4 and CE5). Titers tend to slowly decrease when a cyst becomes inactive (CE4, CE5) and after radical surgery. Titers may remain positive after conservative surgery in which the antigen source (the germinal layer) is not completely removed. Antibody titers usually increase immediately after medical or percutaneous treatments because of the mobilization of the antigen following disruption of cyst integrity.[9]

Other Diagnostic Procedures

Fine-needle aspiration of the cyst performed under ultrasonographic guidance, with a transhepatic approach, under anthelmintic coverage, is useful for differentiation of CE, malignant neoplasms, abscesses, and nonparasitic cysts. The procedure must be carried out in the presence of an anesthesiologist ready to manage the rare but possible anaphylactic reaction.

TREATMENT

Rx

The appropriate treatment depends on factors of the individual patient, the characteristics of the cyst, the therapeutic resources available, and the physician's preference. There are few randomized clinical trials evaluating treatment options, so a low level of evidence supports one therapeutic modality over another.

Surgery

Surgery has long been the only option in the treatment of CE. However, in the past two decades, medical treatment, percutaneous procedures, and a "watch and wait" approach have been successfully introduced and replaced surgery as the treatment of choice in selected cases. Surgery remains the main therapy in complicated cysts (i.e., those with rupture, biliary fistula, compression of vital structures, superinfection, or hemorrhage), cysts at high risk of rupture, or large cysts with many daughter vesicles that are not suitable for percutaneous treatments. Surgery can be performed as an open procedure, with either radical or conservative techniques, or laparoscopically, but there are controversies as to the safest and most effective technique and in which cases it should be applied. In all cases, perioperative albendazole prophylaxis, from 1 week before surgery until 4 weeks postoperatively, is recommended as a cautionary measure to minimize the risk of fluid spillage and consequent secondary echinococcosis from seeding of protoscolices in the abdominal cavity. Some authorities treat with praziquantel as well.

Percutaneous Treatments

Percutaneous techniques provide an alternative to surgery and benzimidazole derivatives. These treatment modalities aim either to destroy the germinal layer with scolicidal agents or to evacuate the entire endocyst. The most popular method aimed at destroying the germinal layer is PAIR (puncture, aspiration, injection of a scolicidal agent, and reaspiration). Many modified catheterization techniques are used to evacuate the endocyst and are generally reserved for cysts that are difficult to drain or tend to relapse after PAIR, such as multivesiculated cysts or cysts with predominantly solid content and daughter cysts. A growing number of articles have reported its safety in treating abdominal, especially liver, echinococcal cysts. In a study on 5943 percutaneous punctures of echinococcal cysts, lethal anaphylaxis occurred in 0.03% of procedures, whereas reversible allergic reactions complicated 1.7% of procedures. Prophylactic administration of albendazole for at least 30 days after puncture is a cautionary measure that should always accompany PAIR. PAIR is generally successful at inducing permanent solidification in CE1 and CE3a cysts. A few reports with long-term follow-up indicate that multivesicular cysts (i.e., CE2 and CE3b) tend to relapse repeatedly after PAIR.

Chemotherapy

Albendazole (Chapter 344) is the antiparasitic drug of choice for CE. It is administered orally at a dosage of 10 to 15 mg/kg/day; administration should be continuous without treatment interruptions. However, the optimal dosage and optimal duration of treatment with albendazole have not been formally assessed, and data from the small clinical trials generally fail to take into account the cyst's characteristics. A recent systematic review on the effect of albendazole showed that the efficacy of the drug may have been overstated in previous retrospective, nonrandomized studies. Albendazole induces solidification in small and medium-sized CE1 and CE3a cysts, whereas it has generally little effect on giant (diameter > 10 cm) CE1 and CE3a cysts. It has no effect on most cases of CE2 and CE3b cysts.

Adverse effects of benzimidazoles (Chapter 344) include hepatotoxicity, leukopenia, thrombocytopenia, and alopecia. Increases in aminotransferases may be due to drug-related efficacy or real drug-related toxicity. Whereas teratogenic risks are theoretical, it is nonetheless good practice to avoid use during pregnancy when possible and to delay treatment until after delivery unless it is absolutely necessary.

Watch and Wait

Inactive liver cysts that are free of complications, such as compression on neighboring organs, are increasingly monitored without being treated.[10] Prospective studies need to be carried out to confirm the safety of this option.

Follow-up

Follow-up is crucial to evaluate the efficacy of treatment. Long-term follow-up, generally more than 5 years, is required to evaluate local recurrences, which have been reported up to 10 years after apparently successful treatment. When the combination of imaging and serology is inconclusive, fine-needle aspiration should be performed to ascertain the viability of the cyst contents.

Alveolar Hydatid Disease (*Echinococcus multilocularis*)

Alveolar hydatid disease is caused by the tissue forms of *Echinococcus multilocularis*. In tissues, typically the liver, *E. multilocularis* grows as a budding mass rather than as a large cystic lesion. The tissues resemble lung tissues, hence the name "alveolar." The normal definitive hosts are canines, including wolves and foxes. The normal intermediate hosts are rodents. Humans are accidentally infected by contact with soil containing the ova.

EPIDEMIOLOGY

E. multilocularis is endemic in arctic and alpine areas of the Northern Hemisphere. It is highly endemic in western China, Tibet, and central Asia. In recent years, *E. multilocularis* has emerged as an important problem in Alpine areas of central Europe and adjacent forested areas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Human *E. multilocularis* infection almost invariably involves the liver, in which it is manifested as a tumor-like mass that gradually expands during decades. The main symptoms are liver discomfort and swelling. Diagnosis is by demonstration of a characteristic mass on imaging studies, with the etiology confirmed by serologic tests.[11]

TREATMENT AND PROGNOSIS

Rx

Surgery remains the mainstay of treatment of *E. multilocularis*. When feasible, all infected tissues should be removed. Apparently curative therapy should be followed by a 2-year course of albendazole to decrease the risk of relapse. In some cases, resection is feasible only when it is accompanied by liver transplantation. In cases that are not amenable to surgical resection, prolonged courses of albendazole can suppress growth of the lesion. After treatment with benzimidazoles, mortality is similar to that of the age- and-sex-matched general population.

Other Larval Cestode Infections

Sparganosis is caused by infection with the larval (plerocercoid) stage of *Spirometra mansonoides*. Infection is acquired by ingestion or application of infected meat (frogs, birds, fish) or exposure of skin to infected flesh (e.g., poultices of infected tissues). After infection, plerocercoids develop in the tissues, typically presenting as subcutaneous or central nervous system nodules or occasionally larva migrans symptoms. Treatment usually involves removal of the nodule.

Coenurosis is a rare larval cestode infection caused by human infection with the larval stage of the dog tapeworms *Taenia multiceps* and *Taenia serialis*. In the tissue, the larva forms a cystic lesion containing multiple scolices (the coenurus). The cystic lesion is usually single and most frequently identified in brain, eye, or soft tissues. Treatment usually involves removal.

Echinococcus oligarthrus and *Echinococcus vogeli* have been associated with polycystic hydatid disease in northern South America. *Taenia crassiceps* has been identified in the eye and in tissues of compromised hosts. *Hymenolepis*-like organisms have also been identified in tissues of AIDS patients.

REVIEW QUESTIONS

1. Active cysts in the WHO Informal Working Group on Echinococcosis classification are

A. CE1
B. CE1, CE2
C. CE3a, CE3b
D. CE4
E. CE4,CE5

Answer: B CE1 (unilocular) and CE2 (cysts with daughter cysts) are categorized as viable or active in the WHO Informal Working Group on Echinococcosis. When aspirated, viable protoscolices are found in the fluid.

2. The risk of lethal anaphylactic shock after an echinococcal cyst puncture is

A. 2%
B. 3%
C. 4%
D. 5%
E. <1%

Answer: E In an analysis of the literature that included 5943 percutaneous puncture procedures of 5517 hepatic and nonhepatic echinococcal cysts, two cases of lethal anaphylaxis and 99 reversible anaphylactic reactions were reported. Lethal anaphylaxis occurred in 0.03% of percutaneous puncture procedures, corresponding to 0.04% of treated cysts, whereas reversible allergic reactions complicated 1.7% of percutaneous punctures, corresponding to 1.8% of treated echinococcal cysts. Lethal anaphylaxis related to percutaneous treatment of cystic echinococcosis is an extremely rare event and is observed no more frequently than drug-related anaphylactic side effects are.

3. The best imaging technique for staging of cystic echinococcosis (CE) cysts of the liver is

A. Computed tomography (CT)
B. Magnetic resonance imaging (MRI)
C. Ultrasound
D. Positron emission tomography (PET) scan
E. Scintigraphy

Answer: C Imaging plays the key role in diagnosis and staging of CE. The description of CE-specific imaging features and the WHO CE cyst classification are based on ultrasound. The reproducibility of the ultrasound-defined features of CE cysts is variable in MRI and CT. This is of particular importance for cysts that are not accessible by ultrasound and because of the increasing availability and overuse of CT and MRI.

A retrospective study was conducted in patients with abdominal CE cysts seen on ultrasound who had additional CT or MRI scans performed; it showed that MRI reproduces the ultrasound-defined features of CE better than CT does. If ultrasound cannot be performed because of cyst location or patient-specific reasons, MRI with heavily T2-weighted series is preferable to CT.

4. In a patient presenting with seizures and calcified cysticercosis with surrounding edema on MRI, the most appropriate therapy is

A. Antiepileptic drugs alone
B. Antiepileptic drugs and albendazole
C. Antiepileptic drugs and prednisone
D. Antiepileptic drugs, albendazole, and prednisone
E. Placement of a ventriculoperitoneal shunt

Answer: A Patients with calcified lesions no longer have viable cysticerci and thus do not benefit from antiparasitic drugs. Prednisone may transiently decrease edema, but there is no evidence of clinical benefit, and steroid withdrawal has been associated with flares of disease.

5. In a patient presenting with multiple subarachnoid cysticerci complicated by basilar meningitis, which of the following approaches have been associated with the best outcomes?

A. Treatment with a 2-week course of albendazole and dexamethasone
B. Removal of the cysticerci by open craniotomy
C. Treatment with prolonged courses of albendazole, dexamethasone, and methotrexate
D. Neuroendoscopic removal of intraventricular cysticerci
E. Cerebrospinal fluid diversion alone for hydrocephalus

Answer: C Subarachnoid neurocysticercosis responds poorly to the doses of albendazole used for parenchymal infection. Use of cerebrospinal fluid diversion alone carries a high case-fatality rate. The optimal approach includes prolonged courses of antiparasitic drugs along with anti-inflammatory treatment. Higher doses of albendazole, combinations of praziquantel and albendazole, and endoscopic debulking (removal of cysticerci in the basilar cistern, not just the ventricles) have also been reported as helpful.

SCHISTOSOMIASIS (BILHARZIASIS)

EDGAR M. CARVALHO AND ALDO A. M. LIMA

DEFINITION

Schistosomiasis, which is caused by trematodes of the genus *Schistosoma*, is one of the most important parasitic diseases of humans and is a global public health problem in the developing world.[1] *S. mansoni, S. haematobium, S. japonicum, S. intercalatum,* and *S. mekongi* are the five major species of *Schistosoma* affecting humans. Other *Schistosoma* species that occasionally infect humans include *S. bovis, S. mattheei,* and some avian schistosomes.

EPIDEMIOLOGY

Schistosomiasis occurs mainly in tropical and subtropical areas, especially in poor communities without access to safe drinking water and adequate sanitation.[2] It is estimated that 200 million people are infected by the helminth and 600 to 799 million are at risk of infection.[3] *S. mansoni* is found in 55 countries, mainly in Africa, the Middle East, the Caribbean, Brazil, Venezuela, and Suriname. *S. haematobium* is endemic in 53 countries in the Middle East and most of the African continent. *S. japonicum* is endemic in China, Indonesia, and the Philippines. *S. intercalatum* has been reported from 10 countries in Africa. *S. mekongi* is found in Cambodia and Laos.

The endemicity of schistosomiasis depends on the urban disposal of urine (*S. haematobium*) and feces (*S. mansoni, S. japonicum, S. intercalatum, S. mekongi*), the presence of suitable snail hosts, and human exposure to cercariae.[4] The freshwater snail intermediate hosts are *Biomphalaria* sp in Africa and *Biomphalaria glabrata (Australorbis)* and *Tropicarbis* in South America and the West Indies. In some cases, the endemicity of schistosomiasis may be maintained by animal reservoirs. Such is the case with *S. japonicum*, which infects dogs and cows. Rodents, monkeys, and baboons have been found infected in nature, but the role of these animals as reservoirs does not seem to be epidemiologically important.

Etiology and Life Cycle

The schistosomes are digenetic parasitic trematodes (Fig. 355-1). Although they are morphologically distinct, the species of *Schistosoma* that infect humans share some common characteristics. The large male (0.6 to 2.2 cm × 2 to 4 mm) has a ventral gynecophoric canal, in which the female (1.2 to 2.6 cm × 1 to 2 mm) is held during copulation. The sequencing of the *S. mansoni* genome has been determined.

Adult worms live in the mesenteric veins (*S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum*) or in the venous plexus around the lower ends of the ureters and the urinary bladder (*S. haematobium*). In these sites, they start their sexual reproduction by releasing eggs. Once deposited in the host, eggs can stay in the mesenteric vein, be trapped in the intestines, escape to the

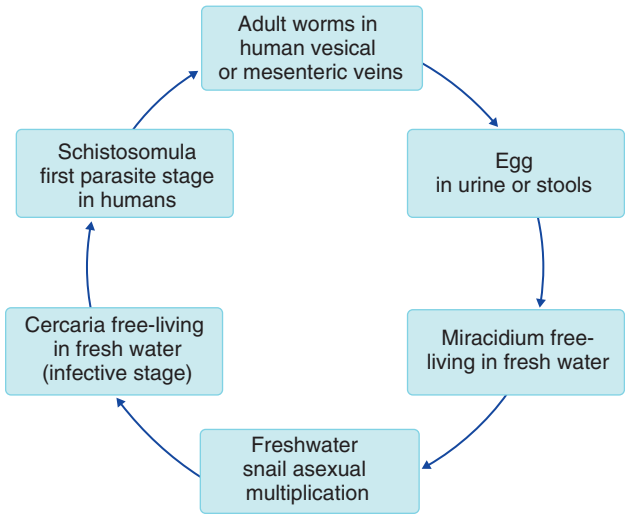

FIGURE 355-1. Schistosome life cycle.

intestinal lumen, and migrate by portal blood to the liver (*S. mansoni, S. japonicum*). Eggs of *S. haematobium* can be trapped in the intestines and bladder, escape to the intestinal or bladder lumen, and be trapped in the female genital tract. After being excreted with feces or urine into fresh water, the eggs hatch and release ciliated motile miracidia that penetrate into the snail intermediate host. Following asexual multiplication in the snail, the development of cercariae, the infective forms for humans, takes 4 to 7 weeks. After leaving the snails, the cercariae can survive in fresh water for almost 72 hours. When penetration of the skin in the human host occurs, the cercariae lose their tails and change into schistosomula. Schistosomula migrate to the lungs and in about 6 weeks mature into adult worms, after which they descend to their final habitat. Viable eggs can be seen in excretions (i.e., stool or urine) 5 to 9 weeks after cercarial penetration. The lifespan of the worms ranges from 5 to 10 years.

PATHOBIOLOGY

The pathogenesis of acute human schistosomiasis is mainly related to egg deposition and liberation of antigens of adult worms and eggs. A strong inflammatory response characterized by high levels of pro-inflammatory cytokines, such as interleukins 1 and 6 and tumor necrosis factor-α, and by circulating immune complexes participates in the pathogenesis of the acute phase of the disease.

In chronic schistosomiasis, tissue injury is mediated by egg-induced granulomas and the subsequent appearance of fibrosis. Because the habitat of *S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum* worms is the mesenteric blood vessels, the intestines are involved primarily, and egg embolism results in secondary involvement of the liver. Host genetics, immunologic response, and parasite load measured by egg count in the stool are associated with a greater chance of liver fibrosis resulting in hepatosplenomegaly. Polymorphisms within the interferon-γ receptor 1 (*IFNGR1*) gene may be related to severe hepatic disease caused by *S. mansoni* infection. There is also evidence that increased levels of interleukin 5 and tumor necrosis factor-αare associated with fibrosis.[5] The granuloma is mainly composed of macrophages, eosinophils, fibroblasts, and collagen deposition. The size of these granulomas and the resulting fibrosis lead to most of the chronic fibro-obstructive lesions in schistosomiasis. In the liver, the granulomas result in perisinusoidal obstruction of portal blood flow, portal hypertension, splenomegaly, esophageal varices, and portosystemic collateral circulation. Liver cell perfusion is consequently preserved, and liver function test results remain normal well into the course of the disease. In *S. haematobium* infection, eggs and granuloma formation are predominantly found in the ureters, bladder, and genital tract.

In schistosome-infected persons, the intensity of infection increases during the first two decades of life as children accumulate worms, with infection intensity declining thereafter. In the *S. haematobium*–infected population, IgE increases progressively with age, and IgE antibodies directed against adult worm antigens are associated with subsequent low intensities of reinfection. Alternatively, in subjects who are highly exposed to contaminated water but have negative stool examination results, there is evidence of higher interferon-γ production in response to *S. mansoni* antigens.[6] The existence of a major codominant gene, called *SM1*, which controls the intensity of infection by *S. mansoni*, has been demonstrated. *S. mansoni* infection levels are controlled by a locus that maps to chromosome 5q31-q33, which is close to a locus regulating IgE levels, indicating that genetic factors are probably critical to susceptibility and resistance to schistosome infection.

Because modulation of the immune response is a characteristic of chronic schistosomiasis, *S. mansoni* infection attenuates the clinical manifestations of autoimmune and inflammatory diseases, but it may also impair the immunologic response to vaccines and change manifestations of other infectious diseases.

CLINICAL MANIFESTATIONS

Clinical manifestations of schistosomiasis are divided into schistosome dermatitis, acute schistosomiasis, and chronic schistosomiasis. Schistosome dermatitis, or swimmer's itch, is an uncommon manifestation seen mainly when avian cercariae penetrate the skin and are destroyed. Schistosome dermatitis is a sensitization phenomenon occurring in previously exposed persons. The cercariae evoke an acute inflammatory response with edema, early infiltration of neutrophils and lymphocytes, and later invasion of eosinophils. A pruritic papular rash occurs within 24 hours after the penetration of cercariae and reaches maximal intensity in 2 to 3 days.

Acute schistosomiasis occurs usually 20 to 50 days after primary exposure. Although it is asymptomatic in endemic areas, acute schistosomiasis is becoming a frequent and major clinical problem in nonimmune individuals from urban regions who are exposed for the first time to a heavy infectious dose in an endemic area. The clinical syndrome (i.e., fever, chills, liver and spleen enlargement, and marked eosinophilia) originally described for *S. japonicum* infection, and still common for this species, is increasingly being diagnosed in Brazil in individuals with *S. mansoni* infection. Malaise, diarrhea, weight loss, cough, dyspnea, chest pain, restrictive respiratory insufficiency, and pericarditis are important findings in this phase. High levels of circulating immune complexes correlate with respiratory manifestations, and tumor necrosis factor-αlevels correlate with the presence of abdominal pain, diarrhea, and weight loss. Abdominal ultrasound may show hepatosplenomegaly. Acute disease is not observed in individuals living in endemic areas of schistosomiasis because of the down-modulation of the immune response by antigens or idiotypes transferred from mother to child.

In chronic schistosomiasis, abdominal pain, irregular bowel movements, and blood in the stool are the main symptoms of intestinal involvement. Colonic polyposis may occur, especially in Egypt. Hepatosplenic involvement is the most important cause of morbidity with *S. mansoni* and *S. japonicum* infection. Patients may remain asymptomatic until the manifestation of hepatic fibrosis and portal hypertension develops. Hepatic fibrosis is caused by a granulomatous reaction to *Schistosoma* eggs that have been carried to the liver. Hematemesis from bleeding esophageal or gastric varices may occur. In such cases, anemia and decreasing levels of serum albumin are observed. Some patients have severe hepatosplenic disease with decompensated liver disease. Jaundice, ascites, and liver failure are then observed. Concomitant infection by *Salmonella* species, and less extensively by other gram-negative bacteria, with *S. mansoni* or *S. haematobium* leads to a picture of prolonged fever, hepatosplenomegaly, and mild leukocytosis with eosinophilia. Glomerulonephritis, infantilism, and hypersplenism are other complications associated with hepatosplenic schistosomiasis. The detection of pulmonary hypertension is increasing with the use of more advanced diagnostic technology. Pulmonary hypertension, which used to be exclusively linked to the hepatosplenic form of the disease, has been documented in patients without liver fibrosis.[7] In hospitalized adult patients with *S. japonicum* infection, cerebral schistosomiasis occurs in 1.7 to 4.3%.[8] It may occur as early as 6 weeks after infection, and the most common sign is focal jacksonian epilepsy. Signs and symptoms of generalized encephalitis may occasionally be found. In *S. mansoni* infection, neurologic involvement is rare and mainly characterized by transverse myelitis, which occurs mainly in patients without liver fibrosis and hepatosplenomegaly.[9]

In *S. haematobium* infection, the main organ system involved is the urogenital tract. The acute granulomatous response to parasite eggs in the early stages causes urinary tract disease, such as urethral ulceration and bladder polyposis. In chronic disease, usually in older patients, granulomas at the lower end of the ureters obstruct urinary flow and may cause hydroureter and hydronephrosis. Bladder fibrosis and calcification are also seen in this phase. Up to 70% of infected individuals have hematuria, dysuria, or urinary frequency. Urine examination reveals proteinuria and hematuria. Radiologic findings include hydronephrosis; hydroureter; ureteral strictures, dilation, or distortion; ureteral calcifications; ureterolithiasis; calcified bladder; polyps; reduction in bladder capacity; irregular contraction of the bladder wall; or a dilated bladder because of bladder neck fibrosis. An increased incidence of squamous cell carcinoma of the bladder has been reported in endemic areas of *S. haematobium* infection.[10] *S. haematobium* eggs have occasionally been found in the lungs, with subsequent focal pulmonary arteritis and pulmonary hypertension. Genital schistosomiasis has been documented in up to 75% of women in *S. haematobium*–endemic areas[11] and has also been documented in girls.[12] Spontaneous bleeding, burning sensation in the genitals, dyspareunia, itching, tumors due to granulomas, and infertility are the more common complaints. The association of genital schistosomiasis and HIV infection has been recognized. Monocytes and $CD4^+$ T cells as well as high expression of chemokine receptors CCR5 and CXCR4 documented in schistosomiasis may facilitate binding of the virus after penetration through an ulcerated friable epithelium.

DIAGNOSIS

A definitive diagnosis of schistosomiasis can be made only by finding schistosome eggs in feces, urine, or a biopsy specimen, usually from the rectum (Table 355-1). However, a steep decrease of sensitivity is found in low-endemicity areas. A history of contact with contaminated water and appropriate clinical manifestations are important steps in establishing the diagnosis. Because schistosome eggs may be few, concentration by sedimentation should be performed. All eggs from feces, urine, or tissues should be examined under high power to determine their viability by visualizing the activity of cilia of the excretory flame cells of the enclosed miracidium. Dead eggs

TABLE 355-1 DIAGNOSIS OF SCHISTOSOMIASIS

SCHISTOSOME	EGGS	DIAGNOSIS
S. haematobium	Mainly found in urine but may be found in stools or rectal biopsy specimens Eggs: 143 × 50 µm; spindle shaped: rounded anterior, conical posterior, tapering to a terminal delicate spine	Obtain urine sample at midday (when eggs are excreted); more than one sample may be needed Examine urine directly or by filtering 10 mL of urine through a Nuclepore membrane Rectal biopsy in suspected cases with normal urine Serologic testing to diagnose early or light infection
S. mansoni	Eggs: 155 × 66 µm; oval with lateral, long spine	Examine stool for eggs Use the Kato-Katz thick smear method for quantification purposes Rectal biopsy or serologic testing to diagnose stool-negative cases, particularly in lightly infected patients
S. japonicum	Found in stool Eggs: 89 × 67 µm; oval or rounded with a lateral, short, sometimes curved spine	Examine stool for eggs Kato-Katz thick smear (for quantitative assessment) Rectal biopsy for those with light infections, especially with less common manifestations (i.e., cerebral schistosomiasis)
S. mekongi	Found in stool Eggs: 60 × 32 µm; smaller than eggs of *S. japonicum*	Examine stool for eggs
S. intercalatum	Found in stool Eggs: 180 × 65 µm; terminal spine	Examine stool for eggs

may persist for a long time after successful therapy or natural death of the worms. Because the intensity of infection is associated with morbidity, quantitative techniques such as the Kato-Katz thick smear method are recommended for *S. mansoni* and *S. japonicum*. Rectal biopsy may be used for those with light infection. Ultrasonography allows determination of the degree of liver fibrosis. *S. mekongi* and *S. intercalatum* infection is diagnosed by examination of the stool for eggs.

Urine examination for *S. haematobium* eggs can be performed by direct or concentration methods. Samples should be obtained at midday, when excretion of eggs is maximal. Rectal biopsy may be performed in patients with negative urine results. Schistosome real-time polymerase chain reaction is sensitive and specific in urine and stool.[13] After *S. haematobium* infection is diagnosed, assessment of urinary tract disease by ultrasonography is recommended. Because of an increased incidence of carcinoma of the bladder, cancer surveillance should be performed in patients with *S. haematobium* infection.

Serologic tests may help the diagnosis of acute infection because the symptoms are not specific and the finding of eggs in stool may reflect chronic infection.

Quantification of circulating antigens in serum and urine is an alternative for the diagnosis of schistosome infection. However, the sensitivity of the method decreases in patients with light infection (<100 eggs per gram of feces). This test has also been used to monitor the efficacy of antischistosome chemotherapy. A significant decrease in antigen levels or negativity of the test is observed as early as 10 days after therapy.

TREATMENT

Chemotherapy is by far the major method used for prophylaxis, control, and cure of schistosomiasis. Several compounds are in use: metrifonate, oxamniquine, praziquantel, and artemisin derivatives (artesunate and artemether).[14] Praziquantel, a pyrazinoisoquinoline derivative, is the drug of choice for the treatment of schistosomiasis for four reasons: high efficacy against all schistosome species and against cestodes, lack of serious short-term and long-term side effects, administration as a single oral dose, and competitive cost. Recent reviews confirm that a single dose of praziquantel (40 mg/kg) is an effective treatment for *S. mansoni* infection.[A1,A2] Doses lower than 40 mg/kg may be less effective, with no additional benefit for higher doses. Oxamniquine (40 mg/kg) is also effective, and on the basis of current limited evidence, it is uncertain which intervention is more effective. A meta-analysis study also confirmed that artemisinin derivatives, unlike oxamniquine, used in combination with praziquantel increased the cure rates in schistosomiasis treatment, but artemisinin derivatives or oxamniquine alone did not.[A3]

The standard recommended treatment consists of a single dose of praziquantel, 40 mg/kg, for *S. mansoni, S. haematobium,* and *S. intercalatum* infection. In *S. japonicum* infection, a total dose of 60 mg/kg is recommended, split into two or three doses in a single day. Although no significant difference was found in the overall cure rates between single-dose (40 mg/kg) and double treatment (40 mg/kg with 2-week interval) regimens of praziquantel for *S. haematobium*, the effect of double treatment resulted in significant reduction in infection intensity and microhematuria, which may have an impact in reducing morbidity.[A4] *S. mekongi* may require two treatments at 60 mg/kg body weight. With these dosages of praziquantel, recorded cure rates are 75 to 85% for *S. haematobium*, 63 to 85% for *S. mansoni*, 80 to 90% for *S. japonicum*, 89% for *S. intercalatum*, and 60 to 80% for double infections with *S. mansoni* and *S. haematobium*. A decrease in the efficacy of praziquantel has been observed in patients coinfected with human T-cell leukemia virus type 1.

Praziquantel is well tolerated and effective in patients of all ages and for different clinical forms of schistosomiasis, including advanced hepatosplenic cases (*S. mansoni*), cerebral schistosomiasis (*S. japonicum*), and neurologic syndromes (*S. mansoni* and *S. haematobium*), possibly in association with corticosteroids.[15] However, praziquantel has a poor prophylactic effect, which reduces its efficacy in areas of high transmission. There have been several reports of persistent schistosome egg shedding after treatment, thus posing a concern about the emergence of drug resistance.[16] A systematic review and meta-analysis show that either artesunate or artemether has a confirmed prophylactic effect across different trials performed in China. Further studies will be necessary to examine the combination of antischistosome chemotherapy for *S. haematobium* infection in which repeated standard treatment fails to clear the infection.

The most common adverse events observed with praziquantel or oxamniquine are related to the gastrointestinal tract: abdominal pain or discomfort, nausea, vomiting, anorexia, and diarrhea. These symptoms can be observed in up to 50% of patients but are usually well tolerated. Other side effects are related to the central nervous system (e.g., headache, dizziness, drowsiness) and the skin (e.g., pruritus, eruptions) or may be nonspecific (e.g., fever, fatigue). In general, the cumulative experience from a large number of studies allows the conclusion that praziquantel is an extremely well tolerated drug that requires minimal medical supervision and is therefore particularly suitable for mass chemotherapy programs. Although a reduction in the intensity of infection and morbidity has been documented after mass chemotherapy, to control the disease, provision of clean water, use of molluscicides, implementation of adequate sanitation, and improvement of socioeconomic conditions should also be undertaken.

TREATMENT

Rx

The effects of praziquantel on schistosomes can be summarized into three mechanisms: muscle contraction, tegumental damage (i.e., vacuolization and blebbing), and metabolic alterations (i.e., decreased glucose uptake, lactate excretion, and glycogen content). Schistosome calcium ion channels are so far the only molecular targets of praziquantel action identified. The drug may also interfere with adenosine uptake, which is relevant because schistosomes are unable to synthesize purines de novo. Several drugs (e.g., phenytoin, rifampin, and azole antifungals) decrease plasma concentrations of praziquantel because they inhibit the cytochrome P450 pathway 3A4. Chloroquine and cimetidine also decrease praziquantel bioavailability. Praziquantel's activity also depends on the patient's immune system. Several studies have reported that praziquantel induces the exposure of worm surface antigens that may function as targets for an immune response.

REVIEW QUESTIONS

1. A 20-year-old man was admitted with a fever (temperature of 39° C), abdominal pain, dyspnea, malaise, and weight loss of 30 pounds in the last 10 days. He has lived in Italy but traveled to areas endemic for *S. mansoni*, where he swam in a lagoon 4 weeks before the start of symptoms. A mild enlargement of the liver and spleen was noted on examination, and chest radiographs showed interstitial infiltrates. Schistosomiasis is suspected. Which of the following is the most appropriate test for diagnosis?

A. Stool examination
B. Urine examination
C. Real-time polymerase chain reaction in stool
D. Serologic test
E. Rectal biopsy

Answer: D Egg deposition can be documented only up to 4 weeks after exposure. Although serologic tests do not rule out previous *S. mansoni* infection, the patient did not have history of previous exposure to *S. mansoni*, and therefore serology is the best test for the diagnosis of acute disease.

2. Which of the following statements is correct about human schistosomiasis?

A. It may be prophylactically treated with praziquantel.
B. Praziquantel is currently the treatment of choice.
C. The combination of praziquantel and oxamniquine is recommended.
D. There is no combination treatment available.
E. Susceptibility or resistance to praziquantel has not been reported.

Answer: B Praziquantel has a poor prophylactic effect, which reduces its efficacy in areas of high transmission of *Schistosoma*. However, praziquantel is considered the drug of choice to treat schistosomiasis for its efficacy, low adverse events including severe adverse events, single oral dose, and competitive cost. There is a combination of praziquantel and artemisin derivatives that shows increased cure rates in schistosomiasis treatment.

¶Diagnosis and treatment also apply for other intestinal flukes.
CT = computed tomography; ELISA = enzyme-linked immunosorbent assay; PZQ = praziquantel; RUQ = right upper quadrant; TCZ = triclabendazole.

Heterophyidae, Echinostomatidae, and Troglotrematidae. With the exception of schistosomes, all flat worms of clinical significance are hermaphroditic. Blood flukes, or schistosomes, are discussed in Chapter 355. The epidemiology, clinical manifestations, diagnosis, and treatment are summarized in Table 356-1.

LIVER FLUKES

Fascioliasis

Fascioliasis is a zoonosis caused by *Fasciola hepatica* (adult: 30 by 13 mm) or *Fasciola gigantica* (adult: 75 by 20 mm). The most common natural hosts are sheep, cattle, and goats.

EPIDEMIOLOGY

The infection is distributed globally. The highlands of Peru, Bolivia, Ecuador, Egypt, and Vietnam are the most affected regions in the world. Prevalence rates higher than 60% have been reported in Peru and Bolivia. Estimates of the number of people infected in some countries are 830,000 in Egypt, 742,000 in Peru, 360,000 in Bolivia, 37,000 in Yemen, 20,000 in Ecuador, and 10,000 in Iran. It has been estimated that between 2.4 and 17 million people are infected worldwide.[1]

PATHOBIOLOGY

The life cycle begins when the parasite's eggs in stool are deposited in water; miracidia appear, develop, and hatch in 9 to 14 days and invade many species of freshwater snails (*Lymnaea* spp), in which they multiply as sporozoites, rediae, and cercariae during a period of 4 to 7 weeks. They then leave as free-swimming cercaria that subsequently attach to watercress, water lettuce, alfalfa, mint, parsley, or khat. The main source of infection is consumption of raw vegetables or water contaminated with metacercariae. Women have a higher incidence of the disease, with more severe infections and complications than seen in men.

CLINICAL MANIFESTATIONS

After consumption of contaminated vegetables, the larvae excyst in the duodenum and then migrate through the bowel wall to the liver through the peritoneal cavity. In 4 weeks, they reach the liver, penetrate Glisson's capsule, and cause inflammation and pain. An acute diarrhea of 2 to 5 days' duration may occur before liver invasion. During their migration through the liver, the ongoing inflammatory process is accompanied by fever, pain, and hypereosinophilia. In a few cases, intense hemorrhage manifested as subcapsular liver hematoma may develop. Computed tomography (CT), magnetic resonance imaging, or ultrasonography can detect these initial lesions. Furthermore, migration of the parasite leaves a trail or track that can be observed in histologic sections or by imaging (CT). The flukes sometimes die and leave cavities filled with necrotic debris that are eventually replaced by scar tissue and then become calcified. After 3 to 5 months of migration in the liver, the juvenile larvae finally reach the bile ducts. During this invasive, migratory, or acute phase the clinical manifestations are prolonged fever, hepatomegaly, abdominal pain, and eosinophilia. Multiple hypodense lesions are seen on CT, similar to metastases, but they change in position, attenuation, and shape in time because the parasites are still migrating. Acute fascioliasis is clinically similar to acute cholecystitis but with the addition of significant eosinophilia. It can occur in travelers with acute subcapsular hematoma or "metastatic-like lesions" seen on CT of the liver. Hyperbilirubinemia is notably absent in this phase. Other manifestations are anorexia, weight loss, nausea, vomiting, cough, diarrhea, urticaria, lymphadenopathy, and arthralgias. Occasionally, the juvenile larvae reach other ectopic or extrahepatic locations, such as subcutaneous tissue, the pancreas, the eye, the brain,[2] and the stomach wall, among others. In endemic areas, the acute phase manifestations can be superimposed on chronic infection.

Arrival of the parasite in the bile ducts marks the beginning of the chronic phase. Mature flukes consume hepatocytes and duct epithelium and reside for years in the hepatic and common bile ducts and sometimes in the gallbladder. In this chronic phase, the liver contains large dilated, thick-walled, and calcareous bile ducts with yellowish-brown bile. The bile ducts have a thickened hyperplastic wall with marked fibrosis. Symptoms usually reflect biliary obstruction with colicky pain in the right upper quadrant and epigastric area. Eosinophilia is absent in half of the chronic cases. Bacterial superinfection of these cysts and consequent cholangitis can develop. Other complications are hemobilia and liver fibrosis. Alkaline phosphatase is commonly elevated because of biliary obstruction, which sometimes requires surgical intervention. On imaging, the initial lesions may be often confused with hepatic metastases. Other findings on CT are hepatomegaly, tracklike

hypodense lesions in subcapsular locations, multiple hypodense nodular areas (abscess-like lesions), or low-density, serpiginous, tortuous, tunnel-like branching lesions ranging from 2 to 10 mm. CT also can show subcapsular hematoma, enhancement of Glisson's capsule, necrotic granuloma, and cystic calcifications. After maturation, the adult flukes start laying eggs, which are passed from the sphincter of Oddi to the intestines and evacuated to the environment along with stool. Adult parasites can live in the bile ducts for up to 13 years. In endemic populations, chronic infection has been reported as mildly symptomatic, whereas in travelers or temporary residents, it has been reported to cause biliary obstruction, with adult parasites being seen on endoscopic retrograde cholangiopancreatography (ERCP).

In summary, the typical clinical presentation of acute fascioliasis must be differentiated from cholecystitis; "liver metastasis" with fever and hypereosinophilia should raise the possibility of this infection; and in children and adolescents, systemic toxocariasis will be the differential diagnosis

Clonorchiasis and Opisthorchiasis

Clonorchiasis is the disease caused by *Clonorchis sinensis,* also called the Chinese or oriental liver fluke (adult: 10 to 25 mm by 3 to 5 mm). Opisthorchiasis is caused by *Opisthorchis viverrini* (adult: 5 mm to 10 mm by 1 mm to 2 mm) and *Opisthorchis felineus* (adult: 7 to 12 mm by 2 to 3 mm). The most common natural hosts are dogs, cats, pigs, and some small wild mammals.

EPIDEMIOLOGY

The global estimate of the number of people infected is 46.2 million: 35 million with *C. sinensis* (15 million in China), 10 million with *O. viverrini* (8 million in Thailand), and 1.2 million with *O. felineus.* There are 601 million and 79.8 million people at risk for infection with *Clonorchis* and *Opisthorchis*, respectively. Both infections are endemic in the Far East, Southeast Asia, and Eastern Europe. *C. sinensis* is endemic in northeast China, southern Korea, Japan, Taiwan, northern Vietnam, and the far eastern part of Russia, whereas *O. viverrini* is endemic in Laos, Thailand, Vietnam, and Cambodia. *O. felineus* infection is prevalent in Russia, Ukraine, and Kazakhstan.

PATHOBIOLOGY

The life cycle starts when the adult worm deposits fully developed eggs, which are then passed to the environment through feces. They hatch in water and the miracidia infect their first intermediate host, a freshwater snail (*Bithynia* spp or *Parafossarulus* spp), where they transform into sporocysts, rediae, and cercariae. Cercariae are released from the snail and then penetrate freshwater fish, which are the second intermediate host (*Cyclocheilichthys* spp, *Puntius* spp, *Hampala dispar*); the cercariae encyst as metacercariae in the muscles or under the scales. In general, the infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas or dishes such as koi-pla, a salad made with raw fish. The metacercariae pass through the stomach and reach the small intestine unharmed. Then, through the ampulla of Vater, they reach the bile ducts, where they mature into adult worms within 4 weeks and deposit yellow, operculated eggs. The parasites may live for up to 45 years in a human host.

CLINICAL MANIFESTATIONS

Clonorchiasis as an acute infection caused by *C. sinensis* is usually asymptomatic, but some patients may have fever, rash, malaise, and right upper quadrant abdominal discomfort.[3] Chronic infections may be manifested as recurrent pyogenic cholangitis, cholecystitis, obstructive jaundice, hepatomegaly, cholecystitis, multiple hepatic tumors, cholelithiasis, or pancreatitis. In chronic carriers with a high load of parasites, cholangiocarcinoma may develop, especially in Thailand.

Opisthorchiasis as an acute infection caused by *O. viverrini* can cause right upper quadrant abdominal pain, flatulence, fatigue, and a hot sensation over the abdomen. In the chronic phase, mild hepatomegaly occurs, mainly in more heavily infected patients (egg counts >10,000/g). Jaundice and splenomegaly are not observed. Intrahepatic duct stones and recurrent suppurative cholangitis are common manifestations of opisthorchiasis. Whenever jaundice and ascending cholangitis are detected, fluke-related cholangiocarcinoma should be suspected.[4]

In opisthorchiasis caused by *O. felineus,* infestation usually follows the consumption of raw, slightly salted, and frozen fish ("stroganina"), and acute symptoms occur 2 to 4 weeks later, including high-grade fever, nausea, vomiting, abdominal pain, malaise, arthralgias, lymphadenopathy, and rash. Peripheral eosinophilia is a common finding, especially during the initial 2 to 6 weeks of the infection, together with raised liver enzyme levels. In chronic infection, the eosinophilia is usually milder. Patients may have suppurative cholangitis and liver abscesses because of biliary obstruction. Ultrasonography or CT demonstrates the pathologic changes in the liver, including intrahepatic duct dilation and periductal changes.

The pathologic and clinical consequences of these flukes are related to the intensity and duration of cumulative infestations. In general, they cause inflammation around the biliary tree, severe hyperplasia of epithelial cells, metaplasia of mucin-producing cells in the mucosa, and progressive periductal fibrosis. There are clear associations between *O. viverrini* infection and cholangiocarcinoma.[5] Several *N*-nitroso compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste (*pla ra*), a condiment that is a ubiquitous component of the cuisine of northeastern Thailand and Laos.

INTESTINAL FLUKES

The most common human intestinal trematode is *Fasciolopsis buski* (adult: 20 to 75 mm by 8 to 20 mm). It is found mainly in the central and southeast parts of Asia. *F. buski* is a common parasite in pigs. Others are *Heterophyes* (adult: 1 to 2 mm in length), *Metagonimus yokogawai* (adult: 1 to 2.5 mm by 0.4 to 0.75 mm), and *Echinostoma* spp (adult: 6.5 by 1 to 2 mm).

EPIDEMIOLOGY

More than 50 species of intestinal trematodes from the Far East, Middle East, and North Africa have been reported to cause human infection. *H. heterophyes* also can be found in the Nile delta region of Egypt. An estimated 40 to 50 million people are infected with one or several species of intestinal flukes. Their life cycles are similar. The adult worm, attached to the intestinal wall of humans, produces eggs that are passed in feces. The eggs reach water, and miracidia develop and penetrate the first intermediate host—snails. During the course of 6 to 7 weeks inside the host snails, they develop into sporocysts, rediae, and cercariae. The cercariae leave the snails to encyst in the second intermediate host, which can be freshwater snails, fish, tadpoles, or vegetables. Humans are infected by the ingestion of raw stems, leaves (especially bamboo shoots), watercress, or water chestnuts with encysted metacercariae. In the human duodenum, the metacercariae attach to the walls and become adult worms in approximately 3 months.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Despite the fact that the majority of intestinal fluke infections are asymptomatic, they may cause inflammation, ulceration, and mucus secretion at the site of attachment, particularly in the duodenum and jejunum. In fact, gastrointestinal hemorrhage, perforation, and abscesses have been observed. The differential diagnoses include typhoid fever, intestinal tuberculosis, and amebiasis. In these endemic cases, ulcerative colitis and other inflammatory diseases of the bowel are uncommon. In heavy infection, intestinal obstruction, protein-losing enteropathy, malabsorption, impaired vitamin B_{12} absorption, hypoalbuminemia, and anasarca have been reported. The adult worm causes traumatic, toxic, and obstructive damage to the intestinal mucosa. Some cases have been diagnosed by direct visualization of the adult parasite via esophagogastroduodenoscopy.

PULMONARY FLUKES

Paragonimiasis is a zoonosis caused by *Paragonimus* spp (adult size: 10 by 5 mm).[6] Reservoir hosts include felids, canids, viverrids, mustelids, some rodents, and pigs. At least 10 species of *Paragonimus* are known to cause human disease; of these, *Paragonimus westermani* is the most common.

EPIDEMIOLOGY

An estimated 22 million people are infected worldwide with *Paragonimus* spp, and 293 million are at risk. Human paragonimiasis is distributed mainly in Southeast Asia, Japan, Korea, China, and the Philippines, where *P. westermani* is the main species. In other areas of low endemicity, other species have been reported, such as *Paragonimus mexicanus* in Latin America, *Paragonimus kellicotti* in North America, *Paragonimus heterotremus* in India, and *Paragonimus africanus,* and *Paragonimus uterobilateralis* in West Africa.

PATHOBIOLOGY

The life cycle starts when the eggs are excreted unembryonated in sputum, or alternatively they can be swallowed and passed in stool. In the external environment the eggs become embryonated, and miracidia hatch, seek the first intermediate host, a snail (families Pleuroceridae and Thiaridae), and penetrate its soft tissues. Within the snail, asexual reproduction occurs for

several weeks, with transformation into sporocysts, rediae, and cercariae; the last emerge from the snail and invade the second intermediate host, a crustacean such as a crab or crayfish, where they encyst and become metacercariae. This is the infective stage for the mammalian host. Human infection occurs by eating inadequately cooked or pickled crab or crayfish that harbor metacercariae of the parasite. The metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate through the peritoneal cavity toward the lungs. During migration through the peritoneum and diaphragm, the inflammatory process causes abdominal pain and dry cough. When invading the lungs, they become encapsulated and develop into adults. Infections may persist for 20 years in humans.

CLINICAL MANIFESTATIONS

Paragonimiasis typically results from the consumption of raw or improperly cooked crustaceans, especially crabs. Recently in the United States, some autochthonous cases have been reported in the Midwest in people who consumed raw crayfish while camping during the summer.[7] Most of the infected people are asymptomatic and have subclinical disease. During the first month of infection, abdominal pain may represent the juvenile larvae migrating through the abdominal cavity before reaching the lungs. Irritation of the diaphragm or pleura may cause dry cough. Fever, chest pain, fatigue, and urticaria may follow, as well as eosinophilia. Pleural effusions may be seen at this stage, with significant eosinophilia noted on analysis of pleural fluid, which can be the first clue to the diagnosis. In fact, pleural manifestations predominate early in the disease process, whereas lesions of the pulmonary parenchyma predominate later in the course of disease. Moreover, pneumothorax and mild eosinophilia may occur only 1 month after the initiation of infection. The migrating worms may cause bronchiectasis, interstitial pneumonitis, transient hemorrhage, or bronchopneumonia. Again, pulmonary lesions and eosinophilia raise the possibility of paragonimiasis. Cough and recurrent hemoptysis are common clinical findings in this phase. The chronic stage occurs when the worms are paired in a cyst in the pulmonary parenchyma. Eggs are produced 6 weeks after infection, and if there is communication with the bronchial tree, eggs may be seen in a sputum sample under microscopy, or they can be swallowed and passed with stool. The rusty discoloration of sputum is caused by the presence of the tan- to brown-pigmented *Paragonimus* eggs; the sputa of these patients have been classically described as resembling "iron filings." Charcot-Leyden crystals can be seen.

Peripheral blood eosinophilia and elevated total serum IgE levels are observed in approximately 80% of patients. Common findings on CT are pleural effusion, hydropneumothorax, pulmonary nodules or consolidation of air spaces, and cysts. The most common ectopic form is cerebral paragonimiasis, which is manifested as eosinophilic meningitis or meningoencephalitis, brain tumor, or just residual calcifications from a past infection.

DIAGNOSIS AND TREATMENT OF LIVER, INTESTINAL, AND LUNG FLUKE INFECTIONS

DIAGNOSIS

In general, transmission of food-borne trematodiases is restricted geographically and distribution is one of the most important factors in suspecting this diagnosis. In the appropriate clinical setting, laboratory and imaging data can add information to narrow the differential diagnosis. Acute fluke infections require a high level of suspicion. Serologic tests, direct visualization of the migrating larvae, or empirical therapy with a significant clinical response (including reduction of eosinophilia) are major criteria to confirm the diagnosis. In the chronic phase, the diagnosis is usually made by visualization of the eggs in stool or, in the case of *Paragonimus,* in sputum. A sedimentation technique must be performed on a series of at least three stool specimens from alternate days or even weeks. Some of the sedimentation or concentration parasitologic techniques used for these infections include the Lumbreras rapid sedimentation technique, the Kato-Katz technique, and the ether-formalin concentration technique. Immunodiagnostics is an excellent tool, particularly for patients who do not have demonstrable eggs in clinical specimens.

If acute fascioliasis is strongly suspected, serology would be the next step. Cathepsin L1–based antibody enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 92% and a specificity of 84%. If negative, the diagnosis is unlikely. If serology is not available, CT of the liver can visualize the characteristic tracklike lesions. However, because the parasitic lesions are very similar to metastases, liver biopsy may be necessary. If serology or CT is not available, a trial of triclabendazole with clinical (including eosinophilia) resolution is the major criterion for diagnosis. In chronic fascioliasis, the Lumbreras rapid sedimentation technique is the method of choice to detect the eggs in stool. At least three stool examinations are preferred. If negative, serology can be helpful. Ultrasonography and CT have low sensitivity in this phase. ERCP usually finds the adult parasites in the bile duct when performed for other reasons. Nonetheless, ERCP can be useful to eliminate the adult parasites causing biliary obstruction.

In opisthorchiasis, serology or stool examinations can be performed to approach the diagnosis. The Ov-CP-1–based enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 95% and a specificity of 96%. For *C. sinensis,* ELISA has a sensitivity between 81.3 and 96% and a specificity between 92.6 and 96.2%. For detection of eggs and to measure the intensity of infection, the Kato-Katz technique is preferred. Intestinal fluke eggs can be detected by performing a sedimentation stool technique, preferably in consecutive stool samples.

For paragonimiasis, an immunoblot assay performed with a crude antigen extract of *P. westermani* has been in use at the Centers for Disease Control and Prevention; the sensitivity of the test is 96%, and its specificity is 99%. This would be the ideal first step to confirm the diagnosis. In the acute phase, the precise location of the migrating larva is unknown and a biopsy may not necessarily target the parasite. When serologic findings are negative (or not available), a trial of praziquantel or triclabendazole with a positive clinical response in 48 to 72 hours is a major criterion for diagnosis. In the chronic phase, several sputum samples have to be examined by a sedimentation technique to increase sensitivity. Stool examinations are complementary because the eggs can be swallowed by the host and then passed through stool. If a pulmonary cyst contains adult parasites with eggs but they do not have communication to the main bronchi, serologic examination is indicated to confirm the diagnosis. If not available, biopsy is warranted.

Under the light microscope, the morphologic characteristics and size of the eggs may be sufficient to identify the specific fluke. For *Fasciola,* the egg is large, ellipsoid, and oval, with an indistinct operculum and thin shell. The *F. hepatica* egg measures 120 to 150 µm by 63 to 90 µm, the *F. gigantica* egg measures 160 to 190 µm by 70 to 90 µm, and the *F. buski* egg measures 130 to 159 µm by 78 to 98 µm. *Opisthorchis* eggs are elongated with an operculum on the anterior end and a pointed terminal "knob" on the posterior end (26 to 30 µm by 11 to 15 µm). *C. sinensis* eggs (27 to 35 µm by 11 to 20 µm) are small, ovoid, or elongated, with broad rounded posterior ends, a convex operculum resting on "shoulders," and a small "knob" on the posterior ends. *H. heterophyes* and *M. yokogawai* eggs are similar in size, 26 to 30 µm by 15 to 17 µm. *Echinostoma* eggs are brownish, operculated, and measure 83 to 116 µm by 58 to 69 µm. *Paragonimus* eggs measure 68 to 118 µm by 39 to 67 µm, are reddish-brown and ovoid or elongated, and have a thick shell; the operculum is slightly flattened and fits into the shoulder area of the shell, and the posterior end is thickened. The egg is often asymmetrical, with one side slightly flattened.

TREATMENT

Rx

The general principles and details of antiparasitic therapy are provided in Chapter 344. For fascioliasis, 10 mg/kg of triclabendazole once or twice has a cure rate higher than 90%, and it is the treatment of choice. Cure is achieved if stool examinations remain negative for at least 3 months. Serology usually can take more than a year to resolve. In treatment of the chronic phase, the dead parasites can occasionally cause biliary obstruction, which may need surgical consultation. In case of failure, some experts recommend double doses of triclabendazole for 2 days. Recently, in Mexico, nitazoxanide has appeared promising, but more experience is needed. For *O. viverrini,* a single dose of praziquantel (40 to 50 mg/kg) has a cure rate of 91 to 97%. For clonorchiasis, the recommended dose of praziquantel is 25 mg/kg three times for 1 day (total dose of 75 mg/kg), which has a cure rate of 83 to 85%. Tribendimidine has been found to be comparably effective as praziquantel in the treatment of *C. sinesis* infection with fewer adverse events in an open-label trial in 74 patients. For intestinal flukes, praziquantel, 25 mg/kg by mouth three times daily for 1 day, is recommended. For paragonimiasis, praziquantel, 25 mg/kg by mouth three times daily for 3 days, or triclabendazole, 10 mg/kg by mouth once or twice, is highly effective. For ectopic cases, surgery may be necessary. In follow-up, negative stool examinations in the ensuing weeks can confirm cure. However, because the rate of reinfection is high in individuals from endemic areas, a suddenly positive stool examination is highly suggestive of a new infection rather than failure to respond to treatment.

PREVENTION

Prevention of infection with these flukes depends on several factors, including recognizing their geographic distribution and avoiding the consumption of raw vegetables, fish, crayfish, or contaminated water in endemic areas. Proper medical advice must be given to individuals traveling or planning to reside in endemic areas, not only to prevent fluke infection but also to inform them about the risk for coinfection with other parasites. Control of these flukes in animals is impractical because of wild animal reservoirs. However, control of human infections is challenging because it involves changing long-established cultural, dietary, and sanitary habits. Massive chemotherapy in highly endemic populations may reduce the infection in humans and in selected animals.

REVIEW QUESTIONS

1. Hepatic *Fasciola* is acquired by ingestion of:

A. Uncooked shellfish
B. Watercress
C. Fresh fish meat products
D. Fresh fish
E. All the above

Answer: B Hepatic *Fasciola* do not invade fish or meat. After invading freshwater snails, they leave as free-swimming cercaria that subsequently attach to watercress (as well as water lettuce, alfalfa, mint, parsley, or khat).

2. *Paragonimus* is acquired by ingestion of:

A. Uncooked crab or crayfish
B. Watercress and fresh fish meat products
C. All the above

Answer: A *Paragonimus* emerges from the snail and invades the second intermediate host, a crustacean such as a crab or crayfish, where they encyst and become the infective stage for a mammalian host.

3. The treatment of choice for *O. viverrini* or clonorchiasis is:

A. Albendazole
B. Praziquantel
C. Ivermectin
D. Triclabendazole
E. Emetina

Answer: B For *O. viverrini* or clonorchiasis, praziquantel regimens have been shown in several studies to have cure rates of 91 to 97% and 83 to 85%, respectively. Albendazole has poor activity. Ivermectin is effective for onchocerciasis and strongyloides. Triclabendazole is the drug for *Fasciola,* but it is second-line option here. Emetina is a parenteral drug that is useful only for *Fasciola* with high toxicity.

4. Cholangiocarcinoma is associated in Southeast Asia with chronic carriage of:

A. *Fasciola hepatica*
B. *Strongyloides*
C. *Toxoplasma*
D. *O. viverrini*
E. *Taenia*

Answer: D Several studies in Thailand have demonstrated a strong association of *O. viverrini* with cholangiocarcinoma. *Fasciola hepatica* is associated with fibrosis but not cancer. *Strongyloides* produces hyperinfection but not cancer. Toxoplasma does not invade the biliary tract. Taenia is not associated with cancer.

5. A 33-year-old man presents with pleural effusion and eosinophilia. In the following weeks he developed a recurrent hemoptysis. The most likely diagnosis is:

A. Tuberculosis
B. Strongyloidiasis
C. Toxocara
D. *Fasciola hepatica*
E. *Paragonimus*

Answer: E The typical clinical pattern for *Paragonimus* is the damaged lung, where hemoptysis and eosinophilia are the more common presentation. Evaluation of the sputum will be the key diagnostic test in this case. TB is the main differential diagnosis, but eosinophilia is not common in TB. Strongyloidiasis produces lung disease (migratory eosinophilic pneumonia) but is rarely associated with pleural effusion. *Toxocara* usually affects children and produces systemic disease with liver involvement; lung involvement is rare and hemoptysis even more so. *Fasciola hepatica* is associated with eosinophilia, but its typical presentation is a liver "abscess"–like or metastatic-like syndrome, and lung involvement with hemoptysis is rare.

357 INTESTINAL NEMATODE INFECTIONS

DAVID J. DIEMERT

DEFINITION

Nematodes are nonsegmented roundworms belonging to the phylum Nematoda. Most species are free-living in soil or water, but a few parasitize humans. Nematode infections are highly prevalent and affect millions worldwide. They are complex multicellular organisms with specialized organs that include a protective outer coating or cuticle, a complete and functional gastrointestinal tract, and muscular, nervous, and reproductive systems.

Nematodes of medical importance can be divided into those that primarily affect the gastrointestinal tract, where adult worms become established and cause disease, and those that affect other tissues and organ systems. The former group is covered in this chapter and includes the roundworm *Ascaris lumbricoides,* the hookworms *Ancylostoma duodenale* and *Necator americanus,* the pinworm *Enterobius vermicularis,* the whipworm *Trichuris trichiura,* and the threadworm *Strongyloides stercoralis*. Zoonotic intestinal nematodes such as *Trichostrongylus* and *Anisakis* also occasionally infect and cause disease in the gastrointestinal tract of humans. Nematodes that invade and cause disease primarily in tissues outside the gastrointestinal tract include those that cause lymphatic filariasis (*Wuchereria bancrofti, Brugia malayi,* and *Brugia timori*), *Onchocerca volvulus, Loa,* the guinea worm *Dracunculus medinensis,* as well as *Trichinella* and *Angiostrongylus* spp (Chapter 358).

Nematodes that infect humans measure from several millimeters to more than a meter in length and often survive for months to years within their host. With the exception of *S. stercoralis* and *Capillaria philippinensis,* adult worms cannot complete their life cycle within a human host. Instead, sexually mature adult worms mate and produce eggs or larvae that must have at least one stage of development outside the host, either in the environment or in an intermediate host.

Nematode infections are rarely fatal; they more commonly result in chronic morbidity such as iron deficiency anemia caused by hookworm or blindness due to onchocerciasis. For most nematodes, the severity of the clinical manifestations of infection is proportional to the number of worms harbored by a given host; although light infections with only a few worms are usually asymptomatic, pathologic features appear with heavier worm burdens.

Nematode infections are prevalent in the temperate and tropical regions of Africa, Asia, and Latin America. They are transmitted by the oral ingestion of embryonated eggs or by penetration of infective larvae through the skin, either by direct contact with contaminated soil or by arthropod vectors. Nematode infections are most common in areas with poor sanitation, where the environment is contaminated by human waste, and in climates that support survival of the insect vector, if one is involved in the life cycle.

In endemic areas most individuals harbor low numbers of worms and a minority have relatively high worm burdens and contribute disproportionally to both transmission and morbidity.

ASCARIASIS

The Pathogen

A. lumbricoides, colloquially known as *roundworm,* is acquired by oral ingestion of embryonated eggs. In the stomach, the egg's protective outer shell is dissolved by gastric acid, releasing larvae into the small intestine, where they penetrate the intestinal wall and enter the portal circulation. The larvae migrate to the liver and then the pulmonary vasculature, where they break into the alveolar spaces, ascend the bronchial tree, and are swallowed to re-enter the small intestine, developing there into adult worms approximately 9 to 11 weeks after egg ingestion. Adult worms (Fig. 357-1) range in length between 15 and 50 cm and survive in the host for approximately 18 months.[1] Female adult *Ascaris* worms produce approximately 240,000 eggs per day, which are expelled in feces. Fertilized eggs embryonate in warm, moist, shady soil, after which they are infectious (Fig. 357-2). Eggs can survive up to 15 years in the environment, being extremely hardy and resistant to extreme temperatures and desiccation.

EPIDEMIOLOGY

A. lumbricoides is the most prevalent nematode infection worldwide, with approximately a billion people chronically infected.[2] Infection is common in sub-Saharan Africa, south and Southeast Asia, and Latin America, especially in rural areas of high population density with inadequate sanitation or treatment of sewage and where untreated human feces are used as fertilizer.

FIGURE 357-1. Mass of adult *Ascaris lumbricoides* worms recovered from a child after the administration of mebendazole. (Reproduced with permission from Dickson Despommier.)

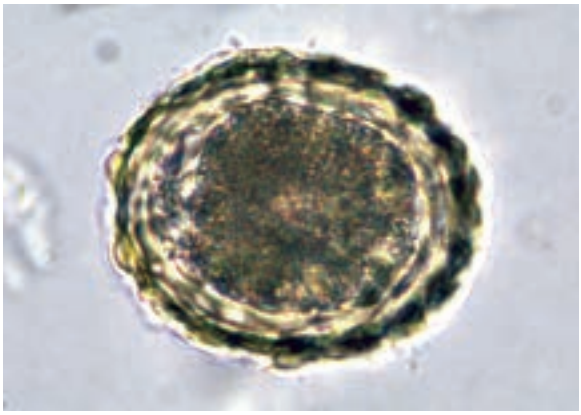

FIGURE 357-2. Fertilized, unembryonated egg of *Ascaris lumbricoides*. (Reproduced with permission from Dickson Despommier.)

Climate is an important determinant of disease in that warm temperature and adequate moisture are required for embryonation of eggs in soil. In endemic areas, the prevalence and intensity of infection with *A. lumbricoides* increase dramatically during the first 2 to 3 years of life; it remains high between the ages of 4 and 15 years and then declines during adulthood.[3]

CLINICAL MANIFESTATIONS

Infection with *A. lumbricoides* is usually asymptomatic. Clinical manifestations are associated with heavy worm burdens and can be classified into those resulting from larval migration through the lungs and those due to parasitism of the gastrointestinal tract by adult worms.

When migrating through the lungs, *A. lumbricoides* larvae can induce an intense reaction that is due to both the physical disruption that their migration causes and a dramatic inflammatory hypersensitivity response to secreted antigens. This phenomenon is more common in areas in which transmission is seasonal, such as on the Arabian Peninsula, where outbreaks of pneumonitis typically follow the rainy season because of resumption of transmission. Symptoms may last for 2 to 3 weeks and include the sudden onset of wheezing, dyspnea, paroxysmal nonproductive cough, and high fever. Respiratory symptoms may coincide with or be preceded by urticarial rash, angioedema, abdominal pain, and vomiting. These symptoms usually resolve spontaneously.

With moderate or heavy infections, signs and symptoms can result from obstruction caused by a mass of worms in the small intestine or migration of worms to the biliary tree, pancreatic duct, or appendix. Intestinal obstruction is more common in young children because of their smaller lumen size and is characterized by colicky abdominal pain and vomiting that may progress to signs of intestinal perforation. Hepatobiliary and pancreatic ascariasis is more common in adults, presumably because their biliary tree is large enough to accommodate a migrating worm. Chronic intestinal infection also can manifest as abdominal pain and distention, diarrhea, and nausea. More insidious effects, especially in children, include decreased protein and fat absorption, development of vitamin A and C deficiencies, and lactose intolerance, which together lead to stunted growth and impaired cognitive development.

DIAGNOSIS

The diagnosis of ascariasis is usually made by microscopic examination of a sample of feces for characteristic thick-shelled eggs.[4] Pulmonary ascariasis cannot be diagnosed on the basis of identification of ova in feces because adult worms have not yet matured and begun producing eggs; instead, larvae, as well as eosinophils or Charcot-Leyden crystals (formed from the breakdown of eosinophils), may be visualized on microscopic examination of sputum. Pulmonary disease is also usually marked by peripheral eosinophilia and transient infiltrates on chest radiographs. The diagnosis of intestinal or biliary obstruction caused by *A. lumbricoides* relies increasingly on radiologic evaluation with ultrasound or endoscopic retrograde cholangiopancreatography (ERCP).

TREATMENT

Rx

Intestinal ascariasis is usually treated with a single oral dose of albendazole (Table 357-1). Alternatives include mebendazole, ivermectin, or pyrantel pamoate. No specific treatment is recommended for symptoms of pulmonary ascariasis because the condition is self-limited. In severe cases of biliary obstruction, including cholangitis, ERCP with or without resection of the ampulla of Vater is highly successful and may reduce the need for surgical intervention.

PREVENTION

The definitive means of preventing *Ascaris* infection is improvement of hygiene and proper disposal of human waste. In endemic communities where this is not feasible, control efforts center on regular (at least annual) mass administration of an anthelmintic medication such as albendazole or mebendazole.[5]

HOOKWORM

The Pathogen

Hookworm infection in humans is due almost exclusively to two species: *N. americanus* and *A. duodenale*. Humans may also be incidentally infected by the zoonotic hookworms *Ancylostoma caninum, Ancylostoma braziliensis, Bunostomum phlebotomum,* and *Uncinaria stenocephala*, which can cause self-limited dermatologic lesions known as cutaneous larva migrans (Fig. 357-3). Additionally, *Ancylostoma ceylanicum,* normally a hookworm infecting cats, has been reported to cause intestinal hookworm disease in humans, especially in Asia, whereas *A. caninum* has been implicated as a cause of eosinophilic enteritis in Australia.

Infection occurs when exposed skin comes in contact with infective filariform larvae in contaminated soil or grass. Larvae penetrate the skin, enter the afferent circulation, and migrate to the pulmonary vasculature, where they break into the alveolar spaces, ascend the bronchial tree to the trachea, and are swallowed into the gastrointestinal tract. Larvae undergo two molts to mature into adult worms approximately 5 to 9 weeks after skin penetration.

TABLE 357-1 TREATMENT OF INTESTINAL NEMATODES

NEMATODE	TREATMENT
Ascaris lumbricoides	Albendazole, 400 mg once. Alternatives: Mebendazole, 100 mg bid for 3 days; ivermectin 150-200 μg/kg once, or pyrantel pamoate, 11 mg/kg for 3 days with the maximum daily dose not to exceed 1 g
Hookworm (*Necator americanus* and *Ancylostoma duodenale*)	Albendazole, 400 mg/day for 3 days. Alternatives: Mebendazole, 100 mg bid for 3 days, or pyrantel pamoate, 11 mg/kg for 3 days with the maximum daily dose not to exceed 1 g
Trichuris trichiura	Mebendazole, 100 mg bid, or albendazole, 400 mg/day, for 3 days; or oxantel pamoate, 20 mg/kg, plus albendazole, 400 mg, administered daily for 2 days*
Enterobius vermicularis	Pyrantel pamoate, 11 mg/kg once, with a second dose 2 wk later; maximum dose of 1 g. Alternatives: Mebendazole, 100 mg once, or albendazole, 400 mg once, repeated in 2 wk
Strongyloides stercoralis	Uncomplicated infection: Ivermectin, 200 μg/kg/day for 2 days.† Alternative: Albendazole, 400 mg/day for 7 days
Trichostrongylus spp	Pyrantel pamoate, 11 mg/kg once; maximum dose of 1 g. Alternatives: Albendazole, 400 mg once, or mebendazole, 100 mg bid for 3 days
Capillaria philippinensis	Albendazole, 400 mg/day for 10 days. Alternative: Mebendazole, 200 mg bid for 20 days

*Oxantel pamoate is not approved by the U.S. Food and Drug Administration for this use at the time of this writing.
†Treatment may need to be extended in immunocompromised patients with disseminated disease.

FIGURE 357-3. Typical lesion of cutaneous larva migrans. An erythematous, serpiginous track caused by intradermal migration of a dog (*Ancylostoma caninum*) or cat (*Ancylostoma braziliense*) hookworm larva is apparent. (Reproduced with permission from Gregory L. Zalar.)

Adult hookworms reside in the lumen of the upper part of the small intestine, where they attach to the mucosa by means of cutting teeth (*A. duodenale*) or a rounded cutting plate (*N. americanus*). After mating in the host intestinal tract, a female adult worm produces thousands of eggs per day, which then exit the body in feces; *A. duodenale* female worms lay approximately 28,000 eggs daily, whereas the output from *N. americanus* worms is considerably less, averaging around 10,000 a day. Hookworm eggs hatch in warm, moist soil and release larvae that can infect another host. Humans are the only major definitive host for these two parasites, and there are no intermediate or reservoir hosts. *A. duodenale* survives on average for 1 year in the human intestine, whereas *N. americanus* lives for 3 to 5 years.

EPIDEMIOLOGY

More than 500 million people are infected with hookworms worldwide. *N. americanus* is the most widespread hookworm, whereas *A. duodenale* is more geographically restricted in distribution. The highest prevalence of infection occurs in rural areas of tropical and less developed countries, where environmental and socioeconomic conditions favor transmission. Climate is an important determinant of hookworm transmission, with adequate moisture and warm temperature being essential for larval development in soil. An equally important determinant of infection is poverty and inadequate sanitation and supply of clean water. In endemic areas, prevalence increases with age in young children and reaches a plateau by approximately 10 years of age, whereas the intensity of infection rises at a slower rate during childhood, reaches a plateau by around 20 years, and then increases again in the elderly. Whether such age dependency reflects differences in exposure, acquired immunity, or a combination of both is controversial.

Although cutaneous larva migrans is found throughout the tropics, in the United States it is diagnosed primarily in tourists who have recently returned from a vacation to a tropical beach destination, especially in the Caribbean, Brazil, Mexico, and Southeast Asia. Occasionally, autochthonous cases (originating where found) have been reported in the United States, usually from southeastern coastal states such as Florida and South Carolina. Most commonly, cutaneous larva migrans occurs when exposed skin comes in contact with the larval stages of the dog or cat hookworms *A. caninum* or *A. braziliense,* respectively, present in moist soil or sand (especially on beaches) contaminated with animal feces. Other animal hookworms such as *U. stenocephala* and *B. phlebotomum* are less common causes.

PATHOBIOLOGY

The major pathology of hookworm infection is due to the associated gastrointestinal blood loss and the resulting iron deficiency anemia. Hookworms attach to the intestinal mucosa and secrete enzymes that enable them to invade submucosal tissues and ingest villous tissue and blood. Hemoglobinases within the hookworm's digestive canal enable degradation of human hemoglobin for use as an essential nutrient source. The amount of blood loss is directly related to the total worm burden. *A. duodenale* causes more blood loss than *N. americanus;* each *N. americanus* worm results in a daily blood loss of 0.03 to 0.1 mL, and the corresponding figure for *A. duodenale* is between 0.15 and 0.26 mL.

CLINICAL MANIFESTATIONS

The clinical features of hookworm infection can be separated into acute manifestations associated with larval migration through the skin and other tissues and acute and chronic manifestations resulting from parasitism of the gastrointestinal tract by adult worms. Repeated skin exposure to hookworm larvae can result in a hypersensitivity reaction known as "ground itch," a pruritic erythematous and papular rash that appears most commonly on the hands and feet. In contrast, when zoonotic hookworm larvae penetrate the skin to produce cutaneous larva migrans, most commonly on the feet, thighs, and buttocks, they are unable to complete their life cycle in the human host and eventually die after causing a typical clinical syndrome of intensely pruritic, erythematous serpiginous tracks (see Fig. 357-3). Tracks appear after an incubation period of a few days, can be single or multiple, and advance by millimeters to a few centimeters each day. Vesiculobullous or papular lesions may develop along the tracks, as can secondary bacterial infection as a result of scratching. Untreated, lesions usually heal spontaneously within weeks to months following death of the larvae in the skin.

Migration of hookworm larvae through the lungs may induce mild and transient pulmonary symptoms consisting of dry cough, sore throat, wheezing, and low-grade fever. Acute symptomatic disease may uncommonly result from the oral ingestion of *A. duodenale* larvae, referred to as the Wakana syndrome, which is characterized by nausea, vomiting, pharyngeal irritation, cough, dyspnea, and hoarseness.

Abdominal symptoms and signs caused by hookworm infection are rare. Instead, the manifestations of hookworm disease occur when intestinal blood loss exceeds the nutritional reserves of the host and results in iron deficiency anemia. Usually only moderate- and high-intensity (≥2000 eggs per gram of feces) hookworm infections produce clinical disease, which resembles that of iron deficiency anemia secondary to other causes (Chapter 159). In addition, the protein losses associated with heavy hookworm infection can result in hypoproteinemia and anasarca. As iron deficiency anemia develops and worsens, an infected individual may have weakness, palpitations, fainting, dizziness, dyspnea, lassitude, and headache. Uncommonly, there may be constipation or diarrhea with occult blood in the stool or frank melena, especially in children; there also may be an urge to eat soil (pica). Overwhelming hookworm infection may cause listlessness, coma, and even death, especially in infants. Because children and women of reproductive age have reduced iron reserves, they are at particular risk for symptomatic disease. Severe iron deficiency anemia caused by hookworm during pregnancy can result in adverse consequences for the mother, her unborn fetus (miscarriage, intrauterine growth restriction), and the neonate (anemia, failure to thrive). In children, the anemia and protein malnutrition associated with chronic intestinal parasitism cause long-term impairments in physical and cognitive development.

DIAGNOSIS

The diagnosis of hookworm infection is made by microscopic identification of characteristic eggs in the stool. The eggs of *N. americanus* and *A. duodenale* cannot be distinguished because both are colorless and have a single thin hyaline shell with blunted ends; they range in size from 55 to 75 µm by 36 to 40 µm. Egg concentration techniques, such as the formalin–ethyl acetate sedimentation method, can be used to detect even light infections, although a direct wet mount examination is adequate for detecting moderate-to-heavy infections. In addition, eosinophilia is a common finding in chronic infection and also during larval migration through the lungs.

TREATMENT

Rx

Three daily oral doses of albendazole, 400 mg, is the recommended treatment for intestinal hookworm infection (see Table 357-1). Less effective alternatives include mebendazole, pyrantel pamoate, and single-dose albendazole. For cutaneous larva migrans, although the disease is self-limited and will resolve spontaneously within weeks to a few months, treatment with a single dose of ivermectin will lead to more rapid resolution of symptoms and skin manifestations. Albendazole is an alternative treatment of cutaneous larva migrans.

PREVENTION

The ideal method for preventing hookworm infection is improvement in hygiene and proper disposal of human waste. Until this occurs, in endemic communities control of disease consists of regular (at least annual) mass administration of an anthelmintic medication such as albendazole or mebendazole. For cutaneous larva migrans, tourists should be advised to wear shoes or sandals when walking to and on beaches and to avoid beaches frequented by stray cats and dogs.

TRICHURIASIS

The Pathogen

Infection with *T. trichiura,* also known as *whipworm,* does not have a tissue migratory phase like *A. lumbricoides* and hookworm, and its entire life cycle in the host is limited to the gastrointestinal tract. After embryonated eggs are ingested orally, larvae are released into the small intestine, where they undergo a series of molts before being carried passively to the transverse and descending colon. The narrow anterior end of adult worms embeds in the columnar epithelium, with the posterior portion protruding into the lumen, thereby allowing eggs to be released into feces, which are then passed into the environment, where they must embryonate in warm, moist soil to complete the life cycle. Adult worms can measure up to 50 mm in length and survive in the host for approximately 1.5 to 2 years. The period between ingestion of eggs and detection of eggs in feces is approximately 90 days.

EPIDEMIOLOGY

Like the other soil-transmitted helminths, trichuriasis is most common in poor, mostly rural areas of the tropics and subtropics where disposal of human waste is inadequate. The estimated prevalence worldwide is 800 million. Children are more frequently infected than adults and more likely to have higher worm burdens. Humans are the only host.

CLINICAL MANIFESTATIONS

Most *T. trichiura* infections are asymptomatic. Disease is mostly seen in children because the majority of heavy infections (>10,000 eggs per gram of feces) occur in this age group. Heavy infections can be accompanied by acute dysentery or chronic colitis resembling inflammatory bowel disease and result in abdominal pain and diarrhea. Chronic mucosal inflammation and edema of the colon and rectum can lead to protracted tenesmus that results in rectal prolapse. Chronic *Trichuris* colitis also can lead to malnutrition, impaired growth, and anemia.

DIAGNOSIS

Infection is diagnosed by microscopic identification of the typical barrel-shaped eggs with bipolar plugs in direct or concentrated smears of fecal specimens.

TREATMENT Rx

Although *T. trichiura* responds less effectively than *A. lumbricoides* or hookworm to treatment with albendazole or mebendazole, a 3-day course of one of these two benzimidazole drugs has been the recommended therapy, as listed in Table 357-1. The addition of ivermectin (200 µg/kg) to either drug increases the response rate significantly. More recently, the combination of oxantel pamoate, 20 mg/kg, plus albendazole, 400 mg, administered daily for 2 days, was found to result in higher cure and egg-reduction rates for *T. trichiura* infection then the rates with standard therapy. (Oxanetel is not approved for this by the U.S. Food and Drug Administration at the time of this writing.)

PREVENTION

As for *A. lumbricoides* and hookworm, control of trichuriasis in endemic areas centers on regular mass anthelminthic drug administration, primarily to school-age children, although single doses of albendazole or mebendazole are poorly effective for this intestinal nematode.

ENTEROBIASIS

The Pathogen

E. vermicularis, or pinworm, is transmitted by the fecal-oral route. Embryonated eggs on fingernails, bedding, or clothing are ingested and hatch in the upper small intestine, where they develop into adults before taking residence in the large intestine. Adult worms measuring between 2 and 5 mm live freely in the lumen of the colon, where they mate. Gravid female worms migrate nightly out of the rectum and deposit large numbers of eggs (11,000 per worm) on the perianal and perineal skin, where they rapidly embryonate within 6 hours of being deposited. If they are still on the skin, infective larvae are released that can migrate back through the anus into the rectum (retroinfection); alternatively, autoinfection occurs when eggs are transferred to the mouth via scratching the perianal skin on which eggs have been deposited, commonly in children. In infected females, larvae may also migrate into the genital tract and establish an ectopic infection.

EPIDEMIOLOGY

E. vermicularis is found worldwide and is the most prevalent nematode infection in temperate climes. Transmission is especially frequent in primary schools and daycare centers, where children are in close contact. Up to a quarter of all children worldwide are estimated to be infected with pinworm.

CLINICAL MANIFESTATIONS

Although most pinworm infections are asymptomatic, perianal pruritus is the most common symptom and is caused by an allergic response to worm proteins. The pruritus can be intense and result in chronic sleep deprivation. Rarely, adult *E. vermicularis* may precipitate appendicitis. When hatched larvae migrate into the female genital tract, vulvovaginitis, salpingitis, or peritonitis may develop.

DIAGNOSIS

Pinworm infection is diagnosed by identifying eggs by examination under a microscope on a piece of cellophane tape applied to the perianal region immediately after waking and before bathing. Characteristic *E. vermicularis* eggs are oval and slightly flattened on one side. It is unusual to find eggs in feces or adult worms in the perianal area. Repeated examination may be necessary.

TREATMENT Rx

Pinworm infection is treated with a single dose of pyrantel pamoate, mebendazole, or albendazole, which must be repeated 2 weeks later because the drugs do not kill eggs or developing larvae (see Table 357-1). Given the high rate of transmission, all household members and individuals in close contact with the patient (e.g., other children attending the same daycare center) should be treated as well. Bedding and underclothes should be thoroughly laundered in hot water followed by a hot dryer to kill the eggs.

STRONGYLOIDIASIS

The Pathogen

S. stercoralis, or threadworm, is endemic in warm climates worldwide, including parts of the United States.[6] Infection occurs when exposed skin comes in contact with free-living filariform larvae in soil contaminated with human feces. After penetrating the skin, larvae enter the afferent circulation and travel to the pulmonary vasculature, where they rupture into the alveolar spaces, ascend the bronchial tree to the pharynx, and are swallowed into the gastrointestinal tract. Further development into adult worms occurs in the upper small intestine, where parasites live embedded in the mucosa. Unlike most nematodes, *S. stercoralis* reproduces by parthenogenesis, with no apparent parasitic male worm present in human infection. Female worms begin laying eggs within 25 to 30 days after infection. The embryonated eggs hatch rapidly in the lumen of the small intestine and release noninfectious rhabditiform larvae that migrate to the colon and are excreted in feces. Alternatively, larvae may directly penetrate the colonic mucosa or perianal skin after migrating out of the anus and enter the circulation directly, a mechanism known as *autoinfection.* This phenomenon can lead to maintenance of parasitism in the host for decades.

Infectious filariform larvae develop in the soil by direct transformation from rhabditiform larvae or indirectly from eggs produced by free-living adult worms that have developed from rhabditiform larvae in warm, moist, sandy soil.

A less common type of strongyloidiasis, called *swollen belly syndrome,* has been attributed to infection with *Strongyloides fuelleborni* in infants living in sub-Saharan Africa and Papua New Guinea.

EPIDEMIOLOGY

S. stercoralis infection is endemic in the tropical and subtropical regions of sub-Saharan Africa, Asia, Latin America, and areas of eastern and southern Europe, with a worldwide prevalence of between 30 and 100 million. In the United States, infection is diagnosed most frequently in immigrants, commonly from Southeast Asia, although strongyloidiasis is still endemic in parts of rural Appalachia. *S. stercoralis* also be transmitted sexually through oral-anal contact, most often among men who have sex with men. Cases of transmission through solid organ transplantation have also been reported.

PATHOBIOLOGY

In immunologically competent individuals, infection is usually asymptomatic or is associated with mild gastrointestinal symptoms. The main complications of infection, however, occur in individuals with cell-mediated immunodeficiency such as those chronically taking corticosteroids, renal transplant recipients, patients with Hodgkin disease and other lymphomas, leukemic patients, and those infected with human T-cell lymphotropic virus type 1.[7] In these individuals, the autoinfection cycle of the *S. stercoralis* life cycle can become amplified and lead to a hyperinfection syndrome with a large increase in the total worm load in the infected person. Hyperinfection can lead to life-threatening dissemination of larvae and adult worms to aberrant sites such as the brain, pancreas, and kidneys. For unknown reasons, advanced acquired immunodeficiency syndrome has not been associated

with hyperinfection syndrome or with disseminated strongyloidiasis. Disseminated strongyloidiasis is frequently accompanied by bacterial sepsis, probably as a result of translocation of enteric organisms carried by migrating larvae.

CLINICAL MANIFESTATIONS

Most *S. stercoralis* infections, especially in immunocompetent hosts, are asymptomatic or are associated with only mild gastrointestinal manifestations such as abdominal pain, bloating, and watery diarrhea. Gastrointestinal bleeding, manifested by hematochezia or melena, occurs in less than 20% of those infected. Rare causes of morbidity include small bowel obstruction, paralytic ileus, and a malabsorption syndrome (especially in children).[8]

During the migratory phase of larvae through the lungs, symptoms are rare in immunocompetent patients, although there may be peripheral eosinophilia. However, pulmonary signs and symptoms in immunocompromised persons with hyperinfection syndrome can be severe and resemble those of acute respiratory distress syndrome with dyspnea, productive cough, and hemoptysis accompanied by fever, tachypnea, and hypoxemia.

Migration of filariform larvae from the anus can lead to a dermatologic manifestation known as larva currens, which is characterized by serpiginous erythematous maculopapular tracks that migrate by 5 to 15 cm/hour, primarily on the skin of the buttocks, upper aspect of the thighs, and lower part of the abdomen.

Autoinfection leading to exceptionally high worm loads (i.e., hyperinfection) and disseminated strongyloidiasis can occur in persons with deficient cell-mediated immunity. Because asymptomatic infection with *S. stercoralis* may persist for decades after initial infection, it is important to remember that a change in immune status associated with conditions such as the administration of immunosuppressive drugs following solid organ transplantation may result in hyperinfection syndrome even though the infection was previously asymptomatic. Massive increases in the number of *Strongyloides* larvae because of hyperinfection can present as acute enteritis with severe diarrhea and ulcerative disease of the small and large intestine. During disseminated infection, larvae and sometimes adult worms penetrate the intestinal mucosa, migrate to aberrant sites, including the central nervous system, and result in metastatic abscesses and gram-negative meningitis due to enteric bacteria being carried by the migrating parasites. Less common complications of disseminated disease include glomerulonephritis and minimal-change nephrotic syndrome, acute respiratory distress syndrome, and alveolar hemorrhage. Mortality from hyperinfection and disseminated disease can be high, although early diagnosis and prompt initiation of treatment are associated with improved outcomes.

Infants with swollen belly syndrome caused by *S. fuelleborni* are often seen acutely with abdominal ascites that is not accompanied by diarrhea or fever. The ascites is due to gastrointestinal protein loss; it can be significant enough to cause respiratory impairment and is associated with a high rate of mortality.

DIAGNOSIS

Definitive diagnosis of *S. stercoralis* infection relies on microscopic identification of larvae in feces or other fluids (such as sputum) or tissues. Detection of filariform larvae in feces implies active autoinfection. Intestinal strongyloidiasis can be diagnosed by identification of larvae in direct smears of freshly passed stool, although the sensitivity of examining a single fecal sample is as low as 30%. Sensitivity can be increased by examining multiple fecal specimens, by using concentration techniques, and by plating feces on an agar plate and inspecting for tracks of colonies created by bacteria being dragged by migrating larvae.

Hyperinfection syndrome and disseminated strongyloidiasis can be diagnosed by detection of filariform larvae in duodenal fluid obtained by endoscopy, in sputum, or in bronchoalveolar lavage specimens. Larvae have also been recovered from cerebrospinal fluid, urine, peritoneal washings, skin, and the brains of immunocompromised persons.

Fluctuating eosinophilia is common with uncomplicated intestinal strongyloidiasis, especially during the pulmonary migration phase of initial infection. However, eosinophilia may be absent in patients with hyperinfection and dissemination. In fact, those with hyperinfection and eosinophilia appear to have a better prognosis than do those without eosinophilia.

Serologic diagnosis using an enzyme-linked immunosorbent assay (ELISA) that detects antibodies to filariform larval antigens is very sensitive, even in immunocompromised hosts with disseminated strongyloidiasis, although false positives may occur in cases of coinfection with other nematodes, particularly filaria. Specificity is improved by using the newer luciferase immunoprecipitation systems (LIPS) assays that incorporate *Strongyloides*-specific recombinant antigens. LIPS assays have the additional advantage of rapid reversion to seronegativity following treatment compared to the slow decline in ELISA titers.[9]

TREATMENT

Rx

Uncomplicated intestinal strongyloidiasis can be treated effectively with ivermectin (200 µg/kg body weight daily for 2 days), with cure rates in excess of 90%. Albendazole is an alternative treatment (see Table 357-1). Decreases in serologic antibody titer and eosinophilia indicate a treatment response in the absence of continued exposure. After 6 months, ELISA titers should decrease significantly whereas LIPS assays should revert to negative.

In immunocompromised patients with hyperinfection or disseminated disease, daily treatment should be extended. Some experts recommend continuing treatment until 2 weeks after fecal examinations have become negative (i.e., for one autoinfection cycle). For severely ill patients who are unable to tolerate oral therapy, parenteral veterinary and enema ivermectin preparations have been used. Combination therapy with ivermectin and albendazole may also be used to treat disseminated strongyloidiasis, but data on whether this improves prognosis over monotherapy are lacking.

PREVENTION

In endemic areas, the risk for infection can be reduced by minimizing skin contact with contaminated soil, although elimination of this infection will occur only with improvements in sanitation and treatment of human waste. To prevent hyperinfection in individuals already infected, diagnosis should be attempted before the onset of immunosuppression if possible, such as before organ transplantation or cancer chemotherapy. Anyone who has resided in or traveled to an endemic area should undergo screening for asymptomatic infection, preferably by serologic tests or, if not possible, by microscopic examination of at least three fecal samples for the presence of larvae. Patients with positive screening test results should be treated empirically with ivermectin. Individuals with negative screening test results but unexplained eosinophilia and a history of exposure should also be considered for empirical treatment. In those undergoing hematopoietic stem cell transplantation, documentation of cure with at least three consecutive negative fecal examinations or a negative LIPS assays is recommended before proceeding with transplantation.

UNCOMMON INTESTINAL NEMATODIASES

Humans may serve as accidental hosts for several nematodes that ordinarily parasitize the intestines of other mammals.

Trichostrongylus

Human infection with several different species of the genus *Trichostrongylus* has been reported in Iran, the Far East, and Australia. Humans are incidentally infected when larvae are ingested with leafy vegetables that have been contaminated with soil containing the feces of herbivorous animals. *Trichostrongylus* worms are similar to hookworms in their morphology, appearance of their eggs on fecal examination, and the pathology that they induce. Heavy infections may be accompanied by diarrhea and anemia. Drugs recommended for treatment are pyrantel pamoate, albendazole, or mebendazole (see Table 357-1).

Anisakiasis

Anisakiasis results from ingestion of the larvae of nematodes that normally infect sea mammals such as dolphins, whales, and seals. Larvae of the genera *Anisakis, Phocanema,* and *Pseudoterranova* infect the flesh of a number of saltwater fish species as intermediate hosts. Consumption of raw or undercooked fish, often in the form of sushi or sashimi, results in release of the infective larvae into the stomach, followed by invasion of the stomach or duodenal wall, which causes upper abdominal pain that can be intense. Anisakid worms cannot further develop in humans and die within a few days; an eosinophilic granulomatous reaction may result that mimics a gastric tumor. Diagnosis and treatment are accomplished by endoscopic removal of the parasite. Infection is prevented by cooking or freezing seafood before consumption. Of note, salting, smoking, and marinating fish do not kill anisakid larvae.

Capillaria philippinensis

C. philippinensis can cause a serious intestinal infection that has been reported primarily in the Philippines and Thailand, although it has also been observed in Japan, Taiwan, Korea, and Egypt. Adult worms resemble those of *Trichinella spiralis,* although biologically they mimic *S. stercoralis* in that they have an autoinfectious cycle of reproduction in which larvae can develop into adult worms without having to leave the host. Even though the life cycle is not completely known, this nematode probably parasitizes waterfowl that feed on fish and crustaceans, which serve as intermediate hosts. Humans become infected by eating raw or undercooked infected shrimp or fish. Adult worms travel to the mucosal crypts of the small intestine, where they deposit living larvae, sometimes resulting in overwhelming infection. Clinical disease consists of severe diarrhea associated with anorexia, vomiting, and weight loss. Mortality rates as high as 10% have been reported, with death resulting from severe malabsorption and protein-losing enteropathy. Diagnosis depends on finding eggs or larvae in feces. The treatment of choice is albendazole or mebendazole (see Table 357-1).

Other Intestinal Nematode Infections

Several nematodes that normally parasitize the intestine of nonhuman primates very rarely infect the human gastrointestinal tract. *Oesophagostomum bifurcum* infections have been reported from Africa, Asia, and South America and result from the oral ingestion of infective larvae. Adult worms can result in the formation of nodules in the intestinal wall that may be manifested as abdominal masses. Finally, infection with *Ternidens diminutus* has been reported to result in colonic ulcerations and nodular lesions in people living in southern Africa.

REVIEW QUESTIONS

1. A 21-year-old woman living in rural Indonesia is in her third trimester of pregnancy and is found to have severe microcytic anemia, with a hematocrit of only 19%. She denies vaginal bleeding but consistently has darkened stools that are positive when tested for occult blood. Blood laboratory testing is also remarkable for eosinophilia and low serum albumin concentration. Which of the following parasitic infections is the most likely to result in this syndrome?

A. Enterobiasis
B. Amoebiasis
C. *Diphyllobothrium latum* infection
D. Hookworm infection
E. Strongyloidiasis.

Answer: D Intestinal blood loss is the principal clinical manifestation of hookworm infection, which can lead to iron deficiency and microcytic anemia. Pregnant women and children are at greater risk due to their higher iron needs. *Diphyllobothrium latum* infection is associated with development of megaloblastic anemia as a result of vitamin B_{12} deficiency and is thus associated with an elevated, rather than low, red blood cell mean corpuscular volume. Infection with *Enterobius vermicularis, Entamoeba histolytica,* or *Strongyloides stercoralis* is not usually associated with intestinal blood loss or iron deficiency.

2. A couple has just returned from their honeymoon in the Caribbean complaining of an intensely pruritic rash on their feet, buttocks, and legs. On examination, the rash consists of multiple raised, serpiginous red tracks. Most of their time was spent relaxing on a beach owned by the resort where they were staying. Which of the following is the most likely causative organism?

A. *Dracunculus medinensis*
B. *Ancylostoma duodenale*
C. *Ancylostoma braziliense*
D. *Strongyloides stercoralis*
E. *Enterobius vermicularis*

Answer: C The description of the skin lesions is typical of cutaneous larva migrans. This syndrome is most commonly caused by penetration of the skin by the larvae of the dog or cat hookworms, *Ancylostoma caninum* or *Ancylostoma braziliense*. *Strongyloides stercoralis* also may cause a migrating serpiginous dermatologic rash known as larva currens, but it is found most commonly on the buttocks and lower back because the larvae that cause the tracks originate from the anus. *Dracunculus medinensis* results in a dramatic ulcerative, painful, nonmigratory skin lesion from which the adult female worm emerges to release eggs into the environment. Neither *Ancylostoma duodenale* nor *Enterobius vermicularis* produce rashes.

3. A 60-year-old male kidney transplant recipient from rural Eastern Kentucky is admitted to the hospital with a 14-day history of fever and profuse diarrhea. His medications include prednisone, tacrolimus, mycophenolate mofetil, and lisinopril. Laboratory examination is remarkable for a leukocyte count of 13,000/mm^3, of which 25% are eosinophils. In the hospital, blood cultures are repeatedly positive for *Escherichia coli*. Besides treating the bacteremia with antibacterial therapy, which of the following medications is indicated to treat the most likely underlying predisposing parasitic infection?

A. Pyrantel pamoate
B. Ivermectin
C. Praziquantel
D. Mebendazole
E. Metronidazole

Answer: B The patient's clinical picture is suggestive of disseminated strongyloidiasis. *Strongyloides stercoralis* is endemic in rural parts of Appalachia and infection can be maintained in a host for decades due to the autoinfection cycle of this parasite. Immunosuppression, particularly with corticosteroids, may lead to hyperinfection and dissemination of larvae to aberrant locations in the body. Enteric bacteria such as *E. coli* can be carried by the migrating larvae throughout the body, resulting in gram-negative sepsis, meningitis, and abscess formation. Ivermectin is the treatment of choice for strongyloidiasis. Although albendazole is a second-line therapy, mebendazole, also a benzimidazole, has poor oral bioavailability and would therefore not be an ideal choice. Pyrantel pamoate and praziquantel are anthelminthics but have poor activity against *S. stercoralis*.

4. A young boy who recently emigrated from Guatemala to the United States with his parents is brought by them to the emergency room because of lethargy and severe abdominal pain that has persisted for about 2 days. He is unable to walk due to the pain. On physical examination, he is afebrile; bowel sounds are absent, and there is significant diffuse abdominal tenderness that is more pronounced in the right lower quadrant. Radiographic studies suggest acute intestinal obstruction at the level of the ileum. How did this child become infected with the most likely causative organism?

A. Drinking water contaminated with cysts
B. Ingesting soil contaminated with embryonated eggs
C. Walking barefoot outside, thus permitting larvae in contaminated soil to penetrate the skin
D. Swimming in lakes that harbor snails and cercariae
E. Eating insufficiently cooked meat infected with cysts

Answer: B Infection with *Ascaris lumbricoides* causing intestinal obstruction is the most likely diagnosis. This nematode is a soil-transmitted helminth that to be infective to humans requires that eggs undergo a phase of development and embryonation in warm, moist soil. Infection results from ingestion of contaminated soil. Drinking contaminated water containing cysts is the means of transmission for protozoan organisms such as *Giardia intestinalis* and *Entamoeba histolytica*. Meat is the vehicle for *Taenia* tapeworm or *Trichinella spiralis* infections, skin exposure to water containing the intermediate snail host is the means of acquiring schistosomiasis, and skin contact with contaminated soil pertains to the transmission of hookworm or *Strongyloides stercoralis*.

5. A young boy in Kenya is taken to the doctor because of episodes of blood-streaked diarrhea, fever, and lower abdominal pain. Examination of a smear of his feces under the microscope reveals many oval eggs with bipolar plugs. Which of the following complications might occur if the child is not treated for the causative helminth?

A. Obstruction of the duodenum
B. Rectal prolapse
C. Asthma-like symptoms
D. Gram-negative meningitis
E. Severe megaloblastic anemia

Answer: B Usually, light infections with the whipworm *Trichuris trichiura* are asymptomatic. However, heavy infections may produce symptoms that include those of dysentery, as in this child. Failure to treat with an anthelminthic could result in rectal prolapse due to the chronic straining induced by the sensation of rectal fullness caused by the presence of many whipworms in the rectum and colon. Although microcytic anemia may develop due to intestinal blood loss associated with *T. trichiura* infection, megaloblastic anemia resulting from vitamin B_{12} deficiency is associated with infection with the tapeworm *Diphyllobothrium latum*. *T. trichiura* is small and the adult worms are located in the large intestine, making obstruction of the duodenum unlikely. Also, whipworm has no pulmonary phase like *Ascaris lumbricoides* or hookworm and is therefore not associated with respiratory symptoms. Meningitis due to gram-negative bacilli is associated with disseminated strongyloidiasis but not with whipworm infection.

358

TISSUE NEMATODE INFECTIONS

DAVID J. DIEMERT

The tissue nematodes can be broadly divided into those for which humans serve as the principal host (the filariases) and those that usually infect animals but can incidentally infect humans. Several zoonotic nematodes, such as *Toxocara, Trichinella,* and *Angiostrongylus,* can infect humans through accidental oral ingestion of helminth eggs or larvae but are unable to complete their life cycle in the host. Clinical manifestations are primarily due to the aberrant migration of larvae through various tissues.

TOXOCARIASIS

DEFINITION

Accidental ingestion of embryonated eggs of the dog roundworm *Toxocara canis,* or less frequently of the cat ascarid *Toxocara cati,* can lead to the clinical syndromes of visceral larva migrans and ocular larva migrans.[1] Symptoms are caused by the migration of larvae through the body, invading organs to cause serious disease and even death.

EPIDEMIOLOGY

Toxocara infections in animals are ubiquitous in their distribution throughout the world and are more common in younger animals than in adults. In humans, children are most frequently infected, probably due to exposure to soil contaminated with dog or cat feces when playing in sandboxes or playgrounds. Visceral larva migrans occurs most commonly in children younger than 5 years of age, whereas ocular larva migrans typically affects older children between the ages of 5 and 10 years.

PATHOBIOLOGY

The life cycle of *Toxocara* in the animal host resembles that of *Ascaris lumbricoides* in humans; larvae penetrate the intestinal wall after being released into the lumen from ingested eggs, migrate through the vasculature to the lungs, enter into the alveolar space, and ascend the bronchial tree until they are swallowed back into the gastrointestinal tract, where they develop into adult worms that can produce eggs. However, when embryonated *Toxocara* eggs are ingested by humans, the released larvae migrate throughout the body (most commonly to the lungs, the liver, the central nervous system [CNS], and occasionally the eyes) but cannot develop into adult worms. Ultimately, the larvae die, inducing significant immediate-type and delayed-type hypersensitivity reactions that result in eosinophilic granuloma formation. Visceral larva migrans and ocular larva migrans seem to be mutually exclusive, suggesting that different *Toxocara* strains may have different tissue tropisms. Alternatively, visceral larva migrans may result from repeated infections whereas ocular larva migrans may be a manifestation of infection in children who have not been previously sensitized.

CLINICAL MANIFESTATIONS

Most *Toxocara* infections in humans are asymptomatic. Visceral larva migrans is characterized by low-grade fever, pulmonary symptoms including cough and wheeze,[2] and less frequently hepatosplenomegaly accompanied by right upper quadrant pain. Symptoms appear gradually and resolve over 4 to 8 weeks. Myocarditis, nephritis, and CNS disease are less common. CNS involvement can result in seizures, encephalopathy, neuropsychiatric symptoms, or eosinophilic meningoencephalitis. A more subtle syndrome referred to as *covert toxocariasis* has been described that may result from less dramatic migration of larvae through organs. For example, *T. canis* has been suggested as an environmental risk factor for asthma in inner-city populations.

Ocular larva migrans typically manifests as unilateral visual impairment that is sometimes accompanied by strabismus.[3] The degree of vision loss depends on the particular ocular structure involved, and permanent blindness can occur. Ocular larva migrans involving the retina can be difficult to distinguish from other causes of focal intraretinal lesions, such as retinoblastoma or tuberculosis.

DIAGNOSIS

Toxocariasis can be presumed on the basis of a compatible clinical presentation and history of exposure to dogs or cats. Eosinophilia and hypergammaglobulinemia are often present. Serologic diagnosis by an enzyme-linked immunosorbent assay (ELISA) that employs antigens secreted by second-stage larvae to measure anti-*Toxocara* antibodies may be informative. Although establishment of sensitivity and specificity is difficult because of the inability to make a definitive parasitologic diagnosis, it is estimated that when a titer cutoff of 1 : 32 is used, the sensitivity of the ELISA is 78% for visceral larva migrans but lower for ocular larva migrans; specificity for both syndromes is greater than 90%. Biopsy of tissues to document the presence of larvae is not recommended because of low sensitivity.

Computed tomography and fluorescein angiography may be helpful in the diagnosis of ocular larva migrans, especially to differentiate it from retinoblastoma and other causes of intraocular space-occupying lesions. Anti-*Toxocara* antibodies can be detected in aqueous and vitreous humor fluid, and elevated levels relative to serum are suggestive of ocular larva migrans.

TREATMENT

Rx

Albendazole (400 mg twice daily for 5 days) is the treatment of choice for toxocariasis (Table 358-1). Mebendazole is not recommended because of its poor oral bioavailability. In patients with severe pulmonary, cardiac, or neurologic involvement, corticosteroids may reduce the severity and duration of symptoms. Ocular larva migrans is treated by vitrectomy, corticosteroids, or albendazole. See also Chapter 344.

TABLE 358-1 TREATMENT OF TISSUE NEMATODE INFECTIONS

NEMATODE INFECTION	TREATMENT
Toxocariasis	Albendazole, 400 mg twice daily for 5 days
Trichinellosis	Albendazole, 400 mg twice daily for 8-14 days*
Angiostrongyliasis	Treatment with albendazole or mebendazole is controversial but may relieve symptoms.
Gnathostomiasis	Albendazole, 400 mg daily for 3 wk Alternative: Ivermectin, 200 µg/kg/day for 2 days ± Surgical removal
Lymphatic filariasis	Diethylcarbamazine, 6 mg/kg/day divided in three doses for 12 days† Alternative: Doxycycline, 100-200 mg/day for 4-8 wk
Onchocerciasis	Ivermectin, 150 µg/kg once, repeated every 6-12 mo until resolution of symptoms
Loiasis	Diethylcarbamazine, 9 mg/kg/day divided in three doses for 21 days†,‡
Mansonella perstans	Doxycycline, 200 mg/day for 6 wk
Mansonella ozzardi	Ivermectin, 200 µg/kg once
Mansonella streptocerca	Diethylcarbamazine, 6 mg/kg/day divided in three doses for 12 days Alternative: Ivermectin, 150 µg/kg once
Dracunculiasis	Extraction of the adult worm

*Treatment is effective only if it is initiated during the intestinal phase of infection.
†Start at a dose of 50 mg on the first day, 50 mg three times daily on the second, 100 mg three times daily on the third, and then 6 mg/kg/day on day 4 onward.
‡Repeated treatment after 6 mo is often necessary if symptoms and eosinophilia persist.

PREVENTION

Visceral larva migrans and ocular larva migrans may be prevented by periodic anthelminthic treatment of dogs and cats, proper disposal of pet feces, covering sandboxes, washing hands after playing with dogs or cats, and keeping children from playing in areas where pets have defecated.

BAYLISASCARIASIS

Baylisascariasis is a rare zoonosis caused by infection with the ascarid *Baylisascaris procyonis,* which is primarily a nematode parasite of raccoons and other small carnivores. In North America, infection is most commonly associated with contact with raccoons or environments contaminated with their feces and occurs predominantly in infants and young children who ingest the embryonated eggs while playing with soil. Clinically, disease is manifested as neural larva migrans because of the larval invasion of the CNS after release from ingested eggs in the gastrointestinal tract. Characteristic findings include fever and altered mental status accompanied by focal neurologic deficits and seizures; examination of the cerebrospinal fluid (CSF) reveals eosinophilic meningitis. *B. procyonis* also has been associated with ocular larva migrans, usually in otherwise healthy adults. Infection can be fatal or result in significant permanent neurologic or visual impairment. Once neural larva migrans is present, response to treatment with anthelmintics is poor, although corticosteroids may be helpful. Successful use of photocoagulation in ocular larva migrans has been reported. Prophylactic albendazole (25 mg/kg/day for 20 days) started within days of an exposure may prevent clinical disease.

TRICHINELLOSIS

DEFINITION

Trichinella infects a range of mammalian hosts, with the domestic pig serving as the most important reservoir worldwide. Humans are infected through eating raw or undercooked pork or other meats of domestic or wild animals that are contaminated with larvae that are encysted in muscle tissue. Although larvae develop into adults in the human intestinal tract, mate, and produce offspring larvae, clinical disease is characterized not so much by the intestinal infection as by the newborn larvae that penetrate the intestinal wall and disseminate throughout the body.

EPIDEMIOLOGY

Several different species of *Trichinella* can cause disease in humans, although *Trichinella spiralis* is the most important. *T. spiralis* is enzootic throughout the world in omnivorous and carnivorous wild animals, including bears, boars, and rats. *Trichinella nativa* affects predominantly carnivores (e.g., walruses, polar bears, and seals) living in the Arctic and subarctic regions of North America, Europe, and Asia. *Trichinella* is introduced into domestic animal populations, usually pigs or horses, by giving them unprocessed feed containing meat scraps of infected animals, most commonly rats. Because of regulations banning this practice in the United States, Canada, and the European Union, human infection by consumption of undercooked or smoked pork products or beef contaminated with the encysted larvae has been virtually eliminated, although it still occurs throughout the rest of the world. Instead, ingestion of poorly cooked wild game, especially bear or boar meat, is now the most common source of infection in these places. An important source of infection with *T. nativa* in Alaskan and Canadian Arctic native populations is eating of uncooked walrus meat.

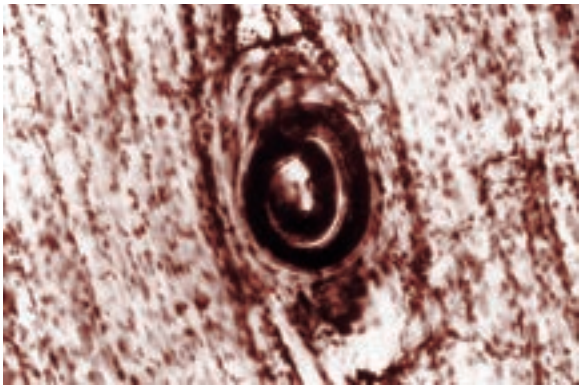

FIGURE 358-1 Nurse cell in muscle tissue containing a larva of *Trichinella spiralis*. (Courtesy Dr. I. Kagan, Centers for Disease Control and Prevention, Atlanta, GA.)

PATHOBIOLOGY

Trichinellosis results from ingestion of striated muscle containing encysted infective larvae.[4] Larvae are released from muscle tissue by digestive enzymes in the stomach and then migrate to the upper two thirds of the small intestine, where they rapidly develop into sexually mature adult worms after only 2 days. Adults live embedded in the columnar epithelium, where they grow to a length of 3 mm (females) or 1.5 mm (males). Females begin producing newborn larvae within 5 days of mating. Adult worms remain viable for an additional 3 to 5 weeks, after which acquired immunity develops that leads to their expulsion from the host.

Newborn larvae possess a sword-like stylet in their oral cavity that permits them to penetrate the lamina propria and enter the lymphatic and blood vessels of the host, allowing them to migrate throughout the body. Larvae enter all types of cells, where they usually die, with the exception of striated skeletal and cardiac muscle cells. Unique among nematodes, mature *Trichinella* larvae have an intracellular phase, developing and transforming muscle cells into "nurse cells" that support larval growth and development (Fig. 358-1). In nurse cells, *Trichinella* larvae can survive for decades. Although nurse cells do not result in any disease in most mammals, they can induce an eosinophilic granulomatous reaction in humans that may result in significant tissue damage and dysfunction.

CLINICAL MANIFESTATIONS

Clinical disease in humans can be divided into an initial intestinal phase followed by a systemic or muscle phase. The initial phase of infection that occurs within days after ingestion of larvae may be associated with mild diarrhea, abdominal pain, and vomiting. This phase is self-limited and usually resolves spontaneously within 10 days.

The systemic dissemination of *Trichinella* larvae can result in myocardial, pulmonary, and focal neurologic manifestations,[5] although usually only in the most heavily infected persons. This systemic phase of infection usually begins 2 to 3 weeks after ingestion of infective larvae and may persist for several weeks. Clinical manifestations typically include fever, periorbital or facial edema, a diffuse inflammatory myositis (Chapter 421) that is characterized by myalgias and muscle tenderness, and petechial hemorrhages most easily observed in the subungual skin and conjunctivae. Larval invasion of the myocardium can lead to myocarditis (Chapter 60) that may result in heart failure or arrhythmias.

As with most nematodes, the severity of symptoms is related to the total worm burden. Because adult worms are incapable of reproducing within the host, the number of encysted larvae ingested is the most important determinant of the number of larvae that invade muscle and other tissues.

DIAGNOSIS

A diagnosis of trichinellosis should be suspected in individuals with a compatible clinical presentation, a history of eating raw or undercooked meat, eosinophilia, and increased muscle enzymes such as creatine kinase and lactate dehydrogenase. Definitive diagnosis depends on visualization of nurse cells in a muscle biopsy specimen or detection of *Trichinella*-specific DNA by the polymerase chain reaction (PCR) technique, although this tool is not widely available. Findings on muscle biopsy may be normal even in heavily infected patients because of sampling error. Detection of anti-*Trichinella* antibodies can be very useful in making a diagnosis; ELISA is the most commonly used method. Antibodies can be detected as early as 12 days after initial infection.

TREATMENT

Rx

If patients present during the intestinal phase of infection, albendazole is recommended at a dosage of 400 mg twice daily for 8 to 14 days to kill the adult worms and thus prevent release of more newborn larvae (see Table 358-1). Although it is not known if albendazole is effective against newborn larvae, administration of this drug during the systemic phase of infection could potentially worsen symptoms by exacerbating the host inflammatory response to dying larvae. Treatment of severe systemic disease, including myocarditis and neurologic disease, should be directed toward reducing inflammation, most commonly with corticosteroids, although albendazole also should be given in such cases because corticosteroids may delay expulsion of adult worms from the intestine, thus increasing the number of newborn larvae that may be released. Symptomatic treatment with antipyretics and analgesics also should be considered. See also Chapter 344.

PREVENTION

Trichinella infection is prevented by thoroughly cooking meat products to kill the encysted larvae. Freezing meat solid at −20° C for at least 3 days will kill *T. spiralis* but not all other species of *Trichinella*. Of note, curing and smoking techniques do not reliably kill this nematode.

ANGIOSTRONGYLIASIS

DEFINITION

Angiostrongylus cantonensis and *Angiostrongylus costaricensis* are nematodes that normally infect rodents, primarily rats.[6] The adult worms of *A. cantonensis,* or rat lungworm, inhabit the pulmonary arteries of rodents; larvae are produced that migrate to the pharynx, are swallowed, and then are passed in the feces. Mollusks such as snails, slugs, and prawns serve as intermediate hosts until they are ingested by definitive hosts. Released larvae migrate to the brain, where they develop into immature adult worms before traveling to the pulmonary vasculature to become sexually mature adults. Humans are incidentally infected after eating poorly cooked or raw intermediate mollusk hosts; larvae can migrate to the CNS but cannot develop further. Fresh vegetables also may serve as a vehicle of human infection if they are contaminated with parts of mollusks containing infective larvae. As opposed to *A. cantonensis,* the larvae of *A. costaricensis* can develop into sexually mature adult worms in the local lymphatics and mesenteric arterioles of humans and release eggs and larvae into the intestinal tissue, causing an intense eosinophilic granulomatous reaction.

EPIDEMIOLOGY

Human infections with *A. cantonensis* occur mainly in Southeast Asia and the South Pacific and less frequently in Brazil, the Caribbean, and recently, in the United States in Louisiana. Abdominal angiostrongyliasis due to *A. costaricensis* has been reported mainly in Latin America, mostly in young children.

CLINICAL MANIFESTATIONS

In human cases of *A. cantonensis* infection, ingested larvae penetrate the intestinal wall and migrate to the brain, the meninges, and less commonly the spinal cord and eye. Fever, severe headache, meningismus, nausea, vomiting, seizures, and focal neurologic deficits may develop. *A. costaricensis* infection can mimic appendicitis with right-sided abdominal pain, vomiting, and fever. Less frequently, gastrointestinal bleeding may occur.

DIAGNOSIS

Diagnosis of *A. cantonensis* infection is based on a history of ingestion of potentially contaminated food, the presence of peripheral eosinophilia, and detection of eosinophils and rarely larvae in the CSF.[7] In neither CNS nor intestinal angiostrongyliasis are larvae or eggs found in the feces, although both may be seen in tissue specimens for *A. costaricensis*. Serology is not commercially available.

TREATMENT AND PREVENTION

Rx

Most patients infected with either species of *Angiostrongylus* recover completely after approximately 2 weeks. The use of anthelmintics (Chapter 344) is controversial, with only a few reports of benefit with albendazole or mebendazole, usually administered in combination with analgesics and corticosteroids to relieve symptoms. Serial lumbar punctures to remove CSF can relieve symptoms of raised intracranial pressure caused by infection with *A. cantonensis*. Proper cooking of food and washing of vegetables can prevent this infection.

GNATHOSTOMIASIS

Gnathostoma spinigerum is an intestinal nematode of dogs and cats; intermediate hosts include tiny crustaceans (copepods), amphibians, freshwater fish, and birds.[8] Accidental human infection occurs throughout the Far East, Thailand, and Latin America, particularly Mexico, on eating of raw or undercooked invertebrate hosts harboring larvae. Larvae are released in the intestine and subsequently migrate through the body but are unable to reach sexual maturity in humans. The most common clinical presentation is migrating painful and pruritic subcutaneous swellings. Eosinophilic meningitis and ocular larva migrans also may occur, with potentially devastating results, including paralysis, subarachnoid hemorrhage, and permanent visual loss. Peripheral eosinophilia, often marked, is usually present; with meningitis, eosinophils are also present in the CSF. Although serologic testing is not available in the United States, laboratories in Thailand and Mexico can perform it. Treatment of cutaneous disease with either a 3-week course of albendazole or a 2-day course of ivermectin (200 µg/kg/day) is recommended (see Table 358-1); for neurologic or ocular involvement, anthelminthics are not advised because they may worsen manifestations. Gnathostomiasis may be prevented by thoroughly cooking fish.

FILARIASES

DEFINITION

The filariases are a group of arthropod-borne nematode infections that are endemic mostly in tropical areas of the world. Instead of residing in the intestine, mature adult filarial worms live in the lymphatics or in connective tissue (Table 358-2). Eight filarial species infect humans: *Wuchereria bancrofti, Brugia malayi, Onchocerca volvulus, Brugia timori, Loa loa, Mansonella streptocerca, Mansonella perstans,* and *Mansonella ozzardi.* The first three are the most common filariases worldwide. Although not usually fatal, these infections can result in significant disability and disfigurement, such as irreversible limb lymphedema (*W. bancrofti* and *B. malayi*) or blindness (*O. volvulus*). Most of the filariases require prolonged exposure for disease to manifest and are therefore uncommon in short-term travelers to endemic areas. The one exception is loiasis, which can occur in returned travelers and expatriates who have spent extended periods in endemic regions.

For all of the filarial nematodes, infection begins with the bite of an infected arthropod vector that deposits infective larvae called *microfilariae* into the skin or blood. Over several months, microfilariae mature into adult worms capable of mating to produce microfilariae that can be ingested by another arthropod vector to complete the life cycle. Adult worms can survive for 5 to 17 years in the human host; microfilariae live for between 5 months and 5 years. For most of the filarial nematodes except *B. malayi* and *M. perstans,* humans are the only definitive host.

Clinical manifestations of infection are varied and are caused by either adult worms or migrating microfilariae. Severity of disease is in most cases

TABLE 358-2 FILARIAL PARASITES OF HUMANS

			MICROFILARIAE		
SPECIES	**DISTRIBUTION**	**VECTOR**	**PRIMARY LOCATION**	**PERIODICITY**	**PRESENCE OF SHEATH**
Wuchereria bancrofti	Tropics worldwide	Mosquitoes	Blood	Nocturnal, subperiodic	+
Brugia malayi	India, Southeast Asia	Mosquitoes	Blood	Nocturnal, subperiodic	+
Brugia timori	Indonesia	Mosquitoes	Blood	Nocturnal	+
Onchocerca volvulus	Africa, Central and South America	*Simulium* black flies	Skin, eye	None or minimal	–
Loa loa	West and Central Africa	*Chrysops* flies	Blood	Diurnal	+
Mansonella perstans	Africa, South America, Caribbean	Midges	Blood	None	–
Mansonella ozzardi	Central and South America, Caribbean	Midges, *Simulium* black flies	Blood	None	–
Mansonella streptocerca	West and Central Africa	Midges	Skin	None	–

proportional to the worm burden harbored by an individual, with relatively light infections commonly being asymptomatic. For several of the filariases, the host inflammatory response to infection becomes apparent only on the death of the adult worm or microfilariae. This may be triggered by exposure to filarial antigens that were previously hidden from the immune system or by release of bacterial endosymbionts of the genus *Wolbachia* that live inside several of the filariae. *Wolbachia* are of the order Rickettsiales and are found in the hypodermis of adult worms and in oocysts, embryos, and microfilariae; they play a critical role in worm viability and fertility.[9]

Diagnosis of filarial infections usually depends on the microscopic examination of either blood or skin specimens for characteristic microfilariae (see Table 358-2). Microfilariae of the different filarial species measure between 170 and 320 µm in length and can be distinguished on the basis of the tissue source of the specimen, the presence or absence of a sheath, and the arrangement of nuclei in the tail. For some filarial species, microfilariae are present in the blood only during certain periods of the day to coincide with biting habits of the arthropod vector, which must be taken into account in timing blood sampling for diagnosis based on microscopy. Serology is not useful in endemic areas because a positive result does not distinguish between previous and current infection, and there is considerable antigenic cross-reactivity between the filariae and other nematodes. Detection of antifilarial antibodies may, however, be useful in returned long-term travelers or expatriates who are not originally from endemic areas.

Diethylcarbamazine (DEC), ivermectin, and albendazole are the principal antifilarial drugs, although they have varying efficacies against the different filarial species (see Table 358-1). DEC is macrofilaricidal (active against the adult worm) for *W. bancrofti*, *Brugia* spp, and *L. loa*, although prolonged or repeated courses are required for this effect. More commonly, the goal is to suppress microfilaria production by adult female worms, which can be achieved by single doses of antifilarial drugs administered alone or in combination annually or biannually. In some cases, reduction of microfilariae in the blood or skin can ameliorate symptoms or prevent progression of disease and interrupt transmission. Furthermore, targeting the *Wolbachia* endosymbionts of some filarial species with extended courses of antibiotics such as doxycycline can be macrofilaricidal.

Lymphatic Filariasis

DEFINITION

The three etiologic agents of lymphatic filariasis, *W. bancrofti, B. malayi,* and *B. timori,* are transmitted to humans through the bite of an infected mosquito.[10] Microfilariae deposited at the bite wound subsequently migrate through the subcutaneous tissue to the lymphatic system, where adult worms develop after approximately 4 to 12 months. The worms reside coiled in lymph nodes and may extend into afferent lymph vessels and surrounding subcutaneous tissue. The lymphatics of the lower and upper extremities and male genitalia are most commonly affected. After mating, females, which measure between 4 and 10 cm in length, twice the length of males, release more than 10,000 microfilariae per day that migrate into the blood stream until ingestion by mosquito intermediate hosts taking a blood meal. In most endemic areas, microfilariae are present in the peripheral blood only at night, when mosquito vectors are most likely to bite. Adult filariae live between 5 and 8 years within the host, although infections lasting for decades have been reported.

EPIDEMIOLOGY

An estimated 120 million people are affected by lymphatic filariasis worldwide; most cases are caused by *W. bancrofti,* and only approximately 10 to 20 million are due to *B. malayi*. *B. timori* is of minor importance, being restricted to southeastern Indonesia. *W. bancrofti* is widely distributed in the tropics, especially in Southeast Asia, the Indian subcontinent, Africa, South America, the Caribbean, and the South Pacific. The major vectors of bancroftian filariasis are *Culex* mosquitoes in urban areas, anopheline mosquitoes in rural areas of Africa, and *Aedes* species in the Pacific.

Humans are the only definitive host for *W. bancrofti*. *B. malayi,* however, can be zoonotic, with both monkey and feline species serving as reservoir hosts and transmission to humans by *Mansonia* mosquitoes. Brugian filariasis is found primarily in India, Malaysia, and other areas in Southeast Asia.

PATHOBIOLOGY

The pathologic process of filarial infections is primarily due to obstruction of lymphatic circulation resulting from damage induced by adult worms, specifically a local inflammatory lymphangitis with components of the innate and adaptive immune response that lead to hypertrophy of the vessel walls.[11] This inflammatory response can be triggered by release of antigens from dead or dying worms, although evidence suggests that it also is induced by living worms and *Wolbachia* antigens that are excreted or secreted into the surrounding milieu. Inflammatory damage is also exacerbated by secondary bacterial and fungal infections.

The initial inflammatory response leads to endothelial and connective tissue proliferation and vessel dilation, which impairs normal lymphatic function and results in lymphedema that is initially reversible. However, worm death results in a granulomatous reaction to released worm and *Wolbachia* antigens. The infiltration of giant cells, plasma cells, eosinophils, and neutrophils can completely occlude the lumen of the lymphatic vessel. Over time, progressive fibrosis and obstruction of lymph flow result in irreversible edema.[12] Although recanalization and collateralization of lymph vessels may occur, lymphatic function remains compromised.

CLINICAL MANIFESTATIONS

The clinical manifestations of lymphatic filariasis cover a wide spectrum from asymptomatic infection to severe chronic lymphatic obstruction accompanied by lymphedema and enlargement of the affected limb or body part (referred to as *elephantiasis*). Other common clinical outcomes include acute episodic lymphadenitis (also called *filarial fever*) and tropical pulmonary eosinophilia. Most infected individuals living in endemic regions are clinically asymptomatic, although microfilariae can be observed in their blood. Despite the absence of a significant inflammatory response, these individuals may nevertheless exhibit dilation of the affected lymphatics on ultrasound, which precedes the onset of clinically apparent disease.

For unknown reasons, newly exposed individuals may develop acute inflammatory reactions that can rapidly progress to chronic or irreversible changes compared with those born in endemic areas. Severe episodes of lymphadenitis, often with genital involvement, may lead to the relatively rapid development of lymphedema and elephantiasis within a year of arrival. Findings usually resolve quickly if the individual is promptly removed from the endemic area. Microfilariae are usually not detected in these patients.

FIGURE 358-2. Elephantiasis, or chronic lymphedema due to infection with *Wuchereria bancrofti*. (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

ACUTE LYMPHADENITIS

Acute episodes of retrograde lymphadenitis occur most commonly in adolescents in endemic areas, often in response to dying adult worms. Painful, erythematous enlargement of an affected lymph node, most commonly inguinal, precedes the onset of lymphangitis and is accompanied by fever and chills. Episodes usually last for approximately a week, frequently recur, and can be incapacitating. Defervescence is abrupt and associated with desquamation of the overlying skin. In men, inguinal lymphadenitis can be complicated by epididymitis and orchitis. Patients with filarial fevers may be microfilaremic but often are not.

ELEPHANTIASIS

Repeated episodes of lymphadenitis eventually lead to dilation of the lymphatic vessels, resulting in chronic lymphedema over the course of months to years (Fig. 358-2). The extremities, breasts, and genitalia are most commonly affected, although with *B. malayi* infection, usually only the lower parts of the legs are involved. The edema is initially pitting, but the subcutaneous tissue eventually loses its elasticity, resulting in woody edema with thickening of subcutaneous tissue and hyperkeratosis. Secondary bacterial or fungal infection contributes significantly to the chronic pathologic process of elephantiasis.

In bancroftian filariasis, development of hydrocele is a common manifestation of chronic filariasis in men and sometimes can become massive and debilitating; lymphedema of the vulva is less commonly seen in women. Involvement of the retroperitoneal lymphatics can lead to their rupture to produce intermittent chyluria or chylocele.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia develops in a small minority of individuals with filarial infections. The syndrome is most commonly seen in young men living in southern India, although it also occurs in Pakistan, Sri Lanka, Southeast Asia, and Brazil. Characteristic clinical findings include nocturnal paroxysmal cough, wheeze, and low-grade fever that are accompanied by weight loss and prominent peripheral eosinophilia. Levels of both total IgE and antifilarial antibodies are typically high. Chest radiographs may show diffuse interstitial infiltrates or mottled opacities in the middle and lower lung fields. Without treatment, chronic restrictive lung disease may develop.

DIAGNOSIS

Definitive diagnosis usually relies on microscopic examination of a Giemsa-stained blood smear for microfilariae. Although thick blood smears are relatively insensitive except in cases of high microfilaremia, concentration or filtering techniques can increase diagnostic yield. Characteristic microfilariae are 250 to 320 μm in length. Collection of blood should be timed according to the known periodicity of the microfilariae.

A rapid immunochromatographic card test is available for *W. bancrofti* (there is no equivalent test for *Brugia* infections), and has the advantage of not requiring nocturnal collection of blood because it detects circulating antigen of the adult worm and not microfilariae. PCR methods also have been developed to detect filarial antigens in blood, although these are not widely available. Serologic detection of antifilarial antibodies is of limited value because of extensive antigenic cross-reactivity with other nematodes. Furthermore, actively infected individuals cannot be distinguished from those previously infected, and those merely exposed but not infected also may have positive serologic test results.

Ultrasound examination of the lymphatic vessels of the spermatic cord of men can be used to visualize the "filarial dance sign," which is pathognomonic for a nest of filarial parasites.

Individuals with elephantiasis may be amicrofilaremic. Diagnosis therefore depends on a compatible clinical history and physical examination in the context of the appropriate epidemiology, and it may be supported by a positive antigen test or, in men, by a suggestive scrotal ultrasonogram. It should be distinguished from podoconiosis, a tropical lymphedema that results from long-term barefoot exposure to red-clay soil derived from volcanic rock and that may be a T-cell–mediated inflammatory disease.

TREATMENT

Rx

Management of lymphatic filariasis differs according to whether the aim is disease control or curative treatment of an individual patient. In endemic areas, annual mass drug administration with a combination of two antifilarial drugs can reduce transmission by decreasing the number of microfilariae in the blood available to biting mosquitoes. These programs use different combinations of single-dose DEC, ivermectin, and albendazole, administered at least once a year. DEC is administered with albendazole except in areas where onchocerciasis or loiasis is also found, in which case ivermectin plus albendazole is used.

It is recommended that all individuals with active infection by a lymphatic filarial parasite, whether symptomatic or asymptomatic, be treated with an antifilarial medication (see Table 358-1). The treatment of choice is DEC (6 mg/kg/day in three divided doses for 12 days). In the United States, DEC is available only through the Centers for Disease Control and Prevention (CDC) drug service (http://www.cdc.gov/laboratory/drugservice/formulary.html). For patients with high levels of microfilariae in the blood, treatment can be started at a low dose of 50 mg daily and scaled up during the first 3 days to reduce side effects of treatment such as fever, headache, dizziness, nausea, vomiting, rash, myalgias, and arthralgias. These normally resolve after a few days of treatment and can be treated with antipyretics, antihistamines, and, if symptoms are severe, corticosteroids.

DEC is both microfilaricidal and partially macrofilaricidal. In individuals who will not be returning to endemic areas, repeated treatments with DEC are often attempted to kill the adult worms instead of just reducing the levels of microfilariae in the blood. Typically, courses of DEC are repeated every 6 to 12 months. Although the adult worm burden is reduced in most treated individuals, all parasites are eliminated in less than a quarter. In men with dancing live adult worms visible by ultrasound in the scrotal lymphatics, serial studies may be performed to monitor the effects of therapy.

Unfortunately, lymphedema due to lymphatic filariasis usually is not reversible with DEC treatment, except in the very early stages. Nevertheless, several management modalities can be employed to limit the chronic sequelae of lymphatic filariasis. Critical among these is the prevention of secondary bacterial and fungal infection through meticulous hygiene and prompt treatment of suspected infections with antimicrobials. Limb elevation, physiotherapy, and use of elastic stockings may slow the worsening of lymphedema. Surgery is usually not indicated except for cases of hydrocele.

Interestingly, treatment directed against the *Wolbachia* endosymbiont has been shown to be effective in killing adult *W. bancrofti* and *Brugia* worms. Doxycycline, 100 or 200 mg daily for 4 to 8 weeks, reduces female worm fertility, with a resulting suppression of microfilaremia for up to a year, and reduces the number of live adult worms. Given the duration of treatment, these regimens are not ideal for disease control programs in endemic countries.

DEC is highly effective in the treatment of tropical pulmonary eosinophilia. Treatment with 6 mg/kg/day for 14 to 21 days results in resolution of symptoms within a week, although relapse may occur even after an interval of years. See also Chapter 344.

PREVENTION

Annual mass treatment with single doses of two antifilarial drugs can significantly reduce the prevalence of infection within a community.[13] In some areas, DEC-fortified table salt has been used to reduce the levels of microfilaremia in affected communities to interrupt the transmission cycle. Vector control through use of insecticide-treated bed nets and residual indoor spraying of insecticides appears to be effective.[14]

Onchocerciasis

DEFINITION

Onchocerciasis, or river blindness, caused by the nematode *O. volvulus,* is transmitted to humans by *Simulium* black flies. Infective microfilariae develop into male and female adult worms over several months and live for 9 to 14 years coiled within subcutaneous fibrous nodules (onchocercomas). Adult females measure between 20 and 70 cm in length and remain confined to the nodules; males are only 3 to 5 cm long and freely migrate through the subcutaneous tissues between nodules to inseminate females. Mature female worms produce up to 1500 microfilariae per day, which leave the nodule to migrate primarily through the skin and ocular tissues.[13] Microfilariae live within the host for 12 to 18 months.

EPIDEMIOLOGY

Onchocerciasis is endemic in equatorial Africa, with small foci in four Latin American countries (Guatemala, southern Mexico, Venezuela, and Brazil) and in Yemen. More than 37 million people are estimated to be infected, 500,000 of whom have significant visual impairment and 270,000 of whom are blind.[15] More than 99% of cases occur in sub-Saharan Africa, with Nigeria being the most highly endemic country. Because *Simulium* black flies require fast-flowing, well-oxygenated water for egg laying and reproduction, onchocerciasis is concentrated around streams and rivers, often in the most fertile farming areas. In communities bordering such waterways in endemic areas, up to 50% of the population can be affected.

Blindness caused by *O. volvulus* results in significant morbidity, long-term disability, and reduced economic productivity. In addition, onchocerciasis has been associated with a reduced life expectancy of at least 10 years compared with that of uninfected individuals in the same area, an effect that appears to be independent of the blindness that develops.

PATHOBIOLOGY

The pathologic changes of onchocerciasis are primarily due to an inflammatory reaction elicited by microfilariae, mostly in the skin, eyes, and lymph nodes. Adult worms contained in nodules are relatively isolated from the host immune response. Tissue damage results from a cell-mediated immune response to dying microfilariae, which becomes more pronounced as infection persists. The degree of tissue damage is directly related to the intensity of infection and magnitude of the host response. Sclerosing keratitis, the major cause of blindness, is caused by an inflammatory reaction to dying intraocular microfilariae that appears to be dependent on T helper cell type 2 (T_H2) cytokines. With time, neovascularization and scarring of the cornea lead to corneal opacification and eventual blindness. In the skin, similar immune responses result in pruritus and angioedema. Ongoing low-grade inflammation in the skin eventually leads to loss of elasticity and atrophy. Chronic inflammatory changes and fibrosis are also seen in lymph nodes.

Like the nematodes responsible for lymphatic filariasis, *O. volvulus* adult worms contain endosymbiotic *Wolbachia* bacteria that are obligatory for the development, survival, and fertility of these worms. Pro-inflammatory *Wolbachia* proteins released by dying microfilariae may be responsible for a significant amount of the immunopathology associated with onchocerciasis. For example, *Wolbachia* antigens have been shown to interact with the innate immune system through a toll-like receptor 2–mediated mechanism (Chapter 45).

CLINICAL MANIFESTATIONS

Onchodermatitis

Onchocerciasis commonly manifests with a diffuse papular dermatitis that is intensely pruritic. In heavily infected individuals in endemic areas, the pruritus is intractable, leading to scratching and excoriation to the point of bleeding and even suicide. Hypersensitivity reactions, scabies, insect bites, and atopic or contact dermatitis should be considered in the differential diagnosis of the acute papular dermatitis seen with onchocerciasis. The skin of affected areas becomes edematous and thickened, losing its elasticity and taking on an orange-peel texture. A lichenified dermatitis (referred to as *sowda*) may occur; it consists of an intensely pruritic eruption limited to one extremity, usually a leg, with hyperpigmented papules and plaques accompanied by edema of the entire limb. Over time, the skin will atrophy and fine wrinkles appear, especially over the buttocks. Pruritus is uncommon at this point. Areas of depigmentation may occur most commonly over the shins, a phenomenon called *leopard skin.*

Subcutaneous Nodules

Subcutaneous onchocercomas containing adult worms are most often palpable over bony prominences. In Africa, the nodules are most commonly found over the hips and lower limbs; in Latin America, they are often located on the head and upper part of the body. Nodules usually measure between 0.5 and 3 cm in diameter and are freely mobile. In lightly infected individuals, such as expatriates, nodules are usually not detectable.

Ocular Lesions

Initial ocular involvement is characterized by conjunctivitis, excess tearing, and photophobia in response to dying microfilariae. At this time, the corneal disease consists of a punctate keratitis or snowflake corneal opacities. Over 20 to 30 years, this leads to sclerosing keratitis, neovascularization, and corneal opacification. The anterior chamber of the eye also may be involved, with iritis, iridocyclitis, and secondary glaucoma. Posterior ocular disease can manifest as chorioretinitis, optic neuritis, and optic atrophy.

Lymphadenopathy

Lymphadenopathy is frequently found in the inguinal and femoral areas in Africa and in the head and neck in Latin America. Advanced disease in the inguinal region can result in the so-called hanging groin, with elongated atrophic skin containing nontender and fibrotic lymph nodes.

DIAGNOSIS

Definitive diagnosis has traditionally been made by observing unsheathed motile microfilariae measuring 200 to 300 µm in length that are released from superficial skin snips. To take a skin snip, a thin piece of skin overlying a bone prominence that has been tented up with a needle is sliced with a scalpel blade, or a corneal-scleral punch instrument is used to obtain a small piece of skin without drawing blood. Avoidance of blood contamination is critical so as to avoid confusion with blood-borne microfilariae in cases patients are coinfected with other filariases. Typically, six snips are taken, one from over each scapula, iliac crest, and lateral aspect of each calf, and then incubated with warm physiologic saline and examined microscopically for motile microfilariae after at least 30 minutes of incubation, although longer periods of up to 24 hours may be necessary. Newer techniques include PCR amplification of filarial DNA directly from skin snips that are far more sensitive than direct visualization. With ocular disease, free microfilariae may be visible by slit lamp examination in the anterior chamber or aqueous humor.

Subcutaneous nodules can be sampled or examined by ultrasound to demonstrate the presence of adult worms. Serologic tests are usually positive for antifilarial antibodies but are not specific because of extensive antigenic cross-reactivity with other nematodes. Eosinophilia is a common but inconsistent finding.

In the past, the Mazzotti test was used to diagnose onchocerciasis. In this test, a challenge dose of DEC was administered to patients suspected of having onchocerciasis; with *O. volvulus* infection, an intense pruritic skin reaction would develop within hours. However, in patients with high-intensity infections, the Mazzotti reaction could be severe and even worsen ocular disease, resulting in permanent visual loss. Therefore, this test is no longer recommended, although some instead suggest the application of a small amount of cream that contains DEC to the skin to provoke a localized Mazzotti reaction.

TREATMENT

Rx

Ivermectin is the treatment of choice for onchocerciasis (see Table 358-1).[16] Administration of a single dose of ivermectin (150 µg/kg) is effective in ameliorating ocular and dermatologic disease by destroying microfilariae and suppressing their release from female worms. Because ivermectin is not active against the encapsulated adult worms, treatment must be repeated every 6 to 12 months, probably for at least 10 years in those without further exposure. For unknown reasons, pruritus in lightly infected expatriates may require more aggressive and frequent treatment for the first 2 years. Within 24 hours of treatment with ivermectin, fever and pruritus may occur in reaction to the dying microfilariae or released *Wolbachia* antigens, especially in those with high pretreatment levels of microfilariae. Use of ivermectin in areas where *L. loa* (see later) is co-endemic should be undertaken with caution because treatment may precipitate severe reactions including encephalopathy in those with high levels of microfilaremia. DEC should never be used for treatment of onchocerciasis because of frequent unacceptable reactions to dying

microfilariae ranging from urticaria and angioedema to hypotension and death. Although the drug suramin (available from the CDC drug service) is active against adult *O. volvulus* worms, because of its excessive toxicity and potentially life-threatening effects, it is used only in rare situations. Surgical removal of palpable nodules has been successful in resolving the infection in some areas, notably in Central America.

Doxycycline, 200 mg/day administered for 4 to 6 weeks, followed by single-dose ivermectin, has been shown to deplete *Wolbachia* endosymbionts from adult worms and to suppress *O. volvulus* embryogenesis and production of microfilariae for up to 18 months. Some experts now recommend this regimen for patients with onchocerciasis who have left an endemic area and will not be re-exposed. See also Chapter 344.

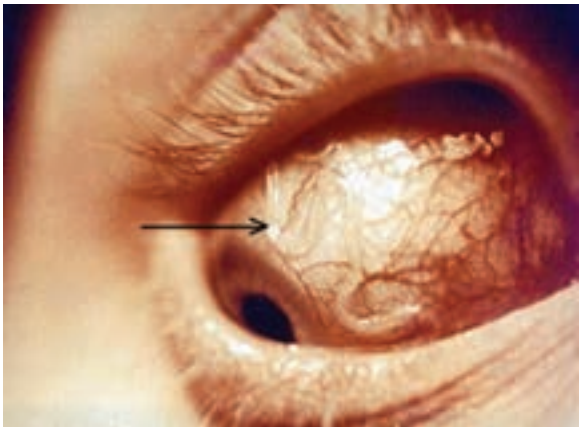

FIGURE 358-3. Adult *Loa loa* worm migrating across the eye (*arrow*).

PREVENTION

Regular mass administration of ivermectin to affected communities forms the core of the global eradication strategy for onchocerciasis.[17] Implementation of this program has been made easier because the drug is donated by the manufacturer. In addition to benefiting infected individuals, mass drug administration reduces the microfilariae available to vectors and thus interrupts the transmission cycle. For travelers to endemic areas, use of insect repellent may be beneficial.

Loiasis

DEFINITION

Loiasis is caused by infection with the filarial nematode *Loa,* otherwise known as the African eye worm. *L. loa* are transmitted by flies of the genus *Chrysops* during a blood meal. Adult worms develop during a period of 1 to 4 years and live for up to 17 years.[18] They migrate freely in the subcutaneous tissue, including the subconjunctiva or sclera of the eye. Adult females measure between 40 and 70 mm in length; males are shorter, measuring between 25 and 35 mm. After mating, females release microfilariae into the blood. *L. loa* microfilariae exhibit a diurnal periodicity coinciding with the feeding habits of *Chrysops,* with microfilaremia peaking around noon.

EPIDEMIOLOGY

Loiasis is endemic in the rain forest regions of central and western Africa. Although accurate numbers are not available, loiasis appears to be most prevalent in Gabon, Cameroon, the Democratic Republic of the Congo, Nigeria, and the Central African Republic. Loiasis requires a shorter period of exposure than other filarial infections and can be seen in returning travelers or expatriates who have spent extended periods in Africa.

PATHOBIOLOGY

Neither adult *L. loa* worms nor microfilariae have any direct pathologic effects. In a subset of infected individuals, a hypersensitivity response, termed a *Calabar swelling,* develops to secretions from adult worms or released microfilariae, resulting in recurrent localized angioedema that often precedes the migrating worm. These patients have very high serum levels of immunoglobulin E (IgE) antibodies and eosinophilia. This reaction is more commonly observed in visitors to endemic areas rather than in native residents. Unlike other filariae, *L. loa* does not contain *Wolbachia* endosymbionts.

CLINICAL MANIFESTATIONS

Most individuals with loiasis are asymptomatic despite being microfilaremic. Clinical manifestations of infection are more common in long-term visitors to endemic areas than in people native to the regions. Recurrent Calabar swellings are the most common finding in these individuals, who are not usually microfilaremic. They are nonerythematous swellings measuring 5 to 20 cm in diameter that typically occur on the extremities and the face and last for a few days. The onset is often preceded by pruritus and pain. On occasion, adult worms may migrate across the subconjunctiva or sclera of the eye in both groups of patients, causing severe pain and inflammation (Fig. 358-3). Rare complications of infection include nephropathy and encephalitis, which usually develop in those with high levels of microfilariae after receiving DEC or ivermectin treatment for other filarial infections. Endomyocardial fibrosis resulting from eosinophilic infiltration of the myocardium has been reported in association with loiasis.

DIAGNOSIS

Definitive diagnosis depends on microscopic examination of a Giemsa-stained blood film for characteristic sheathed microfilariae. Blood should be collected between 10 AM and 2 PM because of the diurnal periodicity of the microfilariae. Because individuals who are not native to endemic areas usually are not microfilaremic, diagnosis relies on a compatible history, clinical findings, peripheral eosinophilia, and elevated antifilarial antibody levels. Adult worms sometimes can be surgically removed while migrating across the eye or through subcutaneous tissues. Calabar swellings must be distinguished from onchocercomas and other causes of angioedema.

TREATMENT

Rx

DEC (9 mg/kg/day for 21 days) is active against both adult *L. loa* worms and microfilariae (see Table 358-1). Treatment usually is increased from a dose of 50 mg/day on the first day to the full dose on the fourth day to minimize the likelihood of treatment-associated complications, the most serious of which are glomerulonephritis and potentially fatal encephalopathy. Treatment-associated complications are more common with high pretreatment microfilarial levels and result from host allergic reactions to dying microfilariae. Antihistamines and corticosteroids may be employed to reduce allergic side effects. Alternatively, apheresis can be used to remove circulating microfilariae before initiation of DEC in these individuals. Albendazole, which is microfilaricidal but has no activity against adult worms, also has been used to reduce microfilaria levels before treatment with DEC. Repeated courses of DEC may be necessary in approximately half of patients before clinical manifestations completely resolve. Persistent or increasing eosinophilia or levels of antifilarial antibodies 6 months after treatment also should prompt re-evaluation for repeated treatment. Adult worms in the eye may be surgically removed.

Ivermectin is microfilaricidal but has no macrofilaricidal effect and may cause toxic encephalopathy in individuals with high microfilaria levels. In areas where onchocerciasis is co-endemic, this infection should be ruled out before the initiation of DEC for loiasis to prevent toxicity from dying *O. volvulus* microfilariae. See also Chapter 344.

PREVENTION

Weekly chemoprophylaxis with DEC administered as a 300-mg dose is effective in preventing loiasis in long-term residents of endemic areas.

Less Common Filarial Infections

MANSONELLA PERSTANS

M. perstans infection occurs throughout central Africa, in northeastern South America, and in parts of the Caribbean. Microfilariae are transmitted by *Culicoides* midges and develop into adult worms that live in serous body cavities, such as the pleural, pericardial, and peritoneal spaces, as well as in mesenteric and retroperitoneal tissues. Most infections are asymptomatic, although painless conjunctival nodules with eyelid edema have been reported. Transient angioedema and Calabar-like swellings, fever, headache, arthralgias, and neurologic manifestations also may occur. Microfilariae do not exhibit periodicity and can be observed on stained blood films. Eosinophilia is common.

M. perstans harbor *Wolbachia* endosymbionts, and treatment with doxycycline, 200 mg/day for 6 weeks, has been shown to be highly effective in suppressing microfilaremia for up to 3 years, suggesting that the treatment is macrofilaricidal.■

MANSONELLA OZZARDI

Infections with *M. ozzardi* occur in Central and South America and parts of the Caribbean, especially Haiti. Vectors include *Simulium* black flies and midges. Adult worms locate to the peritoneal and thoracic cavities or the lymphatics; microfilariae circulate in the blood without periodicity. Infection usually results in asymptomatic eosinophilia, although arthritis and allergic symptoms such as urticaria and lymphadenopathy may occur. Administration of ivermectin as a single dose of 200 µg/kg has been reported to provide long-term suppression of microfilaremia and improvement of symptoms. Neither DEC nor the benzimidazoles are effective.

MANSONELLA STREPTOCERCA

M. streptocerca is endemic in the tropical forest zone of western and central Africa and is transmitted by biting midges. Similar to *O. volvulus,* adult worms live in the subcutaneous tissues, as do microfilariae. In contrast to onchocerciasis, however, microfilariae do not invade the eye. Infection is usually asymptomatic, although a pruritic dermatitis with depigmentation similar to onchodermatitis can affect the trunk and upper extremities. Associated axillary or inguinal adenopathy is common. Microfilariae have characteristic hooked tails and can be visualized in skin snips. In areas where onchocerciasis is co-endemic, skin specimens must be stained to differentiate *M. streptocerca* from *O. volvulus*. DEC is microfilaricidal and macrofilaricidal and is given as 6 mg/kg/day for 12 days. Ivermectin is effective against microfilariae but not adult worms.

ZOONOTIC FILARIAL INFECTIONS

A rare accidental filarial infection of humans with the dog heartworm *Dirofilaria immitis* occurs worldwide. Transmitted by mosquitoes, *D. immitis* microfilariae cannot reach maturity in humans but embolize to the lung after dying in the right ventricle. Most infections are asymptomatic, but some people experience cough, chest pain, and hemoptysis consistent with lung infarction. Chest radiographs demonstrate typical coin lesions that may be mistaken for carcinoma. Other animal filariae, including *Dirofilaria repens* of dogs and *Dirofilaria tenuis* of raccoons, can infect humans and result in subcutaneous nodules that may be migratory. Eosinophilia and antifilarial antibodies are not usually present in zoonotic filarial infections. Surgical removal of lesions is both diagnostic and curative.

DRACUNCULIASIS

Dracunculiasis is a disfiguring disease caused by the nematode *Dracunculus medinensis,* also known as the Guinea worm. Although previously found in India, Pakistan, and Latin America, it is now endemic in only five countries in sub-Saharan Africa (South Sudan, Sudan, Chad, Mali, and Ethiopia) because of concerted efforts at eradication. As of 2014, fewer than 200 cases are thought to exist, with the largest concentration being in South Sudan. Transmission to humans occurs through ingestion of tiny crustacean intermediate hosts called *copepods* that harbor infective larvae. Released larvae penetrate the intestinal wall and migrate to the subcutaneous tissues, where they develop into adult worms. After approximately a year, female worms induce vesicular skin lesions, usually on the lower extremities, that eventually ulcerate. On direct contact with fresh water, the female worm releases thousands of motile larvae that can then complete the transmission cycle by infecting copepods in the water. Adult worms can measure up to a meter in length. Fever and allergic symptoms, including wheezing and urticaria, may precede rupture of the blister or occur with attempts to extract the worm. Secondary bacterial infection of the skin lesions is frequent. Although not usually fatal, dracunculiasis can result in significant disability.

Traditionally, emerging worms are extracted by slowly winding a few centimeters of the parasite on a stick each day, taking care not to break it. Surgical removal can be attempted but may exacerbate allergic symptoms. There is no effective chemotherapy for this infection. Prevention efforts have been highly successful in breaking the transmission cycle and have led to eradication of the parasite from many countries. Strategies include filtering of drinking water through finely woven cloth, education of infected individuals not to enter fresh water, treatment of water sources with larvicides, and provision of safe drinking water from wells.

REVIEW QUESTIONS

1. A 40-year-old woman from southern India has severe lymphedema of her right lower extremity and left breast. She has had this condition for at least a decade, and it is a common condition in her rural village. She now has difficulty going to work and is extremely embarrassed by her deformity to the point at which she tries not to venture outside of her home except at night. What is the most likely diagnosis?

A. Lymphatic filariasis
B. Loiasis
C. Onchocerciasis
D. Dracunculiasis
E. Podoconiosis

Answer: A The most likely diagnosis is lymphatic filariais due to chronic infection with *Wuchereria bancrofti*. Although loiasis, onchocerciasis, and dracunculiasis all have dermatologic manifestations, none result in chronic, irreversible lymphedema. *Loa loa* is associated with transient and migratory Calabar swellings that are hypersensitivity reactions to migrating adult worms; *Onchocerca volvulus* infection can result in generalized chronic dermatitis, and adult *Dracunculus medinensis* worms can rupture through intact skin from their location in the subcutaneous tissues to release eggs into the environment. Podoconiosis can result in chronic lymphedema due to irritant skin exposure to red clay, although this occurs mainly in the lower extremities, almost always starting in the foot.

2. A 28-year-old graduate student in physical anthropology has been experiencing unusual swellings over different parts of her body for the past 2 months. The swellings range in size from 5 to 15 cm and generally last 2 to 4 days before resolving; they are preceded by mild pain and intense pruritus that lasts a couple of hours. The field research for her dissertation is based on observational studies of gorillas in Gabon. A complete blood count is remarkable for very high eosinophilia (4000/mm^3) and an unusual finding on the peripheral blood smear (collected at mid-day) that prompts an urgent page from the laboratory technologist. What is the most likely explanation of the phenomenon seen on the blood smear?

A. Microfilaria of *Onchocercia volvulus*
B. Microfilaria of *Wuchereria bancrofti*
C. Promastigote of *Trypanosoma brucei gambiense*
D. Larva of *Dracunculus medinensis*
E. Microfilaria of *Loa loa*

Answer: E The skin manifestations are most likely Calabar swellings due to migrating adult *Loa loa* worms in the subcutaneous tissue. These are usually transient and are preceded by pain and pruritus. Loaiasis is endemic in Gabon. *Onchocerca volvulus* is also endemic in this country and may result in subcutaneous nodules, although these are usually neither migratory nor transient. In addition, microfilariae of *O. volvulus* are visualized after exiting from skin snip specimens, whereas those of *Loa loa* are seen in blood. The microfilariae of *Wuchereria bancrofti,* which is endemic in Africa, are present in the blood, although their periodicity differs from that of *L. loa*. *W. bancrofti* microfilariae are best visualized in blood collected at night whereas those of *L. loa* are more likely to be seen in a sample collected during the day, preferably between 10 AM and 2 PM. *Trypanosoma brucei,* the causative agent of African sleeping sickness, does not cause migratory skin swellings and is not associated with eosinophilia, although promastigotes can be observed on a Giemsa-stained blood smear. Finally, *Dracunculus medinensis* is associated with nonmotile skin lesions due to the adult female worm rupturing through subcutaneous tissue to the external environment to release larvae; however, no part of the life cycle occurs in the blood.

3. Within 2 weeks of eating jerky that he made from a cougar he shot while hunting, an Oklahoma man develops severe vomiting and diarrhea, followed 2 days later by a fever of 38.7° C, throbbing headache, and myalgias. After a few more days of continued symptoms, he seeks medical attention. His white blood cell count at presentation is 17,300/mm^3, with 25% eosinophils. Which of the following laboratory tests would be most useful in making the correct diagnosis?

A. Serum creatinine concentration
B. Enzyme-linked immunosorbent assay (ELISA) for the suspected pathogen
C. Examination of a Giemsa-stained blood smear using a light microscope
D. Serum creatine kinase concentration
E. Skin biopsy

Answer: D The most likely diagnosis is trichinellosis, probably due to *Trichinella nativa*. Infected individuals, especially those with myalgias and muscle tenderness, usually have elevated levels of serum creatine kinase, likely because *Trichinella* larvae invade striated muscle cells, inducing myositis. Unless the myositis is severe and rhabdomyolysis develops, associated renal dysfunction is rare. At this point in the disease process, seroconversion has likely not yet occurred, and, therefore, the ELISA for *Trichinella* would be negative. Larvae are not usually detectable in a stained blood smear or a skin biopsy, although nurse cells, which are striated muscle cells containing encysted larvae, can be visualized on muscle biopsy specimens.

4. A 7-year-old boy who has never traveled outside of North America develops decreased visual acuity in his right eye. Visible leukokoria is evident to his parents, which prompts a visit to their pediatrician, who consults an ophthalmologist. Fundoscopy reveals a single lesion of the retina. Assuming that his ocular condition is caused by a parasitic worm, which is the most likely means that this child became infected?

A. Being bitten by an infected black fly
B. Eating dirt while playing in a Boston public park
C. Swimming in a lake containing snails
D. Walking barefoot outside while visiting the family's summer cabin in rural West Virginia
E. Eating ceviche while on a family vacation to Mexico.

Answer: B Although several nematode species have been associated with ocular manifestations in humans, *Toxocara canis* and *Toxocara cati* are the most common etiologies of ocular larva migrans and are found worldwide. Children who eat dirt because of pica are most at risk. Dogs and cats naturally harbor the adult parasitic worms, but humans—especially children—may become accidentally infected when embryonated eggs are ingested, even though humans are unsuitable hosts for maturation into adult worms. Retinal involvement occurs when excysted larvae penetrate the small intestine and disseminate throughout the body, including the eye. Due to the inflammatory response, visually distinguishing the condition in situ from a retinoblastoma or ocular tuberculosis can be challenging. *Onchocera volvulus,* which is transmitted by the bite of a *Simulium* black fly, can cause ocular lesions, but these are almost exclusively corneal. In addition, onchocerciasis is endemic now mostly in Africa. Skin exposure to fresh water containing certain species of snails is the means of acquiring schistosomiasis, which does not result in retinal manifestations. Nor does *Strongyloides stercoralis,* which is endemic in certain rural parts of Appalachia and is acquired through skin exposure to soil containing infective larvae.

5. A 35-year-old woman who has recently immigrated to the United States from Cameroon presents with chronic atrophic dermatitis and punctate keratitis. Laboratory investigations reveal a peripheral eosinophil count of 3500/mm^3. Microfilaria are observed in the anterior chambers of both eyes on slit lamp examination. When considering management of this patient, which of the following antiparasitic medications should be contraindicated?

A. Ivermectin
B. Diethylcarbamazine (DEC)
C. Albendazole
D. Pyrantel pamoate
E. Praziquantel

Answer: B This woman most likely has onchocerciasis due to chronic infection with *Onchocerca volvulus,* resulting in the typical skin and ocular manifestations. DEC should never be used for treatment of onchocerciasis because of frequent unacceptable hypersensitivity reactions to dying microfilariae, which can range from urticaria and angioedema to hypotension and death. Ivermectin is the treatment of choice for *O. volvulus,* whereas albendazole, pyrantel pamoate, and praziquantel are neither effective nor detrimental in this condition.

ARTHROPODS AND LEECHES

DIRK M. ELSTON

ARTHROPODS

The Pathogens

Arthropods act as disease vectors and cause human injury by means of the direct toxic effects of their venom or via an immune response to their antigens (Tables 359-1 to 359-4). Immediate reactions to stings may be related to histamine, serotonin, formic acid, or kinins contained within the venom. Delayed reactions to bites and stings generally represent a host response to proteinaceous allergens contained within venom or saliva.[1]

Whereas many diseases are spread by a single vector, others have multiple potential vectors. For example, tularemia is commonly acquired from ticks or handling of infected carcasses but also may be spread by deerflies and horseflies. Rickettsiae are spread by both ticks and fleas. It is important to note that the vector may influence manifestations of the disease. For example, *Bartonella* transmitted by a flea may produce bacillary angiomatosis, whereas the same organism transmitted by a louse is much more likely to manifest as endocarditis. Disease manifestations also may reflect the underlying immune status of the host, previous sensitization, or associated comorbidities. For example, hypersensitivity reactions to insect stings are more common in those with an atopic diathesis and anaphylaxis may be a manifestation of underlying mastocytosis. Exaggerated bite reactions (Fig. 359-1) may be a manifestation of an underlying lymphoproliferative disease.

TABLE 359-4 CAUSES OF DIRECT TOXIC INJURY BY ARTHROPODS AND LEECHES

ORGANISM	TYPE OF INJURY	DISTRIBUTION AND POPULATION AFFECTED
Australian funnel web spiders (*Hadronyche* and *Atrax*)	Neurotoxin producing tingling around the mouth, muscle twitching, nausea, vomiting, profuse sweating, coma, myocardial injury	Australians
Blister beetles	Bullous reactions	Widely distributed, but more common in hot climates
Brazilian wandering spider (*Phoneutria* spiders)	Neurotoxin resulting in paralysis	Brazilians
Brown *Loxosceles* spiders	Dermonecrotic reactions	Contact through attics and woodpiles
Centipedes	Neurotoxin that may produce pain, paresthesia, erythema, edema, and profuse bleeding. Rarely, coronary ischemia, rhabdomyolysis, proteinuria, and renal failure.	Most toxic species in Asia
Hymenopterids	Anaphylactic reactions	Wide distribution
Leeches	Bleeding	Fresh water exposure
Lepidopterids *Lonomia* caterpillars	Rash, ophthalmia nodosa, keratoconjunctivitis Fatal bleeding diathesis	Wide distribution Brazil
Millipedes	Chemical burns	Most toxic species in Australia and Africa
Pacific funnel web spider (*Tegenaria agrestis*)	Dermonecrotic reactions	Basements in the Pacific Northwest
Scorpions *Centruroides sculpturatus* Buthid scorpions	 Mild systemic symptoms, sometimes severe in children Severe cardiac toxicity	 Southwestern United States Asia, Africa, and Latin America
Tarantulas	Contact urticaria and ophthalmia nodosa	Hot climates
Widow spiders (*Latrodectus*)	Neurotoxin mimicking acute abdomen	Contact through outhouses and woodpiles

INFECTION BY ARACHNIDA

SCABIES

DEFINITION

Human scabies is caused by the mite *Sarcoptes scabiei* variant *hominis,* an obligate human pathogen, belonging to the class Arachnida, subclass Acari, order Astigmata, and family Sarcoptidae. Animal mange or scabies is caused by related *Sarcoptes* or *Psoroptes* mites. These zoonotic mites can produce transient symptoms in exposed humans, but are rarely capable of producing sustained infestation. *Sarcoptes scabiei* variant *hominis* is round to oval with a small anterior portion, dorsal spines, and hairlike projections on the rudimentary legs.

PATHOBIOLOGY

After mating on the skin surface, the female mite begins to burrow and lay eggs at a rate of 1 to 3 per day. The eggs mature and hatch over 3 to 4 days. The larvae pass through protonymph and tritonymph stages before molting into adults. The entire life cycle ranges between 30 and 60 days. All stages of the mite are capable of penetrating the stratum corneum via secretion of enzymes. In immunosuppressed individuals, mite populations may reach staggering proportions within thick, white, highly infectious crusts.

In immunocompetent patients, scabies mites induce a strong host response characterized by a superficial and deep perivascular inflammatory infiltrate composed of lymphocytes, histiocytes, and eosinophils. There is marked production of interleukin-6 (IL-6) resulting in proliferation of keratinocytes, activation of Th1 CD4+ cells causing production of IL-2, and activation of Th2 CD4+ cells causing production of IL-4. Disease manifestations relate to the complex balance of the immune response.

CLINICAL MANIFESTATIONS

In immunocompetent adults, the eruption manifests with severe pruritus with nocturnal exacerbation and a symmetrical erythematous, papulovesicular eruption. Pruritus can be present on both affected and unaffected skin. There is a predilection for involvement of the interdigital web spaces, wrists (Fig. 359-2), anterior axillary folds, periumbilical skin, the areolae in females, and the penis and scrotum in males. In the pediatric population, head, neck, face, palms, and soles are commonly involved. Nodular scabies is a clinical variant accounting for 7% of all cases. Those affected present with intensely pruritic red-brown nodules 2 to 20 mm in size on the genitalia, buttocks, groin, and axillary region. These nodules do not contain mites but represent hypersensitivity to mite products. Crusted scabies manifests in immunosuppressed individuals as silver to white crusts involving any portion of the body, but with a predilection for the hands and ears. In elderly patients, the manifestations may be quite subtle with mild pruritus and prurigo-like papules on the trunk and extremities. In patients with human T-lymphotropic virus type I infection, scabies often manifests with linear, psoriasiform, hyperkeratotic lesions on the dorsal hands and feet. Crusted scabies can result in sepsis, with a 5-year mortality rate of up to 50%.

The most pathognomonic findings are the presence of burrows and genital nodules. The burrow is a short serpiginous gray to white keratotic line measuring 1 to 4 mm in length. They are most common on the hands and feet, particularly on the finger web spaces, the thenar and hypothenar eminences, and the wrists. Genital nodules may involve the glans, scrotum, or labia majora. A history of itch in other family members or sexual partners is highly suggestive of the diagnosis.

DIAGNOSIS

The diagnosis is established by identification of the female mite, ova, or feces in a scraping from a burrow (Fig. 359-3). Definitive diagnosis relies on direct visualization of mites, eggs, or mite pellets under microscopy. Additional diagnostic methods include the burrow ink test, video-dermoscopy, and polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA) for mite product or specific immunoglobulin E (IgE).

TREATMENT

Rx

Commonly employed topical agents include permethrin 5% and precipitated sulfur 2 to 10% in petrolatum. Topical agents used worldwide include benzyl benzoate 10 to 25%, monosulfiram 5 to 25%, malathion 0.5%, and esdepallethrin 0.63%. The topical agent crotamiton 10% has relatively weak antiscabetic activity but has antipruritic as well as antibacterial actions. An alternative to topical therapy is the use of oral ivermectin, 200 to 400 µg/kg given as a single dose, then repeated in 10 days.[2]

Proper application of any topical must include the umbilicus, genitalia, under the nails, and the skin up to the edge of all body orifices. Fomites are important in the spread of crusted scabies, with hospital linens being of particular concern. Caregivers involved in bathing or lifting, sexual partners, and family members are at high risk for infection and should be treated at the same time as the patient regardless of symptomatology. Clothes and bed linens should be machine washed at 60°C followed by heated drying.

OTHER MITES

Mites are ubiquitous in the environment and are a frequent cause of dermatitis. The most common medically important mites are listed in Table 359-3.

The majority of mites are free-living, but thousands of species are obligate parasites of animals or plants. Like ticks, mites mature through various life stages. Typically, there is a single six-legged larval stage, followed by several nymphal stages and an adult stage. Both nymphs and adults typically have eight legs. Although most mites lay eggs, the spiny rat mite (*Laelaps echidninus*) is viviparous, and the straw itch mite (*Pyemotes tritici*) protects its young internally throughout their life cycle until they emerge as sexually mature adults. Manifestations of mite infestations are protean and include papular, vesicular, urticarial, and morbilliform eruptions. Chigger mites most often affect the lower legs, the edges of underwear, and the genitalia. Summer penile syndrome is a manifestation of chigger mite infestation. It presents with tender to itchy papules of the glans and scrotum and may mimic scabies infestation. Chigger (Trombiculid) mites in Asia are vectors for scrub typhus,

FIGURE 359-2. Scabies infestation in children commonly manifests with burrows (shown here between the thenar and hypothenar eminences), papulovesicles, and crusts involving the wrists and flexures.

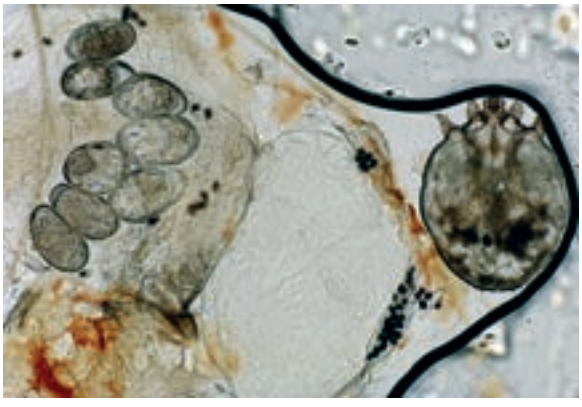

FIGURE 359-3. Scabies preparation demonstrating an adult mite, ova, and feces.

whereas house mouse mites in New York City transmit rickettsial pox. In endemic areas, the presence of an eschar in a patient with acute febrile illness has a high diagnostic value for rickettsial infection.

Most mite-induced rashes represent a "bite and run" injury and can be treated with topical corticosteroids or camphor and menthol lotion for symptomatic relief.

TICKS

Ticks are important disease vectors, and *Dermacentor* ticks can cause fatal tick paralysis in children. It is caused by a neurotoxin secreted by the salivary glands of an engorged female tick. Tick paralysis manifests as the development of unsteady gait, followed by progressive, ascending flaccid paralysis. As the tick attaches to the scalp, often behind the ear, it frequently goes unnoticed, and death occurs in over 10% of affected children due to respiratory failure. Nodular lesions are commonly pseudolymphomatous histologically.

Rickettsial illnesses typically manifest with fever and a headache, and treatment with a tetracycline should never be withheld because of the absence of a rash. Any delay in the initiation of antibiotic therapy may prove fatal, and empirical treatment should never be delayed until confirmatory tests are available. Doxycycline is generally recommended in both adults and children.

Rickettsial diseases, including Rocky Mountain spotted fever, continue to emerge in much of the world, especially in South America. Most of these agents produce milder syndromes similar to Rocky Mountain spotted fever.

Exclusion of animal hosts from recreational areas is key to control of tick-borne illness.[3] Oral agents, including avermectin-laced feed corn can be used to kill ticks that feed on deer. Removal of leaf debris leads to a reduction in tick numbers via dehydration of adults and ova. Permethrin, a pyrethroid insecticide with neurotoxic activity, is widely marketed as a topical acaricide to be applied to clothing. It is stable through several wash cycles. Some North African *Hyalomma* ticks have demonstrated high-level resistance, and permethrin may produce a pheromone-like attachment response in these ticks. Resistance in North American ticks can be esterase-based or related to sodium channel gene mutations, and permethrin resistance has been linked to outbreaks of bovine babesiosis and anaplasmosis.

A veterinarian should be consulted concerning control of ticks in pets and livestock.

Antibiotic prophylaxis after tick bites is rarely justified; it is indicated mostly in highly endemic areas where the ticks are heavily engorged. When signs and symptoms appear, a 10-day course of antibiotic is typically sufficient. A controlled trial comparing 10 days of oral doxycycline (with or without intravenous ceftriaxone) with 20 days of oral doxycycline for the treatment of early Lyme disease found a similar response rate in all three treatment groups.

SPIDERS

Toxic spiders are found worldwide.[4] The most feared include the funnel web spiders of Australia and *Phoneutria* wandering spiders in Brazil, which can be fatal. In North America, brown recluse spiders can produce a severe dermonecrotic reaction, but it should be noted that most spider bites result only in a mild local cutaneous reaction.

Black and brown widow spiders have a worldwide distribution. *Latrodectus mactans* is the most widely distributed black widow spider in North America. *Latrodectus curacaviensis* is common in South America and *Latrodectus tredecimguttatus* in Europe. Both black (*Latrodectus indistinctus*) and brown (*Latrodectus geometricus*) widow spiders are found in Africa and Madagascar, whereas Australia and New Zealand have red-black spiders (*L. mactans hasselti*).

Widow spiders are commonly encountered in woodpiles, and bites are typically defensive, frequently involving the hand after the spider has been disturbed. Latrotoxins act by increasing intracellular calcium concentrations, depolarizing neurons, and stimulating uncontrolled release of neurotransmitters, particularly norepinephrine and acetylcholine. Divalent cation-dependent tetramers of α-latrotoxin produce membrane pores in mammalian cells. Only the females have the ability to deliver venom and can be identified by the red hourglass pattern and shiny, black abdomen. Bites cause an envenomation syndrome comprising localized pain, diaphoresis, hypertension, weakness, muscle cramping, and severe pain in areas such as the abdomen and back. The syndrome may mimic an acute surgical abdomen. Both benzodiazepines and intravenous calcium gluconate have been used to treat associated tetany, but antivenin produces more rapid relief and is indicated for unresponsive tetany and priapism. Purified F(ab)2 fragment antivenin is now available and associated with a low risk for adverse reactions.

FIGURE 359-4. Brown recluse spiders are characterized by a dorsal violin case pattern.

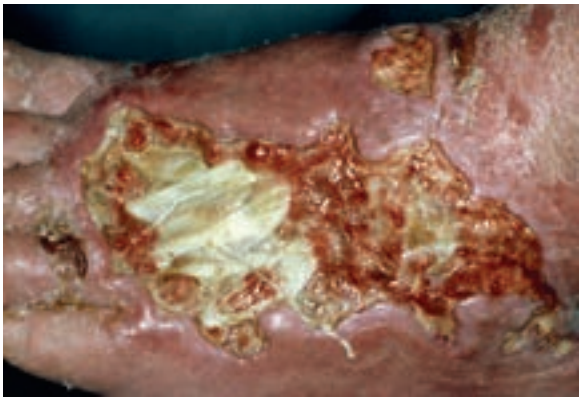

FIGURE 359-5. Dermonecrotic reactions from brown recluse spiders can be severe, but most are mild conditions. Furuncles or pyoderma gangrenosum are common misdiagnoses in patients who actually have brown recluse spider bites. (Courtesy Larry Becker, MD.)

Brown *Loxosceles* spiders are found throughout the world, with the most famous being the brown recluse spider, *Loxosceles recluse* (Fig. 359-4).[5] The resulting necrosis can be severe (Fig. 359-5), but most bites do not result in skin necrosis, and those of related spiders, including *Loxosceles rufescens, Loxosceles deserta,* and *Loxosceles arizonica,* are even milder. Brown recluse spiders are endemic to southeastern and midwestern United States. They are quite shy and bites are very uncommon; however, envenomation can cause severe dermatonecrosis and hemolytic anemia. Most skin reactions diagnosed as "brown recluse bites" represent furuncles or pyoderma gangrenosum. The diagnosis can be confirmed by an enzyme immunoassay, glycophorin A measurement, or a passive hemagglutination inhibition test.

Sphingomyelinase D is the major toxin in brown recluse venom, and hyaluronidase allows the eschars to spread in a gravity-dependent fashion. Systemic reactions include disseminated intravascular coagulation and Coombs'-positive hemolytic anemia, but these reactions are rare as well. Most bites can be treated supportively with rest, ice, and elevation. Intradermal injection of polyclonal anti-*Loxosceles* Fab fragments or antivenin may reduce the ultimate size of the necrotic area, but these agents are not readily available. Studies with dapsone, colchicine, hyperbaric oxygen, and prednisone have generally been disappointing. Dapsone produces hemolysis, especially in individuals who have inherited G6PD deficiency (Chapter 161). Based on limited animal data and anecdotal human data, intralesional triamcinolone appears to be appropriate for patients with rapidly expanding areas of necrosis. The complement inhibitor eculizumab has demonstrated the ability to prevent venom-induced hemolysis in vitro.

Hadronyche and *Atrax* funnel-web spiders are endemic to a region in eastern Australia. Their venom contains small peptide neurotoxins, including the δ-atracotoxins that slow tetrodotoxin-sensitive voltage-gated sodium channel inactivation. Catecholaminergic and cholinergic excess can result in bradycardia or tachycardia, hypertension, shock, hypersalivation, and diaphoresis. Paresthesia, fasciculations, and muscle spasms may occur. Severe myocardial injury also has been reported.

Spiders belonging to the genus *Phoneutria* are found in South America, Costa Rica, and, most notably and clinically important, Brazil. Bites cause localized pain of varying severity that radiates proximally from the bite. Ninety percent of cases show at least mild systemic envenomation. Patients are symptomatic with nausea, vomiting, dizziness, tachycardia, hypertension, diaphoresis, visual changes, and priapism. Severe envenomation results in pulmonary edema and shock. Antivenin therapy is available.

Tegenaria agrestis is found in basements in the Pacific Northwest. In Europe, it exists as a rural spider, because *Tegenaria gigantea* and *Tegenaria domestica* compete for home habitats. Most reactions are mild, although some dermonecrotic reactions have been attributed to these spiders. Tarantulas can cause contact urticaria and ophthalmia nodosa related to hairs that become embedded in the cornea.

SCORPIONS

Local and systemic symptoms of scorpion stings are typically out of proportion to cutaneous signs. *Centruroides sculpturatus* produces somewhat more severe envenomation in the American Southwest, but the most dangerous Buthid scorpions are not found in the United States.[6] Most fatalities are caused by cardiorespiratory manifestations such as cardiogenic shock and pulmonary edema after envenomation and involve children younger than 10 years of age. Pancreatitis is an important cause of morbidity after scorpion envenomation. Toxic Buthid scorpions occur in Asia, Africa, and Latin America. Prazosin reverses the autonomic storm characteristic of the Indian red scorpion (*Mesobuthus tamulus*), and accelerated recovery with preserved myocardial function has been demonstrated when it is used in combination with antivenin.

Infection via Pentastomida, Chilopoda, Diplopoda, and Crustacea

TONGUE WORM (PENTASTOMIASIS)

Pentastomiasis is a zoonotic infestation that sometimes affects humans. The pentastomids *Armillifer* and *Linguatula* are wormlike arthropods endemic to Asia and Africa. They commonly infest the respiratory tracts of birds, reptiles, and small mammals. In humans, severe inflammation associated with the infestation can result in coughing, hemoptysis, lacrimation, coryza, and facial edema. Rarely, asphyxiation has been reported. This syndrome is known as *halzoun* or *marrara,* meaning suffocation.

CENTIPEDES AND MILLIPEDES

Centipedes have powerful jaws that inject a neurotoxic venom. Centipede bites may produce pain, paresthesia, erythema, edema, and profuse bleeding. Rarely, bites have been associated with coronary ischemia, rhabdomyolysis, proteinuria, and renal failure. Millipedes do not bite, but cause arcuate chemical burns via a caustic substance that they secrete when threatened. They may be found in line-dried clothing and the resulting burns may mimic signs of child abuse.

CRUSTACEANS AS A SOURCE OF INFECTION

Copepods are tiny aquatic crustaceans that serve as the intermediate hosts for nematodes including the guinea worm *Dracunculus medinensis* and the sushi worm *Gnathostoma spinigerum.* They may also transmit the cestodes *Spirometra mansonoides* and *Diphyllobothrium latum.*

Pediculosis

Pediculosis is the result of infestation by sucking lice of the phylum Arthropoda, class Insecta, order Phthiraptera, suborder Anoplura, family Pediculidae, or family Pthiridae. Lice are obligate ectoparasites, and three types infest humans: *Pediculus humanus capitis* (the head louse), *Pediculus humanus* (the body louse), and *Pthirus pubis* (the crab louse).

HEAD LICE

EPIDEMIOLOGY

Head lice affect 6 to 12 million people per year in the United States alone. Worldwide, much of the human population is affected, with highest prevalence among children between the ages of 3 and 12. Transmission occurs by means of direct contact or close contact of hats and scarves.

DIAGNOSIS

Head louse infestation should be suspected in any child with scalp pruritus and cervical adenopathy. Visual inspection can demonstrate nits, especially in the retroauricular area. Small bites and crusts of blood are common on the scalp. Definitive diagnosis involves finding at least one live louse on visual inspection of the scalp.

TREATMENT Rx

Current recommendations favor agents that kill lice by occlusion of the respiratory spiracles. One such agent (Ulesfia lotion) uses benzyl alcohol to stun the spiracle open and allow occlusion. For routine infection, a single, 10-minute, at-home application of ivermectin 0.5% lotion is 95% effective at 1 day, 85% effective at 7 days, and 74% effective at 14 days after treatment for eliminating head-louse infestations.■ For difficult-to-treat head lice infestation in children, oral ivermectin (400 µg/kg), given twice at a 7-day interval, had superior efficacy compared with topical 0.5% malathion lotion, suggesting that it could be an alternative treatment.■

Malathion is a prescription organophosphate that acts by interfering with acetylcholinesterase. In the United States, it is marketed in a flammable vehicle that contributes substantially to its efficacy. There is relatively little resistance to this agent, but the trend is away from the use of neurotoxins in children.

Lindane is an organochloride compound that is still available by prescription. Central nervous system toxicity appears rare but together with environmental concerns resulted in banning of the product in California.

BODY LICE

EPIDEMIOLOGY

Body louse infestation is common in refugee situations, during war, and among the homeless in urban areas. This is a major public health concern because the louse can serve as a vector for at least three intracellular disease-causing bacteria: *Bartonella quintana* (causing trench fever and endocarditis), *Rickettsia prowazekii* (causing epidemic typhus), *and Borrelia recurrentis* (causing louse-borne relapsing fever).

CLINICAL MANIFESTATIONS

Early infestation produces a widespread dermatitis that may mimic atopic dermatitis, allergic contact dermatitis, or a viral exanthem. In patients with widespread excoriations, the most likely differential diagnosis is scabies. The diagnosis is made by finding bluish hued maculae cerulea (Fig. 359-6), prompting a search for body lice or nits in the seams of clothing.

TREATMENT Rx

Washing and hot drying or ironing of clothing will kill lice. Permethrin has also been used on clothing; however, a pediculocide is not always necessary.

FIGURE 359-6. Maculae cerulae are bluish red spots that represent sites where body lice have fed.

CRAB LICE

PATHOBIOLOGY

Crab louse infestation is spread as a sexually transmitted disease. Roughly 30% of patients will have another concurrent sexually transmitted disease and adolescents with pubic lice are twice as likely as uninfested adolescents to have chlamydial or gonorrheal infection.

CLINICAL MANIFESTATIONS

Patients present with intense itching, and both lice and nits may be found on pubic hairs as well as hair on the chest, abdomen, and legs. Pubic lice occasionally may cause scalp infestation in patients with thick curly hair. They also may infest the eyelashes, causing phthiriasis palpebrarum infection. When observed in children, sexual exposure should be considered.

TREATMENT Rx

Treatment is by means of shaving or with topical agents used to treat head lice. Oral ivermectin has also been used at a dose of 200 to 400 µg/kg, repeated in 10 days.

Beetle-Related Dermatitis

Blister beetles (order Coleoptera) are widespread throughout the world and include members of the families Meloidae and Staphylinidae. Members of the family Oedemeridae are classified as "false" blister beetles, but can produce similar skin manifestations. Cantharidin accumulates during the larval stages of the beetle and gives it protection from predatory birds. When threatened, the beetles protect themselves by exuding a cantharidin-containing liquid. Contact with blister beetles results in vesicles and bullae. "Nairobi eye," or rove beetle dermatitis, in Northern Kenya is caused by *Paederus eximius*. Rove beetles were implicated in a recent epidemic of pustular eruption among U.S. forces in Pakistan. Treatment for all manifestations of blister beetles is largely symptomatic.

FLEAS

Fleas (order Siphonaptera) are ubiquitous among pets and wild animals. They serve as vectors for endemic typhus, bubonic plague, brucellosis, melioidosis and erysipeloid. The most common flea on dogs is the cat flea, *Ctenocephalides felis*. *Pulex irritans,* the human flea, can be found on dogs and became a major plague vector during the great epidemics. Flea bites cluster on the lower legs and present as intensely pruritic papulovesicles. Tungiasis is caused by the jigger or sand flea, *Tunga penetrans.* It typically presents with a necrotic pustule adjacent to the great toenail.

A veterinarian should be consulted about agents for flea control, including lufenuron and fipronil. Beach areas should restrict pets to prevent infestation.

FLIES

Mosquitoes and other flies belong to the order Diptera and represent major disease vectors. *Anopheles* mosquitoes bite mostly at night and are the major vectors of malaria. They also transmit filariasis. *Aedes* mosquitoes bite during the day and transmit dengue, viral encephalitis, yellow fever, and filariasis. *Culex* mosquitoes bite at night and transmit West Nile encephalitis, filariasis, and viral encephalitis. Cul*ex* mosquitoes also bite at dusk or early evening. Many arthropod diseases have a principal vector but also can be spread by other vectors. For example, although *Culex* mosquitoes are the major vector for West Nile virus in the United States, *Aedes* and *Anopheles* spp also can spread the disease. *Simulium* flies (black flies, humpback flies, buffalo gnats, turkey gnats) transmit onchocerciasis. *Lutzomyia* and *Phlebotomus* sandflies transmit leishmaniasis, *Bartonella bacilliformis,* and sandfly fever. Biting midges (punkies, gnats, no-see-ums) are small enough to pass through screens and cause papulovesicular and nodular reactions in sensitive individuals. Tabanid flies include the horse flies, deer flies, and greenheads. As a group, they are large and colorful and deliver painful bites. *Chrysops* deer flies transmit loiasis in Africa and tularemia in the United States. *Glossina* tsetse flies transmit trypanosomiasis.

Furuncular myiasis caused by the botfly is common in Latin America. *Dermatobia hominis,* glues its eggs to a mosquito, which serves as an intermediate vector. *Cordylobia anthropophaga,* the mango fly, tumbu fly, putzi fly, or skin maggot fly, is native to Africa and lays its eggs on drying clothing. It produces plaque-type myiasis with many maggots. *Cochliomyia hominivorax,* the screwworm, lays its eggs on wounds or mucous membranes. Screwworms are feared because they leave necrotic flesh and continue to travel through viable tissue. Sarcophagid flies deposit their living larvae on the hosts, where they produce a type of larva migrans. Myiasis is treated by means of mechanical removal with tweezers or by incision of the wound. Covering the embedded larvae with an occlusive substance such as surgical lubricant, petrolatum, or bacon encourages them to move upward facilitating removal.

Prevention of vector-borne disease requires control of standing water, use of screening and mosquito netting, and personal protection with repellents. Screening impregnated with pyrethroids is more effective than untreated screening. Secondary prevention includes malaria chemoprophylaxis and early treatment of illness. Other interventions include insecticidal sprays, and gas-powered mosquito traps. Most types of mosquito traps generate carbon dioxide and use chemical attractants such as octenol and butanone. Some *Culex* mosquitoes are repelled by octenol.

N,N-diethyl-3-methylbenzamide (DEET) remains the most widely used insect repellent, although picaridin is widely used in Europe and is gaining market share in the United States. IR3535, KBR 3023, and *para*-menthane diol are also used as repellents for application to skin. Permethrin is largely used for fabric impregnation. DEET has a long safety record, but occasionally can cause bullous dermatitis, anaphylaxis, or toxic encephalopathy. The American Academy of Pediatrics recommends slow-release products below 30% concentration. Neem oil products perform reasonably well against various mosquitoes, but citronella has limited efficacy.

HEMIPTERA: TRUE BUGS

Bedbugs have become pandemic and are increasingly recognized in suburban homes, hotels, and, especially, on college campuses.[7] They are red-brown and about the size of small ticks (Fig. 359-7). The wings are vestigial. *Cimex lectularius* and *C. hemipterus* (the tropical bedbug) parasitize birds and bats, who introduce them into buildings. They also spread readily via luggage. These organisms hide in cracks and crevices of beds, particularly along the seams of mattresses. Hepatitis B has been found in bedbugs, but they have not shown vector competence to transmit human disease. Bites are characteristically found on the face, neck, and arms. In covered areas, a string of bites termed "breakfast, lunch, and dinner" is typical (Fig. 359-8). Treatment of bites is with topical corticosteroids. Disinfestation involves extermination, washing and drying of all bedding on a hot setting, and placing the mattress and box spring in a zippered plastic case. Room hyperthermia has proved to be a viable alternative.

Triatome reduviids are important vectors for American trypanosomiasis (Chagas disease). Their wings overlap and are sclerotic proximally. The striped abdomen is visible lateral to the wings. Unilateral eyelid swelling (Romana sign) is caused by a conjunctival reaction to the bite and to triatome feces infected with trypanosomes.

HYMENOPTERA STINGS

Hymenoptera include membranous winged insects such as wasps, bees, and fire ants. They all result in painful stings and present a potential for anaphylactic reactions.[8] Unexpected stings occur frequently; therefore, allergic individuals must always carry a source of epinephrine such as an EpiPen auto-injector. Bees are eviscerated during the sting and the venom gland

FIGURE 359-7. Bedbugs are red-brown and about the size of small ticks.

FIGURE 359-8. Bedbug bites are often arranged in a characteristic "breakfast, lunch, and dinner" pattern.

continues to inject additional venom. Therefore, bee stingers should be removed as rapidly as possible, with little concern for the exact method of removal. Venom immunotherapy can improve quality of life. Rush immunotherapy (a method for rapidly desensitizing patients to allergens) can be performed in those with severe reactions. Omalizumab has been used in conjunction with immunotherapy and has shown clinical effectiveness but further investigation is warranted to determine its exact role.

LEPIDOPTERIDS

Moths and caterpillars may have toxic hairs that may contain histamine, kinins, plasminogen activators, and other proteinaceous toxins. The reactions are usually toxic rather than allergic in effects. Clinical manifestations include pain, erythema, swelling, and hemorrhage. Systemic reactions may include renal failure. *Lonomia* caterpillars may cause a fatal bleeding diathesis with intracranial hemorrhage. Ocular reactions to hairs include ophthalmia nodosa, keratoconjunctivitis, subconjunctival nodules, iritis, and vitreoretinal involvement. Children who ingest caterpillars may develop edema of the lips, tongue, and buccal mucosa. Esophageal and tracheobronchial involvement occurs less commonly.

DELUSIONS OF PARASITOSIS

Patients with delusions of parasitosis present with an unshakable belief that they are infested with pathogens such as insects, worms, bacteria, parasites, or fungi.[9] Some believe they are infested with inanimate materials such as hairs, filaments, fibers, and particles. It is difficult to help them. A careful evaluation should exclude formications secondary to cocaine addiction and pruritus related to systemic diseases such as renal failure or hyperthyroidism. Although delusions of parasitosis have traditionally been treated with pimozide, newer atypical antipsychotic agents such as risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole reduce the need for electrocardiographic monitoring.

LEECHES AND OTHER ANNELIDS

Leeches occur in fresh water and may be associated with *Pseudomonas* or *Aeromonas* wound infections. Leeches contain anticoagulants, and the attachment sites may bleed freely when the leech is removed. More serious coagulation disorders with massive bleeding have been reported. Saturated salt solutions have been used to facilitate leech removal, but do not reduce the risk for infection.

REVIEW QUESTIONS

1. Which of the following is *not* a mechanism by which arthropod venoms cause human injury?

A. Neurotoxins
B. Extracellular matrix enzymes
C. Dermonecrotic reactions
d. Chemical burns
E. Anticoagulants

Answer: B Whereas snake venoms typically mediate tissue necrosis and extracellular matrix degradation via enzymes such as metalloproteases, hyaluronidase, and myotoxic phospholipase A_2, arthropods are not known to cause injury through these mechanisms. Causes of toxic injury by arthropods (see Table 359-4) include neurotoxins (e.g., Australian funnel web spiders, Brazilian wandering spiders, centipedes, widow spiders); dermonecrotoxins (e.g., brown *Loxosceles* spiders, Pacific funnel web spiders); chemical burns (e.g., millipedes); and anticoagulants (centipedes, leeches, *Lonomia* caterpillars).

2. A 20-year-old college student presents to her student health service clinic with an intensely pruritic papulovesicular eruption of both lower legs. She and her three roommates had recently adopted a stray dog despite their crowded and cluttered apartment. Which of the following should be recommended for management?

A. Treat with topical agents and machine wash clothes and bed linens at 60° C followed by heated drying
B. Evaluate her for underlying inflammatory bowel disease
C. Consult a veterinarian about agents for flea control
D. Apply topical steroids and exterminate or wash and dry all bedding on a hot setting
E. Search for offending agents in the seams of clothing and burn such clothes

Answer: C The patient most likely has flea bites from the stray dog. As in this case, flea bites tend to cluster on the lower legs and manifest as intensely pruritic papulovesicles. A veterinarian should be consulted about agents for flea control, including lufenuron and fipronil. The management in option A applies to scabies. The pruritic lesions of scabies have a predilection for involvement of the interdigital web spaces, wrists, anterior axillary folds, periumbilical skin, areolae in females, and penis and scrotum in males. Option B would be the approach to a patient with classic pyoderma gangrenosum, which usually occurs in the lower extremities. Pyoderma gangrenosum can be confused with brown recluse spider bites. Option E applies to the management of body lice; infestation with body lice produces a widespread dermatitis with widespread excoriations (that can be similar to those seen in scabies) and the diagnostic finding of bluish maculae cerulae (see Fig. 359-6). Bed bugs have become endemic and are increasingly recognized on college campuses, among other sites. Their bites are characteristically found on the face, neck, and arms, typically in strings of bites termed "breakfast, lunch, and dinner." Option D would apply to bed bugs.

3. Which of the following pairings of vector and disease it causes is correct?

A. *Aedes* mosquitoes and malaria
B. Fleas and yellow fever
C. Sandflies and bartonellosis
D. Wood tick and rickettsial pox
E. Tsetse flies and African trypanosomiasis

Answer: E Tsetse flies are vectors for African trypanosomiasis. Triatome bugs are vectors for American trypanosomiasis. *Aedes* mosquitoes are vectors for dengue and yellow fever; anopheline mosquitoes are the vectors for malaria. Fleas are vectors for bartonellosis and endemic typhus; *Aedes* mosquitoes are the vectors for yellow fever. Sandflies are vectors for leishmaniasis, not bartonellosis. Wood ticks are vectors for Rocky Mountain spotted fever (along with dog ticks and *Amblyomma americanum*. See Table 359-2.

ANTIVIRAL THERAPY (NON-HIV)

JOHN H. BEIGEL

Although some viral infections are self-limited, others can cause significant morbidity and mortality. Effective therapy is available for many of these infections. This chapter reviews currently available antiviral agents for the treatment of infections caused by viruses other than human immunodeficiency virus (HIV). Not all agents discussed are licensed in all countries.

Currently available agents can be classified into those that directly inhibit viral replication at the cellular level (antivirals), those that modify the host response to infection (immunomodulators), and those that directly inactivate viral particles (microbicides/virucides). Antiviral agents can be classified based on their mechanism of action. For example, nucleic acid analogues inhibit viral DNA or RNA synthesis by competing with endogenous nucleic acids and block the viral DNA polymerase or RNA transcriptases. By comparison, protease inhibitors prevent viral replication by binding to the enzymes that cleave viral protein precursors into active proteins.

Antiviral strategies that are not covered in this chapter include local destructive measures that destroy both host tissues and virus simultaneously, such as cryotherapy, laser, and podophyllin treatment of warts. Although effective, such measures are useful only for discrete or localized mucocutaneous infections.

ANTIVIRALS FOR HEPATITIS B VIRUS INFECTIONS

Acute hepatitis B infection (Chapter 148) generally does not require antiviral treatment. Currently approved antivirals for chronic hepatitis B (Chapter 149) include five nucleic acid analogues (adefovir, entecavir, lamivudine, telbivudine, and tenofovir) and two immune modulators (interferon alfa-2b and pegylated [PEG]-interferon alfa-2a) (Tables 360-1 to 360-3). Treatment may be initiated with any approved antiviral medications, but tenofovir, entecavir, and PEG-interferon alfa-2a are generally the preferred agents.[1] Tenofovir or entecavir is preferred for patients with compensated cirrhosis (Chapter 153).

TABLE 360-1 ANTIVIRALS FOR HEPATITIS VIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
Chronic hepatitis B	Tenofovir	PO	300 mg/day
	Entecavir		
	Naïve virus	PO	0.5 mg daily; optimal duration of therapy unknown
	Lamivudine-resistant virus	PO	1 mg daily; optimal duration of therapy unknown
	Interferon alfa-2b	SC	6 MU/m^2 (up to 10 MU) 3 times weekly for 16-24 wk
	PEG-interferon alfa-2a	SC	180 µg weekly for 48 weeks
	Adefovir	PO	10 mg/day
	Lamivudine	PO	100 mg/day
	Telbivudine	PO	600 mg/day
Chronic hepatitis C	Ledipasvir/Sofosbuvir	PO	90 mg/400 mg once daily for 12-24 weeks
	Ombitasvir/ Paritaprevir/ Ritonavir plus Dasabuvir	PO	12.5 mg/75 mg/50 mg once daily plus dasabuvir 250 mg twice daily
	Sofosbuvir	PO	400 mg once daily for 12-24 weeks
	Simeprevir	PO	150 mg once daily for 12 weeks
	Boceprevir	PO	800 mg every 8 hours for 24-44 weeks
	PEG-interferon alfa-2a	SC	180 µg weekly for 48 weeks
	or PEG-interferon alfa-2b	SC	1.5 µg/kg weekly for 48 weeks
	plus Ribavirin	PO	800-1200 mg/day, depending on weight

TABLE 360-2 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENT

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	SPECIAL ADJUSTMENT FOR ELDERLY
Adefovir	Renal	CrCl < 50 mL/min	No adjustment	
Entecavir	Renal	CrCl < 50 mL/min	No adjustment	
Lamivudine	Renal	CrCl < 50 mL/min	No adjustment

Boceprevir	Hepatic	No adjustment	No adjustment	

TABLE 360-3 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Adefovir	Severe acute exacerbations of hepatitis B may occur with cessation of therapy. Nephrotoxicity may occur in patients at risk for or undergoing renal dysfunction. Lactic acidosis and severe hepatomegaly with steatosis
Entecavir	Lactic acidosis and severe hepatomegaly with steatosis; severe acute exacerbations of hepatitis B may occur with cessation of therapy.
Lamivudine	Severe acute exacerbations of hepatitis B may occur with cessation of therapy. Lactic acidosis and severe hepatomegaly with steatosis
Ribavirin	Monotherapy for hepatitis C is not effective. Hemolytic anemia Teratogenic and embryocidal
Interferon alfa	May cause or aggravate neuropsychiatric, autoimmune, ischemic, and infectious disorders
Telbivudine	Severe acute exacerbation of hepatitis B may occur with cessation of therapy; lactic acidosis and severe hepatomegaly with steatosis.

Patients with chronic hepatitis B (hepatitis B surface antigen [HBsAg] positive for > 6 months, detectable serum hepatitis B virus (HBV) DNA > 20,000 IU/mL, and an alanine aminotransferase [ALT] level > twice the normal level) should be evaluated for treatment. Patients with clinically decompensated hepatitis B (e.g., icterus or other signs) generally require antiviral treatment. Therapy in hepatitis B e antigen (HBeAg)-positive chronic hepatitis B should be continued until the patient has achieved HBeAg seroconversion and serum HBV DNA is undetectable, followed by at least 6 months of additional treatment after the appearance of anti-HBe. Therapy in HBeAg-negative chronic hepatitis B should continue for at least a year. Patients with decompensated cirrhosis or recurrent hepatitis B after liver transplantation should receive lifelong treatment.

Tenofovir

Tenofovir, which is a nucleotide analogue of adenosine monophosphate, was first approved for the treatment of HIV infection. The commercially available agent, tenofovir disoproxil fumarate, is an ester prodrug of tenofovir, with an effective tenofovir bioavailability of 25%. Administration following a high-fat meal increases the oral bioavailability.

Clinical Uses

Tenofovir is approved for the treatment of chronic hepatitis B in adults with evidence of active viral replication and either persistent elevations in serum aminotransferase levels or histologically active disease. Treatment with tenofovir is more effective than adefovir in producing histologic improvement and viral suppression in patients with HBeAg-negative or HBeAg-positive chronic hepatitis B.[1] Tenofovir also has demonstrated efficacy in patients with lamivudine-resistant HBV.[1]

Toxicity

Tenofovir is generally safe and well tolerated for up to 5 years.[2] The most common side effects are nausea, diarrhea, vomiting, and anorexia. Lactic acidosis with hepatic steatosis has been reported, primarily when it is used in combination with other nucleoside analogues. Acute exacerbations of hepatitis B have been reported after discontinuation of tenofovir in patients who are coinfected with HIV and HBV.

Antiviral Resistance

Mutations in HBV polymerase that confer reduced susceptibility to tenofovir occur during prolonged use (>12 months). In vitro studies showed that adefovir-resistant HBV mutations are associated with three- to five-fold decrease in response to tenofovir, though clinical implications are not known.

Entecavir

Entecavir, which is a deoxyguanosine nucleoside analogue with specific antiviral activity for hepadnaviruses, is more potent than lamivudine and retains some activity against lamivudine-resistant HBV variants. It is well absorbed after oral administration, and its prolonged half-life (128 to 149 hours) allows once-daily dosing.

Clinical Uses

Entecavir is approved for the treatment of chronic hepatitis B in adults with evidence of active viral replication and either persistent elevations in serum aminotransferases or histologically active disease. Compared with lamivudine or telbivudine, entecavir is more efficacious in reducing HBV DNA levels and normalizing serum aminotransferases, as well as in improving histologic abnormalities.[1,2] Like tenofovir, entecavir can be used for lamivudine-resistant HBV infections, but higher doses and longer durations of therapy are needed.

Toxicity

Adverse effects reported during entecavir therapy include headache, fatigue, dizziness, nausea, abdominal pain, rhinitis, fever, diarrhea, cough, and myalgia. Lactic acidosis and severe hepatomegaly with steatosis have been reported. Severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Virologic breakthrough can occur in up to 4% of patients but is usually not indicative of resistant virus. True entecavir resistance, which is caused by specific mutations in HBV polymerase, is uncommon (1.2% after 5 years of treatment). In vitro studies show that entecavir-resistant mutations are susceptible to adefovir and tenofovir, but there is very little supportive clinical data.

Interferons

Interferons are glycoprotein cytokines with a complex array of antiviral, immunomodulating, and antineoplastic properties. Interferons are currently classified as alfa, beta, or gamma. The natural sources of these classes in general are leukocytes, fibroblasts, and lymphocytes, but they now can be produced by recombinant DNA technology. Although the full mechanism of

interferon's action is not defined, interferons generally induce synthesis of new cellular RNA and proteins that mediate antiviral effects through multiple different mechanisms.

Interferons generally must be administered daily or several times per week. However, the combination of interferon with polyethylene glycol to form PEG-interferon significantly prolongs absorption and provides higher, more sustained plasma levels that enable once-weekly administration.

Clinical Uses

In chronic active hepatitis B, treatment with interferon alfa leads to loss of HBV DNA and biochemical and histologic improvement in about 25 to 40% of patients. Administration of PEG-interferon alfa-2a or alfa-2b for 48 weeks converts about 30% of patients to seronegative status after 6 months of treatment. Whether combination therapy with interferons and antivirals confers an additional benefit compared to monotherapy for treating chronic hepatitis B is not known.

Adefovir

Adefovir, an acyclic analogue of adenosine monophosphate, is administered orally as a prodrug, adefovir dipivoxil, which is rapidly converted enzymatically to adefovir in intestinal epithelium.

Clinical Uses

In chronic hepatitis B, prolonged administration of adefovir is effective in improving histologic abnormalities of the liver, decreasing HBV DNA levels, and normalizing biochemical (ALT) markers in patients with HBeAg-positive and HBeAg-negative chronic hepatitis B. Adefovir is a slightly weaker antiviral and therefore not considered first-line therapy, but it is useful for resistant viruses (effective against chronic hepatitis B resistant to lamivudine) and HIV/HBV coinfection (see later).

Toxicity

The major adverse effect is nephrotoxicity, which is manifested by increased serum creatinine levels and sometimes hypophosphatemia, both of which are usually reversible with discontinuation of the drug. Common side effects include asthenia, headache, nausea, vomiting, and diarrhea. In addition, severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Adefovir resistance due to point mutations in HBV polymerase develops in about 6% of patients after 3 years of therapy. Lamivudine generally retains activity against adefovir-resistant variants.

Lamivudine

Lamivudine is a deoxycytidine nucleoside analogue active against retroviruses and hepadnaviruses. The triphosphate inhibits HBV polymerase, and its incorporation into viral DNA results in termination of the DNA chain.

Clinical Uses

Lamivudine suppresses hepatitis B viral replication, improves histologic abnormalities of the liver, reduces progression of fibrosis, and decreases the risk for late complications. Monotherapy with lamivudine appears to be inferior to the newer antivirals, as well as monotherapy with interferon, for sustained control of HBV replication. Combination therapy with lamivudine and interferon has shown inconsistent benefit compared with either drug alone.

Toxicity

Adverse effects of lamivudine include diarrhea, headache, and elevated liver enzymes. Severe post-treatment exacerbations of hepatitis B, including fatalities, have occurred after discontinuation of lamivudine, especially in patients who are coinfected with HBV and HIV.

Antiviral Resistance

Lamivudine resistance caused by mutations in HBV polymerase is common during prolonged treatment of hepatitis B and emerges in about 20% of treated patients annually. Resistance is associated with increases in viral replication and aminotransferases.

Telbivudine

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV, including some lamivudine-resistant variants. The triphosphate form competitively inhibits the HBV DNA polymerase (reverse transcriptase).

Clinical Uses

In comparative trials against lamivudine or adefovir, telbivudine demonstrated greater virologic response at week 52 (60% vs. 40% of subjects HBV DNA negative by polymerase chain reaction analysis). The development of resistance with telbivudine is up to 5% after 1 year and 25% after 2 years. Telbivudine-resistant viruses are cross-resistant with lamivudine. Owing to the high development of resistance and cross-resistance, telbivudine is not considered a first-line therapeutic for hepatitis B.

Toxicity

Common side effects include headache, nausea, and vomiting. Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy. Myopathy, manifested by muscle aches or weakness with increased serum creatine kinase levels, has rarely been reported.

Special Considerations—HIV/HBV Coinfection

Lamivudine and tenofovir are licensed and have activity against both HIV and HBV. Entecavir is licensed for the treatment of HBV, but it is also weakly active against HIV. Monotherapy treatment of HBV with these agents should not be used in HIV coinfected patients, owing to the development of HIV resistance. Emtricitabine is licensed only for the treatment of HIV but is also weakly active against HBV. Withdrawal of this medication, like withdrawal of tenofovir or lamivudine, may cause acute, sometimes fulminant, exacerbations of hepatitis B in HIV/HBV coinfected patients.

If concurrent treatment of HBV and HIV is warranted, tenofovir plus emtricitabine or tenofovir plus lamivudine should be considered as the nucleoside backbone. In coinfected patients who require treatment for HBV but not HIV (e.g., HBeAg-positive patients with high CD4 counts) or who are already well controlled on anti-HIV viral therapy but now need hepatitis B treatment as well, PEG-interferon alfa-2a or adefovir should be considered to avoid the addition of one antiviral with HIV and HBV activity and the potential development of HIV resistance. If the antiretroviral regimen must be changed owing to HIV virologic failure and the HBV is adequately suppressed, antiviral drugs active against HBV should be continued for HBV treatment.

ANTIVIRALS FOR HEPATITIS C VIRUS INFECTIONS

The treatment of chronic hepatitis C (Chapter 149) has significantly changed in the last few years. The goal of HCV therapy is sustained virologic response (absence of HCV RNA for at least 12 weeks after completion of therapy). Treatment has been shown to decrease liver inflammation and cirrhosis, as well as reduce the risk of hepatocellular carcinoma.

Interferon free regimens are now preferred over interferon based regimens. (Tables 360-1 to 360-3). Ledipasvir/sofosbuvir, sofosbuvir plus simeprevir, or ombitasvir/paritaprevir/ritonavir plus dasabuvir are preferred regimens for HCV genotype 1. Sofosbuvir and weight-based ribavirin are preferred for HCV geneotypes 2 and 3. Ledipasvir/sofosbuvir, or sofosbuvir plus simeprevir are preferred regimens for HCV genotype 4. Little data are available to guide recommendations for HCV genotype 5 or 6.

Interferon based regimens now are generally reserved for patients that do not have access to interferon free regimens. Sofosbuvir in combination with ribavirin and pegylated interferon has good efficacy for all genotypes.[3,4] Simpeprevir may be used as alterative regimens for genotypes 1 and 4.

Treatment of acute hepatitis C remains symptomatic, and antiviral therapy generally is not indicated.

Ledipasvir/Sofosbuvir

Ledipasvir is a HCV NS5A inhibitor. Sofosbuvir is a nucleotide prodrug that, when triphosphorylated, inhibits HCV NS5B, a RNA dependent RNA polymerase. Both NS5A and NS5B are important for HCV viral replication. Ledipasvir/sofosbuvir is available as a combination fixed dose once daily oral tablet.

Clinical Uses

Ledipasvir/sofosbuvir is currently licensed in the treatment of genotype 1 chronic HCV. For treatment naïve patients with or without cirrhosis, treatment should continue for 12 weeks. This regimen has been associated with a sustained virologic response of 99% at 12 weeks. The duration of treatment may be reduced to as low as 8 weeks without significant changes in efficacy. For treatment-experienced patients, 12 weeks of treatment is recommended for those without cirrhosis and 24 weeks for those with cirrhosis; the

sustained virologic response is also 94-99%.[5] Ledipasvir/sofosbuvir has also been recommended in the treatment of genotype 4 chronic HCV.

Toxicity
The most common side effects are headaches and fatigue. Significant drug interactions may occur with medications such as rifampin or St. John's wort.

Resistance
Resistance to the individual component drug may occur but is rare. Ledipasvir is active against sofosbuvir-resistant viruses, and sofosbuvir retains activity against ledipasvir-resistant viruses, so the clinical significance of resistance mutations is not known.

Ombitasvir/Paritaprevir/Ritonavir plus Dasabuvir
Ombitasvir is a HCV NS5A inhibitor and paritaprevir is an inhibitor of the HCV NS3/4A protease. Ritonavir has no activity against HCV, but it is an inhibitor of hepatic CYP3A and is added to increase paritaprevir levels. These three drugs are coformulated into one tablet that is packaged with dasabuvir, an inhibitor of the HCV NS5B polymerase.

Clinical Uses
Ombitasvir/paritaprevir/ritonavir plus dasabuvir is currently licensed in the treatment of genotype 1 chronic HCV. In patients without cirrhosis, treatment for 12 weeks has been associated with a sustained virologic response of 97-99%. For geneotype 1a, the addition of ribavirin may decrease virologic failures.[5]

Toxicity
The many drug interactions that exist due to the ritonavir inhibition of CYP3A should be closely evaluated prior to initiation of therapy. The most common side effects include nausea and diarrhea, as well as rash, headache, and fatigue.

Resistance
Treatment-emergent mutations were observed in patients with virologic failure, though the clinical significance of this is not known.

Sofosbuvir
Clinical Uses
Sofosbuvir is currently licensed as a component of a combination antiviral treatment regimen for HCV genotypes 1 to 4. For genotypes 1 and 4, sofosbuvir is used in combination with PEG-interferon and ribavirin for 12 weeks. This regimen has been associated with a sustained virologic response of about 90% at 12 weeks.[5] In genotypes 2 and 3, sofosbuvir in combination with ribavirin for 12 or 24 weeks also has been associated with about a 90% sustained virologic response.[5] For patients who cannot tolerate an interferon-based regimen (autoimmune disorders, decompensated hepatic disease, leukopenia, thrombocytopenia, anemia, or preexisting cardiac disease), sofosbuvir may be used with simeprevir or ribavirin for 24 weeks.

Toxicity
Common side effects include headache, fatigue, anemia, and diarrhea. Severe pancytopenias and severe depression have been reported. Sofosbuvir is a substrate of drug transporter P-gp, and drugs that are potent P-gp inducers (e.g., rifampin or St. John's wort) may decrease sofosbuvir's plasma concentration.

Resistance
The emergence of resistance while on sofosbuvir treatment is extremely rare.

Simeprevir
Simeprevir is a protease inhibitor that binds to the NS3/4a of hepatitis C.

Clinical Uses
Simeprevir is currently licensed for the treatment of chronic hepatitis C genotype 1 as either initial therapy or for use after failure of prior interferon-based therapy. Simeprevir is given for 12 weeks in combination with peginterferon alfa and ribavirin, followed by peginterferon alfa and ribavirin for an additional 12 weeks (treatment naïve) or 36 weeks (prior nonresponse). In naïve patients, virologic response is about 80%.[5] Although not as effective as sofosbuvir, simprevir is superior to other protease inhibitors and has become second-line therapy in genotype 1 (FDA approved) and genotype 4 (not FDA approved) hepatitis C.

Toxicity
Dermatologic (including rash, pruritus, and photosensitivity) and gastrointestinal side effects are the most common adverse reactions.

Resistance
Intrinsic resistance of the NS3 to simeprevir can be caused by the Q80K polymorphism. Patients should be screened for baseline mutation of this gene prior to initiation of therapy.

Boceprevir
Boceprevir is a protease inhibitor that binds to the NS3/4a of hepatitis C.

Clinical Uses
Boceprevir is currently licensed only for the treatment of genotype 1 in patients with compensated liver disease.[5] It is used in combination with PEG-interferon and ribavirin in treatment-naïve patients as well as patients who have not responded adequately to PEG-interferon and ribavirin. Boceprevir should not be used as monotherapy. Boceprevir is started 4 weeks after initiation of therapy with PEG-interferon and ribavirin, and combination therapy is continued for an additional 24 to 44 weeks based on virologic response.[5] Subjects with undetectable HCV RNA level at weeks 8 and 24 may be considered for a shorter duration of treatment (28 weeks in total). In patients with evidence of virologic failure (HCV RNA level is > 100 IU/mL at treatment week 12 or detectable at treatment week 24), treatment with all three drugs should be stopped. Because of its inferior efficacy, boceprevir is not considered a first-line therapy for hepatitis C.

Toxicity
Common side effects include fatigue, nausea, shivering, alopecia, and dysgeusia. Patients should be monitored for serious side effects such as anemia and neutropenia, which occasionally can be dose-limiting. Patients who develop anemia on combination therapy including boceprevir may be managed by reducing the ribavirin dose. Boceprevir is a strong inhibitor of cytochrome P450 3A4/5, so drug-drug interactions (including over-the-counter and oral contraceptives) must be considered.

Resistance
Resistance to boceprevir can occur on therapy. Because boceprevir and telaprevir are structurally similar, cross-resistant mutations may emerge, and patients should not be retreated with another protease inhibitor.

Telaprevir
Telaprevir was previously licensed for the treatment of chronic HCV but was withdrawn from the market in 2014.

Pegylated Interferon 2b and Ribavirin
Clinical Uses
Neither ribavirin nor interferon should be used as monotherapy for hepatitis C. In genotype 1, the combination of PEG-interferon and ribavirin may be considered in treatment-naïve subjects who cannot be given interferon-free regimens, although sustained virologic response rates are significantly inferior. Longer durations of treatment, up to 72 weeks, may improve virologic response.[5] PEG-interferon and ribavirin should be administered for 24 weeks for HCV genotypes 2 and 3 and for 48 weeks for HCV genotypes 4, 5, and 6.

Toxicity
Common side effects of interferon administration include influenza-like symptoms (fever, chills, headache, malaise), but these symptoms usually become less severe with repeated treatments. Major toxicities include bone marrow suppression, especially granulocytopenia and thrombocytopenia, which are generally reversible when therapy is discontinued. Neuropsychiatric disturbances may be manifested by depression, anxiety, somnolence, confusion, and behavioral changes. Other side effects include profound fatigue and anorexia, weight loss, hypothyroidism or hyperthyroidism, alopecia, and cardiotoxicity with arrhythmias and reversible cardiomyopathy. Some side effects (e.g., hypothyroidism) can present a year or longer after therapy has finished.

Systemic ribavirin is frequently associated with hemolytic anemia (in up to 60% in some series) and sometimes with electrolyte abnormalities, including hypocalcemia and hypomagnesemia. Arrhythmias, pruritus, rash, nausea, and myalgia have been reported, as have neurologic side effects including insomnia and irritability. Ribavirin may be gonadotoxic and teratogenic in humans.

Special Considerations

HIV/HCV coinfection can be treated concurrently, but treatment can be complicated by drug interactions and significant toxicities.[6] Ledipasvir/sofosbuvir is considered first line therapy. Ledipasvir can increase tenofovir levels, and HIV regimens without tenofovir should be considered. Ombitasvir/paritaprevir/ritonavir plus dasabuvir will have interactions with many antiretroviral drugs. This regimen can be used with most nucleoside inhibitors and raltegravir, but use of other protease inhibitors, especially ritonavir-boosted regimens, requires expert consultation.

The HIV antiviral didanosine (DDI [Chapter 388]) should not be used with ribavirin because DDI levels and its active metabolite are increased when administered with ribavirin and can cause hepatic failure, severe peripheral neuropathy, pancreatitis, and lactic acidosis. Zidovudine (or azidothymidine [AZT]) administered with ribavirin can cause severe neutropenic anemia, and the combination should not be used. If ribavirin is the preferred therapy, discontinuation of DDI and AZT should be considered prior to initiation of ribavirin.

ANTIVIRALS FOR HERPESVIRUS INFECTIONS

Acyclovir and Valacyclovir

Acyclovir, which is an acyclic analogue of the nucleoside guanosine, is converted to its active form through initial monophosphorylation by a virus-encoded thymidine kinase (TK). Although normal human cells possess TK, the affinity of acyclovir for viral TK is approximately 200 times greater than for human TK. The monophosphate then undergoes two additional host cell enzyme-mediated phosphorylations to acyclovir triphosphate (acycloguanosine triphosphate), which preferentially inhibits viral DNA polymerase. The higher concentrations of the activated form in infected cells and its affinity for viral polymerases result in low toxicity to normal host cells.

Valacyclovir is the L-valyl ester prodrug of acyclovir. Addition of the L-valyl ester fosters greater oral absorption, after which valacyclovir is converted to acyclovir; the prodrug provides three to five times greater bioavailability than oral acyclovir.

Clinical Uses

Acyclovir and valacyclovir (Tables 360-4 to 360-6) are used principally to treat infections caused by herpes simplex virus (HSV [Chapter 374]) and varicella-zoster virus (VZV [Chapter 375]). Depending on the country, acyclovir is available in a topical ointment and cream, oral capsules, and intravenous and ophthalmic formulations. Valacyclovir is available only as an oral capsule.

Oral acyclovir or valacyclovir decreases the duration of symptoms by approximately 50% and reduces the duration of viral shedding by about 90% in initial episodes of genital herpes. Two or 3 days of therapy appears to be sufficient for recurrent genital herpes. Chronic suppression is highly effective in reducing clinical and viral recurrences, and valacyclovir reduces the risk of

TABLE 360-4 ANTIVIRALS FOR HERPESVIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
HERPES SIMPLEX VIRUS			
Genital herpes			
First episode	Acyclovir	PO	400 mg tid or 200 mg 5 times/day for 7-10 days
	Famciclovir	PO	250 mg tid for 7-10 days
	Valacyclovir	PO	1 g bid for 7-10 days
Recurrent	Acyclovir	PO	800 mg tid for 2 days, or 400 mg tid or 200 mg 5 times/day for 5 days
	Famciclovir	PO	1000 mg bid for 2 doses
	Valacyclovir	PO	500 mg bid for 3 days or 1 g/day for 5 days
Suppression	Acyclovir	PO	400 mg bid or 200 mg tid
	Famciclovir	PO	250 mg bid
	Valacyclovir	PO	500 mg/day or 1 g/day (10 or more episodes/year)
Orolabial herpes	Penciclovir 1%	Topical	Apply cream every 2 hr while awake for 4 days
	Acyclovir 5%	Topical	Apply cream 5 times/day for 4 days
	Docosanol 10%	Topical	Apply cream 5 times/day until healing
	Valacyclovir	PO	2 g q12h × 2 doses
	Acyclovir	PO	400 mg 5 times/day for 5 days
	Famciclovir	PO	1500 mg single dose
Mucocutaneous disease	Acyclovir	IV	5 mg/kg/8 hr for 7-14 days
	Acyclovir	PO	400 mg 5 times/day for 7-14 days
	Valacyclovir	PO	500 mg or 1 g bid for 7-10 days
Encephalitis	Acyclovir	IV	10 mg/kg/8 hr for 10 days
Neonatal	Acyclovir	IV	10-20 mg/kg/8 hr for 14-21 days
Keratoconjunctivitis	Trifluridine	Topical	1 drop of 1% solution q2h up to 9 drops/day
	Vidarabine	Topical	½-inch ribbon of 3% ointment 5 times daily
Acyclovir-resistant HSV	Foscarnet	IV	40 mg/kg q8-12 h until healed.
CYTOMEGALOVIRUS			
CMV retinitis	Ganciclovir	IV	Induction: 5 mg/kg/12 hr for 14-21 days (maintenance: 5 mg/kg/day)
	Valganciclovir	PO	Induction: 900 mg bid for 21 days (maintenance: 900 mg/day)
	Cidofovir	IV	5 mg/kg once weekly × 2, then every other week (maintenance: 5 mg/kg q2wk)
	Foscarnet	IV	60 mg/kg/8 hr or 90 mg/kg q12h for 14-21 days (maintenance: 90-120 mg/kg daily)
	Fomivirsen	Intravitreal	330 μg q2wk × 2, then q4wk (maintenance: 330 μg every month)
HIV infection, CMV colitis or esophagitis	Ganciclovir	IV	5 mg/kg/12 hr for 14-28 days (until symptoms resolved)
Prophylaxis (transplantation)	Ganciclovir	IV	5 mg/kg/12 hr for 7-14 days, then 5 mg/kg IV once a day
	Valganciclovir	PO	900 mg daily
Prophylaxis (advanced HIV infection)	Ganciclovir	IV	5 mg/kg daily
VARICELLA-ZOSTER VIRUS			
Varicella	Acyclovir	PO	800 mg qid for 5 days
Varicella in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Herpes zoster in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Herpes zoster in normal hosts	Acyclovir	PO	800 mg 5 times daily for 7-10 days
	Valacyclovir	PO	1 g tid for 7 days
	Famciclovir	PO	500 mg tid for 7 days

TABLE 360-5 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENT

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	ADJUSTMENT FOR OBESITY
Acyclovir IV	Renal	CrCl < 50 mL/min	No adjustment	Dose by ideal body weight
Acyclovir PO	Renal	CrCl < 25 mL/min	No adjustment	Dose by ideal body weight
Valacyclovir	Renal	CrCl < 50 mL/min	No adjustment	Unknown
Famciclovir	Renal	CrCl < 60 mL/min	No adjustment	Unknown
Foscarnet	Renal	CrCl < 1.4 mL/min/kg	No adjustment	Unknown
Ganciclovir IV	Renal	CrCl < 70 mL/min	No adjustment	Unknown
Valganciclovir	Renal	CrCl < 60 mL/min	No adjustment	Unknown
Cidofovir	Renal	CrCl < 55 mL/min	No adjustment	Unknown

TABLE 360-6 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Cidofovir	Renal impairment, including renal failure; prehydrate and use probenecid Neutropenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Foscarnet	Nephrotoxicity; prehydrate Seizures related to minerals and electrolyte disturbances
Ganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Valganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia

transmission of genital HSV between heterosexual partners by 48%. For herpes labialis (cold sores), 1 day of therapy with oral valacyclovir improves time to healing and reduces pain, whereas acyclovir ointment has no consistent clinical benefit.

Parenteral acyclovir is indicated for the initial treatment of mucosal or cutaneous HSV infection in immunocompromised patients, neonatal HSV infections, and disseminated or organ-invasive infections in immunocompetent patients. A subsequent switch to oral valacyclovir is possible in some circumstances. High-dose parenteral acyclovir is the therapy of choice for treatment of HSV encephalitis.

Acyclovir is also effective treatment of VZV infections, although higher doses are needed than for mucosal HSV infections. In adults treated within 24 hours of the development of a varicella rash, acyclovir decreases the severity of disease and number of lesions, but oral valacyclovir may be more effective than oral acyclovir. Intravenous acyclovir is warranted for initial treatment of varicella and zoster in immunocompromised hosts. Both acyclovir chemoprophylaxis and valacyclovir chemoprophylaxis reduce the incidence of recurrent HSV in recipients of stem cell and solid organ transplants, but valacyclovir is superior for prevention of cytomegalovirus (CMV) disease.

Toxicity

Acyclovir and valacyclovir have excellent safety profiles and are generally well tolerated. Common side effects include nausea, vomiting, and headaches. Major adverse effects include renal dysfunction and central nervous system (CNS) toxicity. Dehydration and preexisting renal dysfunction predispose to the development of renal impairment. Neurologic side effects include tremor, myoclonus, confusion, lethargy, agitation, and hallucination. Renal dysfunction predisposes to the development of neurotoxicity. Neutropenia and other signs of bone marrow toxicity have also been reported rarely.

Antiviral Resistance

Despite widespread use of acyclovir, the development of HSV resistance in immunocompetent subjects is uncommon (prevalence < 1%). However, antiviral resistance is higher in immunocompromised subjects, including those with HIV infection (prevalence of 5%) or bone marrow transplants (prevalence of up to 30%). Drug-resistant refractory VZV infections can occur in highly immunocompromised patients. Intravenous foscarnet or cidofovir may be effective for infections caused by acyclovir-resistant viruses.

Penciclovir and Famciclovir

Penciclovir is an acyclic guanine analogue that unlike acyclovir is not an obligate chain terminator and may be incorporated into DNA. Penciclovir is phosphorylated by viral TK to penciclovir monophosphate, which is then converted to penciclovir triphosphate. Penciclovir demonstrates in vitro activity against VZV and HSV comparable to that of acyclovir. The bioavailability of penciclovir after oral administration is less than 2%. In contrast, famciclovir is an oral prodrug that is deacetylated and oxidized in the liver to form penciclovir; the bioavailability of penciclovir averages 77% after administration of famciclovir.

Clinical Uses

Penciclovir and famciclovir are used to treat HSV and VZV infections. Penciclovir is available as a topical cream and in some countries as an intravenous formulation. Famciclovir is available as a capsule.

Topical penciclovir, which is approved for the treatment of recurrent HSV labialis, reduces pain and lesions by about 1 day. Famciclovir is approved for the treatment of recurrent HSV labialis and genital infections and for herpes zoster, and its effectiveness is similar to valacyclovir or acyclovir. Famciclovir may also be used for suppressive therapy.

Toxicity

Topical penciclovir is well tolerated; the majority of adverse reactions are local irritation and mild erythema. Adverse effects of oral famciclovir include headache, dizziness, nausea, and diarrhea.

Antiviral Resistance

Penciclovir resistance in HSV has been uncommon in immunocompetent subjects but, like acyclovir resistance, more frequent in immunocompromised hosts (2.1%). Most acyclovir-resistant HSV isolates are cross-resistant to penciclovir.

Ganciclovir and Valganciclovir

Ganciclovir is an acyclic deoxyguanosine analogue with antiviral activity against multiple herpesviruses, including HSV, VZV, CMV (Chapter 376), Epstein-Barr virus (EBV [Chapter 377]), and human herpesvirus 8. It is much more active than acyclovir against CMV and EBV. The bioavailability of oral ganciclovir is less than 10%. Valganciclovir, the L-valyl prodrug of ganciclovir, increases the bioavailability of ganciclovir to approximately 60% after oral administration.

Clinical Uses

Ganciclovir is available as an oral capsule, a parenteral injection, and an ocular implant; valganciclovir is available only as a tablet. Ganciclovir and valganciclovir are effective for treatment of CMV retinitis, for which they are comparably active. In the absence of immune reconstitution, long-term suppression therapy is necessary. They are also used for life-threatening CMV diseases in patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised conditions and for prevention of CMV disease in transplant patients. For immunocompromised patients with organ-invasive CMV infections, intravenous ganciclovir provides clinical response rates of 70 to 90%, although response rates are lower for CMV pneumonitis after stem cell transplantation or CMV encephalitis in patients with AIDS. Oral valganciclovir provides long-term outcomes similar to those of intravenous ganciclovir for the treatment of CMV disease.

Long-term prophylaxis with ganciclovir or valganciclovir reduces the incidence of CMV disease after solid organ and stem cell transplantation,

but this therapy has substantial side effects, including bone marrow suppression. These drugs can also be used as preemptive therapy for patients who have CMV viremia or antigenemia. In the prevention of CMV disease, preemptive valganciclovir therapy may be equally effective to chronic valacyclovir prophylaxis.

Toxicity

The most common adverse effect with ganciclovir and valganciclovir is bone marrow suppression, particularly neutropenia and thrombocytopenia, which occur in up to 50% of patients given intravenous ganciclovir. Fever, edema, phlebitis, headache, neuropathy, disorientation, nausea, anorexia, rash, and myalgias have also been reported with ganciclovir therapy. Intravitreal ganciclovir implants may cause vitreous hemorrhage and retinal detachment.

Antiviral Resistance

Ganciclovir resistance secondary to mutations in CMV kinase and sometimes DNA polymerase is related to the length of ganciclovir exposure and the degree of immunosuppression. Resistance may be associated with progressive disease during continued ganciclovir use; foscarnet and cidofovir are alternative treatments.

Cidofovir

Cidofovir, which is an acyclic phosphonate derivative of cytosine, is phosphorylated to its active diphosphate form by host cellular enzymes. Cidofovir diphosphate competitively inhibits viral DNA polymerase and viral DNA synthesis. Despite a short serum half-life, the antiviral effects are protracted because of prolonged intracellular concentrations of the phosphorylated metabolite.

Clinical Uses

Cidofovir is commercially available as an intravenous infusion, and investigational formulations have included topical gel and intravitreal and intralesional injections. Intravenous cidofovir is licensed for the treatment of cytomegalovirus retinitis. Because of its toxicities, it is generally reserved for when ganciclovir or foscarnet therapy is failing. Limited data suggest that intravenous cidofovir may be effective in other CMV infections (pneumonitis, gastroenteritis), acyclovir- or foscarnet-resistant HSV infections, certain forms of human papillomavirus disease, invasive adenoviral infections in transplant recipients, and possibly BK virus infection in renal transplant patients. In addition, in vivo and animal data suggest efficacy of cidofovir against smallpox, vaccinia, and monkeypox infections.

Toxicity

Dose-related nephrotoxicity, characterized by increased serum creatinine, proteinuria, and tubular dysfunction, is the main side effect of intravenous cidofovir. Adequate hydration and concomitant oral probenecid reduce the risk. Other common side effects include diarrhea, asthenia, nausea, vomiting, neutropenia, fever, and rash. Iritis, intraocular pressure changes, loss of visual acuity, and uveitis have been reported with intravenous cidofovir. Intravitreal cidofovir is effective but locally toxic.

Antiviral Resistance

Sustained exposure to cidofovir does not easily induce resistance, although resistance has infrequently been described in HSV and CMV.

Foscarnet

Foscarnet is a pyrophosphate analogue that acts as a noncompetitive inhibitor of many viral RNA and DNA polymerases. When a nucleotide is incorporated into a DNA or RNA strand by a polymerase, pyrophosphate is released. Foscarnet directly inhibits viral polymerases without phosphorylation, so TK-deficient acyclovir-resistant HSV and VZV are susceptible to this agent.

Clinical Uses

Foscarnet is as effective as ganciclovir for the treatment of CMV retinitis in patients with AIDS, and combination therapy with ganciclovir may be superior to monotherapy with either agent for recalcitrant retinitis. For extraretinal CMV disease, foscarnet has demonstrated efficacy similar to that of ganciclovir. The choice of agent may be dictated by the side-effect profile. Foscarnet is also effective for the treatment of acyclovir-resistant HSV and VZV infections.

Toxicity

Nephrotoxicity with azotemia and proteinuria is dose limiting and occurs in more than a third of patients. A slow infusion rate and saline hydration reduce the risk. Other common side effects include anemia (30 to 50% of patients), granulocytopenia, diarrhea, nausea, vomiting, fever, seizures, paresthesias, headache, and genital ulcers. Marked electrolyte disturbances may develop, including hypophosphatemia, hypocalcemia, hypokalemia, and hypomagnesemia. Foscarnet can prolong the QT interval and be associated with cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes.

Antiviral Resistance

The development of CMV resistance to foscarnet as a result of mutations in viral DNA polymerase is uncommon except after prolonged administration. In AIDS patients with retinitis, foscarnet resistance is detectable in 13% of patients at 6 months and in 37% at 12 months.

Fomivirsen

Fomivirsen, which is an antisense oligonucleotide that inhibits CMV replication, is currently available as an intravitreal injection that is effective for both newly diagnosed CMV retinitis and CMV retinitis failing usual therapies, although direct comparisons with other agents are lacking. Intravitreal administration of fomivirsen may cause increased intraocular pressure, iritis, vitreitis, and cataracts in 10 to 20% of patients. Topical corticosteroids may be useful for treating inflammatory changes.

Docosanol

Docosanol, which is a 22-carbon saturated fatty alcohol that inhibits intracellular penetration of lipid-enveloped viruses, is approved as a cream for the treatment of herpes labialis. Frequent topical applications have shown reductions in time to cessation of pain and healing, but direct comparison to other agents is lacking. Local reaction, rash, and pruritus are common side effects.

ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

Currently approved antivirals for the treatment of influenza include two neuraminidase inhibitors (oseltamivir and zanamivir) and two adamantanes (amantadine and rimantadine) (Tables 360-7 and 360-8). The choice of treatment for influenza should be dictated by circulating strains, antiviral resistance within those strains, and side-effect profiles.

Oseltamivir, Zanamivir, and Peramivir (Neuraminidase Inhibitors)

Oseltamivir, zanamivir, and peramivir are sialic acid analogues that inhibit influenza virus by competitively interacting with the neuraminidases of influenza A and B viruses. Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin. By this mechanism, the drugs inhibit the release of virus from infected cells, thereby preventing viral aggregates and spread within the respiratory tract.

Oseltamivir is administered orally as the phosphate prodrug, which is rapidly absorbed and hydrolyzed to the active form oseltamivir carboxylate. Bioavailability exceeds 75%. Conversely, the oral bioavailability of zanamivir is poor, so it is delivered as an orally inhaled powder. Peramivir is available only as a parenterally-infused solution.

Clinical Uses

Oseltamivir and zanamivir are effective for the treatment and prophylaxis of acute influenza A and B infections. Early treatment in adults decreases the duration and severity of illness and reduces lower respiratory tract complications, antibiotic use, and, with oseltamivir, hospitalizations.[7,8] In low-risk ambulatory subjects, oseltamivir alleviates symptoms faster than placebo, and it also decreases the risk for lower respiratory complications. In cohort studies of hospitalized subjects, treatment with oseltamivir has been associated with a significant reduction in death.[9] Zanamivir is also effective in alleviating symptoms and decreasing the risk for lower respiratory complications. Both zanamivir and oseltamivir are also highly effective for the

TABLE 360-7 ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

VIRUS	DRUG	ROUTE	USUAL ADULT TREATMENT DOSAGE
Influenza A and B virus	Oseltamivir	PO	75 mg bid for 5 days
	Peramivir	IV	600 mg single IV dose
	Zanamivir	Inhalation	10 mg bid by inhaler for 5 days
Influenza A virus	Amantadine	PO	100 mg bid or 200 mg daily for 5 days
	Rimantadine	PO	100 mg bid for 5 days

TABLE 360-8 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENTS

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	SPECIAL ADJUSTMENT FOR THE ELDERLY
Amantadine	Renal	CrCl < 50 mL/min	No adjustment	>65 years: 100 mg daily
Rimantadine	Hepatic and renal	CrCl < 10 mL/min/1.72 m^2	100 mg daily	100 mg daily
Oseltamivir	Renal	CrCl < 30 mL/min/1.72 m^2	No adjustment	
Peramivir	Renal	CrCl < 50 mL/min	No adjustment	
Zanamivir	Renal	No adjustment	No adjustment	

prevention of influenza. Peramivir is licensed as a single-dose IV infusion for uncomplicated influenza. However, as a daily infusion in patients hospitalized with influenza, its efficacy is similar to oseltamivir.[A1]

Toxicity

The most common side effects with oseltamivir are nausea and vomiting. They also may be associated with headache, rash, and possibly abnormal aminotransferase levels. Zanamivir is generally well tolerated, but severe bronchospasm has been reported primarily in patients with underlying airway disease. The most common side effects of peramivir are nausea, diarrhea, and mild neutropenia.

Antiviral Resistance

Oseltamivir resistance can be can be preexisting (widespread or local) or can emerge during therapy. In the immunocompromised host and possibly in individuals with H5N1 or H1N1, the development of resistance is associated with treatment failure. Zanamivir resistance is rare, and zanamivir retains clinical effectiveness against the most common oseltamivir-resistant variants.

Amantadine and Rimantadine (Adamantanes)

Amantadine and rimantadine are symmetrical tricyclic amines with activity against many influenza A viruses (Chapter 364). By inhibiting the ion channel function of the M2 protein of influenza A, they interfere with uncoating of the virus and release of the viral genome.

Clinical Uses

Amantadine and rimantadine decrease the length and severity of uncomplicated influenza A virus infection by susceptible strains if they are initiated within the first 2 days after the onset of symptoms, but it is uncertain whether they reduce the risk for complications. Both drugs are formulated for oral administration, and amantadine also has a pediatric syrup formulation. In recent years, marked increases in antiviral resistance in community isolates have limited the utility of these drugs.

When adamantine-susceptible viruses are circulating, both rimantadine and amantadine are effective when they are used for prophylaxis (overall 66% average for rimantadine and 74% for amantadine). Despite prophylaxis, subclinical infections may still develop and elicit immune responses that are protective against antigenically related viruses.

Toxicity

Amantadine causes CNS side effects in 10 to 30% of healthy young adults who take the standard adult dose of 200 mg/day; the frequency is significantly lower with rimantadine. Neuropsychiatric side effects include anxiety, nervousness, insomnia, and, particularly in the elderly or those with renal insufficiency, hallucinations, confusion, disorientation, and psychosis or coma. Amantadine (or less often rimantadine) is associated with an increased risk for seizures. Both drugs cause gastrointestinal side effects. Orthostatic hypotension occurs in 1 to 5%. Anticholinergic side effects, including dry mouth, occur in amantadine recipients.

Antiviral Resistance

Single point mutations in M2 confer high-level resistance to these drugs and make them ineffective. Such resistant variants emerge commonly during treatment and are transmissible. Currently circulating H1N1 and H3N2 viruses are highly resistant to adamantanes.

OTHER ANTIVIRALS

Ribavirin

Ribavirin is a purine nucleoside with antiviral activity against some DNA viruses and many RNA viruses, including influenza A and B, parainfluenza, coronaviruses including Middle East respiratory syndrome (Chapter 366), measles (Chapter 367), respiratory syncytial virus (RSV [Chapter 362]), retroviruses (Chapter 378), arenaviruses such as Lassa virus (Chapter 381), and some hantaviruses (Chapter 381).

Clinical Uses

Aerosol administration of ribavirin has been used to treat RSV bronchiolitis and pneumonia in children and to treat influenza A and B infections. Limited benefit has been seen with oral ribavirin in uncomplicated influenza. Aerosol ribavirin combined with intravenous immune globulin, particularly with the anti-RSV monoclonal antibody palivizumab, appears to reduce the mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients.

Systemic ribavirin reduces the mortality associated with Lassa fever and Asian (Korean) hemorrhagic fever with renal syndrome (Chapter 381), although not mortality in patients with hantavirus-associated cardiopulmonary syndrome. It appears to have activity in Congo-Crimean hemorrhagic fever and in Nipah virus infections. Ribavirin is often recommended as treatment of hemorrhagic fevers of unknown etiology or secondary to arenaviruses or bunyaviruses in the event these viruses are used as biological weapons.

Given the breadth of ribavirin's activity against many viruses, it is often used for emerging infectious diseases (e.g., severe acute respiratory syndrome [SARS] and Middle East respiratory syndrome). However, the concentrations needed to show efficacy in cell cultures and animal models may be significantly higher than can be obtained in humans. Caution is therefore urged when ribavirin is suggested for treating these diseases.

Imiquimod

Imiquimod and the related compound resiquimod are topical immune response modifiers that lack direct antiviral effects. Instead, these agents induce activation of immune cells (monocytes, macrophages, natural killer cells) to produce antiviral cytokines, particularly interferon-α and tumor necrosis factor-α.

Topical imiquimod cream is approved for the treatment of condyloma acuminatum (Chapter 373). In immunocompetent patients, imiquimod leads to complete clearance of warts in 37 to 52% of patients. It is administered as a topical cream three times weekly for a maximum of 16 weeks and is washed off 6 to 10 hours after application.

Side effects are primarily local and include erythema, irritation, tenderness, and (less often) erosion. The side effects usually resolve with cessation of the drug.

REVIEW QUESTIONS

1. A 47-year-old man who has sex with men recently was diagnosed with HIV (HIV RNA = 22,400 copies and CD4 = 70 cells/mL) and hepatitis B (hepatitis B surface antigen [HBsAg] positive). He was started on tenofovir, emtricitabine, and efavirenz with a good response (HIV viral load < 50 and CD4 = 220). Two months later, he now has developed several days of severe nausea and vomiting and is unable to keep his medications down. The patient recalls your counseling about the risks of developing HIV resistance with intermittent doses and stops all his medications. The nausea and vomiting resolve over the subsequent few days.

He is between jobs and has travel planned. Since he now feels well with the good control of his HIV, he decides to remain on a drug holiday. Seven weeks later he develops malaise and general weakness. Biochemical testing of his blood now reveals the following: total bilirubin, 7.7 mg/dL; alanine aminotransferase (ALT), 2157 U/L; aspartate aminotransferase (AST), 2693 U/L; and alkaline phosphatase (Alk-P), 137 U/L. Which of the following is most likely to be responsible for his current clinical condition?

A. HIV
B. Hepatitis B
C. Hepatitis D
D. Syphilis
E. Herbal medications

Answer: B The patient's HIV regimen of tenofovir, emtricitabine, and efavirenz is also an effective treatment for hepatitis B. The withdrawal of medications during the drug holiday will lead to active HIV replication. Although moderate increases in AST and ALT can occur, fulminant hepatitis as described in this case is unusual. Severe acute exacerbations of hepatitis, including fatalities, have been reported in hepatitis B virus (HBV)-infected patients who stop anti-hepatitis B therapy. Hepatitis D, syphilis, or herbal medication can all cause an acute severe hepatitis but would be much less common than reactivated hepatitis B.

2. A 48-year-old man has HIV (CD4 560 and RNA 14,000) and hepatitis B (ALT 5 times the upper limit of normal and HBV DNA 35,000 IU/mL). Treatment for both HIV and HBV is recommended. However, the patient is concerned about drug toxicities. Because of his high CD4 count and relatively low HIV viral load, he does not want to begin treatment for HIV but is willing to be treated for HBV. Which of the following would be the most appropriate treatment?

A. Tenofovir
B. Entecavir
C. Ribavirin
D. PEG-interferon alfa-2a
E. Emtricitabine

Answer: D With the elevated ALT and HBV DNA, treatment is needed for this patient's hepatitis B. Treatment may be initiated with any approved antiviral medications, but tenofovir, entecavir, or PEG-interferon alfa-2a are the generally preferred agents. Emtricitabine, lamivudine, and tenofovir have activity against both HIV and HBV, and monotherapy (for HBV) with these agents would likely lead to HIV resistance. Therefore, the most appropriate treatment is PEG-interferon. Ribavirin may be used with interferon for the treatment of hepatitis C, but it has no role in the treatment of hepatitis B.

3. A 44-year-old heterosexual man with chronic hepatitis C and asthma (on inhaled corticosteroids) has been treated with telaprevir, interferon, and ribavirin for 7 weeks with good virologic response (hepatitis C virus [HCV] RNA level is > 1000 IU/mL at week 4). He routinely engages in high-risk sexual activity and now presents with 3 days of fever and fatigue as well as 1 day of pain with swallowing. On examination, he is afebrile, he has no cutaneous rashes, but examination of his mouth shows patchy desquamation of his tongue. Which of the following is the most appropriate recommendation?

A. This could be acute HIV, so an HIV viral load should be sent.
B. This could be a severe drug reaction, so the telaprevir, interferon, and ribavirin should be stopped.
C. This could be severe leukocytoclastic vasculitis from hepatitis C, so the patient should receive intravenous solumedrol.
D. This could be mucocutaneous candidiasis, so the patient should receive fluconazole.
E. This could be secondary syphilis, so the patient should receive benzathine penicillin.

Answer: B The patient is at risk for HIV and secondary syphilis, and both can both be associated with pharyngitis, myalgia, and a mucocutaneous rash. However, isolated oral involvement with frank desquamation would be very unusual for these diseases. Inhaled corticosteroids can cause oropharyngeal candidiasis, which would present with pharyngitis, dysphagia, and white mucosal plaques on examination, but desquamation of the mucosal membrane would be unusual. Hepatitis C is associated with leukocytoclastic vasculitis, usually with cutaneous findings. Telaprevir has been associated with both mild and severe dermatologic manifestations. Mild rashes can be treated with withdrawal of telaprevir. Desquamation of the tongue would suggest a more severe dermatologic reaction such as the Stevens-Johnson syndrome, which can present with mucosal desquamation before any cutaneous eruption. In this case, stopping telaprevir, interferon, and ribavirin would be the appropriate recommendation.

4. A 61-year-old man with severe chronic obstructive pulmonary disease (COPD) presents with a 36-hour history of fever, cough, myalgia, and mild shortness of breath. Rapid antigen assay from a throat swab is positive for influenza B. His current medications include tiotropium, prednisone 10 mg daily, and albuterol as needed. When advised of the diagnosis of influenza B, he asks for the least expensive medication because he recently lost his health insurance. Which of the following is the most appropriate treatment?

A. Amantadine
B. Rimantadine
C. Oseltamivir
D. Zanamivir
E. No treatment is required

Answer: C Oseltamivir, which is active against influenza B and is well tolerated, is the appropriate treatment. The patient has influenza B. Because of his history of severe COPD, his influenza B should be treated. Amantadine and rimantadine are both available as generic medications, but all strains of influenza B are resistant to amantadine and rimantadine. Inhaled zanamivir powder can cause bronchospasm in patients with underlying asthma or COPD and would not be an appropriate treatment in this patient.

361 THE COMMON COLD

RONALD B. TURNER

DEFINITION

The common cold is an upper respiratory syndrome of rhinorrhea and nasal obstruction, frequently accompanied by sore throat, sneezing, and cough. This viral syndrome is among the most common illnesses of humankind.

The Pathogens

The rhinoviruses cause at least half of all common cold illnesses. Rhinoviruses, which are RNA viruses that infect the respiratory epithelium, have long been known as common cold viruses, but they also are important causes of exacerbations of chronic bronchitis and asthma. More recent data suggest that rhinoviruses may also be associated with bronchiolitis in young children.

The coronaviruses (Chapter 366), parainfluenza viruses (Chapter 363), respiratory syncytial virus (RSV [Chapter 362]), metapneumoviruses[1], adenoviruses (Chapter 365), and influenza viruses (Chapter 364) may also cause common cold illnesses (Table 361-1). Bocavirus has recently been associated with the common cold, but these viruses are also frequently isolated from healthy control subjects, so their role as pathogens is uncertain. Bacterial pathogens such as *Bordetella pertussis* (Chapter 313) and group A streptococcus (Chapter 290) are occasionally associated with rhinorrhea, but these illnesses are generally readily distinguished from the common cold.

EPIDEMIOLOGY

The incidence of common colds decreases with age, from at least six episodes per year in young children to approximately two episodes per year in adults. The incidence of illness is higher in adults who have occupational or household exposure to children and in children who are cared for in childcare centers. Common cold illnesses occur year-round in temperate climates but have a substantially increased incidence between the early autumn and late spring. This common cold "season" consists of sequential outbreaks caused by the different respiratory viruses. In tropical climates, colds occur year-round without defined seasonality.

TABLE 361-1 VIRUSES ASSOCIATED WITH THE COMMON COLD

VIRUS GROUP	ANTIGENIC TYPES	PERCENTAGE OF CASES
Rhinoviruses	>100	40-50
Coronaviruses	5	10-15
Parainfluenza virus	5	5
Respiratory syncytial virus	2	5
Influenza virus	3	25-30
Adenovirus	47	5-10
Metapneumovirus	2	5
Other viruses: enteroviruses, bocavirus		

From Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases.* 7th ed. Philadelphia: Churchill Livingstone; 2010:810.

PATHOBIOLOGY

Respiratory pathogens are spread from person to person by direct contact with either infected individuals or contaminated objects in the environment, by large-particle aerosols, or by small-particle aerosols. The rhinoviruses may be spread by direct contact, but recent data suggest a role for other mechanisms.[2] RSV (Chapter 362) may be spread by either direct contact or large-particle aerosols, and influenza (Chapter 364) may be spread by small-particle aerosols.

Regardless of the route of spread, the common cold syndrome is initiated by infection of the nasal epithelium. Influenza and adenovirus produce obvious damage to the respiratory epithelium. Rhinovirus and RSV, in contrast, have little or no detectable impact on the epithelium. Regardless of the histopathology, all these viruses stimulate a nonspecific host inflammatory response that appears to be responsible for many of the symptoms associated with the common cold.

The nasal obstruction of the common cold appears to result primarily from increased nasal blood flow and pooling of blood in the capacitance vessels of the nose. The increase in nasal secretion associated with the common cold may also contribute to the nasal obstruction. Rhinorrhea is primarily a result of increased vascular permeability, with leakage of serum into the nasal secretions. Increased mucus production contributes to the secretions during the later stages of the illness.

Multiple factors may play a role in the pathogenesis of cough. Cough may be related to infection of the lower airway, irritation of upper airway receptors with neurologically mediated airway reactivity, or postnasal drip with pharyngeal irritation.

The risk of infection after exposure to the respiratory viruses is primarily dependent on the presence of specific neutralizing antibodies. Antibody responses to the rhinoviruses, adenoviruses, and influenza viruses are protective against subsequent infection. The frequency of infection with these viruses is a result of the large number of distinct serotypes of rhinovirus and adenovirus and the ability of the influenza viruses to behave as though there are multiple virus serotypes by virtue of the rapid mutation of the antigens presented on the surface of the virus. The parainfluenza viruses, RSV, and metapneumoviruses do not produce protective immunity, so reinfection is common, although preexisting antibody moderates the severity of illness.

Mannose-binding lectin deficiency has been associated with an increased incidence of common colds in young children. Protection by this innate response may become less important as children experience a variety of infections and develop specific immunity. Polymorphisms that enhance inflammatory cytokine responses may be associated with more severe respiratory illness.

CLINICAL MANIFESTATIONS

The incubation of common cold illness is generally short, ranging from 2 to 8 days, although the adenoviruses may have an incubation of as long as 13 days. A sore or scratchy throat is frequently reported as the first manifestation. Sneezing is also a common early symptom. Nasal obstruction and rhinorrhea develop rapidly and, by day 2 or 3 after the onset of illness, are the most

bothersome symptoms. Cough generally develops later in the illness and frequently is the most bothersome symptom as the cold resolves. Common cold illnesses generally persist for about 1 week, although about 25% may persist for as long as 2 weeks.

Physical findings are restricted to the upper respiratory tract. Increased nasal secretion may be obvious to the examiner. A change in the color or consistency of nasal secretions is common during the course of the illness and is not indicative of sinusitis or bacterial superinfection.

DIAGNOSIS

The differential diagnosis of the common cold includes noninfectious disorders as well as other upper respiratory tract infections. Allergic rhinitis (Chapter 251) has a symptom complex similar to that of the common cold, although the presence of nasal or conjunctival itching suggests allergic disease. Most patients can reliably differentiate these illnesses.

Sinus involvement is present in uncomplicated cold illnesses, and superimposed bacterial sinusitis (Chapter 426) is difficult to differentiate from an uncomplicated cold.[3] Rhinorrhea that persists without improvement for more than 10 days may suggest the presence of bacterial sinusitis that will respond to antibiotics.

Routine laboratory studies are not helpful for the diagnosis or management of the common cold. Although the viral pathogens associated with the common cold may be detected by culture, antigen detection, polymerase chain reaction, or serologic methods, these studies are of little value unless treatment with an antiviral agent is contemplated.

TREATMENT

Rx

Specific antiviral therapy is generally not useful for the treatment of common cold illnesses. The neuraminidase inhibitors oseltamivir and zanamivir (Chapter 360) have a modest effect on influenza virus infections, but the difficulty of distinguishing influenza from other common cold pathogens and the need to start treatment early in the illness for maximum benefit are practical limitations to the use of these agents for mild upper respiratory infections. Antibacterial therapy is of no benefit in the treatment of the common cold.

Management of the common cold relies on symptomatic remedies. For example, a combination of acetaminophen, chlorpheniramine, and phenylephrine (an adrenergic agonist) is safe and effective in treating the symptoms of the common cold.[A1] However, it is preferable to use specific therapies targeted just to an individual adult's specific symptoms of nasal obstruction, rhinorrhea, or sore throat so as to avoid the side effects of unnecessary medications.

Nasal Congestion

Both topical and oral adrenergic agents (Table 361-2) are effective nasal decongestants. Although direct comparison has not been performed in the common cold, it is generally accepted that topical over-the-counter agents such as intranasal xylometazoline are more effective than oral drugs for nasal congestion. Prolonged use of the topical adrenergic agents should be avoided to prevent development of an apparent rebound effect when the drug is discontinued. Systemic absorption of oxymetazoline and xylometazoline has rarely been associated with bradycardia, hypotension, and coma. The systemic side effects of the oral adrenergic agents are central nervous system stimulation, hypertension, and palpitations. The antihistamines have no effect on nasal congestion.

TABLE 361-2 TREATMENTS FOR THE COMMON COLD

DRUG	DOSE AND DURATION	SIDE EFFECTS
Topical adrenergic agents: oxymetazoline	2-3 sprays of 0.05% solution every 12 hr as needed for up to 3 days	Rebound nasal congestion with prolonged use Nasal stinging or burning
Oral adrenergic agents: pseudoephedrine	60 mg every 4-6 hr up to 240 mg/day as needed for nasal congestion	Insomnia, agitation
Antihistamines: chlorpheniramine	4 mg orally every 4-6 hr up to 24 mg/day as needed for rhinorrhea or sneezing	Sedation
Anticholinergics: ipratropium bromide	2 sprays per nostril of 0.06% solution every 6-8 hr as needed for rhinorrhea	Nasal dryness

Rhinorrhea

The treatment of rhinorrhea is primarily by blockade of cholinergic stimulation of glandular secretion. Intranasal ipratropium bromide reduces rhinorrhea in colds by 22 to 31% compared with placebo.[A1] The most common side effects of intranasal ipratropium are nasal irritation and bleeding.

The first-generation (sedating) antihistamines reduce rhinorrhea by approximately 25% compared with placebo.[A1] These observations, the absence of histamine in the secretions of most subjects with colds, and the similarity of the response to ipratropium and first-generation antihistamines suggest that any effect of antihistamines on rhinorrhea is related to their anticholinergic rather than their antihistaminic properties. The major side effects associated with the use of the antihistamines are sedation and drying of the eyes, mouth, and nose.

Cough

Cough during colds is produced by several different mechanisms, and treatment should be directed at the most likely underlying cause (Chapters 83 and 429). If cough is caused by nasal obstruction or postnasal drip, it may respond to treatment with an antihistamine or antihistamine-decongestant combination.[A1] If a more persistent cough is the result of virus-induced reactive airway disease or viral infection of the lower airways, patients may benefit from bronchodilator therapy (Chapter 87). Cough that persists after the resolution of other cold symptoms or that persists in association with unremitting rhinorrhea may be due to sinusitis and may respond to antibiotic therapy (Chapter 426). Nonspecific cough suppression with codeine or dextromethorphan hydrobromide has not been demonstrated to be efficacious, and expectorants such as guaifenesin are not effective antitussive agents.

Pain-Related symptoms

Nonsteroidal anti-inflammatory agents are effective for sore throat, headache, ear pain, and myalgia but do not relieve nasal congestion, rhinorrhea, or cough.[A1]

Other Remedies

Zinc is an inhibitor of rhinovirus 3C protease, which is essential for virus replication. However, zinc does not have a significant antiviral effect at doses that can be used for treatment and has shown either no or relatively modest effects in reducing the severity of the common cold.[A1] This uncertain benefit must also be viewed in light of zinc's side effects; oral zinc lozenges may be associated with sore mouth and occasional nausea, whereas intranasal zinc may cause nasal irritation. Echinacea has not been shown to be beneficial in reducing symptoms of the common cold in several studies.[A1] Given the variation in echinacea products, it is possible that echinacea preparations with different phytochemical profiles might be helpful. The accumulating evidence, however, suggests that it is prudent to assume that echinacea has no beneficial effect until positive evidence of a treatment effect is produced. Antibiotics are not useful, even in patients with a purulent nasal discharge, and may cause adverse effects.[A1]

PREVENTION

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold. Immunization or chemoprophylaxis against influenza (Chapter 364) may be useful for prevention of colds caused by this pathogen, but influenza is responsible for only a small proportion of all colds. Vitamin C, even in megadoses, is of no benefit. Other nonpharmacologic interventions touted as effective prophylaxis for the common cold but of unproven benefit include zinc, vitamin E, echinacea, ginseng, exercise, and handwashing. Handwashing and exercise have undeniable benefits for health in general and can be recommended despite the paucity of evidence specific to common cold prevention. The other interventions, although probably safe, have no demonstrable benefit and simply contribute to the unnecessary health care expenditures related to the common cold.

PROGNOSIS

The common cold generally has little medical significance. However, these illnesses are frequently complicated by otitis media (Chapter 426) or sinusitis (Chapter 426) that may be a direct result of the viral infection or may be due to bacterial superinfection. Exacerbations of asthma (Chapter 87) and chronic bronchitis (Chapter 88) are also important complications of the common cold.

RESPIRATORY SYNCYTIAL VIRUS

EDWARD E. WALSH

DEFINITION

Respiratory syncytial virus (RSV), which causes yearly winter outbreaks in temperate climates, is the most important cause of bronchiolitis and pneumonia in young infants, a common cause of illness in older children and young adults, and can be severe in elderly persons, adults with underlying cardiopulmonary disease, and the severely immunocompromised.[1]

The Pathogen

RSV is a single-stranded RNA-enveloped virus of the family Paramyxoviridae, genus *Pneumovirus*; it is related to human metapneumovirus. Two major transmembrane glycoproteins (G, attachment protein; F, fusion protein) carry neutralizing epitopes, and two nonstructural proteins (NS1 and NS2) block the antiviral activity of type I interferons, whereas a secreted form of G bearing a CX3C chemokine motif may modulate immune responses. Two major virus groups (A and B), each with multiple genotypes, are distinguishable.

EPIDEMIOLOGY

In the United States, epidemics begin in the south in late fall, move steadily north, and peak in February and March in colder climates.[2] In tropical areas, RSV may occur throughout the year, with peaks during the rainy season. RSV annually causes approximately 100,000 hospitalizations and accounts for 60% of bronchiolitis and 25% of pneumonia cases in infants. Mortality is rare in the United States (<400 deaths annually), but deaths are substantially greater in underdeveloped countries.[3] About half of infants become infected in their first winter and all by age 2. RSV is transmitted principally by direct contact with large-particle fomites of respiratory secretions rather than by small-particle aerosolization.

Between 1 and 3% of primary infections result in hospitalization, but lower socioeconomic status, crowding, underlying prematurity, congenital cardiac abnormalities, bronchopulmonary dysplasia, and immunosuppression are each associated with increased risk for serious disease. Severe disease is also associated with specific polymorphisms in the promoter regions of cytokine genes. Hospitalization is most frequent between the ages of 1 and 6 months, peaking at 2 months of age with a rate of 25.9 per 1000 children.[4] However, the majority of hospitalized infants are normal healthy infants without identifiable risk factors. The overall burden of RSV in infants 0 to 6 months of age is 132 office visits, 55 emergency room visits, and 17 hospitalizations per 1000. Reinfection occurs frequently throughout life, although subsequent illness is less severe and hospitalization infrequent, except for persons with underlying cardiac or pulmonary conditions.

Though often not considered in adults, RSV infection is common and may be severe in the elderly.[5,6] In a British study, RSV accounted for 17% of medically attended outpatient respiratory illnesses in persons older than 45 years, and a recent study from The Netherlands calculated that RSV-associated mortality among persons age 65 and older is about 90% as high as influenza A and greater than double that of influenza B.[7] In two recent U.S. studies, RSV infection was implicated in 6 to 10% of hospitalizations for acute pulmonary symptoms in the winter among community-dwelling elderly persons, numbers that are similar to those for influenza.[8,9]

PATHOBIOLOGY

Virus most commonly enters through the nose or eye and then spreads from the upper to the lower respiratory tract. Pathologic findings include a lymphocytic peribronchiolar infiltration with edema, obstruction, and necrosis. Bronchiolitis with multiple areas of atelectasis, and pneumonia with interstitial infiltration of mononuclear cells, as well as alveoli filled by edema and necrosis, develop in infected patients.

CLINICAL MANIFESTATIONS

Infants experience upper respiratory symptoms of conjunctival injection, mucopurulent nasal discharge, cough, and low-grade fever after an incubation period of 2 to 8 days. Otitis media (Chapter 426) is often associated with secondary bacterial infection. After several days, lower respiratory tract symptoms appear in 25 to 50% of infants, with cough, wheezing, tachypnea, and use of accessory muscles as the disease progresses. Expiratory wheezes, rhonchi, and fine rales are the most common findings on lung examination. Sudden apnea may develop in the youngest infants. Hyperinflation and diffuse interstitial pneumonitis are the most frequent radiographic findings. High-titer virus shedding lasts 7 to 10 days, although immunocompromised infants may excrete virus for a month or longer, even when asymptomatic. Coinfection with other respiratory viruses occurs in up to 30% of patients, but it usually is neither clinically discernible nor definitively associated with more severe illness.

Adults with RSV typically begin with upper respiratory symptoms, but many patients have lower respiratory symptoms, especially wheezing. Low-titer virus shedding often persists for 10 days or longer. In elderly persons, RSV attack rates are 3 to 5% annually; wheezing is more common than with influenza (Chapter 364), whereas fever is less common. In frail elderly persons or in patients with underlying chronic obstructive pulmonary disease or heart failure, severe disease can develop. Attack rates in nosocomial nursing home outbreaks average 10 to 15%, with crackles and wheezes evident in a third of patients and radiographically confirmed pneumonia in approximately 10%. The precise incidence of bacterial superinfection in hospitalized adults is unknown but can range from 15 to 40%, similar to what is seen with influenza.

RSV infection has been documented in up to 10% of bone marrow transplant recipients (Chapter 178), patients with acute leukemia (Chapter 183), and heart/lung transplant recipients (Chapters 82 and 101) during the winter months.[10] Upper respiratory symptoms lead to lower respiratory tract symptoms in about 30% of patients.

DIAGNOSIS

In infants, a presumptive diagnosis is suggested by typical symptoms during the epidemic season, but the diagnosis often is not considered in adults. Diagnosis can be made by reverse transcription–polymerase chain reaction (RT-PCR), which is the test of choice and has high sensitivity and specificity. Viral culture, which can take up to 10 days, has a sensitivity of only about 75%.

In adults, viral culture has poor sensitivity (30%), whereas RT-PCR detects infection in three quarters of culture-negative cases that are seropositive, using acute and convalescent serum. Owing to very poor sensitivity, antigen detection by immunofluorescence and enzyme immunoassay are not useful in adults, even if immunocompromised. In immunocompromised patients, chest radiographs demonstrate diffuse interstitial and alveolar infiltrates. A useful clinical clue to the presence of RSV is the frequent presence of radiographically proven sinusitis. Upper respiratory tract symptoms distinguish this illness from cytomegalovirus pneumonia (Chapter 376).

TREATMENT

Rx

Therapy for most infants is symptomatic and generally is limited to hydration and supplemental oxygen.[11] Bronchodilators have not been demonstrated to be effective, although they are occasionally used. Similarly,

glucocorticosteroids have not been shown to have benefit in most studies. Inhaled ribavirin (20-mg/mL solution administered by aerosol for 6 hours three times daily for 3 to 5 days, or 60 mg/mL for 2 hours three times daily) may be beneficial for infants at high risk for serious disease and those who are severely ill, although clinical trails have not demonstrated benefit for most infants.

No placebo-controlled studies of the effect of inhaled ribavirin have been conducted in adults with severe RSV disease, but the evidence suggests benefit in immunocompromised adults with RSV pneumonia (2 g at 60 mg/mL for 5 to 10 days), especially if begun before development of lower respiratory symptoms.[12]

Some studies using antibody therapy (the monoclonal antibody palivizumab, 15 mg/kg once, or polyclonal immunoglobulin) combined with inhaled ribavirin suggest benefit in the treatment of RSV pneumonia in immunosuppressed adults, although conclusive randomized studies have not been performed.[13] A new oral RSV-entry inhibitor has shown promise in reducing the viral load.[14] Bacterial superinfection can develop, with *Streptococcus pneumoniae* (Chapter 289) and *Haemophilus influenzae* (Chapter 300) being the most frequent organisms. For such patients, appropriate antimicrobial treatment (Chapter 97) is mandatory.

PREVENTION

Adherence to standard infection-control principles (e.g., gloves, gowns, frequent handwashing) substantially reduces nosocomial spread. A vaccine is not available. Parenteral humanized RSV monoclonal antibody (palivizumab, 15 mg/kg monthly during the RSV season) has demonstrated benefit when administered prophylactically to specific high-risk infant groups.■ Palivizumab prophylaxis in healthy late-preterm infants (32 to 35 weeks' gestation) also can reduce subsequent wheezing by 50% during the first year of life.■

PROGNOSIS

RSV infection in severely immunocompromised adults such as bone marrow transplant recipients (Chapter 178) and those with acute leukemia (Chapter 183) undergoing cytotoxic chemotherapy can carry a 60% mortality rate when pneumonia develops.[15] Lymphopenia (<100/μL) and high-dose total body irradiation are associated with more severe disease, but progression to pneumonia is very unusual in patients with an absolute lymphocyte count above 1000/μL. In lung transplant recipients, bronchiolitis obliterans syndrome may occur in 10 to 50% of patients as a late sequela of RSV infection.

Mortality is rare in otherwise healthy infants but can reach 37% in infants with cardiac disorders. In children, a link between severe bronchiolitis and subsequent asthma remains unresolved. In normal infants and healthy adults, the outcome is generally good.

REVIEW QUESTIONS

1. A 78-year-old woman with a history of chronic obstructive pulmonary disease (COPD) and heart failure presents to her physician 5 days after the New Year complaining of 3 days of nasal congestion, worsening cough, increased sputum, and increasing dyspnea. She has a temperature of 38.8° C and diffuse inspiratory and expiratory wheezing. SaO_2 on 2 L/min nasal O_2 is 90%. She received influenza vaccine 2 months ago but states that over the holidays she was with several family members, including young children, with the "flu." Which is the optimal diagnostic test to identify respiratory syncytial virus (RSV) infection?

A. Serology demonstrating a single high titer of serum immunoglobulin (Ig)G to RSV
B. A rapid RSV antigen detection assay on a nasal swab or nasal wash specimen
C. Viral culture of nasal swab or nasal wash specimen
D. Reverse transcription–polymerase chain reaction (RT-PCR) of nasal swab or nasal wash specimen

Answer: D Adults with RSV have relatively high levels of serum and mucosal antibody and subsequently shed relatively low titers of virus compared with infants. Rapid antigen tests and culture are significantly less sensitive than RT-PCR. Although serology is highly sensitive in adults, both acute and convalescent samples are required, so this an impractical diagnostic method for clinical use.

2. A 42-year-old man with acute myeloid leukemia received an allogeneic stem cell transplant from his brother 20 days ago and now presents with nasal congestion and rhinorrhea. His white blood cell (WBC) count is 400/μL with a lymphocyte count of 50/μL. A nasal swab sample is positive for RSV by multiplex PCR. His lung examination is normal, and his chest radiograph is clear. SaO_2 is 96% while breathing ambient air. Which one of the following statements is most accurate regarding this patient?

A. Therapeutic intervention is never indicated for upper respiratory tract symptoms associated with RSV infection in such a patient.
B. Palivizumab (an RSV neutralizing monoclonal antibody) infusion will clear the virus from the upper respiratory tract and hasten recovery.
C. Progression of RSV infection to lower respiratory tract involvement is uncommon unless the lymphocyte count is less than 50/μL.
D. In nonrandomized studies, administration of inhaled ribavirin is associated with a decreased risk of progression to lower respiratory tract disease
E. The use of intravenous IgG infusion in combination with inhaled ribavirin has been proven to provide optimal outcomes.

Answer: D RSV infection in hematopoietic cell transplants recipients can be severe. Disease will progress to lower respiratory involvement in about 25% of such patients and carries a 20 to 40% mortality. Factors associated with progression include total body irradiation and low absolute lymphocyte counts (<100/μL). In one analysis, RSV did not progress in patients with lymphocyte counts above 1000/μL. Adequately sized studies of palivizumab treatment, given alone or in combination with ribavirin, have not been performed. An analysis of 288 immunocompromised subjects from one large center found that treatment with inhaled ribavirin was associated with decreased risk of disease progression.

3. A 56-year-old man with COPD on 2 liters/min of home O_2 presents in February with a 3-day illness characterized by rhinitis, sore throat, increase in his daily cough, and change in color and amount of sputum production. He is afebrile and has a respiratory rate of 26 and pulse of 110. He is breathless and is wheezing on examination. His WBC count is 6700 with a normal differential, his chest radiograph is unchanged from prior films, and his SaO_2 is 78% on 2 L/min O_2, which is significantly below his baseline of 92%. He is admitted to the hospital and cautiously placed on 4 liters of nasal O_2. A nasal swab is positive for RSV by RT-PCR, and his sputum Gram stain shows more than 25 WBCs per high-power field, with mixed flora. In addition to standard hand hygiene, which of the following infection-prevention measures should be implemented?

A. Use of gowns and gloves for all patient contact
B. Isolation of the patient in a negative pressure room
C. Use of gloves, gowns, and facemask for all contact
D. None of the above
E. All of the above

Answer: A RSV can persist on hard surfaces for several hours, so gowns and gloves should be used to prevent transmission. RSV is transmitted by large fomites, not by small-particle aerosol, so neither negative pressure nor masks are necessary to prevent transmission to health care workers or other patients.

4. A 24-year-old medical student is seen in the student health service for nasal congestion, mild sore throat, and wheezing in late July. She has a history of mild untreated asthma since childhood. A rapid antigen test for influenza A is negative, and a rapid antigen test for RSV is weakly positive. On examination, her lungs show expiratory wheezes but are otherwise clear. Three days earlier she returned from rural Thailand, where she had worked for 2 months in a family medicine clinic. Which of the following statements is most correct:

A. The rapid antigen test for RSV is reliable and confirms RSV as the cause of her symptoms.
B. RSV infection is uncommon in July, so the positive antigen test should be considered a false positive.
C. RSV is the most common cause of asthma exacerbations in young adults, so the positive antigen test should be considered definitive.
D. To confirm the diagnosis of RSV, an RT-PCR assay should be performed.

Answer: D The most reliable diagnostic assay for RSV in adults is RT-PCR. In adults, the rapid antigen test for RSV has poor sensitivity and cannot be considered definitive. July is atypical for RSV in the United States, but the student had recently traveled to a tropical area in which RSV can circulate throughout the year. Although RSV can cause exacerbations of asthma, rhinovirus is a much more common precipitant of asthma in older children and adults.

363

PARAINFLUENZA VIRAL DISEASE

GEOFFREY A. WEINBERG AND KATHRYN M. EDWARDS

DEFINITION

Human parainfluenza viruses (hPIVs) are important causes of a wide spectrum of respiratory illnesses. In infants and young children, they produce acute upper and lower respiratory tract infections ranging from the common cold (Chapter 361) and otitis media (Chapter 426) to severe croup, bronchiolitis, and pneumonia (Chapter 97). In older children and adults, hPIV infections are usually limited to the upper respiratory tract (Chapter 96), although immunocompromised individuals may develop fatal respiratory failure.

The Pathogen

The hPIVs are enveloped, single-stranded, nonsegmented RNA viruses that belong to two genera in the family Paramyxoviridae. Members of this family also include respiratory syncytial virus (RSV [Chapter 362]), human metapneumovirus (Chapter 361), measles virus (Chapter 367), mumps virus (Chapter 369), Hendra and Nipah viruses, and the pathogenic animal viruses of Newcastle disease, canine distemper, and rinderpest. The hPIV genome encodes six structural proteins. The hemagglutinin-neuraminidase (HN) and fusion (F) proteins, which are exposed on the bilayered lipid envelope surrounding the helical nucleocapsid–RNA complex, mediate both attachment to host sialic acid–containing glycoproteins and penetration of the virus into susceptible mammalian cells.[1] These proteins have retained their antigenic stability for many years, unlike the "drift and shift" of the hemagglutinin and neuraminidase of influenza viruses. The four serotypes of hPIV are called types 1 to 4, including two subgroups (A and B) of type 4 virus.

The hPIVs replicate in the ciliated epithelial cells that line the respiratory tract on its luminal surface. This selective tropism is consistent with the absence of invasive disease or viremia in the immunocompetent host. Syncytium formation, which is noted in viral cell cultures and in the lungs of immunocompromised patients with severe pneumonia, is not thought to be important in typical infections of previously healthy individuals.

EPIDEMIOLOGY

The hPIVs are ubiquitous, with a worldwide geographic distribution. Their transmission is principally by large-particle fomites via close person-to-person contact. Parainfluenza virus activity displays both endemic and epidemic patterns, with each serotype favoring different age groups and distinct clinical syndromes but with enough overlap to preclude specific diagnosis based solely on clinical and epidemiologic grounds.

Primary infection with hPIV occurs early in childhood.[2,3] Of the parainfluenza viruses, type 3 (hPIV-3) generally infects infants first, such that 50 to 67% of infants demonstrate serologic evidence of infection by 1 year of age. Parainfluenza viruses 1 and 2 (hPIV-1 and hPIV-2, respectively) then most commonly infect children between 2 and 5 years of age. Parainfluenza virus 4 (hPIV-4) less commonly causes symptomatic respiratory infections; in some studies hPIV-4 is found more often in viral coinfection with other pathogens.[4]

Until the early 1960s, hPIV-1 caused endemic annual disease in the United States. For the past several decades, however, hPIV-1 has been associated with biennial outbreaks in the fall of odd-numbered years. Infections with hPIV-2 largely follow this same curious pattern but occur much less commonly than hPIV-1 infections. Infections with hPIV-3 have remained endemic throughout the year, with peaks in the late spring. The incubation period for all serotypes of hPIV is between 3 and 6 days in experimentally infected adults, but natural infections in children have incubation periods of 2 to 4 days.

The hPIVs are second only to RSV as the cause of acute upper and lower respiratory tract infections in young children in the United States. In a population-based study of children younger than 5 years hospitalized with fever or acute respiratory tract infection, 7% of children had laboratory-confirmed hPIV infection (by cell culture and molecular amplification techniques), compared with 19% with RSV and 6% with influenza A or B virus infections. The hospitalization rate for hPIV infection in children younger than 5 years was 1.02 per 1000 children per year. Extrapolating to the entire U.S. population, these data suggest that approximately 23,000 hPIV annual hospitalizations occur in children younger than 5 years. The rates of emergency department and outpatient health care visits attributable to hPIV infections in young children are 10- to 50-fold greater than hospitalization rates. Further, immunity to hPIV infection is neither complete nor durable, so older children and adults can exhibit symptomatic infection, sometimes leading to office visits and hospitalization.

CLINICAL MANIFESTATIONS

Primary Infection

Illness associated with primary hPIV infection varies by age and viral serotype. Underlying medical conditions such as cardiopulmonary compromise and immune disorders increase the severity of disease. Large cohort and longitudinal family studies have shown that hPIV infections are responsible

for about 65% of croup, 20 to 40% of lower respiratory infection, and 20% of upper respiratory infection in young children. The majority of children have experienced primary hPIV infection by the time they enter elementary school. Thus, although hPIV also causes upper respiratory infections in adults, these are reinfections rather than primary infections (see later). In general, hPIV-1 and hPIV-2 are most commonly associated with croup, whereas hPIV-3 infection often presents as undifferentiated febrile illness, bronchiolitis, or pneumonia.

Infection typically begins with upper respiratory signs and symptoms, notably coryza, rhinorrhea, pharyngitis without cervical adenopathy, and low-grade fever. Symptoms, which typically persist for 3 to 5 days, may be unpredictable and can result in sudden respiratory failure. About 15 to 25% of infected children develop signs of croup or progress to lower respiratory tract disease (e.g., bronchiolitis, pneumonia) indistinguishable from RSV infection.

Croup is characterized by a raspy barking cough with notable inspiratory stridor, dyspnea, and respiratory distress. These symptoms, which are generally spasmodic, result from subglottic inflammation and edema. On occasion, severe stridor may develop and make differentiation from epiglottitis caused by *Haemophilus influenzae* type b (Chapter 300) difficult, although epiglottitis is much less common in the United States since universal Hib vaccination became routine in 1990.

Croup is very rare in adults but has been associated with hPIV in isolated case reports. Epiglottitis is seen more often in adults, but it is more commonly associated with staphylococcal or streptococcal infection. Epiglottitis is a medical emergency for patients of all ages and must be distinguished from croup to allow proper therapy, including emergent intubation of the airway (Chapter 429). For patients who are judged to have a stable enough airway to permit urgent radiography rather than emergent tracheostomy, the differences between these two entities are clearly shown in lateral neck radiographs, on which subglottic edema and narrowing are seen with croup, and swelling of the epiglottis is seen with epiglottitis (Figs. 363-1 and 363-2). Children with bronchiolitis or pneumonia caused by hPIV have cough, rales, and wheezing associated with hypoxia, and their chest radiographs often exhibit air trapping.

Reinfection

Reinfection with hPIV is less severe and typically causes rhinorrhea in normal children and adults. Reinfection with hPIV is estimated to account for 1 to 15% of all acute respiratory illnesses in adults, the majority of whom present with simple upper respiratory tract infections.[5] However, as with RSV, some adults may develop severe disease that requires hospitalization and even ventilatory support. In such patients, fever, cough, dyspnea, and wheezing are common. Radiographic changes, primarily lobar or interstitial infiltrates, are seen in more than 50% of adults hospitalized with hPIV infection.

Elderly and Immunocompromised Patients

Nursing home outbreaks of hPIV infection may include a high incidence of pneumonia, just as hPIV infections often cause severe pneumonia in immunocompromised children and adults. Among healthy elderly residents of long-term care facilities, hPIV infections are as common as infections caused by influenza A virus, influenza B virus, or RSV. Ten percent of children and 2 to 7% of adults with leukemia or hematopoietic stem cell transplant recipients develop hPIV infections, with about 90% of those due to hPIV-3.[6-8] Although 80 to 90% of hPIV infections among patients with malignancy are community acquired, nosocomial outbreaks have occurred even in stem cell transplant units.

Approximately 25% of hPIV-infected stem cell transplant recipients develop lower respiratory disease, mostly in the first 100 days after transplantation, when lymphopenia and neutropenia are most pronounced. The strongest identified risk factors for hPIV infection in this setting are neutropenia, lymphopenia, more severe disease, and the use of corticosteroids, especially at higher doses. Fever, cough, dyspnea, and sputum production are the most common symptoms. Coinfection with *Aspergillus* (Chapter 339) and other pathogens has been reported in hematopoietic stem cell transplant recipients with pneumonia as well.

DIAGNOSIS

Although hPIV may be suspected on clinical and epidemiologic grounds, specific diagnosis requires isolation of the virus or detection of viral antigen or RNA in respiratory secretions. Reverse transcription–polymerase chain reaction (RT-PCR) assays are highly sensitive and specific for diagnosis. Alternatively, cultures of monkey kidney or human embryonic kidney cells can be used to grow the virus, with cytopathic effects detected in 5 to 10 days (except for hPIV-4, which requires up to 3 weeks). Rapid direct or indirect immunofluorescence tests are less sensitive than culture but still are used in many clinical laboratories.

Definitive diagnosis of parainfluenza infection in adults, even by RT-PCR, may be more difficult than in children, presumably because less virus is shed in partially immune adults. However, virus can usually be recovered from the

FIGURE 363-2. Epiglottitis. nasopharyngeal secretions or bronchoalveolar lavage fluid in hematopoietic stem cell transplant recipients with pneumonia.

TREATMENT

Specific antiviral treatment of hPIV infection is currently unavailable. Aerosolized ribavirin has in vitro activity against hPIV and is approved for use in RSV infection. Although it has shown few benefits in immunocompromised children and adults with severe hPIV pneumonia, even when administered with concomitant intravenous immunoglobulin, some experts will offer aerosolized or intravenous ribavirin, with or without intravenous immunoglobulin, to immunocompromised patients with severe disease.

For previously healthy children with croup, general comfort, which usually means sitting in the lap of a parent or caregiver, is widely recommended.[9] Humidified air (mist) repeatedly has been shown to have no benefits and actually is associated with adverse effects, including anxiety, difficulty with cardiorespiratory monitoring, and bacterial and fungal contamination of both hot and cold mist humidifiers. Oxygen may be given by holding the end of the tubing near the nose and mouth ("blow-by" oxygen).

Children with mild to moderate croup (i.e., without stridor or significant chest wall indrawing at rest, or with stridor and indrawing but without agitation) may be given oral dexamethasone, 0.6 mg/kg body weight, and observed; if they improve, they may be discharged to home. Children with severe croup (stridor, chest wall indrawing, and agitation) may benefit from blow-by oxygen, inhaled racemic epinephrine (0.05 mL/kg body weight of a 2.25% solution of racemic epinephrine for nebulization, up to a maximum dose of 0.5 mL) or nebulized L-epinephrine (0.5 mL/kg of 1:1000 L-epinephrine, up to a maximum dose of 5 mL), and concomitant dexamethasone. Children should be admitted to the hospital if no significant clinical improvement is seen after several hours of observation and therapy.

Oral dexamethasone is as effective as intramuscular dexamethasone or nebulized budesonide and easier to administer. Corticosteroids decrease the need for hospitalization and return visits, decrease length of stay both in emergency departments and after hospital admission, and decrease the need for intubation. In general, there are no reasons to institute either antibiotic therapy or short-acting bronchodilator therapy in children with croup.

Investigational therapies for hPIV infection include both nonspecific and specific measures. Inhalation of heliox (helium-oxygen mixture) may decrease the work of breathing and improve gas exchange in children with moderate to severe croup, but adequately controlled clinical trial data are not yet available.[10] The novel antiviral agent DAS181, a sialidase fusion protein with activity against both influenza and parainfluenza viruses, has shown beneficial effects in a few adults with severe hPIV infection and is undergoing clinical trials.[11]

PREVENTION

Clinical trials of live attenuated hPIV vaccines are ongoing. Two approaches have been taken to produce live-attenuated intranasal hPIV-3 vaccines. One approach has been to attenuate an hPIV-3 isolate by repeated cold-temperature passage and manipulation by recombinant technology. A second has been to use a related but nonvirulent bovine PIV-3 as a backbone in which to insert

hPIV-3 genes to produce an attenuated chimeric vaccine virus.[12] Another vaccine candidate under study uses the chimeric bovine-human PIV-3 virus, but with an additional RSV gene inserted into the vaccine virus genome in an attempt to prevent both of these common infections in young children.[13]

PROGNOSIS

In otherwise healthy children, mortality after hPIV infection is less than 0.1%. By comparison, mortality after hPIV pneumonia in patients undergoing stem cell transplantation is as high as 10 to 30%.[14]

REVIEW QUESTIONS

1. A 2-year-old girl presents to the emergency department with stridor and dyspnea of 4 hours' duration. Her parents relate that she has had about 3 days of preceding low-grade fever, coryza, and rhinorrhea. When she woke up this morning, her parents heard a barking cough coming from the child's room and noted that her breathing was progressively noisier on the way to the hospital. On physical examination, the child is not toxic appearing, but she is uncomfortable, with obvious inspiratory stridor and a raspy barking cough. Which represents the most likely diagnosis and most appropriate management plan?

A. The child likely has community-acquired bacterial pneumonia; obtain a chest radiograph and administer oral antibiotics.
B. The child likely has community-acquired viral pneumonia; obtain a chest radiograph but do not administer oral antibiotics.
C. The child likely has epiglottitis; obtain a lateral neck radiograph, begin intravenous antibiotics, then secure the airway.
D. The child likely has croup; keep her quiet by allowing her to stay in mother's lap, provide blow-by oxygen, administer oral dexamethasone, and observe for improvement.
E. The child likely has croup; perform a careful pharyngeal examination in an attempt to visualize the epiglottis, provide oxygen by rebreather mask, and administer intramuscular dexamethasone and subcutaneous epinephrine.

Answer: D This child likely has mild to moderate croup, based on the history and physical examination findings of stridor but her nontoxic appearance. The best course is to keep her quiet in a comfortable setting such as her parent's lap, give her oxygen in the least intrusive manner (blow-by), and give oral dexamethasone 0.6 mg/kg. Oral dexamethasone can decrease symptoms, shorten the stay in the emergency department or hospital, and reduce the need for intubation. Stridor and barking cough are generally not associated with community-acquired bacterial pneumonia. Viral pneumonia with hPIV can accompany croup; but if so, dexamethasone and oxygen also would be appropriate. Epiglottitis should always be considered when examining a young child with respiratory distress, but these children tend to be more toxic in appearance; ideally the airway should be secured before performing radiographs, intravenous lines, and other procedures that might upset the child and provoke airway collapse.

2. The grandfather of the child in Question 1 underwent bone marrow transplantation for malignancy 4 weeks before the child became ill. She visited with him extensively at home a few days before she herself became ill. Now, 4 days after that contact, the grandfather is reporting fever, cough, dyspnea, and increased sputum production. His wife is concerned because he has not "looked this bad" since the transplantation was performed. Which statement best characterizes his illness?

A. He likely has hPIV pneumonia, having acquired the infection from his granddaughter; he should be admitted to the hospital and treated with aerosolized or intravenous ribavirin and intravenous immunoglobulin in view of his high risk for mortality.
B. He likely has acquired hPIV infection from his granddaughter but because adult airways are larger, he is unlikely to exhibit symptomatic croup; reassurance and continued monitoring at home will be sufficient.
C. He likely has community-acquired pneumonia and should be given antibiotics.
D. He likely has *Pneumocystis pneumonia* and should be hospitalized for intravenous trimethoprim-sulfamethoxazole. Further diagnostic studies are unnecessary and would be not be cost-effective.
E. None of the above

Answer: A This adult is likely significantly immunocompromised (first 100 days after bone marrow transplantation) and has a 10 to 30% of mortality with hPIV infection. The incubation period of hPIV and the timing of the illness in the child are consistent with transmission. Although the efficacy of ribavirin and intravenous immunoglobulin have not been proven in randomized clinical trials, their use should be considered because of the severity of his illness and his high risk of mortality. Hospitalization is likely warranted, with oxygen and supportive care given at minimum. Although adults with hPIV infection do not generally present with croup, this immunocompromised patient's condition warrants an urgent medical visit, likely with subsequent hospitalization. Many other causes of respiratory infection are possible in the first 100 days following bone marrow transplantation, but administering antibiotics without considering the contact history or obtaining further diagnostic specimens would be inappropriate.

364 INFLUENZA

FREDERICK G. HAYDEN

DEFINITION

Influenza is an acute febrile respiratory viral illness that usually occurs in annual outbreaks of varying severity and occasionally occurs in worldwide epidemics (pandemics) and as sporadic zoonotic infections. Influenza viruses infect the respiratory tract, are highly contagious, and typically produce prominent systemic symptoms early in the illness. Influenza infection causes various clinical syndromes in adults, including nonfebrile common colds (Chapter 361), pharyngitis (Chapters 290 and 429), tracheobronchitis (Chapter 96), pneumonia (Chapter 97), and a range of nonrespiratory complications. Conversely, infections with other respiratory viruses, such as respiratory syncytial virus (RSV [Chapter 362]) or adenovirus (Chapter 365), may produce influenza-like illness. Influenza A viruses have caused five pandemics of varying severity within the past 120 years (Table 364-1). The pandemic in 1918-1919 caused at least 500,000 deaths in the United States and more than 40 million worldwide, whereas the 2009 H1N1 pandemic was associated with substantially less mortality. Seasonal epidemics may cause enormous morbidity, economic loss, and often substantial mortality. Recent epidemics have caused on average more than 24,000 respiratory- and circulatory-related deaths and more than 200,000 hospitalizations in the United States alone.

TABLE 364-1 ANTIGENIC SUBTYPES OF INFLUENZA A VIRUS ASSOCIATED WITH PANDEMIC AND PANDEMIC-LIKE INFLUENZA

YEAR	INTERVAL (YR)	SUBTYPE DESIGNATION	EXTENT OF ANTIGENIC CHANGE IN INDICATED SURFACE PROTEIN*	SEVERITY OF PANDEMIC (MORTALITY)
1889	?42-59	H3N?	H+++N?	Severe
1918	18	H1N1†	H+++N+++	Very severe
1957	39	H2N2	H+++N+++	Severe
1968	11	H3N2	H+++N–	Moderate‡
1977	9	H1N1	H+++N+++	Negligible§
2009	32	H1N1	H++N++	Mild-moderate§

*Compared with antecedent or cocirculating virus.
†Formerly designated H0N1 (swine virus prototype) or Hsw1N1.
‡The population had some immunity to N2 neuraminidase.
§The older population was largely immune because of previous infection with earlier circulating, antigenically identical (1977) or related (2009) viruses; those born after 1957 were primarily affected. The impact of the 2009 pandemic virus, based on estimated years of life lost, was comparable to that observed in the 1968 pandemic in the United States.
+ = Minor change; ++ = moderate change; +++ = major change; – = no change.

The Pathogen

Influenza viruses belong to the family Orthomyxoviridae and are divided into three types (A, B, and C) based on their protein composition and other properties (Table 364-2). The virion (Fig. 364-1) is a medium-sized enveloped pleomorphic particle covered with two types of surface glycoprotein spikes, the trimeric hemagglutinin (H or HA) and the tetrameric mushroom-shaped neuraminidase (N or NA). The envelope is composed of a lipid bilayer overlying the matrix (M1) protein that surrounds the viral genome, which consists of eight segments of single-stranded negative sense RNA in influenza A and B viruses. Influenza C viruses have seven segments and only a single surface glycoprotein. Genomic replication occurs in the nucleus of infected cells, and multiple cellular proteins and pathways are involved during the infection of host cells.

Whereas influenza B and C viruses are principally human pathogens, influenza A viruses primarily infect aquatic birds and sometimes establish lineages that circulate in other animal hosts, including other avians, swine, horses, marine mammals, and dogs. Influenza A viruses are further classified into subtypes on the basis of their HA and NA glycoproteins. Sixteen HA and nine NA subtypes are currently recognized in avians, and two others are recognized in bats. Only three HAs (H1, H2, and H3) and two NAs (N1 and N2) have been documented thus far in epidemic and pandemic human influenza A viruses, although other HAs (e.g., H5, H6, H7, H9, H10) and NAs (e.g., N4, N7, N8, N9) have been found in zoonotic infections. Each strain is identified by type, subtype if influenza A, site, sample number, and year of isolation.

EPIDEMIOLOGY

Antigenic and Genetic Variation

Influenza viruses are unique among the respiratory viruses with regard to their extent of genetic and antigenic variation, epidemic behavior, and frequent association with excess mortality during community outbreaks—characteristics that exemplify influenza virus's dependence on efficient host-to-host transmission for its survival. The changing antigenicity of the surface glycoproteins largely accounts for repeated influenza epidemics. Antibody to HA can neutralize viral infectivity and is thus the major determinant of immunity. Current vaccines are based largely on inducing hemagglutination-inhibition (HAI) or neutralizing antibodies to HA. Anti-NA antibody limits viral replication and probably reduces the severity of infection. Variation involves either relatively minor (antigenic drift) or major (antigenic shift) changes in antigenicity. Significant antigenic variation is much less frequent with influenza B or C than with influenza A.

Antigenic drift results from point mutations in the HA gene segment that cause amino acid substitutions in at least one of five key antigenic sites on HA. Drift can also occur in NA and in T-cell epitopes on internal proteins. Antigenic variants emerge frequently (every year or every few years) within an influenza A or B virus. For example, the original H3N2 variant, A/Aichi/68, has undergone successive drifts resulting in epidemic strains that include the recent circulation of A/Switzerland/9715293/2013-like-viruses. Immunologic selection favors transmission of the new variant over the old because of the less frequent presence of antibody to the new virus in the population.

Antigenic shift results from the appearance of a novel influenza A virus with HA or HA and NA glycoproteins that are new to humans or that reappear after decades of absence. Because of the lack of population immunity, a new strain that is transmissible from person to person can cause pandemic disease (see Table 364-1). The origin of new pandemic strains and the basis for their possible recirculation remain incompletely understood. Avian influenza viruses have served as the reservoir of new genes for human pandemic viruses. Reassortment of gene segments may occur when two influenza viruses simultaneously infect a single cell, and reassortment events in which human viruses acquired avian genes led to both the 1957 and 1968 pandemic viruses. Because swine can support replication of both human and avian viruses, they have been postulated to serve as a mixing vessel for the generation of new strains or as the host in which avian viruses can adapt to mammals. The 2009 H1N1 pandemic virus arose as a quadruple reassortant that derived

TABLE 364-2 INFLUENZA A VIRUS PROTEINS

DESIGNATION	LOCATION (APPROXIMATE SIZE)	FUNCTION	OTHER
Hemagglutinin (HA)	Surface, transmembrane (566 aa)	Cell attachment via sialic acid–bearing receptors and penetration; fusion of host cell and viral membranes	Type-, subtype-, and strain-specific antigens; key antigen in inactivated vaccines
Neuraminidase (NA)	Surface, transmembrane (454 aa)	Virus release and spread; enzymatic activity causes removal of sialic acid residues from receptors	Type-, subtype-, and strain-specific antigens; activity linked to risk for pneumonia; site of action of neuraminidase inhibitors
M1 or matrix	Internal (252 aa)	Major structural envelope protein; virus assembly	Type-specific antigen; conserved T-cell epitopes
M2	Surface, transmembrane (97 aa)	Ion channel; virus uncoating and budding	Influenza A only; site of action of amantadine/rimantadine; ectodomain as possible vaccine candidate
Nucleoprotein (NP)	Internal (498 aa)	Major ribonucleoprotein complex component; associated with RNA and polymerase proteins	Type-specific antigen; conserved T-cell epitopes
Polymerase proteins (PB1, PB2, PA)	Internal (PB1-757 aa, PB2-759 aa, PA-716 aa)	Viral RNA replication and mRNA transcription (endonuclease, cap-snatching, nucleotide addition)	Determinant of replication efficiency; specific PB2 mutations associated with mammalian adaptation; site of action of favipiravir
NS1	Nonstructural (230 aa)	Multifunctional; regulation of virus RNA and protein synthesis; host protein interactions	Interferon antagonist; inhibition of innate immune signaling
NEP (NS2)	Internal (121 aa)	Nuclear export factor	From splicing of NS1 mRNA
PB1-F2	Nonstructural (87 aa)	Proapoptotic factor; proinflammatory effects; interferon antagonist	Expressed from 1+ reading frame of PB1 of certain viruses
PA-X	Nonstructural (41-61 aa)	Endonuclease activity; repression of cellular gene expression	Modulation of the host response to infection; expressed by 1+ ribosomal frame-shifting

Modified from Krug RA, Fodor E. Chapter 4, The virus genome and its replication. In: Webster RG, Monto AS, Braciale TJ, Lamb RA, eds. *Textbook of Influenza*. 2nd ed. Oxford: John Wiley and Sons; 2013:57-66.
NOTE: Influenza B also has eight gene segments, one of which encodes both NA and NB proteins, the latter a membrane protein of uncertain function, and another encoding the M1 (matrix) and BM2 proteins, the latter functioning as an ion channel but not inhibited by adamantanes. Nonstructural proteins are present only in infected cells. Other small nonstructural proteins (PB1-N40) have been described in influenza A and are under study.

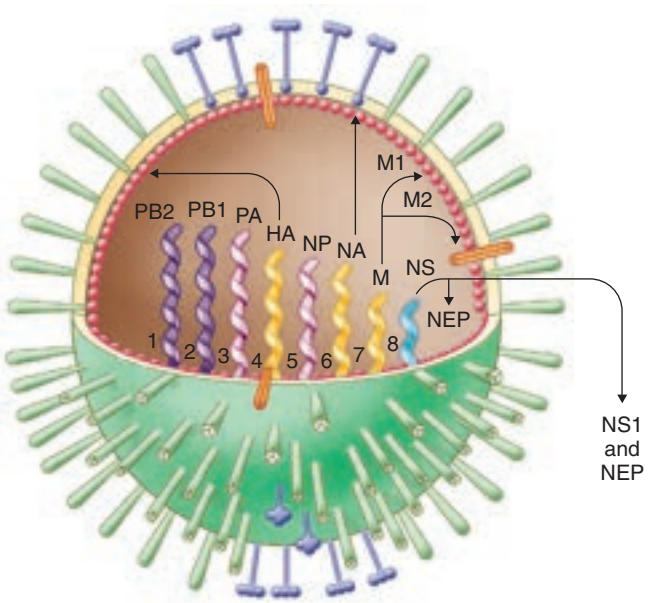

FIGURE 364-1. Diagram of influenza virus structure. Eight segments of viral RNA are contained within the lipid envelope and matrix (M1) shell. Each codes for one or more proteins that form the virus or regulate its intracellular replication. The presumed functions of each are listed in Table 364-2. (Courtesy Dr. Robert G. Webster.)

gene segments from Asian and North American swine lineage viruses that harbored genes derived from swine, avian, and human viruses.

Multiple reassortment events may occur over a period of years before a pandemic emerges. For example, the 1918 pandemic virus was probably a reassortant composed of both human and swine genes, including some of avian origin, that underwent adaptation in a mammalian host, perhaps human or swine, before causing the pandemic. Frequent intrasubtypic reassortment also occurs among seasonal human influenza A viruses and sometimes leads to new antigenic variants or altered virulence.

Modified from Glezen WP. Anatomy of an urban influenza epidemic. In: Hannoun C, Kendal AP, Klenk HD, et al, eds. *Options for the Control of Influenza II*. Amsterdam: Elsevier; 1993:12.

Epidemic or Interpandemic Influenza

An epidemic is an outbreak of influenza confined to one geographic location. In temperate climates, community epidemics of influenza A virus infection often have a characteristic pattern, typically reaching a sharp peak in 2 or 3 weeks after initial recognition and persisting for 6 to 10 weeks. Increased numbers of schoolchildren with febrile respiratory illness are often the first indication of influenza in a community, soon followed by illnesses in adults and, 1 to 2 weeks later, by increased hospital admission of patients with influenza-related complications. Hospitalization rates in high-risk persons increase two- to five-fold during major epidemics (Table 364-3). School and employment absenteeism increases, as does mortality from pneumonia and underlying conditions, especially in older adults during A/H3N2 epidemics. Epidemics occur almost exclusively during the late autumn and winter months in temperate areas, but influenza activity may occur year-round in the tropics or display other patterns. The reasons for the distinct seasonality of influenza in temperate climates are uncertain but may include the school calendar, increased close indoor contact, and absolute humidity, which affects airborne transmissibility. In the United States, the onset of wintertime influenza has been associated with low absolute humidity levels during the

preceding weeks. Outbreaks sometimes occur in tour groups (land or ship) and in chronic care facilities during summer months, particularly after the appearance of a drift variant. Regional differences in the timing, magnitude, and causative viruses of influenza outbreaks are common. During epidemics, overall attack rates typically range from 5 to 20% in adults. Attack rates of 40 to 50% may occur in semiclosed populations, such as in hospitals and chronic care facilities, and in highly susceptible age groups such as children. Influenza A and B viruses, two different influenza A subtypes, two different influenza B lineages, or two different strains within a single subtype may cocirculate or occur sequentially during one season in a given location. In addition, simultaneous outbreaks of influenza A virus and RSV or other respiratory viruses occur. Strains circulating at the end of one season's epidemic are sometimes responsible for the next season's outbreak (the so-called herald wave phenomenon).

Pneumonia- and influenza-related deaths fluctuate annually, with peaks in the winter months in temperate climates. When such deaths exceed the expected threshold, the cause is typically influenza A, but influenza B virus or RSV can occasionally be responsible. Influenza A/H3N2-dominant seasons are associated with two to three times higher mortality rates than are H1N1 and B-dominant seasons. Although mortality is usually greatest during pandemics, substantial mortality occurs with epidemics. During seasonal influenza, more than 85% of pneumonia- and influenza-related deaths occur in persons aged 65 years and older. Mortality risk is especially high in those aged 85 years and older. Other cardiopulmonary and chronic diseases also result in increased mortality after influenza epidemics, so the overall influenza-associated mortality is two- to four-fold higher than pneumonia- and influenza-related deaths.

Pandemic Influenza

Pandemics of influenza A result from the emergence of a new virus capable of sustained person-to-person transmission and to which the population contains no or limited immunity. The virus spreads worldwide, often circulating outside of the usual influenza season, and usually infects persons of all ages. Preexisting immunity due to prior infection with antigenically related viruses can provide partial protection, as occurred in older adults during the 2009 H1N1 pandemic. Pandemics are associated with high morbidity rates, especially in children, and sometimes notably increased mortality rates in pregnant women and young and middle-aged adults. For example, more than 90% of deaths in the 1918 and 2009 pandemics occurred in persons younger than 65 years. In the 2009 pandemic, adults hospitalized with H1N1 were more likely to have severe pneumonia, shock, sepsis, and organ failure, and to require ICU care than were patients with seasonal influenza.

The interval between pandemics is variable (10 to 40 years) and unpredictable. The most severe pandemics have been associated with major antigenic alterations in both major surface antigens. Depending on population susceptibility and perhaps changes in the virus, one or more waves, sometimes with increased severity, may follow the initial one. As the level of immunity in the population increases, antigenic drift within the subtype may cause repeated epidemics in subsequent years, and excess mortality in persons younger than age 65 may continue for some years. For example, the pandemic 2009 H1N1 virus has continued to cause fatal infections in younger adults at least 4 years after its initial emergence.

Zoonotic Influenza

Zoonotic infections may be acquired from swine, poultry, or rarely other animals. Although most avian influenza viruses do not cause infections directly in humans, zoonotic infections due to avian H5, H7, H9, and rarely other subtypes continue to represent potential threats to global health. Initially recognized by a cluster of human cases in Hong Kong in 1997, an epizootic of avian H5N1 infections has affected poultry in many areas of Asia, the Middle East, Europe, and Africa and continues to cause sporadic human illnesses with high mortality and occasional instances of nonsustained human-to-human transmission. Since 2013, an outbreak of avian H7N9 infections in eastern China has been associated with case-fatality of approximately 30% in hospitalized patients.[1] Temporary closure of live bird markets and perhaps seasonal decreases in avian infections rapidly reduced the number of persons affected initially, but a second larger wave developed during late 2013. This outbreak has included limited family clusters, many milder illnesses in the community, and increasing geographic spread; its trajectory remains uncertain.

In the United States, infrequent zoonotic infections have been recognized for decades in people exposed to swine. Since 2012, reassortant swine H3N2 viruses that acquired the M gene and sometimes other genes from the pandemic 2009 H1N1 virus (designated variant H3N2, or H3N2v) have caused hundreds of sporadic infections, particularly in the context of agricultural fairs, sometimes followed by limited human-to-human transmission and serious infections. Other variant swine-origin viruses (H1N1v, H1N2v) have also caused zoonotic infections.

PATHOBIOLOGY

Influenza virus infection is transmitted from person to person by virus-containing respiratory secretions. Large-droplet and small-particle aerosols over short distances (1 to 2 meters) both appear to contribute,[2] but transmission by other routes, including hand contamination from secretion-laden fomites followed by self-inoculation into the eye or nose, may be possible. Infection by avian viruses can occur after direct contact with infected birds or their excreta, exposure to contaminated environments, ingestion of inadequately cooked food, and sometimes by inoculation into the conjunctiva.

The cellular receptor binding patterns and tissue tropism of influenza viruses are key determinants in transmissibility and pathogenesis. Efficient virus transmission between humans depends on virus attachment to and replication in cells bearing α-2,6-linked sialosaccharides in the upper respiratory tract and tracheobronchial tree. By comparison, the α-2,3-linked sialosaccharides, which are the preferred receptors for avian viruses, are concentrated on cells in the distal bronchioles, alveoli, and conjunctiva. Once the virus initiates infection of the respiratory tract epithelium, successive cycles of viral replication infect large numbers of cells and result in destruction of respiratory epithelium and sometimes pneumocytes through direct cytopathic effects or apoptosis. Virulence, which is a multigenic characteristic with contributions from HA, NA, NS, and polymerase proteins (see Table 364-2), varies widely among strains and is not necessarily linked to transmissibility.

The incubation period averages 2 days and varies from about 1 to 4 days for seasonal influenza but may be up to 1 week and possibly longer in infections caused by avian viruses. The quantity of virus in respiratory tract specimens generally correlates with the severity of illness and levels of host pro-inflammatory cytokine-chemokine responses—findings that support the importance of ongoing viral replication in producing acute illness. Rapid innate cellular responses are induced through Toll-like receptors and retinoic acid inducible gene I (*RIG-1*) that detect viral RNA and lead to the production of cytokines and interferons. Elevated levels of mediators such as interferon (IFN)-α, interleukin (IL)-6, and tumor necrosis factor (TNF)-α occur in blood and respiratory secretions and probably contribute to systemic symptoms and fever. Deficient IFN responses have been associated with severe influenza. The duration of viral replication depends on age, immune status, underlying conditions, viral strain, and assay method. In seasonal influenza, upper respiratory viral detection generally continues for 3 to 5 days in adults but is longer in the elderly and hospitalized patients and may persist for weeks to months in immunocompromised hosts. Higher level and more prolonged viral replication, sometimes for weeks, occurs in the lower respiratory tract of patients with viral pneumonia, including pandemic 2009 and avian H5N1 and H7N9 infections. This course typically occurs in association with high plasma pro-inflammatory cytokine-chemokine responses,[3] particularly IL-6, IL-8, and macrophage inflammatory protein (MIP)-1β, which likely reflect production in the infected lung. Viremia or extrapulmonary dissemination is rarely detected in typical human influenza, but both occur in some patients with avian H5N1 infections, in whom gastrointestinal replication may also occur.

Nasal and bronchial biopsy specimens from persons with uncomplicated influenza reveal desquamation of the ciliated columnar epithelium and loss of cilia. The lungs in fatal influenza may show necrotizing bronchitis, diffuse alveolar damage with epithelial necrosis, alveolar edema and hemorrhage, and hyaline membrane formation, followed later by squamous metaplasia and fibrosis. Secondary bacterial infections develop as a result of altered bacterial flora, damage to bronchial epithelium with depressed mucociliary clearance, decreased polymorphonuclear and alveolar macrophage functions, accumulation of alveolar fluid, and suppression of other host immune responses.

Humoral immunity to influenza appears to be largely subtype specific and durable for a particular strain. Neutralizing, hemagglutination-inhibiting (HAI), anti-NA, complement-fixing, enzyme-linked immunosorbent assay and immunofluorescent antibodies begin to develop in the sera of persons with primary influenza virus infection during the second week after infection and reach a peak by 4 weeks. Secretory antibodies develop in the upper respiratory tract and consist predominantly of immunoglobulin (Ig)A

antibodies. Antibody responses are brisker in subsequent infections. Protective immunity against influenza virus infection is mediated by neutralizing antibodies, and protection against illness is generally associated with serum HAI titers of 1 : 40 or greater, serum-neutralizing antibody titers of 1 : 8 or greater, or nasal-neutralizing antibody titers of 1 : 4 or greater.

Cell-mediated immune responses usually develop by 1 week after infection and are considered important for termination of viral replication.[4] Memory lymphocytes from previous infections can limit the severity of disease even in the absence of specific antibodies and may confer some degree of heterosubtypic immunity. Both virus-specific $CD4^+$ and $CD8^+$ T-lymphocyte responses to conserved epitopes on internal proteins appear to contribute.

An increasing number of host genetic factors are being recognized as increasing the risk of severe influenza. One allele in the IFN-induced transmembrane 3 (*IFITM3*) gene has been linked to both severe pandemic H1N1 and avian H7N9 illness.

CLINICAL MANIFESTATIONS

Influenza Syndrome

An abrupt onset of feverishness, chilliness, rigors, headache, myalgia, and malaise is characteristic of influenza but occurs in less than two thirds of cases. Systemic symptoms predominate initially, and prostration occurs in more severe cases. Myalgia, arthralgias, malaise, and headache are usually the most troublesome early symptoms, and their severity is generally related to the level of fever. Ocular symptoms, including photophobia, tearing, burning, and pain on moving the eyes, are sometimes present. Conjunctivitis is characteristic in some avian H7 virus infections, although not in recent H7N9 cases. Respiratory symptoms, particularly dry cough and nasal discharge, are typical early in the illness but are overshadowed by the systemic symptoms. Nasal obstruction, hoarseness, and sore throat are likewise common. Pandemic H1N1 2009 and avian influenza illness are associated with nausea, vomiting, and diarrhea in some adults. As systemic illness diminishes, respiratory complaints and findings become more apparent. Cough is the most frequent and troublesome symptom and may be accompanied by substernal discomfort or burning. Cough, lassitude, and malaise may persist for several weeks before full recovery.

Fever is the most common initial physical finding, but it may be minimal or absent, especially in elderly patients or immunocompromised hosts. The temperature usually rises rapidly to a peak of 38° to 40° C within 12 hours of onset, concurrently with systemic symptoms. Fever is usually continuous but may be intermittent, especially if antipyretics are administered. Typically, the duration of fever in adults is about 3 days, but it may persist from only 1 to 5 or more days. Early in the course of illness, the patient appears toxic, the face is flushed, and the skin is hot and moist. The eyes are watery and reddened. Clear nasal discharge is common. The mucosa of the nose and throat is hyperemic, but exudate is not observed. Small, tender cervical lymph nodes are often present. Transient scattered rhonchi or localized areas of rales are found in less than 20% of cases.

The same pattern of illness occurs with any strain of influenza A or B virus. However, illness is more frequent and severe in smokers. In children, maximum temperatures are often higher, cervical adenopathy may be more frequent, and nausea, vomiting, and abdominal pain are more common. Persons at higher risk for influenza-associated complications and hospitalization (Table 364-4) include pregnant women (especially during the second and third trimesters or early postpartum period), morbidly obese patients, immunosuppressed persons, and patients with various comorbidities. Older adults, especially the infirm elderly, develop fever, muscle aches, sore throat, and headache less often but have higher rates of altered mental status and pulmonary complications. Immunocompromised hosts may also have an apparently mild initial illness but subsequently progress to severe lower respiratory tract involvement. In sporadic illness attributable to H5N1 or H7N9 virus, upper respiratory complaints are less frequent, diarrhea is more common, and progressive viral pneumonia with high mortality is much more likely. Influenza C virus generally causes sporadic upper respiratory tract illness or febrile bronchitis. Most adults hospitalized with seasonal influenza have exacerbations of underlying cardiopulmonary (e.g., myocardial ischemia, heart failure, chronic obstructive pulmonary disease) or metabolic (e.g., diabetes) conditions, and about one third have pneumonia.

TABLE 364-4 PARTICULAR TARGET GROUPS FOR SEASONAL INFLUENZA IMMUNIZATION*

GROUPS AT INCREASED RISK FOR INFLUENZA COMPLICATIONS
Persons aged 50 years and older
Residents of nursing homes and other chronic care facilities
Patients with a chronic pulmonary (including asthma) or cardiac (except isolated hypertension) disorder
Patients with chronic metabolic (including diabetes), renal, hepatic, hematologic (including hemoglobinopathies), or neurologic (including those that compromise respiratory function or increase aspiration risk) disorder
Patients with immunosuppression (including that caused by medications or HIV infection)
Women who will be pregnant or within 2 weeks postpartum during the influenza season
Persons who are morbidly obese (body mass index ≥ 35)
Persons who are American Indians or Alaskan Natives
Children aged 6 months through 59 months, especially those aged < 24 months
Children and teens receiving long-term aspirin
GROUPS IN CONTACT WITH HIGH-RISK PERSONS†
Physicians, nurses, and other health care providers, including those in training
Employees of nursing homes and chronic care and assisted-living facilities
Household contacts (including children) and caregivers of at-risk persons, including children aged < 5 years (particularly contacts of children aged < 6 months), adults aged ≥ 50 years, and persons with medical conditions associated with risk of severe influenza complications (above)

*Routine annual immunization is recommended for all persons aged 6 months or older who do not have contraindications. Those listed are priority groups in the circumstance that vaccine supply is limited or delayed. The risk groups for influenza complications have been expanded because of observations from the 2009 influenza pandemic.
†Inactivated influenza vaccine is recommended for vaccination of household members, health care personnel, and others who have close contact with severely immunosuppressed persons (e.g., patients with hematopoietic stem cell transplants) during those periods in which the immunosuppressed person requires care in a protective environment.
HIV = human immunodeficiency virus.
Modified from Centers for Disease Control and Prevention. Summary recommendations: prevention and control of influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices (ACIP)—United States, 2013-14. Available at: http://www.cdc.gov/flu/professionals/acip/2013-summary-recommendations.htm.

Respiratory Complications

Three pneumonic syndromes have been described—primary influenza viral pneumonia, secondary bacterial pneumonia, and mixed viral and bacterial pneumonia (Chapter 97)—but their clinical presentations and courses overlap considerably. Influenza A and B virus infections are often associated with other respiratory tract complications, including exacerbations of chronic bronchitis, asthma, or cystic fibrosis; croup and bronchiolitis in young children; and otitis media, sinusitis, and rarely parotitis or bacterial tracheitis. Apparently uncomplicated influenza frequently causes tracheobronchitis and is often accompanied by abnormal tracheobronchial clearance, airway hyperactivity, and dysfunction of small airways lasting weeks. A syndrome mimicking pulmonary embolism with transiently altered perfusion scans has also been described.

Severe primary influenza viral pneumonia and associated acute respiratory distress syndrome (ARDS [Chapter 104]) is uncommon during epidemics but accounts for 20 to 50% of pneumonias during pandemics and has been the principal manifestation of severe pandemic H1N1 or avian H5N1 and H7N9 illness. Severe viral pneumonia occurs predominantly in persons with underlying pulmonary and cardiac disorders, pregnancy, or immunodeficiency states, although up to 40% of reported cases and almost all patients with H5N1 have no recognized underlying disease. After a typical onset of influenza, patients often have progressive cough, dyspnea, sometimes hemoptysis, and even cyanosis within 3 to 7 days. Bilateral pulmonary infiltrates and hypoxemia, often indicative of ARDS, may evolve rapidly. Gram staining of sputum may show abundant polymorphonuclear leukocytes but scant bacterial flora. Sputum and endotracheal aspirates usually yield high titers of influenza virus by RNA detection or culture, but upper respiratory samples are sometimes negative.

In patients with classic bacterial superinfection, transient improvement for 1 to 4 days may be followed by recrudescence of fever, increased cough, sputum production, pleuritic chest pain, and a localized area of consolidation. Some patients develop fulminant pneumonia. Gram staining and culture of sputum or blood cultures most often reveal *Streptococcus pneumoniae* (Chapter 289), *Staphylococcus aureus* (Chapter 288) including community-acquired methicillin-resistant *S. aureus*, *Haemophilus influenzae* (Chapter 300), or

Streptococcus pyogenes. Such patients usually respond to specific antibiotic therapy, although staphylococcal infections may be particularly virulent and cause destructive pulmonary lesions. Corticosteroid use is a risk factor for invasive aspergillosis (Chapter 339), which occurs rarely after influenza.

In addition, during an outbreak of influenza, many less distinct syndromes are observed; patients may have viral tracheobronchitis (Chapter 96), milder forms of localized viral pneumonia, or mixed viral and bacterial infection. Many such patients respond to antibiotics. Immunocompromised hosts, including transplant recipients and acute leukemia patients undergoing chemotherapy, may have high rates of pneumonia and associated mortality after influenza if they are not treated with appropriate antiviral and antimicrobial medications.

Nonrespiratory Complications

Severe influenza, including both pandemic H1N1 and avian H5N1 or H7N9 disease, may be associated with sepsis syndrome (Chapter 108), acute renal insufficiency (Chapter 120), and multiorgan failure. Lymphopenia and thrombocytopenia are common in severe influenza; the hemophagocytic syndrome and disseminated intravascular coagulation (Chapter 175) can occur. Myositis with tender leg muscles and elevated serum creatine kinase levels is uncommon in adults, but rhabdomyolysis (Chapter 113) can be severe and cause myoglobinuria. Pregnant women have increased risk of premature labor and spontaneous abortion. Toxic shock syndrome (Chapter 288) caused by respiratory tract infection with toxin-bearing *S. aureus* or *Streptococcus pyogenes* can occur, and outbreaks of meningococcal infection (Chapter 298) have been associated with both influenza A and B virus infections. Myocarditis (Chapter 60) or pericarditis (Chapter 77) occurs uncommonly. Neurologic complications can include aseptic meningitis (Chapter 412), myelitis (Chapter 411), encephalopathy (Chapter 414), necrotizing encephalitis, postinfluenzal Guillain-Barré syndrome (Chapter 420), or immune-mediated encephalitis or cerebellitis. Reye's syndrome (Chapter 150), which is a well-recognized hepatic and central nervous system complication of influenza A and B virus infections in children and rarely in adults, is associated with salicylate use. Possible associations with late-onset Parkinson's syndrome or with neuropsychiatric disorders in the offspring of women experiencing intrapartum infection remain uncertain.

DIAGNOSIS

In an individual case, influenza often cannot be distinguished from infection with a number of other viruses or nonviral pathogens that produce similar clinical manifestations (Chapters 96 and 429). Conversely, when public health authorities report an epidemic of influenza in a given community and an adult patient is seen with typical febrile respiratory illness, it is highly likely that these symptoms are caused by an influenza A or B virus infection.[5] In such circumstances, the presence of fever and cough has a positive predictive value of about 80% for laboratory-proven influenza in ambulatory adults. However, the predictive value of influenza-like illness in hospitalized patients is lower.

Detection of viral RNA by nucleic acid amplification testing (NAAT) is more sensitive than viral culture and is the rapid test of choice for patients who are hospitalized with suspected influenza infection. Some commercial multiplex assays that detect influenza and a variety of other respiratory viruses can be completed within 1 to 2 hours.

By comparison, commercially available rapid influenza diagnostics tests, which can detect influenza virus antigens in less than 15 minutes, have low sensitivity (<20 to 70%) in adults, so negative results should not guide individual treatment decisions. However, such tests may be helpful in investigating outbreaks while awaiting more definitive test results. The limited specificity (generally 90 to 95%) of some rapid tests makes their predictive value low outside the influenza season, although optical readers appear to enhance their reliability.

Viral culture of nasal, sputum, or tracheal secretions during the first 2 or 3 days of illness is more sensitive than rapid influenza diagnostic tests, but results usually take 48 to 72 hours. Serologic methods are less useful clinically because they require convalescent serum obtained 14 to 21 days after the onset of infection.

Detection of secondary bacterial infections generally relies on standard microbiological studies (e.g., blood culture, sputum Gram stain and culture, urinary antigen testing). In hospitalized patients, a low serum procalcitonin level may help discriminate viral from mixed influenza-bacterial pneumonia (Chapter 97).

PREVENTION

Vaccination

Annual influenza immunization is recommended for all persons aged 6 months or older in the United States (Chapter 18).[6] Persons at higher risk for influenza-related complications or who care for or are exposed to them remain particular priorities of immunization efforts (see Table 364-4), especially when vaccine delays or shortages occur. Influenza vaccine policies differ across countries. Because influenza immunization benefits both mother and infants, the WHO has ranked pregnant women as the highest priority, followed (in no particular order) by health care workers, children 6 to 59 months of age, the elderly, and individuals with high-risk conditions.

Seasonal vaccine should be given each year in the fall as soon as available, preferably by October before the influenza season in northern temperate areas. Quadrivalent vaccines with two A (H1N1, H3N2) and two B lineage (Yamagata, Victoria) antigens are increasingly replacing trivalent vaccines. In recent seasons, pandemic 2009 virus has been incorporated as the H1N1 component.

Egg-grown intramuscularly administered inactivated influenza vaccines for persons 6 months of age and older, a high-dose inactivated vaccine for persons aged 65 years and older, and a live-attenuated intranasal vaccine for otherwise healthy persons aged 2 to 49 years are currently licensed in the United States (E-Table 364-E1). An intradermally administered inactivated vaccine, a mammalian cell culture-grown vaccine, and a recombinant DNA-produced HA vaccine, particularly useful in those with serious egg allergies, are also available for seasonal use. Racial and ethnic disparities in influenza vaccination rates persist, and rates for other target groups, including health care workers, remain suboptimal. Immunization of health care personnel, which represents an important patient safety issue, can be enhanced by strategies to improve access, and especially by employer mandates.

Inactivated vaccines (Chapter 18) given by intramuscular injection provide about 50 to 70% protection against seasonal influenza illness in young and middle-aged adults, albeit with substantial year-to-year variations in effectiveness,■ and reduce work absenteeism, use of health care resources, and antibiotics when the vaccine is well matched to the epidemic strain. Live-attenuated vaccines are highly protective against influenza in children but appear less effective in adults compared with inactivated vaccine.■ Inactivated pandemic 2009 H1N1 vaccines are highly immunogenic in older children and adults after one standard 15-μg HA dose, perhaps in part related to preexisting immunity, and the effectiveness of monovalent pandemic 2009 H1N1 vaccine ranges from 60 to 93%.

Immunogenicity and hence protection rates with inactivated seasonal vaccines are lower in elderly persons, particularly infirm nursing home residents, and in immunosuppressed patients. The effectiveness of influenza vaccine for prevention of medically attended acute respiratory illness among the elderly in nursing homes is estimated to be 20 to 40%. In ambulatory high-risk patients, immunization reduces hospitalizations from pneumonia, influenza, and major cardiovascular events,■ as well as all-cause mortality during the influenza season. Higher-dose inactivated vaccines (four-fold more HA per strain) are more immunogenic and protective than standard vaccine against seasonal influenza illness in older ambulatory adults.■ Immunization of children appears to reduce respiratory illness in household and community contacts.■ Immunization of health care providers reduces the risk of transmission to patients as well as their own risk of infection.[7] Maternal immunization benefits both mother and child.

Because protection is greatly reduced or absent in some seasons and some patient groups, new vaccines with improved immunogenicity are being developed. Oil-in-water adjuvants (e.g., MF-59, AS03) are immunogenic at lower HA doses and appear to be especially effective for inducing adequate immune responses to novel influenza viruses like avian H5N1 and H7N9. For H5 and H7 vaccines, two doses with an oil-in-water adjuvant appear to be necessary for adequate immunogenicity. An AS03-adjuvanted H5N1 vaccine (containing only 3.75 μg HA antigen) was approved for adults in the United States in 2013. Seasonal MF59-adjuvanted vaccine is approved in Europe and Canada for adults age 65 years and older, and a virosome-adjuvanted vaccine is approved in Europe. An AS03-adjuvanted vaccine provides somewhat greater protection in the ambulatory elderly.■

With inactivated vaccine, fever and systemic symptoms occur at rates comparable to those of adults given placebo but are more common in young children. Among adults, 25% or more may have mild local reactions at the site of injection. Ocular or respiratory symptoms have occasionally been

E-TABLE 364-1 CURRENTLY APPROVED INFLUENZA VACCINES IN THE UNITED STATES (2013-14 SEASON)*

VACCINE TYPE	SUBSTRATE FOR PRODUCTION	NO. COMPANIES	FDA-APPROVED AGE RANGE (YR)	ROUTE	DOSE IN ADULTS
Inactivated influenza vaccine, trivalent (IIV3), standard dose	Eggs	Multiple	≥0.5†	IM	0.5 mL containing 15 µg per HA antigen
Inactivated influenza vaccine, quadrivalent (IIV4)	Eggs	Multiple	≥0.5†	IM	0.5 mL containing 15 µg per HA antigen
Inactivated influenza vaccine, trivalent (IIV3), high dose	Eggs	1	≥65	IM	0.5 mL containing 60 µg per HA antigen
Inactivated influenza vaccine, trivalent (IIV3), cell culture (ccIIV3)	MDCK cells	1	≥18	IM	0.5 mL containing 15 µg per HA antigen
Inactivated influenza vaccine, trivalent (IIV3), intradermal	Eggs	1	18-64	Intradermal with special microinjection system	0.1 mL containing 9 µg per HA antigen
Recombinant inactivated influenza vaccine, trivalent (rIIV3)	Insect cells	1	18-49	IM	0.5 mL containing 45 µg per HA antigen
Live-attenuated influenza vaccine, quadrivalent (LIV4)	Eggs	1	2-49‡	Intranasal	0.2 mL

*Package inserts for U.S.-licensed vaccines are available at http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm093833.htm.
†Lower age limit of approval depends on specific vaccine product.
‡LAIV is approved only for otherwise healthy nonpregnant persons. It should be avoided in close contacts and caregivers of severely immunosuppressed persons who require a protected environment and in children and adolescents receiving concomitant aspirin therapy.
FDA = U.S. Food and Drug Administration; IM = intramuscular.

TABLE 364-5 ANTIVIRAL DOSE RECOMMENDATIONS IN ADULTS

DRUG	ROUTE	TREATMENT	PROPHYLAXIS	DOSE REDUCTIONS	COMMENT
Oseltamivir	Oral	75 mg bid	75 mg once daily†	CrCl ≤ 60 mL/min	Gastrointestinal and occasional CNS side effects
Zanamivir	Inhaled	10 mg bid	10 mg once daily†	Avoid in those with underlying airways disease	Training in use of the inhaler device is important
Peramivir*	Intravenous	600 mg single IV dose	Not studied	CrCl < 50 mL/min	Single dose approved for uncomplicated influenza in adults in US
Laninamivir*	Inhaled	40 mg once (Japan)	20 mg once daily for two days (Japan)	Avoid in those with underlying airways disease	Currently investigational in United States (US)
Zanamivir*	Intravenous	600 mg q12h	Not studied	CrCl < 80 mL/min	Currently investigational in US
Favipiravir*	Oral	1600 mg twice on day 1, 600 mg bid (Japan)	Not studied	Pending; avoid in pregnancy	Currently investigational in US; inhibitory for NAI-resistant viruses
Amantadine	Oral	100 mg bid	100 mg bid	Age > 64 yr, CrCl < 50-80 mL/min	Gastrointestinal and CNS side effects
Rimantadine	Oral	100 mg bid	100 mg bid	Age > 64 yr, CrCl < 10 mL/min, or severe hepatic dysfunction	Lower risk of CNS side effects than with amantadine

*Currently, intravenous zanamivir is available on a compassionate use/emergency investigational new drug (eIND) basis in the United States. Inhaled laninamivir is licensed in Japan; higher treatment doses (80 mg) are being studied in the United States. Oral favipiravir is approved in Japan but only for treating novel or reemerging influenza infections when other drugs are ineffective or not sufficiently effective; higher dose regimens are being studied in the United States.
†Full therapeutic doses for postexposure prophylaxis (i.e., twice-daily dosing) are appropriate for infections due to novel influenza viruses and in immunocompromised hosts.
The standard duration of treatment in uncomplicated illness is 5 days, except for laninamivir or IV peramivir, for which single doses suffice. A longer treatment duration (e.g., 10 days) should be considered for infections in seriously ill patients, immunosuppressed hosts, or infections caused by novel viruses. Higher doses (e.g., 150 mg or 225 mg twice daily) of oseltamivir have been used in patients with serious lower respiratory illness, immunocompromise, or infections by novel viruses. The duration of prophylaxis depends on the epidemiologic setting; durations of 2 weeks after immunization or 7 to 10 days for postexposure prophylaxis are appropriate. Antiviral prophylaxis may interfere with response to intranasal live-attenuated vaccine but not to intramuscular inactivated vaccine.
CNS = central nervous system; CrCl = creatinine clearance; NAI = neuraminidase inhibitor.

reported within 24 hours after administration but typically resolve quickly without specific treatment. Injection site reactions and systemic complaints (headache, fatigue, myalgia, arthralgia) are more frequent after the high HA content or oil-in-water adjuvanted inactivated vaccines. An AS03-adjuvanted pandemic 2009 H1N1 vaccine was associated with narcolepsy in children and adolescents, apparently related to a specific genetic predisposition.[8] Intranasal vaccine causes coryza and sore throat in adults.

Hypersensitivity reactions to residual egg proteins or other vaccine components occur rarely, and vaccine is contraindicated in persons with chicken egg anaphylactic hypersensitivity unless the patient has been desensitized. Inactivated vaccine does not cause exacerbation of asthma but is rarely associated with Guillain-Barré syndrome in older adults.

Medications

Inhaled zanamivir and oral oseltamivir are effective for chemoprophylaxis of both influenza[9] A and B virus infections, including postexposure prophylaxis in households (Table 364-5), with each reducing the risk of symptomatic influenza infections by about 60 to 80%. Because of widespread resistance, rimantadine and amantadine are no longer effective for prophylaxis or treatment. When an outbreak develops, unimmunized high-risk persons can be given chemoprophylaxis and inactivated vaccine simultaneously, with cessation of chemoprophylaxis after 14 days. Alternatively, if vaccine is not available or contraindicated, is a poor match, or if the patient is highly immunosuppressed, chemoprophylaxis may be continued for the duration of the community outbreak. When given to patients and staff alike, these drugs may be helpful in managing nosocomial outbreaks. Therapeutic doses (i.e., twice daily) should be considered for postexposure prophylaxis in immunocompromised hosts and in individuals exposed to novel influenza viruses to increase effectiveness and possibly reduce antiviral resistance emergence.

Most public health authorities do not advise routine use of antiviral chemoprophylaxis, largely because of concerns regarding promotion of antiviral resistance and drug availability. In the community setting, close monitoring and early initiation of antiviral treatment is an alternative approach after suspected influenza exposures. Chemoprophylaxis is generally not recommended if more than 2 to 3 days have elapsed since exposure to a person with seasonal influenza.

Precautions

Upon entry to a health care facility, source control (e.g., facemask placement) and instruction in respiratory hygiene and cough etiquette should be implemented for symptomatic patients. Patients hospitalized with suspected or proven influenza should be managed with standard and droplet precautions and, when possible, private rooms. Facemasks likely provide some degree of protection during routine patient care, but compliance with a properly fitted N95-type respirator provides better protection. A N95-type respirator should be used with other precautions (including gloves, gown, and eye protection with face shield or goggles; an airborne infection isolation room) during aerosol-generating procedures. Other strategies for preventing nosocomial influenza include influenza vaccination of both health care providers and patients, appropriate management of ill health care providers, and engineering infection-control measures (e.g., adequate air exchanges). Early implementation and compliance with masks and hand hygiene appears to reduce the risk of secondary infections in household contacts.

The risk of zoonotic infections can be reduced by avoiding exposure to potentially infectious poultry or swine or their environments in affected countries. Of note, while the highly pathogenic H5N1 virus causes lethal poultry outbreaks, the low pathogenic H7N9 virus does not cause discernible illness in affected birds.

TREATMENT Rx

Inhaled zanamivir and oral oseltamivir (see Table 364-5) are active against both influenza A and B viruses.[10] Antiviral treatment is recommended as soon as possible for patients who have proven or suspected influenza and who manifest severe, complicated, or progressive illness; are hospitalized; or have underlying conditions that increase the risk for complications (see Table 364-4), including adults older than 64 and children younger than 5 (especially those < 2 years). In patients with serious illness or high-risk conditions, decisions about initiating antiviral therapy should not wait for laboratory confirmation of influenza. Treatment within 2 days of the onset of symptoms also may be considered in low-risk outpatients with uncomplicated febrile illness, in whom therapy reduces the duration of symptoms by 1 to 2 days, the time to functional recovery, and the risk for lower respiratory complications that lead to antibiotic use. Early oseltamivir therapy also decreases the risk for pneumonia and hospitalization, and even delayed use appears to reduce mortality in hospitalized patients. Double-doses of oseltamivir do not appear more effective than standard doses even though they clear influenza B viruses more rapidly. Longer courses (e.g., 10 days) and perhaps higher doses are warranted in critically ill patients and immunocompromised hosts, in whom monitoring for virologic clearance is warranted. A single dose of intravenous peramivir appears to be as effective as a 5-day regimen of oseltamivir in treating uncomplicated influenza.

During therapy, the emergence of oseltamivir resistance is infrequent but is more common in children and immunocompromised hosts; it has developed in H5N1 and pandemic 2009 H1N1 infections owing to a specific NA substitution (H275Y). Global circulation of oseltamivir-resistant seasonal H1N1 viruses in 2008-2009 and other resistance-conferring NA substitutions in avian H7N9 virus during neuraminidase therapy highlight the need for ongoing susceptibility monitoring for it and other neuraminidase inhibitors.[11] Zanamivir is inhibitory for most oseltamivir-resistant variants, including those with

H275Y, and intravenous zanamivir is currently preferred for treating severe infections that are suspected or proven to be oseltamivir-resistant. Agents with other mechanisms of action, such as the polymerase inhibitor favipiravir, are inhibitory for neuraminidase-resistant variants. Inhaled zanamivir may be infrequently associated with bronchospasm, sometimes severe, and nebulization of the lactose-containing commercial form is contraindicated in intubated patients. Oseltamivir is associated with nausea, vomiting, rash, and possibly rare neuropsychiatric symptoms. Oral rimantadine or amantadine shortens the duration of fever and symptoms in uncomplicated influenza A caused by susceptible strains (see Table 364-5), but these drugs are not currently recommended for use because of widespread antiviral resistance.

Symptomatic measures include antipyretics and cough suppressants. Salicylates should not be used, especially in children younger than 16 years, because of their association with Reye's syndrome.

Fulminant influenza viral pneumonia, particularly following pandemic H1N1 or avian influenza infection, requires intensive care including ventilatory support (Chapter 105), often renal replacement therapy, and sometimes even extracorporeal membrane oxygenation. Early oseltamivir appears to reduce mortality in patients if it is initiated before onset of respiratory failure. Intravenous formulations of zanamivir provide reliable delivery of high drug levels in seriously ill persons and are available for compassionate use in the United States. Intravenous peramivir, intravenous ribavirin, aerosolized ribavirin, nebulized zanamivir, and a triple drug regimen of amantadine, ribavirin, and oseltamivir have been used with uncertain benefit. Timely administration of convalescent plasma or hyperimmune globulin-containing neutralizing antibodies appeared effective in reducing mortality in critically ill patients during the H1N1 pandemic. Adding sirolimus to oseltamivir accelerated viral clearance and clinical recovery in mechanically ventilated pandemic 2009 H1N1 patients, but this combination remains investigational for treating influenza.[12] By comparison, the combination of oseltamivir and zanamivir appears to be inferior to oseltamivir monotherapy. Systemic corticosteroids given for influenza-associated pneumonia or ARDS have been associated with prolonged viral replication, adverse effects, and increased mortality, so their routine use should be avoided.[13]

Adults admitted with community-acquired pneumonia (Chapter 97) during the influenza season should initially receive both antiviral therapy and antibiotics, with subsequent therapy guided by microbiological study results. Intensive care unit complications, including ventilator-associated pneumonia, are common.

PROGNOSIS

Most influenza patients make a full recovery, but they may require several weeks to return to full function. Influenza in elderly persons can cause prolonged loss of function and impairment of activities of daily living. The mortality from seasonal influenza or pandemic 2009 H1N1 illness has been low (≈1 in 10,000 persons), but their impact differs across age and risk groups. Although approximately 90% of seasonal influenza-related deaths occur in persons who are older than 65 years or at high risk because of comorbid conditions, most pandemic 2009 virus deaths have been in patients younger than 65. Mortality occurs in about 5 to 10% of adults hospitalized with seasonal influenza but is as high as 40 to 60% in zoonotic H5N1 and H7N9 infections. Bacterial infections (Chapter 97) were associated with more than 90% of fatal pneumonias in the 1918 pandemic and about 20 to 40% in the 2009 H1N1 pandemic.[14] Detection of viral RNA in the blood is a poor prognostic finding that may reflect high viral burden in the lower respiratory tract.[15] Once viral pneumonia progresses to respiratory failure, the mortality rate is often 50% or higher, but the risk is reduced by early antiviral therapy and high quality intensive care support.

REVIEW QUESTIONS

1. A 23-year-old woman who is 6 months pregnant presents with fever, increasing cough, and dyspnea of 4 days' duration during a known community outbreak of influenza. Physical examination shows T 39° C, P 110, R 25, Sao_2 (room air) 92%, bibasilar crackles, 2/6 systolic murmur at left heart border, and 1+ pretibial edema bilaterally without cords or calf tenderness. Abdomen shows gravid uterus with normal fetal heart sounds. Nose swab is negative for influenza antigen by rapid test. WBC count is 4000 with 75% PMNs, 15% lymphs, and 10% monos. Chest radiograph shows patchy bilateral mid- and lower lung zone densities. Lower extremity ultrasound shows no evidence for deep venous thrombosis. You administer oxygen, hospitalize her, request urgent maternal-fetal and pulmonary consultations, and in the meantime decide to start which of the following regimens:

A. Antibiotics for community-acquired pneumonia (CAP), acetaminophen, and oral oseltamivir
B. Antibiotics for CAP, acetaminophen, and systemic glucocorticoids
C. Inhaled zanamivir and oral oseltamivir
D. Oral oseltamivir, systemic corticosteroids
E. Antibiotics for CAP, acetaminophen, and antitussives

Answer: A Pregnant women are at increased risk for complications of influenza, with their risk increasing across trimesters and extending into the early postpartum period. This patient appears to be rapidly deteriorating, with progression toward acute respiratory distress syndrome (ARDS) and requires urgent intervention. The negative rapid influenza antigen test and the delay in presentation from onset of symptoms should not dissuade empirical use of antiviral therapy. The possibility of bacterial coinfection mandates the use of antibiotics pending microbiological studies. The combined use of two neuraminidase inhibitors has not been shown to be superior to oseltamivir alone, and in one trial an inhaled zanamivir-oral oseltamivir regimen was inferior in uncomplicated influenza in adults. Systemic corticosteroids have not been associated with improved outcomes in severe influenza, and observational studies indicate an increased risk of secondary infections, other complications, and even mortality in patients with pandemic H1N1 pneumonia and/or ARDS.

2. A 55-year-old woman presents for routine follow-up in late November. Aside from moderate obesity (BMI 32) and long-term smoking of ½ pack per day, she has no recognized chronic medical conditions. She has refused influenza vaccines in the past, claiming egg allergies, and is often noncompliant with her scheduled visits. She reports experiencing tongue swelling after ingesting eggs. You advise:

A. Intramuscular recombinant hemagglutinin vaccine
B. Oral egg protein challenge in the office, followed by standard intramuscular vaccine
C. Intranasal live-attenuated influenza vaccine
D. Intradermal influenza vaccine
E. Allergy consultation, followed by desensitization if necessary and standard intramuscular vaccine

Answer: A Standard inactivated vaccine, intradermal vaccine, and live-attenuated intranasal vaccine are all produced in eggs and contain egg proteins. The risk of anaphylactic egg allergy may be significant in this patient, and an allergy evaluation is one course of action. However, the influenza season may well begin shortly, and her history of missing appointments may indicate that this may be the only opportunity to immunize her in advance of the season. The recombinant vaccine is produced in insect cells and does not contain egg proteins.

3. A 60-year-old man who returned 2 days ago from a business trip to Shanghai presents to the emergency department with 3 days of fever, fatigue, and nonproductive cough in January. He denies sore throat or coryza but reports nausea. None of his travelling companions report illness. He recalls having walked through various marketplaces during his trip but does not recall seeing live poultry. His physical examination shows T 38.5° C, P 95, R 18, chest clear. A rapid antigen test is negative for influenza. After consultation with local public health authorities, you submit a nasopharyngeal swab for diagnostic testing, start oral oseltamivir, and hospitalize him for close observation. On the following day, the swab is reported negative for respiratory viruses, but he has developed worsening cough and respiratory distress, with Sao_2 of 85% on a 5 L/min facemask. Chest radiographs show bilateral ground glass opacifications. WBC count is 3.0 with 10% lymphocytes; platelets 95,000; serum creatinine 1.2 mg/dL. Electrocardiogram shows nonspecific ST-T wave changes; serum troponin is normal. Antibiotics are started, pulmonary consultation is requested, and he is intubated for mechanical ventilator support. Gram stain of a tracheal aspirate shows some PMNs but only rare bacterial forms. Reverse-transcription polymerase chain reaction (RT-PCR) on the aspirate is positive for influenza A. You decide to adjust his regimen by:

A. Switching to intravenous zanamivir
B. Doubling oral oseltamivir dose by nasogastric tube
C. Adding inhaled zanamivir
D. Adding amantadine
E. Adding systemic glucocorticoids

Answer: A His recent travel history raises concern of avian H7N9 infection (also consistent with the paucity of upper respiratory symptoms and negative initial nasopharyngeal RT-PCR for influenza and other respiratory viruses), but other influenza A viruses including A(H1N1)pdm09 are also circulating, and the first case of avian H5N1 in North America occurred in a Canadian traveler returning from Beijing. The patient is rapidly progressing, with apparent viral pneumonia despite initial oseltamivir therapy. Although multiple conditions warrant consideration (e.g., secondary bacterial infection, pulmonary emboli, heart failure from infarct or myocarditis), there are also the concerns that oseltamivir may not be adequately absorbed in critically ill patients and that oseltamivir resistance can emerge rapidly. Limited data indicate that extemporaneous preparations of oral oseltamivir can be effectively administered by nasogastric tube in mechanically ventilated patients, but double doses of oseltamivir do not appear more effective than standard ones. Intravenous zanamivir provides reliable delivery of high drug levels and is active against most but not all oseltamivir-resistant variants. Amantadine is not active for currently circulating human influenza A viruses, avian H7N9, or most avian H5N1 viruses. The commercial formulation of inhaled zanamivir should not be used in mechanically ventilated patients.

365 ADENOVIRUS DISEASES

MICHAEL G. ISON

DEFINITION

Human adenoviruses, which are members of the Adenoviridae family and the *Mastadenovirus* genus, are divided into 57 serotypes and seven species (A, B, C, D, E, F, and G; Table 365-1). Adenoviruses are double-stranded DNA, nonenveloped viruses that code for 20 early and 15 late proteins. The knobbed fiber protrudes from the fiber base (E-Figure 365-E1).

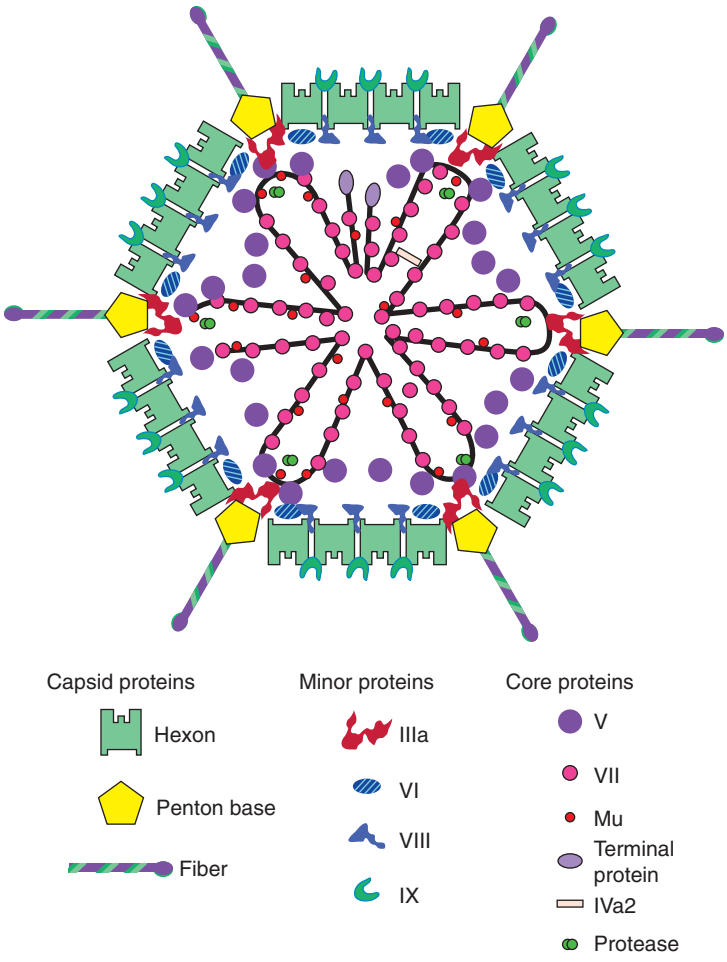
EPIDEMIOLOGY

Adenoviruses cause a range of infections from mild self-limited respiratory viral infections, conjunctivitis, and diarrhea to severe disseminated disease.[1] Adenoviruses have a worldwide distribution, and infections occur throughout the year without significant seasonal variability. Most infections occur as sporadic events, although local or regional epidemics have been described. Asymptomatic respiratory infection is common and is associated with

TABLE 365-1 ADENOVIRUS SUBGROUPS & SEROTYPES WITH THEIR MAJOR SITES OF INFECTION

SUBGROUP	SEROTYPE	MAJOR SITE OF INFECTION
A	12, 18, 31*	Respiratory, urinary, GI
B1	3, 7, 16, 21, 50	Respiratory, eye (including pharyngoconjunctival fever), GI
B2	11,† 14,‡ 34,† 35†	Urinary tract infections
C	1, 2, 5, 6, 57	Respiratory, urinary, GI (especially hepatitis)
D	8§-10, 13, 15, 17, 19,§ 20, 22-30, 32, 33, 36, 37§-39, 42-49, 51, 53, 54, 56	Eye, GI
E	4	Upper respiratory tract infection, pneumonia
F	40,* 41*	GI
G	52	GI

*Associated with infantile gastroenteritis.
†Associated with hemorrhagic cystitis and interstitial nephritis.
‡Associated with epidemic pneumonia with high mortality.
§Associated with epidemic keratoconjunctivitis.
GI = gastrointestinal.



E-FIGURE 365-1. Adenovirus.

prolonged carriage, particularly in feces and tonsilar tissue. Most patients with adenovirus infection are children, generally younger than 5 years, and most individuals have serologic evidence of exposure to adenovirus by age 10. Only about 25% of symptomatic cases occur in adults. AdV1, 2, and 5 are most common among children, whereas AdV3, 4, and 7 are more common in adults.

Recent outbreaks in the United States have resulted in cases requiring hospitalization, and nosocomial transmission can cause severe infections in health care workers. Adenovirus is the leading cause of respiratory viral infections among military recruits. Unlike the year-round circulation of adenovirus in civilians, peaks of disease are recognized within the first 4 weeks of fall training exercises among military recruits.[2] Rates of adenovirus among military recruits declined significantly with widespread use of an oral live-attenuated vaccine in 1971, increased when supplies of vaccine were depleted by 1999, then declined again after an oral live-attenuated adenovirus type 4 and 7 vaccine was approved in 2011 (E-Figure 365-E2).

PATHOBIOLOGY

Adenoviruses enter susceptible hosts by the mouth, nasopharynx, or ocular conjunctiva. The fiber protein of the virus binds to a cellular receptor that varies by serotype. Upon initial infection, local replication can induce considerable cellular damage owing to tissue invasive infection. Necrotizing bronchitis, bronchiolitis, interstitial pneumonia, and fibrin and hyaline membranes are seen within the alveoli during pulmonary infections. In ocular infections, exudative and mononuclear infiltrates develop beneath the epithelium. Replication results in desquamated epithelial cells, which induce hypertrophy in regional lymphatic tissue and active proliferative germinal centers. This reaction can cause swollen adenoids or intussusception (Chapter 142) associated with enlarged mesenteric lymph nodes, particularly in children.[3]

Components of both the innate and adaptive immune responses are important for the control of adenovirus replication. Alveolar macrophages and Kupffer cells help eliminate adenovirus from the lung and liver and also secrete inflammatory cytokines such as tumor necrosis factor (TNF), interferon (IFN)-γ, interleukin (IL)-1β, IL-6, IL-8, and IL-12. $CD4^+$ and $CD8^+$ T lymphocytes play a particularly important role in the control and clearance of replicating adenovirus in humans, and the absolute lymphocyte and $CD4^+$ T-lymphocyte levels correlate inversely with adenovirus infection and the risk for developing disseminated adenoviral infections in immunosuppressed transplant patients.[4]

Both group- and type-specific neutralizing and non-neutralizing antibodies are produced in response to infection and also play a role in limiting infection. Group-specific antibodies do not neutralize the virus but can confirm infection. Neutralizing antibodies may protect against disease manifestations in the previously infected host or against reinfection with the same serotype, but they do not eliminate the carrier state.

CLINICAL MANIFESTATIONS

Adenovirus infections have a wide range of clinical manifestations that are linked to the virus type (see Table 365-1) as well as to the age and immunocompetence of the host. Common syndromes include infections of the respiratory tract, eye, gastrointestinal tract, genitourinary tract, and central nervous system (CNS). Disseminated infection also occurs, especially in immunosuppressed patients.

Respiratory Tract Infections

About 10% of pneumonias in childhood and up to 5% of community-acquired pneumonias in some series of adults[5] may be attributable to adenovirus. Typical symptoms include nasal congestion, coryza, and cough, which may mimic pertussis infections (Chapter 313). Generalized malaise, fever, chills, myalgia, headache, and abdominal pain are common systemic symptoms. Exudative tonsillitis and cervical adenopathy are also seen. If conjunctivitis accompanies these signs and symptoms, the disease is designated as pharyngoconjunctival fever.[6] Otitis media is a common presentation, particularly among infants under 1 year of age. Cases in children and in adults, especially military recruits, are indistinguishable from other viral respiratory infections such as influenza (Chapter 364), parainfluenza (Chapter 363), and respiratory syncytial virus (Chapter 362).

Ocular Infections

The two most common manifestations of ocular adenovirus infection are pharyngoconjunctival fever and epidemic keratoconjunctivitis. Pharyngoconjunctival fever is typically a mild form of acute follicular conjunctivitis that accompanies febrile pharyngitis or cervical adenitis following a 6- to 9-day incubation period and may affect both eyes. Both bulbar and palpebral conjunctival involvement may occur. Swimming pools or lakes are a common source of infection. Symptoms typically resolve without treatment and without sequelae.

Unlike pharyngoconjunctival fever, epidemic keratoconjunctivitis is a more serious disease, with edema of the eyelids, pain, lacrimation, and photophobia. Painful corneal opacities may occur, although they typically resolve over time. The disease typically involves just one eye, is self-limited, and rarely results in permanent corneal damage, although recovery may take up to 4 weeks.[7]

Gastrointestinal Tract Infections

Adenovirus can infect any part of the gastrointestinal tract and cause fever, nausea, vomiting, and diarrhea. Up to 10% of pediatric cases of diarrhea are caused by adenovirus, often with symptoms persisting for 8 to 12 days. Some adenoviruses can also cause mesenteric adenitis, which may clinically mimic appendicitis and rarely result in intussusception (Chapter 142). Adenovirus inclusions are seen in about one third to one half of appendices removed at surgery.

Genitourinary Tract Infections

Hemorrhagic cystitis, which typically manifests as microscopic or macroscopic blood in the urine and pain and cramping of the bladder, has been reported in children with AdV 11 and 21 infection. Adults can present with urethritis with or without cystitis due to AdV 19 and 37. Both diseases typically resolve over time without intervention.

Other Manifestations of Adenovirus

Meningitis (Chapter 412) and encephalitis (Chapters 383 and 414) have been reported occasionally in association with adenovirus infection. Adenovirus infection also can cause myocarditis and dilated myocardiopathy (Chapter 60).

A number of studies have found an association between detection of adenovirus in amniotic fluid associated with abnormal fetuses. In particular, echogenic liver lesions with or without hydrops and neural defects in fetuses were more common with patients with adenovirus detected in the amniotic fluid.

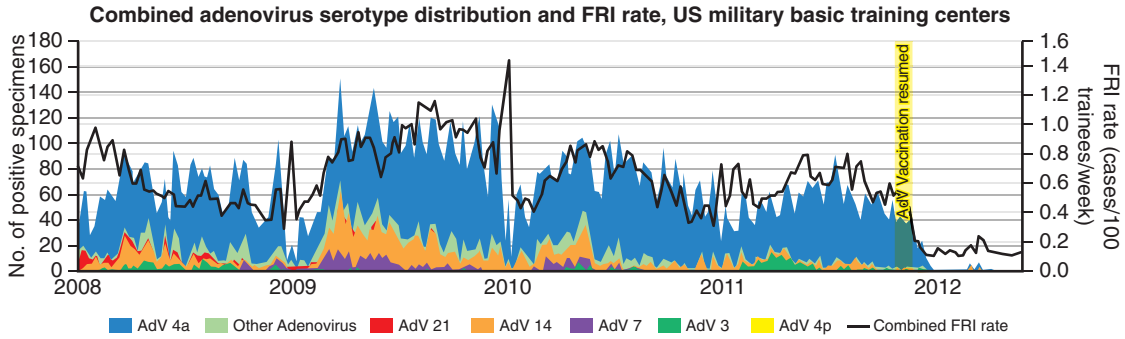
Adenovirus Diseases in Immunocompromised Patients

Primary adenovirus infection or reactivation of infection causes a wide range of infectious syndromes in immunocompromised children and adults. In the hematopoietic stem cell transplantation (HSCT) population (Chapter 178), the incidence of disease ranges from 3 to 47%.[8] Risk factors include an allogeneic transplant, T cell–depleted grafts, use of alemtuzumab, and acute graft-versus-host disease (GVHD).

Severe respiratory disease, hepatitis, colitis, hemorrhagic cystitis, and adenoviral keratoconjunctivitis can occur. Severe lymphopenia (<300 cells/μL) is associated with disseminated disease.[9] Although disseminated disease only effects 1 to 7% of HSCT recipients, it is associated with a significant risk of mortality (8 to 26%).

Among various solid organ transplant recipients, asymptomatic adenovirus viremia is common. However, progression to symptomatic disease is more common in small bowel and liver transplant recipients, pediatric transplant recipients, patients who receive antilymphocyte antibodies, and patients with donor-positive/recipient-negative adenovirus status.[10] Adenoviral hepatitis, typically caused by AdV 1, 2, or 5, is most common among liver transplant recipients and can be diagnosed by detection of viremia or visualization of viral intranuclear inclusions on biopsy. Adenovirus enterocolitis occurs in small bowel transplant recipients and may mimic rejection. Adenoviral pneumonia is associated with graft loss, death, or progression to obliterative bronchiolitis for lung transplant recipients. Adenovirus causes hemorrhagic cystitis with or without interstitial nephritis in kidney transplant recipients. Adenovirus DNA in biopsy specimens is associated with worse outcomes among pediatric heart transplant patients.

Primary adenoviral infections can cause severe, frequently fatal disease in children with primary immunodeficiency syndromes, including severe combined immunodeficiency disease (Chapter 250). Fatal cases have been reported in patients with acquired immunodeficiency syndrome (AIDS), but most are self-limited, particularly in patients on highly active antiretroviral therapy or without significant CD4 lymphopenia.



E-FIGURE 365-2. Adenovirus serotype distribution in U.S. military basic training centers before and after reintroduction of adenovirus vaccination. FRI = febrile respiratory illness. (From Hoke CH Jr, Snyder CE Jr. History of the restoration of adenovirus type 4 and type 7 vaccine, live oral [Adenovirus Vaccine] in the context of the Department of Defense acquisition system. *Vaccine.* 2013;31:1623-1632.)

DIAGNOSIS

Diagnosis of adenovirus depends on isolation of the virus from infected tissue and either histopathologic evidence of local replication or clinical symptoms consistent with infection. Detection of virus alone is not diagnostic of an adenovirus disease, because the virus can be latent in some tissues and can be intermittently shed from the throat or in the stool for months to years after primary infection. Quantitative polymerase chain reaction (PCR) has a higher diagnostic yield than culture or direct fluorescent antigen detection. Quantitative PCR assays are also useful to predict progression to disseminated disease in pediatric and, to a lesser extent, adult HSCT recipients and to determine response due to therapeutic interventions.

TREATMENT

Rx

No antiviral agents are specifically approved for the treatment of adenovirus. Cidofovir, which is a potent inhibitor of adenovirus in cell culture, has been used (either 5 mg/kg weekly for 2 weeks, then every other week or 1 mg/kg three times a week), but data suggest that its efficacy/toxicity (predominantly nephrotoxicity) ratio is too narrow to be clinically useful, except perhaps as preemptive treatment of pediatric HSCT patients with persistent or rising adenovirus viral loads. Ribavirin has not been helpful.

Brincidofovir, an experimental drug, is not nephrotoxic and is under active study in pediatric HSCT patients, in whom it has been generally well tolerated and shown to suppress adenovirus compared with placebo.[11] Further trials are ongoing. A newer approach using adenovirus- and multivirus-specific T cells is also being studied in prospective trials.[12]

PREVENTION

Strict attention to contact and droplet precautions can prevent health care–associated and institutional outbreaks of adenovirus infections, including epidemic keratoconjunctivitis. An oral live-attenuated AdV 4 and 7 vaccine is well tolerated, with a vaccine efficacy of 99.3%.[A1] Currently, the vaccine is only indicated and available to U.S. military personnel, ages 17 to 50 years.

PROGNOSIS

Prognosis is strongly linked to immune competence. Immunocompetent patients typically have self-limited illnesses that can be generally managed with symptomatic care, although some epidemics, including an AdV 14 epidemic, have resulted in high case-fatality rates.[13] In immunocompromised adults, persistent or rising adenovirus viremia predicts progressive infection and may encourage reduction of immunosuppression and institution of antiviral therapy in some cases, especially because viremia can clear without specific intervention when lymphocyte recovery occurs.

REVIEW QUESTIONS

1. In early October, a U.S. Army recruit in week 3 of his basic training exercises presents with a febrile respiratory illness consisting of minimally productive cough, fever, rhinorrhea, mild conjunctival injection, and cervical lymphadenopathy. A chest radiograph demonstrates bilateral scant infiltrates. Several other members of his troop have had a similar illness. He was appropriately vaccinated, including oral adenovirus vaccine. Which virus is likely the cause of this recruit's illness:

A. Influenza A/H1N1
B. Influenza A/H3N2
C. Adenovirus 14
D. Influenza B
E. Rhinovirus

Answer: C Adenovirus 14. Adenovirus is the most common cause of respiratory viral infection among military recruits. Typical symptoms include minimally productive cough, fever, rhinorrhea, mild conjunctival injection, and cervical lymphadenopathy. Influenza typically occurs from late November until early March. Although rhinovirus also circulates during this season, it is unlikely to cause an infection as severe as described. Additionally, because recruits are now getting adenovirus live-attenuated vaccine that includes types 3 and 7, adenovirus type 14 has become a frequent cause of infection.

2. A 30-year-old woman presents to your office with conjunctivitis, edema of the eyelids, pain, lacrimation, and photophobia. What is the most likely information to discuss with the patient?

A. The disease is likely caused by adenovirus 8, 19, or 37.
B. Blurry vision is common and likely will require missing work.
C. The problem will typically involve only one eye.
D. The infection is contagious, so careful hand hygiene and not sharing anything that touches her eye is critical.
E. All of the above

Answer: E All of the above. This is a case of epidemic keratoconjunctivitis (EKC). EKC typically is associated with a follicular conjunctivitis with edema of the eyelids, pain, lacrimation, and photophobia that develop after an 8- to 10-day incubation period. The hallmarks of the disease include significant pain and blurry vision that typically prevents patients from being able to work. Although bilateral disease has been described, involvement of a single eye is more typical. As symptoms improve over time, so will the vision, generally without any long-term effects on the eye or vision. The infection is highly contagious and can easily be spread to other members of the household or other patients if infection control is not fastidious.

3. An otherwise healthy 54-year-old woman presents to your office in July with a 3-day history of cough, nasal congestion, generalized malaise, fever, myalgias, tonsillitis, and cervical adenopathy. Her chest radiograph is normal. You perform a multiplex respiratory virus polymerase chain reaction (PCR), which returns positive for adenovirus. What do you recommend?

A. Admission to the hospital for evaluation of fever
B. A single dose of intravenous cidofovir (1 mg/kg)
C. Moxifloxacin 400 mg daily for 7 days for prevention of bacterial superinfection
D. Symptomatic treatment with cough drops and acetaminophen
E. Report the case to the health department for contact tracing.

Answer: D Symptomatic treatment with cough drops and acetaminophen. This is a classic case of adenovirus upper respiratory tract infection. This infection is associated with cough, nasal congestion, generalized malaise, fever, myalgias, tonsillitis, and cervical adenopathy; if there is concomitant conjunctivitis, the syndrome is termed *pharyngoconjunctival fever*. The infection is clinically indistinguishable from other viral causes of upper respiratory tract infection. Infection will typically resolve over the course of several days, and symptomatic treatment is all that is indicated. This patient has no signs of lower tract disease (pneumonia on chest radiograph, shortness of breath), so more severe infection is unlikely.

CORONAVIRUSES

SUSAN I. GERBER AND LARRY J. ANDERSON

DEFINITION

Human coronaviruses were, until 2003, recognized as a frequent cause of common cold symptoms, occasionally a cause of lower respiratory tract disease, but rarely if ever a cause of serious disease. In 2003, a novel coronavirus was recognized in humans from animals as the etiologic agent of the outbreak of severe acute respiratory syndrome (SARS).[1,2] The SARS outbreak demonstrated that coronaviruses can be serious human pathogens and led to discovery of other novel human coronaviruses as well as multiple novel coronaviruses in bats, the likely reservoir for SARS coronavirus. Furthermore, in 2012, the Middle East respiratory syndrome (MERS) coronavirus emerged and provided another example of coronavirus's ability to cause severe human disease.[3,4]

The Pathogens

Coronaviruses are members of the family Coronaviridae, which includes two subfamilies, Coronavirinae and Torovirinae. Coronaviruses are single-stranded positive-sense RNA viruses with a genome of approximately 30 kD, the largest genome among RNA viruses. These viruses were named coronaviruses because by electron microscopy they have club-shaped surface projections that give them a crown-like appearance. The genome encodes four or five structural proteins (a spike protein [S], a small envelope protein [E], a membrane protein [M], a nucleocapsid protein [N], and sometimes a hemagglutinin-esterase protein [HE]), a varying number of open reading frames scattered among the structural genes, and a polyprotein that is processed into multiple (usually 16) nonstructural proteins. These nonstructural proteins participate in virus replication but are not incorporated into the virion. Coronaviruses have also been isolated from a variety of animals and birds and, in their respective species, cause a wide range of respiratory, gastrointestinal (GI), neurologic, and systemic illnesses. The coronaviruses are divided into four genera: alpha, beta, gamma, and delta. The 229E and NL63 viruses are alphacoronaviruses, whereas OC43 and HKU1 are betacoronaviruses. SARS and MERS are both betacoronaviruses but belong to different lineages. Detection and characterization of novel coronaviruses in bats has greatly expanded our understanding of diversity among coronaviruses and will likely continue to do so.

EPIDEMIOLOGY

The common human coronaviruses—229E, OC43, NL63, and HKU1—appear to be transmitted through close contact that probably includes contamination of hands from person-to-person contact or from fomites, followed by autoinoculation to the mucosal surfaces of the mouth, nose, or eyes or inhalation of infectious droplets and possibly aerosols. Symptoms occur 2 to 4 days after infection. These coronaviruses are detected in patients with acute respiratory illnesses, most often a mild upper respiratory tract illness (i.e., common cold) but also in patients with more serious respiratory illnesses including pneumonia, bronchiolitis, and croup. Coronavirus infections are detected early in childhood, and repeated infections can occur throughout life. About 50% of children have antibodies against OC43 by 3 years of age, and about 70% of adults have such antibodies. Up to 75% of children have antibodies against NL63 and 229E by 3 to 4 years of age. Studies looking for 229E- and OC43-like infections suggest that coronaviruses are associated with about 15% of cases of the common cold and with up to 10% of cases of acute respiratory illnesses in children and adults. Individually, 229E, OC43, HKU1, and NL63 are detected in less than 1 to 4% of cases, and their individual contributions will vary by location and year. Serious illness has been reported in outbreaks among elderly patients in nursing homes. In one outbreak associated with OC43 infection, for example, 23 residents and 24 staff reported influenza-like illness, and three residents died. However, some reports have found rates of detection of coronaviruses among hospitalized children with acute respiratory illness and/or fever to be similar to the rates of asymptomatic controls, thereby raising questions about the virus's role in more severe disease and hospitalization. The 229E, OC43, NL63, and HKU1 coronaviruses can be detected throughout the year, but peak detection is often during fall and winter months in temperate climates. A second respiratory viral pathogen can be detected in 20 to 60% of specimens positive for one of these coronaviruses.

Most documented SARS coronavirus infections in humans occurred in persons ill with a SARS-like illness during the 2002-2003 global outbreak. It is likely that wild animal markets in Guangdong Province, China, played a key role in amplifying and introducing the virus into humans, but the original source of the outbreak virus was likely bats. Detection of multiple SARS-like and other coronaviruses in bats suggests that they are a rich source of coronaviruses. A coronavirus recently isolated from bats has 95% nucleotide sequence identity to the SARS viruses and can infect humans via the ACE2 receptor. Although animals were the original source of human infections, global spread of SARS coronavirus occurred through human-to-human

transmission and involved droplet, fomite transmission and, in some instances, probably small-particle aerosol transmission. Most transmission occurred within households, hospitals, or other health care facilities; little transmission occurred in the community. The fact that most transmission occurred after the patient's illness had become serious and required hospitalization helps explain the importance of transmission in health care settings and the relative lack of transmission in the community.

More recently, MERS coronavirus emerged in the Arabian peninsula, with the first documented cases retrospectively identified in April 2012 in Jordan. Like the SARS coronavirus, detection of coronaviruses similar to the MERS coronavirus suggests that bats may be a source of this virus. There is, however, likely an intermediate host species. MERS coronavirus gene sequences and antibodies that neutralize MERS coronavirus have been reported in dromedary camels. These data suggest a role for camels in the transmission of MERS coronavirus. Person-to-person spread of virus has been documented primarily among family members in households and within healthcare settings,[5] although as of December 2013, there has been no evidence of sustained community transmission.[6] The incubation period has been estimated to be just over 5 days (range, 2 to 14 days), and sporadic cases of MERS coronavirus infections continue to be seen.

TABLE 366-1 PERCENTAGE OF HOSPITALIZED SARS AND MERS CORONAVIRUS–INFECTED PATIENTS WITH SELECTED CLINICAL AND LABORATORY FEATURES OF SARS AND MERS CORONAVIRUS INFECTIONS

	SARS	MERS
Clinical or Laboratory Finding	***At Hospital Admission***	***At Presentation***
Fever	90-100%	≈90-100%
Cough or shortness of breath	40-75%	83%
Diarrhea	20-30%	26%
Chest radiograph abnormalities	65-90%	100%
Lymphopenia*	50-90%	34%

*Both $CD4^+$ and $CD8^+$ lymphocyte counts are decreased.
MERS = Middle East respiratory syndrome; SARS = severe acute respiratory syndrome.
From Assiri A, Al-Tawfiq JA, Al-Rabeeah AA, et al. Epidemiological, demographic, and clinical characteristics of 47 cases of Middle East respiratory syndrome coronavirus disease from Saudi Arabia: a descriptive study. *Lancet Infect Dis.* 2013;13:752-761.

PATHOBIOLOGY

The human coronaviruses characterized to date infect humans through the respiratory tract. The sites where the virus then replicates is determined at least in part by which cells express the respective receptors. The receptors for 229E and NL63 coronaviruses are aminopeptidase N and angiotensin-converting enzyme 2 (ACE2), respectively. The receptors for OC43 and HKU1 coronaviruses have not yet been determined, but OC43 may use several cell surface molecules as receptors, including 9-*O*-acetylated neuraminic acid. The primary receptor for SARS coronavirus is ACE2, but the virus also binds to two C-type lectins expressed on dendritic cells, DC-SIGN and L-SIGN. Aminopeptidase N is expressed in various cells, including respiratory, GI, kidney epithelial, and myeloid cells, but 229E is known to infect only respiratory epithelial cells. ACE2 is found in various tissues, including the lung, GI tract, heart, and kidneys. The SARS coronavirus has consistently been detected in pneumocytes in the lung and enterocytes in the GI tract and is occasionally found in other cells, including distal tubular cells in the kidney and macrophages in various tissues. Autopsy studies suggest that infection in the lung leads initially to diffuse alveolar damage and later may lead to a repair process that includes fibrosis in the alveolar walls. It is not known whether NL63, which also uses ACE2 as its receptor, infects sites other than the respiratory tract. The MERS coronavirus receptor is the exopeptidase dipeptidyl peptidase 4 (DPP4), also known as CD26. DPP4 is found on many different cell types including non-ciliated bronchial epithelial cells, bronchiolar epithelial cells, alveolar epithelial cells, endothelial cells, and lung ex vivo organ cultures. In addition, DPP4 is expressed on the epithelial cells in kidney, small intestine, liver, and prostate as well as in activated leukocytes.

It is likely that the illness associated with coronavirus infections results from both the cytopathic effect of the virus and the host immune and inflammatory response to the viral infection. How this interplay contributes to disease, however, is not understood. The biphasic course of SARS in some patients, with the onset of severe disease in the second week of illness and the decrease in lymphocyte numbers, suggest a role for the host response and virus-induced immune suppression in the disease process. It is likely that the host response and virus-induced immune suppression also contribute to MERS coronavirus disease.

CLINICAL MANIFESTATIONS

229E, OC43, NL63, and HKU1 coronavirus infections are commonly associated with acute respiratory illnesses that are usually mild and consistent with the common cold (Chapter 361) but can also result in the full range of acute respiratory illnesses, including pneumonia (Chapter 97), croup (Chapter 429), bronchiolitis (Chapter 92), and bronchitis (Chapter 96). The best studied of these coronaviruses, human coronaviruses 229E and OC43, cause respiratory symptoms (e.g., rhinorrhea, nasal congestion, sore throat, cough) as well as systemic symptoms (e.g., fever, headache, malaise) when they are inoculated intranasally into adult volunteers. Symptoms develop 2 to 4 days after inoculation, but about 30% of volunteers who excrete virus have no associated illness. Symptoms usually persist for about 1 week but sometimes for as long as 3 weeks. Previous infection does not induce high levels of protective immunity. Humans can be reinfected with respiratory coronaviruses throughout life, and human volunteers can be symptomatically reinfected with the same strain of coronavirus 1 year after the first infection. As with other infections, the severity of disease varies among individual patients during the same outbreak and among groups of patients during different outbreaks in the same community.

In contrast to the mild illness associated with 229E and OC43, SARS coronavirus infection nearly always results in a serious illness that requires hospitalization, often in an intensive care unit (ICU), and a high fatality rate. Radiologic evidence of pneumonia was seen in nearly all SARS coronavirus–infected persons, and acute respiratory distress syndrome (Chapter 104) requiring admission to an ICU and mechanical ventilation developed in 20% or more of patients. The initial clinical manifestation of SARS was often systemic symptoms of fever, malaise, and myalgias from 2 to 10 days (rarely > 10 days) after exposure. Several days after the onset of systemic symptoms, lower respiratory tract symptoms of nonproductive cough and shortness of breath were noted. Unlike patients with other respiratory virus infections, the majority of patients never experience upper respiratory tract symptoms such as rhinorrhea, sore throat, or nasal congestion (Table 366-1). As with other infections, the expected signs and symptoms with SARS coronavirus infection initially may be obscured or not present in elderly patients or patients with underlying chronic illnesses. During the course of their illness, most SARS coronavirus–infected patients had elevated liver enzyme levels and lymphopenia, including a substantial drop in numbers of both $CD4^+$ and $CD8^+$ T cells. SARS coronavirus–infected patients with severe complications also often suffered complications associated with intensive supportive care, such as secondary bacterial infections. A more severe illness with infection has been associated with older age, underlying chronic illness, higher liver enzyme values, lower lymphocyte levels and platelet counts, and higher titers of virus or viral RNA. Asymptomatic or mild illness occurred but was uncommon. In studies of exposed health care workers and patients who did not have a SARS-like illness, less than 1% of those tested had definitive serologic evidence of SARS coronavirus infection (i.e., a positive neutralization test result). In general, children had less severe illness than adults did.

The clinical spectrum of MERS coronavirus illness ranges from asymptomatic infection to severe illness.[7] Symptoms include cough, fever, malaise, chills, arthralgias, rigors, and dyspnea. Approximately 25% of patients have GI symptoms that include diarrhea, vomiting, and abdominal pain. Patients who are severely ill have pneumonia that sometimes progresses to acute respiratory distress syndrome.[8]

Laboratory findings include leukopenia and lymphopenia, and some patients have thrombocytopenia and abnormal liver enzymes. Chest radiographic findings have included patchy infiltrates, lobar opacities, and similar to the SARS coronavirus, a ground-glass appearance.

DIAGNOSIS

Because illness is usually mild and there is no effective treatment, the diagnosis of 229E, OC43, NL63, and HKU1 coronavirus infections have not been important to the management of patients. The accurate diagnosis of SARS and MERS coronavirus infections, however, are critical for the management of individual patients and for the public health response to

reemergence of SARS coronavirus and the current circulation of MERS coronavirus in the Middle East.

229E, OC43, HKU1, and NL63 Coronavirus Infections

Coronavirus polymerase chain reaction (PCR) assays, which can be designed to detect both known and novel coronaviruses, are the assays of choice for diagnosis of infection. Most coronavirus PCR assays are type specific—that is, specific to MERS coronavirus, SARS coronavirus, 229E, OC43, HKU1, or NL63 RNA. Coronavirus diagnostic assays are becoming more generally available and are sometimes part of a PCR panel designed to detect respiratory viruses. Presence of the virus can also be inferred by electron microscopy and confirmed by in situ or immunohistologic assays of affected tissues. Positive immunohistologic and in situ hybridization studies document the site of infection and help support a link between the virus and the disease process. A variety of enzyme or fluorescent immunoassays for antibodies have been used successfully to detect infection. Most assays detect immunoglobulin (Ig)G antibodies, but virus neutralization antibody assays are more specific. The need to detect a diagnostic rise in antibodies between acute and convalescent serum specimens for 229E, OC43, HKU1, and NL63 coronavirus infections means that serologic tests are not helpful for managing an acute illness but can be helpful for epidemiologic studies.

SARS

Three features of SARS cases help guide approach to its diagnosis. First, SARS has occurred only in persons who have some potential exposure—that is, to patients with SARS, to a location with SARS transmission, to a laboratory working on SARS coronavirus, or to a setting where SARS-infected animals might be located (e.g., southern China). Second, nearly 100% of infected patients develop chest radiographic abnormalities by day 10 of their illness. Finally, SARS nearly always develops within 10 days of exposure. Thus, a suspicion of SARS and a diagnostic evaluation can be limited to patients who have a severe lower respiratory tract illness and some potential exposure to SARS within 10 days before the onset of illness.

Laboratory confirmation of SARS coronavirus infection early in the illness proved to be problematic even with sensitive real-time PCR assays. Unlike in most respiratory viral infections, the highest titer of virus or viral RNA was found in clinical specimens from the second week of illness. During the first week of illness, the best way to detect infection is by a sensitive PCR assay or a sensitive enzyme immunoassay for N protein antigen applied to respiratory and serum specimens. During the second week of illness, respiratory and stool specimens are most likely to be positive for viral RNA. Because most populations are negative for SARS coronavirus antibodies, detection of serum SARS coronavirus antibodies is a reliable indicator of infection. Antibodies were sometimes detected early in the second week of illness but at times were not detected until 4 weeks into the illness. Because antibodies persist in serum, a specimen can be collected late without compromising the ability to detect antibodies. Serologic assays, unlike PCR assays, are not confounded by problems with specimen contamination. Because antibodies to SARS coronavirus were rarely present before the 2003 outbreak, a single positive antibody test result from an ill person could be considered diagnostic of an acute SARS coronavirus infection. However, because the reemergence of SARS coronavirus will have substantial public health, social, and economic impact, and because of occasional cross-reacting antibodies induced by other coronaviruses, a neutralization antibody test and confirmatory testing by a reference laboratory are required to confirm the diagnosis. Public health departments should be consulted for questions about SARS diagnostic tests.[9]

MERS

Though less is known about transmission of MERS coronavirus, an approach similar to SARS is appropriate. A diagnosis of MERS coronavirus infection should be considered in patients with severe acute respiratory infection of unknown cause and a possible exposure or epidemiologic link to the Middle East. PCR assays have been used to detect RNA in upper and lower respiratory tract specimens (nasopharyngeal, oropharyngeal, sputum, tracheal aspirate, and bronchoalveolar lavage fluid), serum, stool, and urine. A confirmed case of MERS coronavirus infection requires a positive PCR on at least two specific gene targets or a single positive target with sequencing on a second.

A number of serologic assays can detect antibodies to the nucleocapsid and spike proteins. The sensitivity and specificity of these assays for diagnosing current or past MERS coronavirus infection have not yet been determined. Public health departments should be consulted for questions about MERS diagnostic tests.

TREATMENT

Rx

There is no virus-specific treatment for 229E, OC43, HKU1, and NL63 coronavirus infections, but the illnesses are mild and usually resolve in a few days to a week. Patients require symptomatic therapy or, uncommonly, management of complications of infection.

Treatment of SARS and MERS coronavirus infections are more complex. Currently, no antiviral drug has proved to be effective. With the high death rate for both of these viruses and the lack of clinical or in vitro data to guide treatment, supportive measures, including mechanical ventilation and oxygenation regimens (Chapter 104), are used. In the SARS coronavirus outbreak, in vitro data showed little if any antiviral effect with ribavirin and suggested that interferon alfa, SARS convalescent phase immune globulin, and lopinavir plus ritonavir might have been useful. Although many people were treated during the outbreak, lack of control groups makes it impossible to determine which if any therapies were beneficial. For MERS coronavirus, in vitro data demonstrate inhibitory effects for a number of antiviral agents, including interferons, ribavirin, cyclosporine A, and mycophenolic acid. However, no data are currently available regarding their efficacy for treating human infection.

PREVENTION

Handwashing and other infection-control measures probably decrease the spread of coronaviruses in the home, health care facilities, and other settings. These strategies focus on reinforcing the need for patients with respiratory illnesses to cover the nose and mouth when coughing or sneezing, to use tissues to contain respiratory secretions, and to wash the hands after contact with respiratory secretions. Staff should use good infection-control practices.

Within 4 months of the initiation of the 2003 SARS outbreak, the outbreak was contained and human-to-human transmission stopped without a vaccine or effective antiviral therapy but thorough implementation of the classic public health tools of case finding, isolation, and contact tracing and management, including quarantine of contacts. The low risk of SARS transmission early in the illness and the very low rate of asymptomatic infection were key factors to the success of these preventive measures.

The cases of laboratory-acquired SARS coronavirus infection and the subsequent transmission of disease to others after one such case reinforces the importance of strict attention to safe laboratory practices. Because the reemergence of SARS could lead to global spread, the local, national, and global public health and health care communities must be alerted quickly and updated regularly about new cases and the status of transmission.

Strict attention to standard contact and airborne precautions are recommended for SARS and MERS coronavirus–infected patients within hospital settings. MERS coronavirus infections continue to occur in the Middle East, and local, national, and global public health and health care communities should be immediately notified of a case. Vaccine development is underway for both SARS and MERS coronaviruses.

PROGNOSIS

Patients with typical community-acquired coronavirus infections typically recover completely. However, patients with compromised cardiac, pulmonary, or immune systems are at increased risk of more serious lower respiratory tract illness, and outbreaks of human coronavirus infections in elderly patients in chronic care facilities can cause severe lower respiratory illnesses and deaths. In the SARS outbreak, nearly 10% of patients died. The death rate was especially high, approaching 50%, in elderly patients and patients with underlying illnesses. Although most survivors of SARS coronavirus infection appeared to achieve full recovery, as many as 25% had abnormal pulmonary findings such as ground-glass opacities on chest radiograph or abnormal pulmonary function test results (e.g., decreased diffusing capacity) 6 months or more after their illness. The MERS fatality rate initially was reported to be about 40%, but many of the patients were older adults with comorbid conditions. The case-fatality rate will likely be lower as less severe cases are identified.

REVIEW QUESTIONS

1. Middle East respiratory syndrome (MERS) coronavirus may be diagnosed from which patient specimens?

A. Respiratory tract specimen
B. Serum
C. Stool
D. Urine
E. All of the above

Answer: E Virus has been demonstrated to be detectable in all of these patient specimens. Although respiratory tract specimens are most important for diagnosis, specimens from additional sites may aid in the diagnosis of patients.

2. What statement is most true about common human coronaviruses (OC43, 229E, NL63, and HKU1)?

A. Whenever a common human coronavirus is detected, there are associated severe clinical symptoms.
B. Occasionally, common human coronaviruses are detected in individuals with mild or no clinical symptoms.
C. All common colds are associated with common human coronaviruses.
D. Common human coronaviruses have never been associated with croup or pneumonia.

Answer: B Human coronaviruses may be detected from clinical specimens from mildly ill or asymptomatic individuals. Human coronaviruses are only one cause of the common cold, and these viruses also have been associated with croup and pneumonia.

367

MEASLES

MARTIN WEISSE AND MARK PAPANIA

DEFINITION

Measles (synonyms: rubeola, red measles, hard measles, 7-day measles) is a highly contagious systemic viral disease characterized by generalized maculopapular rash, fever, cough, coryza (rhinitis), and conjunctivitis. The measles virus is a negative-stranded RNA virus of the genus *Morbillivirus*, family Paramyxoviridae, with only one serotype and 24 genotypes.[1]

EPIDEMIOLOGY

In the prevaccine era, measles was a nearly universal rite of childhood, affecting almost every child by 15 years of age. As a result of high vaccination coverage, measles has not been endemic in the United States for more than a decade (incidence < 1 case/million people).[2] However, measles cases still occur annually in the United States because of the importation of the virus from other countries, followed by limited local transmission.[3] Many other countries have eliminated endemic measles, including almost all countries in the Americas. Unfortunately, measles remains endemic in many developed and developing countries and still caused an estimated 145,000 deaths worldwide in 2013, down from an estimated 545,000 deaths in 2000. Countries in the Southeast Asian region now account for about 25% of measles mortality, whereas countries in the African region account for about 50%. An estimated 10,000 measles deaths occurred in India in 2013, the highest in any country and about 7% of the global total estimated deaths.[4]

Measles, which is one of the most contagious diseases, infects more than 90% of susceptible people who come into close contact with an infectious patient. The measles virus is transmitted mainly by direct contact with large respiratory droplets, but airborne spread is also possible. Persons with measles are considered infectious from 4 days before the onset of the rash until 4 days after its onset. Immunocompromised patients may shed virus for a prolonged time and should be considered infectious as long as they have catarrhal symptoms.

Measles infection and measles vaccination usually confer lifelong immunity. However, antibody titers are lower following vaccination and wane over time in the absence of reexposure.[5] Serologic surveys in the United States show a measles antibody seroprevalence of over 95% among people older than age 6, which is above the threshold population immunity level (90 to 95%) required to sustain interruption of endemic measles transmission. Maternal measles antibody, which is transferred through the placenta, protects infants of immune mothers during the first months of life. However, lower antibody titers among mothers born in the vaccine era result in less antibody transfer and increased susceptibility to measles among infants.

PATHOBIOLOGY

Measles infection usually occurs through inhalation of infectious droplets into the respiratory epithelium or direct inoculation onto the conjunctiva. The virus attaches to host cells by its hemagglutinin protein, and its fusion protein allows viral entry and facilitates spread between cells. The virus initially replicates in the respiratory epithelial tissues or the adjacent lymph nodes. A primary viremia disseminates the virus to the reticuloendothelial tissues of the tonsils, lungs, gastrointestinal tract, spleen, and distant lymph nodes. Several days later, the onset of prodromal symptoms heralds a secondary viremia that results in further spread of the virus to the skin, viscera, kidney, and bladder. Histologic changes in the skin and mucous membranes consist of epithelial giant cells with surrounding mononuclear infiltrates and edema. Koplik spots, which are inflammatory lesions of the buccal submucous glands, have similar histologic features.

The development of immunoglobulin (Ig)M antibody coincides with the appearance of the rash; during the next week, IgG antibodies appear and usually persist for life. Cell-mediated immunity is also critical for resolution of acute infection. Measles virus infection causes a significant immunosuppression that predisposes infected patients to secondary bacterial and viral infections, which increase the mortality rate of measles. The exact mechanisms of immunosuppression are unknown.

CLINICAL MANIFESTATIONS

The incubation period of measles is usually 8 to 12 days after exposure until the development of the first symptoms. The measles prodrome includes fever associated with cough, coryza, conjunctivitis, and Koplik spots, often accompanied by malaise, myalgia, and headache. Fever increases with the severity of catarrhal symptoms and peaks at the onset of the exanthem; it frequently reaches 40° or 41° C and may persist for 6 days. Koplik spots, an enanthem of small bluish white spots on a red background on the buccal mucosa lateral to the molar teeth (Fig. 367-1), are considered to be pathognomonic for measles.[6] Koplik spots precede the rash by 1 day and are no longer evident 2 days into the rash.

The measles rash (Fig. 367-2) typically arises 2 to 6 days after the onset of the catarrhal symptoms. It begins on the face or behind the ears as individual red macules that blanch with pressure. During 12 to 24 hours, the macules become papular and tend to coalesce. The rash progresses from head to trunk to extremities and maintains the same pattern of progression from macules to coalescing papules. By the fourth day of the rash, the entire body is typically involved, although the hands and feet may be spared. The rash fades in the same head-to-toe order in which it appeared and often peels with a brawny desquamation during the subsequent weeks. In darkly pigmented individuals, the erythema may be difficult to appreciate, and the rash may be better felt than seen.

FIGURE 367-1. Typical Koplik spots.

FIGURE 367-2. Typical morbilliform eruption of measles, with broad areas of confluent red maculopapular lesions interspersed with islands of normal skin.

Important variations in the classic presentation of measles include "modified measles" in patients who have received immune globulin prophylaxis and "mild measles" in previously vaccinated persons. In both variations, any of the classic symptoms may be attenuated or absent. Such cases are extremely difficult to diagnose in the absence of known exposure to measles. Also, immunocompromised patients can have severe measles pneumonia without rash. Measles should be considered in any immunocompromised patient with pneumonia of unknown etiology.

Complications

The most common complications of measles are diarrhea, otitis media, and pneumonia. Diarrhea occurs early in the disease and is probably the result of intestinal measles virus infection. Measles-associated diarrhea significantly contributes to morbidity and mortality in malnourished patients.[7] Pneumonia is the most severe common complication and is responsible for the majority of deaths associated with measles. Measles-associated pneumonia may be a giant cell pneumonitis consistent with direct infection by measles virus or be caused by a secondary bacterial pathogen, most often *Staphylococcus aureus* (Chapter 288) or *Streptococcus pneumoniae* (Chapter 289).

Overall, children younger than 5 years and adults older than 20 years have the highest complication rates. Complication rates do not vary substantially by sex except that pregnant women are at high risk. Measles is especially hazardous during the first trimester, often leading to fetal demise. Later in pregnancy, the rate of prematurity is high, as is maternal pneumonia.

Malnutrition is associated with increased fatality rates, and children with vitamin A deficiency are at high risk for severe keratoconjunctivitis, which can lead to blindness. Immunocompromised patients (e.g., those with human immunodeficiency virus [HIV] infections, with cancer, or receiving chemotherapy or immunosuppressive drugs such as steroids) are at higher risk for severe measles complications. Interstitial pneumonia occurs 1 to 2 weeks after the onset of measles and is the most common cause of measles-related death in immunocompromised patients. Measles inclusion body encephalitis occurs in immunocompromised patients 1 to 6 months after acute measles and is usually fatal.

Postinfectious encephalomyelitis occurs in 1 in 1000 measles cases. Patients present during the 2 weeks after the onset of the rash with headache, recurrence of fever, vomiting, and stiff neck. Up to 25% of patients die, and 33% of survivors suffer neurologic sequelae. Elevated IgG and IgM can be found in cerebrospinal fluid, but measles virus cannot be isolated, thereby suggesting an autoimmune pathologic process. A rare late central nervous system complication of measles is subacute sclerosing panencephalitis (Chapter 370), a degenerative demyelinating disease due to chronic infection. Subacute sclerosing panencephalitis occurs years after the acute measles infection and is almost universally fatal.[8]

DIAGNOSIS

In many countries, measles has become such a rare disease that most physicians have never seen a patient. One key to making the diagnosis is to consider measles in any patient with a generalized maculopapular rash and fever. The index of suspicion should be raised if cough, coryza, and conjunctivitis are present and if measles virus transmission is occurring in the area or if the patient has traveled internationally or had any association with international travelers. Although Koplik spots are considered pathognomonic, the absence of Koplik spots does not exclude the diagnosis. The lack of vaccination should increase the level of suspicion, but measles can occur despite two documented doses of measles vaccine.

Confirmation of measles requires laboratory testing. The standard laboratory test for measles is an IgM measles antibody assay on a single serum specimen. However, during the first 3 days of rash, up to 25% of cases may not have detectable IgM; the test can be repeated if the rash and fever persist for 3 days. Acute and convalescent sera to test for a rise in IgG antibody are sometimes useful. Urine, throat swabs, or blood specimens can be sent for viral culture or for detection of viral RNA by reverse transcription–polymerase chain reaction (RT-PCR).[9] Genotype sequence analysis aids in tracking the source of the virus, monitoring transmission patterns, and distinguishing a mild case of measles from a vaccine reaction in patients who have recently received measles vaccine.

Differential Diagnosis (Table 367-1)

Other viral infections that may be confused with measles are rubella (Chapter 368), human herpesvirus 6 and 7 infection (Chapter 374), infectious mononucleosis (Chapter 377), and parvovirus B19 infection (erythema infectiosum [Chapter 371]). In general, these infections have a milder course. Bacterial infections that may mimic measles include secondary syphilis (Chapter 319), scarlet fever (Chapter 290), streptococcal or staphylococcal toxic shock syndrome (Chapter 439), and leptospirosis (Chapter 323). Drug eruptions (Chapter 440) and Kawasaki disease (Chapter 270) must also be considered. It can be extremely difficult to distinguish measles vaccine reactions, which may include fever and rash, from a mild case of measles. In highly vaccinated populations, measles is rare and clinical symptoms may be attenuated; serologic and virologic assays are critical in distinguishing measles from other diseases and conditions.

TREATMENT Rx

Vitamin A can reduce blindness due to severe keratoconjunctivitis and decrease mortality by as much as 50%. Vitamin A treatment is recommended for all children with measles, at doses of 50,000 IU for infants younger than 6 months of age, 100,000 IU for children 6 to 12 months of age, and 200,000 IU for children older than 1 year of age. An additional age-specific dose should be given 2 to 4 weeks later to children with clinical evidence of vitamin A deficiency. There are no recommendations for or against vitamin A treatment of adults with measles.

No specific antiviral or other therapies are recommended for measles. Ribavirin, isoprinosine, and interferon alfa have demonstrated modest benefit in small studies, but no controlled trials have been conducted. For most patients, treatment of measles consists of symptomatic therapy with antipyretics and analgesics and encouraging fluids to maintain hydration.

PREVENTION

Vaccination

Live-attenuated measles virus vaccines (Chapter 18) are the best means of preventing measles. Although the vaccine virus strains vary from different manufacturers, all provide equivalent protection. Measles vaccine is typically given as a component of the combination measles-mumps-rubella (MMR) vaccine or the measles-mumps-rubella-varicella (MMRV) vaccine. Measles-containing vaccines can be given at the same time as other live or killed

TABLE 367-1 A GUIDE TO THE DIFFERENTIAL DIAGNOSIS OF MEASLES

	CONJUNCTIVITIS	RHINITIS	SORE THROAT	ENANTHEM	LEUKOCYTOSIS	DIAGNOSTIC TESTS AVAILABLE
Measles	++	++	0	+	0	Yes
Rubella	±	0	0	0	0	Yes
Exanthem subitum	0	0	0	0	0	Yes
Enterovirus infection	0	0	±	±	0	Yes
Adenovirus infection	+	+	+	0	0	Yes
Scarlet fever	0	0	++	+	+	Yes
Infectious mononucleosis	0	0	++	+	±	Yes
Drug rash	0	0	0	0	0	No

0 = not usually present or no test available; ± = variable in occurrence; + = present: test available (virus or bacterial culture, serology); ++ = present and severe.
Modified from Brunell PA. Measles. In: Ausiello D, Goldman L, eds. *Cecil Textbook of Medicine.* 23rd ed. Philadelphia: Saunders Elsevier; 2008:2477.

vaccines. In the United States, the first dose of measles vaccine is usually given at 12 to 15 months of age, but it can be given as early as 6 months of age in infants who have a high risk of measles exposure, such as with international travel. A second dose is recommended when a child enrolls in school at 4 to 6 years of age. HIV-infected children should be vaccinated on the same schedule if they are not severely immunosuppressed. Children with perinatal HIV infection who received measles vaccination before they received antiretroviral therapy (ART) should be revaccinated with two doses after effective ART has been established.[10,11]

The first dose of vaccine is given at 9 months of age in developing countries where transmission in infancy is widespread and mortality is high. The World Health Organization recommends infants with known or suspected HIV infection also should be vaccinated at age 6 months.■ (Chapter 18). Most countries also recommend a routine second dose at various ages or provide a second opportunity for vaccination in mass campaigns to ensure protection. However, a high rate of first-dose coverage is always the top priority.

Contraindications to measles vaccination include pregnancy, immunodeficiency, leukemia and other immunosuppressive diseases, administration of immunosuppressive drugs such as systemic corticosteroids or antimetabolites, and untreated active tuberculosis. Extreme caution should be used in considering vaccination in patients with severe allergies to gelatin, neomycin, or other vaccine components or a history of thrombocytopenic purpura. Persons with HIV infection should be vaccinated against measles unless they have signs of severe immunosuppression.

Common adverse events after vaccination with measles vaccine include transient fever and mild rash, each of which occurs in roughly 5% of vaccine recipients. More serious adverse events, which are rare, include febrile seizures (<1 case/10,000 doses) and immune thrombocytopenic purpura (<2 cases/100,000 doses).[12,13]

Prevention of Measles Virus Transmission

To prevent transmission of measles, contact should be minimized between persons with suspected or confirmed measles and all persons who might be susceptible to measles; isolation and airborne precautions are indicated for hospitalized patients. When a case of measles is suspected, the local health department should be contacted immediately to assist with measures to prevent virus transmission.

Postexposure Prophylaxis

Unless otherwise contraindicated, vaccination is recommended for susceptible persons aged 6 months or older who are identified within 72 hours of exposure to measles to prevent or alter the course of the disease.■ Immune globulin should be given to susceptible household contacts of measles cases within 6 days of exposure, especially contacts who are too young (birth to 6 months) for measles vaccination, have contraindications to vaccination (e.g., pregnancy, immunodeficiency), or were not identified within 72 hours of exposure. Immune globulin may prevent measles or result in a less severe case of measles.

PROGNOSIS

In well-nourished populations with access to modern medical care, the case-fatality rate is typically 1 to 3 deaths/1000 cases, but case-fatality rates as high as 20% are seen in some developing countries as a result of malnutrition, limited access to health care, and immunodeficiency. Most measles deaths are associated with pneumonia or encephalitis. Antimicrobial treatment of secondary infections, especially pneumonias, can significantly reduce measles deaths. Vitamin A deficiency is associated with more severe disease, blindness, and increased mortality from respiratory and diarrheal causes, but vitamin A supplementation can reduce the severity of these complications. Patients with HIV infection and other immunocompromising conditions often have more severe cases with higher complication rates and case-fatality rates.

REVIEW QUESTIONS

1. A 21-year-old man presents to your travel clinic complaining of fever to 104° F and rash. He returned 5 days ago from a 1-month trip to Indonesia, where he served in a remote village. He was scrupulous about taking his malaria prophylaxis but was bothered by many mosquito bites per day. His fever started 3 days ago and was accompanied by headache, runny nose, and watery eyes. The rash started on his trunk 2 days ago and is also evident on his upper extremities. He was vaccinated for measles, mumps, and rubella at age 1 and again at age 5. The most likely etiology of his fever and rash are:

A. Measles
B. Malaria
C. Dengue
D. Parvovirus B19
E. Rubella

Answer: C Dengue is the most likely cause of this young man's illness. Dengue is spread by mosquitoes and is the most common arboviral infection in the world. There is no specific therapy, so treatment is supportive with analgesics, hydration, and antipyretics. Measles is not very likely because the patient had received two MMR vaccines, the onset of the rash was only 1 day into the fever, and the rash did not progress cephalocaudally. However, the presentation of measles can be altered in vaccinated people. Given the risk of transmission to other people, it would be prudent to send a serum specimen for measles IgM testing. Malaria is a less likely possibility because of the malaria prophylaxis, but malaria testing also would be recommended in this situation. Parvovirus B19 infection is unlikely because its rash typically follows the prodrome by approximately 1 week, as compared with 1 day in this patient. Rubella is unlikely because its fever is rarely above 38.5° C and the rash progresses cephalocaudally.

2. A 5-year-old girl presents to your office with a 5-day history of increasing fever, runny nose, mild photophobia, conjunctivitis, and a brassy cough. A rash that started on her face 2 days ago has now spread to her neck and upper torso. On physical examination, she has white plaques on an erythematous base on her buccal mucosa. Her lungs are clear, and her chest radiograph is consistent with a diffuse patchy bronchopneumonia. The most appropriate therapy to start is:

A. Ceftriaxone
B. Vitamin A, 200,000 IU/day for 2 days
C. Azithromycin
D. Antipyretics and symptomatic cough suppressant alone
E. Ribavirin

Answer: B Although measles can present with a secondary bacterial pneumonia, it is common to have a viral pneumonia due to the measles virus. The absence of a consolidation on chest radiograph or abnormal lung findings on physical examination suggests a viral etiology. There is no indication for ceftriaxone or azithromycin. Vitamin A treatment of children with measles has been associated with decreased morbidity and mortality rates. The World Health Organization currently recommends two doses of vitamin A for all children with acute measles, regardless of their country of residence. Antipyretics, symptomatic cough suppressants, and analgesics are recommended for patients with uncomplicated measles. Although ribavirin has been demonstrated to offer modest benefits in a few small clinical trials, it is not recommended for treatment of measles.

3. A 33-year-old woman is admitted to the hospital on her fourth day of measles rash with a secondary bacterial pneumonia due to methicillin-resistant *Staphylococcus aureus* (MRSA). The most appropriate isolation precautions for this patient consist(s) of:

A. Contact isolation precautions
B. Airborne isolation precautions
C. Droplet isolation precautions
D. Contact and airborne isolation precautions
E. Contact and droplet isolation precautions

Answer: D Patients with measles should be on airborne precautions for at least the first 4 days of rash. Immunocompromised patients may shed measles virus for extended periods and should remain on airborne precautions for the duration of their hospitalization for the acute illness. Contact precautions are necessary for MRSA.

4. A 35-year-old mother comes to your travel clinic in the United States with her healthy 9-month-old infant in anticipation of a leaving in 2 weeks for a trip to France. To reduce the risk of measles associated with international travel you recommend:

A. No preventive measures are needed for measles for travel to Europe.
B. Confirm the mother has received at least one dose of measles-containing vaccine. If not, give her a dose of measles, mumps, rubella vaccine. Give the infant immune globulin prophylaxis, followed by revaccination according to the routine schedule after return from the trip.
C. Confirm the mother has received at least two doses of measles-containing vaccine. If not, give her a dose of measles, mumps, rubella vaccine. Vaccinate the infant with single-antigen measles vaccine, followed by revaccination according to the routine schedule after return from the trip.
D. Confirm the mother has received at least two doses of measles-containing vaccine. If not, give her a dose of measles, mumps, rubella vaccine. Vaccinate the infant with measles, mumps, rubella vaccine, followed by revaccination according to the routine schedule after return from the trip.
E. Give both the mother and the infant immune globulin prophylaxis, followed by revaccination of the infant according to the routine schedule after return from the trip.

Answer: D Measles remains endemic in many developed countries, and many of the measles cases imported into the United States originate in Europe, including U.S. residents returning from travel, as well as foreign visitors. For adults preparing for international travel, documented receipt of two doses of measles containing vaccine is recommended. Single-antigen measles vaccine is not available in the United States. Vaccination is preferred over immune globulin in infants as young as 6 months of age without contraindications. In infants younger than 6 months, immune globulin may be indicated.

5. A 28-year-old mother and her 4-month-old infant were exposed to measles in a daycare setting 2 days before coming into your office. The mother has a documented history of receiving two doses of measles vaccine, the last dose at age 6. How do you provide postexposure prophylaxis for this mother and child?

A. Give the mother another dose of measles, mumps, rubella vaccine. Vaccinate the infant with single-antigen measles vaccine, followed by revaccination according to the routine schedule.
B. No prophylaxis is necessary; the mother is considered immune with two doses of vaccine, and the infant is protected by maternal antibody.
C. Give the infant immune globulin prophylaxis, and consider the mother immune with two doses of vaccine. Vaccinate the infant according to the routine schedule after 12 months of age.
D. Give the mother immune globulin prophylaxis. Vaccinate the infant with measles, mumps, rubella vaccine, followed by revaccination according to the routine schedule.
E. Give both the mother and the infant immune globulin prophylaxis, followed by revaccination of the infant according to the routine schedule.

Answer: C The mother should be considered immune because she has received two doses of vaccine. However, the amount of antibody she transfers to her infant is less than would be transferred by a mother who had measles disease. As a result, the infant may become susceptible to measles in the first 6 months of life, when the risk of severe measles is high. Immune globulin is recommended for postexposure prophylaxis; measles vaccine is not given before 6 months of age.

368

RUBELLA (GERMAN MEASLES)

SUSAN E. REEF

DEFINITION

Rubella, also known as German measles, is an acute viral illness that usually presents with a generalized maculopapular rash of 1 to 3 days' duration, low-grade or no fever, and associated clinical symptoms such as lymphadenopathy, arthropathy, and conjunctivitis. However, about 20 to 50% of persons infected with rubella may present without a rash or other symptoms.

The Pathogen

Rubella virus is a member of the Togaviridae family and the genus *Rubivirus*. Rubella virus is a single-stranded enveloped RNA with a single antigenic type. It measures 50 to 70 nm in diameter and has two envelope proteins (E1, E2) and a core protein (c). The core protein is surrounded by a single-layer lipoprotein envelope with spike-like projections that contain the two glycoproteins, E1 and E2. Humans are the only known reservoir.

EPIDEMIOLOGY

In the prevaccine era, rubella epidemics occurred approximately every 6 to 9 years in the United States. The last major American epidemic, which occurred in 1964-1965, resulted in an estimated 12.5 million cases and approximately 20,000 cases of congenital rubella syndrome. In 1969, live-attenuated rubella vaccines were licensed in the United States and were introduced into the routine childhood immunization program. The initial rubella vaccination strategy was to target children from 12 months of age to puberty with a catch-up mass campaign. During the first 8 years of the vaccination program, the reported number of cases of rubella and congenital rubella syndrome decreased by 78 and 66%, respectively. When a rubella resurgence occurred mainly among adolescents and young adults in 1977-1978, however, the rubella vaccination program was modified to include susceptible postpubertal girls, persons in military service, college students, and persons in certain work settings (e.g., health care). In 1979, the RA 27/3 rubella virus vaccine replaced the other rubella virus vaccines (HPV-77 and Cendehill). Since 2003, 18 or fewer cases have been reported annually in the United States, and rubella is no longer endemic in the United States.[1]

With the success of the vaccination strategy in the Americas, the number of reported rubella cases decreased from 135,947 in 1998 to 11 in 2013, and in 2009, Argentina reported the last endemic rubella case. In Europe, nearly all cases of rubella in 2013 occurred in Poland.[2]

Although rubella and congenital rubella syndrome are no longer endemic in the the Western Hemisphere, they continue to be of global public health importance. For most countries, the epidemiology of rubella mirrors the epidemiology seen in the United States during the prevaccine era, when rubella occurred mainly among children. The number of reported rubella cases globally has decreased from 875,000 in 1999 to about 101,331 in 2013, but the incidence is substantially underestimated because rubella cases in many countries are identified through case-based measles surveillance, which focuses only on the detection of suspected measles cases. Even developed countries like Japan continue to report outbreaks.[3] The annual number of new cases of congenital rubella syndrome globally is estimated to be about 100,000 in 2010.

During the 1970s and 1980s, the use of rubella-containing vaccine (RCV) was mainly limited to industrialized countries. The number of World Health Organization (WHO) member countries using RCV in national childhood immunization schedules increased from 83 (43%) in 1996 to 141 in 2014. As of the end of 2013, rubella control and congenital rubella syndrome prevention or elimination goals have been established in four of six WHO regions (Americas, European, western Pacific, Southeast Asia). In 2013, the other two WHO regions (i.e., eastern Mediterranean, Africa) have not

established regional rubella control or congenital rubella syndrome prevention goals.[4]

PATHOBIOLOGY

Rubella

Rubella virus is transmitted through person-to-person spread by droplets shed from the respiratory secretions of infected persons. The first point of entry is the nasopharynx, where replication occurs and then spreads to the lymph nodes. Subsequent viremia may seed multiple organs, including the placenta. Viremia occurs between 8 and 9 days after exposure and peaks at 10 to 17 days, just before the onset of the rash, which usually occurs 16 to 18 days after exposure. Although individuals with rubella are considered to be only moderately contagious, they may shed virus from 7 days before the onset of the rash to approximately 5 to 7 days or more after its disappearance. Persons with both clinical and subclinical infections are considered contagious.

Congenital Rubella

Rubella virus viremia can infect the placenta of pregnant women, and viral replication can infect all fetal organs. In tissue specimens, infections with rubella virus have diverse effects ranging from small foci of infected cells in apparently normal tissue to hypoplasia, generalized vasculitis, and cell destruction. The hallmark of fetal infection is chronic infection that persists throughout fetal life, with shedding of virus up to 1 year of age.

Infants with congenital rubella syndrome may shed large quantities of virus from body secretions, particularly from the throat. Rubella virus can be found in the nasopharyngeal secretions of more than 80% of these infants during the first month of life. Rubella virus is found in 11% of infected infants between 9 and 12 months of age and in only 3% in the second year of life. Viral shedding by infants with congenital rubella syndrome can result in nosocomial outbreaks, so only individuals immune to rubella virus should be in contact with infants with congenital rubella syndrome or with congenital infection even in the absence of clinical signs of congenital rubella syndrome.

CLINICAL MANIFESTATIONS

Postnatally Acquired Rubella

Acquired rubella, which occurs in 50 to 80% of persons infected with rubella virus, is characterized by a generalized maculopapular rash that usually persists for 1 to 3 days (Fig. 368-1). The rash usually starts on the face and neck and progresses downward. The rash is fainter than the rash of measles (Chapter 367) and does not coalesce. Because of the mildness of the rash, it may be difficult to detect in persons with darker skin. Children usually have few or no prodromal symptoms, so the rash is usually the first sign of illness. However, in older children and adults, a 1- to 5-day prodrome of low-grade fever, malaise, and upper respiratory symptoms often precedes the rash. The incubation period is 14 days, with a range of 12 to 23 days. Lymphadenopathy, particularly occipital and postauricular, may be noted during the second week after exposure.

FIGURE 368-1. Rash of rubella on the skin of a child's back. The distribution is similar to that of measles, but the lesions are less intensely red. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 712.)

Rubella disease is usually mild and results in few complications. Arthralgia and arthritis are commonly observed in infected adults, particularly in postpubertal females. Other less common complications are thrombocytopenia (1 in 3000 rubella cases) and encephalitis (1 in 6000 rubella cases).

Congenital Rubella Syndrome

The most serious consequences of rubella virus infection occur when a woman becomes infected during pregnancy, particularly during the first trimester. Complications can include miscarriage, fetal death, or a live birth with a constellation of congenital defects known as congenital rubella syndrome. The most common defects of congenital rubella syndrome affect the eyes (e.g., cataracts, pigmentary retinopathy, microphthalmos, congenital glaucoma), the ears (e.g., sensorineural hearing impairment), and the heart (e.g., patent ductus arteriosus, pulmonary arterial stenosis). Other clinical manifestations of congenital rubella syndrome may include microcephaly, developmental delay, and purpura, including dermal erythropoiesis (blueberry muffin syndrome).

Among pregnant women infected with rubella virus during the first 10 weeks of gestation, up to 90% of their live born infants may have congenital rubella syndrome. Among women infected during the first 20 weeks of pregnancy, the rate of congenital rubella syndrome in live born infants is 20%. Infants who are born with rubella virus infection but who do not have any apparent signs or symptoms of congenital rubella syndrome are referred to as infants with congenital rubella infection only.

DIAGNOSIS

Postnatally Acquired Rubella

Because many rash illnesses may mimic rubella virus infection and because 20 to 50% of rubella virus infections may be subclinical, laboratory testing is the only way to confirm the diagnosis. Some illnesses with clinical presentation similar to that of rubella include scarlet fever (Chapter 290), roseola (Chapter 439), fifth disease (Chapter 371), and measles (Chapter 367).

Serologic testing is the most common method of diagnosis of acquired rubella. Immunoglobulin (Ig)M antibody is generally detectable for up to 6 weeks after the onset of the rash. Because IgM antibodies may not be detectable before day 5 of the rash, serologic testing should be repeated no sooner than then. Diagnosis also can be made on the basis of a significant rise in the IgG antibody titer in paired acute and convalescent specimens. The acute serum specimen should be collected within 7 to 10 days after the onset of the rash, and the convalescent serum specimen should be collected 14 to 21 days after the first specimen.

Rubella virus can be isolated from nasopharyngeal (i.e., nasal, throat), blood, urine, and cerebrospinal fluid specimens of persons with rubella and congenital rubella syndrome. The most frequently positive results are from throat swabs. Rubella virus can be isolated during the prodromal period and up to 2 weeks after onset of the rash. For viral cultures, specimens should be obtained during the time of maximum virus secretion—up to 4 days after the onset of rash. During the first 4 days after the onset of the rash, rubella RNA detection by reverse transcription–polymerase chain reaction (RT-PCR) is more sensitive than rubella IgM testing.

Diagnosis in Pregnant Women

In the United States, all pregnant women should be screened for rubella IgG antibodies as part of routine prenatal care. Pregnant women who have a positive serologic test result for IgG antibody to rubella virus are considered to be immune if they do not have a recent history of exposure to rubella virus. Susceptible pregnant women should be vaccinated postpartum. Pregnant women exposed to rubella virus should be evaluated for evidence of acute infection by testing for presence of IgM antibodies in sera or a significant rise of IgG antibodies in acute and convalescent sera. Pregnant women with evidence of acute infection should be monitored clinically and evaluated for gestational age at infection to assess the risk of fetal infection.

Congenital Rubella

Diagnosis of congenital rubella syndrome in infants can be confirmed by either serologic or virologic methods. Serum IgM antibodies may be present

in an infant with congenital rubella syndrome for up to a year after birth; however, IgM antibody may not be detectable during the first month of life. Thus, infants younger than 1 month and with symptoms consistent with congenital rubella syndrome should be tested at 1 month of age. Congenital rubella syndrome also can be confirmed by documentation of a persistent rubella serum IgG titer beyond the time expected from passive transfer of maternal IgG antibody (i.e., a rubella titer that does not decline at the expected rate of a two-fold dilution per month).

Rubella virus from congenitally infected infants can be isolated most commonly from throat swabs and less commonly from urine and cerebrospinal fluid specimens. Infants with congenital rubella may excrete virus for up to 1 year, but specimens for virus isolation are most likely to be positive if they are obtained within the first 6 months after birth. Rubella virus in infants with congenital rubella syndrome also can be detected by RT-PCR with use of the same specimens as for viral isolation.

TREATMENT

Rx

There is no specific treatment for rubella or congenital rubella syndrome. For persons with rubella, symptomatic treatment may be warranted for clinical manifestations such as arthralgias, myalgias, and fever. Infants with congenital rubella syndrome should be evaluated and treated by specialists for their specific clinical manifestations.

PREVENTION

Passive Immunization

Administration of immune globulin after exposure to rubella virus will not prevent infection or viremia but might modify or suppress symptoms. Therefore, immune globulin is not recommended for routine postexposure prophylaxis of rubella in any circumstance.

Active Immunization

One dose of live-attenuated rubella vaccine (RA 27/3, RCV) induces rubella IgG antibody seroconversion in 95% or more of persons. Immunity is considered long term, probably lifelong. RCV is available as a monovalent formulation or in combination with measles-mumps (MMR) and measles-mumps-varicella (MMRV) vaccines (Chapter 18).

In the United States, the routine rubella vaccination policy is to immunize children with the first dose of MMR at 12 to 15 months of age and to provide a second dose at 4 to 6 years of age. The MMRV vaccine also can be given to children up to age 12 years. Persons who were born in 1957 or later (except women of childbearing age who are or could become pregnant) and who do not have a medical contraindication (e.g., pregnancy) should receive at least one dose of MMR unless they have documentation of one dose of live rubella virus vaccine or laboratory evidence of immunity or laboratory confirmation of disease. High-risk groups who should be targeted for vaccination include health care personnel, persons attending post–high school educational facilities, the military, international travelers, and nonpregnant women of childbearing age.

In follow-up studies of more than 2700 susceptible women who were unknowingly pregnant and who received a live-attenuated rubella vaccine, none of their infants was born with congenital rubella syndrome. Nevertheless, because of the theoretical risk of congenital rubella syndrome in infants born to pregnant women vaccinated with RCV, the vaccine should not be given to pregnant women, and pregnancy should be avoided for at least 28 days after receipt of vaccine. Receipt of RCV during pregnancy is not generally considered to be an indication for termination of pregnancy.

PROGNOSIS

Because rubella is usually a mild disease, the prognosis is excellent, with complete recovery in almost all persons. Deaths are seen in 0 to 50% of patients who develop rubella encephalitis. The prognosis for infants with congenital rubella syndrome is dependent on their clinical manifestations and access to quality medical care.

MUMPS

JOHN W. GNANN, JR.

DEFINITION

Mumps is an acute systemic viral infection that occurs most commonly in children, is usually self-limited, and is clinically characterized by nonsuppurative parotitis.

The Pathogen

Mumps virus is a member of the family Paramyxoviridae. Mumps virions are pleomorphic, roughly spherical enveloped particles with an average diameter of 200 nm. Glycoprotein spikes project from the surface of the envelope. A helical nucleocapsid composed of nucleoproteins and of linear, nonsegmented, single-stranded, negative-sense RNA approximately 15.3 kilobases in size encodes seven major proteins as well as several minor proteins. Humans are the only natural hosts for mumps virus, although infection can be induced experimentally in a variety of mammalian species. In vitro, mumps virus can be cultured in many mammalian cell lines and in embryonated hens' eggs.

EPIDEMIOLOGY

In unvaccinated urban populations, mumps is a disease of school-aged children (5 to 9 years); more than 90% of individuals have mumps antibodies by 15 years of age. Before the mumps vaccine was released in the United States in 1967, mumps was an endemic disease with a seasonal peak of activity between January and May. The largest number of cases reported in the United States occurred in 1941, when the incidence of mumps was 250 cases per 100,000 population. In 1968, when the mumps vaccine was first entering clinical use, the incidence of mumps was 76 cases per 100,000 population. In 1985, only 2982 cases of mumps were reported, an incidence of 1.1 per 100,000 population, which represents a 98% decline from the number of cases reported in 1967. Sporadic outbreaks of mumps in secondary schools between 1985 and 2005 were attributed to primary vaccine failure. After 1989, when the Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) issued a recommendation that all children receive a second dose of the measles-mumps-rubella (MMR) vaccine at the time of school entry, the problem of primary vaccine failure was reduced. In 2003, the CDC reported only 231 cases of mumps in the United States, the lowest annual total ever recorded. In 2006, however, 6584 cases of mumps were reported, with a national incidence of 2.2 cases per 100,000 population. Since that time, several outbreaks have been reported. In 2010, another mumps outbreak resulted in 3500 cases in New York and New Jersey, with the highest rate among boys 13 to 17 years of age who attended tradition-observant Jewish schools[1]; 89% of cases had received at least two doses of a mumps-containing vaccine, suggesting their illness was because of intense exposure, particularly among boys in school. In another outbreak in New York City, 90% of cases had received one dose of vaccine, and 77% had received two doses. The effectiveness of a two-dose regimen for preventing mumps was 86%.[2] In an outbreak in Guam during 2009 and 2010, 505 mumps cases occurred among school-aged children, even though 93% had received two doses of vaccine; crowding at home and high student contact rates were identified as risk factors for transmission.[3] Although some cases in recent outbreaks can be attributed to failure to vaccinate, most represented primary (insufficient initial immune response) or secondary (waning immune response) vaccine failure, thereby suggesting the need either for a mumps vaccine with a longer duration of protection or for a revised vaccination policy focusing on young adults.

PATHOBIOLOGY

Mumps is highly contagious and can be transmitted experimentally by inoculation of virus onto the nasal or buccal mucosa, suggesting that most natural infections result from droplet spread of upper respiratory secretions. The mean incubation period for mumps is 18 days. Primary viral replication takes place in epithelial cells of the upper respiratory tract, followed by spread of virus to regional lymph nodes and subsequent viremia.[4] Because virus can be

isolated from saliva for 5 to 7 days before and up to 9 days after the onset of clinical symptoms, an infected individual is potentially able to transmit mumps for up to 2 weeks. An estimated 30% of mumps infections in children are subclinical or associated only with nonspecific upper respiratory infection symptoms. Transient IgM antibody responses are detected early in the course of mumps infection, followed by the appearance of IgG antibody and cytotoxic T lymphocytes. Mumps-specific IgG can be detected during the first week of acute infection, peaks at 3 to 4 weeks, and persists for decades. Lifelong immunity follows natural infection. Patients who report more than one episode of mumps probably had parotitis of another cause.

CLINICAL MANIFESTATIONS

Parotitis

Mumps usually begins with a short prodromal phase of low-grade fever, malaise, headache, and anorexia.[5] Young children may complain of ear pain initially. The characteristic parotid tenderness and enlargement, in which the earlobe is lifted forward and obscures the angle of the mandible, then develops (Fig. 369-1). The parotid glands are involved most commonly, although other salivary glands may occasionally be enlarged. Parotitis may initially be unilateral, with swelling of the contralateral parotid gland occurring 2 to 3 days later; bilateral parotitis with symptomatic salivary gland involvement eventually develops in 70% of patients. Painful parotid gland enlargement progresses for a period of about 3 days, followed by defervescence and resolution of the parotid pain and swelling within about 7 days. Long-term sequelae of mumps parotitis are uncommon.

Aseptic Meningitis

Symptomatic meningitis occurs in 15% of cases and is the second most common manifestation of mumps. About 50% of patients with mumps parotitis have cerebrospinal fluid (CSF) pleocytosis, but many have no clinical evidence of meningitis. Signs and symptoms of meningeal inflammation (headache, neck stiffness, vomiting, and lethargy) plus high fever usually develop 4 to 5 days after the onset of parotitis, although the meningitis may occasionally precede the parotitis. Indeed, 40 to 50% of all cases of documented mumps meningitis occur in patients who never exhibit clinical parotitis. For unexplained reasons, symptomatic central nervous system (CNS) involvement with mumps is two to three times more common in boys than in girls. Examination of CSF usually reveals normal opening pressure and a mononuclear cell pleocytosis with an average cell count of 450/μL. Polymorphonuclear leukocyte predominance in CSF may be seen in some patients early during the course of mumps meningitis. CSF protein is generally normal or mildly elevated (<100 mg/dL). Hypoglycorrhachia, which is not usually seen in viral meningitis, may be present in 10 to 30% of patients with mumps meningitis. Mumps virus can be recovered from CSF. Whereas the symptoms of mumps meningitis typically resolve within 7 to 10 days, the CSF abnormalities may persist for up to 5 weeks. Mumps meningitis is generally benign, and significant neurologic complications are rare.

Encephalitis

The spectrum of mumps-induced CNS disease ranges from mild "aseptic" meningitis (which is common) to severe encephalitis (which is rare). Some cases of encephalitis develop concurrently with the parotitis and are thought to result from direct extension of viral infection from the choroid plexus ependyma into parenchymal neurons. Other cases of mumps encephalitis occur 1 to 2 weeks after the onset of parotitis and may represent a demyelinating postinfectious encephalitis. Clinical findings in mumps encephalitis include obtundation (and less commonly delirium), generalized seizures, and high fever. Other neurologic findings can include focal seizures, aphasia, paresis, and involuntary movements. Recovery from mumps encephalitis is generally complete, although complications such as aqueductal stenosis with hydrocephalus, seizure disorders, and psychomotor retardation have been reported. The overall mortality rate from mumps encephalitis is 0.5 to 2.3%.

FIGURE 369-1. Mumps. Child with submandibular swelling due to mumps parotitis. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 4491.)

Orchitis

Epididymo-orchitis is rare in young boys with mumps, but it occurs in 15 to 35% of postpubertal males with mumps.[6] Orchitis is most often unilateral (bilateral involvement occurs in 17 to 38% of cases) and results from replication of mumps virus in the seminiferous tubules, with resulting lymphocytic infiltration and edema. Orchitis typically develops within 1 week of the onset of parotitis, although orchitis, like mumps meningitis, can develop before or even in the absence of parotitis. Mumps orchitis is characterized by marked testicular swelling and severe pain accompanied by fever, nausea, and headache. The pain and swelling resolve within 5 to 7 days, but residual testicular tenderness can persist for weeks. Testicular atrophy may follow orchitis in 35 to 50% of cases; however, sterility is an uncommon complication, even in men with bilateral orchitis.

Other Manifestations

Mumps can cause inflammation of other glandular tissues, including pancreatitis and thyroiditis. Oophoritis and mastitis have been reported in postpubertal women with mumps. Transient renal function abnormalities are common in mumps, and virus can be isolated readily from urine; significant renal damage is rare, however. Other infrequent manifestations of mumps include sensorineural deafness (either transient or permanent), arthritis, myocarditis, and thrombocytopenia. Maternal mumps infection during the first trimester of pregnancy results in an increased frequency of spontaneous abortions, but no clear association between congenital malformations and maternal mumps has been demonstrated.

DIAGNOSIS

The diagnosis of mumps is usually based on clinical findings in a child with fever and parotitis, particularly if the individual is known to be susceptible and has been exposed to mumps during the preceding 2 to 3 weeks. An atypical clinical presentation (e.g., meningitis or orchitis without parotitis) requires laboratory confirmation. Culturing for mumps virus has largely been replaced by reverse transcription–polymerase chain reaction (RT-PCR) assays. Detection of mumps virus RNA is diagnostic of infection.[7] RT-PCR appears to be more sensitive than culture for detection of mumps virus from oropharyngeal swabs or CSF samples. Serologic demonstration of mumps immunoglobulin M (IgM) antibody provides good evidence of recent infection; IgM is detectable during the first week of illness and persists for at least 6 weeks. Alternatively, testing of acute and convalescent sera by enzyme-linked immunosorbent assay (ELISA) should demonstrate a diagnostic four-fold rise in mumps IgG antibody titer. About 30% of patients have an elevated serum amylase level that may be due to parotitis or pancreatitis.

The differential diagnosis of a mumpslike syndrome includes infections caused by other viruses, such as Epstein-Barr virus (Chapter 377), human herpesvirus type 6, adenovirus (Chapter 365), influenza A virus (Chapter 364), parainfluenza virus (Chapter 363), coxsackievirus (Chapter 379), or lymphocytic choriomeningitis virus. Among 101 sporadic cases of parotitis assessed in the United States in 2009 to 2011, for example, the most commonly detected viruses were Epstein-Barr virus (23%) and human herpesvirus type 6 (10%); mumps virus was not detected in any specimens, although 17% of cases demonstrated positive mumps IgM.[8] Bacteria such as *Staphylococcus aureus* can cause suppurative parotitis. Parotid gland enlargement can also occur in patients with AIDS, particularly children. Parotid gland enlargement can also be associated with Sjögren's syndrome (Chapter 268), sarcoidosis (Chapter 95), amyloidosis (Chapter 188), thiazide ingestion, iodine sensitivity, tumor, or salivary duct obstruction. Careful examination should distinguish parotitis from lymphadenopathy.

TREATMENT

Rx

Management of a patient with mumps consists of conservative measures to provide symptomatic relief, adequate hydration, and nutrition. Treatment of orchitis includes bed rest, scrotal support, analgesics, and ice packs. Patients with significant CNS involvement require hospitalization for observation and supportive care. There is currently no established role for antiviral drugs, interferon, corticosteroids, or passive immunotherapy in the treatment of mumps.

PREVENTION

The cornerstone of mumps prevention is active immunization with the live attenuated mumps vaccine (Chapter 18). In the United States, mumps vaccine is administered in combination with the measles and rubella vaccines (MMR) to children at 12 to 15 months of age, with a second dose at 4 to 6 years of age.[9] Efficacy of the mumps vaccine is estimated to be 70 to 80% after two doses.[10] The mumps vaccine is also indicated for susceptible adults. Administration of the live mumps vaccine is contraindicated in pregnant women. Vaccination is also not recommended in persons who have received immunoglobulin therapy, which might interfere with the immune response to the vaccine, within the preceding 3 months or in persons with severe systemic immunosuppression caused by disease or medical therapy.

The Jeryl-Lynn strain of attenuated mumps virus used in the United States since 1967 is a very well tolerated vaccine, although rare instances of fever, parotitis, and possibly aseptic meningitis have been reported after immunization. Beginning in 1988, an increased frequency of cases of vaccine-related mumps meningitis was recognized in other countries. These cases occurred after the administration of MMR vaccines containing other mumps strains, such as Urabe AM9 or Leningrad 3. This problem has not been seen in the United States, where the Jeryl-Lynn mumps vaccine continues to be used.

Questions about prevention often arise when an individual with no history of mumps (typically an adult male) is exposed to a patient with active mumps. The immune status of the exposed individual can be determined by serologic testing (mumps IgG by ELISA), although there may be some delay. The mumps skin test is not a reliable indicator of immune status. Most adults (>90%) born in the United States before 1957 were naturally infected and are therefore immune. Mumps vaccine can be safely administered to an individual of unknown immune status, although the efficacy of postexposure vaccination for preventing mumps has not been determined.

For infection control purposes, patients with mumps require both standard precautions and droplet precautions for at least 5 days after the onset of parotitis.[11] In the outpatient setting, a patient with suspected mumps should wear a mask and be isolated from other potentially susceptible persons. When a patient with mumps is hospitalized, a private room is required; caregivers should wear masks, and the patient should wear a mask while being transported.

REVIEW QUESTIONS

1. A 19-year-old college student presents with a 1-day history of fever, mild headache, and bilateral parotitis. She relates that she received all of the appropriate childhood vaccinations. After examining her, you suspect mumps. What is your best option for diagnostic testing?

A. Collect urine for mumps virus culture.
B. Collect throat swab for mumps virus culture.
C. Collect throat swab for mumps virus polymerase chain reaction (PCR).
D. Collect cerebrospinal fluid (CSF) for mumps virus PCR.
E. Collect acute and convalescent sera for mumps immunoglobulin G (IgG) by enzyme-linked immunosorbent assay (ELISA).

Answer: C All of the suggested testing modalities could provide confirmation of the diagnosis of mumps. However, mumps viral culture may not be routinely available and is expensive. Real-time PCR is a rapid and very sensitive assay for detecting mumps RNA and has replaced viral culture in most situations. CSF is a suitable specimen for PCR, but there is no evidence for serious CNS involvement in this case; lumbar puncture is not indicated. Acute and convalescent sera (collected after an interval of 4 to 6 weeks) will provide a retrospective diagnosis. Serologic testing for mumps IgM would also be an acceptable diagnostic approach but may be negative very early in the clinical course.

2. A 62-year-old man who has been in good health calls your office for advice. His 15-year-old grandson visited his home 3 days ago and has now been diagnosed with mumps. Your patient grew up in the United States and relates that his mother told him that he never had mumps. He does not recall receiving a mumps vaccine. He has heard stories about mumps orchitis and is very concerned. What do you recommend?

A. Administer measles-mumps-rubella vaccine (MMR) as soon as possible.
B. Administer mumps hyperimmune globulin as soon as possible.
C. Administer the mumps skin test.
D. Send blood for mumps IgG serology.
E. Send blood for mumps IgM serology.

Answer: D More than 90% of adults who grew up in the United States between 1957 and 1967 (when the mumps vaccine was introduced) are seropositive for mumps, so the probability that this man is susceptible to mumps is low. Because approximately 30% of mumps infections are asymptomatic, many adults are seropositive with no history of disease. His serologic status can be confirmed by testing for mumps IgG. Mumps IgM testing is appropriate for diagnosing acute mumps but not for determining mumps susceptibility. Mumps vaccine (or MMR) could be safely administered, but there are no data regarding the efficacy of postexposure immunization. Mumps hyperimmune globulin was used in the past as therapy for mumps orchitis, but it is no longer recommended or available. The mumps skin test is an unreliable indicator of mumps immune status, and the antigen is no longer widely available.

3. There is an ongoing outbreak of mumps in your community, primarily involving high school and college students. Several of your adult patients have requested that they be tested for mumps susceptibility because they do not recall having mumps and can provide no documentation of vaccination. Based on mumps IgG serologic results, you have identified a few patients who are seronegative and therefore susceptible to mumps. Which of the following patients should receive mumps vaccination?

A. A 31-year-old man with type 1 diabetes mellitus, chronic kidney disease, and hypertension
B. A 23-year-old man who was recently diagnosed with AIDS ($CD4^+$ lymphocyte count = 41 cells per μL) and is receiving antiretroviral therapy
C. A 36-year-old woman who recently emigrated from Central America, is pregnant (gestational age 20 weeks), and has a teenaged child at home
D. A 55-year-old man who is 2 years status post–cardiac transplantation and is currently doing well on an antirejection regimen of mycophenolate, tacrolimus, and prednisone
E. A 40-year-old woman who has had a flare of her sarcoidosis with pulmonary and CNS involvement and is on a prolonged corticosteroid taper and is currently taking prednisone 30 mg daily

Answer: A Mumps is a live-virus vaccine containing replication-competent virus. Its use is contraindicated in (1) pregnant women; (2) persons with primary or acquired immunodeficiency syndromes; (3) persons with hematologic or lymphoproliferative malignancies; (4) persons receiving systemic immunosuppressive therapy (including prednisone ≥20 mg/day or equivalent for ≥2 weeks); or (5) persons with allergies to any mumps vaccine components. Mumps immunization (using MMR) is recommended for children or adults who are infected with HIV and who do not have evidence of severe immunosuppression (defined as CD4 count <200 lymphocytes/μL or CD4 <15%). Diabetes mellitus is not a contraindication to vaccination.

CYTOMEGALOVIRUS, EPSTEIN-BARR VIRUS, AND SLOW VIRUS INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

JOSEPH R. BERGER AND AVINDRA NATH

CYTOMEGALOVIRUS INFECTION

Human cytomegalovirus (CMV) is a ubiquitous herpesvirus that is acquired throughout life (Chapter 376). In children, CMV is an important and relatively common cause of congenital neurologic deficits. In the United States, seroprevalence rates are 40% in adolescents and 60 to 90% in adults. Primary infection is usually asymptomatic in young, healthy adults but may be associated with a transient mononucleosis-like syndrome. CMV results in major neurologic disability in the setting of immunosuppression, particularly in transplant recipients, in persons with acquired immunodeficiency syndrome (AIDS), and in those with hematologic malignant neoplasms. In addition to the retina, CMV may involve the meninges, brain, spinal cord, peripheral nerves, and muscle.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Cytomegalovirus Encephalitis

In patients with AIDS, CMV encephalitis generally occurs only in the presence of profound immunosuppression (CD4 T lymphocyte counts <100 cells/μL). The most typical presentation in patients with AIDS is a subacute, diffuse encephalopathy evolving over a period of weeks and characterized by headache, impaired cognition and sensorium, apathy, and social withdrawal. Neurologic examination reveals abnormal mentation and variable motor features, including hyperreflexia, ataxia, and weakness. CMV ventriculitis is characteristically present, and progressive ventricular enlargement may be observed. Other features may suggest brain stem encephalitis, including internuclear ophthalmoplegia, nystagmus, cranial nerve palsies, gaze paresis, ataxia, and quadriparesis. Other findings in these patients include cerebral infarction resulting from CMV vasculitis, acute subarachnoid hemorrhage, and intracerebral hemorrhage. Virtually all patients with CMV encephalitis have systemic CMV infection. CMV myelitis, polyradiculitis, and multifocal neuritis may also occur with CMV encephalitis. Distinctive retinal lesions can often be seen ophthalmoscopically (Chapter 376) and may serve as a useful diagnostic clue. CMV can also be vertically transmitted and cause a congenital infection in the fetus with a classic triad of chorioretinitis, microcephaly, and cerebral calcifications.

Cerebral imaging studies are of limited sensitivity and low specificity in patients with CMV encephalitis. Ependymal or meningeal enhancement as well as areas of focal infarction or necrosis may be visualized. Restricted diffusion or high signal intensity lesions lining the ependyma of the lateral ventricles may be best seen on diffusion-weighted images.[1] Progressive ventricular enlargement should suggest CMV ventriculitis. Rarely, CMV infection may be manifested as a cerebral mass lesion.

Cerebrospinal fluid (CSF) findings are variable. Most patients have elevated protein levels and a CSF pleocytosis, but leukocytes may be absent and glucose levels may be normal or decreased. In contrast to other viral infections that usually cause a lymphocytic predominance in the CSF, a marked pleocytosis with a polymorphonuclear leukocyte preponderance may occur in patients with CMV ventriculoencephalitis. CMV can rarely be cultured from CSF. CSF real-time polymerase chain reaction (PCR) is the most specific diagnostic method, but the diagnosis is often difficult and relies on a high index of clinical suspicion. CMV serology is not helpful for diagnosing an active infection. Histopathologic examination reveals multinucleate cells with intranuclear cytomegalic inclusions (Fig. 370-1).

Myelitis

CMV transverse myelitis, which may be seen in both immunocompetent and immunosuppressed patients, is indistinguishable neurologically from other forms of transverse myelitis (Chapters 400 and 411). A severe necrotizing CMV myelitis, which is usually longitudinally extensive and involves several spinal segments, may occur in the immunosuppressed host, particularly with human immunodeficiency virus (HIV) infection, and is commonly associated with polyradiculitis. Some cases of necrotizing myelitis in the absence of a typical polyradiculitis syndrome have been described, with patients displaying acute or progressive paraplegia and disturbances in urinary and rectal sphincter function. Reflexes are preserved or enhanced in the legs unless concurrent neuropathy is present. A sensory level may be demonstrable. The combination of radicular complaints and a CSF polymorphonuclear pleocytosis may serve as a clue to the diagnosis. Serology for CMV may be useful in immunocompetent individuals.

Polyradiculomyelitis

As many as 25% of patients dying of AIDS have neuromuscular disease from CMV, predominantly localized to the perineurial and epineurial regions. CMV polyradiculomyelitis in HIV-infected patients is manifested subacutely during a period of days to weeks. Initial symptoms of paresthesias or dysesthetic pain localized to the perineum and lower extremities are followed by rapidly progressive paraparesis with hypotonia and diminished or absent lower extremity reflexes. Urinary retention is characteristic, and rectal

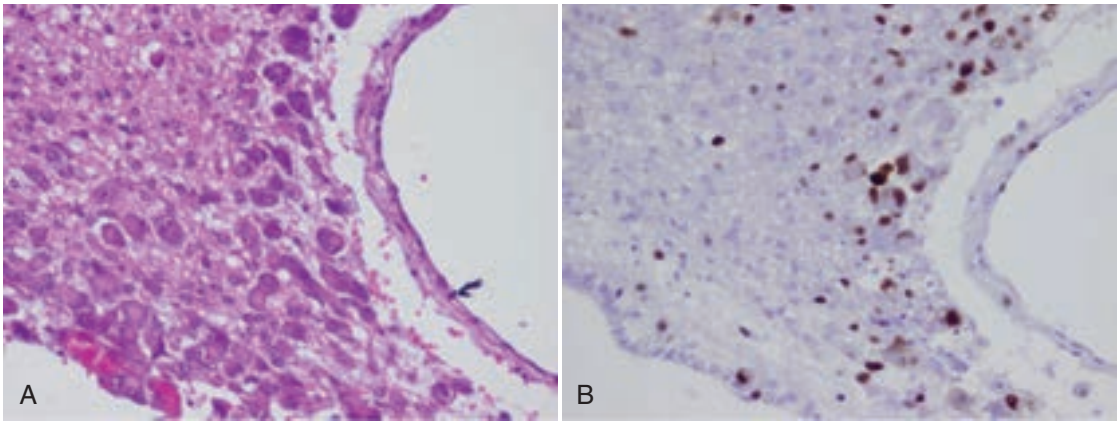

FIGURE 370-1. Pathology of CMV encephalitis. A, Large cells are seen in the perivascular region, some are multinucleated. **B**, The cytomegalic inclusions are present in the nucleus and stain with an antibody to CMV *(brown)*. Magnification is 40×. (Courtesy Martha Quezado, National Institutes of Health, Bethesda, MD.)

sphincter incontinence is common. Variable sensory findings are typically overshadowed by weakness. Babinski signs and diminished sensation below a discrete level across the trunk are evidence of an associated myelitis. With time, symptoms progress by ascending to involve the upper limbs and sometimes the cranial nerves. CSF examination generally shows polymorphonuclear pleocytosis, prominent elevation of protein levels, and a low glucose level. Spinal magnetic resonance imaging (MRI) may be normal or show enhancement of the conus medullaris, cauda equina, meninges, and nerve roots. Electrophysiologic studies reveal axonal neuropathy with evidence of acute denervation. Variable slowing of nerve conduction may occur.

The appearance of acute cauda equina syndrome in a patient with AIDS or in a solid organ or bone marrow transplant recipient is suggestive of CMV infection when a polymorphonuclear pleocytosis is present in CSF; however, the syndrome is not pathognomonic. Other conditions that may produce a cauda equina syndrome in AIDS patients include lymphomatous meningitis, syphilis, toxoplasmosis, other herpesvirus infections, and cryptococcal or bacterial meningitis. Progressive multifocal motor and sensory neuropathy that evolves during a period of weeks to months has also been seen in patients with CMV infection. Paresthesia and dysesthesia are quickly followed by prominent motor weakness involving both the upper and lower limbs asymmetrically. Neurogenic atrophy may be prominent. Nerve biopsy reveals necrotizing neuritis with mononuclear and polymorphonuclear infiltrates and cytomegalocytes localized around endoneurial capillaries in the nerve trunks and roots. Some patients may have necrotizing arteritis. PCR for CMV in CSF and comparison of levels of antibody to CMV in the serum and CSF may be useful in establishing the diagnosis.

TREATMENT

Rx

CMV neurologic complications should be treated with ganciclovir (5 mg/kg intravenously every 12 hours) plus foscarnet (60 mg/kg intravenously every 8 hours or 90 mg/kg intravenously every 12 hours until symptomatic improvement), followed by maintenance therapy with oral valganciclovir (900 mg daily) and intravenous foscarnet (90 to 120 mg/kg intravenously during 2 hours, every 24 hours); however, evidence of efficacy in these conditions is limited chiefly to case reports and small series. Cidofovir is a second-line agent (5 mg/kg by intravenous infusion during 1 hour once a week for 2 consecutive weeks, with saline hydration and probenecid, 2 g orally 3 hours before the dose and 1 g orally at 2 hours and 8 hours after the dose). CMV strains resistant to these agents have emerged, and CMV encephalitis has developed in the presence of maintenance ganciclovir therapy for CMV retinitis. Combination therapy (foscarnet and ganciclovir) or different drugs should be considered in patients already undergoing suppressive monotherapy or in those with persistent CSF pleocytosis. Maintenance therapy, which is the same regimen given every other week, is required unless the patient experiences immune reconstitution, such as after highly active antiretroviral therapy (HAART) in an AIDS patient or discontinuation of immunosuppressive regimens in a transplant or cancer patient. CMV retinitis can be treated with intravitreal ganciclovir or fomivirsen.

PROGNOSIS

The prognosis for long-term survival, especially with AIDS, is very poor, and most patients have only limited neurologic recovery.

EPSTEIN-BARR VIRUS INFECTION

Epstein-Barr virus (EBV), the major cause of infectious mononucleosis (Chapter 377), is distributed worldwide. Individuals in areas of high population density and lower social strata acquire the virus in early childhood. However, seroepidemiologic studies indicate that virtually all persons are infected by EBV by 30 years of age.

Neurologic manifestations occur in 1 to 5% of patients with primary EBV infection and may be the predominant clinical finding. The most common neurologic disorder associated with infectious mononucleosis is meningoencephalitis, which is rare in early childhood and is most often observed in persons between the ages of 15 and 25 years. Its onset may be gradual during a span of several days or be explosive. Fever, headache, mild stiff neck, confusion, lethargy, seizures, and hyperreflexia are the most typical features. Some patients may present predominantly with ataxia, cerebellitis, or other focal neurologic features, including hemiparesis, focal seizures, and brain stem findings. Hyperintense signal abnormalities on T2-weighted and fluid attenuated inversion recovery (FLAIR) cranial MRI are frequently observed but are nondiagnostic. PCR for EBV in CSF and comparison of levels of antibody to EBV in the serum and CSF may be diagnostically useful.

Ganciclovir treatment (10 mg/kg/day intravenously for 3 weeks followed by 1000 mg/day orally for another 3 weeks or until the virus is cleared) has been used in some cases but is of unproven value. The prognosis for patients with EBV meningoencephalitis is excellent, with complete resolution anticipated in 1 to 2 weeks.

SLOW VIRUS INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Human T-Lymphotropic Virus Type 1 and Human Immunodeficiency Virus

These viruses and their neurologic sequelae are considered in Chapters 378 and 394, respectively.

Subacute Sclerosing Panencephalitis

EPIDEMIOLOGY AND PATHOBIOLOGY

Subacute sclerosing panencephalitis (SSPE), which is caused by the measles virus (Chapter 367), usually affects children but can present in young adulthood. Patients generally have a history of measles within the first 2 years of life, and it is speculated that such early host exposure allows the emergence of persistent but defective virus replication because the SSPE virus genome, particularly the matrix gene, differs from wild-type measles. SSPE occurs after a latency period of months to years following acute measles infection. As a result of effective vaccination strategies against measles virus, the incidence of SSPE has decreased markedly to about 4 to 5 cases per year in the United States, but it remains 21 cases per million population in India.[2]

Gray matter is most prominently involved. The pathologic features of SSPE include gliosis, loss of myelin, and perivascular infiltrates of lymphocytes and plasma cells in white and gray matter. Neuronal cell loss is seen in later stages of the illness. Intranuclear Cowdry type A inclusions containing viral nucleocapsids are identified in neurons and glia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

SSPE usually begins with cognitive and behavioral changes, and cortical blindness is often an early feature. Progression is associated with motor dysfunction, including prominent myoclonus, cognitive decline, choreoathetosis, dystonia, and rigidity. Its course progresses during a period of 1 to 3 years to rigid quadriparesis and a vegetative state, frequently accompanied by autonomic features, such as hyperthermia, excessive sweating, and altered pulse and blood pressure. The condition is more common in rural settings and affects boys more often than girls. Retinal changes such as macular retinitis and pigmentary changes can precede the neurologic manifestations by several months.

The electroencephalogram typically reveals unilateral or bilateral periodic complexes with synchronous bursts of two or three high-amplitude slow waves per second, with recurrence at regular intervals of 5 to 8 seconds and a 1 : 1 relationship with myoclonic jerks.[3] MRI of the brain shows high signal intensity lesions that are diffuse in the subcortical and periventricular white matter with cortical atrophy, but also rarely may involve the basal ganglia and brain stem. In early stages of the illness, the MRI may be normal. Computed tomography (CT) of the brain shows generalized atrophy. CSF protein, glucose, and cell levels are usually normal; CSF is characterized by a high immunoglobulin concentration, oligoclonal bands, and intrathecal synthesis of antibody to measles virus antigens. Serum measles antibody titers are also high. These findings are usually sufficiently characteristic for diagnosis, but measles RNA can be detected in the brain by PCR. Rarely, brain biopsy is needed for definitive diagnosis in atypical cases. Measles virus may also cause subacute encephalitis in an immunocompromised host. The prominence of cognitive and motor dysfunction in these patients resembles that of SSPE, but in the clinical setting, its subacute onset and more rapid evolution and the presence of generalized seizures rather than myoclonus are distinctive. Brain abnormalities include abundant intranuclear inclusions, but inflammation is minimal, and neither serum nor CSF antibody titers against measles virus are high. For this reason, brain biopsy is generally needed for diagnosis.

TREATMENT AND PROGNOSIS

Rx

There is no established, unequivocally effective treatment of SSPE, but arrest of the disease has been reported in some patients with SSPE after long-term treatment with intrathecal interferon-α with intravenous ribavirin or oral inosine pranobex. About 5% of patients remit spontaneously, but SSPE progresses inexorably to coma, brain stem involvement, and death in 2 to 5 years in the remainder of patients. In immunosuppressed children, such as those with HIV infection, SSPE may be fulminant and may result in death over weeks to 3 to 4 months.

Progressive Rubella Panencephalitis

Progressive rubella panencephalitis is a rare disorder resembling SSPE but caused by rubella virus (Chapter 368). It occurs as a complication of congenital rubella syndrome or, more typically, after childhood rubella. With the advent of widespread rubella immunization, this disorder has been nearly eliminated in the United States.

A hiatus of years separates early infection from the onset of neurologic deterioration, which is characterized by behavioral changes, cognitive impairment, cerebellar ataxia, spasticity, and sometimes seizures. Myoclonus is a less prominent feature than it is in SSPE. Serology or isolation of the virus from brain or peripheral blood lymphocytes confirms the cause. There is no effective treatment, and the prognosis is similar to that for SSPE.

Progressive Multifocal Leukoencephalopathy

DEFINITION

This demyelinating disease is associated with infection of oligodendrocytes by JC virus, a papovavirus that is widely distributed in humans and must undergo genetic rearrangements in its noncoding control region to enable it to replicate efficiently in glial tissue.[4] Progressive multifocal leukoencephalopathy (PML) was the first demyelinating disease to be unequivocally associated with a viral infection.

EPIDEMIOLOGY

Serologic studies indicate that the infection predominantly occurs during childhood, and more than half of the population has been infected by age 20 years. Lesser increments of JC virus seropositivity are observed in each decade thereafter. Despite the wide dissemination of JC virus infection, PML is rarely observed in the absence of underlying cellular immunosuppression. It is also rarely observed in childhood. Until the AIDS epidemic, PML was most commonly observed in patients with lymphoproliferative disorders (62% of cases) and less commonly with myeloproliferative diseases (7%), carcinomatous diseases (2%), other immunodeficiency states, and granulomatous disorders such as tuberculosis and sarcoidosis. The prevalence of PML has increased dramatically during the AIDS pandemic: as many as 5% of AIDS patients develop PML, and AIDS is now the most common underlying disorder associated with it. PML also occurs in association with the administration of monoclonal antibodies for diseases that had not previously been associated with it, including natalizumab, an α4β1 and α4β7 integrin inhibitor used in the treatment of multiple sclerosis (Chapter 411) and Crohn's disease (Chapter 141), and efalizumab, an anti-CD11a antibody that is effective in the treatment of psoriasis (Chapter 438). Other therapeutic agents (e.g., rituximab, an anti-CD20 antibody; brentuximab vedotin, a monoclonal antibody used in treatment of lymphoproliferative disorders; and mycophenolate mofetil) have also been associated with PML, but usually when used to treat disorders that already carry a risk for PML and with incidence rates that are orders of magnitude lower than are seen with natalizumab.[5]

PATHOBIOLOGY

The cardinal feature of PML is demyelination, which is typically multifocal but occasionally unifocal (Fig. 370-2). These lesions may occur in any location in the white matter but have a predilection for the parieto-occipital regions. The lesions range in size from 1 mm to several centimeters; larger lesions may reflect the coalescence of multiple smaller lesions. The other histopathologic hallmark of PML is the presence of hyperchromatic, enlarged oligodendroglial nuclei and enlarged bizarre astrocytes with lobulated hyperchromatic nuclei. Electron microscopic examination reveals the JC virions, which are 28 to 45 nm in diameter and appear singly or in dense crystalline arrays in oligodendroglial cells and, less frequently, in reactive astrocytes. Inflammatory infiltrates are typically absent, except in patients who have reconstitution of their immune system, such as HIV-infected patients being treated with HAART, in whom macrophages and lymphocytes may be found.

CLINICAL MANIFESTATIONS

The clinical hallmark of PML is the presence of focal neurologic symptoms and signs associated with radiographic evidence of white matter disease in the absence of a mass effect.[6] The most common initial symptoms include weakness, speech and language abnormalities, and behavioral and cognitive disturbances. Gait disturbances, sensory loss, and visual impairment all occur in approximately 20 to 30%. Seizures and brain stem symptoms are less common. Signs noted on physical examination parallel the reported symptoms, with weakness, typically a hemiparesis, detected in more than half of patients at initial evaluation. Gait abnormalities, cognitive problems, and speech and language disorders (i.e., dysarthria and dysphasia) are observed in about 25% of patients at initial contact. Limb and trunk ataxia, which reflects cerebellar involvement, is detected in as many as 10% of patients but may occasionally result from severe impairment in position sense (i.e., sensory ataxia). Neuro-ophthalmic symptoms occur in 50% of patients with PML and are often the initial manifestation of the disorder. The most common visual deficit is homonymous hemianopia or quadrantanopia secondary to lesions of the optic radiations. Cortical blindness may develop. Other neuro-ophthalmic manifestations include optic agnosia, alexia without agraphia, and oculomotor abnormalities. Sensory disturbances occur with PML but are distinctly less common than impairment of strength or visual function.

DIAGNOSIS

The diagnosis of PML may be strongly suggested by the clinical manifestations and the radiographic imaging. When the clinical manifestations are coupled with a positive JC virus PCR finding in CSF, the diagnosis of PML is virtually certain. Brain biopsy with demonstration of the characteristic

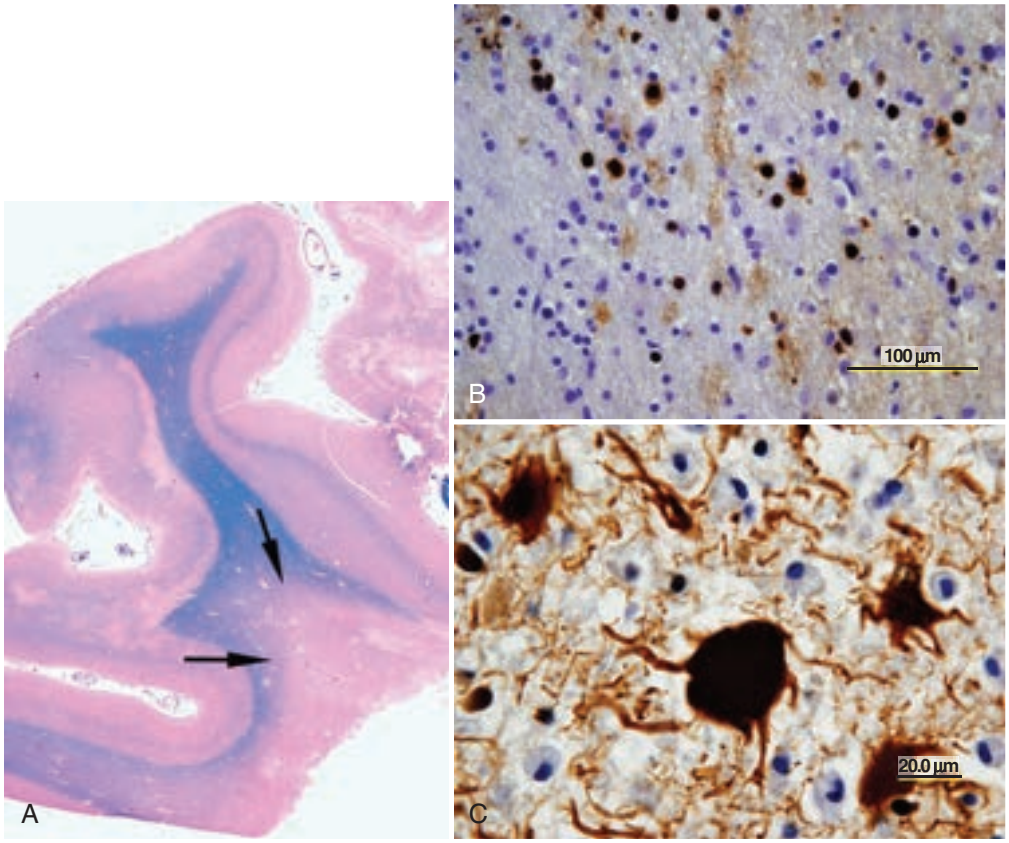

FIGURE 370-2. Pathology of progressive multifocal leukoencephalopathy. A, An area of demyelination is seen in the white matter that fails to stain with Luxol fast blue dye. **B**, Immunohistochemical staining with antibody to papovavirus shows brown-staining nuclei in oligodendrocytes, indicative of JC virus infection. **C**, Immunohistochemical staining for glial fibrillary acidic protein shows large bizarre astrocytes. (Courtesy Dr. Carlos Pardo, Johns Hopkins University, Baltimore, MD.)

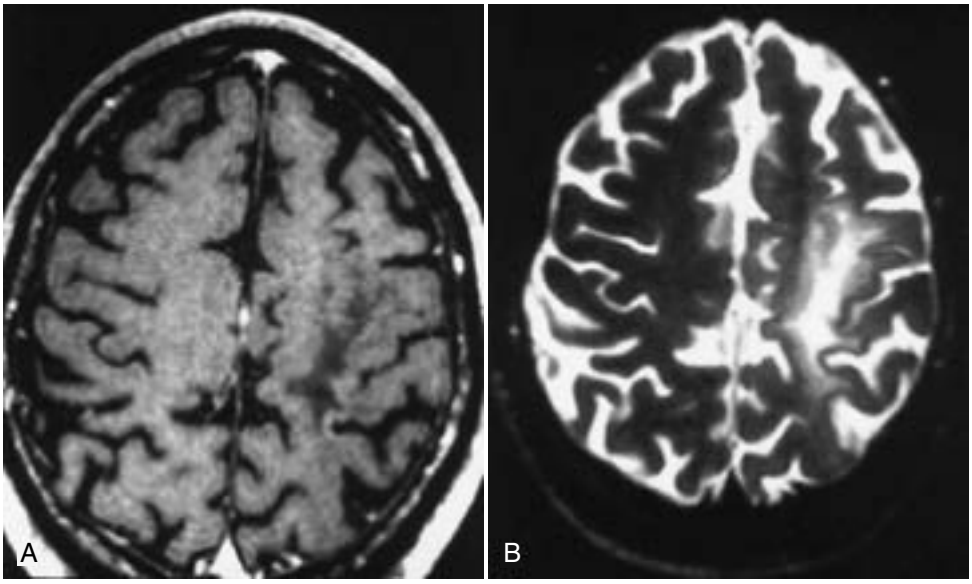

FIGURE 370-3. Cranial magnetic resonance images of progressive multifocal leukoencephalopathy. A, A T1-weighted image shows a hypointense signal abnormality of the left frontal lobe white matter. **B**, On T2-weighted imaging, the lesion is hyperintense.

histopathologic triad of PML coupled with immunohistochemical or electron microscopic evidence of JC virus remains the "gold standard" for diagnosis.

CT of the brain reveals hypodense lesions of the affected white matter that generally have a "scalloped" appearance because of involvement of the subcortical arcuate fibers lying directly beneath the cortex. Cranial MRI shows a hyperintense lesion on T2-weighted or FLAIR images in the affected regions (Fig. 370-3) and usually shows a hypointense lesion on T1-weighted images. Faint contrast enhancement, typically at the periphery of lesions, is seen in approximately 5 to 10% of pathologically confirmed cases of AIDS-associated PML and in 40 to 50% of natalizumab-associated PML on MRI. Intense intralesional nodular enhancement may be seen in patients with immune reconstitution. Frontal and parieto-occipital lobe lesions predominate, but the lesions may be observed in other sites, including the basal ganglia, the internal and external capsules, and the posterior fossa structures (i.e., cerebellum and brain stem).

The results of routine analysis of CSF are not diagnostic, but CSF protein may be elevated. CSF PCR for JC virus is of great value in diagnosis. Currently employed ultrasensitive quantitative PCR for JC virus in the CSF is not only highly sensitive but also specific.[7]

TREATMENT

Rx

Although a number of compounds can prevent JC viral replication in vitro, there currently is no effective medication for PML. The best treatment is restoration of a normal immune system by treating the underlying cause. In AIDS-related PML, an effective antiretroviral regimen improves prognosis.[8] In natalizumab-associated PML, plasma exchange can hasten the drug's elimination. When the immune system recovers, patients may develop a PML immune reconstitution inflammatory syndrome, in which a paradoxical clinical and radiographic worsening accompanies the return of a robust immune response.[9]

PROGNOSIS

Previously, PML was regarded as a fatal illness, with survival averaging 3 to 4 months in the typical patient. After the introduction of HAART, approximately 50% of patients with AIDS-associated PML survive for more than 12 months, often with partial or nearly complete clinical and radiographic recovery.[10] Factors associated with a more benign course include the presence of PML as the heralding manifestation of AIDS, high or climbing $CD4^+$ T-lymphocyte counts, contrast enhancement of the lesions on radiographic studies, and any clinical or radiographic evidence of recovery. JC virus–specific T lymphocytes appear to be critical for control of the infection.

REVIEW QUESTIONS

1. Clues to the diagnosis of cytomegalovirus (CMV) encephalitis in an AIDS patient presenting with cognitive impairment include all but which one of the following?

A. Profound immunosuppression (CD4 count <100 cells/μL)
B. Ring-enhancing lesions in the white matter of the brain on magnetic resonance imaging (MRI)
C. The presence of CMV retinitis characterized by cotton-wool spots and/or the presence of CMV pneumonitis.
D. A polymorphonuclear preponderance in the cerebrospinal fluid (CSF)
E. Progressive ventricular enlargement on brain computed tomography (CT) or MRI

Answer: B Ring-enhancing lesions are not a feature of CMV encephalitis. Brain imaging usually shows progressive increase in the size of the ventricles, as well as ependymal and meningeal enhancement. CMV encephalitis is one of the few viral encephalitides in which polymorphonuclear cells may predominate with the CSF pleocytosis. Evidence of widely disseminated CMV, such as pneumonitis and retinitis, is commonly seen in profoundly immunosuppressed patients in whom CMV encephalitis develops.

2. Which of the following disorders carries the highest risk for progressive multifocal leukoencephalopathy (PML)?

A. Sarcoidosis
B. Multiple sclerosis treated with natalizumab
C. Chronic lymphocytic leukemia
D. AIDS
E. Small cell cancer of the lung

Answer: D Almost 1 in 20 individuals, particularly in the pre-HAART era, developed PML in association with HIV infection. This incidence dwarfs that of any other disorder, although the risk exceeds 1 in 100 in individuals who are JC virus antibody positive and whose multiple sclerosis has been treated with natalizumab for more than 2 years.

3. Which of the following is the most effective treatment for PML?

A. Restoring the immune system by eliminating an offending therapeutic agent or treating HIV infection with antiretroviral therapy
B. Cyclophosphamide
C. Camptothecin
D. Mefloquine
E. Mirtazapine

Answer: A All of the drugs listed have been tried in the treatment of PML, but none has demonstrated a meaningful benefit in clinical studies. However, restoration of the immune system allows for the return of a robust JC virus–specific CD8 response in the central nervous system and may arrest the disease.

371 PARVOVIRUS

NEAL S. YOUNG

DEFINITION

B19 parvovirus, which was discovered in the mid-1970s by electron microscopic observation of an anomalous precipitin reaction of a normal blood donor's serum (occupying position 19 in plate B), was first linked to human disease by the observation of virus-specific immunoglobulin M (IgM) antibody or the virus itself in the sera of sickle cell disease patients suffering transient aplastic crisis (Chapter 163). The common illness caused by the virus was identified later during outbreaks of fifth disease, a highly contagious rash illness of childhood long suspected of having a viral etiology. The ability of parvovirus to persist and to be manifested as an isolated hematologic syndrome was demonstrated by the presence of the virus in fetal liver at autopsy of hydropic newborns and in immunosuppressed patients with chronic pure red cell aplasia (Chapter 165).

The Pathogen

The parvoviruses form small icosahedral capsids of about 25 nm. They have a limited genome of single-stranded DNA. The approximately 5600 nucleotides of B19 parvovirus show remarkably little sequence variation among isolates; two variants, V9 and A6, are of uncertain clinical significance.

The Parvoviridae family contains many pathogenic animal viruses: feline panleukopenia virus, the cause of a fatal agranulocytosis in cats; canine parvovirus, which probably arose from the cat virus as a host range variant in the 1970s to produce a global pandemic and can cause fatal myocarditis in puppies; Aleutian mink virus infection, a model of immune complex disease; and porcine parvovirus, responsible for fetal wastage in pig litters. Antibodies to human adeno-associated viruses, which are dependoparoviruses that are used as gene therapy vectors, occur naturally in humans, but B19 is the only parvovirus known to be pathogenic in humans.

EPIDEMIOLOGY

B19 infection is global; infectivity rates, inferred from the presence of antiparvovirus IgG antibody in sera, are similar worldwide. Only isolated populations, Amazonian tribesman, and residents of remote islands off the coast of Africa have escaped exposure. B19 parvovirus infection is common in childhood, and half of 15-year-old adolescents have specific antiparvovirus B19 antibodies. Infection continues throughout adult life, and most elderly people are seropositive. In temperate climates, most infections occur in the spring, with small epidemics every few years being typical. Transmission is respiratory by droplet spread, and secondary infection rates among household contacts are high. Nosocomial infection can occur, and B19 parvovirus has been transmitted in blood products, especially pooled components such as factor VIII and IX concentrates. Producers of plasma derivatives now voluntarily screen by quantitative measurement of B19 DNA to reduce the risk for iatrogenic transmission.[1] The lack of a lipid envelope and the stable DNA genome make parvoviruses notoriously resistant to heat inactivation and solvent detergents.

PATHOBIOLOGY

The biology of the Parvoviridae makes them especially dependent on helper function from host cells or other viruses.[2] The autonomous parvoviruses propagate in actively dividing cells; the family Parvoviridae includes disease-causing animal parvoviruses. Adeno-associated viruses grow in tissue cultures infected with adenoviruses and herpesviruses and are popular vectors for gene transduction and therapy. B19 is the type member of the *Erythrovirus* genus, which includes very similar simian viruses, all of which are best propagated in the erythroid progenitor cells that are responsible for red blood cell production in the bone marrow. Active replication of virus can be detected by the presence of double-stranded intermediate forms by simple DNA hybridization methods. The transcription map of the erythroviruses differs markedly from that of other Parvoviridae. Only three genes produce proteins of known function. Many antigenic determinants recognized by the host immune system are located in helical loops that form the surface of each capsomere. Most of the capsid is composed of a major structural protein, called VP2, but about 5% of the capsid is the minor structural protein, VP1, which differs from VP2 only by an additional 226 amino acids at the amino terminus; this VP1 unique region is located external to the capsid surface and contains linear epitopes recognized by neutralizing antibodies.

The only known natural host cell of B19 parvovirus is the human erythroid progenitor. The tropism of the virus for an erythroid cell host results from its cellular receptor, globoside, a neutral glycolipid also known as erythrocyte P antigen. Rare individuals with the p phenotype, who congenitally lack globoside on their erythrocytes, are genetically insusceptible to B19 parvovirus infection; they show no serologic evidence of previous infection, and their marrow erythroid progenitors proliferate normally in the presence of high concentrations of virus. Parvovirus kills erythroid progenitors by expression of its nonstructural protein, and it is possible that some cells, such as megakaryocytes, may be lysed by restricted expression of viral proteins in the absence of viral propagation. B19 can be efficiently propagated in tissue culture of primary human hematopoietic cells in which erythropoietic differentiation is stimulated by erythropoietin.

The humoral immune response is dominant in B19 parvovirus infection. Natural antibody production correlates with disappearance of the virus from blood, and the presence of IgG appears to confer lasting protection against a second infection. Parvovirus infection can persist if immunoglobulin production is defective such that antibody fails to neutralize the virus; reactivity of antibodies to the unique amino-terminal region of VP1 is especially important.

CLINICAL MANIFESTATIONS

Fifth Disease

Most B19 parvovirus infections are asymptomatic. The most common clinical manifestation of infection is erythema infectiosum, or fifth disease, a rash illness of childhood characterized by a "slapped cheek" appearance (Fig. 371-1). In adult volunteers inoculated intranasally with B19, nonspecific influenza-like complaints occurred early along with viremia; the cutaneous eruption a week later corresponded to the appearance of antiviral antibodies. These more specific symptoms of B19 parvovirus infection are secondary to immune complex formation and deposition. Serologic testing generally shows seroconversion, IgM antibody or the appearance of IgG antibody to parvovirus. The rash of fifth disease may be evanescent, and recurrences can be provoked by sunlight, heat, emotion, or exercise. Fifth disease can be confused with rubella. In adults, the rash is less characteristic, can present as palpable purpura, may be associated with pruritus in up to 50% of patients,[3] and can be difficult to visualize in dark-skinned individuals.

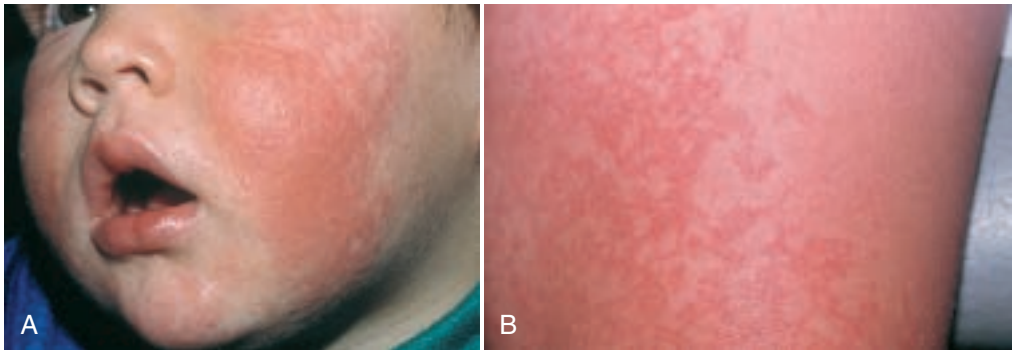

FIGURE 371-1. Erythema infectiosum. In this infection by parvovirus B19, a child will develop prominent erythema of the cheeks, "slapped cheeks" (A), followed by a lacelike erythema on the extremities (B) and buttocks. It is also known as fifth disease.

B19 Arthropathy

In contrast to the mild course in children with fifth disease, acute parvovirus infection in adults, particularly middle-aged women, may cause significant arthropathy.[4] Not only arthralgia but also a true inflammatory arthritis occurs in about 50% of older patients. Symmetrical joint involvement of the hands, ankles, knees, and wrists can resemble rheumatoid arthritis (Chapter 264), and the test result for rheumatoid factor may be positive. B19 arthropathy usually resolves within a few weeks; joint destruction does not occur. Parvovirus is not the cause of rheumatoid arthritis, but case reports suggest that B19 infection may mimic, precipitate, or worsen a variety of rheumatologic diseases, including juvenile rheumatoid arthritis, systemic lupus erythematosus, and fibromyalgia.

Transient Aplastic Crisis

In persons with underlying hemolysis or a high demand for production of circulating erythrocytes, acute B19 parvovirus infection causes transient aplastic crisis, an abrupt cessation of red blood cell production that exacerbates or, in previously compensated states, provokes severe anemia. Erythropoiesis is temporarily suppressed in all B19 parvovirus infections, but hemoglobin levels remain stable because of the long lifespan of erythrocytes. The anemic crises associated with low or absent reticulocytes in hereditary spherocytosis and sickle cell disease are virtually always secondary to B19 parvovirus infection. Parvoviremia is present in patients with transient aplastic crisis, and red cell production resumes once antibodies to the virus are produced and the infection is cleared. Transient aplastic crisis is generally a unique event in the patient's life, thus suggesting induction of long-lasting protective immunity. Although it is self-limited, aplastic crisis often requires transfusion and can lead to severe, occasionally fatal anemia that precipitates congestive heart failure and cerebrovascular accidents. Transient aplastic crisis is associated with a stereotypical bone marrow morphology, absence of maturing erythroid precursors, and the presence of "giant pronormoblasts" (Fig. 371-2) that are the cytopathic effect of parvovirus infection.

White blood cell and platelet counts may fall modestly during transient aplastic crisis, especially in patients with functioning spleens. Occasional cases of agranulocytosis may be due to B19; thrombocytopenia and pancytopenia have been reported, and B19 can precipitate a benign virus-associated hemophagocytic syndrome.

Persistent Infection

In patients who cannot mount an appropriate host antibody response, B19 parvovirus persists in the circulation, often at extremely high levels ($>10^{12}$ genome copies per milliliter). Patients do not develop the clinical features of fifth disease but instead have an entirely hematologic syndrome of pure red cell aplasia. The anemia is severe and requires transfusion; reticulocytes are absent from blood, as are erythroid precursors from marrow. Observation of giant pronormoblasts in the marrow may lead to the diagnosis. The failure to produce neutralizing antibodies to B19 parvovirus occurs in patients with congenital immunodeficiency (Nezelof's syndrome), with iatrogenic immunodeficiency (chemotherapy or immunosuppressive drugs), and with acquired immunodeficiency. Pure red cell aplasia secondary to parvovirus may be the first manifestation of the acquired immunodeficiency syndrome (AIDS), but this presentation is less common in the era of highly active antiretroviral therapy. Epidemiologic studies have suggested that parvovirus infection may worsen the manifestations of malaria (Chapter 345), especially the severity of anemia.[5]

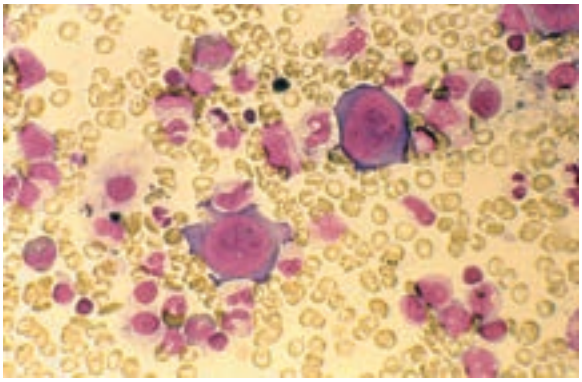

FIGURE 371-2. Bone marrow aspirate of a patient with chronic pure red cell aplasia secondary to persistent B19 parvovirus infection. Mature erythroid precursors are absent, and the prominent giant pronormoblasts are typical of B19 infection.

Hydrops Fetalis

B19 parvovirus infection of the pregnant mother followed by transplacental transmission to the fetus can lead to an adverse outcome, either miscarriage or hydrops fetalis.[6] Parvovirus infects the fetal liver, the site of erythrocyte production during early development. Hydrops is the result of severe anemia as well as perhaps myocarditis, contributing to congestive heart failure. Prospective studies have led to an estimated 30% risk for transplacental infection and 9% risk for fetal loss in women who are exposed to B19 during pregnancy. Infection during the second trimester poses the greatest risk for birth of a hydropic infant; B19 parvovirus accounts for 10 to 20% of all cases of nonimmune hydrops fetalis. The risk for spontaneous abortion resulting from first-trimester infections has been more difficult to quantitate. The likelihood of an infection increases in epidemic years and correlates with the level of contact of the pregnant woman with children. Although most B19 infections during pregnancy probably do not lead to either loss of the fetus or congenital anomalies, B19 infection is a cause of fetal death. Congenital malformations have not been consistently associated with intrauterine parvovirus infection. However, severe anemia at birth with bone marrow histology consistent with either constitutional pure red cell aplasia (Diamond-Blackfan anemia) or congenital dyserythropoietic anemia has occurred in infants salvaged by in utero blood transfusions or exchange transfusion at birth.

Other Syndromes

Elevated hepatic aminotransferase levels can accompany fifth disease, and parvovirus infection has been associated with severe but usually self-limited hepatitis in some children.[7] The presence of B19 genetic sequences in cardiac tissue has led to a diagnosis of parvovirus myocarditis.[8] Serologic and DNA evidence of B19 infection implicated parvovirus in some patients with necrotizing vasculitis, Kawasaki disease, Henoch-Schönlein purpura, and giant cell arteritis. Glove-and-sock syndrome, an exanthem localized to the hands and feet and consisting of edema, erythema, paresthesia, and pruritus has

TABLE 371-1 DIAGNOSIS OF PARVOVIRUS B19

been linked to B19. Chronic fatigue syndrome may follow parvovirus infection. Meningitis, encephalitis, and a variety of neurologic complications may occur with fifth disease and parvovirus infection.[9]

False-positive results arise when the diagnosis of infection rests on detection of amplified B19 genome by polymerase chain reaction, and, furthermore, B19 parvovirus can persist at low levels in normal individuals for many months after infection.

DIAGNOSIS

Laboratory diagnosis relies on serologic and DNA tests[10] (Table 371-1). Virus-specific antibodies are measured in standardized commercial solid-phase enzyme-labeled immunoassays, generally using recombinant capsid proteins. "Capture" formats are preferred to detect serum IgM, which is first bound to a solid phase coated with anti-μ-chain antibodies, followed by the addition of viral antigen and an antiviral monoclonal antibody. IgM antibodies are diagnostically positive in almost all cases of fifth disease at initial evaluation and appear within a few days of the onset of transient aplastic crisis; IgM may persist for months after acute infection. IgG is usually assayed in conventional indirect assays. IgG circulates later than IgM, generally at the end of the first week of illness. Although titers of IgG are generally highest in the year after an acute infection, substantial interindividual variation and the presence of IgG in a large proportion of the population make measurement of IgG less helpful than other tests for diagnosis of parvovirus. DNA assays are required for persistent B19 infection, in which antibody production is absent or minimal. Parvovirus can also be found in the sera of patients with early transient aplastic crisis. Direct hybridization methods are reliable, and they detect clinically relevant viral titers of greater than 10^6 international units (orders of magnitude below levels present in both acute and persistent infection). Gene amplification methods are more sensitive but less reliable because of false-positive results. Virus can be detected in amniotic fluid, and both virus and IgM antibody to B19 are found in umbilical cord blood; the mother's serum will show seroconversion during pregnancy, but maternal IgM may be absent at the onset of hydrops fetalis.

PREVENTION

Effective vaccines exist for animal parvoviruses, and human B19 infection can also probably be prevented. A recombinant immunogen in development for the human virus lacks DNA and is therefore noninfectious; the empty capsids have been engineered to overexpress the highly immunogenic minor structural protein VP1, and a single 2.5-μg dose of empty capsids elicited excellent neutralizing antibody responses in normal volunteers. Vaccination could prevent transient aplastic crisis in patients with sickle cell disease and other hemolytic anemias, pure red cell aplasia in some immunodeficient individuals, and hydrops if seronegative mothers were inoculated early in pregnancy.

TREATMENT

Most parvovirus infections in normal children and adults do not require specific therapy. Isolation of infected individuals is impractical, with the exception of hospitalized cases. Pure red cell aplasia and the underlying persistent B19 parvovirus infection can be dramatically terminated by discontinuation of immunosuppressive therapy or institution of effective antiretroviral drugs in patients with AIDS. Commercial immunoglobulins are a good source of antibodies to parvovirus, and persistent B19 infection responds to a 5- or 10-day course of IgG at 0.4 g/kg with a prompt decline in serum viral DNA, as measured by hybridization methods, accompanied by reticulocytosis and increased hemoglobin levels. This regimen has been curative in congenital immunodeficiency, but parvovirus in AIDS patients can persist at lower levels, and relapses of anemia may require repeated IgG administration. Immunoglobulin therapy can precipitate fifth disease rash and arthralgia.[11] Hydrops fetalis may resolve spontaneously, but intrauterine blood transfusions have been used with apparent success. Chronic arthropathy has been treated symptomatically with anti-inflammatory drugs, and there is not a role for the administration of immunoglobulin. As important as recognizing parvovirus infection is avoiding misinterpretation of laboratory studies, such as positive IgG serology or borderline IgM and DNA test results, and misguided maneuvers that delay appropriate alternative treatments.

REVIEW QUESTIONS

1. A 5-year-old is brought by her concerned parents because of sudden onset of a rash over her face and chest. The patient has no other complaints or physical findings. Her older sibling suffered the same symptoms, and a fifth disease "epidemic" has been publicized in the local school district. Which is the appropriate action?

A. Order appropriate serologic tests for viruses that can cause rash, including measles, rubella, human herpesvirus 6, and parvovirus; then treat her accordingly.
B. Reassure the child and family.
C. Reassure the family, but recommend that the child not attend school until the rash clears.
D. Test all family members for antibodies to parvovirus B19 and for the presence of virus by sensitive DNA assays.
E. Assess for B19 DNA; if positive, administer a short course of immunoglobulin.

Answer: B Expensive and intrusive testing is to be avoided in the evaluation of acute parvovirus infection in children, who are almost always minimally symptomatic and will have an uncomplicated clinical course. Fifth disease frequently appears as an epidemic, often at 3-year intervals in a population. Further evaluation would be warranted only in the unlikely event of more serious symptoms in any family member. Because the cutaneous eruption occurs after the formation of antibodies to parvovirus, the child is no longer infectious and may attend school.

2. You follow an 18-year-old girl who has sickle cell disease with only occasional pain crises on hydroxyurea therapy. Her parents inform you that she is more tired than usual, unwilling to attend school, and sleeping much of the day. You are aware of an epidemic of fifth disease in the community. What is your response to the child's parents?

A. Reassure them that she is suffering from parvovirus infection, which is not a serious infection of childhood.
B. Immediately hospitalize the child and administer human immunoglobulin in order to clear any active parvovirus infection.
C. Recommend laboratory testing in the next few days, including a blood count and parvovirus B19 serology. If the hemoglobin is below normal, transfuse her; then if anti-B19 immunoglobulin G (IgG) is detected, administer immunoglobulin.
D. Have the child seen that day to determine her hemoglobin level and reticulocyte count. If both are lower than expected, transfuse packed red blood cells.
E. Ask the parents to be alert to new, worrisome complaints, either a skin rash or joint symptoms, that would then trigger a more extensive evaluation.

Answer: D The symptoms and setting are highly suggestive of transient aplastic crisis of sickle cell disease, in which marked worsening of anemia can be life-threatening. The child should be seen emergently; a low reticulocyte count establishes the diagnosis, and erythrocyte transfusion will alleviate the symptoms. In transient aplastic crisis, serology is not useful because specific IgG and IgM to parvovirus likely will not be detected. Viral levels of B19 would be expected to be very high. However, children with sickle cell disease mount normal responses to B19 antigens and will resolve the infection within a few days or a week, so immunoglobulin therapy is unnecessary.

3. A 38-year-old mother of three presents with a history of several weeks of severe joint pains and swelling, especially of her hands and knees, as well as morning stiffness and fatigue. She relates that two of her children had a rash a few weeks preceding her illness and that a community outbreak of parvovirus was suspected. On physical examination, she has mild swelling and marked tenderness over the proximal phalangeal joints, tenderness on palpation of her knees, but no cutaneous eruption. Laboratory screening is largely unrevealing, including normal blood counts and routine chemistries, sedimentation rate, antinuclear antibody, and rheumatoid factor. However, serologic testing for antibodies to B19 parvovirus shows a high level of anti-IgG and above normal IgM. What do you recommend?

A. Reassure the patient that she likely has a self-limited illness and prescribe nonsteroidal anti-inflammatory drugs for symptom control.
B. Perform polymerase chain reaction testing to detect B19 parvovirus; if the virus is detected, administer immunoglobulin.
C. Perform an invasive evaluation—including arthroscopy, synovial biopsy, bone marrow biopsy, and cardiac imaging—to detect other evidence of parvovirus infection.
D. Monitor serologic assays and perform B19 by gene amplification before deciding on therapy.
E. Refer her to a specialist because there is insufficient evidence to link her symptoms to a parvovirus infection.

Answer: A Arthopathy after a parvovirus infection may be debilitating in an adult. The pattern of symptoms and joint involvement can mimic rheumatoid arthritis, but without synovial destruction. The diagnosis is clinical, and tissue sampling is not known to be helpful. The typical patient relates a convincing history of exposure, as for example to children with fifth disease, and the laboratory shows evidence of past infection without viremia. The pathophysiology is not well understood, but immunoglobulin is not indicated, nor has it been effective. In most patients, only symptomatic treatment is required, and gradual resolution without sequelae is expected.

4. A 23-year-old woman in the second trimester of pregnancy reports that her children were exposed to a parvovirus B19 outbreak at school and now show the "slapped cheek" rash. She feels well. What is your advice?

A. Because parvovirus leads to early fetal loss, mid-trimester abortion, and congenital malformation, you should recommend early termination of the pregnancy.
B. Watchful waiting for symptoms
C. Intrauterine red blood cell transfusion
D. Immunoglobulin injections
E. Serologic testing and ultrasound

Answer: E Most women who are exposed to B19 during pregnancy do not become infected, and only a minority of those who are infected have adverse consequences in their fetuses. The most prudent approach is to determine whether infection has occurred by evidence of IgM antibody or IgG seroconversion; if infection is documented, the course of pregnancy should be followed with ultrasounds of the fetus. The mother will mount a neutralizing antibody response, so immunoglobulin is not necessary. Intrauterine transfusion is of uncertain benefit even to the hydropic fetus.

5. A 30-year-old man with severe anemia is found on screening to be HIV positive. Laboratory testing shows a very low reticulocyte count, and there are no erythroblasts on his bone marrow examination. He is seronegative for parvovirus B19. What therapy do you recommend?

A. Blood transfusions
B. Immunoglobulin therapy followed by highly active antiretroviral therapy
C. Corticosteroids
D. Thymectomy
E. Highly active antiretroviral therapy

Answer: B Pure red cell aplasia in an HIV-infected individual is likely secondary to persistent parvovirus infection, and anemia may be the presenting manifestation of AIDS. In the absence of an adequate immune response, the virus infects red cell progenitors. Serology is often negative because of the absence of an immune response. However, the diagnosis can be established by detecting the virus itself in blood, where it should be abundant. This syndrome has become less prevalent in the era of highly active antiretroviral therapy, which is indicated in this patient. In addition, a course of immunoglobulin therapy is likely to clear the parvovirus and quickly resolve the pure red cell aplasia.

SMALLPOX, MONKEYPOX, AND OTHER POXVIRUS INFECTIONS

INGER K. DAMON

DEFINITION

Human illness caused by a poxvirus is characterized by a cutaneous manifestation; illness may be localized or systemic, depending on the particular poxvirus and the route of introduction. DNA-based assays, including DNA sequencing, are the most precise methods for identification and differentiation of poxvirus genera, species, strains, and variants. The guanosine plus cytosine content of orthopoxviruses, yatapoxviruses, molluscum contagiosum virus, and parapoxviruses is approximately 33%, 32%, 60%, and 63%, respectively.

The Pathogens

All poxviruses described in this chapter (Table 372-1) belong to the family Poxviridae, subfamily Chordopoxvirinae.

EPIDEMIOLOGY

Recognition of the epidemiologic characteristics of poxvirus diseases is valuable in assessing the potential etiologic agent of a particular suspected poxvirus lesion. Knowledge of zoonotic reservoirs, geographic localizations, and capacity for epidemic transmission is critical for clinical assessment and control measures. All human poxvirus infections are zoonotic in nature, with the exception of molluscum contagiosum and variola, which are solely human pathogens. Transmission of virus to humans and to animals is through direct contact with lesions or by fomites.

Parapoxvirus and molluscipoxvirus infections are endemic worldwide; orthopoxvirus and yatapoxvirus infections are geographically restricted, probably by the distribution of competent reservoir hosts. With the exception of variola virus (the causative agent of smallpox, a disease declared eradicated in 1980), none of these diseases is required to be reported to public health systems; furthermore, diagnostics are not widely available, so it is difficult to estimate disease incidence and prevalence with any certainty. In addition to variola virus, Congo Basin clade monkeypox viruses are considered to be select agents by the U.S. government; they must be reported and appropriately handled if discovered and if samples are maintained in the United States.

Orthopoxvirus

The epidemiology of smallpox, caused by the orthopoxvirus variola, is understood through detailed studies conducted during the end of the eradication campaign. Interhuman transmission of variola virus generally occurred through the inhalation of large airborne respiratory droplets of infectious

TABLE 372-1 TAXONOMY OF POXVIRUSES KNOWN TO INFECT HUMANS

GENUS	SPECIES
Orthopoxvirus	Variola virus, vaccinia virus, cowpox virus, monkeypox virus
Parapoxvirus	Orf virus, milker's node virus, bovine papular stomatitis virus, sealpox virus
Yatapoxvirus	Tanapox virus (Yaba-like disease virus), Yaba monkey tumor virus
Molluscipoxvirus	Molluscum contagiosum virus

variola virus. Transmission usually required prolonged face-to-face or other close contact, although airborne transmission over longer distances had been reported. Transmission by fomites or contact with infectious material from the rash also occurred. Aggregate data, collected during the smallpox eradication campaign, suggest a secondary attack rate of 58.4% in unvaccinated close or household contacts and a secondary attack rate of 3.8% in previously vaccinated close or household contacts. Case-fatality rates for variola major varied with the type of disease manifested, but aggregate rates of 10 to 30% in various outbreaks have been recorded. Severity of disease correlated with rash burden and was also more severe in children and pregnant women. Variola alastrim minor, a variant of variola with a case-fatality rate of less than 1%, has similar human-to-human disease transmission characteristics.

Monkeypox has a more complex epidemiology. The virus is zoonotic, and two genetically discrete virus clades have been described, each with apparent distinct clinical and epidemiologic parameters. Human infections in western and central Africa were first identified in 1970. Investigations in the Congo basin country Zaire, now the Democratic Republic of Congo, demonstrated that human-to-human transmission of monkeypox was less prevalent than that of smallpox. The secondary attack rate in unvaccinated contacts of monkeypox cases was calculated to be 9.3% versus 37 to 88% for smallpox. Previous smallpox vaccination (3 to 19 years previously) appeared to be 85% protective in preventing disease acquisition in contacts and also ameliorated the severity of disease. Overall, most identified cases acquired disease from presumed animal exposure; only 28% of cases were ascribed to person-to-person transmission. A case-fatality rate of approximately 10% was observed in unvaccinated persons, and the majority of fatalities and the most severe disease manifestations were observed in children younger than 5 years. Serosurveys suggested that subclinical infection may have occurred in up to 28% of close contacts of monkeypox patients in some communities; this relatively low rate may contribute to the rarity of sustained generations of human-to-human transmission in household and other close contact situations.

Among primary cases, recent close contact—through hunting, skinning, killing, cooking, or playing with carcasses—was identified with *Cercopithicus, Colobus,* and *Cercocebus* (primate); *Cricetomys* (terrestrial rodent); and *Funisciurus* and *Heliosciurus* (squirrel species). Samples of animals collected in areas of western and central Africa surrounding human cases demonstrated orthopoxvirus and sometimes monkeypox-specific seroprevalence in various members of these species, except in *Cricetomys* species. The prevailing hypothesis was that squirrel species were the probable reservoir of disease.

The disease reemerged in 1996 in the Democratic Republic of Congo, this time with 88% of cases derived from secondary human-to-human contact presumed to be because of the cessation of routine smallpox vaccination in 1980 after the eradication of smallpox. Mortality was only 1%. Ecologic serosurveys showed orthopoxvirus seroprevalence in terrestrial rodents *(Cricetomys emini)* and in one domestic pig *(Sus scrofa).*

Monkeypox virus was introduced to the United States in 2003 through a consignment of animals from the West African country of Ghana. The virus was identified as belonging to a distinct clade of monkeypox that included previous West African monkeypox isolates as well as isolates derived from earlier outbreaks in primate colonies. The U.S. cases had a less pronounced rash and a less severe illness, with no mortality or human-to-human transmission. When cases in the United States (2003) were compared with cases in Congo Basin (1980 to 1986), disease in the United States was less severe based on clinical criteria, the extent of the rash, and the case-fatality rate after controlling for age and vaccination status.[1] These data, along with comparison of the genomes of West African and Congo Basin monkeypox viruses, suggest at least two populations or clades of monkeypox virus. The apparent decreased pathogenicity and transmissibility of West African clade monkeypox virus infection led, in part, to its declassification as a U.S. select agent in 2013.

Cowpox virus is found in Europe and Asia and is maintained in rodents; in Britain, the reservoirs are bank voles and wood mice. Human infection is a zoonosis. The domestic cat has been a common source of human infection, which probably explains the occurrence of cases in children; 26% of 54 cases occurred in children younger than 12 years. Most feline and human cases occur between July and October, with only occasional cases between January and June. Recent outbreaks in Europe have documented pet rats, or feeder rats, to be a source of transmission to humans. No case of bovine cowpox has been detected since 1976. Cowpox virus also is prevalent in European zoos, where cheetahs, lions, anteaters, rhinoceros, elephants, and okapi have occasionally transmitted infection to animal handlers.

Vaccinia is the live virus contained in preparations of the smallpox vaccines used to eradicate smallpox. In the United States, the vaccine is recommended for laboratory workers who use replicative orthopoxviruses and for selected military personnel. Contacts of vaccinees occasionally develop vaccinia infections. The origin of vaccinia is unknown, and no natural host for the virus is known. Recent studies have further distinguished cowpox and vaccinia viruses, both of which have been used as smallpox vaccines, and have identified at least three groups of cowpox and most vaccinia viruses group with one of these cowpox clades.[2] Vaccinia "variants" have been described, including buffalopox from contact with infected animals in India and vaccinia viruses in cattle handlers in Brazil.

Parapoxvirus

Human infection is an occupational hazard of farm workers, abattoir workers, veterinary surgeons, and students. It is most common in the lambing and calving seasons and among sheep workers.

Factors responsible for ongoing transmission have been attributed both to the environmental stability of orf virus in scab material and to the manifestation of chronic infections in some animals. A new parapoxvirus has been identified in deer hunters found to have cutaneous lesions after hunting and field dressing deer.[3]

Molluscipoxvirus

Molluscum contagiosum virus occurs worldwide, and increasing reports of the disease have paralleled the number of reported cases of acquired immunodeficiency syndrome (AIDS).[4] Traditional modes of transmission are associated with mild skin trauma such as abrasions, direct contact with a lesion, and fomites (e.g., shared towels) in some cases. However, the disease appears to be sexually transmitted, and genital lesions are more common than lesions elsewhere on the body. Children in daycare or school situations may transmit the disease to other children. Secondary spread of lesions may occur by autoinoculation (excoriation of primary lesions and spread to areas of normal skin) as well as by shaving. No known animal reservoir exists.

Yatapoxvirus

Tanapox virus is restricted to Africa, principally to Kenya and the Democratic Republic of Congo, and probably has a simian reservoir. Direct primate-to-human transmission through a break in skin has rarely been described in animal handlers, but an insect or arthropod intermediary may be involved in the transmission of tanapox virus to humans. No human-to-human transmission has been reported. Yaba monkey tumor virus causes localized infections after contact with infected primate lesions. Little is known about the epidemiology of this virus.

PATHOBIOLOGY

The majority of smallpox infections were initiated by inhalation of respiratory droplets and implantation of virus on the oropharyngeal and respiratory mucosa. No primary localized site of infection was evident if the route of exposure was by inhalation. Disease could also be introduced through suspensions of virus obtained from scabs of patients that were introduced percutaneously and constituted the practice of variolation. In these cases (when skillfully administered), illness was usually less virulent, a localized primary infectious lesion was present, and the asymptomatic incubation period was truncated.

After entry, virus moves to local lymph nodes and then disseminates to the reticuloendothelial system to replicate further. At this time, the individual is asymptomatic. In 10 to 14 days, secondary viremia occurs and heralds the prodrome of symptomatic illness. During this time, virus seeds the oropharynx and epidermis. The absence of a keratinized structure in the mucosa of

the oropharynx leads to ulceration and release of virus in saliva; virus replicates in the epidermis to cause the characteristic macular, papular, and vesicular eruptions of smallpox.

In experiments in monkeys, high levels of type I interferons, interleukin-6, and interferon-γ are seen; D-dimers and thrombocytopenia suggest disseminated intravascular coagulation. Apoptosis with loss of T cells in lymphoid organs was also observed. Of note, tumor necrosis factor-α (TNF-α) levels were minimal in the infected animals, with a notable decrease in the expression of genes regulated by nuclear factor κB and TNF-α.

In humans, the viral lesions characteristic of illness primarily develop in the epidermis, where the cells of the malpighian layer swell and vacuolate to undergo ballooning degeneration. The cytoplasm continues to enlarge, loss of nuclear material is noted, and coalescence of vacuoles through cell rupture creates reticulating degeneration of the middle and upper layers of the stratum spinosum. In the next stages, the vesicle is formed. High titers of virus are found within the lesions. In mucosal surfaces, the absence of a horny layer allows the necrosis caused by proliferation of virus within the epithelium to create ulcers and leads to liberation of large quantities of virus into the oropharynx. Evaluation of other organs in human smallpox has been done only in select autopsy cases. Mild pathologic changes are seen in the lungs.

CLINICAL MANIFESTATIONS

Orthopoxvirus

Smallpox

Naturally acquired variola virus infection is characterized by fever and a distinctive rash, with several different clinical presentations (Table 372-2).[5] When the disease still existed, an asymptomatic incubation period of 10 to 14 days (range, 7 to 17) was followed by a fever that quickly rose to about 103° F (38° to 40° C), sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash with a characteristic centrifugal distribution (i.e., lesions present in greater numbers on the oral mucosa, face, and extremities than on the trunk) appeared. The fever typically abated as the rash developed. Lesions commonly appeared on the palms and soles. The rash lesions were initially macular and then advanced to the papular stage, at which point they enlarged and progressed to a vesicle by day 4 to 5 and a pustule by day 7. When lesions became pustular, the fever typically returned. Lesions became encrusted and scabbed by day 14 and then sloughed off. Skin lesions in the vesicular and pustular stages were deep seated and in the same stage of development in any one area of the body (Fig. 372-1). The ordinary disease type was subgrouped into three categories based on the extent of rash on the face and the body: confluent, semiconfluent, and discrete. In *ordinary confluent disease,* no area of skin was visible between vesiculopustular rash lesions on the trunk or the face. In *ordinary semiconfluent* and *discrete disease,* patches of normal skin were visible between rash lesions on the trunk and face, respectively. Less severe manifestations (modified smallpox or variola sine eruptione) occurred in both unvaccinated and, more commonly, vaccinated individuals. The mortality rate correlated with the rash burden.

Four main clinical types of variola can be subgrouped according to the World Health Organization (WHO) classification schema: *ordinary smallpox* (≈90% of cases) produced viremia, fever, prostration, and rash, and mortality rates were generally proportional to the extent of rash and ranged as described earlier; *(vaccine) modified smallpox* (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people and had a mortality rate well below 10%; *flat smallpox* (≈5% of hospitalized cases) produced slowly developing lesions that were difficult to ascertain because they appeared flush with the (edematous) skin at the vesicular stage, and it was almost always fatal; and *hemorrhagic smallpox* (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal. A discrete type of the ordinary form, with a typical febrile prodrome and rash, resulted from alastrim variola minor infection. Individuals with this form of disease were not nearly as moribund or "toxemic" as individuals with variola major infection. Previous vaccination was not necessarily protective against the hemorrhagic forms of disease but seemed to be protective against flat forms of disease.

In flat smallpox, illness was heralded by the abrupt onset of fever with temperatures of 38.3° to 38.9° C and the appearance of the rash after 3 to 4 days. The oral enanthem was often confluent, and sloughing of rectal mucosal membranes was also reported. At the papulovesicular stage of disease, lesions appeared as small indentations (day 6) with hemorrhages in the bases and were surrounded by an erythematous ring. By day 7 or 8, the lesions appeared flat. Bullous lesions that would slough were reported. Fever persisted throughout the disease course, and respiratory complications were often observed by day 7 or 8 of illness. Thrombocytopenia, neutropenia, and lymphocytosis were reported.

In hemorrhagic forms of smallpox, illness began with fever and typical prodromal symptoms; the fever never abated. Early after the onset of fever, petechiae and purpuric rashes became apparent; subconjunctival hemorrhages, hematuria, and vaginal bleeding were also seen. Patients usually died by day 6 of illness, well before any classic vesiculopustular rash was evident. In late hemorrhagic disease, after the onset of fever, typical maculopapular lesions developed, but the fever did not abate. The lesion evolved slowly, and areas of hemorrhage were evident at the base of the lesions. Bleeding occurred in the mucous membranes, thrombocytopenia was profound, and death occurred between days 8 and 10 of illness.

Monkeypox

After an incubation period of 7 to 17 days (mean, 12 days), a prodrome of fever, headache, backache, and fatigue begins.[6] The cutaneous eruption evolves similar to that of smallpox. Lesions evolve in the same stage in any one part of the body from macules, papules, and vesicles to pustules, and then they crust and scar (Fig. 372-2). After resolution of the rash, hypopigmentation is followed by hyperpigmentation of the scarred lesions. Pronounced

TABLE 372-2 WORLD HEALTH ORGANIZATION SMALLPOX TYPES

WHO SMALLPOX TYPE	CLINICAL DEFINITION
Variola sine eruptione	Fever, no rash
Modified	Like ordinary, with an accelerated course
Ordinary discrete	Fever, rash; areas of normal skin between pustules, even on the face
Ordinary semiconfluent	Fever, rash; pustules confluent on the face, discrete elsewhere
Ordinary confluent	Fever, rash; pustules confluent on the face and forearms
Flat	Fever, erythema, and edema of the skin; vesicles soft, flat, and bullous
Hemorrhagic, early	Fever (persistent), hemorrhages and petechiae, purpuric rash at illness onset
Hemorrhagic, late	Fever (persistent), rash, hemorrhage into the base of vesicles late in illness

FIGURE 372-1. Pustular lesions of smallpox and beginning of scarring on the face and upper part of the torso. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 7055. Photograph by Stan Foster.)

FIGURE 372-2. Rash of monkeypox of the head (A) and extremities (B) in a 7-year-old girl in central Zaire. (From Peters W, Pasvol G. *Tropical Medicine and Parasitology.* 5th ed. New York: Mosby; 2002:238.)

cervical, postauricular, submandibular, and inguinal lymphadenopathy clinically distinguishes monkeypox from smallpox.

Vaccinia

Multiple-puncture vaccinia virus infection by a bifurcated needle is the current smallpox vaccination regimen used for laboratory personnel working with orthopoxviruses, public health care personnel, and military in the United States. Most commonly, the infection progresses through a standard course of events from vesicle to pustule. However, of all vaccines used today, the smallpox vaccine, which is composed of live, replicative vaccinia virus, has one of the highest rates of adverse events. Major complications include progressive vaccinia, eczema vaccinatum, generalized vaccinia, postvaccinial encephalitis, accidental infection, and carditis.[7]

Progressive vaccinia, which is a rare and often fatal vaccine complication in persons with severe deficiencies in cellular immunity, occurs in about 1 per million vaccines, with a case-fatality rate of about 35%. Progressive vaccinia is characterized by frequently painless growth and spread of the vaccine virus beyond the inoculation site, often leading to necrosis and sometimes metastases to other body sites. The possibility of progressive vaccinia should be considered if the vaccination site lesion continues to progress and expand without apparent healing more than 15 days after vaccination.

Eczema vaccinatum[8] can occur in people with a history of atopic dermatitis (eczema), irrespective of its severity or activity, owing to local spread or dissemination from the primary vaccination site or contact with the unscabbed vaccination site of another person. A localized or generalized papular, vesicular, or pustular rash can develop anywhere on the body or be localized to previous eczematous lesions. Systemic illness with fever, malaise, and lymphadenopathy may occur. In the 1968 national U.S. surveillance of smallpox vaccination, there were 66 cases (no deaths) of eczema vaccinatum among 14.5 million vaccinees (4.6 cases/million) and 60 cases (1 death) among their several million contacts.

Generalized vaccinia describes the vesicular rash that develops after vaccination. Excluding dissemination associated with eczema vaccinatum and progressive vaccinia, it has been extremely rare to document virus in these lesions. True generalized vaccinia is believed to represent the end product of viremic spread of virus, and no predisposing factors have been identified. Generalized vaccinia was estimated to occur in about 242 of every million primary vaccinations. Studies done during the vaccination program in 2002 in the United States indicate that the majority of cases previously reported to be generalized vaccinia likely were generalized rashes caused by inflammatory or allergic responses to the vaccine, and not true generalized vaccinia. *Postvaccination encephalomyelitis* is a rare but serious complication that usually occurs only in primary vaccinees. Patients have variably displayed clinical and diagnostic features suggestive of a postimmunization demyelinating encephalomyelitis or direct viral invasion of the nervous system. This postvaccination reaction typically occurs 11 to 15 days after vaccination. Symptoms include fever, headache, vomiting, confusion, delirium, disorientation, restlessness, drowsiness or lethargy, seizures, and coma. Cerebrospinal fluid can demonstrate elevated pressure but generally has a normal cell count and chemistry profile. The diagnosis is one of exclusion, and no specific tests are available to confirm it. However, a few cases have been demonstrated to have anti-orthopoxvirus immunoglobulin M (IgM) or IgG responses in their cerebrospinal fluid.

FIGURE 372-3. Vaccinia autoinoculation of an eye. (From the Centers for Disease Control and Prevention Public Health Image Library, ID #: 3322.)

Accidental infection occurs when virus from the vaccination site is transferred to another site or to another person through intimate skin contact. This complication generally occurs with primary vaccinees rather than revaccinees. Accidental self-inoculation, which most commonly occurs on the face, mouth, lips, or genitalia, is not usually serious and requires no specific treatment. Inoculation of the eye or eyelid is more serious and can be sight threatening if it is not evaluated and treated appropriately (Fig. 372-3). Between 1963 and 1968, ocular vaccinia was observed in 348 persons, including 22 who had evidence of corneal involvement and 11 who experienced permanent defects.

With buffalopox viruses in India and the Cantagalo virus in Brazil, up to 10 lesions have been described on the hands or arms of human handlers; fever, lymphadenopathy, backache, and fatigue are also associated symptoms. Transmission is believed to occur by unprotected contact with active lesions present on animal teats and udders. Interhuman transmission of buffalopox to family members has been reported to occur through contact.

Cowpox

Cowpox lesions are generally restricted to the hands and face; most patients (72%) have only one lesion. Multiple lesions may be caused by multiple primary inoculations, by autoinoculation, and very infrequently by lymphatic or viremic spread. The cowpox lesion passes through macular, papular, vesicular, and pustular stages before forming a hard black crust. The lesion is generally very painful, and erythema and edema are common at the late vesicular and pustular stages. Patients usually have lymphadenitis, fever, and general malaise. These features are generally severe in children, and absence from school or work is common. About 30% may be hospitalized. Most patients take 6 to 8 weeks to recover, but up to 12 weeks may be required. On occasion, a very severe infection and death may occur, typically in immunosuppressed individuals. Scarring is usually permanent.

Parapoxvirus

Lesions, such as from the orf virus, start as erythematous papules and progress in 1 to 2 weeks to target lesions with a red center surrounded by a white halo and an outer inflamed halo. Lesions then progress to a nodular and then a papillomatous stage, which often has a "weeping" surface. In some patients, lesions may enlarge and persist for weeks before resolving by a crusting stage, which also may persist for weeks. Very large granulomatous lesions may occasionally require surgical removal.

Most patients have only one lesion, but multiple primary lesions may develop. Systemic reaction is relatively uncommon, and the lesion is often not particularly painful. Lymphadenopathy is present in some patients, and lymphangitis is relatively uncommon. Erythema multiforme (Chapter 439) can develop in up to one third of patients.

Molluscum Contagiosum Virus

Molluscum infection occurs when molluscum contagiosum virus comes into contact with nonintact skin. The characteristic lesion begins as a small papule and, when mature, is a discrete, 2- to 5-mm-diameter, smooth, dome-shaped, pearly or flesh-colored nodule that is often umbilicated (see Fig. 440-9 in Chapter 440). A cheesy, off-white or yellowish material is easily expressed from lesions. Most patients have 1 to 20 lesions, but hundreds of lesions may occasionally be present. Because of multiple simultaneous infections or mechanical spread, the lesions may become confluent along the line of a scratch, and satellite lesions are sometimes seen.

In children, molluscum lesions occur mainly on the trunk and proximal ends of the extremities; in adults, lesions tend to occur on the trunk, pubic area, and thighs. In all cases, however, infection can be transmitted to other areas by autoinoculation. In men infected with human immunodeficiency virus (HIV), molluscum lesions can occur along the beard line and result in ocular involvement.

Individual lesions persist for about 2 months, but the disease usually persists for 6 to 9 months. Individuals with impaired cell-mediated immunity, including persons with HIV infection, tend to have more severe and prolonged infection.

Yatapoxvirus

Tanapox infection begins with a short febrile (38° to 39° C) illness that persists for 2 to 4 days and is sometimes accompanied by headache, backache, or prostration. The eruption of a lesion is frequently heralded by pruritus at the site of the outbreak. The lesion appears as a hyperpigmented macule, which often has central elevation and evolves to a papule with palpable induration. About 80% have a solitary nodule, but as many as 10 lesions can occur. Most lesions (72%) occur on the lower extremities, and the fewest occur on the face and areas normally covered by clothing.

Fever and systemic symptoms wane as the lesion erupts. The papule then becomes more "pocklike" but contains no fluid; umbilication or a pseudocrust may develop. Typically, the papule evolves into a firm, deep-seated, elevated nodule. At the end of the first week, the lesion is surrounded by erythema and indurated skin, and regional lymphangitis is common. Lesions then either ulcerate or become larger nodules (up to 2 cm in diameter) within about 2 weeks, after which the local inflammatory response wanes and the lesions began to granulate. Resolution of lesions occurs within 6 weeks. Infection appears to confer lifelong immunity.

DIAGNOSIS

Before its eradication, smallpox was relatively easy to recognize. Chickenpox (Chapter 375) produces a centripetally distributed rash and rarely appears on the palms and soles; in chickenpox, prodromal fever and systemic manifestations are mild, the lesions are superficial in nature, and lesions in different developmental stages may be present in the same area of the body. Other diseases and conditions that could be confused with vesicular-stage smallpox include monkeypox, generalized vaccinia, disseminated herpes zoster or herpes simplex virus infection (Chapters 374 and 375), drug reactions (eruptions), erythema multiforme (Chapter 439), enteroviral infections (Chapter 379), scabies (Chapter 359), insect bites, impetigo (Chapter 439), and molluscum contagiosum. Diseases confused with hemorrhagic smallpox included acute leukemia (Chapter 183), meningococcemia (Chapter 298), and idiopathic thrombocytopenic purpura (Chapter 172). The Centers for Disease Control and Prevention have developed a protocol for evaluation of patients for potential smallpox (available at http://emergency.cdc.gov/agent/smallpox/diagnosis/evalposter.asp) and an algorithm for laboratory assessment of the vesiculopustular stage of rash (available at http://emergency.cdc.gov/agent/smallpox/diagnosis/pdf/poxalgorithm1-5-12.pdf).

Orthopoxvirus

Viral culture or electron microscopic evaluation of virion particles from clinical rash specimens has been the approach to diagnosis of orthopoxvirus infections. Serologic tests are largely genus specific, detect IgG, and usually cannot differentiate among species, although IgM levels can help differentiate recent orthopoxvirus infection from remote vaccination. Nucleic acid–based tests and polymerase chain reaction (PCR) assays are other options. If the diagnosis of smallpox is being considered, viral culture requires a biosafety level 4 (BSL-4) containment facility that is sanctioned by the World Health Organization to use variola virus.

Parapoxvirus

The differential diagnosis of parapoxvirus lesions can include ecthyma gangrenosum as a result of a *Pseudomonas aeruginosa* infection (Chapter 306), vaccinia or cowpox infection, cutaneous anthrax (Chapter 294), erysipeloid (Chapter 295), tularemia (Chapter 311), and tumor. Farm workers recognize the infection and tend not to seek medical attention for routine cases, so about 45% of reported cases may have no known contact with infected animals, and the clinical diagnosis of such cases may be difficult. With negative-stain electron microscopy, virions with the characteristic morphology of parapoxviruses are usually seen easily in lesion extracts, thereby providing a rapid, certain diagnosis of the genus. The virus can be grown in cell culture, and PCR detection can be performed. Species-specific and species-generic protein-based diagnostics have also been developed for parapoxviruses.

Molluscum Contagiosum Virus

The clinical appearance of molluscum lesions usually is sufficiently characteristic to permit a clinical diagnosis. Brick-shaped virions typically can be seen in large numbers if the cheesy material expressed from the lesion is examined by electron microscopy. The virus has not been cultured in standard tissue culture systems. The characteristic histopathology of these lesions is diagnostic, but PCR methods can also identify molluscum contagiosum.

Yatapoxvirus

The limited geographic distribution of tanapox virus and the patient's travel history help with the diagnosis of tanapox infection. Unique clinical features that differentiate tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted resolution of the rash. The solid nodular and ulcerated lesions are larger and develop more slowly than those of monkeypox, but they are smaller and develop more rapidly than those of tropical ulcers.

Tanapox virus can be detected by electron microscopy, but the appearance of the virions cannot exclude infection with other morphologically similar brick-shaped poxviruses. Nucleic acid testing or cell line culture can make the definitive diagnosis.

TREATMENT AND PREVENTION Rx

Orthopoxvirus

Vaccination with smallpox vaccine is the mainstay for prevention of orthopoxvirus infection and was the primary method used to eradicate smallpox. Stockpiles of vaccine are available should smallpox recur. In the United States, however, smallpox vaccine is currently recommended only for laboratory

personnel who work with infectious orthopoxvirus, certain public health personnel, and certain members of the military. In part because of stringent prescreening procedures, recent adverse events are rare with vaccination, but myocarditis or pericarditis was documented in 18 of 230,734 (8 per million) U.S. military primary vaccinees immunized in 2002 and 2003. In recent trials, both an attenuated tissue-cultured smallpox vaccine (LC16m8) and a replication-deficient smallpox vaccine (MVA) were about 95% effective both in newly vaccinated adults and as a booster.[A1,A2] Animal studies have demonstrated protective efficacy against a lethal monkeypox challenge.[9]

Currently, no antiviral drugs are licensed to treat orthopoxvirus or other poxvirus illnesses. Early administration of vaccinia immune globulin (VIG) may reduce the mortality of eczema vaccinatum from 30 to 40% to 7%, and VIG may also be useful for other complications (e.g., progressive vaccinia, severe generalized vaccinia, or contact infection) of vaccinia (smallpox) vaccine administration and for other orthopoxvirus infections. However, VIG alone has no clear benefit for treatment of smallpox infection itself.

Antiviral compounds (Chapter 360) with in vitro and in vivo activity against poxviruses include specifically 5-iodo-2′-deoxyuridine, adenine arabinoside, and trifluorothymidine. Because of their systemic toxicity, these compounds have been used topically for the treatment of orthopoxvirus ocular infections. In vitro, cidofovir is active against cowpox, vaccinia, monkeypox, and variola; in vivo, it protects challenged animals when it is given prophylactically or early in the evolution of disease. Cidofovir has known renal toxicity and is administered with hydration and probenecid. CMX-001/brincidofovir has been effective in treatment of systemic rabbitpox infection in rabbits and was used as part of a multidrug regimen to treat a case of progressive vaccinia.

Tecovirimat is an effective small-molecule antiviral in animal models of systemic orthopoxvirus infection[10] and has been used successfully as part of a multidrug regimen to treat a human case of eczema vaccinatum and a case of progressive vaccinia. Although not currently licensed, it is part of the U.S. Strategic National Stockpile and available for compassionate use to treat orthopoxvirus infections, including smallpox, as an investigational new drug sponsored by the Centers for Disease Control and Prevention.

Parapoxvirus

Most workers at risk for parapoxvirus become infected, and reinfection also occurs. The vaccine used to control orf in sheep is fully virulent and has caused human infection. Treatment options are limited; anecdotal reports have described the use of topical cidofovir, and other options may be topical formulations of interferon-modulating compounds such as imiquimod.

Molluscum Contagiosum Virus

Molluscum contagiosum infection is benign, and recovery is usually spontaneous, but treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Options include cryotherapy, mechanical curettage, and chemical treatments such as podophyllin or podofilox, cantharidin, iodine, and tretinoin. Irritation has been a side effect of many of the chemical treatments. Topical application of a 3% cidofovir antiviral cream or suspension has been reported to be beneficial, as has the use of potentially immune-modulating cimetidine or topical imiquimod therapy. However, no therapy is documented to be beneficial by well-controlled randomized trials,[A3] although topical 10% potassium hydroxide solution, applied twice daily, is sometimes recommended. Covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations. For individuals with AIDS and molluscum, highly active antiretroviral therapy with a resulting improvement in the $CD4^+$ cell count appears to be efficacious.[11]

PROGNOSIS

Monkeypox and smallpox both cause human illness, with mortality rates ranging from 10 to 40%; variola minor variants, however, have mortality rates of less than 1%. Yatapoxvirus infections are self-limited, and the illness resolves in the course of a few weeks. Parapoxvirus infections are manifested chiefly by localized symptoms, and the lesions resolve within a month or so in nonimmunocompetent hosts. Molluscum contagiosum infection is benign, usually with a spontaneous recovery, but the infection can persist for months. Variola minor has a mortality rate of less than 1%.

REVIEW QUESTIONS

1. A 24-year-old man presents to your office. He has a 2-cm nodular lesion on his right forearm. He does not appear systemically ill. He reports he was recently treated for malaria; he had a temperature of 103° F a week prior. He recently returned from work in Africa at a primate preserve in the Republic of Congo. Biopsy and electron micrographs of the lesion demonstrate poxvirus-particles. What is your diagnosis?

A. Tanapox virus (*Yatapoxvirus* species)
B. Monkeypox (*Orthopoxvirus* species)
C. Myiasis
D. Orf virus (*Parapoxvirus* species)
E. Smallpox (*Orthopoxvirus variola*)

Answer: A The electron micrograph demonstrates poxvirus particles. These are of a characteristic size and shape that renders them distinguishable from herpesvirus particles and bacterial and parasitic particles. Tanapox virus infections typically present with high fever followed by the development of one or a few nodular lesions. The lesions are distinct from the classic vesiculopustular lesions of orthopoxvirus infections (such as cowpox, vaccinia, monkeypox, or smallpox). Monkeypox virus typically also causes lymphadenopathy. Myiasis is caused by the bot fly and could be found in a returning African traveller, but the electron micrograph would not be consistent with it. Pain would also be associated with the lesion. Orf lesions typically are not associated with a high-antecedent fever and are usually associated with exposure to a ruminant (commonly sheep or goat). Smallpox disease is typically a fulminant disease, with a more generalized vesiculopustular rash, especially in someone unlikely to have been previously vaccinated.

2. A 35-year-old woman is seen in the emergency department with an extensive pustular rash that covers more than 30% of her body. Lesions are apparent on the palms of her hands and soles of her feet. The distribution is centrifugal. The lesions are round and feel like buckshot. She is having difficulty swallowing because of pain. She has track marks on her arms. On further questioning, she reports "having the flu" 7 days ago, despite having received the flu vaccine 2 months prior. She reveals a history of illicit intravenous drug use and claims to use clean needles from the laboratory. She works as a clinical microbiologist in a virology laboratory that has an archival collection of materials. She has recently been characterizing various unknown historic clinical specimens to update the inventory. What would be your next step?

A. Institute airborne precautions and call the health department.
B. Take pictures of the lesions, get blood cultures, sample specimens and send for bacterial analysis, and start treatment for endocarditis.
C. Perform a rapid plasma reagin test.
D. Ask about her vaccination status.
E. Get an infectious disease consult.

Answer: A The signs and symptoms are consistent with smallpox. Institution of airborne precautions will provide infection control and limit potential exposure to this patient. Notification of the health department will enable notification of the Centers for Disease Control and Prevention's Emergency Operations Center. A complete assessment of the patient can then ensue, using appropriate personnel protective equipment, ideally by a person previously vaccinated against smallpox.

3. A 25-year-old man reports to your office with a single vesiculopustular lesion on his forehead. He works on a farm with sheep and goats, none of which are ill. His wife is a laboratory postdoctoral fellow who works in a laboratory that studies monkeypox virus. You find out that she was recently vaccinated, 3 weeks ago, with smallpox vaccine before beginning work in the laboratory. What is the most likely cause of the forehead lesion?

A. Vaccinia virus
B. Orf virus
C. Monkeypox virus
D. Smallpox
E. Pseudo cowpox

Answer: A Vaccinia virus is the live virus in smallpox vaccine. Although it is possible he could have a parapoxvirus infection acquired from the sheep or goats on the farm, none of the animals appears ill. Smallpox vaccine does not contain smallpox virus, which is the variola virus. The likely source of the vesiculopustular lesion is accidental implantation of vaccinia virus during close contact with his wife.

4. An epidemiology graduate student comes to your emergency department with a 5-day history of rash. The rash initially manifest as small red spots, which then became vesicular. She also notes painful adenopathy in her cervical and axillary lymph nodes. She describes a fever before the onset of the rash. She returned from Africa 1 week ago. On the plane, she had a fever. She had been working in the Democratic Republic of Congo (DRC) on maternal-fetal health issues of indigenous people in the equatorial region of the DRC. She has been living within the community and helping with all household and village activities. You suspect she may have monkeypox. What antiviral agent might you consider using if the diagnosis is confirmed?

A. Brincidofovir or tecovirimat
B. Acyclovir
C. Ganciclovir
D. Adefovir
E. Stavudine

Answer: A Both brincidofovir (CMX-001), the orally bioavailable derivative of cidofovir, and tecovirimat (ST-246 or Arestyvyr) have activity against orthopoxvirus infections.

5. In the above case, what samples would you take for diagnosis?

A. Rash lesions and sera
B. Blood culture
C. Serum chemistries
D. Complete blood count
E. Thick and thin smears

Answer: A Poxvirus infections are usually identified by evaluation of material from the rash lesion itself. Polymerase chain reaction and culture can identify and characterize the virus. Electron microscopy can also help to exclude a herpesvirus infection. Serology can be useful if the rash lesions have resolved.

373

PAPILLOMAVIRUS

JOHN M. DOUGLAS, Jr.

DEFINITION

Human papillomaviruses (HPVs) are a group of small DNA viruses that cause a variety of benign and malignant lesions of the skin and mucous membranes. The most commonly recognized HPV-associated diseases include warts (Chapter 440) at anogenital sites (condyloma acuminatum), other skin surfaces (common warts or verruca vulgaris), and the plantar surface of the foot (verruca plantaris). In addition, HPV infection causes squamous intraepithelial lesions of the cervix, also known as cervical intraepithelial neoplasia (CIN), and of other anogenital sites. It is considered the etiologic agent of a variety of cancers, especially cervical cancer.

The Pathogen

HPV is a member of the family Papillomaviridae. Like all papillomaviruses, HPV is nonenveloped, measures 55 nm in diameter, and has a double-stranded circular DNA genome of approximately 7900 base pairs enclosed by an icosahedral capsid. The HPV genome contains three functional regions: early genes (six total—E1, E2, E4, E5, E6, E7), which are expressed soon after infection and control replication, transcription, and cellular proliferation; late genes (two total—L1, L2), which are expressed in later stages of infection and encode the structural capsid proteins; and the long control region, which contains regulatory sequences that control the replication and transcription of early and late genes. Papillomaviruses complete their life cycle only in terminally differentiated epithelial cells and thus are difficult to grow in cell culture. Papillomavirus taxonomy is based on a genotyping system involving the use of DNA sequence relatedness of the gene encoding L1, the major capsid protein, with different types defined as having less than 90% homology.[1]

Papillomaviruses are classified taxonomically by genus (Greek letters) and species (numbered), each containing one or more types. Most HPV types are included in three large genera: alpha (primarily mucosal or genital types), beta, and gamma (both of which cause cutaneous lesions). Currently, more than 150 types of HPV have been identified, over 40 of which infect genital skin and mucosa. Of the genital types, approximately 15 are considered high risk because they are associated with high-grade squamous intraepithelial lesions and cancers of the cervix, anus, penis, vulva, vagina, and oropharynx, whereas others are considered low risk because they are largely associated with genital warts and low-grade squamous intraepithelial lesions.

EPIDEMIOLOGY

HPV infections are primarily transmitted by direct contact of skin or mucous membranes with an infected lesion. Genital HPV infection is typically contracted through sexual intercourse, although nonpenetrative genital contact, oral-genital contact, and manual-genital contact are also possible routes of transmission. In addition, genital HPV infection can be transmitted to the mouth and upper respiratory tract perinatally from infected mothers to newborns. For nongenital HPV infection, personal skin-to-skin contact also plays a primary role, although for plantar warts, fomite transmission from moist surfaces is likely to be an important source of infection. Both genital and nongenital infection can be transmitted to new sites by autoinoculation.

Regarding genital HPV, in the United States, an estimated 80 million or so persons are infected and about 14 million new infections occur annually, thereby making genital HPV the most common sexually transmitted infection.[2] The prevalence of anogenital warts is estimated to be approximately 1% in the sexually active adult population. Acquisition of infection begins shortly after sexual debut, with an estimated 40 to 60% incidence of at least one type within 2 years of initiation of sex. Risk factors for infection include variables

related to probable exposure (e.g., younger age at onset of sexual activity, increased number of recent and lifetime partners, and number of partners of the sex partners), susceptibility (e.g., lack of circumcision for men), and absence of prevention factors (e.g., lack of consistent condom use or immunization). Most infections are asymptomatic and clear without treatment; only 10% are estimated to persist longer than 2 years.[3] The incidence of genital HPV infection and genital warts appears to be declining in some countries that have initiated immunization programs.[4]

Oral HPV infection is usually asymptomatic. Its prevalence in U.S. adults is approximately 5 to 7%, almost half of which are high-risk types.[5] Newly acquired oral oncogenic HPV infections are rare in healthy men, and most are cleared within 1 year.[6] Cutaneous HPV infection is most typically recognized as common and plantar warts, especially in children, in whom annual incidence rates of up to 30% have been reported.

All types and manifestations of HPV infection are more common in persons with impaired cell-mediated immunity, such as those infected with human immunodeficiency virus (HIV) or receiving immunosuppressive therapy. Among HIV-infected men who have sex with men, the prevalence of anal high-grade squamous intraepithelial lesions is almost 30%, and the anal cancer incidence is 46 per 100,000.[7] Of note, genital HPV infection may increase susceptibility to HIV infection, analogous to other sexually transmitted infections, raising the possibility that HPV vaccines could help prevent HIV infection.

Cervical cancer has declined in developed countries since the initiation of cytologic screening programs, although an estimated 12,000 cases and 4000 deaths still occur in the United States annually.[8] However, the disease is a major problem in the developing world, where screening is limited, and it is the third most common cancer in women worldwide, with an estimated 500,000 cases annually. Considering all anatomic sites, it is estimated that more than 600,000 HPV-associated cancers (5% of all cancers) occur globally each year.[9] In the United States, HPV causes about 18,000 cancers annually among females and about 8000 annually among males. HPV-associated oral cancers have been rising in the United States and are projected to become the most common HPV-associated cancer by 2020.[10]

PATHOBIOLOGY

HPV infections cause disease by producing aberrant cell growth. In the case of cutaneous and low-risk types, lesions such as warts result from HPV-induced benign proliferation of epidermal layers. For high-risk genital types, precancerous and cancerous lesions result from replacement of the epithelium by undifferentiated cells as a result of HPV-induced interference with normal cellular growth.

Infection begins in the lowest and least well-differentiated layer of the epithelium, the basal cells, where exposure is facilitated by microtrauma. Transcription and protein expression are highly coordinated with the level of cellular differentiation. In the basal layer, the viral genome becomes established in the nucleus as an episome that replicates in tandem with cellular replication, thus maintaining a stable copy number of viral genomes. As basal cells migrate up and differentiate in the superficial layers of the epithelium, full vegetative viral DNA replication and expression of structural proteins occur, with assembly of infectious virions in the most superficial layer of the epithelium, where they are released with the sloughing of dead cells during normal cellular turnover.

Persistent infection with various high-risk types of genital HPV is firmly established as the cause of squamous cell carcinoma and adenocarcinoma of the cervix, and HPV 16 in particular plays a causal role in other anogenital and oropharyngeal squamous cell cancers. There are also associations of beta-HPV types with squamous cell cancer of the skin. HPV DNA can be detected in more than 99% of cervical cancer cases, with 70% of cancers caused by the two most common high-risk types, HPV 16 and 18. The pathogenesis of HPV-induced cancer involves viral integration into the host genome with resulting disruption of the E2 transcription regulatory gene and increased expression of E6 and E7 proteins. These proteins have oncogenic activity and affect cell growth by binding with tumor suppressor proteins, E6 with p53 and E7 with the retinoblastoma tumor suppressor protein, thereby disrupting apoptosis and cell cycle regulation.

Although persistent infection with high-risk types is "necessary" for the development of cervical cancer, it is not considered "sufficient" because cancer does not develop in most infected women. Possible cofactors include cigarette smoking, prolonged hormonal contraceptive use, multiparity, micronutrient deficiency, immunodeficiency (e.g., HIV infection), and other infections, (i.e., *Chlamydia trachomatis* and herpes simplex virus type 2). In addition, data supporting a familial risk for cervical cancer point to possible genetic factors, including genes controlling the immune response (e.g., *HLA, TNF*) and cell cycle (e.g., *p53*).

Cervical cancers (Chapter 199) most commonly arise in the cervical transformation zone, the border between the squamous epithelium of the ectocervix and columnar epithelium of the endocervix. Analagously, anal cancer (Chapter 145) occurs primarily at the anatomically similar anocolumnar transition zone.

The immune response to HPV infection is less robust than for most viral infections. Viral proteins and infectious virions develop in superficial cells with limited contact with the immune system, and there is no cell lysis or viremia to trigger an inflammatory response. In addition, HPV suppresses several components of the immune response, including the interferon pathway and the expression of inflammatory cytokines and major histocompatibility complex class I. Antibody to HPV develops in only an estimated 60% of infected individuals, often as long as 6 to 12 months after infection. In contrast, the dynamics of the immune response are quite different after immunization, with almost 100% seroconversion within several months and antibody levels many-fold higher than those after natural infection. The high efficacy of HPV vaccines, which are believed to produce primarily humoral immunity, supports the importance of the antibody response in protection from infection. In contrast, once infection occurs, cellular immunity appears to be critical for clearance of infection.

The histopathologic changes of warts include epithelial papillomatosis and acanthosis, with hyperkeratosis, parakeratosis, and hyperplasia of the parabasal cells. A characteristic feature is the presence of koilocytes, which are large atypical keratinocytes with irregular, hyperchromatic nuclei surrounded by a perinuclear halo, in the upper epidermis. Squamous intraepithelial lesions are characterized by hyperkeratosis, parakeratosis, koilocytosis, and epidermal hyperplasia, with increased mitotic figures in the upper half of the epidermis. Several classification systems have been used to classify these lesions and their risk for progression based on the proportion of the epithelium replaced by undifferentiated cells. The CIN system grades lesions as CIN 1 (with undifferentiated cells occupying the lower third), CIN 2 (with undifferentiated cells in the lower third to two thirds), and CIN 3/carcinoma in situ (CIS, with undifferentiated cells across the full thickness of the epithelium). Alternatively, the Bethesda system, originally developed for use with cytology but increasingly used for histologic classification, includes only two categories: low-grade squamous intraepithelial lesions (equivalent to CIN 1) and high-grade squamous intraepithelial lesions (equivalent to CIN 2 and CIN 3/CIS).

CLINICAL MANIFESTATIONS

The clinical manifestations of HPV infection vary by anatomic site and viral type. Common warts are exophytic, hyperkeratotic papules that typically occur on the hands but can appear on any skin surface, including the genital skin; they are most commonly caused by HPV types 1, 2, 4, 27, and 57. Plantar warts, which are caused by similar types of HPV, are hyperkeratotic, endophytic, and often very painful. In contrast, flat warts (verruca plana), which are small flat-topped papules that occur more commonly on the face, hands, and legs, are caused by a different group of nongenital HPV types (e.g., types 3, 10, 28, 38, 42, 49, 75, and 76).

Epidermodysplasia verruciformis is an uncommon autosomal recessive disease that is usually manifested in childhood as diffuse warts that respond poorly to treatment and typically are caused by beta-HPV types, most commonly type 5, that are uniquely associated with it. This disease, which is thought to be due to a selective defect in cell-mediated immunity because other opportunistic infections do not occur, is associated with two types of lesions: flat warts caused by the same HPV types as in normal hosts, and scaly tinea versicolor–type lesions caused by epidermodysplasia verruciformis–associated types. The latter are associated with the development of squamous cell cancer in sun-exposed areas in 30 to 70% of persons. Similar skin lesions and, rarely, associated skin cancers can develop in other patients with acquired defects in cell-mediated immunity.

The most common clinical manifestations of oral HPV infection include oral squamous cell papillomas and condyloma acuminatum, which are caused by HPV types 6 and 11. Less frequent are common skin warts and focal epithelial hyperplasia, which are round, flat papules caused by HPV types 13 and 32. Warts caused by genital HPV types can also rarely occur in the upper respiratory tract, where they can cause a serious condition known as recurrent respiratory papillomatosis, which can result in hoarseness and even airway compromise. Oral leukoplakia (Chapters 190 and 425), which

presents as a white patch or plaque and is considered to have premalignant potential, has been associated with HPV 16 and 18 infection.

Anogenital warts are papillomatous growths that occur throughout the anogenital skin and mucosa, typically at sites of genital friction. Most such warts are caused by HPV types 6 and 11, with approximately half of infected persons developing warts. Perianal warts are most common in persons with a history of anal intercourse and are often associated with intra-anal warts, but they also can occur without such contact, presumably through autoinoculation. Anogenital warts can range from flat or papular lesions to the classic pedunculated, cauliflower-shaped condyloma acuminatum. Warts are typically asymptomatic, noticed either by the patient as a "bump" or inadvertently during a genital examination, although they can cause itching, burning, pain, or, rarely, bleeding or mechanical obstruction of the birth canal in pregnant women.

Squamous intraepithelial lesions are most commonly found on the cervix as a result of screening for cervical cancer precursors by cytology (Papanicolaou [Pap] test) or HPV molecular testing, with confirmation by colposcopy and biopsy. Like warts, they also occur at other anogenital sites; and like cervical lesions, they are categorized either as low-grade or high-grade squamous intraepithelial lesions or as various stages of intraepithelial neoplasia (e.g., vulva—VIN; vagina—VaIN; anus—AIN; penis—PIN). Low-grade squamous intraepithelial lesions can be caused by either low- or high-risk types, whereas high-grade squamous intraepithelial lesions are primarily due to high-risk types. Most squamous intraepithelial lesions are not visible on mucosal surfaces without the application of 3 to 5% acetic acid and magnification, although they can appear as flat hyperpigmented papules known as bowenoid papulosis on the external genitalia.

DIAGNOSIS

Both cutaneous (Fig. 373-1) and genital (Fig. 373-2) warts generally present an easily recognized clinical picture and can be diagnosed by history and physical examination without laboratory testing. The application of 3 to 5% acetic acid causes whitening of HPV lesions on genital mucosa ("acetowhitening") and may be useful with magnification in women; however, because sensitivity and specificity of this application have not been defined, it is not recommended for routine use. Oral lesions are also generally recognized by physical examination.

The differential diagnosis of cutaneous warts includes seborrheic and solar keratoses, nevi, irritated acrochordons, clavi, and squamous cell carcinoma (Chapters 203 and 440); lichen planus (Chapter 438) can mimic flat warts and calluses of the foot or plantar warts. Genital warts must also be distinguished from the condyloma latum lesions of secondary syphilis (Chapter 319) and molluscum contagiosum (Chapters 372 and 440). Biopsy for histopathologic examination may be helpful for lesions at all anatomic sites that are atypical or not responsive to therapy, those suggestive of high-grade squamous intraepithelial lesions or cancer (e.g., pigmented, indurated, fixed, bleeding, or ulcerated), or lesions in immunocompromised patients.

Cervical squamous intraepithelial lesions have traditionally been detected by cervical cytology through Pap tests, with assessment of abnormal results by colposcopy and biopsy for histopathologic examination. However, molecular testing for high-risk HPV is beginning to be used both for screening and for management of low-grade cytologic abnormalities.[11,12] Several large comparative trials have shown HPV testing to be more sensitive than Pap tests for detection of CIN 2/3 and more effective in prevention of cervical cancer.[■■] HPV testing in combination with cytology (co-testing) has been approved to enhance the sensitivity of screening in women older than 30 years. HPV tests are also recommended for triage of women whose Pap test results show atypical squamous cells of undetermined significance, which is an equivocal test result. Although HPV testing has been recently approved by the U.S. Food and Drug Administration as a single test for primary cervical cancer screening, at present, its use as a single test in the absence of cytology is not recommended. Furthermore, HPV screening is not recommended for detecting possible infection at other sites (e.g., anus, oropharynx).

TREATMENT

Rx

Management of HPV infection is directed toward diagnosis and treatment of the lesions themselves because there are no virus-specific therapies. Many lesions resolve spontaneously, so the goal of treatment is amelioration or

FIGURE 373-1. Plantar wart. A hyperkeratotic, verrucous papule or plaque beneath a pressure point on the sole of the foot is characteristic. Human papillomavirus types 1 (myrmecia), 2 (mosaic), and 4 are most common. Because plantar warts are driven into the skin by the pressure of walking or standing, they are usually the most treatment resistant.

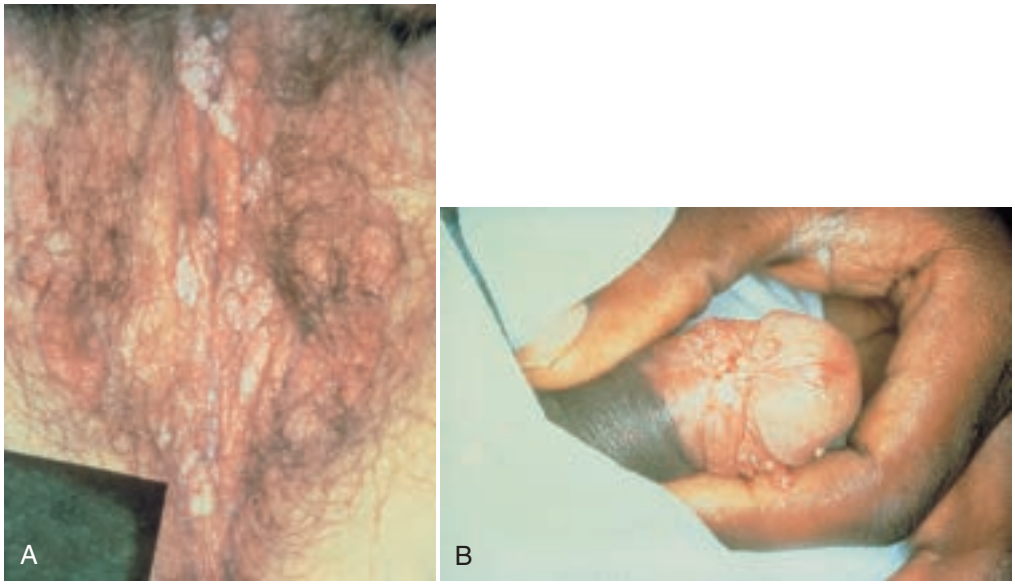

FIGURE 373-2. Genital human papillomavirus (HPV) infection. A, Vulvovaginal HPV infection. **B,** Penile HPV infection. (From Vermund SH, Bhatta MP. Papillomavirus infections. In: Cohen J, Powderly WG, eds. *Infectious Diseases,* 2nd ed. St Louis: Mosby; 2004.)

TABLE 373-1 RECOMMENDED TREATMENT OF GENITAL WARTS

PATIENT APPLIED
Podophyllotoxin (podofilox) 0.5% solution or gel; to be applied in up to 4 weekly cycles (twice daily for 3 days, followed by 4 days without treatment)
Imiquimod 3.75% cream (to be applied once daily at bedtime) or 5% cream (to be applied once daily at bedtime 3 times per week) for 6 to 10 hours for up to 16 weeks
Sinecatechins 15% ointment; to be applied 3 times daily for up to 16 weeks
PROVIDER ADMINISTERED
Cryotherapy with liquid nitrogen or cryoprobe; to be applied once every 1 to 2 weeks*
Trichloroacetic or bichloroacetic acid 80 to 90% solution; to be applied once weekly*
Office surgery* (excision, electrocautery, curettage)

*Safe for use in pregnancy.
Modified from Workowski KA; Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines, 2014. *MMWR Morb Mortal Wkly Rep.* 2014 (in press).

TABLE 373-2 U.S. ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES RECOMMENDATIONS FOR QUADRIVALENT (HPV 6, 11, 16, 18) AND BIVALENT (HPV 16, 18) HPV VACCINES

FEMALES

- Routine vaccination with three-dose series of quadrivalent or bivalent vaccine recommended in females aged 11 to 12 years, starting as young as 9 years
- Catch-up vaccination recommended in females aged 13 to 26 years who have not previously received full vaccine series

MALES

- Routine vaccination with three-dose series of quadrivalent vaccine recommended in males aged 11 to 12 years, starting as young as 9 years
- Catch-up vaccination recommended in immunocompromised persons and in males aged 13 to 21 years who have not previously received full vaccine series
- Catch-up vaccination recommended in men who have sex with men through age 26 years who have not previously received full vaccine series

Recommended dosage and schedule: 0.5 mL intramuscularly at 0, 2, and 6 months
Schedule modifications: if doses are missed, series does not need to be restarted, but second and third doses should be given as soon as possible.
Cervical cancer screening: no change in recommended interval
Special situations: females with genital warts, abnormal Papanicolaou test results, or positive human papillomavirus test results are unlikely to be infected with all four vaccine types and should be immunized per other recommendations; males with genital warts should also be immunized per other recommendations.
Pregnant and lactating women: not recommended for use in pregnancy based on lack of data; may be used in lactating women
Immunocompromised persons: no safety concerns because vaccine is noninfectious, but immune response and effectiveness might be reduced
Not recommended for females or males <9 and >26 years of age

Modified from Markowitz LE, Dunne EF, Saraiya M, et al; Centers for Disease Control and Prevention. Human papillomavirus vaccination. Recommendations of the Advisory Committee on Immunization Practices. *MMWR.* 2014;63:1-30.

prevention of symptoms or, in the case of high-grade squamous intraepithelial lesions, prevention of progression to cancer. Treatment involves destruction of lesions by physical techniques or topically applied or injected cytotoxic agents. Because treatment does not eradicate infection in surrounding tissues, recurrent lesions are common.

Treatment of warts depends on their location and size, the patient's preferences, and the provider's experience. Recommended first-line treatment of common, flat, and plantar warts includes the application of topical salicylic acid and cryotherapy; second-line treatment of recalcitrant lesions includes topical imiquimod (5% cream applied once daily at bedtime three times a week for up to 16 weeks), intralesional bleomycin, pulsed dye laser therapy, and surgical excision. Recommended treatment of genital warts (Table 373-1) includes patient-applied podophyllotoxin (0.5 or 0.15% solution or gel applied twice a day for 3 days, repeated weekly for four cycles), imiquimod, or sinecatechins, as well as provider-administered cryotherapy, trichloroacetic acid, or surgical excision; alternative treatments include intralesional interferon and laser surgery.[13] Oral lesions can be treated by locally destructive physical techniques.

For cervical lesions, treatment depends on histologic staging after colposcopy and biopsy and clinical context. Because CIN 1 usually regresses spontaneously, follow-up (by cytology, HPV test, and/or colposcopy) without treatment is recommended.[14] Treatment is generally recommended for all CIN 2/3 lesions, except in pregnant women, who have higher rates of spontaneous regression and a greater risk for reproductive tract complications after treatment, and in young woman with CIN 2. Treatment options include a variety of ablative and excisional techniques, such as cryosurgery, loop electrosurgical excision procedure, and laser surgery. Treatment is 90 to 95% effective in preventing the recurrence of lesions, and comparative clinical trials have shown similar efficacy for different treatment modalities.

PREVENTION

Primary Prevention

Primary prevention of HPV infection depends on avoidance of contact with infectious lesions and reduction of susceptibility through immunization. For example, the use of footwear in locker rooms may prevent plantar warts. For genital HPV infection, correct and consistent condom use can reduce the risk for both HPV infection and the HPV-associated diseases of genital warts, cervical squamous intraepithelial lesions, and cervical cancer. Male circumcision reduces the prevalence of both high-risk and low-risk types of genital HPV infection in men and transmission of HPV to their sex partners.

Of greatest importance for prevention are HPV vaccines (Chapter 18), which are composed of virus-like particles assembled from the major capsid protein, L1. Recommendations have been made for two currently licensed vaccines, a quadrivalent vaccine (types 6, 11, 16, and 18) and a bivalent vaccine (types 16 and 18). Recommendations are pending for a newly-licensed 9-valent vaccine (types 6, 11, 16, 18, 31, 33, 45, 52, and 58) which could prevent a higher proportion of HPV-associated disease outcomes.[15,16] The quadrivalent vaccine, given in three doses during a period of 6 months, is highly effective. In women, it prevent CIN 1 and CIN 2/3 as well as genital warts, VaIN, and VIN caused by any of the four types. In men, it prevent genital warts and AIN. The bivalent vaccine provides a high level of protection against CIN but not genital wart. Both vaccines are recommended for routine immunization of 11- to 12-year-old girls as well as females 13 t 26 years of age (Table 373-2). However, these vaccines provide protection against only two of the types of HPV that are associated with cancer, so immunized women continue to need cervical cancer screening.

The quadrivalent vaccine is also recommended for routine immunization of 11- to 12-year-old boys as well as males aged 13 to 21 years of age for prevention of genital warts (Chapter 18). Among men who have sex with men, immunization is recommended up to 26 years of age because of the additional benefit of preventing AIN (see Table 373-2). Both girls and boys 9 to 10 years of age may also be vaccinated at the discretion of the provider.

These vaccines have no therapeutic benefit against existing infection or lesions, and they are most effective if given before initiation of sexual activity. Because the HPV vaccines contain no live virus, they can be safely given to persons with impaired immunity (e.g., HIV infection). Research priorities include determining the duration of immunity after immunization, the efficacy of a two-dose regimen,[17] the extent of cross-protection against nonvaccine types, and benefit in prevention of nongenital HPV–associated cancers.

Secondary Prevention

Screening plus treatment of high-grade cervical squamous intraepithelial lesions is one of the most successful of all cancer prevention strategies. Screening has been conventionally conducted using Pap tests, but HPV tests are increasingly used as well for both primary screening and management of low-grade cytologic abnormalities. Current guidelines in the United States have evolved and now recommend screening at 3-year intervals beginning at age 21 years.[18] HPV testing is not recommended in younger women because of the high prevalence of often recently acquired and likely transient HPV infection. In contrast, among women older than 30 years, co-testing with HPV plus cytology is a recommended alternative to cytology alone because its enhanced sensitivity allows extension of screening to 5-year intervals (Chapter 199). Women with negative cytology who test HPV positive can be followed with repeat co-testing in 1 year or triaged by use of an HPV

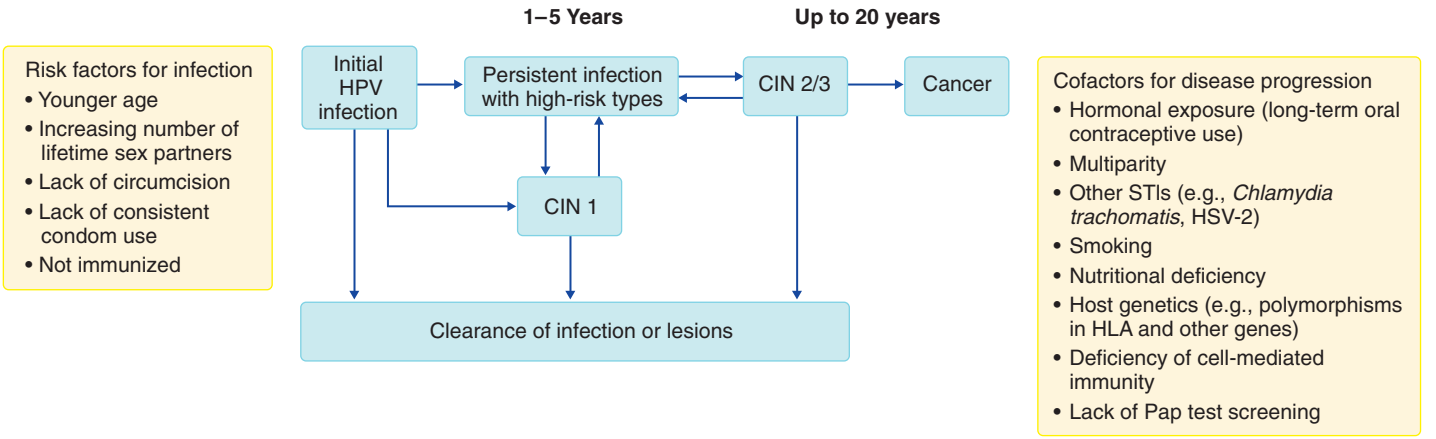

FIGURE 373-3. Natural history of genital human papillomavirus (HPV) infection and cervical cancer. CIN = cervical intraepithelial neoplasia; HSV = herpes simplex virus; STIs = sexually transmitted infections.

16/18 test. Management of other abnormalities is based on the degree of cytologic finding and age, with a higher threshold for treating younger women in whom abnormalities are more likely to resolve. With improvement in screening tests, a major prevention challenge remains increasing access to and use of screening services because approximately half of cervical cancers in the United States occur in women who were infrequently or never screened.

The value of cytologic screening for anal intraepithelial lesions in HIV-positive men who have sex with men is controversial but not currently recommended because of limited data on the natural history of these precursor lesions, the reliability of screening methods, and the safety and effectiveness of treatment.[13]

PROGNOSIS

Although the natural history of HPV infection is not fully characterized, the large majority of infections and premalignant lesions are self-limited in most immunocompetent patients. Whether infections no longer detectable have been cleared by the immune system or remain latent in the basal layer of the epithelium with the potential for reactivation is not clear, but the higher prevalence of detectable infection in advanced than in early HIV infection supports the possibility of long-term infection. Many if not most clinical lesions resolve spontaneously after the patient develops cell-mediated immunity. Spontaneous regression is estimated to occur in 25% of genital warts and more than 50% of common warts in children.

The natural history of CIN has been most intensively studied because of its relationship to cervical cancer, although many questions remain unanswered. Estimates of the likelihood of regression versus the risk for progression to invasive cancer are 90% and 1% for CIN 1, 40% and 5% for CIN 2, and 32% and 30% for CIN 3. The various stages of precursor lesions were traditionally viewed as a biologic continuum, with CIN 1 progressing through higher grades to cancer. However, newer data indicate that low-grade and high-grade squamous intraepithelial lesions may be distinct processes, in which low-grade lesions (CIN 1) represent a usually transient infection characterized by production of capsid protein (and probably infectious virions) and only minor cellular abnormalities, whereas high-grade lesions (CIN 2/3) represent proliferation of immature cells as a result of the activity of oncogenic proteins of high-risk types (Fig. 373-3). Initial infection frequently leads to a transient low-grade squamous intraepithelial lesion, with persistent infection in less than 10% of cases. Persistent infection can, in turn, lead directly to high-grade squamous intraepithelial lesions within several years of initial infection and can progress to invasive cancer after several decades. The natural history of squamous intraepithelial lesions at other anogenital sites is less well defined, but they may be associated with higher rates of spontaneous regression.

The majority of patients with HPV infection have an excellent prognosis, with the most serious outcomes of cancer occurring infrequently among the large number of persons infected. Treatment can hasten the resolution of cutaneous and genital warts and is highly effective for cervical lesions. Among women with CIN 3, long-term studies indicate that a 30% risk for cancer in untreated women can be reduced to less than 1% with treatment.

REVIEW QUESTIONS

1. A 24-year-old woman comes into a university health service for counseling. She has become romantically involved with a 25-year-old man and is contemplating the initiation of a sexual relationship but is afraid to do so because he has genital warts and she has heard that human papillomavirus (HPV) is an incurable infection. She received thee doses of the quadrivalent HPV vaccine 5 years ago and wants to know if her potential partner can be tested to determine whether she is protected against the HPV type with which he is infected. Which of the following is the most appropriate recommendation?

A. Her partner should come to the health service for assessment and treatment of his warts and typing of his HPV. If it is a type that is included in the HPV vaccine, sexual activity is safe.
B. Both she and her partner should be vaccinated, after which sexual activity would be safe.
C. She should avoid vaginal intercourse but can safely engage in oral sex.
D. Her partner should come to the health service for assessment and treatment of his warts but not testing. Sexual activity would then be safe with condoms.
E. She should be tested to determine whether she has protective levels of immunity to see if sexual activity would be safe.

Answer: D It is highly likely that her potential partner's warts are caused by HPV 6 or 11, both of which are included in the quadrivalent vaccine and against which she likely has a very high level of protection. Tests to provide specific typing information on HPV-related lesions or levels of HPV-antibody are not commercially available or recommended. In addition to vaccine, lesion treatment and condom use can further reduce the risk for transmission. Booster doses of HPV vaccine are not currently recommended, and the vaccine does not have therapeutic benefit against existing infection. Genital HPV can be transmitted by oral-genital sex, although oral warts occur only infrequently. See Veldhuizen NJ, Snijders PJF, Reiss P. Factors affecting transmission of mucosal papillomaviruses. *Lancet Infect Dis.* 2010;10:862-874; and Workowski KA; Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2014. *MMWR Morb Mortal Wkly Rep.* 2014 (in press).

2. A 28-year-old woman presents with genital bumps 6 weeks after a brief sexual encounter while on vacation. The lesions are slightly itchy but are otherwise asymptomatic. She is concerned that this represents a recurrence of a prior episode of genital warts and would like to refill a prescription for imiquimod cream. Her physical examination is notable for moist bilateral condylomatous lesions on her labia minora and bilateral nontender inguinal lymphadenopathy. Which of the following would be the most appropriate diagnostic test?

A. A skin biopsy of the lesion
B. A blood test for syphilis
C. A swab of the lesion for HPV testing
D. A Pap test and an HPV co-test of her cervix
E. It would be most cost-effective not to perform any test, but an empirical course of imiquimod should be initiated.

Answer: B Although a skin biopsy is the definitive method for diagnosing genital lesions, such as suspected warts, genital warts can often be diagnosed by clinical examination without diagnostic testing. In this case, the clinical presentation (moist bilateral painless lesions with nontender lymphadenopathy) would be suspicious for the condyloma lata lesions of secondary syphilis, which can be easily diagnosed by a serologic test for syphilis; empirical treatment without such a test could delay appropriate treatment. HPV testing is recommended only as part of cervical cancer screening, not to diagnose a lesion. Cervical cancer screening would not help to assess her clinical presentation, and HPV co-testing is not recommended for women younger than 30 years because of its poor specificity. See Workowski KA; Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2014. *MMWR Morb Mortal Wkly Rep.* 2014 (in press).

3. You have recommended a quadrivalent HPV vaccine for a 17-year-old bisexual man visiting your adolescent health clinic. He has read that this vaccine, like many others, can have serious side effects and wants to know why this vaccine might be beneficial for him to receive. Which of the following is *not* a potential benefit of HPV vaccine for him?

A. Prevention of genital warts
B. Prevention of cervical cancer in a future female partner
C. Prevention of plantar warts
D. Prevention of anal cancer
E. Prevention of oropharyngeal cancer

Answer: C The quadrivalent HPV vaccine is highly effective in preventing anogenital lesions due to the four HPV types contained in the vaccine (types 6/11, which commonly cause genital warts, and types 16/18, which cause a variety of types of genital and anal cancer). The vaccine is recommended in the United States for all males because of its benefit in preventing genital warts, anal intraepithelial neoplasia, and probably anal cancer. Preventing infection in young males has the potential to reduce the chance of infection in their future sexual partners, a phenomenon that has already been demonstrated for vaccinated females. Because HPV types 16/18 are also a cause of oropharyngeal cancer, the vaccine could potentially provide benefit in preventing this outcome as well. Plantar warts are generally caused by HPV 1 and other nongenital types, and the vaccine has no potential for preventing these lesions. See Bosch FX, Broker TR, Forman D, et al. Comprehensive control of human papillomavirus infections and related diseases. *Vaccine.* 2013;31S:H1-31.

4. HPV molecular testing is recommended in which of following clinical situations?

A. Combined with a Pap test to screen for cervical cancer in a 35-year-old woman
B. Screening for oral cancer in a 50-year-old man
C. Combined with a Pap test to screen for cervical cancer in a 26-year-old woman who had previously received the HPV vaccine
D. Combined with a Pap test to screen for cervical cancer in a 22-year-old woman
E. Screening for anal cancer in a 45-year-old man who has sex with men

Answer: A The explosion of knowledge regarding HPV and its role in a variety of cancers has led to great interest in the use of molecular tests for screening and diagnosis. Testing is currently recommended only in limited circumstances, specifically for cervical cancer screening in combination with a Pap test for women 30 years of age or older and for triage of women with cytologic findings of atypical squamous cells of undetermined significance. Because of the higher prevalence of HPV in women younger than 30 years, HPV testing is not recommended for screening owing to its low specificity for detecting significant cervical lesions; prior vaccination status does not affect this recommendation. There are no data to support the use of HPV testing in screening for cancer at sites other than the cervix. See Bosch FX, Broker TR, Forman D, et al. Comprehensive control of human papillomavirus infections and related diseases. *Vaccine.* 2013;31S:H1-31; Schiffman MH, Solomon D. Cervical cancer screening with human papillomavirus and cytologic co-testing. *N Engl J Med.* 2013;369: 2324-2331; and Workowski KA; Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines 2014. *MMWR Morb Mortal Wkly Rep.* 2014 (in press).

5. A 45-year-old HIV-infected man recently saw a news report that warned about HPV-related health issues in HIV infected men. He now comes to you for counseling. In considering how to address his concerns, all of the following are true except which of the following?

A. HIV-infected persons are at increased risk for cervical and anal cancer.
B. HPV-related lesions are more difficult to treat in HIV-infected persons.
C. HPV may increase the risk that HIV-uninfected persons will acquire HIV.
D. Cancer screening with anal Pap tests has been proved to prevent anal cancer in HIV-infected men who have sex with men.
E. Although its protective benefit is unproved, HPV vaccines can be safely given to HIV-infected persons.

Answer: D Although cancers of both the cervix and anus occur with increased frequency in HIV-infected persons, cytologic screening has not been proved to prevent anal cancer and is not a recommended prevention strategy. Like many infections controlled by cell-mediated immunity, HPV infections are more common and difficult to treat in HIV-infected persons, especially those with advanced immunodeficiency. Although there is no proven benefit of HPV immunization in HIV-infected persons, there are no safety risks because the vaccine contains no live virus. Recent data indicate that HPV infection can increase the risk for HIV transmission, analogous to what is observed for many other sexually transmitted infections. 374

HERPES SIMPLEX VIRUS INFECTIONS

RICHARD J. WHITLEY

DEFINITION

The Pathogen

Herpes simplex virus (HSV), a member of the family Herpesviridae, has been implicated in human infections since descriptions of cutaneous spreading lesions in ancient Greek times. In 1968, well-defined antigenic and biologic differences were demonstrated between HSV type 1 (HSV-1) and HSV type 2 (HSV-2). Of all the herpesviruses, HSV-1 and HSV-2 are most closely related, with approximately 60% genomic homology. Historically, HSV-1 was more frequently associated with nongenital infection and HSV-2 with genital

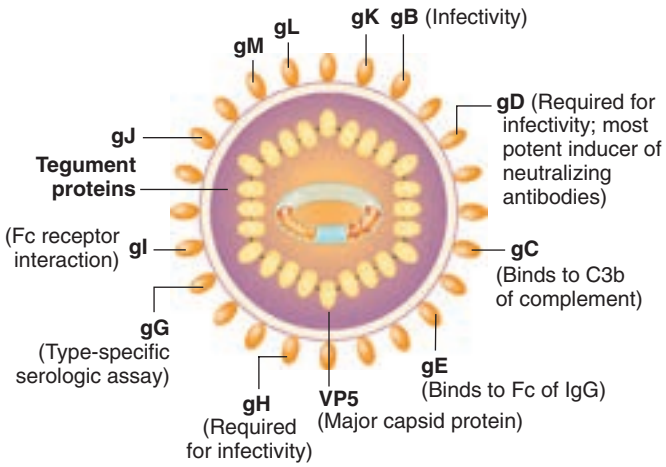

FIGURE 374-1. Schematic diagram of the herpes simplex virion. IgG = immunoglobulin G.

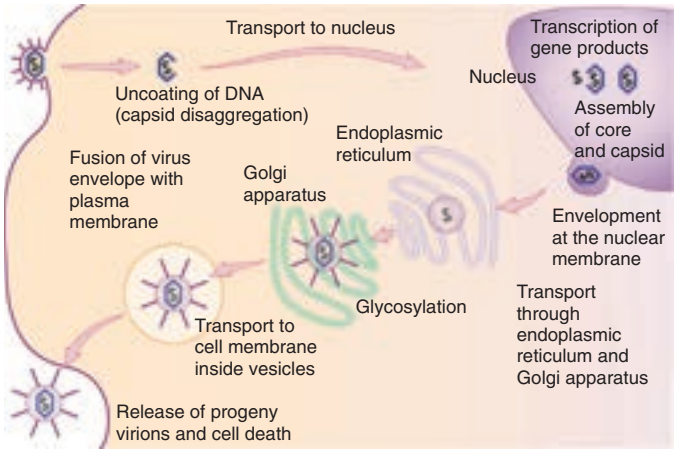

FIGURE 374-2. Schematic diagram of replication of herpes simplex virus.

disease, but these distinctions are much less relevant now that HSV-1 causes more than 50% of genital infection in some populations. These two viruses can be distinguished most reliably by DNA restriction enzyme analysis, but differences in antigen expression and biologic properties also serve as methods for differentiation.

Inclusion in the family Herpesviridae is based on the structure of the virion (Fig. 374-1). HSV contains double-stranded DNA at its central core, has a molecular weight of approximately 100 million, and encodes at least 80 polypeptides. The DNA core is surrounded by a capsid that consists of 162 capsomers arranged in icosapentahedral symmetry. The capsid is 100 to 110 nm in diameter. Tightly adherent to the capsid is the tegument, which consists of amorphous material. Loosely surrounding the capsid and tegument is a lipid bilayer envelope derived from host cell membranes. The envelope consists of polyamines, lipids, and glycoproteins. These glycoproteins confer distinctive properties to the virus and provide unique antigens to which the host is capable of responding. Notably, glycoprotein G (gG) provides antigenic specificity to HSV and therefore results in an antibody response that allows distinction between HSV-1 (gG-1) and HSV-2 (gG-2).

EPIDEMIOLOGY

HSV infections occur worldwide and have been reported in both developed and developing countries. Animal vectors for human HSV infections have not been described, and there is no seasonal variation in the incidence of HSV infections. HSV is transmitted from infected to susceptible individuals during close personal contact, and the virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. Because approximately a third of the world's population has recurrent HSV infections and because infection is rarely fatal, a large reservoir of HSV exists in the community.

Seroprevalence studies have demonstrated that acquisition of HSV-1 infection is related to socioeconomic factors. Antibodies, which indicate past infection, are found early in life among individuals of lower socioeconomic groups, presumably a consequence of crowded living conditions that provide a greater opportunity for direct contact with infected individuals. Antibodies develop in as many as 75 to 90% of individuals from lower socioeconomic populations by the end of the first decade of life. In contrast, only 30 to 40% of persons in the middle and upper socioeconomic groups are seropositive by the middle of the second decade of life.

Because infections with HSV-2 are usually acquired through sexual contact, antibodies to this virus are rarely found until the onset of sexual activity. There is a progressive increase in infection rates with HSV-2 in all populations beginning in adolescence. Overall, about one in five Americans has genital HSV-2 infection. As with HSV-1 infections, the rate of acquisition of HSV-2 infection appears to be related to socioeconomic factors. The number of sexual partners is also an important risk factor for the acquisition of HSV-2. Genital herpes infection has been found to be a risk factor for another sexually transmitted virus, human immunodeficiency virus (HIV; Chapter 386).

Localized, recurrent HSV-2 infection is the most common form of HSV infection during gestation. Transmission of infection to the fetus is most frequently related to shedding of the virus at the time of delivery. The incidence of cervical shedding in pregnant women with asymptomatic HSV infection is approximately 1%. Most infants in whom neonatal disease develops are born to women who are completely asymptomatic for genital HSV infection at the time of delivery and who have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash. These women account for 60 to 80% of all women whose children acquire neonatal HSV infection. Women who experience a symptomatic or asymptomatic primary infection in the third trimester of gestation have a 30 to 50% risk for transmitting infection to the child.

PATHOBIOLOGY

Replication of HSV is a multistep process (Fig. 374-2). After the onset of infection, DNA is uncoated and transported to the nucleus of the host cell. This step is followed by transcription of immediate-early genes, which encode the regulatory proteins, and is followed by the expression of proteins encoded by early and then late genes.[1] These proteins include enzymes necessary for viral replication and structural proteins.

Assembly of the viral core and capsid takes place within the nucleus. Envelopment at the nuclear membrane and transport out of the nucleus occur through the endoplasmic reticulum and the Golgi apparatus. Glycosylation of the viral membrane occurs in the Golgi apparatus. Mature virions are transported to the outer membrane of the host cell inside vesicles. Release of progeny virus is accompanied by cell death. Replication for all herpesviruses is considered inefficient, with a high ratio of noninfectious to infectious viral particles.

A critical factor for transmission of HSV, regardless of virus type, is intimate contact between a person who is shedding virus and a susceptible host. With inoculation onto skin or mucous membranes, HSV replicates in epithelial cells; the incubation period is 4 to 6 days (Fig. 374-3). As replication continues, cell lysis and local inflammation ensue and result in the characteristic vesicles on an erythematous base. Regional lymphatics and lymph nodes become involved as a result of draining of infected secretions from the area of viral replication. Viremia and visceral dissemination may develop, depending on the immunologic competence of the host. In all hosts, the virus generally ascends peripheral sensory nerves to reach the dorsal root ganglia. Replication of HSV within neural tissue is followed by spread of the virus to other mucosal and skin surfaces by means of peripheral sensory nerves. HSV replicates further in epithelial cells and reproduces the lesions of the initial infection until infection is contained through host immune responses.

The histopathologic changes induced by HSV replication are similar in both primary and recurrent infection. Changes induced by viral infection include ballooning of infected cells and the appearance of condensed chromatin within the nuclei of cells, followed by subsequent degeneration of cellular nuclei. Cells lose intact plasma membranes and form multinucleated giant cells. They may also demonstrate intranuclear inclusions known as Cowdry type A bodies, which are suggestive but not diagnostic of HSV infection. With cell lysis, clear vesicular fluid containing large quantities of virus accumulates between the epidermis and dermal layer. The dermis reveals an intense inflammatory response, more so with primary infection than with recurrent disease. As healing progresses, the clear vesicular fluid becomes

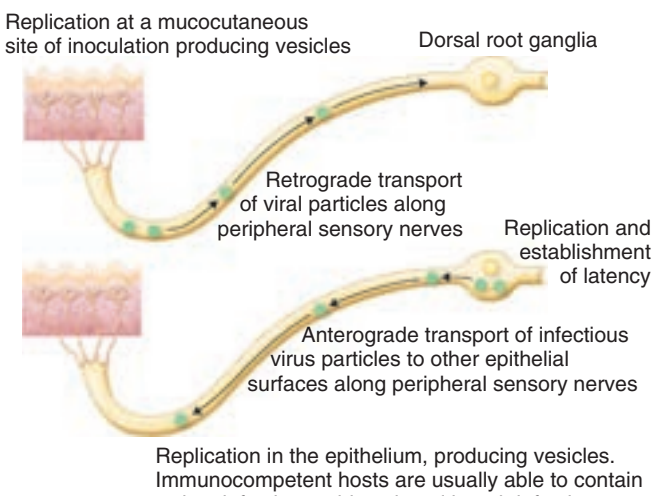

FIGURE 374-3. Schematic diagram of primary herpes simplex virus infection.

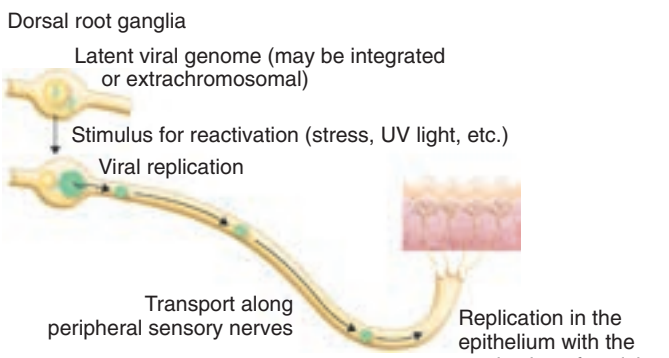

FIGURE 374-4. Schematic diagram of herpes simplex virus latency and reactivation. UV = ultraviolet.

FIGURE 374-5. Herpes labialis, classic grouped blisters.

pustular with the recruitment of inflammatory cells. The pustule then forms a scab; scarring is uncommon.

Vascular changes in the area of infection include perivascular cuffing and hemorrhagic necrosis. These changes are particularly prominent when organs other than skin are involved, as is the case with herpes simplex encephalitis or disseminated neonatal HSV infection. Local lymphatics can show evidence of infection with intrusion of inflammatory cells because of draining of infected secretions from the area of viral replication. As host defenses are mounted, an influx of mononuclear cells can be detected in infected tissue.

A unique characteristic of all herpesviruses is their ability to establish latent infection, to persist in an apparently inactive state for varying lengths of time, and then to be reactivated (Fig. 374-4).[2] The latent viral genome may be either extrachromosomal or integrated into host cell DNA, depending on the virus.

Latency is established when HSV reaches the dorsal root ganglia after retrograde transmission through sensory nerve pathways. Latent virus may be reactivated and enter a replicative cycle at any point in time. Reactivation of latent virus is a well-recognized biologic phenomenon but not one that is understood from a molecular standpoint. Stimuli associated with the reactivation of latent HSV have included stress, fever, menstruation, and exposure to ultraviolet light. Precisely how these factors interact at the level of the ganglia remains to be defined. Reactivation may be clinically asymptomatic, or it may produce life-threatening disease.

CLINICAL MANIFESTATIONS

Gingivostomatitis

Gingivostomatitis (usually caused by HSV-1) occurs most frequently in children younger than 5 years. Illness is characterized by fever, sore throat, pharyngeal edema, and erythema, followed by the development of vesicular or ulcerative lesions on the oral and pharyngeal mucosa. Recurrent HSV-1 infections of the oropharynx are most frequently manifested as herpes simplex labialis (cold sores) and usually appear on the vermilion border of the lip (Fig. 374-5). Recurrences are triggered by fever, stress, and exposure to ultraviolet light as well as by other factors. Intraoral lesions as a manifestation of recurrent disease are uncommon.

Genital Herpes

Genital herpes is often caused by HSV-2, but approximately 50% of all new primary cases in young adults are caused by HSV-1. Primary infection in women usually involves the vulva, vagina, and cervix. In men, initial infection is most often associated with lesions on the glans penis, prepuce, or penile shaft. In individuals of either gender, primary disease is associated with fever, malaise, anorexia, and bilateral inguinal adenopathy. Women frequently have dysuria and urinary retention as a result of urethral involvement. Aseptic meningitis develops in as many as 10% of individuals with primary infection. Sacral radiculomyelitis may occur in both men and women and results in neuralgias, urinary retention, or obstipation. Complete healing of primary infection may take several weeks. The first episode of genital infection is less severe in individuals who have previously had HSV-1 infections at other sites. Antibodies to HSV-1 appear to ameliorate the expression of HSV-2 clinical disease, although this effect is controversial.

Recurrent genital infections in either men or women can be particularly distressing. The frequency of recurrence varies significantly from one individual to another. Of note, viral DNA can be detected by polymerase chain reaction (PCR) in genital secretions three- to four-fold more frequently than symptomatic recurrences. Furthermore, recurrences detected by PCR can occur frequently during 24 hours and persist for brief periods. A third of infected individuals have virtually no or few clinical recurrences, a third have approximately three recurrences per year, and another third have more than three per year. Several seroepidemiologic studies have found that between 25 and 65% of individuals in the United States have antibodies to HSV-2 and that seroprevalence is correlated with the number of sexual partners.

Shedding of HSV from the genital tract can be either symptomatic or, more frequently, asymptomatic. Transmission can occur in the absence of symptoms. Genital ulcerative disease attributed to HSV is a risk factor for the acquisition of HIV infection.

Herpetic Keratitis

Herpes simplex keratitis (Chapter 423) is usually caused by HSV-1 and is accompanied by conjunctivitis in many cases. It is considered the most common infectious cause of blindness in the United States. The characteristic lesions of HSV keratoconjunctivitis are dendritic ulcers best detected by fluorescein staining of the cornea. Deep stromal involvement has also been reported and may result in visual impairment.

Other Cutaneous Manifestations

HSV infections can occur at any skin site. Common among health care workers are lesions on abraded skin or the fingers, known as herpetic whitlow. Similarly, in wrestlers, disseminated cutaneous lesions known as herpes gladiatorum may develop as a result of physical contact.

HERPES SIMPLEX VIRUS INFECTIONS IN IMMUNOCOMPROMISED HOSTS

HSV infections in immunocompromised hosts, including patients with acquired immunodeficiency syndrome, are usually due to reactivation of

latent infection and are clinically more severe, may be progressive, and require a longer time to heal. Manifestations of HSV infections in this population of patients include pneumonitis, esophagitis, hepatitis, colitis, and disseminated cutaneous disease. Individuals suffering from HIV infection may have extensive perineal or orofacial ulcerations. HSV infections are also noted to be of increased severity in individuals with extensive burns.

DIAGNOSIS

Definitive diagnosis of HSV infection requires detection of viral DNA by PCR testing or isolation of the virus. DNA amplification has become the diagnostic method of choice in assessing cerebrospinal fluid (CSF) specimens for evidence of HSV infection of the central nervous system and has significantly improved sensitivity for confirmation of HSV as the cause of lip and genital herpes infection. The main role for viral cultures is to assess possible resistance to antiviral therapy.

In the absence of PCR or diagnostic virologic facilities, cytologic examination of cells scraped from a clinical lesion may be useful in making a presumptive diagnosis of HSV infection. Material obtained from scraping the base of a lesion should be smeared on a glass slide and promptly fixed in cold ethanol. The slide can be stained according to the methods of Papanicolaou, Giemsa, or Wright. The presence of intranuclear inclusions and multinucleated giant cells is indicative but not diagnostic of HSV infection. This method has a sensitivity of only 60 to 70% and should not be the sole diagnostic method used.

In addition to new tests for viral DNA, type-specific serologic assays are commercially available. These tests are based on differences between HSV-1 and HSV-2.

TREATMENT

Rx

For *immunocompromised* patients, such as patients who have cancer or are receiving immunosuppressive drugs, patients with disseminated mucocutaneous infections, or patients with herpes encephalitis, the treatment of choice is intravenous acyclovir (5 to 10 mg/kg every 8 hours for 5 to 7 days). Caution must be exercised when acyclovir is used intravenously because it may crystallize in the renal tubules when it is given too rapidly or to dehydrated patients. Valacyclovir (500 to 1000 mg two or three times daily) and famciclovir (250 to 500 mg three times daily), depending on severity, are equally efficacious and have improved pharmacokinetics, as demonstrated by improved biodistribution and less frequent dosing intervals compared with oral acyclovir. Thus, they should preferentially be used for the treatment of non-life-threatening HSV infection.[3] For life-threatening disease, only intravenous medications should be given. Immunocompromised individuals with non-life-threatening mucocutaneous HSV infections can be given oral valacyclovir (500 to 1000 mg once or twice daily for 5 to 7 days), famciclovir (250 to 500 mg three times daily for 7 days), or acyclovir (400 mg two or three times daily for 7 to 10 days).

High-risk immunocomprised hosts are at risk for developing an acyclovir-resistant infection, usually as a consequence of either an altered or deficient thymidine kinase enzyme that activates acyclovir in infected cells. Such patients can be managed with foscarnet or cidofovir, continued until there is evidence of healing, with the doses based on renal function (see Tables 360-4 and 360-5 in Chapter 360).

In *immunocompetent* hosts with mucocutaneous infections, oral acyclovir (200 mg five times daily for 5 days) reduces lesions and speeds recovery. Oral valacyclovir (1 g/day for 5 days or 500 mg twice daily for 3 days) and oral famciclovir (1 g twice daily for 1 day) are equally effective. Pritelivir (an inhibitor of the viral helicase-primase complex at 25 to 75 mg daily or 400 mg weekly) has recently been shown to reduce viral shedding and the duration of genital lesions in men and women, but is on clinical hold on the part of the FDA because of potential toxicity issues. Topical acyclovir is not as reliable as oral acyclovir and is not recommended.[4]

HSV has been used for experimental gene therapy. By removal of the $\gamma_1 34.5$ gene, both neurovirulence and the propensity to establish latency are ablated. These engineered viruses are being experimentally tested in patients with glioblastoma multiforme and colorectal metastases to liver.

PREVENTION

Some patients with particularly disabling oral recurrences or genital recurrences are candidates for chronic suppressive therapy. Potential regimens include oral acyclovir 400 mg twice daily, oral valacyclovir 500 mg or 1 g/day, and oral famciclovir 250 mg twice daily. Such regimens are approved by the U.S. Food and Drug Administration for genital herpes but not for herpes labialis. However, such therapy does not prevent recurrent HSV-2 meningitis.

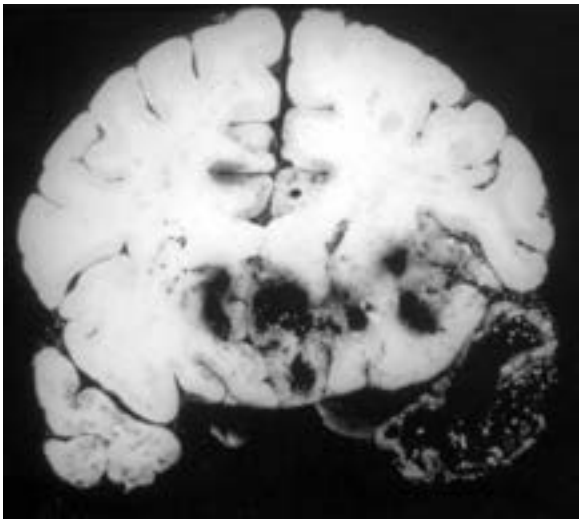

FIGURE 374-6. Hemorrhagic necrosis in herpes simplex encephalitis.

At present, experimental vaccines for HSV-1 and HSV-2 remain under investigation.[5] Acyclovir, valacyclovir, and famciclovir are given to recipients of solid organ and bone marrow transplants in the immediate post-transplantation period in an effort to prevent reactivation of latent disease at the doses noted previously. Valacyclovir (500 mg daily) decreases person-to-person transmission of HSV-2. Suppressive therapy of an HSV-2-infected but HIV-seronegative patient does not prevent HIV acquisition from HIV-seropositive partners.[6]

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex encephalitis[7] is characterized by hemorrhagic necrosis of the temporal lobe (Chapter 414). Disease begins unilaterally and spreads to the contralateral temporal lobe (Fig. 374-6). It is the most common cause of focal, sporadic encephalitis in the United States today and occurs in approximately 1 in 150,000 individuals. Most cases are caused by HSV-1. The actual pathogenesis of herpes simplex encephalitis requires further clarification, although it has been speculated that primary or recurrent virus can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of herpes simplex encephalitis are characteristic of temporal lobe involvement and include headache, fever, altered consciousness, aphasia, and behavioral abnormalities. Focal seizures also may occur. CSF findings in these patients are variable but usually consist of a pleocytosis with both polymorphonuclear leukocytes and monocytes present. The protein concentration is characteristically elevated, and the glucose level is usually normal. Magnetic resonance imaging can suggest the diagnosis by demonstrating edema of either temporal lobe. Diagnosis can be confirmed by PCR detection of HSV DNA in the CSF by experienced laboratories.

TREATMENT AND PROGNOSIS

Rx

Mortality and morbidity are high, even with appropriate acyclovir antiviral therapy. At present, the mortality rate is approximately 30% 1 year after treatment. In addition, approximately 60% of survivors have moderate or severe neurologic impairment.

NEONATAL HERPES SIMPLEX VIRUS INFECTION

Neonatal HSV infection is estimated to occur in approximately 1 in 3500 deliveries in the United States each year.[8] Approximately 70% of cases are caused by HSV-2 and usually result from contact of the fetus with infected maternal genital secretions at the time of delivery. Manifestations of neonatal HSV infection can be divided into three categories: skin, eye, and mouth disease; encephalitis; and disseminated infection. As the name implies, skin, eye, and mouth disease consists of cutaneous lesions and does not involve other organ systems. Involvement of the central nervous system may occur

with encephalitis or disseminated infection and generally results in diffuse encephalitis. CSF assay characteristically reveals elevated protein levels and mononuclear pleocytosis. Disseminated infection involves multiple organ systems and can cause disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, and cutaneous lesions. Diagnosis is difficult in the absence of skin lesions, which occurs in as many as 36% of cases. The mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 5% for encephalitis and 25% for neonates with disseminated infection, even with appropriate antiviral treatment. In addition to the high mortality associated with these infections, morbidity is significant in that children with encephalitis or disseminated disease develop normally in only 40% of cases, even with appropriate antiviral therapy (acyclovir, 20 mg/kg every 8 hours for 14 days for skin, eye, and mouth infections and 21 days for central nervous system or disseminated disease).

REVIEW QUESTIONS

1. A 55-year-old woman presents in the emergency department with fever, expressive aphasia, and altered behavior during the month of September. Her husband reports that the symptoms began approximately 6 hours before presentation. She is an avid hiker and spelunker. Her physical examination, aside from fever and expressive aphasia, is otherwise normal. Her cerebrospinal fluid findings are as follows: protein 75 mg/dL, 36 white blood cells (equally divided between lymphocytes and neutrophils), 0 red blood cells, and a normal glucose level. A computed tomographic scan of her head is normal. Which of the following is the most likely cause of her illness?

A. Enterovirus encephalitis
B. Rabies
C. Acute HIV infection
D. Herpes simplex virus
E. West Nile virus

Answer: D This is a classic presentation of a focal encephalopathic illness that is characteristic of herpes simplex virus encephalitis. Expressive aphasia and altered behavior are key to the diagnosis. About 20% of patients will not have red blood cells in their cerebrospinal fluid. Enterovirus very rarely causes a focal encephalopathic process; and when it does, it is in children. Rabies involves the cerebellum, whereas West Nile virus presents with anterior horn motor disease without altered behavior or expressive aphasia. Acute HIV encephalitis is a diffuse symmetrical encephalitis.

2. You elect to perform diagnostic studies on the aforementioned patient in order to determine the best management. Which of the following is most likely to confirm the diagnosis?

A. A serum immunoglobulin M (IgM) level
B. An electroencephalogram
C. A serum IgG (acute and convalescent) level
D. Biopsy of the nape of the neck
E. Polymerase chain reaction (PCR) analysis of her cerebrospinal fluid

Answer: E The "gold standard" for diagnosing herpes simplex encephalitis is PCR analysis of cerebrospinal fluid for detection of HSV DNA. Serology is of no value in making this diagnosis acutely. A neck biopsy is reserved for patients suspected of having rabies. An electroencephalogram might show spike and slow wave activity characteristic of HSV infection, but the sensitivity and specificity are low.

VARICELLA-ZOSTER VIRUS (CHICKENPOX, SHINGLES)

JEFFREY COHEN

DEFINITION

Primary infection with varicella-zoster virus (VZV) results in the rash of varicella (chickenpox). The virus establishes a latent infection in the nervous system and can reactivate later in life to cause zoster (shingles).[1]

The Pathogen

VZV is a member of the alpha herpesvirus family and has a DNA core surrounded by a nucleocapsid, which is in turn surrounded by a viral envelope that is studded with glycoproteins. Antibody to viral glycoproteins is important for neutralizing the virus's infectivity and for protecting against primary infection. The virus encodes a thymidine kinase, which phosphorylates acyclovir, which in turn inhibits viral DNA replication by inhibiting the VZV DNA polymerase.

EPIDEMIOLOGY

Before the advent of an effective vaccine, more than 95% of children in temperate climates were infected with VZV. By comparison, infection is usually delayed until adulthood in tropical climates. Varicella usually occurs in children younger than 5 years. Zoster is less common in tropical areas, probably because of a delay in acquisition of varicella. Varicella is more common in the winter and spring, whereas zoster has no seasonal predilection.

Primary varicella infection can occur after exposure to either chickenpox or zoster. The virus is spread by droplets and aerosols from patients or by contact with vesicular lesions. Persons are infectious beginning about 2 days before the rash appears and continuing until all lesions have crusted. Although 60 to 90% of susceptible household contacts develop varicella, only 20 to 30% of susceptible persons exposed to zoster become infected. More than 95% of primary infections result in the symptoms of varicella, and second episodes of varicella are rare. Varicella is more severe in persons with impaired cellular immunity, including patients with acquired immunodeficiency syndrome (AIDS) and infants whose mothers present with varicella 5 days before to 2 days after delivery.

About 50% of persons who have had varicella and live to age 85 years will develop zoster. The risk for zoster rises with increasing age (especially 50 years and older) and with increasing impairment of cellular immunity. For example, men with AIDS have a 20-fold higher risk for development of zoster than age-matched controls. Less than 5% of persons have a second episode of zoster, but recurrent zoster is more common in persons with impaired cellular immunity.

PATHOBIOLOGY

Varicella is transmitted by the respiratory route. The virus is thought to infect epithelial cells and lymphocytes in the oropharynx and upper respiratory tract or in the conjunctiva, and then infected lymphocytes subsequently spread the virus throughout the body. The virus then enters the skin through endothelial cells in blood vessels and spreads to epithelial cells, where it causes the vesicular rash of varicella. Lesions initially are vesicular but become pustular after the infiltration of inflammatory cells. Later the lesions break open and dry to form crusts that usually heal without scarring. During primary infection, neurons in cranial nerve ganglia and dorsal root ganglia become latently infected with the virus.

If VZV-specific cellular immunity declines, the virus can reactivate from a ganglion, travel down the axon, and replicate in epithelial cells to cause dermatomal zoster. In highly immunocompromised persons, high-grade viremia during reactivation causes disseminated zoster.

Antibodies, which usually are present at the time varicella presents clinically, persist for life. Antibody is important for protection against varicella, as evidenced by the ability of varicella immune globulin to attenuate the disease. Cytotoxic T cells are present within 2 to 3 days after the onset of varicella and limit its severity. Varicella is more severe in persons with impaired cellular immunity but not in patients with hypogammaglobulinemia. Cellular immunity, not antibody, is required to prevent reactivation of virus and zoster.

CLINICAL MANIFESTATIONS

Varicella

Varicella begins with fever and malaise followed 1 to 2 days later by a disseminated, pruritic, vesicular rash (Fig. 375-1).[2] The usual incubation period for varicella is 2 weeks (range, 10 to 21 days) after exposure to an infected person. The lesions begin as papules that become vesicles, followed by pustules and then crusts. Lesions appear on the head and then spread to the trunk and then to the extremities; the mucosa can also be involved. There are typically 200 to 500 lesions in different stages on the skin. New lesions occur for up to 5 days in normal hosts, and crusting is complete within 2 weeks.

The most common complication of varicella is bacterial superinfection of skin lesions. Group A streptococcus (Chapter 290) or *Staphylococcus aureus* (Chapter 288) infections can cause cellulitis, bacteremia, and necrotizing fasciitis. Other complications include cerebellar ataxia, viral pneumonitis, hepatitis, and thrombocytopenia. Less frequent complications include viral meningitis, encephalitis, vasculopathy (which presents as a stroke), disseminated intravascular coagulopathy (Chapter 175), and Reye syndrome (more common in children receiving aspirin). Complications involving the lungs and liver are more common in children with impaired cellular immunity including those receiving systemic steroids, children with chronic pulmonary or skin disease, adults, and pregnant women during the third trimester. The fetal varicella syndrome, which occurs in fetuses infected during the first trimester, is characterized by atrophy of limbs with scarring of skin, chorioretinitis or cataracts, and central nervous system abnormalities. Patients with AIDS and moderately reduced CD4 cell counts may develop recurrent varicella lesions in the absence of new exposures, and patients with CD4 cell counts below 200/μL may develop progressive varicella with new lesions occurring for at least 1 month or chronic verrucous lesions.

Zoster

In healthy persons, zoster presents with localized pain and increased sensation for 1 to 3 days before the development of a dermatomal vesicular rash

FIGURE 375-1. Child with varicella. (Courtesy of Centers for Disease Control and Prevention.)

FIGURE 375-2. Dermatomal zoster. (Courtesy of Centers for Disease Control and Prevention.)

that does not cross the midline (Fig. 375-2). Zoster most frequently presents in the dermatomes innervated by trigeminal or thoracic ganglia. The rash is usually accompanied by itching, tingling, or pain. The lesions evolve from vesicles to pustules, and crusting is usually complete by 10 days. In normal hosts, a few lesions may develop outside of the dermatome owing to low-grade viremia. Some patients with zoster sine herpete never develop a rash. In persons with very impaired cellular immunity, reactivation is often associated with high-grade viremia with dissemination to large areas of the skin and involvement of multiple organs. As a result, patients with underlying malignancies are more likely to develop more serious complications from their zoster infections.[3]

A dreaded complication of zoster is post-herpetic neuralgia (Chapter 30) with pain persisting for at least 1 month after the rash has resolved. Patients may have allodynia (sensation of pain after nonpainful stimuli), paresthesias, dysesthesias, or severe neuropathic pain. Post-herpetic neuralgia is more common in persons older than 50 years. Other complications of zoster include bacterial superinfection; ocular disease, involving any of the structures of the eye, due to reactivation in the ophthalmic branch of the trigeminal ganglia; facial palsy caused by reactivation in the VII cranial nerve; Ramsay Hunt syndrome, with pain and vesicles in the ear, numbness of the anterior tongue, and ipsilateral facial palsy due to reactivation in the geniculate ganglion of the VII cranial nerve; motor neuropathy; and meningitis. Zoster vasculopathy, occurring at the time of zoster or a few months later, can present with stroke due to inflammation of the cerebral arteries.

Progressive outer retinal necrosis, with few inflammatory ocular cells, occurs when VZV reactivates in the eye of severely immunocompromised persons, including patients with AIDS and low CD4 cell counts. In contrast, acute retinal necrosis with a marked inflammatory response occurs when the virus reactivates in otherwise healthy persons. Patients with AIDS or recipients of hematopoietic stem cell transplants can have pancreatitis, hepatitis, and pneumonitis in the absence of or preceding a rash.

DIAGNOSIS

Most cases of varicella and zoster are diagnosed on the basis of their clinical presentation. A disseminated vesicular rash with lesions in various stages of evolution is usually sufficient for a diagnosis of varicella. The differential diagnosis includes impetigo (Chapter 441), enterovirus infections (Chapter 379), herpes simplex (Chapter 374), Stevens-Johnson syndrome (Chapter 440), and guttate psoriasis (Chapter 438). A dermatomal vesicular rash that does not cross the midline in a patient with a prior history of pain in the area is usually diagnostic of zoster. Herpes simplex is the most common disease that resembles zoster.

When the diagnosis of varicella or zoster must be confirmed definitively, polymerase chain reaction (PCR) for VZV from vesicular fluid is the most sensitive and specific test. PCR for VZV in the blood can be useful for diagnosis of visceral zoster in highly immunocompromised persons before the onset of rash. PCR for VZV in the cerebrospinal fluid and intrathecal synthesis of VZV-specific antibody is useful for diagnosis of VZV neurologic diseases. Culture is less sensitive than PCR because the virus is very labile. Direct fluorescent antibody testing of vesicle fluid is rapid but less sensitive than PCR. Detection of multinucleated giant cells (Tzanck smear) is less specific because lesions of herpes simplex virus have a similar appearance. Biopsy specimens show eosinophilic intranuclear inclusion bodies and multinucleate giant cells.

Serology for VZV is useful to determine the need for postexposure prophylaxis in persons who are at high risk for disease after exposure to varicella or zoster. Enzyme-linked immunosorbent assay tests are less sensitive than latex agglutination assays and may not detect antibodies in vaccinees.

TREATMENT Rx

Varicella

Symptomatic treatment includes acetaminophen for fever and lotion or baths for pruritus. Although acyclovir is licensed for the treatment of varicella, the drug is not recommended for otherwise healthy children because it only modestly decreases symptoms by about 1 day. Acyclovir reduces visceral dissemination in immunocompromised persons, in whom intravenous acyclovir (500 mg/m^2 every 8 hours for children, 10 mg/kg every 8 hours for adults) is recommended for 7 to 10 days or until all lesions have crusted. Oral acyclovir (20 mg/kg four times daily for children or 800 mg five times daily for adults) given within 24 hours after the onset of rash reduces the duration of symptoms and is recommended for treatment of adolescents, adults, newborns whose mothers developed varicella near the time of delivery, immunocompromised persons, children with chronic pulmonary or skin disease, and persons with complications of varicella. Acyclovir also should be considered for household contacts of persons with varicella or for pregnant women in the third trimester; these patients often have more severe disease. Oral valacyclovir is also approved for treatment of children ages 2 years to <18 years with varicella (20 mg/kg three times daily with a maximum dose of 1 g). Oral valacyclovir, 1 g three times daily, or famciclovir, 500 mg three times daily result in higher antiviral drug levels than does oral acyclovir and can be used in nonpregnant adults.

Zoster

Acyclovir, valacyclovir, and famciclovir (for 7 days at the same doses as for varicella) are licensed for the treatment of zoster. Oral valacyclovir and famciclovir result in higher levels of antiviral activity than oral acyclovir does. Although therapy should be started within 3 days of the rash, therapy may still be of benefit if new lesions continue to occur after this time. Because patients younger than 50 years usually have little pain associated with zoster, antiviral therapy is often not used in these patients unless they have moderate to severe pain, have disease involving the eye, have other complications, or are immunocompromised. Antiviral drugs (see earlier) reduce the duration of lesions and zoster-associated pain but not the incidence of post-herpetic neuralgia. In severely immunocompromised persons, intravenous acyclovir (7 to 10 days or until all lesions have crusted) reduces the risk for visceral dissemination. Oral valacyclovir or famciclovir may be used in persons who are less severely immunocompromised.

Corticosteroids (e.g., prednisone, 60 mg/day and tapered over 21 days), in combination with acyclovir, reduce acute pain and improve the quality of life in persons older than 50 years but do not reduce the risk for post-herpetic neuralgia. Patients with moderate to severe pain often require narcotics.

Treatment of post-herpetic neuralgia is challenging.[4] Gabapentin (initiated at a dose of 300 mg at bedtime and titrated to a maximum dose of 1200 mg three times daily) or pregabalin (initiated at a dose of 75 mg at bedtime and titrated to a maximum dose of 300 mg twice daily) may reduce pain. Additional agents include nortriptyline (initiated at a dose of 25 mg at bedtime and titrated to a maximum dose of 150 mg daily), lidocaine patches, and topical capsaicin (which itself causes pain that is not tolerated in up to one third of patients). Opioid analgesics (see Table 30-5) may be needed, but there are concerns about long-term efficacy and safety.

Treatment of VZV Complications and Acyclovir-Resistant VZV

Intravenous acyclovir is recommended for persons with acute retinal necrosis. Corticosteroids (e.g., prednisone, 1 mg/kg per day for 3 to 5 days) and intravenous acyclovir (10 to 15 mg/kg every 8 hours for 14 days) are recommended for nonimmunocompromised persons with VZV vasculopathy. Zoster involving the eye should be evaluated by an ophthalmologist to assess the potential value of topical or intraocular therapy, such as the need to reduce intraocular pressure to treat glaucoma or to use mydriatics to prevent synechiae.

Acyclovir-resistant VZV infections are rare and are limited almost exclusively to patients with AIDS or recipients of transplants. Foscarnet (40 mg/kg every 8 hours) for 2 weeks or until all lesions have crusted is the treatment of choice for acyclovir-resistant VZV.

PREVENTION

Varicella

Patients with varicella or zoster are considered infectious until all lesions have completely crusted. Airborne and contact precautions are recommended for varicella, whereas only contact precautions are necessary for immunocompetent persons with localized zoster.

The live attenuated varicella vaccine is recommended for children aged 1 to 12 years and for persons 13 years and older without immunity to the virus. The vaccine is 75 to 90% effective in protection against symptomatic varicella and more than 95% effective in protecting against severe disease.[A] Two doses of vaccine are given subcutaneously. The varicella vaccine is also given as part of a combined measles, mumps, rubella vaccine (MMRV) for children 1 to 12 years of age in the United States. The rate of disease due to varicella declined by 90% in the United States during the first 13 years after the vaccine was licensed.[5]

The most common complications of varicella vaccination are pain at the injection site, fever, and a mild rash within 2 weeks after vaccination. The rash is usually localized to the area of vaccination and is often papular; in some healthy persons, the rash can be disseminated, although there are fewer lesions and symptoms are much less severe than with wild-type virus. In persons with severely impaired cellular immunity, rash is more common, can be extensive, and may be accompanied by organ dysfunction. The varicella vaccine establishes latency and can cause shingles, although this complication occurs less commonly with vaccine virus than with wild-type virus. The vaccine strain of varicella has been transmitted to third parties only by vaccinees who developed a rash. Varicella vaccine is contraindicated in pregnant women and persons receiving high-dose immunosuppressive therapy (e.g., ≥2 mg/kg of prednisone daily) or with hematologic malignant neoplasms. Vaccination should be considered for human immunodeficiency virus (HIV)–infected children with age-specific $CD4^+$ T cells of 15% or more and adolescents and adults with $CD4^+$ T-cell counts of 200 cells/μL or higher. Serologic testing to verify immunity is not recommended for health care workers who have received two doses of vaccine because the currently available commercial antibody assays are not sensitive enough to detect protective levels of antibody.

Zoster

Zoster vaccine is approved by the U.S. Food and Drug Administration (FDA) for persons 50 years of age or older[A] and recommended by the Advisory Committee on Immunization Practices for persons 60 years of age or older (Chapter 18). This vaccine is similar to the varicella vaccine, except that the titer of virus is about 14-fold higher. The vaccine is about 50% protective in preventing zoster and 66% effective in preventing post-herpetic neuralgia.[6] Although the vaccine's efficacy to prevent zoster declines in persons older than 70 years, efficacy to prevent post-herpetic neuralgia does not decline.[A] Transient pain and erythema at the injection site are not uncommon, but serious complications attributable to the vaccine have not been reported. The vaccine also can be given safely to adults with a prior history of zoster.[7] The vaccine is contraindicated in persons with hematologic malignant neoplasms, AIDS, or HIV infection with CD4 count of 200/μL or lower and in persons receiving high-dose immunosuppressive therapy (e.g., ≥20 mg of prednisone daily) or anti–tumor necrosis factor-α therapy.

Postexposure Prophylaxis

In persons exposed to varicella, three options are available. Varicella vaccine is preferred if exposure occurred within the prior 3 days and the patient is not immunocompromised.[A] Vaccine is estimated to be 70 to 90% effective in healthy persons. VariZIG (formerly available as varicella immune globulin) prevents or attenuates varicella in 90% of susceptible persons if it is given within 4 days of exposure. The FDA recently approved VariZIG for use within 10 days of exposure, but it should be given as soon as possible after exposure.[8] VariZIG (given intramuscularly at 125 units/10 kg body weight, up to a maximum of 625 units) is indicated for susceptible persons at risk for severe varicella (e.g., pregnant women, preterm infants, neonates whose mothers have varicella between 5 days before and 2 days after delivery, immunocompromised persons) who are in close contact with patients with varicella or zoster. VariZIG has no effect in the treatment of zoster.

Oral acyclovir (40 to 80 mg/kg for 1 week beginning 7 to 9 days after exposure) is estimated to be 80 to 85% effective as postexposure prophylaxis. It is often used when the exposure occurred too long ago for vaccination or VariZIG.

PROGNOSIS

Before vaccination, about 100 children died of varicella each year in the United States. Now varicella is the underlying cause of death in an average of less than 3 Americans younger than 20 years annually.

REVIEW QUESTIONS

1. Which of the following people is at lowest risk for severe zoster and would not necessarily need to receive antiviral medication?

A. A 40-year-old woman with zoster involving the eye
B. A 65-year-old man with no underlying disease
C. A 30-year-old woman being treated for Hodgkin lymphoma
D. A 40-year-old woman with severe pain associated with the rash
E. A 45-year-old man with no other underlying disease

Answer: E The 45-year-old man is at least risk for complications associated with zoster. Antiviral therapy can reduce the risk for disseminated disease in immunocompromised persons and also reduce organ disease, including the eye. Antiviral therapy can reduce the acute pain associated with zoster. Persons older than 50 years are more likely to have complications associated with zoster and should be treated with antiviral therapy. (Recommendations for antiviral therapy are reported in Cohen JI. Herpes zoster. *N Engl J Med.* 2013;369:1766-1767.)

2. Which of the following persons should receive the zoster vaccine?

A. An 80-year-old woman
B. A 65-year-old man with Hodgkin disease
C. A 45-year-old man
D. A 66-year-old woman receiving 25 mg of prednisone daily for lupus
E. A 60-year-old man with HIV and a CD4 cell count <200/μL

Answer: A Vaccine is approved by the Advisory Committee on Immunization Practices for persons older than 60 years. The vaccine is contraindicated in persons with hematologic malignancies and patients receiving 20 mg or more of prednisone daily. It is not approved by the U.S. Food and Drug Administration for persons younger than 50 years. The vaccine is contraindicated in persons with CD4 cell counts of ≤200/μL. (Recommendations for the zoster vaccine are reported in Harpaz R, Ortega-Sanchez IR, Seward JF, et al. Prevention of herpes zoster: recommendations of the Advisory Committee on Immunization Practices [ACIP]. *MMWR Recomm Rep.* 2008;57:1-30.)

3. A 30-year-man who received a hematopoietic stem cell transplant 2 months ago has a disseminated vesicular rash. He had stopped taking his valacyclovir prophylaxis. Which is the most sensitive and specific test to determine whether his rash is due to varicella-zoster virus (VZV)?

A. Direct fluorescent antibody staining of cells from a skin lesion
B. Culture of a skin lesion for VZV
C. Polymerase chain reaction testing of a skin lesion for VZV
D. Tzanck smear (cytology) of a skin lesion
E. Antibody test for VZV

Answer: C The patient's rash could be due to herpes simplex or enterovirus. Polymerase chain reaction is the most sensitive and specific test for VZV. The direct fluorescent antibody test is very specific but requires sufficient numbers of cells and lesions and therefore is less sensitive. VZV is very labile, and cultures are often negative, especially if not received in the laboratory rapidly. The Tzanck smear does not distinguish HSV from VZV. Antibody testing is not useful to make a diagnosis of the cause of the rash. (Comparison of the VZV polymerase chain reaction test with other tests is reported in Sauerbrei A, Eichhorn U, Schacke M, et al. Laboratory diagnosis of herpes zoster. *J Clin Virol.* 1999;14:31-36.)

CYTOMEGALOVIRUS

W. LAWRENCE DREW

DEFINITION

Cytomegalovirus (CMV) is a member of the herpesvirus family and shares, with the other members, the ability to establish a long-lived latent infection. Most of the clinical disease caused by this virus results from reactivation of latent virus in immune-impaired patients, although primary infection in such patients can also be devastating.

The Pathogen

CMV has a linear, double-stranded DNA genome with about 250,000 base pairs that encode about 160 proteins. On microscopic examination, the hallmark of CMV infection is a large (cytomegalic), 25- to 35-μm cell containing

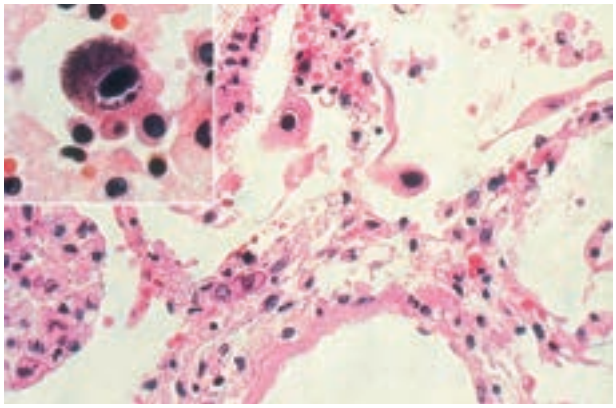

FIGURE 376-1. Cytomegalovirus (CMV) pneumonia. A lung biopsy specimen was stained with hematoxylin and eosin and magnified 250-fold. The *inset* shows a CMV "owl's eye" inclusion.

a large central, basophilic intranuclear inclusion (Fig. 376-1), referred to as an owl's eye.

EPIDEMIOLOGY

Multiple mechanisms account for the spread of this virus, including vertical (in utero, during vaginal delivery, and by breast milk) and horizontal (saliva, genital, urine) contact. These routes of transmission lead, collectively, to a 15 to 20% seroprevalence by 15 years of age in developed countries, with a higher seroprevalence in lower socioeconomic settings.[1] From that age on, there is a steady upward trend of 1 to 2% per year that is due in part to sexual transmission. As a result, approximately 50% of the general population of the United States is antibody positive by 35 years of age, and a 1% per year rate of increase occurs thereafter. In underdeveloped countries, up to 90% of persons may be seropositive by 2 years of age. Presumably, crowded living conditions permit spread of the virus through close contact with body fluids. A recent study showed that CMV was viable on metal and wood for up to 1 hour, glass and plastic to 3 hours, and rubber, cloth, and crackers to 6 hours.[2] CMV was more likely to be isolated from wet, highly absorbent surfaces. These considerations were felt to be particularly important because children may actively shed CMV in saliva and urine for months to years, and exposure to bodily fluids from young children poses substantial risk for CMV exposure among women of reproductive age. Two additional mechanisms of transmission are blood transfusion and organ transplantation. A final important epidemiologic fact is that reinfection with a different strain of CMV may occur in CMV-seropositive persons, especially those who are immunocompromised, pregnant, or sexually promiscuous.

PATHOBIOLOGY

In fully immunocompetent individuals, CMV rarely causes clinically evident end-organ disease. When immune mechanisms are deficient, especially those mediated by $CD4^+$ and $CD8^+$ lymphocytes, latent virus replicates and causes both direct and indirect effects.[3] Examples of direct virally mediated diseases are necrotizing CMV retinitis and esophagitis. In contrast, CMV pneumonitis is frequently manifested as subtle histologic alterations accompanied by limited viral replication, thus suggesting that immune-mediated injury may be the primary pathologic mechanism. Such injury may result from the upregulation and release of cytokines, including tumor necrosis factor-α, interferon-γ, and interleukin-2. Immune-mediated tissue injury may also be effected by $CD8^+$ cytotoxic T lymphocytes directed against CMV-infected target cells. The clinical manifestations of CMV infection, including meningoencephalitis, retinitis, enteritis, vasculitis, pneumonitis, myocarditis, lymphadenitis, hepatitis, adrenalitis, and pancreatitis, reflect the range of cell types that CMV is capable of infecting.

The immune response to CMV infection involves both the humoral and cell-mediated arms, but the $CD8^+$ cytotoxic T-cell response appears to be the most important. The CMV envelope glycoproteins that participate in viral entry are gB, gH/gL, and gCII. Humoral immunity directed at gB has been detected in convalescent phase sera and has been shown to block viral entry, cell-to-cell transmission, and syncytium formation in CMV-infected cells.

Fundamental to the pathogenesis of CMV is latency, or persistence of the viral genome in host cells without evidence of productive viral replication. It is thought that monocytes and bone marrow progenitor cells are sites of human CMV latency. Reactivation from the latent state has classically been associated with immunosuppression. Exposure to a rich milieu of cytokines and growth factors results in the activation of signal transduction pathways, generation of increased levels of intracellular transcription factors, and production of viable virus.

CLINICAL MANIFESTATIONS

Congenital and Neonatal Infection

In the developed world, congenital infection occurs in approximately 0.2 to 0.7% of newborns.[4] Thus in the United States each year, approximately 40,000 infants are born excreting CMV, and about 4000 (or ~10%) of these newborns show clinical evidence of congenital disease, such as microcephaly, intracerebral calcification, hepatosplenomegaly, and rash. About 90% of these clinically infected newborns will survive, but half of the survivors will have unilateral or bilateral hearing loss, mental retardation, or both. Mothers of most infants with these stigmata had a primary infection during pregnancy, although it is now well known that clinically evident congenital infection also occurs in infants born to mothers with past as well as with primary CMV infection.

Infection in Immunocompetent Persons

Virtually all CMV infections occurring in immunocompetent persons are asymptomatic. In some patients, a clinical illness resembling infectious mononucleosis may develop (Chapter 377), but with minimal pharyngitis and lymphadenopathy. Atypical lymphocytosis develops in these patients, similar to Epstein-Barr virus infection, but they have a negative heterophil antibody test result. CMV reactivation is common (33%) in critically ill immunocompetent patients, in whom it is associated with prolonged hospitalization and mortality, but whether it causes these effects is unclear.

Infection in Transplant Recipients

When a CMV-seronegative recipient receives a solid organ from a CMV-seropositive donor, the resulting illnesses include the "CMV syndrome," characterized by fever, neutropenia, atypical lymphocytes, and often hepatosplenomegaly. CMV disease may also develop in the transplanted organ. For example, CMV hepatitis in liver transplant recipients is associated with fever, hyperbilirubinemia, and elevated liver enzymes; liver failure may ensue and necessitate retransplantation. CMV-seropositive recipients of a solid organ transplant may develop CMV disease by either reactivation of latent infection or by transmission of CMV from a seropositive donor. Disease in CMV-seropositive recipients is, fortunately, less severe than that resulting from primary infection. CMV infection occurs more commonly in recipients of lung or liver transplants than in recipients of kidney transplants.

CMV pneumonia may occur after solid organ transplantation but is most common after stem cell transplantation. Fever, nonproductive cough, and dyspnea can progress rapidly. The diagnosis is suggested by interstitial to nodular infiltrates rather than by alveolar densities on chest radiographs. In contrast to solid organ transplantation, CMV disease after stem cell transplantation usually results from reactivation of latent CMV in a seropositive recipient rather than from a new, primary infection.

CMV may cause disease throughout the gastrointestinal tract. Colitis, which is a common syndrome in transplant recipients, is manifested as diarrhea, weight loss, and fever. It is characterized by diffuse submucosal hemorrhages and ulcerations.

Infection in Patients with Acquired Immunodeficiency Syndrome

In the era before highly active antiretroviral therapy, CMV retinitis occurred in approximately one third of patients with acquired immunodeficiency syndrome (AIDS), most often in those with CD4 counts below $50/mm^3$. It usually begins unilaterally with visual blurring, floaters, decreased acuity, and loss of visual fields and progresses to blindness if it is untreated. The retinal examination is abnormal, and the finding of apparent hemorrhages and exudates is the best diagnostic test (Fig. 376-2). CMV colitis is similar to that seen in transplant recipients, but esophagitis is also common and characterized by distal ulceration, which may be single but extensive. CMV neurologic disease occurs in multiple forms, including encephalitis and a polyradiculopathy/myelitis syndrome. With the efficacy of combination antiretroviral therapy, the incidence of all of these CMV syndromes has decreased dramatically, but they are still seen before HIV treatment or when such treatment is interrupted or ineffective.

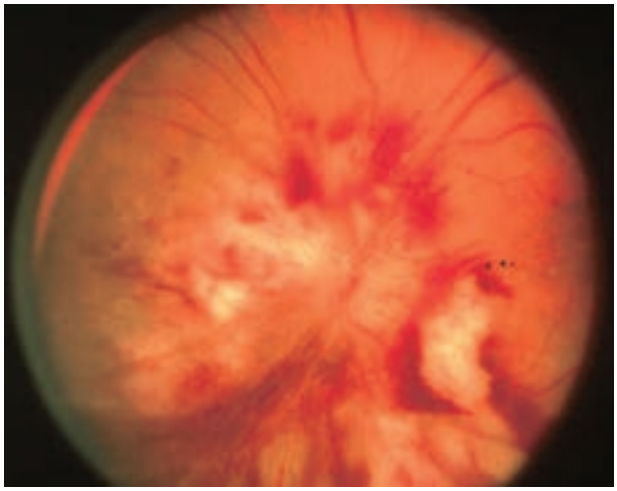

FIGURE 376-2. Cytomegalovirus retinitis as seen by direct ophthalmoscopic examination.

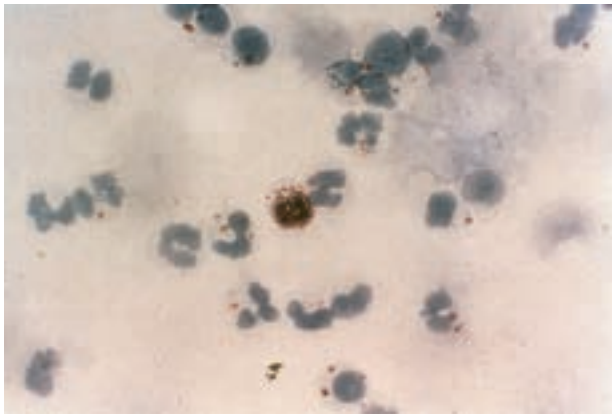

FIGURE 376-3. Peripheral blood leukocytes stained with monoclonal antibody to cytomegalovirus pp65 antigen by the immunoperoxidase technique (magnification ×500).

DIAGNOSIS

Assay of viral DNA by the polymerase chain reaction (PCR) is more sensitive than viral culture and is the best assay for the early detection of CMV disease. The assay can quantify the CMV viremia and thereby help to determine its clinical significance and to monitor therapy. Monoclonal antibodies can also be used to quantify viremia by counting CMV antigen–positive cells directly in peripheral blood leukocytes (antigenemia) (Fig. 376-3).

Seroconversion is an excellent marker for primary CMV infection, but increases in immunoglobulin G (IgG) titers, even four-fold or greater, are not diagnostic of newly acquired infection. CMV-specific IgM antibody develops during primary infection but may reappear during reactivation of latent CMV. The presence of IgG antibody is a sensitive marker of past infection and is used to screen transplant recipients and donors as well as certain blood product recipients and donors. An avidity assay can help in determining whether an infection is recent.

Viral culture, which was the prior "gold standard" for diagnosing CMV, has been supplanted by the assays described previously. Routine culture may require at least 4 to 6 weeks, whereas newer methods incorporating immunofluorescence can yield results in several days. The clinical significance of positive CMV cultures may be difficult to ascertain, particularly in immunosuppressed patients. For example, CMV may be present in the saliva or urine of up to 60 to 90% of transplant recipients and patients with AIDS, and virus in these sites does not prove that CMV is the cause of a patient's illness. Cytologic and histologic abnormalities are not sensitive measures of CMV infection, but they are specific and indicative of CMV disease.

PREVENTION

A nonviable CMV vaccine, containing the gB antigen, decreases primary infection in young women by 50% but is not commercially available. Other vaccine candidates are being developed but remain experimental.

Because CMV is transmitted by exchange of secretions or excretions, infection can be diminished by reducing exposure to body fluids. For example, transmission by both vaginal and anal intercourse, which are bidirectional risks, can be diminished by "safe sex." Similarly, limiting the contact of seronegative pregnant women with the secretions and excretions of children, especially preschoolers in daycare, can decrease primary infection and, in turn, congenital disease.

The risk for acquiring CMV disease can be reduced in seronegative, immunosuppressed patients through the use of blood products or organ grafts from CMV-seronegative donors. Valganciclovir and ganciclovir provide effective prophylaxis in solid organ transplantation.[4,5] Prophylaxis has been uncommon for stem cell transplant recipients, and these patients typically have been monitored weekly (from day 10 to day 100 after transplantation) for CMV DNA or antigenemia, with antiviral therapy introduced preemptively if seroconversion occurs or PCR testing is positive.[4] With this strategy, infection is not prevented, but end-organ disease is avoided. However, late-onset CMV end-organ disease may occur when the antiviral is eventually discontinued.[6] More recently, letermovir, a CMV terminase substitute, at a dose of 120 mg or 240 mg daily has been shown to reduce the incidence of CMV infection in such patients.[4] CMV-specific hyperimmune globulin (CMVIG) may be effective in treating pregnant women with primary CMV infection and preventing congenital infection, but controlled trials are needed. CMVIG has also been used prophylactically in high-risk seronegative organ transplant recipients, in whom it reduced CMV disease and CMV mortality. It is very expensive, however, and antivirals are more commonly used alternatives.

TREATMENT

Rx

Oral valganciclovir, intravenous ganciclovir, intravenous ganciclovir followed by oral valganciclovir, intravenous foscarnet, intravenous cidofovir, and ganciclovir intraocular injection coupled with valganciclovir are all effective treatments of CMV syndromes (Table 376-1).

Ganciclovir (dihydroxypropoxymethylguanosine [DHPG], Cytovene) is given intravenously, 5 mg/kg two times daily during initial induction (2 to 3 weeks); maintenance therapy consists of 5 mg/kg once daily (Chapter 360). Valganciclovir achieves levels comparable to intravenous ganciclovir at 5 mg/kg when it is given orally in a 900-mg dose. Initial response in retinitis (improvement or stabilization of vision or ophthalmoscopic appearance) occurs in approximately 75% of patients treated with ganciclovir or valganciclovir.[4] CMV retinitis can also be treated locally by intraocular ganciclovir injection, but this approach should be accompanied by valganciclovir to treat and/or prevent extraocular end-organ disease. Ganciclovir together with CMV hyperimmune globulin may reduce the mortality of CMV pneumonia after stem cell transplantation from approximately 85 to 40%, although the benefit of the antibody is unproved. Ganciclovir resistance may occur as a result of mutations in the phosphorylating gene (*UL97*) and/or in the DNA polymerase gene (*UL54*).[7] Granulocyte colony-stimulating factor may be needed to offset neutropenia.

Foscarnet, or phosphonoformic acid, blocks the pyrophosphate-binding site of viral DNA polymerase, thereby preventing cleavage of pyrophosphate from deoxyadenosine triphosphate. The recommended initial therapy with foscarnet is 60 mg/kg intravenously every 8 hours or 90 mg/kg every 12 hours. The maintenance dose ranges from 90 to 120 mg/kg daily. Adverse effects include renal impairment, anemia, hypocalcemia (especially ionized calcium), hypomagnesemia, and hypophosphatemia. Resistance to foscarnet can develop because of mutations in DNA polymerase. Although it is effective for treating CMV retinitis, its toxicity and the absence of an oral formulation make foscarnet a second choice for treatment of CMV disease. It is sometimes used in combination with ganciclovir for infections such as central nervous system disease or for treatment of ganciclovir-resistant virus.[8]

Cidofovir, or 3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC), appears to the cell as a nucleotide and does not require phosphorylation by virus-encoded enzyme. It is therefore active against ganciclovir-resistant CMV strains that have resistance mutations only in *UL97,* the phosphorylating gene. When DNA polymerase *(UL54)* mutations occur in ganciclovir-treated patients, cross-resistance to cidofovir is frequent. These resistance mutations also occur in patients treated with cidofovir alone. The drug has an extremely long half-life that permits intravenous administration as infrequently as every 2 weeks during maintenance treatment.

Cidofovir is nephrotoxic, especially to the proximal renal tubule, but this side effect appears to be diminished by prehydration and concomitant probenecid therapy. Cidofovir toxicities make it a second- or third-line agent for CMV. Other drugs under investigation include brincidofovir, maribavir, and letermovir.[9]

TABLE 376-1 TREATMENT OF CYTOMEGALOVIRUS INFECTION

	PREFERRED THERAPY	ALTERNATIVE THERAPY
Cytomegalovirus (CMV) retinitis*		
Sight-threatening lesions	Valganciclovir 900 mg bid PO plus ganciclovir intraocular injection	Ganciclovir IV; foscarnet IV; plus ganciclovir intraocular injection
Peripheral lesions	Valganciclovir 900 mg bid PO	Ganciclovir IV or foscarnet IV
Maintenance therapy	Valganciclovir 900 mg od PO	Ganciclovir IV or foscarnet IV
Relapsing	Reinduction with ganciclovir IV or valganciclovir 900 mg bid PO ± ganciclovir intraocular injection	
Ganciclovir resistant	Foscarnet IV ± ganciclovir intraocular injection	Cidofovir (if only *UL97* mutation)
CMV gastrointestinal disease	Ganciclovir IV for 3-6 wk or valganciclovir 900 mg bid PO for 3-6 wk	Foscarnet IV for 3-6 wk
CMV neurologic disease	Ganciclovir IV + foscarnet IV	
CMV viremia syndrome	Valganciclovir 900 mg bid PO or ganciclovir IV until viremia clears	Foscarnet IV
Ganciclovir resistant	Foscarnet IV	

*If not already begun, antiretroviral therapy should be initiated concurrently with anti-CMV therapy, except possibly when treating central nervous system disease. For retinitis, anti-CMV therapy should be continued until the CD4 count has exceeded 100-150 cells/mm^3 for ≥6 months and the retinitis is inactive. If anti-CMV therapy is discontinued, regular monthly eye examinations should be continued. Early relapses of CMV retinitis in patients treated systemically are usually due to inadequate drug penetration, and reinduction with the same drug is often effective. Drug resistance may occur in patients treated for ≥3 months. Therapy of these patients may be guided by antiviral susceptibility testing.

Adapted from Drew WL, Erlich KS. Management of herpesvirus infections (cytomegalovirus, herpes simplex virus, and varicella-zoster virus). In: Volberding PA, Greene WC , Lange J, et al, eds. *HIV/AIDS Medicine Medical Management of AIDS 2012*. Philadelphia: Saunders Elsevier; 2012:433.

PROGNOSIS

In immunocompetent patients, the mononucleosis-like CMV syndrome resolves spontaneously. Infections in immunocompromised patients are much more serious and may result in failure of a transplanted solid organ and/or systemic CMV disease. For CMV pneumonia, death often occurs even with antiviral therapy, especially after stem cell transplantation. In AIDS patients, CMV infection generally resolves when CD4 counts exceed 100/mm^3, but it is a grave prognostic sign if counts do not recover to those levels.

REVIEW QUESTIONS

1. Which of the following is the best diagnostic test to document clinically important cytomegalovirus (CMV) infection?

A. Tissue culture of blood
B. Tissue culture of urine
C. Cytology of urine
D. CMV-specific immunoglobulin M (IgM) antibody in blood
E. Quantitative polymerase chain reaction (PCR) for CMV DNA

Answer: E Tissue culture of blood is very insensitive compared with either antigenemia or DNAemia. Urine may remain positive by any assay for months to years after primary infection and is therefore not a specific marker of clinically important CMV disease. Cytology of urine is an insensitive assay. IgM antibody may be undetectable during infections associated with CMV reactivation or may be detectable in the absence of CMV disease. CMV PCR is a sensitive assay for CMV viremia, which usually is positive in clinically significant CMV infection of any organ.

2. CMV retinitis is best diagnosed by which of the following?

A. PCR of vitreous fluid
B. Tissue culture of blood
C. Ophthalmologic examination
D. Retinal biopsy
E. CMV PCR on blood

Answer: C PCR of vitreous fluid or retinal biopsy requires a specimen obtained by a highly skilled operator and is not readily available. Tissue culture of blood is an insensitive assay for active CMV infection. CMV PCR on blood is a sensitive assay for CMV viremia but does not identify specific end organ disease.

3. Which is the best choice for treating systemic CMV infection?

A. Oral valganciclovir
B. Cidofovir
C. Foscarnet
D. Intravenous valganciclovir
E. Oral ganciclovir

Answer: A Cidofovir and foscarnet are more toxic than valganciclovir and are thus not first-line therapy. Valganciclovir is not available in an intravenous form, and oral ganciclovir has been supplanted by oral valganciclovir and is no longer commercially available in many countries.

4. Which of the following is true?

A. Nearly 90% of U.S. adults are infected with CMV by age 25 years.
B. Primary CMV infection is usually asymptomatic.
C. Aerosols are the primary route of CMV spread in the population.
D. All CMV-seronegative patients should receive blood transfusions only from CMV-seronegative donors.
E. Retinitis is the most frequent manifestation of CMV infection in transplant recipients.

Answer: B Approximately 50% of U.S. adults are CMV-seropositive by age 35 years. The primary means of spread is by direct contact with bodily secretions. CMV-seronegative blood is preferable for immunocompromised or pregnant seronegative recipients. In developed countries, little, if any, CMV is transmitted by blood transfusion. Retinitis is a rare manifestation of CMV disease in transplant recipients, in marked contrast to untreated patients with AIDS.

5. Which of the following is true for stem cell transplant (SCT) recipients?

A. Only CMV-seronegative recipients need to be monitored for CMV viremia.
B. Valganciclovir is the best prophylactic medication.
C. Hyperimmune CMV immunoglobulin should be given to all recipients before transplantation.
D. Three months of therapy with valganciclovir prevents 95% of late-onset CMV disease.
E. None of the above

Answer: E *All* STC recipients need to be monitored for the development of CMV viremia, irrespective of CMV serostatus. CMV disease occurs more commonly by reactivation of latent virus in a seropositive patient than primary infection from a seropositive donor to a seronegative recipient. Valganciclovir prophylaxis for SCT recipients should be used only if the patient cannot be monitored for the development of CMV viremia. Many SCT patients will not become viremic and would not have required prophylactic drug with the attendant toxicities, especially to bone marrow. Hyperimmune CMV immunoglobulin is very expensive and not superior to monitoring SCT patients for CMV viremia and treating when blood assays are positive. "Late-onset" CMV viremia and disease is a frequent event after valganciclovir treatment has been discontinued.

EPSTEIN-BARR VIRUS INFECTION

ROBERT T. SCHOOLEY

DEFINITION

Epstein-Barr virus (EBV), a member of the gamma human herpesvirus family, is the etiologic agent of infectious mononucleosis and of a diverse assortment of neoplastic syndromes.

EPIDEMIOLOGY

Ubiquitous in the human population, EBV is found in 90 to 95% of adults throughout the world. As in the case of other herpesviruses, infection with EBV is lifelong. The virus resides in B lymphocytes and is intermittently shed asymptomatically in oropharyngeal secretions, which accounts for the bulk of its transmission in the human population. The virus is not highly contagious; it is usually acquired during early childhood through sharing of saliva-bearing fomites or during adolescence through kissing, although it can be acquired at any decade of life. Thus, for example, EBV-seronegative platonic roommates of patients with acute infectious mononucleosis in college dormitory settings are not at higher risk for acquiring the virus than others in the college population. In addition to oropharyngeal spread, the virus can be transmitted by blood transfusion or through organ donation.

Most childhood EBV infections are clinically silent, but infection of adolescents and adults results in the clinical syndrome of infectious mononucleosis between 25 and 50% of the time, depending on the setting. The incidence of infectious mononucleosis is highest in the 15- to 24-year-old age group. Incidence rates in men and women are equal, but the peak incidence is 2 years earlier in women than in men. Incidence rates are lower in lower socioeconomic populations, in whom the likelihood of acquisition is greater in childhood than in adolescence.

PATHOBIOLOGY

EBV enters B lymphocytes through the CD21 molecule (also known as the C3d receptor) on the surface of B cells or nasopharyngeal epithelial cells. Major histocompatibility complex class II molecules serve as secondary receptors on B cells. Once inside the cell, the virus expresses several nuclear proteins (termed Epstein-Barr nuclear antigens [EBNAs]) that activate EBV-encoded latent membrane proteins and other gene products responsible for regulation of B-cell growth. These events are associated with the transformation or immortalization of the B cell that is the phenotypic hallmark of B-cell infection. EBV-transformed B cells proliferate vigorously and maintain EBV DNA within progeny cell nuclei in an episomal state. During acute EBV infection, up to 20% of peripheral blood B cells express EBNA.

The host response to acute EBV infection consists of a vigorous and coordinated cellular and humoral immune response. The humoral immune response includes IgM and IgG antibodies directed at the viral capsid (VCA) and to EBNA, as well as *heterophile* antibodies to surface antigens of sheep red blood cells. Heterophile antibodies are useful diagnostically and are present at some point in up to 90% of cases. These antibodies are an epiphenomenon in host defense and are not cross-reactive with any known viral antigens.

The cellular immune response includes both natural killer (NK) and EBV-specific $CD4^+$ and $CD8^+$ T lymphocytes. The expansion of the $CD8^+$ subset of T lymphocytes during acute EBV infection includes a subset of large, activated cells demonstrable on standard peripheral blood smears as "atypical" lymphocytes. This vigorous cellular immune response is associated with an outpouring of cytokines, including tumor necrosis factor, interleukin-1, and interleukin-6, that are responsible for many of the symptoms and signs of infectious mononucleosis. Over a period of 4 to 6 weeks after initial evaluation in most patients, immune response mechanisms gain control of the EBV-driven B-cell proliferation, and the virus enters into a lifelong period of symbiosis with the host. The virus is asymptomatically shed approximately 15% of the time in the oropharyngeal fluids of healthy human immunodeficiency virus type 1 (HIV-1)-seronegative adolescents and adults. The shedding rate increases significantly in patients with defects in cellular immunity, such as those that occur with HIV-1 infection or immunosuppression associated with organ allografts.

CLINICAL MANIFESTATIONS

Most cases of acute EBV infection are clinically silent. The syndrome of infectious mononucleosis consists of the clinical triad of fever, sore throat (Chapter 429), and lymphadenopathy, in association with an atypical lymphocytosis and the transient appearance of heterophile antibodies. The incubation period between exposure and the onset of symptoms is generally 30 to 50 days. The onset of symptoms may be abrupt, or it may be heralded by a several-day nonspecific prodrome of malaise and low-grade fever. Although the classic syndrome includes fever, sore throat, and adenopathy, the findings may be dominated by only one or any combination of these symptoms. Other common clinical manifestations include headache, malaise, and anorexia. On physical examination, patients are usually febrile. Pharyngeal erythema, tonsillar enlargement (see Fig. 429-5 in Chapter 429), and cervical adenopathy are generally present. Mild periorbital edema may also be observed. Abdominal findings may include splenomegaly or hepatomegaly, or both. Splenomegaly can be demonstrated by ultrasonographic examination in virtually all patients with infectious mononucleosis, although palpable splenomegaly is only present in about 20% of patients. Splenic enlargement is usually maximal in the second or third week of illness and might not be detectable at the initial presentation. Adenopathy may be observed in noncervical regions, but it is usually much less prominent than in cervical regions. Approximately 5% of patients will exhibit a rash that may be macular, scarlatiniform, or urticarial in nature. If patients with acute EBV infection are given ampicillin or its derivatives, a pruritic maculopapular eruption will develop in 90 to 100% of them. Patients with an ampicillin-induced rash during acute EBV infection generally tolerate the drug and other penicillin products when administered later in life.

DIAGNOSIS

Because clinical manifestations of acute EBV infection are variable and other organisms may cause similar clinical syndromes, laboratory tools are required to confirm an etiologic diagnosis. Heterophile antibodies to sheep red blood cells are classically used to diagnosis EBV-induced infectious mononucleosis. Although ultimately demonstrable in approximately 90% of symptomatic acute EBV infections, these antibodies are present in only about two thirds of patients at initial encounter. If antibodies are negative at the outset and clinical suspicion is high, repeat testing in the second or third week of the illness is warranted. Although EBV-specific antibodies remain the "gold standard" for the diagnosis of acute EBV infection, if heterophile antibodies are demonstrated in a straightforward case of infectious mononucleosis, it is not generally necessary to order EBV-specific serologic studies. IgM antibodies to the EBV capsid antigen (VCA) are the most useful serologic study in the diagnosis of acute EBV infection. Relatively high titers of IgG antibodies to VCA persist for life after initial infection and are not useful in making the diagnosis of acute EBV infection. Antibodies to EBNA are slower to arise than those to capsid antigens, and acute infection may be diagnosed by demonstration of seroconversion to this antigen. If the diagnosis is based on the emergence of antibodies to EBNA, both tests should be performed in the same laboratory.

Among pathogens causing clinical syndromes that can be mistaken for acute EBV infection, cytomegalovirus (Chapter 376) is the most frequent. Patients with cytomegalovirus infection are less likely to have an acute onset of illness, and pharyngitis is less frequently a prominent manifestation of the illness. *Toxoplasma gondii* (Chapter 349) infection can also present as a nonspecific febrile illness that can be confused with infectious mononucleosis. Streptococcal pharyngitis (Chapter 290) and primary herpes stomatitis (Chapter 374) may occasionally cause symptoms that are mistaken for acute EBV infection. None of these syndromes is associated with heterophile antibodies or with other serologic evidence of acute EBV infection. The differential diagnosis is generally made by serologic studies directed at these organisms or by culture. Nonetheless, physicians should be cognizant that organisms such as group A β-hemolytic streptococci (Chapter 290) and herpes simplex virus are also common in the human population and may be demonstrated in people whose symptoms are nonetheless due to acute EBV infection.

PREVENTION AND TREATMENT

Because the virus is usually transmitted by asymptomatic oral shedders and is so common in the human population, epidemiologic interventions to prevent spread are not practical. No vaccine yet has been developed. The clinical course is generally self-limited and does not usually require specific therapeutic intervention beyond the use of aspirin or acetaminophen for antipyresis and mild pain relief, except in the presence of specific complications such as when lymphadenopathy threatens the airway or in certain cases of autoimmune hemolytic anemia (Chapter 160) or thrombocytopenia (Chapter 172). Short courses of corticosteroids have been used to hasten symptomatic recovery in cases in which the symptoms are severe or refractory. Corticosteroids should not, however, be used routinely and should be given for no longer than a 10- to 14-day tapering course that begins at a dose equivalent of 0.5mg/kg of prednisone. Although EBV replication can be inhibited in vitro or in vivo by acyclovir and related antiviral agents, the symptoms of infectious mononucleosis are primarily driven by the immune response to the virus and come later than the time of maximal viral replication. Antiviral agents have not been demonstrated to significantly accelerate resolution of symptoms or prevent complications of the disease. One small randomized trial has reported 1-day reduction in length of hospital stay when patients with severe infectious mononucleosis are given metronidazole, but confirmatory data are required before this therapy becomes routine.[1]

PROGNOSIS

Most patients recover uneventfully from the acute symptoms and signs of infectious mononucleosis over a 2- to 3-week period, although many patients may have a variable period of malaise and fatigue that can last for another 3 to 4 weeks. Some patients may take longer to make a full recovery and experience fatigue and difficulty concentrating for up to 6 months after diagnosis. Symptoms often wax and wane and can be extremely troublesome. Reassurance is usually the best approach to these patients. Corticosteroids are not of benefit in this setting. Recovery may be less straightforward in patients with certain specific complications of acute EBV infection (outlined in the next section). Death from infectious mononucleosis is rare. When it does occur, it is most frequently associated with neurologic complications of the illness, splenic rupture, or the X-linked lymphoproliferative syndrome (discussed later).

Complications

Although most patients recover spontaneously from acute EBV infection, a number of complications may arise. In some patients, these complications dominate the clinical findings, and seroconversion to EBV may be the only evidence of acute EBV infection. The most serious complication of acute EBV infection arises in individuals with the X-linked lymphoproliferative syndrome. This syndrome occurs in males with mutations in the signaling lymphocyte activation molecule (SLAM)-associated protein (SAP) that regulates T and natural killer cells. These otherwise healthy individuals have severe clinical symptoms, a large lymphocytosis consisting of T and B cells, and severe hepatitis. If patients survive the acute infection, the syndrome may evolve into progressive agammaglobulinemia or lymphoma in the following months. The genetic defect associated with this syndrome can be diagnosed in utero, and early bone marrow transplantation has been recommended for the prevention of the devastating clinical syndrome associated with acquired EBV infection.

A number of less severe, organ system–specific complications are seen substantially more frequently than the X-linked lymphoproliferative syndrome. Patients should specifically be warned about splenic rupture, a complication attributable to splenomegaly (Chapter 168) and associated stretching of the splenic capsule that occurs most frequently in the second or third week of the illness, when other symptoms of the disease are abating. It may be accompanied by major or minor trauma but may also occur without an obvious antecedent event. Patients should be counseled against activities that might result in abdominal trauma for 6 to 8 weeks after the onset of symptoms. Left upper quadrant pain, especially pain radiating to the subscapular region, should raise this diagnostic consideration. As with other complications of acute EBV infection, splenic rupture may occur occasionally in patients without other prominent clinical manifestations of acute EBV infection. Other hematologic complications include autoimmune hemolytic anemia (Chapter 160), thrombocytopenia (Chapter 172), and neutropenia (Chapter 167). These complications usually arise from a combination of self-reactive antibodies and hypersplenism and are generally self-limited and resolve with resolution of the illness. Corticosteroids may be of benefit in more severe cases of autoimmune hemolytic anemia or thrombocytopenia.

A variety of neurologic syndromes are unusual complications of acute EBV infection. EBV DNA has been detected in brain tissue from rare patients with clinical manifestations compatible with herpes simplex encephalitis (Chapter 414). Although these patients have a much better

prognosis than patients with herpes simplex encephalitis, they should receive parenteral acyclovir or ganciclovir as for herpes simplex (Chapters 360 and 414). Other neurologic complications include aseptic meningitis (Chapter 412), cerebellitis, mononeuritis multiplex (Chapter 420), Bell's palsy (Chapter 420), Guillain-Barré syndrome (Chapter 420), and transverse myelitis (Chapters 400 and 411). These complications may be clinically dramatic but are usually self-limited and associated with full recovery in 85% of patients without specific antiviral therapy.

Mild hepatomegaly can occur in acute infectious mononucleosis, and biochemical evidence of hepatitis (Chapter 148) should be expected in virtually every case of acute infection. More severe hepatic complications are uncommon, and renal, cardiac, pulmonary, and skeletal muscle complications are rare.

OTHER CLINICAL MANIFESTATIONS

In addition to infectious mononucleosis, EBV is also associated with neoplasia and lymphoproliferative disorders, which are seen most frequently in patients with defects in cellular immunity but are not restricted to such patients.

Post-transplantation Lymphoproliferative Disease

EBV-driven B-cell proliferation that is insufficiently regulated in the presence of prolonged periods of severe T-cell immunodeficiency may result in a polyclonal proliferation of B cells that is initially similar to that seen in acute infectious mononucleosis. Although most frequently occurring in the setting of organ transplantation, especially when patients are immunosuppressed with agents directed specifically at T lymphocytes, such as anti-CD3 antibodies or cyclosporine, this syndrome can be seen in other conditions with similar levels and durations of immunodeficiency such as HIV-1 infection. Post-transplantation lymphoproliferative disease (PTLD)[2] is seen more often when the donor is EBV seropositive and the recipient is seronegative, with the more intense immunosuppression of hematopoietic stem cell transplantation[3] (Chapter 178) in association with graft-versus-host disease, in patients who undergo splenectomy before transplantation, and in patient-donor pairs with higher degrees of HLA mismatch. These tumors are less frequently seen in the current era, in which allograft-associated immunosuppression is better targeted and less intense.

Patients with PTLD often present with fever, adenopathy, and splenomegaly. If the immunodeficiency persists, these disorders often proceed from a polyclonal stage, which can be reversed with restoration of immunity, to a monoclonal or oligoclonal stage that is progressive despite restoration of cellular immunodeficiency.

The diagnosis is not generally difficult to make in the appropriate clinical setting and can be made histopathologically. Elevated plasma levels of EBV DNA are associated with increased risk for PTLD after hematopoietic stem cell transplantation,[4] but their predictive value is less well established after solid organ transplantation.

There is some evidence that PTLD may be less frequent in patients who have received acyclovir or ganciclovir after transplantation, but these agents are less useful after the syndrome develops. Successful management depends on the extent to which the immunosuppressive condition can be reversed before the evolution of restricted clonality. Therapy with anti-CD20[5] antibodies with or without chemotherapy[6] is the treatment of choice for PTLD (Chapter 185). Radiation therapy is also used in some patients.

Burkitt's Lymphoma

EBV was initially described in patients with African Burkitt's lymphoma (Chapter 185). The tumor is composed of small, noncleaved B cells and, unless aggressively treated, is rapidly fatal. This aggressive B-cell lymphoma with a predilection for the head and neck is endemic in equatorial Africa and is geographically linked to *Plasmodium falciparum* malaria. EBV DNA is readily demonstrable in tumor biopsy specimens, and high titers of antibodies to EBV structural antigens are found in plasma. Sporadic cases of abdominal B-cell lymphomas with a histologic appearance compatible with Burkitt's lymphoma are also observed but are associated with EBV only about 25% of the time. The tumor is likewise seen in patients with HIV-1 infection. Although an etiologic role for EBV in Burkitt's lymphoma is widely accepted, the molecular basis by which EBV causes the neoplasm has not yet been fully delineated.

The risk for HIV-associated Burkitt's lymphoma increases with advancing immunodeficiency, but it may also be seen in patients with relatively preserved CD4 cell counts. Antiretroviral therapy reduces but does not eliminate the risk for Burkitt's lymphoma in HIV-1-infected persons. Despite the high-grade clinical behavior of the tumor, it should be vigorously treated because it is usually quite responsive to combination chemotherapy with or without radiation therapy (Chapter 185).

Hodgkin's Lymphoma

EBV is also associated with a subset of Hodgkin's lymphomas (Chapter 186), especially those of the lymphocyte-depleted or mixed-cellularity histologic subtypes. EBV DNA and proteins are detected in the Reed-Sternberg cells that are characteristic of Hodgkin's lymphoma. Therapy for EBV-associated Hodgkin's lymphoma is directed at the tumor's histology and stage (Chapter 186) and is not determined by whether it is related to EBV.

Central Nervous System Lymphoma

EBV is also associated with central nervous system (CNS) lymphoma (Chapter 185).[7] This tumor was most frequently observed in the post-transplantation setting before the HIV epidemic but is now the most frequent CNS neoplasm in HIV-1-infected individuals. The major differential diagnostic challenge is with *T. gondii* infection (Chapter 349). Although a tissue-based diagnosis is definitive, noninvasive neurodiagnostic approaches, coupled with the demonstration of EBV DNA in cerebrospinal fluid by polymerase chain reaction, can strongly support the diagnosis of lymphoma over that of *T. gondii* infection. Radiation therapy may be used, but its effects are generally palliative.

Nasopharyngeal Carcinoma

EBV has also been associated with certain cases of nasopharyngeal carcinoma (Chapter 190). This tumor is rare in Western countries, but it is much more frequent in southern China and in the Inuit population of Alaska. EBV-associated cases are generally less histologically differentiated than sporadic forms of nasopharyngeal carcinoma. EBV DNA is demonstrable in tumor tissue, and high titers of immunoglobulin A (IgA) and IgG antibodies to the EBV capsid antigens are found in plasma. The prognosis for this tumor is poor, although it is often treated with radiation therapy (Chapter 190).

Other EBV-Associated Neoplasms

EBV collaborates with another human gamma-herpesvirus, human herpesvirus type 8, to cause lymphoma in the HIV-1-infected population. These aggressive tumors present in body cavities such as the pleural, peritoneal, and pericardial spaces.

EBV DNA may also be found in moderate to slowly progressive destructive midline facial angiocentric tumors of T- and NK-cell phenotypes. This neoplasm presents clinically as a syndrome that was previously known as lethal midline granuloma (Chapter 185). EBV also plays a key role in the pathogenesis of an angiocentric EBV-associated B-cell tumor that presents clinically as lymphomatoid granulomatosis (Chapter 270).

Oral Hairy Leukoplakia

This clinical manifestation of EBV infection is characterized by a corrugated or "hairy" plaquelike lesion that extends around the lateral aspects of the tongue (Chapter 425). Oral hairy leukoplakia is most often observed in individuals with chronic forms of cellular immunodeficiency, especially those with HIV-1 infection and CD4 cell counts less than 200/μL. It is most often clinically confused with mucocutaneous candidiasis (Chapter 338) but can be differentiated because its distribution is restricted to the lateral surface of the tongue. Unlike thrush, it does not involve the buccal mucosa, palate, or pharynx and is not readily removed by superficial scraping. Biopsies demonstrate a characteristic histopathologic pattern, as well as the presence of EBV antigens and DNA within squamous epithelial cells. Although the lesions may be cosmetically troublesome, they are not generally painful. In the case of HIV-1-associated oral hairy leukoplakia, the lesions resolve with successful antiretroviral chemotherapy. If the immunosuppression cannot be reversed, oral hairy leukoplakia usually responds to valacyclovir, valganciclovir, or foscarnet (Chapter 425).

Chronic Active EBV Infection

Infrequent patients with no apparent defect in cellular immunity have been described in which chronic EBV infection has been associated with persistent or intermittent hepatitis or interstitial pulmonary disease (or both). These rare patients with bona fide organ system disease should not be confused with patients who have chronic fatigue syndrome or fibromyalgia rheumatica (Chapter 274), which have no relationship with EBV.

DEFINITION

There are now four members of the human T-lymphotropic virus (HTLV) family: HTLV-1, discovered in 1979; HTLV-2, discovered in 1982; and HTLV-3 and HTLV-4, discovered in 2005. HTLV-1 has been causally linked to adult T-cell leukemia/lymphoma (ATL) and to several chronic degenerative conditions, most notably HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP), whereas disease associated with HTLV-2 is rare, and no disease associations have been established with HTLV-3 or HTLV-4.

The Pathogens

Within the taxa of RNA reverse transcribing viruses, the HTLV viruses, along with bovine leukemia virus, are classified in the subfamily Retroviridae within the genus Deltaretrovirus (formerly termed *oncovirus*). The oncogenic properties of these viruses and their molecular structure distinguish them from the human immunodeficiency retroviruses HIV-1 and HIV-2 (Chapter 386), which are members of the genus Lentivirus. Both deltaretroviruses and lentiviruses are capable of prolonged asymptomatic infection. In vitro, however, HIV-1 and HIV-2 have cytopathic effects on human T cells, whereas HTLV-1 and HTLV-2 are capable of transforming T cells into immortalized cell lines. The HTLVs are diploid single-stranded RNA viruses that replicate through cDNA, a proviral intermediate, by reverse transcriptase, a viral polymerase.

EPIDEMIOLOGY

HTLV-1 is widely disseminated worldwide and is estimated to infect 10 to 25 million persons, with the aggressive T-cell malignant neoplasm ATL developing in 2 to 6% and chronic inflammatory diseases, mainly HAM/TSP, developing in another 1 to 5% in their lifetime.[1] Similar to HIV, molecular epidemiology suggests that the four major subtypes of HTLV identified in humans arose from separate interspecies transmission from simians to humans. The discovery of HTLV-3 and HTLV-4 was made in Cameroon, where closely related viruses in nonhuman primates led to discovery in humans with exposure as bush meat hunters. Related to such interspecies transmission, there are four major geographic subtypes of HTLV-1: Cosmopolitan subtype A, Central African subtype B, Australio-Melanesian (Papua New Guinea, Melanesia, and Australian aborigines) subtype C, and Central African/Pygmies subtype D. Central Africa also carries a few rare subtypes (E, F, G). Within the cosmopolitan group are four subgroups: transcontinental, Japanese, West African, and North African. The virus from Australio-Melanesia differs molecularly from the Japanese and African strains by 5 to 10%, the result of independent evolution of the virus in these populations separated for tens of thousands of years. The stability of HTLV-1 in comparison to HIV-1 reflects the observation that HTLV favors viral expansion through proliferation of proviral DNA-harboring cells rather than infection of new cells by cell-free virions. The HTLV subtypes differ phylogenetically by approximately 30 to 40% among each other.

HTLV-1 is not universally present in all human populations but rather clusters geographically: southern Japan; Melanesia; Australia, in aboriginal peoples; West Africa and, by the slave trade from Africa, the Caribbean and the United States in African Americans; Central and South America; and the Mashhad region of Iran. In the United States, HTLV-1 infection is often found in persons who migrate from these regions. HTLV-2 is found in Native American people throughout North, Central, and South America and in West Africa. Most HTLV-2 infections in the United States and Europe occur in injection drug users, in whom the virus is spread by needle sharing and other injection practices. HTLV-3 and HTLV-4 were originally detected in Cameroon, but their extent in West Africa is not yet known.

Routes of Transmission

HTLV, like HIV-1, is transmitted sexually, perinatally, and by transfusion or injection drug use (Table 378-1).

Sexual Transmission

Sexual transmission of HTLV-1 from male to female and from female to male as well as from male to male has been documented. HTLV-1 transmission is cell associated and appears to be at least an order of magnitude less infectious than HIV-1. Coincidental infection with other sexually transmitted diseases, particularly those associated with ulcerative and inflammatory genital lesions, amplifies the risk of transmission. For HTLV-1, elevated viral load is linked to heightened transmission. In regions endemic for the virus, there is a characteristic age-dependent rise in HTLV-1 seroprevalence. This increase first becomes evident in the adolescent years; it is steeper in women than in men and continues in women after 40 years of age, whereas rates in men plateau around the age of 40 years. This pattern reflects more efficient male-to-female transmission. For HTLV-2, the rates for both genders are equal, thus suggesting that there may be differences in the kinetics of transmission between the two viruses.

Perinatal Transmission

For HTLV-1, transmission through breast-feeding is more efficient than in utero or perinatal transmission. Major risk factors that increase the efficiency of transmission include high proviral loads and increased duration of breast-feeding (>6 months). On average, 20% of infants breast-fed by HTLV-1–positive mothers seroconvert to HTLV-1, whereas only 1 to 2% of bottle-fed infants of HTLV-1–positive mothers become infected. In contrast, in utero and perinatal transmission accounts for virtually all HIV-1 transmission in the West, and breast-feeding accounts for an additional 15 to 20% of infant HIV infection in Africa. This difference may reflect the fact that maternal antibody to HTLV-1 transmitted across the placenta appears to neutralize perinatal HTLV-1 but not the highly mutable HIV-1. HTLV-2 is detectable in breast milk and, similar to HTLV-1, accounts for many childhood infections.

Transfusion and Injection Drug Use

Parenteral transmission, through either transfusion or injection drug use, is a major source of HTLV infection. Among blood donors in the United States, more than half of HTLV infections are due to HTLV-2. Among injection drug users, most infections are due to HTLV-2, and HTLV-2 is more efficiently transmitted by this route than HTLV-1 is.

Both HTLV-1 and HTLV-2 are transmitted in association with cellular components through a "virologic synapse,"[2] unlike HIV-1, which is transmitted by cells, plasma, or plasma products. Approximately 50% of the recipients of HTLV-1/HTLV-2–positive blood seroconvert, compared with more than 95% for HIV-1.

The only documented illness linked to HTLV-1 or HTLV-2 transfusion-associated transmission is the HTLV-associated demyelinating neurologic syndrome HAM/TSP. Leukemia has not been associated with transfusion of HTLV-positive blood. Among U.S. blood donors who are confirmed to be HTLV positive (slightly less than half are HTLV-1 positive and the others are HTLV-2 positive), the major risk factors are intravenous drug use, birthplace in an area in the Caribbean or Japan endemic for the virus, and sexual contact with a person with this profile.

Coinfection with HTLV-1 and HIV-1 appears to increase the progression to acquired immunodeficiency syndrome (AIDS) through unexplained mechanisms, possibly related to the cell-proliferative effects of HTLV-1 on HIV-1–infected T cells. Such a relationship has not been shown for HTLV-2. Other modes of transmission involving "casual contact" are not a source of infection. Health care and laboratory workers who experience a needlestick or skin or mucous membrane exposure in the absence of protective barriers have little or no risk for infection but should be monitored.

PATHOBIOLOGY

Virology

The HTLV viruses, which are single-stranded RNA viruses that contain a diploid genome, replicate through a DNA intermediary that integrates into the genome of the target T cell as a provirus, thereby resulting in lifelong infection. HTLV-1 is approximately 100 nm in diameter and has a thin, electron-dense outer envelope and an electron-dense, roughly spherical core. The total provirus genome contains 9032 nucleotides with two identical sequences termed *long terminal repeats* (LTRs) at the 5′ and 3′ ends of the genome, which contain regulatory elements that control virus expression and virion production. The retroviral structural genes (*gag* and *pol*) code for large overlapping polyproteins that are later processed into functional peptide products by virally encoded protease and cellular proteases. The encoding genes of the virus are *gag* (group-specific antigen), *pol* (polymerase/integrase/protease), and *env* (envelope), and it has a series of regulatory genes, *tax* and *rex*, and several smaller gene products that regulate infection and virus expression. A newly discovered viral gene is the basic leucine zipper factor (*HBZ*) gene, encoded by the minus strand of the HTLV-1 provirus and transcribed from the 3′ LTR. Tax protein plays a central role in enhancing the transcription of viral and cellular gene products that promote viral replication and transformation of human T lymphocytes. Through binding to the LTR, Tax promotes transcriptional activation of the viral genome, and by binding to key regulatory proteins of the NF-κB signaling pathway, it promotes cell activation and disease pathogenesis. Through binding to regulatory enhancers of the cell and through abrogation of key suppressor genes, Tax initiates the immortalization of the infected T cells. However, the Tax gene is susceptible to genetic mutations and is expressed in only about 60% of ATL cases. Rex stabilizes viral mRNA, essential for export of full-length Gag/Pol and single-spliced Env mRNA from the nucleus to the cytoplasm. *HBZ*, which is the only viral gene consistently expressed in all ATL patients, appears to be essential for persistent HTLV-1 infection.[3] HBZ inhibits the Tax-mediated activation of viral gene transcription through the 5′ LTR, which ultimately represses expression of viral proteins while simultaneously promoting the proliferation and survival of infected cells, regardless of Tax expression. An estimated 500 to 5000 HTLV clones exist in persons with asymptomatic infection, with a large proportion of clones detectable during years of follow-up.[4]

Viral Life Cycle

The initial stage of HTLV infection engages several mechanisms: *viral synapse*, cell-to-cell contact; *cellular conduits*, transient membrane extensions; *extracellular viral assembly*, membrane-bound virus; and *transinfection through dendritic cells*, virus captured on the cell surface of dendritic cells. After infection, the viral life cycle involves membrane fusion, followed by reverse transcription from an RNA template to a circular DNA provirus that is transported to the cell nucleus and integrated into the host genome. After the cell is infected, viral expansion is primarily achieved through proliferation of proviral DNA-harboring cells rather than through repeated cycles of cell-to-cell infection. For viral entry, HTLV-1 uses three distinct molecules for infection of activated $CD4^+$ cells: heparin sulfate proteoglycans, neuropilin 1, and glucose transporter 1. HTLV-2 uses neuropilin 1 and glucose transporter 1 for entry into activated $CD8^+$ T cells. After uptake and uncoating, viral RNA is transcribed by reverse transcriptase, an RNA-dependent DNA polymerase complexed to the RNA in the core of the virus particle, into double-stranded DNA. This double-stranded viral DNA is integrated into the host cell nucleus by the virally encoded integrase, which results in lifelong cell infection. The viral LTR elements are essential for integration and regulation of viral genome expression, which is controlled mainly by Tax and HBZ.

Pathogenesis of Adult T-Cell Leukemia

HTLV-1 is integrally involved in the pathogenesis of ATL through a multistage process that includes clonal integration of virus (sometimes including partial viral sequences that always include *HBZ*) into active cellular gene sequences. Interestingly, the *HBZ* gene is always present in ATL, and its quantification may be a useful marker for monitoring of the response to treatment. The clonal pattern of integration indicates that ATL is derived from a single transformed tumor cell that evolved from a virus infection *before* transformation rather than afterward as a passenger virus. Tax is an oncoprotein that interacts with numerous cellular proteins to reprogram cellular processes to alter transcription, cell cycle regulation, DNA repair, and apoptosis, thereby allowing cells with potential carcinogenic mutations to survive and to escape cell death. HBZ is also emerging as a key oncogenic protein involved in modulating cellular pathways related to cell growth, immune response, and T-cell differentiation.

In some healthy carriers, T-cell polyclonal and oligoclonal proliferations develop that can later progress to malignant transformation or may disappear spontaneously. Morphologically distinct "flower cells" (Fig. 378-1), which represent T cells with deeply lobulated nuclei resembling ATL leukemic cells, are seen on peripheral blood smears of healthy carriers, and increased numbers are detected in persons with higher HTLV viral loads.

Pathogenesis of Myelopathy/Spastic Paraparesis

Viral overproduction, as measured by high viral loads, appears to result from defective host immune responses characterized by very high levels of cytotoxic T cells. Local pathologic changes in neuronal tissue may result from immune-mediated damage caused by misdirected responses to molecular mimics of viral proteins or by local damage due to cytokine-induced damage of neuronal tissue as HTLV-1 cells infiltrate the perivascular space and the neurons of the central nervous system (CNS), particularly the spinal cord.

ADULT T-CELL LEUKEMIA/LYMPHOMA

EPIDEMIOLOGY AND PATHOBIOLOGY

The cumulative lifetime incidence of adult T-cell leukemia/lymphoma (ATL) in persons infected with HTLV-1 is between 2 and 6%, so about 2500 to 5000 cases per year occur in the approximately 10 to 25 million infected persons worldwide. The latency period is approximately 20 to 30 years after infection, with a slightly higher risk among HTLV-infected males. The age-adjusted incidence rate of ATL in the United States is 0.05 case for men and 0.03 for women per 100,000 people.[5] In areas endemic for HTLV-1, such as southern Japan and the Caribbean Islands, ATL accounts for half or more of adult lymphoid malignant neoplasms. ATL is rarely seen in children, but in one series of pediatric cases of ATL, four of the eight patients shared a homozygous deletion in the p16 gene locus, and deletion of exons 7 and 8 of p53 was detected in another child, thereby suggesting that a genetic predisposition interacts with viral infection to accelerate the progression of the disease.

CLINICAL MANIFESTATIONS

The most common disease caused by HTLV-1 is ATL, a type of T/natural killer–cell lymphoma in the new World Health Organization classification (Table 378-2). ATL is a high-grade lymphoma (Chapter 185), usually of large, medium, or pleiotropic morphology (or combined morphology) and advanced clinical stage.

The acute form of ATL, which accounts for about 55% of cases, is characterized by an aggressive, mature T-cell lymphoma that presents with a high

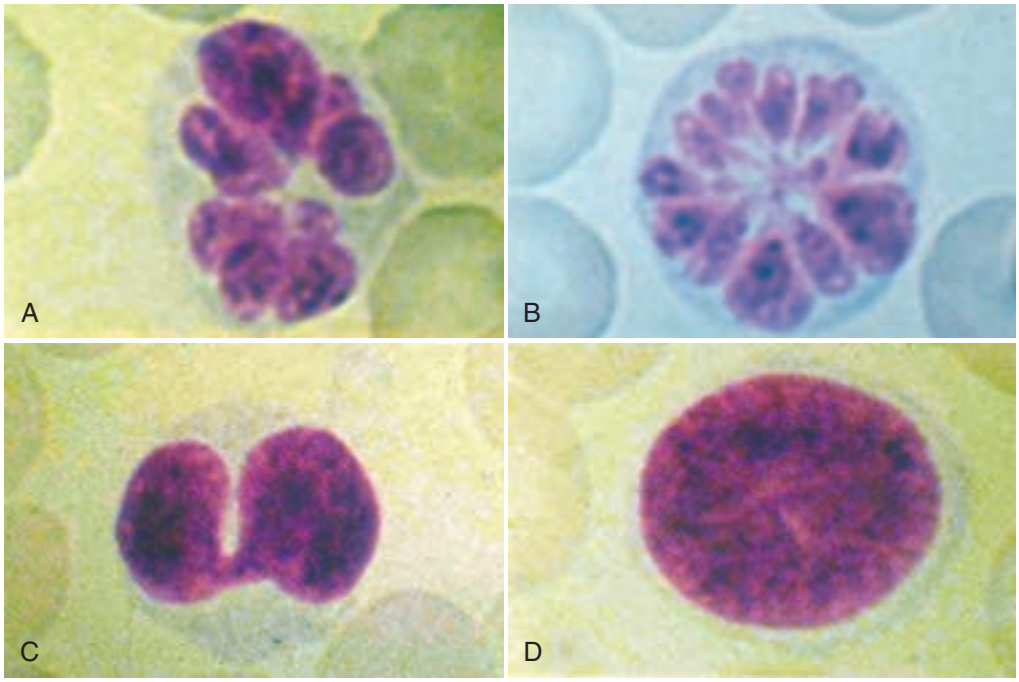

FIGURE 378-1. **Photomicrographs demonstrating the morphologic features of leukemic cells observed in different subtypes of adult T-cell leukemia/lymphoma (ATL). A and B, Polylobulated morphology of the acute type, with the highly characteristic "flower cell" shown in B. C, Typical cleaved cell seen in chronic-type ATL. TABLE 378-2 HTLV-ASSOCIATED DISEASES

DIAGNOSIS	NATURE OF SYNDROME	STRENGTH OF ASSOCIATION
HTLV-1–ASSOCIATED DISEASES		
Adult T-cell leukemia/lymphoma	Aggressive lymphoproliferative malignant disease of mature T lymphocytes	Strong
HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP)	Chronic progressive demyelinating syndrome of long motor tracts of spinal cord	Strong
Polymyositis	Degenerative inflammatory syndrome of skeletal muscles	Probable
Sporadic inclusion body myositis	Recently described HTLV-associated inflammatory muscle disease	Possible
Infective dermatitis	Chronic generalized eczema in adults and children; potential for pre-leukemia and immunodeficiency	Strong
Uveitis	Inflammatory infiltration of the uvea of the eye	Strong
Sjögren syndrome/keratoconjunctivitis sicca	Loss of tear production and dry eyes and dry mouth	Probable
Pulmonary lymphocyte alveolitis/ cryptogenic fibrosing alveolitis	Pulmonary infiltrate involving T lymphocytosis in lungs of patients with HAM/TSP and HTLV uveitis	Possible
HTLV-associated arthritis	Large-joint polyarthropathy; rheumatoid factor positive, with HTLV-1–positive cells infiltrating the synovia	Probable
Immunodeficiency	Subclinical (e.g., decreased PPD response) or clinical (e.g., association with clinical tuberculosis and poor response to therapy for symptomatic strongyloidiasis)	Probable
Miscellaneous clinical conditions	Case reports of small cell lung cancer with monoclonal HTLV-1 integration and invasive cervical cancer	Uncertain
HTLV-2–ASSOCIATED DISEASES		
HTLV-associated myelopathy	Increased numbers of cases among blood donors	Definite but rare

PPD = purified protein derivative.

white blood cell count, hypercalcemia, and cutaneous involvement. Lymphoma type (about 20% of cases) shares all features of acute ATL except for peripheral blood involvement. Other cases resemble T-prolymphocytic leukemia and are termed *chronic ATL* (about 20% of cases). A subset of patients with chronic ATL and with high serum levels of lactate dehydrogenase (LDH) and blood urea nitrogen (BUN) and low levels of albumin have a poor response to treatment, and their survival rates are similar to those of patients with the more aggressive acute and lymphoma types of ATL. Smoldering ATL (about 5%) may clinically resemble mycosis fungoides/Sézary syndrome (Chapter 185), with cutaneous involvement manifested as erythema or as infiltrative plaques or tumors (Fig. 378-2). A long prodrome of signs (e.g., cutaneous rashes) and symptoms (e.g., fevers) is sometimes noted in chronic and smoldering ATL before transformation to an acute or lymphoma-type ATL that is rapidly fatal.

DIAGNOSIS

The diagnosis should be considered in an adult with mature T-cell lymphoma and hypercalcemia or cutaneous involvement (or both) with characteristic flower cells (see Fig. 378-1), particularly if the individual is from a known risk group or endemic region. The diagnosis is established by testing of serum for HTLV-1 antibodies. Polymerase chain reaction (PCR) can detect infection and distinguish the type of virus. The cytologically distinct flower cell,

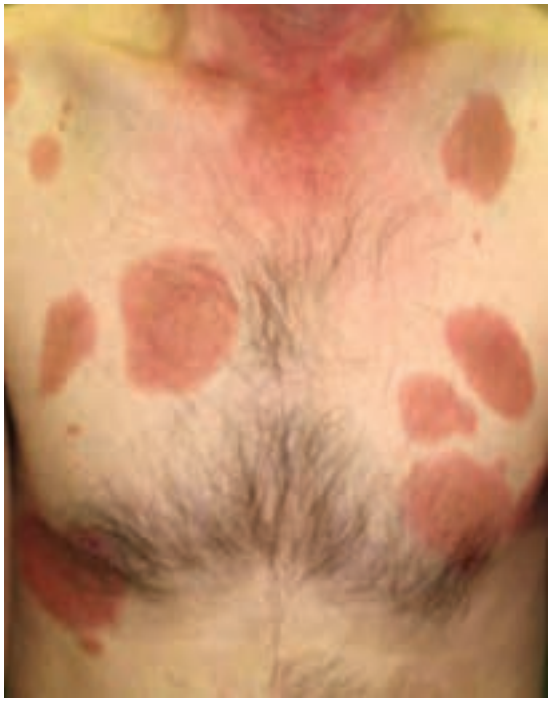

FIGURE 378-2. Cutaneous involvement in adult T-cell leukemia/lymphoma. (From Tomita H, Fumihide O, Kuwatsuka S, et al. Attenuation of an adult T-cell leukemia lesion after treatment of a concomitant simplex infection: a case study. *Virol J*. 2012;9:224. http://www.virologyj.com/content/9/1/224. Creative Commons Attribution License).

a sine qua non of HTLV-1–associated leukemia, is also seen in apparently healthy carriers. Occasional cases with characteristic clinical features are antibody negative but provirus positive as detected by PCR in blood cells or in biopsy specimens.

TREATMENT

Rx

Treatment is based on the type of ATL and its natural history, but it is also influenced by the patient's age and the presence of selected biomarkers.

Smoldering and Chronic ATL

Watchful waiting traditionally has been recommended for patients with smoldering ATL and some patients with chronic ATL with a favorable biomarker profile (normal LDH, BUN, and albumin levels) because cytoablative therapy increases the risk of lethal opportunistic infections. Some observational data suggest, however, that 5-year survival could be improved by treating smoldering and selected chronic ATL with high doses of the antiviral agent zidovudine (800 to 1000 mg/day in divided dosage) in combination with interferon alfa (6 to 9 million units)[6] on a daily basis for 30 to 60 days, but controlled trials are needed to define the optimal dose and regimen.[7]

Acute, Lymphoma-type, and Aggressive Chronic ATL

In a randomized trial, a nine-drug regimen (vincristine, cyclophosphamide, doxorubicin, and prednisone [VCAP]; doxorubicin, ranimustine, and prednisone [AMP]; and vindesine, etoposide, carboplatin, and prednisone [VECP] [Chapter 185]) was significantly better than biweekly cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) for inducing a complete remission.■ The nine-drug regimen provided nonsignificant improvements in progression-free survival at 1 year (28% vs. 16%), in median survival time (13 months vs. 11 months), and in 3-year overall survival (24% vs. 13%), but it was associated with more hematologic and infectious complications. Retrospective case series report a long-term survival of 20 to 40% after allogeneic hematopoietic stem cell transplantation (Chapter 178) but with significant treatment-related mortality.[8] Small case series have reported some benefit with zidovudine and interferon alfa, with potentially incremental benefit from the addition of arsenic triphosphate. Newer therapies, such as defucosylated humanized anti-CCR4 antibody (mogamulizumab) and denileukin diftitox (interleukin-2–diphtheria toxin conjugate), that target the high-affinity interleukin-2 receptor on ATL cells have shown some promise but need further study. In the absence of definitive data from randomized trials, a reasonable approach for patients with aggressive forms of ATL and favorable prognostic factors is VCAP-AMP-VECP alone. For patients with an unfavorable prognostic profile (thrombocytopenia, eosinophilia, bone marrow involvement, elevated LDH levels, high interleukin-5 serum level, C-C chemokine receptor 4 expression, lung resistance–related protein, p53 mutation, or p16 deletion), however, VCAP-AMP-VECP chemotherapy followed by allogeneic stem cell transplantation is recommended.

PROGNOSIS

Smoldering ATL has a relatively good prognosis, with a 5-year survival rate of 70%. For the chronic subtype, the 5-year survival is only 20%, even including the more favorable subset of patients with normal LDH, BUN, and albumin levels. For the aggressive forms of acute and lymphoma-type ATL, median disease-free survival is 0.6 year, with an overall survival of 0.8 year with high mortality linked to rapid tumor growth, infectious complications, and metabolic complications, especially hypercalcemia. Significant negative prognostic factors also include poor performance status at diagnosis, older age, advanced stage, and elevated serum LDH levels. Death usually results from rapid growth of tumor cells, hypercalcemia, bacterial sepsis, and opportunistic and other infectious complications.

HTLV-ASSOCIATED MYELOPATHY/TROPICAL SPASTIC PARAPARESIS

EPIDEMIOLOGY AND PATHOBIOLOGY

HTLV-1 causes an inflammatory neurologic syndrome known as HAM/TSP.[9] The lifetime incidence is approximately half the rate for ATL, with approximately 1 to 2% of carriers affected. HAM/TSP is approximately two times more likely to develop in females. The majority of adult cases occur in the 30- to 50-year age group, but cases have occurred in children as young as 3 years. These patterns suggest that the latency period for HAM/TSP is shorter than that for ATL and that both early-life and adult exposure causes disease. More than a dozen HAM/TSP cases associated with HTLV-2 have been reported, but the occurrence is infrequent compared with HTLV-1 carriers.

The pathogenesis results from trafficking of infected T cells in the perivascular areas and parenchyma of the spinal cord, where they cause astrocytosis. Ongoing inflammation of spinal gray and white matter results in a progressive and preferential demyelination and degeneration of the lateral and posterior columns, followed over time by loss of myelin and axons in the anterior columns.

CLINICAL MANIFESTATIONS

Symptoms include stiff gait, spasticity, lower extremity weakness, back pain, urinary incontinence and impotence, and (rarely) ataxia. The presenting symptom is stiff gait that progresses (usually slowly) to increasing spasticity and weakness, with incontinence and impotence developing later. In contrast to classic multiple sclerosis (Chapter 411), HAM/TSP is characterized by a generally slow and progressive course, absence of waxing and waning symptoms, and demyelination of long motor neurons rather than the CNS. However, some cases are acutely progressive, especially those associated with transfusion of HTLV-1–positive blood. It is not uncommon for other manifestations of HTLV-1–associated "autoimmune" disease to present coincident with the neurologic syndrome.

DIAGNOSIS

The diagnosis is suspected in patients with unexplained CNS disease and loss of pyramidal tract functions and is confirmed by testing of sera for HTLV-1 antibodies. Oligoclonal immunoglobulin bands in the cerebrospinal fluid (CSF) of patients with HAM/TSP react to HTLV-1 antigens, and the CSF to serum ratio of HTLV-1 antibodies is greater than 1. PCR quantification of the HTLV-1 cell-associated provirus in the CSF is also diagnostic. Spinal cord lesions often appear hyperintense on T2-weighted magnetic resonance imaging.

TREATMENT

Rx

Corticosteroids (e.g., intravenous methylprednisolone 1.5 g for 3 consecutive days in the first week, 2 consecutive days in the second week, 1 day in the third week, and then monthly for 6 months; an alternative is oral prednisone, 1 mg/kg/day in tapering doses for 2 to 4 months) reduce symptoms in

approximately 40% of cases, especially in early disease or in patients who are progressing rapidly. Studies evaluating antiviral drugs, such as lamivudine and zidovudine, have been inconclusive. Interferon alfa (3 MU three times per week) can improve neurologic symptoms. Pentoxifylline (400 to 1200 mg daily) decreases tumor necrosis factor-α and interferon-γ levels and has improved motor disability, especially spasticity, in uncontrolled trials. Cyclophosphamide also benefits some patients. Spasticity can be treated with tizanidine (2 to 12 mg daily) and botulinum toxin injection (100 to 400 IU every 4 to 6 months). Urinary incontinence is treated with oxybutynin (5 to 30 mg daily), imipramine (10 to 75 mg daily), or doxazosin mesylate (1 to 6 mg daily), and urinary retention is treated with bethanechol (10 to 50 mg daily). Treatment with danazol (100 to 400 mg daily in two divided doses) has resulted in improvement in urinary and fecal incontinence but not in the underlying neurologic deficit. Clinical trials are under way with Hu-Mik-(Beta)1, a genetically engineered antibody that blocks the action of interleukin-15 with the goal of blunting the autoimmune response that results in HAM/TSP.

PROGNOSIS

The prognosis of HAM/TSP is poor, with inexorable progression of neurologic deterioration.

OTHER HTLV-ASSOCIATED CONDITIONS

HAM/TSP is the prototype for a series of immune-mediated syndromes characterized by a high viral load, immune activation, and an indirect pathogenic mechanism produced by virally induced perturbations in immune function. Examples include skeletal muscle polymyositis, sporadic inclusion body myositis, uveitis (30 to 40% of cases in areas endemic for HTLV), large-joint arthropathy, pulmonary lymphocyte alveolitis/cryptogenic fibrosing alveolitis, Sjögren syndrome/keratoconjunctivitis sicca, and infective dermatitis, which is a pediatric syndrome characterized by inability to clear saprophytic skin infections (see Table 378-2). Carriers of HTLV-1 also have elevated rates of invasive cervical cancer, tuberculosis, parasitic infestations (e.g., strongyloidiasis), scabies, and refractory generalized eczema associated with infective dermatitis. One prospective study of HTLV-2–positive drug users showed an excess of asthma-related deaths and an increased frequency of skin and soft tissue infections.

PREVENTION

Patients often seek medical attention when confronted with a positive HTLV test result based on blood bank screening.[10] Confirmation with Western blot or PCR is needed. Confirmed positive patients must be told that complications related to HTLV-1 infection are rare and that HTLV-2 is hardly ever responsible for clinical disease. Second, it should be emphasized that these viruses are not easily transmitted. Third, the patient should be clearly counseled concerning the distinction between HTLV and HIV because the greatest fear that patients may experience is that they have the "AIDS virus." Other guidelines for prevention include the following:

- Blood for donation should be screened before transfusion, and positive donors should be deferred from donating.
- HTLV-1/HTLV-2–positive mothers should be discouraged from breast-feeding to prevent mother-to-infant transmission (except in particular settings, such as in the tropics, where diarrheal disease in non–breast-fed infants presents a high risk for morbidity and mortality).
- Condoms should be used by discordant couples, but given the relatively low frequency of sexual transmission per sexual encounter, couples who desire a pregnancy could time unprotected sexual intercourse to coincide with periods of maximal fertility. Such decisions, however, require careful discussion between the physician and the patient.

Postexposure prophylaxis with zidovudine is not recommended because the efficacy of such prophylaxis for HTLV infection has not been established. Vaccines containing whole virus and recombinant HTLV-1 envelope antigens have successfully prevented HTLV-1 infection in monkeys and in a rabbit model. However, a vaccine for humans is unlikely to be a high priority because of the relatively low incidence of clinical disease.

REVIEW QUESTIONS

1. A 35-year-old white woman from suburban Chicago arrives at your office having called for an emergency appointment because she was refused as a first-time blood donor owing to a positive virus test result. She received a blood transfusion as a child in the early 1980s and is concerned that she is positive for AIDS. When you contact the blood bank, the test result is positive for HTLV-2 (based on multiple bands on Western blot) and negative for HIV. After you explain to her the difference between HIV and HTLV, you make the following recommendations.

A. She should be seen every 6 months for a complete blood count to monitor her for possible leukemia.
B. She should see a neurologist annually to look for neurologic disease.
C. If she becomes pregnant, she should avoid breast-feeding her baby.
D. She can resume sexual activity with no restrictions.
E. She should have a CD4 test to make sure that she does not have AIDS.

Answer: C In the United States, all blood donors are screened for HTLV in addition to other blood-borne viruses. A positive HTLV test result is often misinterpreted as HIV, and the first task of the physician is to reassure the patient about the difference between HIV and HTLV. Because the patient is infected with HTLV-2, she is not at risk for hematologic disease. For HTLV-1, the risk for leukemia is mainly in patients with early-life exposure, whereas HTLV-associated myelopathy can occur as a result of later blood transfusion with HTLV-1–infected blood. There is no need for frequent monitoring for disease among patients with either HTLV-1 or HTLV-2, although a baseline complete blood count with differential is warranted, as is careful attention to neurologic signs and symptoms during routine annual physicals. Because HTLV-1 and probably HTLV-2 can be transmitted through breast milk, breast-feeding should be avoided. Because HTLV-1 and probably HTLV-2 can be sexually transmitted, couples may consider using condoms. A CD4 test is not warranted for HTLV infection.

2. Which geographic region is not endemic with HTLV-1?

A. United States
B. West Africa
C. Southern Japan
D. Caribbean
E. Iran

Answer: A The United States has a low prevalence and incidence of HTLV-1, and most of the cases arise from people who have migrated from endemic regions, such as the West Indies, Japan, and West Africa. In a recent serosurvey of first-time blood donors, the prevalence of HTLV-1 (5.1 per 100,000) and HTLV-2 (14.7 per 100,000) was low. The strongest risk factors for both HTLV-1 and HTLV-2 seropositivity are female sex, older age, and nonwhite race/ethnicity.

3. Which factor uniquely distinguishes HTLV-1 from HIV-1?

A. Prolonged asymptomatic infection
B. Sexual transmission
C. Integration into the host genome
D. Targets $CD4^+$ T cells
E. Immortalized cells

Answer: E HIV-1 and HIV-2 belong to the genus Lentivirus, whereas HTLV viruses belong to the genus Deltaretrovirus. Both deltaretroviruses and lentiviruses are associated with prolonged asymptomatic infections, both target $CD4^+$ T cells, both integrate into the host genome, and both are transmitted sexually. However, HIV-1 and HIV-2 have cytopathic effects on T cells, whereas the HTLVs transform T cells into immortalized cell lines.

379 ENTEROVIRUSES

JOSÉ R. ROMERO

DEFINITION

The enteroviruses belong to the genus Enterovirus in the family Picornaviridae. With the advent of molecular virology, the more than 100 recognized strains are classified on the basis of phylogenetic analysis of the nucleic acid sequence of VP1, the major enteroviral capsid protein (Table 379-1).

The Pathogens

Enteroviruses are small (30 nm in diameter), nonenveloped, icosahedral-shaped viruses. The viral capsid is composed of four viral proteins (VP1 to VP4). The enteroviruses possess an approximately 7.4-kilobase positive-sense single-stranded RNA genome. The 5′ end of the genome is covalently linked to a small protein, VPg. The genome is organized into a long (about 740 nucleotides) 5′ nontranslated region that precedes a single continuous open reading frame measuring about 6.63 kilobases. The open reading frame, which is followed by a short 3′ nontranslated region and a terminal polyadenylate tail, yields a single large polyprotein that is post-translationally modified to produce four capsid proteins, seven nonstructural proteins, and several functional protein intermediates. The 5′ and 3′ nontranslated regions of VPg participate in replication of the viral genome. The 5′ nontranslated region of the enterovirus is essential for translation and contains determinants of neurovirulence in the polioviruses.

EPIDEMIOLOGY

Worldwide, an estimated 1 billion or more enteroviral infections occur annually. In the United States, about 30 to 50 million annual infections result in approximately 10 to 15 million symptomatic cases, with coxsackievirus B1, echovirus 6, echovirus 9, echovirus 18, and coxsackievirus A9 accounting for more than 50% of these enteroviral infections.[1]

Humans are the only known reservoir for enteroviruses. Enteroviral infections are seasonal, and the majority of infections occur during the summer and early autumn in temperate regions. For example, more than 80% of infections occur in the United States from June through October. However, winter outbreaks highlight their panseasonal occurrence. In tropical and subtropical regions, infections continue year-round, with an increased incidence during the rainy season.

Globally, the dominant circulating enterovirus serotypes may vary annually by geographic region. In the United States, 15 serotypes accounted for about 90% of all isolates reported (Table 379-2).

TABLE 379-1 CLASSIFICATION OF ENTEROVIRUSES

Total	89.6

From Centers for Disease Control and Prevention (CDC). Nonpolio enterovirus and human parechovirus surveillance—United States, 2006-2008. *MMWR Morb Mortal Wkly Rep.* 2010;59:1577-1580.

More than 80% of infections occur in individuals younger than 20 years, with the highest incidence in infants and children 4 years and younger. Nearly 45% of all infections occur in infants younger than 1 year. Among household members of infected children, clinical or serologic evidence of secondary infection can be seen in more than 50% of susceptible individuals. A male preponderance is noted in persons younger than 20 years (male-to-female ratio of 1.4 : 1), but not in older individuals.

Localized enteroviral outbreaks have been reported in neonatal units, nurseries, daycare centers, schools, camps, and sports teams. Community-wide outbreaks are common. Extensive regional outbreaks of EV-A71 have occurred in the Asia-Pacific region. Occasional pandemics, such as acute hemorrhagic conjunctivitis caused by EV-D70 and CV-A24, also have occurred.

Effective antipolio immunization programs have eradicated wild-type poliovirus serotype 2 worldwide and have also eradicated serotypes 1 and 3 from almost all countries except Afghanistan, Pakistan, and Nigeria, where they unfortunately remain endemic.[2] As a result, sporadic poliovirus outbreaks continue to occur in Africa, west Asia, China,[3] and war-torn Syria[4] from local reservoirs or imported infections. The use of live attenuated poliovirus vaccines has led to the problem of vaccine-derived polioviruses (VDPVs) as a result of the excretion of neurorevertant vaccine (Sabin) strains from individuals who have primary humoral immunodeficiencies, but not secondary humoral or other immunodeficiencies, or as a result of natural recombination between Sabin strains and members of the Enterovirus C species.[5] VDPVs that can circulate in the environment with evidence of person-to-person transmission have been termed circulating vaccine-derived polioviruses (cVDPVs). A third group of VDPVs, designated ambiguous VDPVs, are clinical isolates from individuals without known immunodeficiency or sewage isolates whose ultimate source is unknown. Similar to wild-type poliovirus, cVDPVs can cause acute flaccid paralysis in unimmunized or incompletely immunized individuals and have caused multiple outbreaks worldwide.

PATHOBIOLOGY

The polioviruses and the majority of the nonpolio enteroviruses are transmitted through a fecal-oral route. Notable exceptions include CV-A21 and EV-D68, which are spread by the respiratory route, and EV-D70, which may spread by contaminated fomites or ocular and respiratory secretions. Evidence also supports transplacental transmission of the enteroviruses.

Ingestion of the enteroviruses results in infection of cells of the pharynx and, because the virus is acid resistant, the lower gastrointestinal tract. Initial viral replication, which is thought to occur in the mucosal tissues of the nasopharynx and intestinal tract (i.e., tonsils and Peyer patches), leads to seeding of the deep cervical and mesenteric lymph nodes. Further replication at these sites results in a minor viremia with seeding of multiple organs, including the liver, lungs, heart, and central nervous system (CNS). Viral replication at these sites causes many of the clinical manifestations of infection and is followed by a major viremia that may infect the CNS if it was spared during the initial viremia. The virus is cleared by type-specific neutralizing antibodies directed at the capsid proteins by day 7 to 10 after infection. IgA antibodies appear in the respiratory and gastrointestinal tracts 2 to 4 weeks after infection.

The host humoral immune response is pivotal in the prevention and eradication of enteroviral infections. Congenital or acquired B-cell immunodeficiencies may result in chronic or prolonged infection. Experimental evidence suggests that the interferons are important in limiting the spread of poliovirus once infection has occurred. Natural killer cells and gamma or delta T cells may play roles in regulating the host T-cell response.

Histopathologic findings in patients who died of poliomyelitis reveal neuronal necrosis in association with mononuclear and polymorphonuclear infiltrates that are initially perivascular in distribution but are later found diffusely within the gray matter of the anterior horns of the spinal cord, the reticular formation of the hindbrain, the vestibular nuclei, and the roof nuclei of the cerebellum. In nonpolio enterovirus CNS infections in immunocompetent hosts, findings include edema of the meninges and cerebral parenchyma, with microscopic perivascular lymphocytic infiltration, increased numbers of oligodendrocytes, and focal areas of necrosis and hemorrhage. In cases of enteroviral myocarditis (Chapter 60), a mononuclear cell inflammation is associated with widespread myocardial necrosis followed by fibrosis, which may be focal but results in myocardial damage.

CLINICAL MANIFESTATIONS

The incubation period for enterovirus infections is generally 3 to 6 days, with a range of 2 days to 2 weeks. Depending on serotype and the age of the patient, as many as 90% of infected individuals may have subclinical infections. The enteroviruses are responsible for a wide array of clinical syndromes affecting nearly every organ system, and no enterovirus serotype is uniquely associated with a single disease or clinical syndrome (Table 379-3).

The most frequent enteroviral syndrome, seen in about 50 to 80% of cases, is nonspecific febrile illness, which occurs most commonly in infants, toddlers, and young children. The onset of illness is abrupt, with fever, poor appetite, lethargy, irritability, emesis, diarrhea, and upper respiratory tract symptoms. Physical findings are minimal and consist of mild pharyngeal and conjunctival injection and lymphadenopathy. Exanthems may be present in about 25% of cases.

DIAGNOSIS

Nucleic acid amplification techniques (e.g., reverse transcription–polymerase chain reaction [RT-PCR] and nucleic acid–based sequence amplification) are the preferred methods for detection and identification of all enteroviruses. Multiple studies have documented that nucleic acid amplification techniques are more sensitive and rapid than cell culture for the detection of enteroviruses in cerebrospinal fluid (CSF). RT-PCR can detect enteroviruses in CSF, blood, tissue, stool, and other body fluids within hours, and the results can shorten hospitalizations, decrease the use of antibiotics, and reduce health care costs.

Serologic testing is of limited use, although a four-fold change in antibody titer to a specific serotype of enterovirus in paired acute and convalescent sera can establish the diagnosis. Cell culture is not recommended because of limited sensitivity, prolonged positivity even after the related clinical syndrome may have resolved, and the several days required for viral detection.

TREATMENT AND PROGNOSIS

Rx

Nonspecific febrile enteroviral infections generally resolve in less than 5 days without sequelae. Because of concern for possible occult bacterial infection, however, significant numbers of young infants and children are hospitalized for evaluation and empirical therapy. After infection, virus may be shed into the nasopharynx for 2 to 6 weeks and in feces for several months.

TABLE 379-3 CLINICAL MANIFESTATIONS OF NONPOLIO ENTEROVIRUS INFECTIONS*

CLINICAL SYNDROME	GROUP A COXSACKIEVIRUSES†	GROUP B COXSACKIEVIRUSES	ECHOVIRUSES	ENTEROVIRUSES

*A great many enterovirus serotypes have been implicated in most of these syndromes, at least in sporadic cases. The serotypes listed are those that have been clearly or frequently implicated. Serotypes with a strong association are underlined.
†Because detection of many of the group A coxsackieviruses originally required suckling mouse inoculation, they are likely to be underreported as causes of illness.
§Conjunctivitis without hemorrhage is frequently seen in association with other manifestations in patients infected with many group A and group B coxsackieviruses and echoviruses, especially coxsackieviruses A9, A16, and B1 to B5 and echoviruses 2, 7, 9, 11, 16, and 30.From Modlin JR. Enterovirus. *Cecil Textbook of Medicine.* 23rd ed. Philadelphia: WB Saunders; 2008, with minor changes.

SPECIFIC CLINICAL SYNDROMES

Central Nervous System Infections

ACUTE FLACCID PARALYSIS

CLINICAL MANIFESTATIONS AND DIAGNOSIS

During poliovirus epidemics, 90 to 95% of infections are subclinical. In another 4 to 8% of patients, infection results in fever, fatigue, headache, anorexia, myalgia, and sore throat, which resolve in 2 to 3 days. Paralytic polio develops in less than 1 to 2% of infected individuals.

Sporadic cases of acute flaccid paralysis can also be seen with other enteroviruses, especially coxsackievirus CV-A7 and enterovirus EV-A71 and occasionally EV-D68. With the exception of EV-A71, the paralysis associated with nonpolio enteroviruses tends to be milder, and fever is absent at the time of onset of the paralysis.[6] The upper extremities and face are more commonly involved. Sensory pathways remain intact.

CSF may reveal a mild lymphocytic pleocytosis (<100 cells/μL) in association with mildly increased protein and normal glucose concentrations. Neuroimaging is not generally useful, but increased signal may be seen on T2-weighted magnetic resonance imaging in the anterior horn regions of the spinal cord in patients whose acute flaccid paralysis is caused by poliovirus and nonpolio enteroviruses.

TREATMENT AND PROGNOSIS

Rx

No specific therapy exists. Efforts should focus on monitoring for the development of respiratory failure or airway compromise as well as control of pain associated with muscle spasms.

The mortality associated with spinal poliomyelitis is about 5%. The mortality rates for enteroviruses associated with nonpolio enteroviral acute flaccid paralysis are not known. Before modern methods of respiratory and cardiovascular support, mortality rates higher than 50% were common in patients with bulbar or medullary poliomyelitis. The ultimate outcome of the paralysis is highly variable and can range from complete resolution to lifelong persistence. The greatest gains in recovery of strength occur during the first 6 months of convalescence. Paralytic limbs become atrophic, thereby leading to skeletal deformities. Patients with nonpolio enteroviruses usually have a more rapid recovery and less atrophy than do those with classic polio.

A syndrome of postpoliomyelitis muscle atrophy, which may be seen in 25 to 85% of individuals 2 to 3 decades after recovery from paralytic disease, is characterized by the gradual development of weakness, pain, and atrophy. Possible mechanisms include aging and neuronal dropout in compromised neuromuscular connections[7] or, less likely, reactivation/ongoing poliovirus infection.

MENINGITIS

The enteroviruses, especially echoviruses and group B coxsackieviruses, are the dominant cause of viral meningitis (Chapter 412) in all ages.[8]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical picture varies with age. The predominant symptoms of meningitis in neonates are nonspecific fever, irritability, lethargy, and poor feeding, often with a full fontanelle and a generalized rash. In neonates with meningoencephalitis, clinical findings may consist of fever, lethargy, seizures, full fontanelle, and focal neurologic abnormalities. Hepatitis, myocarditis, or pneumonitis, singly or in combination, may be present in severe cases.

In older infants and children, an abrupt onset of fever is the most frequent initial symptom. The fever may persist for 1 to 5 days and may exhibit a biphasic pattern. Irritability or lethargy is common. Other nonspecific symptoms include poor feeding, vomiting, diarrhea, and rash. Headache is present in nearly all children old enough to report it. Rash, malaise, sore throat, abdominal pain, and myalgia are common, and photophobia may be reported. Seizures occur in less than 5% of cases. Examination may reveal a full fontanelle. Signs of meningeal irritation (i.e., nuchal rigidity, Brudzinski and Kernig signs) occur in less than 10% of infants younger than 3 months and increase with age.

In adolescents and adults, headache is nearly always present and severe enough to require narcotic analgesics for control. Some patients report temporary relief of headache after lumbar puncture. Fever is not universal, but photophobia, signs of meningeal irritation, nausea, emesis, and neck stiffness occur in more than two thirds of patients. Myalgia is reported in 20 to 90% of patients. Less frequent findings include rash and abdominal pain.

CSF analysis generally reveals a mild to moderate lymphocytic pleocytosis (<500 cells/μL). Some patients, however, may have lymphocyte counts higher than 1000 or have neutrophilic pleocytosis early in the course of illness and then progress to a predominance of lymphocytes hours to days later. In a small percentage of patients, particularly infants, no pleocytosis is present even though enterovirus can be detected. The protein concentration

may be increased. Although the glucose concentration is generally normal, hypoglycorrhachia may occur, particularly in association with group B coxsackievirus meningitis. Neuroimaging in cases of meningitis is generally unrevealing. Nucleic acid amplification testing can detect enteroviruses in CSF. The serotypes most frequently identified from CSF specimens are, in descending order, E-9, E-11, E-30, CV-B5, E-6, CV-B2, CV-A9, E-4, CV-B4, E-7, E-18, E-5, and E-13.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive, with control of fever and pain. Currently available antiviral agents are not helpful. Hospitalization may not be necessary in adolescents and adults who appear well if a bacterial cause can be confidently excluded. In children and infants or when bacterial infection cannot be confidently excluded in adults, hospitalization and initial empirical antimicrobial therapy are advisable (Chapter 412) while awaiting the results of bacterial cultures of blood and CSF. Intravenous fluids may be required to prevent dehydration. Control of headache pain may require narcotic analgesics. Uncommon complications in all ages include coma, increased intracranial pressure, and inappropriate secretion of antidiuretic hormone.

The overwhelming majority of patients recover fully. The duration of illness in infants and children is generally less than 1 week. In adults, full recovery may take up to 3 weeks.

ENCEPHALITIS

The enteroviruses are responsible for up to 22% of identifiable causes of viral encephalitis (Chapter 414). In the single largest report of enterovirus-related encephalitis, 73% of confirmed cases occurred in individuals younger than 20 years, including about 40% of cases in patients younger than 10 years.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of neurologic findings may be abrupt or be preceded by fever, headache, malaise, myalgia, upper respiratory symptoms, rash, nausea, emesis, or diarrhea. Somnolence, lethargy, and altered consciousness are common. Patients may exhibit irritability, changes in personality, or hallucinations. Generalized or focal seizures occur in up to 30% of patients, and a minority of patients may progress to coma. Neck stiffness and ataxia are frequent physical findings. Focal neurologic findings such as hemiplegia, hemichorea, and paresthesias are reported in nearly 30% of patients. The focal nature of the seizures and abnormal neurologic findings may be reminiscent of herpes simplex virus encephalitis (Chapter 374).

Among enteroviral encephalitides, EV-A71 is uniquely associated with severe brain stem encephalitis (rhombencephalitis), primarily in children. The initial manifestation may be a prodrome of either hand-foot-and-mouth disease or herpangina, which is followed by myoclonus that may be associated with ataxia, tremors, or cranial nerve abnormalities and a rapid onset of neurogenic pulmonary edema, shock, coma, and apnea.

Evaluation of CSF may reveal mild to moderate lymphocytic pleocytosis (<500 cells/μL), but the CSF white cell count may be normal. The protein concentration may be increased and may be the sole abnormality. The glucose concentration is generally normal. Enteroviruses may frequently be detectable by nucleic acid amplification testing of CSF.

TREATMENT AND PROGNOSIS

Rx

Management is supportive, with monitoring for the development of respiratory failure or airway compromise. Nearly 50% of patients require intensive care. In patients with focal neurologic findings, empirical acyclovir (10 to 15 mg/kg every 8 hours) is warranted until herpes simplex virus is excluded.

The median duration of hospitalization is less than 1 week, and mortality is below 10%. For severe EV-A71 rhombencephalitis, however, mortality may approach 70%. Long-term sequelae after rhombencephalitis include myoclonus, abducens nerve palsy, facial diplegia, ataxia, dysarthria, internuclear ophthalmoplegia, and central apnea.

Myopericarditis

Members of the Enterovirus B species and especially the group B coxsackieviruses are responsible for approximately a third of cases of acute myocarditis (Chapter 60). The majority of cases occur in young adults.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

An upper respiratory tract infection may precede the onset of cardiac symptoms by 1 to 2 weeks. Fever may be present, and common initial symptoms include dyspnea, chest pain, and fatigue. Physical examination may reveal a gallop rhythm or a pericardial friction rub.

Cardiomegaly may be seen on the chest radiograph. Electrocardiographic findings vary and include low-voltage QRS complexes, ST segment depression, T wave inversion, pathologic Q waves, ventricular arrhythmias, and heart block. Echocardiographic findings include a decreased ejection fraction, ventricular dilation, and pericardial effusion. Blood troponin levels are frequently elevated. Cardiac magnetic resonance imaging may help localize areas of myocarditis. Myocardial biopsy is recommended in selected patients who have refractory heart failure or suspected giant cell myocarditis (Chapter 60); enterovirus can be detected by nucleic acid amplification tests.

TREATMENT AND PROGNOSIS

Rx

Supportive treatment includes bedrest and management of heart failure (Chapter 59), arrhythmias (Chapters 64 and 65), and pericarditis with or without pericardial effusion (Chapter 77). Immunosuppressive therapy is not generally recommended (Chapter 60). In approximately a third of patients with acute myocarditis, chronic dilated cardiomyopathy develops. In patients with pericarditis, recurrent pericardial effusions or chronic constrictive pericarditis may develop in the future.

Exanthems and Enanthems

Enterovirus infections may result in a wide spectrum of febrile exanthems and enanthems, including macular, papular, maculopapular, morbilliform, rubelliform, vesicular, urticarial, papulopustular, and scarlatiniform types. Exanthems are more commonly observed in children 15 years or younger. Any serotype is capable of causing several different rashes. With the exception of CV-A16, no serotype is associated with a unique rash. Echovirus 9 and CV-A9 can cause petechial or purpuric rashes reminiscent of meningococcemia (Chapter 298).

Hand-Foot-and-Mouth Disease and Herpangina

Hand-foot-and-mouth disease is typically associated with Enterovirus A species, particularly CV-A16, CV-A6, and EV-A71.[9] Herpangina is also most commonly caused by the group A coxsackieviruses in the Enterovirus A species, but it has also been associated with group B coxsackieviruses, echoviruses, and enteroviruses from the Enterovirus B species.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hand-foot-and-mouth disease begins with low-grade fever, malaise, anorexia, and oral soreness. In 1 to 2 days, oral macules appear and then rapidly vesiculate and ulcerate. Oral lesions are typically distributed on the buccal mucosa and tongue, but they may also occur on the palate, uvula, anterior pillars, and gums. In approximately two thirds of patients, the enanthem is accompanied by an exanthem, with tender 3- to 7-mm vesicles on the dorsum of the hands and feet, frequently involving the palms and soles. Lesions may appear on the buttocks but tend not to be vesicular. Hand-foot-and-mouth disease associated with CV-A6 has a wider distribution of skin lesions that enlarge and vesiculate. Onychomadesis (loss of fingernails) can occur 1 to 2 months after the infection.

Herpangina begins with high fever, particularly in young patients. Additional findings include sore throat, mild cervical lymphadenopathy, sialorrhea, anorexia, dysphagia, abdominal pain, and emesis. Examination of the mouth and throat reveals 1- to 2-mm papulovesicular, grayish white lesions with an areola of erythema, primarily located on the anterior pillars of the tonsillar fauces. The soft palate, uvula, and tonsils may also be involved. Rarely, the posterior buccal surfaces and dorsal tip of the tongue may be involved. During a period of 2 to 3 days, the lesions increase to 3 to 4 mm in size. On average, five lesions are present.

TREATMENT AND PROGNOSIS

Rx

Hand-foot-and-mouth disease usually resolves in less than 1 week and herpangina generally resolves in 10 days, both typically uneventfully, without the need for hospitalization and without sequelae. Infants and young children may require hospitalization for administration of parenteral fluids. Disease

associated with CV-A6 has a higher rate of hospitalization. Hand-foot-and-mouth disease due to EV-A71 may precede the development of life-threatening rhombencephalitis (see Encephalitis).

Acute Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis (Chapter 423) is associated with EV-D70 and CV-A24. The illnesses caused by the two serotypes are indistinguishable from each other. However, acute hemorrhagic conjunctivitis caused by CV-A24 may be more commonly accompanied by upper respiratory and systemic symptoms and may be associated with less severe conjunctival hemorrhage. High secondary attack rates within households are common. Other enteroviruses can cause acute conjunctivitis or keratoconjunctivitis but generally without hemorrhagic manifestations.

CLINICAL MANIFESTATIONS

An incubation period of about 1 to 2 days precedes the rapid onset of palpebral swelling associated with lacrimation, photophobia, blurring of vision, and severe ocular pain. The hallmark subconjunctival hemorrhages vary in size from petechiae to large blotches. Although transient keratitis occurs frequently, it seldom results in subepithelial opacities. Preauricular adenopathy is common, but fever is not. An ocular mucopurulent discharge may occasionally be present.

TREATMENT AND PROGNOSIS

Rx

Management is supportive. The illness usually persists for 1 to 2 weeks, but complete recovery is generally the rule. A transient lumbar radiculomyelopathy and acute flaccid paralysis–like illness may develop in some patients.

Respiratory Tract Syndromes

The enteroviruses may cause upper and lower respiratory tract syndromes, alone or accompanying other syndromes. As determined by nucleic acid amplification testing, enteroviruses are responsible for up to 15% of upper respiratory tract syndromes. They also cause 18% of lower respiratory tract syndromes in hospitalized children and 25% of hospitalizations in patients with acute wheezing. Recently, EV-D68 and EV-C104 are increasingly recognized as causes of respiratory tract disease.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The enterovirus "summer cold" (Chapter 361) consists of nasal congestion, rhinorrhea, and sneezing. Malaise and cough may be present. Fever and sore throat are typically absent or minimal.

Pharyngitis, tonsillitis, or pharyngotonsillitis begins abruptly with fever and sore throat. The nasopharynx, tonsils, uvula, and soft palate demonstrate erythema and inflammation. Petechiae may be present, and cervical lymphadenitis is common. Other syndromes associated with the enteroviruses include bronchitis (Chapter 96) and bronchiolitis.

Enteroviral pneumonias begin gradually with coryza, anorexia, and low-grade fever. A nonproductive cough, tachypnea, retractions, nasal flaring, and wheezing may be present. In severe cases, cyanosis may develop. The chest radiograph may demonstrate perihilar infiltrates, patchy consolidation, air trapping, and atelectasis. Recently, EV-D68 has become a cause of significant respiratory disease, primarily in young children and infants but also in adolescents and adults. An underlying pulmonary condition such as asthma or wheezing has been reported in 70% to 80% of cases. EV-D68-associated respiratory syndromes include pneumonia, bronchiolitis, asthmatic bronchitis, asthma exacerbation, and wheezing. Signs and symptoms include cough, wheezing, dyspnea, tachycardia, and inter- and subcostal retractions. Acute flaccid paralysis is a rare complication. Interestingly, fever may be absent, but hypoxia is common. The chest radiograph may show infiltrates and atelectasis.[10]

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive and consists of control of fever and pain. In older children and adults, hospitalization is not usually required. Resolution occurs in 7 days or less. Hospitalization and admission to an intensive care unit may be required for respiratory support of EV-D68 infection. Death is uncommon but does occur.

Myositis

PLEURODYNIA

The group B coxsackieviruses are the major cause of sporadic and epidemic pleurodynia, but the syndrome may also be caused by a limited number of echoviruses and group A coxsackieviruses within the Enterovirus A and B species.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The onset of illness is abrupt in approximately 75% of patients. In the remainder, the onset of pleuritic chest pain is preceded by a prodrome of headache, malaise, anorexia, and vague myalgia lasting up to 10 days. Pain may be referred to the lower ribs or the sternum, and it can radiate to the shoulders, neck, or scapula. Pain is exacerbated by deep breathing, coughing, sneezing, or movement. During paroxysms, patients tend to be tachypneic and to have shallow breathing. Additional findings can include abdominal pain, headache, cough, anorexia, nausea, vomiting, and diarrhea. Fever may be biphasic.

Physical examination does not generally reveal muscle tenderness, obvious myositis, or muscle swelling. A pleural friction rub may be present in 25% of patients. The chest radiograph is typically normal.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive, with an emphasis on nonsteroidal analgesics (e.g., ibuprofen, 200 to 400 mg per dose every 4 to 6 hours) or hydrocodone (5 to 10 mg four times per day) alone or in combination with acetaminophen to control pain. The symptoms may persist for 1 to 14 days (mean of 3.5 days) and resolve without sequelae, although recurrent symptoms may occur in 25% of patients.

INFLAMMATORY MYOSITIS

Multiple enteroviral serotypes are associated with focal or generalized myositis. In patients with B-cell immunodeficiencies, a dermatomyositis-like syndrome may develop.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nonspecific findings include fever and chills. Involved muscles may be weak, tender, and edematous. Chemical evidence of myositis may be evidenced by elevated serum levels of creatine kinase, myoglobinemia, and myoglobinuria.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. With the exception of patients with B-cell immunodeficiencies, recovery is complete and rapid.

Enterovirus Infections in Special Populations

PATIENTS WITH B-CELL IMMUNODEFICIENCIES

Nonpolio enteroviruses and polioviruses may result in chronic or prolonged infections in patients with congenital or acquired B-cell immunodeficiencies (Chapter 250), such as those with X-linked agammaglobulinemia, hyper-IgM syndrome, severe combined immunodeficiency syndrome, or common variable immunodeficiency, or in patients receiving chemotherapy or immunomodulatory therapies, especially rituximab, who are undergoing bone marrow or solid organ transplantation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Meningoencephalitis, pulmonary infections, and severe gastroenteritis can occur. The initial symptoms may consist of only persistent headaches and lethargy. As the disease progresses, additional neurologic findings develop and may include ataxia, loss of cognitive skills and memory, dementia, emotional lability, paresthesias, weakness, dysarthria, and seizures. Non-CNS manifestations include a dermatomyositis-like syndrome, edema, exanthems, and hepatitis. CSF demonstrates a persistently elevated protein concentration and pleocytosis. Enterovirus is detectable in CSF by RT-PCR.

TREATMENT AND PROGNOSIS

Rx

Children with humoral immunodeficiency (Chapter 250) should receive lifelong immunoglobulin replacement therapy in an attempt to prevent chronic infection. However, chronic meningoencephalitis develops in some patients and is usually ultimately fatal. Severe or fatal enteroviral infections have been reported in individuals receiving rituximab.

PREVENTION

Handwashing is the primary method for the prevention of enteroviral infections. Only poliovirus infections are currently preventable through vaccination. However, successful trials of inactivated EV-A71 vaccines have been completed in China.[A1,A2] These vaccines could significantly reduce the incidence of severe EV-A71 CNS disease in China. Whether the vaccine will be effective in other regions of the world will depend on its ability to protect from disease caused by the different genotypes found worldwide.

REVIEW QUESTIONS

1. An 18-year-old female college freshman presents to the emergency department in early autumn for evaluation of severe headache of 36 hours' duration. She has had two episodes of nonprojectile emesis and complains of diffuse myalgia, photophobia, and phonophobia. She has had no ill contacts and has never been sexually active. She received conjugated meningococcal vaccine the summer before beginning college, and her childhood immunizations are complete. She has no significant past medical history and takes no medications other than oral contraceptives. Physical examination findings: temperature, 38.5° C; heart rate, 100/minute; respiratory rate, 20/minute; blood pressure, 110/70 mm Hg. She appears mildly distressed but is awake, alert, and talkative. Her pharynx is slightly injected. Her neck is tender to flexion. Her neurologic examination reveals positive Kernig and Brudzinski signs. Funduscopy reveals normal optic discs. Which of the following is the most likely etiology of this woman's syndrome?

A. Echovirus 9
B. *Neisseria meningitidis* type C
C. Human immunodeficiency virus
D. *Haemophilus influenzae* type b
E. None of the above

Answer: A The symptoms and mild clinical findings together with the time of year are consistent with an enteroviral infection. *Neisseria meningitidis* type C would be unlikely in this patient. She received conjugated meningococcal vaccine before starting college. Strains A, C, W-135, and Y are covered by the conjugated meningococcal vaccine. The patient has no risk factors for the acquisition of human immunodeficiency virus. The patient has received all of the childhood vaccinations, which would have included conjugated *Haemophilus influenzae* type b vaccine.

2. An 18-year-old man is brought to the emergency department for evaluation of fever of 2 days' duration and headache. The onset of the fever was sudden. Eight hours ago, he developed a headache and neck stiffness, and he has vomited three times. He complains that the light hurts his eyes. In the last 2 weeks, multiple siblings have had nonspecific febrile illnesses. His childhood immunizations are up to date, including conjugated meningococcal vaccine. Physical examination findings: temperature, 38.2° C; heart rate, 96/minute; respiratory rate, 29/minute; blood pressure, 118/78 mm Hg. He appears moderately distressed but is awake and alert. His neck is tender to flexion, and his neurologic examination reveals positive Kernig and Brudzinski signs. A lumbar puncture is performed and reveals the following: red blood cells, 0; white blood cells, 75/μL: 95% lymphocytes, 5% neutrophils; protein, 65 mg/dL; glucose, 90 mg/dL; Gram stain, no organisms seen. Which of the following studies would most likely establish the etiology of this adolescent's syndrome?

A. Cell culture detection of the etiologic agent from the cerebrospinal fluid (CSF)
B. Reverse transcription–polymerase chain reaction (RT-PCR) detection of the etiologic agent from the CSF
C. Magnetic resonance imaging of the brain
D. Serologic testing for the etiologic agent from the CSF
E. All of the above

Answer: B RT-PCR is the method of choice for the detection of the enteroviruses. RT-PCR can detect even noncultivable enterovirus serotypes. It has greater sensitivity than cell culture and can be performed in hours. Cell culture has been replaced by RT-PCR as the diagnostic method. The clinical usefulness of cell culture is limited by its lack of sensitivity, the time required to obtain a positive result, and the lack of growth of some enterovirus serotypes. Neuroimaging in cases of viral meningitis is generally unrevealing. Serologic testing is of limited use because of the large number of serotypes that compose the genus Enterovirus. A four-fold change in antibody titer to a specific serotype of enterovirus in paired acute and convalescent sera is required for diagnosis. The clinical utility of serologic testing is limited by the need for acute and convalescent specimens.

3. A 31-year-old man is being evaluated for sudden onset of chest pain involving the lower ribs and sternum. The pain, which is described as stabbing and which occasionally radiates to his shoulder, is exacerbated by deep inspiration or movement. The onset of the pain was preceded by 5 days of fever, headache, malaise, and anorexia. His past medical history is noncontributory. Physical examination findings: temperature, 38.5° C; heart rate, 116/minute; respiratory rate, 32/minute; blood pressure, 128/88 mm Hg. He is in obvious pain but is awake and alert. His ears, nose, and throat are normal. His neck is supple. Heart sounds are normal. He is tachypneic and breathing shallowly, but his lungs are clear. His abdominal examination findings are normal. A chest radiograph and electrocardiogram are both normal. Which of the following is the most likely syndrome?

A. Pneumonia due to enterovirus 68
B. Myocarditis due to coxsackievirus B3
C. Pleurodynia due to coxsackievirus B5
D. Herpangina due to coxsackievirus A4
E. None of the above

Answer: C The sudden onset of chest pain, preceded by fever and vague constitutional symptoms, is characteristic of pleurodynia. The pain may be exacerbated by deep breathing or movement. Radiation of the pain to the shoulders, back, or neck may occur. The absence of pulmonary findings (cough, wheezing) and a normal chest radiograph argue against an enteroviral pneumonia. Enteroviral myocarditis may be preceded by an upper respiratory tract infection. Common symptoms include dyspnea, chest pain, and fatigue. Physical examination may reveal a gallop rhythm or a pericardial friction rub. Cardiomegaly may be seen on the chest radiograph. Electrocardiographic findings vary and include low-voltage QRS complexes, ST segment depression, T wave inversion, pathologic Q waves, ventricular arrhythmias, and heart block. Herpangina begins abruptly with high fever; sore throat, mild cervical lymphadenopathy, sialorrhea, and dysphagia are common. An enanthem consisting of papulovesicular, grayish white lesions with an areola of erythema is seen in the mouth and throat.

4. A large community epidemic of echovirus 30 meningitis is affecting all age groups. Which of the following is the most likely mode of transmission of the virus?

A. Respiratory
B. Fomites
C. Blood-borne
D. Fecal-oral
E. All of the above

Answer: D The majority of enteroviruses are transmitted through the fecal-oral route. A few enteroviruses responsible for upper and lower respiratory tract infection are transmitted by the respiratory route. Fomites have been associated with the transmission of enteroviruses associated with hemorrhagic conjunctivitis but are not the major mode of transmission. Blood-borne transmission of the enteroviruses has not been reported.

ROTAVIRUSES, NOROVIRUSES, AND OTHER GASTROINTESTINAL VIRUSES

MANUEL A. FRANCO AND HARRY B. GREENBERG

DEFINITION

Viruses are a principal cause of acute infectious gastroenteritis, a syndrome of vomiting, watery diarrhea, or both that begins abruptly in otherwise healthy persons. Two distinct viruses account for the majority of cases. Rotaviruses are the most frequent cause of sporadic, severe gastroenteritis in young children and are responsible for the death of approximately 1200 children daily worldwide,[1] mainly in developing countries. Noroviruses are the primary cause of epidemic infectious gastroenteritis in both infants and adults in developed countries. For example, outbreaks of gastroenteritis in closed settings, such as cruise ships and nursing homes, are a typical manifestation of norovirus infections. However, noroviruses are also a common cause of sporadic, severe gastroenteritis in young children.[2]

The Pathogens

Noroviruses

Noroviruses, which are one of the five genera of the Caliciviridae family, are nonenveloped, icosahedral viruses with a relatively small, positive-sense, single-stranded RNA genome. The norovirus genus is further classified into five genogroups (GI to GV), only three of which (GI, GII, and GIV) are known to infect humans. GIII and GV viruses infect bovines and mice, respectively, and to date these animal viruses have not been shown to infect humans. Viruses in each genogroup are further divided into genotypes (more than 25 have been described) and subgroups. Norwalk virus is a prototype genogroup I genotype 1 (GI.1) virus. The norovirus genome is approximately 7.7 kilobases in size and consists of three open reading frames, the first of which encodes the nonstructural proteins that are essential for virus replication. The second open reading frame encodes the major capsid protein, viral protein 1 (VP1). When it is expressed as a recombinant protein, 180 molecules of VP1 autoassemble into virus-like particles (VLPs) that are critical to the study of noroviral epidemiology and immunity. Human noroviruses have not yet been adapted to cell culture, so diagnosis generally depends on amplification of virus genes by the polymerase chain reaction (PCR; see later) or use of VLPs as recombinant antigens for serologic analysis.

Rotavirus

Rotaviruses, which belong to the family Reoviridae, are large, icosahedral, nonenveloped viruses with a segmented, double-stranded RNA genome and a triple-layered protein coat. Rotaviruses are classified into groups A through G on the basis of the presence of cross-reactive antigenic epitopes and their overall genetic relatedness. Group A rotaviruses are the most commonly encountered viral enteric pathogens of young humans and many other species. Group B viruses have been identified sporadically in outbreaks of adult diarrheal illness in China and more recently in studies of children with sporadic gastroenteritis, principally in India. Group C rotaviruses are primarily veterinary pathogens and are infrequently associated with diarrheal disease in humans and animals around the world compared with group A rotaviruses. Groups D through G rotaviruses have been isolated only from animals, primarily avian species. Rotaviruses are 100-nm particles that have three concentric layers of proteins: the core is composed of VP1, VP2, and VP3 and the segmented, double-stranded RNA genome; the intermediate layer is formed by VP6, the most abundant and antigenic structural viral protein; and the external layer is composed of VP7 and VP4. The genome, which is composed of 11 segments of double-stranded RNA that together are approximately 18 kilobases in length, encodes six structural and six nonstructural proteins. As is the case among virtually all other RNA viruses, the rotavirus RNA polymerase is error prone and, along with selective pressure such as the evolution of immunity, drives viral diversity. For rotaviruses, gene reassortment, which is the mixing of gene segments from different parental viruses in cells coinfected by two or more strains, and rearrangement of the viral genome also contribute to genetic diversity. Reassortment of gene segments between animal and human rotavirus strains also occurs in natural settings, especially in less developed countries.

Other Agents

Other viral agents that cause human acute infectious gastroenteritis that is difficult to distinguish from disease caused by rotaviruses and noroviruses include the sapovirus (like norovirus, a member of the Caliciviridae family), enteric adenoviruses (Chapter 365) belonging to types 40 and 41, and astroviruses (Table 380-1). The frequency of detection (by PCR assays) of these viruses in individuals with acute gastroenteritis depends on the setting, but they are almost always detected much less frequently than are rotaviruses and noroviruses.[3] Coronaviruses (Chapter 366), toroviruses, picobirnaviruses, picornavirus (Chapter 379), bocavirus, parechoviruses, and pestiviruses have also been isolated occasionally from persons with acute gastroenteritis, but their roles as causative agents of enteric disease remain uncertain. Among patients with acute gastroenteritis, no etiologic agent is found in approximately 25 to 50% of cases.

EPIDEMIOLOGY

Norovirus

Over time, noroviruses appear to undergo antigenic drift in response to the acquisition of immunity in the general population, much like influenza viruses.[4] At present, gastroenteritis cases around the world are most frequently caused by the GII.4 norovirus strain, but new strains generally evolve every 2 to 4 years owing to antigenic drift. Outbreaks frequently take place in settings of close human contact, such as military establishments, cruise ships, nursing homes, and schools, especially in cold and dry weather (see Table 380-1). Viral spread is enhanced by the very high level of infectivity of noroviruses, as data suggest that 1 to 10 particles constitute an infectious dose.

Noroviruses of genotypes GII.4 and GII.3 also are responsible for about 12% of sporadic gastroenteritis in children younger than 5 years in both developed and developing countries. In the United States, noroviruses have recently surpassed rotavirus as the principal cause of medically attended visits for gastroenteritis in children younger than 5 years.[5] In the United States, noroviruses cause an estimated average of 570 to 800 deaths, 56,000 to 71,000 hospitalizations, 400,000 emergency department visits, 1.7 to 1.9 million outpatient visits, and 19 to 21 million total illnesses per year. The

TABLE 380-1 EPIDEMIOLOGIC AND CLINICAL FEATURES OF NOROVIRUS AND ROTAVIRUS

	NOROVIRUS	ROTAVIRUS	ASTROVIRUS
Epidemics	Occurs year-round; outbreaks tend to peak in cold weather	Year-round in equatorial countries; winter peak in others	Winter epidemics in children and endemic year-round
Key driver of epidemics	Antigenic drift strains promoted by population-based immunologic pressure	Size of the susceptible birth cohort	Unknown
Transmission	Fecal-oral, water, and food-borne outbreaks	Fecal-oral	Fecal-oral
Severity of diarrhea in children	Generally mild but can be severe	Most severe	Milder than rotavirus or noroviruses
Reservoir	Humans are the only known reservoir of noroviruses that infect humans	Mostly humans, but rotaviruses from farm animals and pets (especially in developing countries) infect humans	Humans are the only known reservoir of astroviruses that infect humans
Prevention	Viral protein 1–based vaccine in development	Several vaccines available	No vaccine in development
Age predisposition	All ages	Children <5 years; disease transmission in older family contacts is low (<25%)	Generally children, but adults may also get disease

death toll principally occurs in the elderly, and the health care costs principally occur in children younger than 5 years.[6]

Rotavirus

The incidence of rotaviral disease is similar in children in both developed and developing countries, suggesting that measures such as access to clean water will not replace the need for an effective vaccine. Before the introduction of an effective vaccine, rotavirus was estimated to be responsible for about 600,000 annual deaths worldwide. In developed countries, rotavirus rarely is fatal; but before the introduction of vaccines in the United States, it resulted in hospitalization for rotavirus-mediated gastroenteritis in about 1 in 75 children by 5 years of age.

In the temperate zones of the world, rotaviral infection occurs primarily during epidemic peaks in the cooler months of the year (see Table 380-1). This pattern is not seen, however, in countries within 10 degrees of the equator, where infection occurs in an endemic fashion year-round. Before the introduction of rotavirus vaccination, a yearly wave of rotaviral illness spread across the United States and Europe following peculiar spatiotemporal patterns. In the United States, this pattern of spread has been correlated with variation in birth rates, thereby suggesting that the number of babies experiencing their first infection is one of the primary drivers of rotavirus epidemics. The high birth rates in developing countries may also influence the differential epidemiologic distribution of rotaviruses. The widespread use of rotavirus vaccine has greatly reduced or eliminated this spatiotemporal spread of rotavirus in the United States.

Antibodies against the outer capsid proteins are the basis of serotypic classification of rotaviruses into G (glycoprotein, VP7) and P (protease-sensitive, VP4) serotypes. For technical reasons, P serotyping reagents are infrequently available, and classification is based on the P genotype (provided in brackets). Worldwide, most human infections are caused by five types of group A rotavirus; P[8]G1 is by far the most common (approximately 53% of strains), followed by P[8]G3, P[4]G2, P[8]G9, and P[8]G4. In some developing areas like India, Brazil, and Africa, P[6]G9, G5, and G8 rotaviruses, respectively, are frequently encountered. Some human rotavirus strains may have arisen after reassortment with bovine or porcine rotaviruses. A high prevalence of G12 viruses has recently been observed in several countries, thereby suggesting that this serotype may be an emerging rotavirus strain. Results from a large multicenter study in sub-Saharan Africa and south Asia, where most of the gastroenteritis deaths in children younger than 5 years of age occur, confirmed that rotavirus is the most common etiologic agent of this syndrome and causes an important nutritional burden in children.[7]

PATHOBIOLOGY

Norovirus

Histo-blood group antigens (HBGAs) are the receptors for noroviruses and determine susceptibility to disease in a strain-specific manner. The HBGAs are complex carbohydrate oligosaccharides linked to proteins or lipids that are expressed on the mucosal epithelia of the digestive tract. All three major families of HBGA, the ABO, Lewis, and secretor families, are involved in binding noroviruses. The secretor status of a person is controlled by the fucosyltransferase 2 (*FUT2*) gene. Secretor-negative individuals are specifically resistant to infection with the Norwalk virus (GI.1) and some GII viruses.

Although norovirus RNA has been detected in the blood stream of up to 15% of patients with norovirus gastroenteritis, the site of primary viral replication is most probably in the gastrointestinal tract. Consistent with the strong association of vomiting with norovirus disease, gastric emptying is delayed. Proximal jejunal biopsy specimens show blunting of the villi with crypt cell hyperplasia and cytoplasmic vacuolation, sometimes with an increase in epithelial cell apoptosis. A functional alteration of the epithelial barrier is likely to occur. Unknown at present is the effectiveness and persistence of long-term immunity in the context of natural infection, in which the infectious dose is generally quite low.

Rotavirus

For rotaviruses, HBGAs have also been recently proposed as receptors that determine susceptibility to disease in a strain-specific manner. Rotaviruses replicate in the villus tip cells of the small bowel, where the pathologic process includes shortening and atrophy of the villi, vacuolization of enterocytes, mononuclear infiltration in the lamina propria, and distention of the cisternae of the endoplasmic reticulum. However, the severity of clinical disease has not been directly related to the extent of intestinal disease; rather, it is related to levels of viral RNA in stool.

During the initial phases of the disease, altered intestinal secretion, motility, and permeability contribute to the pathophysiologic mechanism of diarrhea. Later in the course of disease, malabsorption can occur. Rotaviral NSP4, encoded by rotavirus gene 10, is a viral enterotoxin that mediates, at least in part, the early secretory components of the diarrhea. It has also been postulated that viral infection increases intestinal motility by stimulating the enteric nervous system, possibly through NSP4. Whether and to what degree the enterotoxic effect of NSP4 is clinically relevant in children or other animal species remains to be determined. Infected individuals have a short period of viremia, but its clinical consequences are unclear other than correlating with the level of fever. However, most rotavirus-infected children have mild elevations in hepatic enzymes, thereby suggesting that low-level hepatitis is a common occurrence.[8]

Rotavirus serum IgA levels measured shortly after natural infection in children generally correlate with intestinal IgA levels and appear to correlate with protection.[9] One explanation for recurrent rotavirus (and norovirus) infections is that protection from reinfection is mediated by intestinal IgA, which is not long-lasting in humans. Another explanation is that protection is dependent on neutralizing antibodies to one or both of the highly variable outer rotaviral proteins. However, a monovalent P[8]G1 vaccine induces significant protection against strains with different serotypes, thereby supporting the conclusion that protective immunity to rotavirus infection is, in large part, heterotypic.

CLINICAL MANIFESTATIONS

Norovirus

The clinical manifestations of norovirus infection are variable and depend in part on the age of the individual infected. About one third of infections are asymptomatic, but symptoms include diarrhea, nausea, vomiting, abdominal cramps, fever, and malaise that generally persist for 1 to 3 days. In children younger than 11 years, disease typically begins with the sudden onset of vomiting and can last 4 to 6 days. Virus can be shed in low titers for up to 8 weeks from otherwise healthy individuals and for more than a year in patients

with severe immunodeficiency syndromes. In neonates and premature infants, vomiting often is not a symptom, and infection has been associated with necrotizing enterocolitis. To support the diagnosis of norovirus outbreaks, the following four criteria have been proposed: (1) vomiting in more than half of affected persons; (2) mean (or median) incubation period of 24 to 48 hours; (3) mean (or median) duration of illness of 12 to 60 hours; and (4) absence of bacterial pathogens in stool culture.

Rotavirus

Rotavirus diarrhea and dehydration tend to be more severe than illness caused by the other childhood enteric pathogens. Rotavirus diarrhea is watery, persists for approximately 5 days, is often preceded by the sudden onset of vomiting, and is frequently accompanied by fever and dehydration. The incubation period of rotavirus is estimated to be less than 48 hours. Viral excretion in feces persists for 10 days in the majority of children and can persist for up to 57 days. Excretion times are longer on examination by sensitive PCR-based assays rather than solid-phase immunoassay. By the age of 5 years, virtually all children have acquired immunity to rotavirus, and severe disease after this age is uncommon.

DIAGNOSIS

Norovirus

Reverse transcription–PCR (RT-PCR) is currently the procedure of choice to detect norovirus in clinical specimens, in food, and in water. Although enzyme-linked immunosorbent assays (ELISAs) to detect noroviruses are available in Europe, their sensitivity is genotype dependent, and diagnostic specificity and sensitivity vary on the basis of the diversity of the circulating strains in the population. Moreover, these immunoassays are not easily adaptable for detection of new strains. Norovirus RNA is detected by RT-PCR in stool samples of up to 16% of healthy individuals, a finding that complicates the diagnosis of norovirus gastroenteritis. Although the relationship between disease symptoms and viral load has not been fully established, a quantitative real-time RT-PCR has been proposed to establish a relative threshold of positivity for attributing disease to norovirus.

Rotavirus

Before the introduction of the rotavirus vaccine in developed countries, well above 50% of the moderate to severe diarrheal episodes in young children during the rotavirus "season" were due to rotavirus. In tropical countries, the presence of other enteric pathogens and the absence of seasonal occurrence of rotaviral disease make it more difficult to determine which diarrheal episodes are caused by rotavirus without a diagnostic assay. Numerous ELISAs for rotavirus are commercially available, and these are generally sensitive, specific, and easy to use under most conditions. PCR has increased sensitivity for detection of rotavirus and has permitted easy typing of viruses. With PCR-based methods, however, up to 29% of healthy children younger than 1 year may be rotavirus positive, so it is difficult to associate the detection of the virus with gastroenteritis. Thus, ELISA or quantitative RT-PCR (using a threshold level as for norovirus) is preferable for diagnosis of rotavirus gastroenteritis.

PREVENTION

Norovirus

The development of a norovirus vaccine for humans is likely to be a challenge owing to the antigenic heterogeneity among circulating strains, the propensity of noroviruses to undergo antigenic drift, waning immunity, and the lack of well-established correlates of protection. Nevertheless, a new VLP-based vaccine candidate has recently shown promising efficacy in the experimental viral challenge setting.

High percentage alcohol-based sanitizers (99.5% ethanol) and 10% povidone-iodine antiseptics are superior to other alcohol-based sanitizers at reducing norovirus contamination. Simple household antimicrobial hand soap and handwashing with tap water also decrease viral contamination.

Rotavirus

The first vaccine (Rotashield [Wyeth-Lederle]), which was a quadrivalent mixture of rhesus-human rotavirus reassortants, each containing a G protein from a common human rotavirus serotype, was licensed for use in the United States but subsequently withdrawn from the market because of its association with intussusception. Subsequently, two second-generation vaccines were shown in large studies to be safe, effective, and cost-effective in developed and developing countries. The two current rotavirus vaccines have been based on two different approaches. One type of vaccine (RV5, RotaTeq [Merck]) uses a modified pentavalent vaccine made of a mixture of bovine and human reassortant rotaviruses. Another approach (RV1, Rotarix [GlaxoSmithKline]) is a monovalent attenuated human virus vaccine. Neither type of vaccine prevents subsequent rotavirus infection or mild illness, but both types effectively prevent severe illness, especially in developed countries.

Protection rates in developed and middle-income countries for each rotavirus vaccine are similar, varying from 70 to 80% against any rotavirus disease and 90 to 100% against severe gastroenteritis. Recent evidence suggests that both licensed vaccines slightly increase the risk of intussusception,[10,11] but their benefits far outweigh this low-level risk. Even in the United States, where the burden of severe disease from rotavirus is lowest, the rotavirus vaccine has significantly reduced health care utilization and expenses for diarrhea in children.

In the United States, vaccination also has had an unexpected effect on rotavirus-induced diarrhea among unvaccinated persons, thereby suggesting the induction of herd immunity. The U.S. Advisory Committee on Immunization Practices (Chapter 18) and the World Health Organization[12] now recommend the routine use of these vaccines.

Currently available vaccines are only about 50% efficacious against severe diseases in the poorest developing countries. Even with this reduced effectiveness, however, the two licensed vaccines are still cost-effective in the less developed world.

TREATMENT Rx

Because both norovirus and rotavirus disease resolves within days without treatment, the basic therapeutic goal is to prevent acute dehydration. The recommended oral rehydration salts solution, which now has an osmolarity of 331 mmol/L, is as effective as higher osmolarity solutions. After rehydration, rapid age-appropriate refeeding is recommended. Rotavirus disease induces self-limited intestinal lactase deficiency, but lactose-containing products, particularly maternal milk, should not be withheld.

Passive oral immunotherapy with diverse preparations of immunoglobulins can shorten the duration of rotavirus infection but probably is economically feasible only for immunodeficient patients or low-birthweight infants in the developed world. Recently in Bangladesh, llama-derived, heavy-chain antibody fragment specific for rotavirus was able to reduce stool output in male infants with severe rotavirus-associated diarrhea. *Lactobacillus*, a bacterium present in yogurt, is safe and, in limited studies, appears moderately effective for treatment of acute rotavirus gastroenteritis. Nonetheless, different preparations of lactobacilli vary greatly in dose of bacteria, and a general recommendation on their use has not been issued. Several studies in developing countries have shown that zinc supplementation (10 mg/day for infants younger than 6 months and 20 mg/day for older children) is useful for the treatment and prevention of diarrhea, but further studies are needed to determine whether treatment will be useful in all developing and developed countries.

At present, no pharmacologic treatment of rotavirus or norovirus diarrhea is recommended.[13] Racecadotril (4.5 mg/kg per day), an enkephalinase inhibitor that acts on the enteric nervous system, has been shown to be useful as an adjunct to treat rotaviral diarrhea in several small studies. Ondansetron (0.15 mg/kg per day), a serotonin antagonist, is effective in reducing the emesis from gastroenteritis during the phase of oral rehydration. In several small studies, nitazoxanide (15 mg/kg per day) was helpful in the treatment of rotavirus gastroenteritis. More studies are needed before any of these various preparations can be generally recommended for treatment of rotavirus diarrhea.

REVIEW QUESTIONS

1. The principal agent of sporadic, severe gastroenteritis in young children worldwide is

A. Rotavirus
B. Norovirus
C. Astrovirus
D. All of the above
E. None of the above

Answer: A With the advent of rotavirus vaccines, norovirus has become the leading cause of medically attended acute gastroenteritis in the United States. Worldwide, however, rotavirus continues to be the first cause of severe gastroenteritis.

2. The most probable diagnosis of an adult with viral acute gastroenteritis related to a food-borne outbreak is

A. Rotavirus
B. Norovirus
C. Poliovirus
D. All of the above
E. None of the above

Answer: B Of these infections, only noroviruses are associated with food-borne gastroenteritis outbreaks and disease in adults.

3. Diagnosis of both norovirus and rotavirus acute gastroenteritis can optimally be performed with

A. Viral culture
B. Enzyme-linked immunosorbent assay (ELISA)
C. Quantitative reverse transcription–polymerase chain reaction (RT-PCR) testing using a threshold level
D. B or C
E. None of the above

Answer: C Quantitative RT-PCR (using a threshold level) is an optimal diagnostic strategy for both rotavirus and norovirus. RT-PCR for rotavirus without use of a threshold level will identify viral RNA in asymptomatic children. ELISA can be used for the diagnosis of rotavirus but not norovirus because these assays have variable sensitivity, depending on the norovirus genotype.

381 VIRAL HEMORRHAGIC FEVERS

DANIEL G. BAUSCH

DEFINITION

Viral hemorrhagic fever is an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock. It may be caused by more than 30 different viruses from four taxonomic families, Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae (Table 381-1), although not every virus in these families causes the syndrome. Hemorrhagic fever viruses are often named after the site of the first recognized case. All are single-stranded lipid-enveloped RNA viruses with small genomes (10 to 19 kilobases) that can be relatively easily inactivated in the environment. Pathogenicity varies widely by the specific virus and sometimes among strains of the same virus. Many of the hemorrhagic fever viruses have been placed on the Centers for Disease Control and Prevention select agents list of pathogens that pose a potential bioterrorism threat (Chapter 21).

EPIDEMIOLOGY

Maintenance in Nature and Transmission to Humans

With the exception of dengue virus, for which humans can now be considered the reservoir, hemorrhagic fever viruses are zoonotic, maintained in nature in mammalian reservoirs (see Table 381-1). Although viral hemorrhagic fevers collectively can be found worldwide, the endemic area of any given hemorrhagic fever virus is usually smaller than the extent of its natural reservoir or arthropod vector. With the exception of dengue and some hantaviruses, human infection is generally infrequent. Humans are dead-end hosts.

Hemorrhagic fever viruses may be transmitted to humans by usually inadvertent, direct exposure of mucous membranes or broken skin to the infected blood or excreta of its animal reservoir or, in the case of the flaviviruses and most of the bunyaviruses, by the bite of an arthropod vector. The infectious dose for most hemorrhagic fever viruses appears to be low, sometimes on the order of just a few virions. Aerosol transmission is not a predominant mode of spread, if it occurs at all, but studies in nonhuman primates show that transmission of many hemorrhagic fever viruses is possible through artificial aerosols, thereby raising the possibility of their potential use as bioweapons (Chapter 21).

Bat-Borne Viruses

The filoviruses (from the Latin *filo,* "thread," referring to their filamentous shape), Marburg and Ebola, are perhaps the most feared of all hemorrhagic fever viruses.[1] Fruit bats appear to be the filovirus reservoir, with transmission to humans likely from exposure to infected bat excreta or saliva. Nonhuman primates, especially gorillas and chimpanzees, and other wild animals may become infected, presumably from similar bat exposure, and transmit filoviruses to humans through contact with blood and body fluids of these animals, usually in association with hunting. Nonhuman primates, which are also dead-end hosts who develop severe and usually fatal disease similar to that seen in humans, may be easier prey for hunters when sick. Because hemorrhagic fever viruses are rapidly inactivated by heating, infection probably occurs by exposure during butchering and preparation. In the Philippines, Ebola Reston virus has been isolated from pigs that were presumably infected from exposure to bats.

In the recent outbreak in West Africa, which began in March, 2014, more than 20,000 cases and 8,000 deaths were confirmed by the end of the calendar year—numbers that dwarf all prior Ebola outbreaks combined.[2] The response has been hampered by limited facilities and trained medical personnel, some of whom have themselves become infected and died.

Rodent-Borne Viruses

Arenaviruses (from the Latin *arena,* "sand," referring to their sandy appearance on electron microscopy) are divided into two groups: the Old World (or lymphocytic choriomeningitis/Lassa) complex and the New World (or Tacaribe) complex.[3] Lassa virus and Lujo virus are found in Africa, whereas Junín, Machupo, Guanarito, Sabiá, and Chapare viruses are found in South America. Although there may be subtle differences among the syndromes produced by the New World arenaviruses, they are usually grouped together simply as the South American hemorrhagic fevers.

The genus Hantavirus of the Bunyaviridae family is similarly divided into Old and New World groups. The Old World hantaviruses, such as Hantaan, Seoul, and Puumala, among many others, cause hemorrhagic fevers with prominent renal involvement across Europe and Asia. New World hantaviruses, such as Sin Nombre and Andes, among many others, cause a viral hemorrhagic fever named hantavirus pulmonary syndrome, sometimes also called hantavirus cardiopulmonary syndrome to emphasize the significant cardiogenic component of this disease.

Pathogenic arenaviruses and hantaviruses are maintained in nature through chronic asymptomatic infection in rodents of the *Muridae* family, with a strict pairing between the specific virus and rodent species. Transmission between rodents may be by vertical or horizontal transmission or both, depending on the specific virus. Transmission to humans occurs through exposure to rodent excreta, either from aerosols produced when rodents urinate or by direct inoculation to the mucous membranes. Secondary aerosol generation is notoriously inefficient, so disturbing shed urine is a less likely mechanism of infection. In West Africa, Lassa virus is sometimes contracted when rodents are trapped and prepared for consumption or, more rarely, through a rodent bite. Experimental data suggest that humans may be infected with arenaviruses by the oral route.

The rodents that transmit Lassa, Machupo, and many of the Old World hantaviruses commonly invade the peridomestic environment, thereby putting housewives, children, and others who spend time at home at risk. In contrast, the reservoirs for Junín, Guanarito, and most of the New World hantaviruses typically inhabit agricultural fields, wood lots, or other rural habitats, thereby putting outdoor workers, campers, and hikers at risk.

Mosquito-Borne Viruses

Rift Valley fever virus is maintained in domestic livestock, such as cattle, buffalo, sheep, goats, and camels, in which it often provokes spontaneous abortion. The virus may be transmitted to humans by direct exposure to these animals, especially during parturition, or by mosquitoes. Farmers, abattoir workers, and veterinarians are at particular risk.[4]

Yellow fever virus is maintained in a cycle between monkeys and forest canopy mosquitoes. Sporadic cases occur when humans are bitten by these mosquitoes. Larger outbreaks occur when humans bring the virus back to more settled environments, where the urban mosquito *Aedes aegypti* can spread the virus directly between humans. *Ae. aegypti*, which typically lay eggs in artificial containers around the home and bite during the day, become infective a few weeks after feeding on a viremic monkey or human. Sanitation and mosquito control measures have virtually eliminated urban yellow fever in the Americas, but urban outbreaks continue to occur in Africa. For example, 849 cases and 171 deaths were reported in a recent outbreak in Sudan.[5]

Although nonhuman primates are also a reservoir for sylvatic strains of dengue, the virus is now largely maintained in humans, with a regular transmission cycle akin to that of urban yellow fever. Despite the presence of dengue virus in the tropics worldwide, less than 10% of infected persons develop hemorrhagic fever, primarily children between the ages of 4 and 12 years.

TABLE 381-1 PRINCIPAL VIRUSES CAUSING HEMORRHAGIC FEVER

VIRUS	DISEASE	GEOGRAPHIC DISTRIBUTION OF DISEASE	PRINCIPAL RESERVOIR/VECTOR	ANNUAL CASES	CASE TO INFECTION RATIO	HUMAN-TO-HUMAN TRANSMISSIBILITY
FILOVIRIDAE						
Ebolavirus[a]	Ebola HF	Sub-Saharan Africa	Fruit bat?	—[b]	1 : 1	High
Marburgvirus	Marburg HF	Sub-Saharan Africa	Fruit bat: Egyptian fruit bat (*Rousettus aegyptiacus*), perhaps others	—[b]	1 : 1	High
ARENAVIRIDAE[c,d]						
Old World Group						
Lassa	Lassa fever	West Africa	Rodent: natal mastomys or multimammate rat (*Mastomys natalensis*)	50,000-100,000	1 : 5-10	Moderate
Lujo[e]	Lujo HF	Zambia	Unknown, presumed rodent	Unknown	Unknown	Moderate to high
New World Group						
Junín	Argentine HF	Argentine pampas	Rodent: corn mouse (*Calomys musculinus*)	≈100	1 : 1.5	Low
Machupo	Bolivian HF	Beni department, Bolivia	Rodent: large vesper mouse (*Calomys callosus*)	≤50	1 : 1.5	Low
Guanarito	Venezuelan HF	Portuguesa state, Venezuela	Rodent: cane mouse (*Zygodontomys brevicauda*)	≤50	1 : 1.5	Low
Sabiá[f]	Proposed name: Brazilian HF	Rural area near São Paulo, Brazil?	Unknown, presumed rodent	Unknown	1 : 1.5	Low?
Chapare[g]	Chapare HF	Cochabamba, Bolivia	Unknown, presumed rodent	Unknown	Unknown	Unknown
BUNYAVIRIDAE[c]						
Old World Group						
Hantaan, Seoul, Puumala, Dobrava-Belgrade, others	HF with renal syndrome	Hantaan: northeast Asia Seoul: urban areas worldwide Puumala and Dobrava-Belgrade: Europe	Rodent Hantaan: striped field mouse (*Apodemus agrarius*) Seoul: brown or Norway rat (*Rattus norvegicus*) Puumala: bank vole (*Clethrionomys glareolus*) Dobrava-Belgrade: yellow-necked field mouse (*Apodemus flavicollis*)	50,000-150,000	Hantaan: 1 : 1.5 Others: 1 : 20	None

New World Group						
Sin Nombre, Andes, Laguna Negra, others	Hantavirus cardiopulmonary syndrome	Americas	Rodent Sin Nombre: deer mouse (*Peromyscus maniculatus*) Andes: long-tailed colilargo (*Oligoryzomys longicaudatus*) Laguna Negra: little laucha or small vesper mouse (*Calomys laucha*)	50,000-150,000	Sin Nombre: 1 : 1 Others: up to 1 : 20	None, except for Andes virus
Rift Valley fever	Rift Valley fever	Sub-Saharan Africa, Madagascar, Saudi Arabia, Yemen	Domestic livestock/mosquitoes (sylvatic *Aedes* and others)	100-100,000[b,h]	1 : 100	None
Crimean-Congo HF	Crimean-Congo HF	Africa, Balkans, southern Russia, Middle East, India, Pakistan, Afghanistan, western China	Wild and domestic vertebrates/tick (primarily *Hyalomma* species)	≈500	1 : 1-2	High
FLAVIVIRIDAE						
Yellow fever	Yellow fever	Sub-Saharan Africa, South America up to Panama	Monkey/mosquito (*Aedes aegypti*, other *Aedes* and *Haemagogus* species)	5000-200,000[i]	1 : 2-20	None
Dengue	Dengue HF	Tropics and subtropics worldwide	Human/mosquito (*Ae. aegypti* and *albopictus*)	100,000-200,000[i]	1 : 10-100, depending on age, previous infection, genetic background, and infecting serotype	None
Omsk HF	Omsk HF	Western Siberia	Rodent/tick (primarily *Dermacentor* and *Ixodes* species)	100-200	Unknown	Not reported
Kyasanur Forest disease	Kyasanur Forest disease	Karnataka state, India; Yunnan Province, China; Saudi Arabia	Vertebrate (rodents, bats, birds, monkeys, others)/tick (*Haemaphysalis* species and others)	≈500	Unknown	Not reported, but laboratory infections have occurred
Alkhumra HF[j]	Proposed name: Alkhumra HF	Saudi Arabia, Egypt	Ticks?	≤50	Unknown	Not reported

[a]Six species or subtypes of Ebolavirus are recognized with varying associated case-fatality ratios (see Table 381-2). All are endemic to sub-Saharan Africa, with the exceptions of Reston ebolavirus, which is found in the Philippines, and Lloviu ebolavirus, which was detected in bats in Spain.
[b]Although some endemic transmission of the filoviruses (Ebolavirus > Marburgvirus) and Rift Valley fever virus occurs, these viruses have most often been associated with outbreaks.
[c]The virus families Arenaviridae and Bunyaviridae are serologically, phylogenetically, and geographically divided into Old World (i.e., Africa) and New World (i.e., the Americas) complexes.
[d]In addition to the arenaviruses listed in the table, Flexal and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been noted in sick persons in California, but its role as a pathogen has not been clearly established.
[e]Discovered in 2008. Only five cases (four of them fatal) from one outbreak have been noted. The index case came to South Africa from Zambia.
[f]Discovered in 1990. Only three cases (one fatal) have been noted, two of them from laboratory accidents.
[g]Discovered in 2003 from a small outbreak from which blood was obtained from one fatal case and Chapare virus isolated. Few other details have been reported.
[h]Although Rift Valley fever virus can be found throughout sub-Saharan Africa, large outbreaks usually occur in East Africa's Rift Valley region.
[i]Based on estimates from the World Health Organization. Significant underreporting occurs. Incidence may fluctuate widely in place and time.
[j]Alkhumra is considered by some to be a variant of Kyasanur Forest disease virus. Disagreement exists over the proper spelling of the virus, written as Alkhurma in some publications.
HF = hemorrhagic fever.

Tick-Borne Viruses

The viruses that cause Crimean-Congo hemorrhagic fever, Omsk hemorrhagic fever,[6] Kyasanur Forest disease, and Alkhumra hemorrhagic fever are maintained in small mammals, such as rodents, hares, and hedgehogs, among which the viruses are spread by ticks. Humans are infected either by tick bites or by exposure to contaminated blood or excreta of the reservoir animals. Ticks also spread Crimean-Congo hemorrhagic fever virus to large mammals, including cattle and other domestic livestock, whose transient and asymptomatic viremia puts farmers, abattoir workers, and veterinarians at risk.

Human-to-Human Transmission

Secondary human-to-human transmission occurs with many of the hemorrhagic fever viruses, but tertiary transmission is unusual and often associated with milder disease (see Table 381-1). Secondary attack rates for hemorrhagic fever viruses are generally low (15 to 20% for Ebola Zaire virus), probably because transmission between humans requires direct contact with contaminated blood or body fluids. Human-to-human infection probably usually occurs through oral or mucous membrane exposure, most often in the context of providing care to a sick family member (community) or patient (nosocomial transmission), and occasionally during funeral rituals that entail the touching of the corpse, especially for the filoviruses. Infection through fomites cannot be excluded. Aerosol infection is thought to be rare or nonexistent. Large outbreaks almost always involve amplification in health care settings in which basic infection control measures have broken down, usually owing to extreme poverty or civil strife.

With the exception of hantaviruses and some of the flaviviruses, infectivity generally parallels the clinical state. Persons are generally most infectious late in the course of severe disease, especially when bleeding. The risk of transmission during the incubation period or from asymptomatic persons is negligible, although a case of Argentine hemorrhagic fever occurred from blood transfusion from an asymptomatic donor. Rarely, Ebola, Marburg, Lassa, and Junín viruses have been sexually transmitted during the first 3 months of convalescence owing to delayed viral clearance from the gonads, which is an immunologically protected site. Despite modern-day travel, imported cases of viral hemorrhagic fever remain extremely rare.

PATHOBIOLOGY

Although the precise mechanism varies with the specific virus, microvascular instability and impaired hemostasis are the pathobiologic hallmarks of viral hemorrhagic fever. Data from animal models suggest that cardiac inotropy may also be directly or indirectly inhibited in some viral hemorrhagic fevers, especially Lassa fever.

After inoculation, virus first replicates in dendritic cells and other local tissues, with subsequent migration to regional lymph nodes and then dissemination through the lymph and blood monocytes to a broad range of tissues and organs, including the liver, spleen, lymph nodes, adrenal glands, lungs, and endothelium. Migration of tissue macrophages results in secondary infection of permissive parenchymal cells. During the acute illness, virus can be found in a wide variety of body fluids, including blood, saliva, stool, and breast milk.

The interaction of virus with immune cells, especially macrophages and endothelial cells, results directly or indirectly (through soluble mediators) in cell activation and the unleashing of an inflammatory and vasoactive process consistent with the systemic inflammatory response syndrome. The synthesis of cell surface tissue factor triggers the extrinsic coagulation pathway. Impaired hemostasis may entail endothelial cell, platelet, or coagulation factor dysfunction. Disseminated intravascular coagulopathy (DIC) is frequently noted, especially with Ebola, Marburg, and Crimean-Congo hemorrhagic fever virus infections.

Tissue damage may be mediated through direct necrosis of infected cells or indirectly through apoptosis of immune cells, as seen in other forms of septic shock. The most affected organs vary with the virus (Table 381-2). For example, renal tubular necrosis and retroperitoneal edema are seen in hemorrhagic fevers with renal syndrome, whereas interstitial pneumonitis and myocardial depression are the hallmarks of hantavirus pulmonary syndrome. The liver is particularly affected in yellow fever, with fatty degeneration, coagulative midzonal necrosis of hepatocytes, and the presence of Councilman bodies. The brain and meninges are particularly affected in Kyasanur Forest disease and Omsk hemorrhagic fever and often in the South American hemorrhagic fevers as well. Reticuloendothelial proliferation is seen in Kyasanur Forest disease, with marked erythrophagocytosis in the spleen.

With the exception of disease caused by the hantaviruses and some of the flaviviruses, the pathogenesis of viral hemorrhagic fever appears to be related to unchecked viremia, with most fatal cases failing to mount a significant antibody response. By comparison, virus is cleared rapidly from the blood in survivors. Inflammatory cell infiltrates, which are usually mild, consist of a mix of mononuclear cells and neutrophils. In some viral hemorrhagic fevers, such as Ebola, virus replication and dissemination are facilitated by virus-induced suppression of the host adaptive immune response. For example, failure of the immune response to adequately respond appears to be a major determinant of severity in Lassa fever.[7]

In dengue, yellow fever, and hantavirus infections, in which viremia is usually cleared before the most severe phase of the disease, the host immune response may play a detrimental role. The unique process of antibody-mediated immune enhancement, in which secondary infection with a different dengue virus serotype is more severe than the primary one, may play a role in the pathogenesis of dengue hemorrhagic fever.

CLINICAL MANIFESTATIONS

Viral hemorrhagic fever is seen in both genders and all age groups, with a spectrum from relatively mild or even asymptomatic infection to severe vascular permeability resulting in shock, multiorgan system failure, and death. Although the clinical presentation may differ for each viral hemorrhagic fever as disease progresses, the limited data do not permit clear distinctions in most cases, especially in the early phases of disease. Dengue and Rift Valley fever viruses cause a range of syndromes, including rash and central nervous system involvement (Chapters 382 and 383). Hemorrhagic fever occurs in a minority of infections with these viruses.

After an incubation period ranging from days to weeks, most patients present with nonspecific signs and symptoms difficult to distinguish from a host of other febrile illnesses (see Table 381-2)[8], including fever, general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, and lumbosacral pain. Conjunctival injection or hemorrhage is frequent but is not accompanied by itching, discharge, or rhinitis (Fig. 381-1). Relative bradycardia (Faget sign) and orthostatic hypotension may be noted, especially in yellow fever and dengue virus infections. The pharynx may be erythemic or, less frequently, exudative, especially in Lassa fever, and incorrectly lead to a diagnosis of streptococcal pharyngitis or mononucleosis. Gastrointestinal signs and symptoms readily ensue, including nausea, vomiting, epigastric and abdominal pain, abdominal tenderness (especially over the liver in filovirus infection), and nonbloody diarrhea or constipation. A misdiagnosis of appendicitis or other acute abdominal emergency (Chapter 142) sometimes prompts potentially hazardous surgical interventions.

In the recent Ebola outbreak in West Africa, the incubation period averaged 6 to 8 days. Most patients presented with some combination of fever (90%), headache (80%), diarrhea (50%), or vomiting (35%), often associated with myalgias, weakness, or abdominal pain. Hiccups also may be seen early in Ebola hemorrhagic fever.[9]

Neck pain and stiffness, retro-orbital pain, photophobia, and other meningeal signs are common in Rift Valley fever, Kyasanur Forest disease, and Omsk hemorrhagic fever. A dry cough, sometimes accompanied by a few scattered rales on auscultation, is common, but prominent pulmonary symptoms are uncommon early in the course of the disease, except with hantavirus pulmonary syndrome. Pregnant women often present with spontaneous abortion and vaginal bleeding. With the exception of yellow fever, jaundice is not typical except in patients with underlying Gilbert syndrome, drug reactions, or coinfection. Hepatosplenomegaly is frequent, but whether it is specific to the viral hemorrhagic fever or simply represents the high underlying prevalence of hepatosplenomegaly in populations in sub-Saharan Africa is unknown.

Various forms of rash, including morbilliform, maculopapular, petechial, and ecchymotic, may be seen (see Table 381-2). A maculopapular rash on the torso or face may be one early and relatively specific although insensitive indicator of Ebola or Marburg hemorrhagic fever. Rash almost always occurs in fair-skinned persons with Lassa fever but, for unclear reasons, rarely in blacks.

In severe cases, patients progress after 7 to 10 days of illness to vascular instability, which may be manifested by conjunctival injection and hemorrhage, facial flushing, edema, bleeding, hypotension, shock, and proteinuria. Facial and neck swelling are classic and relatively specific signs of Lassa fever and Lujo hemorrhagic fever.[10] The likelihood of clinically discernible hemorrhage varies with the infecting virus (see Table 381-2) and may be manifested as hematemesis, melena, hematochezia, metrorrhagia, petechiae, purpura,

TABLE 381-2 PATHOBIOLOGIC AND CLINICAL ASPECTS OF VIRAL HEMORRHAGIC FEVERS

DISEASE	INCUBATION PERIOD (DAYS)	ONSET	BLEEDING	RASH	JAUNDICE	HEART	LUNG	KIDNEY	CENTRAL NERVOUS SYSTEM	EYE	CASE-FATALITY RATIO	CLINICAL MANAGEMENT

Dengue HF	3-15	Abrupt	++	+++	+	++	+	0	+	0	Untreated: 10-15% Treated: ≤1%	Supportive
Omsk HF	3-8	Abrupt	++	0	0	+	++	0	+++	+	1-3%	Supportive
Kyasanur forest disease	3-8	Abrupt	++	0	0	+	++	0	+++	+	3-5%	Supportive
Alkhumra HF[g]	3-8	Abrupt	++	+	+	+	+	0	++	+	20-25%	Supportive

[a]Six species or subtypes of Ebolavirus are recognized with varying associated case-fatality ratios: Zaire, 85%; Sudan, 55%; Bundibugyo, 40%; Tai Forest (also called Côte d'Ivoire), 0% (only one recognized case, who survived); Reston, 0% (not pathogenic to humans); Lloviu, no human infections recognized.
[b]The case-fatality ratio was 22% in the first recognized outbreak of Marburg HF in Germany and Yugoslavia in 1967 but has been consistently above 80% in outbreaks in central Africa, where the virus is endemic. Possible reasons for this discrepancy include differences in quality of care, strain pathogenicity, route and dose of infection, underlying prevalence of immunodeficiency and comorbid illnesses, and genetic susceptibility.
[c]A morbilliform or maculopapular rash almost always occurs in persons with lighter skin, who are usually expatriates, but for unclear reasons is rarely present in darker-skinned Africans from the endemic area.
[d]Data are insufficient to distinguish between the syndromes produced by the various arenaviruses found in the Americas. They are thus frequently grouped as the South American hemorrhagic fevers.
[e]Hemorrhagic fever, encephalitis, and retinitis may be seen in Rift Valley fever independently of each other.
[f]The incubation period of Crimean-Congo HF varies with the mode of transmission: typically 1 to 3 days after tick bite and 5 to 6 days after contact with infected animal blood or tissues.
[g]Based on preliminary observations. Fewer than 100 cases have been reported.
ECMO = extracorporeal membrane oxygenation; HF = hemorrhagic fever; 0 = sign not typically noted/organ not typically affected; + = sign occasionally noted/organ occasionally affected; ++ = sign commonly noted/organ commonly affected; +++ = sign characteristic/organ involvement severe.

epistaxis, and bleeding from the gums and venipuncture sites (Fig. 381-2). Hemoptysis and hematuria are infrequent. Hemorrhage is almost never present in the first few days of illness. Large ecchymoses are characteristic of Crimean-Congo hemorrhagic fever. Central nervous system manifestations, including delirium, tremor, gait anomalies, convulsions, and hiccups, may be noted in end-stage disease, especially in Kyasanur Forest disease, Omsk hemorrhagic fever, and the South American hemorrhagic fevers, particularly Argentine hemorrhagic fever. Nevertheless, the cerebrospinal fluid findings are usually normal, with the exception of patients who have meningoencephalitis due to Kyasanur Forest disease and Omsk hemorrhagic fever, in which an elevated protein level is common. Renal insufficiency or failure is common, especially in hemorrhagic fever with renal syndrome.

Biphasic illnesses are classically noted for the flavivirus hemorrhagic fevers, in which a quiescent period of days (yellow fever, dengue hemorrhagic fever, and Rift Valley fever) to weeks (Kyasanur Forest disease and Omsk hemorrhagic fever) precedes the most severe manifestations, including hemorrhage, shock, renal failure, and meningoencephalitis. Distinct progressive phases of disease and recovery are classically described for hemorrhagic fever with renal syndrome (prodrome, hypotension, oliguria/renal failure, diuresis, and convalescence) and yellow fever (infection, intoxication, recovery) but are not seen in all cases. The initial manifestations for hantavirus pulmonary syndrome may be mild and nonspecific, but the disease may progress to require mechanical ventilation and pressor support within 24 hours; sinus bradycardia and ventricular tachycardia or fibrillation may occur. Encephalitis and retinitis may develop in Rift Valley fever independently of the presence or absence of viral hemorrhagic fever.

Bilateral noncardiogenic interstitial pulmonary edema consistent with the adult respiratory distress syndrome (ARDS) is the hallmark of hantavirus pulmonary syndrome, although chest radiographs may be normal early in the disease even when the patients complain of shortness of breath. Only about 30% of patients with hantavirus pulmonary syndrome have radiographic evidence of pulmonary edema on initial evaluation, although it develops in virtually all persons within 48 hours.

DIAGNOSIS

Because of their associated severity, risk of secondary spread, high degree of public scrutiny, and unfamiliarity to most physicians, consultation with a specialist who has experience with viral hemorrhagic fevers should be sought as soon as the diagnosis is considered. When to "sound the alarm" of viral hemorrhagic fever is a case-by-case decision left to the treating physician in consultation with experts in the field. Most viral hemorrhagic fevers are rare, and routinely practiced universal precautions are protective in most cases.

The early nonspecific presentation of viral hemorrhagic fevers makes them extremely difficult to diagnose clinically, especially outside of the setting of a recognized outbreak, which is usually detected when clusters of cases occur, especially when they involve health care workers. The differential diagnosis includes a broad array of febrile illnesses that varies by geographic region (Table 381-3). A complete epidemiologic history (including details of travel,

TABLE 381-3 DIFFERENTIAL DIAGNOSIS OF THE VIRAL HEMORRHAGIC FEVERS

DISEASE	DISTINGUISHING CHARACTERISTICS AND COMMENTS
PARASITES	
Malaria	Classically shows paroxysms of fever and chills; hemorrhagic manifestations less common; malaria smears or rapid test result usually positive; coinfection (or baseline asymptomatic parasitemia) common; responds to antimalarials
Amebiasis	Hemorrhagic manifestations other than bloody diarrhea generally not seen; amebic trophozoites identified in the stool by microscopy or antigen assays; responds to antiparasitics
Giardiasis	Positive stool antigen test result or identification of trophozoites or cysts in stool; responds to antiparasitics
African trypanosomiasis (acute stages)	Especially the East African form; examination of peripheral blood smear/buffy coat may show trypanosomes
BACTERIA (INCLUDING SPIROCHETES, RICKETTSIA, EHRLICHIA, AND COXIELLA)	
Typhoid fever	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Bacillary dysentery (including shigellosis, campylobacteriosis, salmonellosis, and enterohemorrhagic *Escherichia coli* and others)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Capnocytophaga canimorsus	Associated with dog and cat bites, typically in persons with underlying immunodeficiency, notably asplenic patients; responds to antibiotics
Meningococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; bleeding within the first 24-48 hours after onset of illness and rapidly progressive illness typical; large ecchymoses typical of meningococcemia are unusual in the VHFs except for Crimean-Congo HF; rapid serum latex agglutination tests can be used to detect bacterial antigen in meningococcal septicemia; may respond to antibiotics (critical to administer early)
Staphylococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; may respond to antibiotics
Septic abortion	History of pregnancy and positive pregnancy test
Septicemic or pneumonic plague	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of plague are unusual in the VHFs except for Crimean-Congo HF; pneumonic plague may mimic hantavirus pulmonary syndrome; may respond to antibiotics
Streptococcal or Epstein-Barr virus pharyngitis	May mimic the exudative pharyngitis sometimes seen in Lassa fever
Tuberculosis	Hemoptysis of advanced pulmonary tuberculosis may suggest VHF, but tuberculosis generally has a much slower disease evolution
Tularemia	Ulceroglandular and pneumonic forms more common; responds to antibiotics
Acute abdominal emergencies	Appendicitis, peritonitis, and bleeding upper gastrointestinal ulcer
Pyelonephritis and post-streptococcal glomerulonephritis	May mimic HF with renal syndrome
Anthrax (inhalation or gastrointestinal)	Prominent pulmonary manifestations and widened mediastinum on chest radiograph in inhalation form; responds to antibiotics
Atypical bacterial pneumonia (*Legionella, Mycoplasma, Chlamydophila pneumoniae* and *C. psittaci*, others)	May mimic hantavirus pulmonary syndrome; exposure to birds; symptoms often not present until late in the illness in psittacosis; responds to antibiotics

TABLE 381-3 DIFFERENTIAL DIAGNOSIS OF THE VIRAL HEMORRHAGIC FEVERS—cont'd

DISEASE	DISTINGUISHING CHARACTERISTICS AND COMMENTS
Relapsing fever	Recurrent fevers and influenza-like symptoms, with direct neurologic involvement and splenomegaly; spirochetes visible in blood while febrile; responds to antibiotics
Leptospirosis	Jaundice, renal failure, and myocarditis in severe cases; responds to antibiotics
Spotted fever group rickettsiae (including African tick bite fever, boutonneuse fever, Rocky Mountain spotted fever)	Incubation period of 7-10 days after tick bite, compared with 1-3 days in Crimean-Congo HF; necrotic lesions (eschar) typically seen at site of tick bite in some rickettsial diseases, whereas there may be only slight bruising at the bite site in Crimean-Congo HF; rash (if present) of rickettsial infection classically involves palms and soles
Q fever (*Coxiella burnetii*)	Broad spectrum of illness, including hepatitis, pneumonitis, encephalitis, and multisystem disease with bleeding; responds to antibiotics
Ehrlichiosis	Diagnosis by serology and PCR; blood film may be useful; responds to antibiotics
VIRUSES	
Influenza	Prominent respiratory component to clinical presentation; no hemorrhagic manifestations; influenza rapid test result may be positive; may respond to anti-influenza drugs
Arbovirus infection (including dengue and West Nile fever)	Encephalitis unusual but when present may mimic the VHFs with significant neurologic involvement (Kyasanur Forest disease, Omsk HF); usually less severe than VHF; hemorrhage not reported
Viral hepatitis (including hepatitis A, B, and E; Epstein-Barr; and cytomegalovirus)	Jaundice atypical in HF except yellow fever; test results for hepatitis antigens positive; fulminant infection resembling VHF may be seen in persons with underlying immune deficiencies
Herpes simplex or varicella-zoster	Fulminant infection with hepatitis (with or without vesicular rash); elevated transaminases and leukopenia typical; disseminated disease may be noted in otherwise healthy persons; poor response to acyclovir drugs unless recognized early
HIV/AIDS	Seroconversion syndrome or HIV/AIDS with secondary infections, especially septicemia
Measles	Rash may mimic that seen in early stages of some VHFs and may sometimes be hemorrhagic; prominence of coryza and upper respiratory symptoms in measles should help differentiate; vaccine preventable
Rubella	Rash may mimic that seen in early stages of some VHFs; usually a mild disease; vaccine preventable
Hemorrhagic or flat smallpox	Diffuse hemorrhagic or macular lesions; in contrast to the VHFs, the rash may involve the oral mucosa, palms, and soles; smallpox in the wild has been eradicated
Alphavirus infection (including chikungunya and o'nyong-nyong)	Joint pain typically a predominant feature
FUNGI	
Histoplasmosis	Pulmonary disease may mimic hantavirus pulmonary syndrome; recent entry into mines or caves
NONINFECTIOUS ETIOLOGIES	
Heat stroke	History for extreme heat exposure; absence of sweating; bleeding not typical, but DIC may occur
Idiopathic and thrombotic thrombocytopenic purpura (ITP/TTP)	Presentation usually less acute than in VHF; may have prominent neurologic symptoms in TTP; coagulation factors normal and DIC absent; often respond to corticosteroids (ITP) or plasma exchange (TTP)
Acute glaucoma	May mimic the acute ocular manifestations of Rift Valley fever
Hematologic malignant neoplasms (leukemia, lymphoma)	May resemble leukemoid reaction occasionally seen in HF with renal syndrome
Drug sensitivity or overdose	Stevens-Johnson syndrome and anticoagulant (warfarin) overdose
Industrial and agricultural chemical poisoning	Especially anticoagulants, although other symptoms of VHF absent
Hematoxic snake bite envenomation	History of snake bite

DIC = disseminated intravascular coagulopathy; HF = hemorrhagic fever; PCR, polymerase chain reaction; VHF, viral hemorrhagic fever.

possible exposures, occupational risks, and the progression of illness), physical examination, and preliminary basic laboratory results (Table 381-4) are critical. A diagnosis of viral hemorrhagic fever should be considered in patients with a clinically compatible syndrome who, within the incubation period for the particular viral hemorrhagic fever in question, (1) reside in or traveled to an endemic area (see Table 381-1); (2) had potential direct contact with blood or body fluids of someone who was ill with an acute viral hemorrhagic fever, such as health care workers, persons caring for family members at home or preparing bodies for burial, and laboratory personnel; (3) had contact with live or recently killed wild animals (especially nonhuman primates) in or recently arriving from an area where a viral hemorrhagic fever is endemic (although direct contact with the animal reservoir is not usually reported even in confirmed cases); (4) worked in a laboratory or animal facility where hemorrhagic fever viruses are handled; or (5) had sexual relations with someone recovering from a viral hemorrhagic fever in the last 3 months.

The index of suspicion should be especially high for persons in specific high-risk occupations, including health care workers, abattoir workers, veterinarians, farm workers, hunters, taxidermists, and travelers who have recently returned from endemic areas.[11] ARDS (Chapter 104) or other respiratory compromise in a person living in an endemic area for New World hantaviruses should prompt consideration of hantavirus pulmonary syndrome. Risk of tick infection, including physical examination for an eschar, should be assessed if a tick-borne viral hemorrhagic fever is suspected. However, most viral hemorrhagic fevers are rare even in persons possessing one of the risk factors, so alternative diagnoses should always be aggressively sought, especially malaria and typhoid fever in areas where they are endemic. Acts of bioterrorism (Chapter 21) must be considered if viral hemorrhagic fever is strongly suspected in a patient without any of the aforementioned risk factors, especially if clusters of cases occur. All cases should be immediately reported to local, state, and federal health authorities.

Laboratory Testing

Prompt laboratory confirmation is imperative, but testing is unfortunately only available in a few specialized laboratories except for kits with varying sensitivity and specificity for the serologic diagnosis of dengue fever and hantavirus pulmonary syndrome. Assays commonly used in the diagnosis of viral hemorrhagic fever include polymerase chain reaction,[12] enzyme-linked immunosorbent assays for viral antigen and immunoglobulin M antibody, virus culture, and immunohistochemistry on postmortem tissues. These assays generally appear to have sensitivities and specificities above 90%, although serologic diagnosis of flavivirus infection is often complicated by cross-reactions. In the United States, testing can be arranged through the Centers for Disease Control and Prevention (phone: 404-639-1115, after hours: 770-488-7100; e-mail: dvd-1spath@cdc.gov).

TABLE 381-4 INDICATED CLINICAL LABORATORY TESTS AND CHARACTERISTIC FINDINGS IN PATIENTS WITH VIRAL HEMORRHAGIC FEVER

TEST	CHARACTERISTIC FINDINGS AND COMMENTS
Leukocyte count	Early: moderate leukopenia (except for hantavirus infection, in which early leukocytosis with immunoblasts is classically noted) Later: leukocytosis with left shift; granulocytosis more suggestive of bacterial infection
Hemoglobin and hematocrit	Hemoconcentration (especially noted in hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome)
Platelet count	Mild to moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid-base perturbations, depending on fluid balance and stage of disease
BUN/creatinine	Renal failure may occur late in disease.
Serum chemistries (AST, ALT, amylase, γ-glutamyltransferase, alkaline phosphatase, creatinine kinase, lactate dehydrogenase, lactate)	Usually increased, especially in severe disease; AST > ALT A lactate level >4 mmol/L (36 mg/dL) may indicate persistent hypoperfusion and sepsis. Lactate dehydrogenase is typically markedly increased in hantavirus pulmonary syndrome.
Sedimentation rate	Normal or increased
Blood gas	Metabolic acidosis may be indicative of shock and hypoperfusion
Coagulation studies (PT, PTT, fibrinogen, fibrin split products, platelets, D-dimer)	DIC common in Ebola, Marburg, Lujo virus, Crimean-Congo HF, and New World arenavirus infections
Urinalysis	Proteinuria common; hematuria may be occasionally noted Sediment may show hyaline-granular casts and round cells with cytoplasmic inclusions.
Blood culture	Useful early to exclude VHF and later to evaluate for secondary bacterial infection Blood should be drawn before antibiotic therapy is instituted.
Stool culture	Useful to exclude VHF (in favor of hemorrhagic bacillary dysentery)
Thick and thin blood smears	May aid in the diagnosis of blood parasites (malaria and trypanosomes), bacterial sepsis (meningococcus, capnocytophaga, and anthrax), and ehrlichiosis All negative in VHF unless coinfection
Rapid test, PCR, or other assay for malaria	Negative in VHF unless coinfection with malaria

ALT = alanine aminotransferase; AST = aspartate aminotransferase; BUN = blood urea nitrogen; DIC = disseminated intravascular coagulation; PCR, polymerase chain reaction; PT = prothrombin time; PTT = partial thromboplastin time; VHF = viral hemorrhagic fever.

TREATMENT

Rx

The rarity of most viral hemorrhagic fevers and their typical occurrence in remote and resource-poor settings make controlled studies on treatment difficult. Treatment guidelines generally follow those recommended for septic shock (Chapter 108). Patients should be placed in isolation in an intensive care unit. Intramuscular and subcutaneous injections should be minimized because of the risk of hematoma.

Clinical Management Guidelines

Fluid and Electrolyte Management

Severe microvascular instability, often complicated by vomiting, severe and sometimes voluminous diarrhea, and decreased fluid intake, typically requires aggressive fluid replacement to prevent shock. In the recent Ebola outbreak, patients often required up to 5 liters of intravenous fluids daily and potassium supplementation in addition to oral rehydration.[13,14] However, overaggressive and unmonitored rehydration may lead to significant third-spacing and pulmonary edema, especially in hantavirus pulmonary syndrome.

Early goal-directed therapies with crystalloids, blood products, and vasopressors can mitigate organ dysfunction and probably reduce mortality (Chapter 108). Peritoneal dialysis and hemodialysis (Chapter 131) have been extensively used in patients with hemorrhagic fever with renal syndrome without frequent complications, but there is little published experience with the other viral hemorrhagic fevers. Specific World Health Organization guidelines for the fluid management of dengue shock syndrome in resource-limited environments specify a more conservative fluid repletion strategy because of the inability to monitor hydration status carefully and the resulting risk of fluid overload or pulmonary edema in this syndrome. Significant electrolyte imbalance may be noted, and hypokalemia often requires potassium supplementation.

Blood Products and Management of Disseminated Intravascular Coagulation

Although bleeding may be profuse in some viral hemorrhagic fevers, especially Crimean-Congo hemorrhagic fever and Ebola and Marburg hemorrhagic fevers, blood products should not be given empirically but only to meet defined clinical and laboratory parameters in the face of clinically significant hemorrhage. Transfusions, preferably with packed red blood cells, should be used to maintain a hemoglobin concentration above 7.0 g/dL while avoiding volume overload, taking into account that chronic anemia due to malaria and malnutrition may be frequent in patients in certain geographic areas. Whole blood is a reasonable alternative if packed cells are not available.

The possibility of DIC (Chapter 175) should be assessed by the relevant laboratory parameters (see Table 381-4), such as D-dimer levels. Transfusion of platelet concentrate (1 to 2 U/10 kg) should be considered when the platelet count is less than 50,000/μL in a bleeding patient or less than 20,000/μL without bleeding. The platelet count should generally rise by at least 2000/μL per unit of platelets transfused, although the response may be less if there is ongoing DIC and platelet consumption. Impaired platelet aggregation may promote hemorrhage in some viral hemorrhagic fevers, especially Lassa fever, even when platelet counts are not drastically low. Transfusion of fresh-frozen plasma (FFP) (15 to 20 mL/kg) should be considered when bleeding is present and fibrinogen levels are less than 100 mg/dL. Fibrinogen concentrate (total dose of 2 to 3 g) or cryoprecipitate (1 U/10 kg) may be administered instead of FFP, although FFP has the theoretical advantage of containing all coagulation factors and inhibitors deficient in DIC but no activated coagulation factors. Vitamin K (10 mg intravenously or orally on 3 consecutive days) may be given, especially if underlying malnutrition or liver disease is suspected. Folic acid has also sometimes been added to prevent the detrimental effect of acute folate deficiency on platelet production, especially in malnourished patients, although the efficacy of this treatment is unknown.

Oxygenation and Ventilation

In the early phases of disease and in the absence of iatrogenic pulmonary edema, most patients can be supported with oxygen administered by nasal cannula or face mask. The exception is hantavirus pulmonary syndrome, for which early endotracheal intubation and mechanical ventilation (Chapter 105) are often life-saving. Patients with viral hemorrhagic fever have an elevated risk of ventilator-induced lung injury (i.e., barotrauma) and pulmonary hemorrhage. In neurologically intact patients with hypoxemia, noninvasive positive-pressure ventilation may be a useful adjunct to forestall intubation. When mechanical ventilation is required, lung-protective tidal volumes of 6 to 8 mL/kg of ideal body weight should be employed. Extracorporeal membrane oxygenation has been used with apparent benefit in hantavirus pulmonary syndrome. Because of the risk of bleeding, arterial puncture for blood gas determination should be kept to a minimum.

Antibiotics and Secondary Infection

Patients should be immediately covered with appropriate antibacterial or antiparasitic therapy, with specific consideration of malaria (Chapter 345) and tick-borne rickettsial diseases (Chapter 327), until a diagnosis of viral hemorrhagic fever can be confirmed. These drugs should then be stopped unless there is evidence of coinfection. Secondary bacterial infection should be suspected when patients have persistent or new fever after about 2 weeks of illness, a time when most viral hemorrhagic fevers either have resulted in death or are resolving.

Antiviral Therapy

The only currently available specific antiviral therapy for any viral hemorrhagic fever is the guanosine analogue ribavirin, although it is not approved by the Food and Drug Administration for this indication (Table 381-5). The best data are for Lassa fever and hemorrhagic fever with renal syndrome, for which early treatment is imperative for maximum benefit. Anecdotal data suggest efficacy in other arenavirus hemorrhagic fevers, but controversial controlled trials of ribavirin in Crimean-Congo hemorrhagic fever and Rift Valley fever did not show efficacy. In vitro data generally show activity of ribavirin against dengue, yellow fever, and Omsk hemorrhagic fever viruses, but clinical studies have not been performed. The drug is not efficacious and should not be used for Ebola or Marburg hemorrhagic fevers. The main side effects of intravenous ribavirin are a mild to moderate hemolytic anemia, which infrequently necessitates transfusion and disappears with cessation of treatment, and rigors when the drug is infused too rapidly. ZMapp, which is a combination of three monoclonal antibodies, is effective for treating Ebola virus in non-human primates.[15] It has also been used in humans on a compassionate

TABLE 381-5 RIBAVIRIN THERAPY FOR VIRAL HEMORRHAGIC FEVER

INDICATION	ROUTE	DOSE[a]	INTERVAL
Treatment	IV[b]	30 mg/kg (maximum 2 g)[c]	Loading dose, followed by:
	IV[b]	15 mg/kg (maximum 1 g)[c]	every 6 hours for 4 days, followed by:
	IV[b]	7.5 mg/kg (maximum 500 mg)[c]	every 8 hours for 6 days
Prophylaxis	PO	35 mg/kg (maximum 2.5 g)[c]	Loading dose, followed by:
	PO	15 mg/kg (maximum 1 g)[c]	every 8 hours for 10 days:

[a]Pharmacokinetic and sensitivity testing for ribavirin has not been extensively performed for each viral hemorrhagic fever. The intravenous dose used is derived from that found efficacious in Lassa fever. Oral ribavirin has also been reported to be efficacious in many viral hemorrhagic fevers, especially for Crimean-Congo hemorrhagic fever, but few controlled data are available. Intravenous administration is strongly suggested whenever possible.
[b]The drug should be diluted in 150 mL of 0.9% saline and infused slowly.
[c]Reduce the dose in persons known to have significant renal insufficiency (creatinine clearance of less than 50 mL/minute).

use basis, but controlled trials to demonstrate efficacy definitively have not yet been performed. Other experimental therapies include TKM-Ebola (an RNA inhibitor), brincidofovir, and favipiravir.

A number of experimental antiviral drugs have shown in vitro activity and, in some cases, therapeutic benefit in animal studies, including various nucleoside analogues, inhibitors of *S*-adenosyl-L-homocysteine hydrolase, small interfering RNAs, phosphorodiamidate morpholino oligomers, antisense compounds, tyrosine kinase inhibitors, and other small molecules.[16] The Chinese drug chongcao shenkang has been reported to be efficacious in hemorrhagic fever with renal syndrome. None of these drugs are yet widely approved or available for treatment of viral hemorrhagic fever in humans.

Convalescent Plasma and Antibody Therapy

Although cellular immunity is thought to be the primary protection in most viral hemorrhagic fevers, transfusion of appropriately titered convalescent plasma within the first 8 days of illness has been reported to reduce the case-fatality of Argentine hemorrhagic fever from 15 to 30% to less than 1%. However, this therapy has been associated with a convalescent phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of treated patients. Animal studies show convalescent plasma to be efficacious in Lassa fever as well, but only if it contains a high titer of neutralizing antibody and if there is a close antigenic match between the infecting viruses of the donor and recipient. Convalescent plasma also appears to be efficacious for Crimean-Congo hemorrhagic fever and Rift Valley fever, but there are no controlled data. Convalescent plasma or blood has been given to numerous patients with Ebola hemorrhagic fever, but its efficacy is still unknown. Because of the significant medical and logistical challenges to the use of convalescent immune plasma, including risk of concomitant transmission of other blood-borne pathogens, this therapy should be reserved for Argentine hemorrhagic fever and for severe and refractory cases when ribavirin is not an option. Numerous monoclonal and polyclonal antibody preparations have shown promise in animal models and may soon be ready for safety trials in humans.

Coagulation and Immune Modulators

A growing body of literature suggests that disturbances in the procoagulant-anticoagulant balance play an important role in the mediation of septic shock. A modest survival benefit (33%) was seen in monkeys treated with rNAPc2, a potent experimental recombinant inhibitor of the tissue factor/factor VIIa coagulation pathway.

Various immune modulators, including ibuprofen, corticosteroids, anti–tumor necrosis factor-α, nitric oxide inhibitors, statins, and interleukins, have not shown conclusive benefit in the treatment of sepsis. In a small study, recombinant interleukin-2 reduced the degree of acute renal insufficiency in hemorrhagic fever with renal syndrome, but further studies are needed before it can be considered the standard of care. Clinical trials of corticosteroids in hemorrhagic fever with renal syndrome have shown mixed results. Corticosteroids (e.g., 200 mg intravenous hydrocortisone per day, divided into two to four daily doses or administered by continuous infusion) are not recommended unless adrenal insufficiency is strongly suspected, the target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or cerebral edema is suspected.

Management of Pregnancy

Uterine evacuation in pregnant patients appears to lower maternal mortality and should be considered, given the extremely high maternal and fetal mortality associated with viral hemorrhagic fever. However, this procedure must be performed with extreme caution because it can be considered high risk with regard to potential nosocomial transmission. Although it is technically contraindicated in pregnancy (Food and Drug Administration Category X), ribavirin should nevertheless be considered, in consultation with the patient, as a life-saving measure for the mother who has a viral hemorrhagic fever for which the drug is efficacious (see Tables 381-2 and 381-5).

Other Considerations

Oral or parenteral acetaminophen, tramadol, opiates, or other analgesics should be used as needed for pain control (see Tables 30-4 and 30-5), adjusting as necessary for hepatic insufficiency. Use of salicylates and nonsteroidal anti-inflammatory drugs should be avoided because of the risk of bleeding. Prophylactic therapy for gastrointestinal stress ulcers with proton pump inhibitors or histamine H_2-receptor antagonists is recommended (see Table 138-1). Antiemetics, such as the phenothiazines, are frequently warranted. Seizures can usually be managed with standard medications (Chapter 403).

PREVENTION

Patient Isolation, Personal Protective Equipment, and Nursing Precautions

Normal barrier nursing precautions to prevent parenteral and droplet exposure to blood and body fluids suffice in most instances. Once the diagnosis is suspected, however, precautions should be upgraded to "viral hemorrhagic fever precautions," which include patient isolation and the use of surgical masks, face shields, double gloves, gowns, head and shoe covers, and protective aprons.[17] It is prudent to place the patient in a negative airflow room if it is available, but hermetically sealed isolation chambers are not required. Insecticide-treated bed nets and room screens should be used in open-air settings to prevent transmission of arthropod-borne hemorrhagic fever viruses. Access to the patient should be limited to a small number of designated staff and family members with specific instructions and training on infection control guidelines and the use of personal protective equipment. Small-particle aerosol precautions should be used when procedures are performed that may generate aerosols, such as endotracheal intubation. Disinfection with bleach or a number of other commercially available disinfectants is advised, including chemical or heat inactivation of human waste.

Contact Tracing

The early nonspecific presentation of the viral hemorrhagic fevers poses a serious challenge to effective epidemiologic surveillance. Fortunately, the low secondary attack rates afford a measure of reassurance even when cases go unrecognized as long as proper barrier nursing is maintained. Furthermore, because mild cases, which may be still more difficult to recognize, are usually not very infectious, missed or delayed diagnosis of these patients is unlikely to pose a problem from an infection control standpoint.

Persons with unprotected direct contact with a patient during the symptomatic phase of a human-to-human communicable viral hemorrhagic fever should be monitored daily for evidence of disease for the duration of the longest possible incubation period, starting after their last contact (see Table 381-2). Given the generally low secondary attack rates, especially outside of caretakers, widespread contact tracing, laboratory testing, and postexposure prophylaxis are not indicated for casual contacts. Contacts should check their temperature daily and record the results in a log. Despite lack of evidence for transmission during the incubation period, it is usually recommended that exposed persons avoid close contact with household members that might result in exposure to body fluids, such as sex, kissing, and sharing of utensils for the duration of the incubation period. Confinement of asymptomatic persons is not warranted, but persons who develop fever or other signs and symptoms suggestive of viral hemorrhagic fever should be immediately isolated until the diagnosis can be ruled out.

Vaccines

Vaccines for viral hemorrhagic fevers are at various stages of development. The 17D live attenuated yellow fever vaccine has a generally excellent protection and safety profile, despite recent recognition of rare serious adverse events in elderly persons. Confirmed previous vaccination with 17D should essentially exclude the diagnosis of yellow fever unless the patient was immunocompromised at the time of vaccination. A highly efficacious live attenuated vaccine, Candid 1, also exists for Argentine hemorrhagic fever, although it is licensed only in Argentina. Candid 1 may also be effective in Bolivian hemorrhagic fever but does not protect against other arenavirus infections. Experimental vaccines for hemorrhagic fever with renal syndrome, Rift Valley fever, Omsk hemorrhagic fever, and Kyasanur Forest disease may be efficacious, although most have not been widely tested and are not widely approved or available. A number of vaccine candidates have recently been shown to be efficacious in animal models of Ebola, Marburg, and Lassa virus

infection.[18] Clinical trials of various Ebola vaccines are underway, with early results suggesting that they can safely elicit immunogenicity.[19]

Postexposure Prophylaxis

Postexposure prophylaxis should be considered only in persons with distinct high-risk exposure, defined as follows: (1) penetration of skin by a contaminated sharp instrument (e.g., needlestick injury); (2) exposure of mucous membranes or broken skin to blood or body secretions (e.g., blood splashing in the eyes or mouth); (3) participation in emergency procedures without appropriate personal protective equipment (e.g., resuscitation after cardiac arrest, intubation, or suctioning); and (4) prolonged (i.e., hours) and continuous contact in an enclosed space without appropriate personal protective equipment. The most infectious patients are those with severe clinical conditions, usually late in the course of illness. Prophylaxis should not be used when the only exposure was during the incubation period or after fever has subsided.

Postexposure prophylaxis with oral ribavirin has been recommended for Lassa fever, other arenavirus infections, and Crimean-Congo hemorrhagic fever, although no systematic data are available on its efficacy, and the frequent minor adverse events sometimes can be mistaken for the early signs of disease.[20] Oral ribavirin should be started immediately after the exposure, but not before counseling between the patient and the physician. The drug should be taken with food. Baseline hemoglobin, hematocrit, bilirubin, and creatinine levels should be determined, and therapy should be adjusted or reconsidered if significant anemia or renal insufficiency develops.

Convalescent plasma is given as postexposure prophylaxis for Argentine hemorrhagic fever. Numerous experimental vaccines, monoclonal antibodies, and other compounds have shown efficacy as postexposure prophylaxis in animal models, especially for filovirus infections, but are not yet approved for use in humans.

Reservoir and Vector Control

Avoiding contact with bats, primarily by avoiding entry into caves and mines in endemic areas, is a key prevention measure for Ebola and Marburg viruses. Personal protective equipment may be indicated for miners and other persons who work in these environments. Humans should also avoid exposure to fresh blood, body fluids, or meat of wild animals, especially nonhuman primates.

For rodent-borne viruses whose reservoirs often colonize human dwellings, improved "village hygiene" is recommended, such as eliminating unprotected storage of garbage and foodstuffs and plugging holes that allow rodents to enter homes. Prevention of the mosquito-borne hemorrhagic fever viruses hinges on controlling *Aedes* mosquitoes in and around the home, primarily by elimination of clean standing water containers that serve as larval habitats and by use of screened windows and doors, insecticide-treated bed nets, protective clothing, mosquito repellent, and aerosol bomb insecticides in enclosed spaces. Analogous measures can help protect against tick bites.

PROGNOSIS

The clinical course of viral hemorrhagic fever unfolds quite rapidly. In fatal cases, death usually occurs within 7 to 10 days after the onset of hemorrhagic fever symptoms in filovirus infection and in about 2 weeks with the arenaviruses and some of the other viruses. Mortality usually does not result directly from exsanguination, and external bleeding is seen in a minority of cases of viral hemorrhagic fever. Most deaths result from an intense inflammatory process akin to septic shock (Chapter 108) when insufficient effective circulating intravascular volume leads to hypotension, cellular dysfunction, and multiorgan system failure.

Common indicators of a poor prognosis include shock, bleeding, neurologic manifestations, high levels of viremia (or surrogate measurements of antigen or genome copies), elevated levels of aspartate aminotransferase (>150 IU/L), and pregnancy, especially during the third trimester, in which maternal and fetal mortality may be above 90%.

However, mild and even asymptomatic cases have been reported for what are considered the most virulent viral hemorrhagic fevers. Reasons for this heterogeneity are largely unknown, although differences in route and dose of infection, underlying comorbid illness, and host genetic predisposition have been postulated.

Survivors usually suffer no obvious long-term sequelae. Notable exceptions include deafness in up to 30% of patients after Lassa fever and sometimes after Venezuelan hemorrhagic fever and optic retinopathy with vision loss in Rift Valley fever. Nevertheless, convalescence may be prolonged, especially for Ebola and Marburg hemorrhagic fevers, with persistent myalgia, arthralgia, anorexia, weight loss, alopecia, pancreatitis, uveitis, and orchitis up to a year after infection. The psychological effects of viral hemorrhagic fever may include significant irritability, depression, post-traumatic stress disorder, and social stigmatization. For Ebola virus, mortality rates have been about 70% in West Africa.[21] In contrast, a very high proportion of patients who have been treated in the U.S. and Europe have survived with modern supportive care and experimental therapies.[22] Because these patients received multiple therapies in combination and in an uncontrolled fashion, the efficacy of any one therapy cannot be assessed.

Clinical management during convalescence includes the use of warm packs, acetaminophen, nonsteroidal anti-inflammatory drugs, cosmetics, hair growth stimulants, anxiolytics, antidepressants, nutritional supplements, and nutritional and psychological counseling as indicated. Uveitis in patients recovering from Ebola hemorrhagic fever, recently renamed Ebola virus disease, responds to topical steroids and atropine.

Because the patient's clinical status and infectivity generally correlate with the level of viremia, patients who have recovered from their acute illness can safely be assumed to have cleared their viremia and discharged from the hospital without concern of subsequent transmission at home. RT-PCR testing of blood and other body fluids has sometimes revealed residual nucleic acids, but their significance is unclear without cell culture confirmation of the presence of infectious virus. Clearance of virus may be delayed for weeks to months from a few immunologically protected sites, such as the central nervous system, chambers of the eye, and gonads, with the last resulting in rare sexual transmission months after recovery from acute disease. Consequently, abstinence or condom use is recommended for 3 months after acute illness. Although transmission through toilet facilities or ocular secretions has not been noted, simple precautions to avoid contact with these potentially infected body fluids are prudent, including separate toilet facilities and regular handwashing. Breast-feeding should be avoided during convalescence unless there is no other way to support the baby.

REVIEW QUESTIONS

1. Two distinct diseases caused by hantaviruses are hantavirus pulmonary syndrome and

A. Argentine hemorrhagic fever
B. Lassa fever
C. Hantavirus hepatic syndrome
D. Hemorrhagic fever with renal syndrome
E. Adult T-cell leukemia

Answer: D The genus Hantavirus of the Bunyaviridae family is divided into Old and New World groups. The Old World hantaviruses, such as Hantaan, Seoul, and Puumala, among many others, cause hemorrhagic fevers with prominent renal involvement across Europe and Asia. New World hantaviruses, such as Sin Nombre and Andes, among many others, cause a viral hemorrhagic fever named hantavirus pulmonary syndrome, sometimes also called hantavirus cardiopulmonary syndrome to emphasize the significant cardiogenic component of this disease. A thorough travel history can help narrow the differential diagnosis, although there can be, at times, overlap between the two syndromes. One Old World hantavirus, Seoul, can be found virtually worldwide because its reservoir, the common Norway rat, has been spread globally through transport on ships.

2. The antiviral drug ribavirin is most clearly indicated for which of the following viral hemorrhagic fevers?

A. Ebola hemorrhagic fever
B. Yellow fever
C. Lassa fever
D. Omsk hemorrhagic fever
E. Rift Valley fever

Answer: C The only currently available specific antiviral therapy for any viral hemorrhagic fever is the guanosine analogue ribavirin. The best data are for Lassa fever, in which intravenous ribavirin has been shown to decrease mortality in severe disease from 55% to 5% when it is begun within the first 6 days of illness.[1] Ribavirin efficacy has also been demonstrated for hemorrhagic fever with renal syndrome due to Hantaan virus. The drug appears to be efficacious in other arenavirus hemorrhagic fevers and Crimean-Congo hemorrhagic fever, but few randomized controlled clinical trials have been performed for these syndromes. Ribavirin is not efficacious and should not be used for Ebola or Marburg hemorrhagic fevers.

1. McCormick JB, King IJ, Webb PA, et al. Lassa fever. Effective therapy with ribavirin. *N Engl J Med.* 1986;314:20-26.

3. Viral hemorrhagic fever syndromes

A. Can usually be easily distinguished from other common febrile diseases on clinical grounds early in the course of disease
B. Can be confirmed only through virus culture in a high-containment laboratory
C. Are usually characterized by copious bleeding, often leading to exsanguination and death
D. Typically have incubation periods of days to weeks
E. Should be routinely treated with intravenous corticosteroids

Answer: D After an incubation period ranging from days to weeks, most patients with viral hemorrhagic fever present with nonspecific signs and symptoms difficult to distinguish from a host of other febrile illnesses. Laboratory confirmation is therefore imperative and can be performed through a variety of methods, including the enzyme-linked immunosorbent assay, polymerase chain reaction, virus culture, and immunohistochemistry on postmortem tissues. Most of these assays do not involve live virus and thus can be performed outside of a high-containment laboratory, noting that the specimen to be tested may nevertheless be infectious. Despite the name, external bleeding is seen in a minority of cases of viral hemorrhagic fever, especially early in the course of disease. Death in fatal cases is not typically due to exsanguination but rather to an intense inflammatory process akin to septic shock leading to multiorgan system failure. Adrenal or pituitary gland necrosis with consequent vascular collapse has been postulated but not specifically demonstrated. Corticosteroids are not indicated unless adrenal insufficiency is strongly suspected, the target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or cerebral edema is suspected.

4. Which of the following is the most essential component of control of Lassa virus transmission between humans?

A. Immediate isolation of all patients in the incubation period
B. Placement of insecticide-treated bed nets and room screens in patient rooms
C. Donning of "space suits" by health care personnel working in patient isolation wards
D. Placement of suspected case-patients in hermetically sealed rooms
E. Routine barrier nursing precautions (gloves, gowns, and masks)

Answer: E Human-to-human transmission of Lassa virus, as for the other directly communicable hemorrhagic fever viruses, is through direct contact with infected blood and body fluids. Routine barrier nursing precautions to prevent parenteral and droplet exposure are protective in most cases, although "viral hemorrhagic fever precautions" consisting of the use of surgical masks, face shields, double gloves, gowns, head and shoe covers, and protective aprons are implemented for added safety once the syndrome is suspected. Patients are not infectious during the incubation period. There is little evidence for aerosol transmission between humans. Hermetically sealed isolation chambers are not required, although it is prudent to place the patient in a negative airflow room if it is available. The reservoir for Lassa virus is the rodent *Mastomys natalensis*, commonly called the natal mastomys or multimammate rat. There is no arthropod vector.

5. A 23-year-old otherwise healthy woman is seen with complaints of fever, malaise, headache, and muscle aches for the past 5 days. She recently returned from a church mission trip in which she assisted physicians and nurses treating patients in a resource-poor area of Bolivia. She is in moderate distress with vital signs as follows: temperature, 102.5° F; blood pressure,105/65 mm Hg; pulse, 120; and respiratory rate, 24. Her conjunctivae are injected, and a petechial rash is noted over her torso. Initial laboratory findings show moderate leukopenia, hemoconcentration, and mild to moderate thrombocytopenia. You suspect infection with which of the following hemorrhagic fever viruses?

A. Machupo virus
B. Lujo virus
C. Ebola virus
D. Junín virus
E. Sin Nombre virus

Answer: A With the exception of dengue virus, hemorrhagic fever viruses are zoonotic and are maintained in nature in mammalian reservoirs. The endemic area of any given hemorrhagic fever virus is restricted by the distribution of its natural reservoir or arthropod vector. Knowledge of the geographic limits of the reservoir, along with a detailed travel history, is key to assessing the likelihood of exposure to a given hemorrhagic fever virus. In this case, the patient may have been exposed to Machupo virus, the causative agent of Bolivian hemorrhagic fever, which is endemic only in Bolivia. Junín virus is also found in South America but is restricted to the Argentine pampas. Ebola and Lujo viruses are endemic in Africa. Sin Nombre virus, which is one of the causative agents of hantavirus pulmonary syndrome, is found in North America. Other hantaviruses are found in Bolivia, but the patient's presentation and laboratory results are not consistent with hantavirus pulmonary syndrome, in which rash would be unusual and leukocytosis with immunoblasts is classically noted. The fact that she had potential exposure to human blood or body fluids while assisting physicians and nurses should heighten suspicion of a viral hemorrhagic fever.

ARBOVIRUSES CAUSING FEVER AND RASH SYNDROMES

STANLEY J. NAIDES

COLORADO TICK FEVER

DEFINITION

Colorado tick fever (mountain fever, American mountain fever) is an acute, often self-limited, typically biphasic febrile illness that is common in the Rocky Mountain areas, the Sierra Nevada and Wasatch ranges, and the Black Hills mountain areas.[1] The virus is transmitted through the bite of the hard-shelled tick *Dermacentor andersoni* (Rocky Mountain wood tick), and the disease's range corresponds to the vector's range. Other coltiviruses, such as the Salmon River, Eyach, Banna, Beijing, and Gansu viruses, have also been implicated in human disease.

The Pathogen

The causative agent, Colorado tick fever virus, is a member of the genus Coltivirus, family Reoviridae. Coltiviruses have a genome consisting of 12 double-stranded RNA segments. Colorado tick fever virus is the prototype member.

EPIDEMIOLOGY

D. andersoni is found at elevations of 4000 to 10,000 ft. Seasonal temperatures tend to influence the range, with the vector being found at higher elevations in warmer seasons and at lower elevations in colder seasons. Human exposure usually occurs during outdoor recreational activities in these areas. Occasional exposure occurs in nonendemic areas from ticks exported out of the endemic region in clothes, hiking equipment, or baggage. Infections generally take place between March and September, when the adult tick is most plentiful. Ticks are most abundant in south-facing dry and rocky slope habitats that favor small rodents (e.g., chipmunks, ground squirrels, marmosets), with underbrush cover, burrows, and humidity for the ticks. Colorado tick fever virus is found in nymphal and adult ticks that overwinter on the rodent host, in which viremia persists for weeks to months. In the endemic area, as many as 14% of *D. andersoni* ticks carry Colorado tick fever virus. Humans are an incidental host. Fewer than 50 cases have been reported annually in Colorado beginning in 1992. The actual number of cases is probably significantly larger and includes subclinical, mild, and unreported cases.

The geographic range of Colorado tick fever may be larger than the well-recognized endemic mountain areas. Serologically confirmed cases in California have been attributed to the Colorado tick fever–related virus S1-14-03, which is transmitted by *Dermacentor variabilis* (American dog tick). Salmon River virus causes a Colorado tick fever–like illness in rafters on the Salmon River in Idaho. Another similar virus, Eyach virus, has been implicated in neurologic illness in France and Germany and has been isolated from the deer ticks *Ixodes ricinus* and *Ixodes ventalloi*. Colorado tick fever has been reported rarely in mainland China.

PATHOBIOLOGY

Colorado tick fever virus replicates in $CD34^+$ stem cells in bone marrow and leads to mild to moderate leukopenia and thrombocytopenia. The virus also replicates in committed erythrocyte precursors and may be detected in circulating erythrocytes up to 4 weeks after infection.

CLINICAL MANIFESTATIONS

Patients report a tick bite or exposure in 90% of cases, but there is no notable local reaction to the tick bite. After a mean incubation of 3 to 4 days (range, 0 to 14 days), sudden-onset fever develops in association with malaise, chills, myalgia, weakness, headache, photophobia, retro-orbital pain, and cutaneous hyperesthesia. Conjunctival and oropharyngeal injection, palatal enanthem, lymphadenopathy, and splenomegaly may be present. The absence of prominent respiratory and gastrointestinal symptoms helps exclude other febrile illnesses. A petechial or maculopapular exanthem, found in 15% of patients, may be confused with the rash of Rocky Mountain spotted fever (Chapter 327). The illness has a "saddleback" fever pattern consisting of resolution of the initial fever within 1 week and recrudescence after a 2- to 3-day hiatus. A third fever episode may occur.

Leukopenia develops 5 to 6 days after onset of the illness. Mild thrombocytopenia and anemia may occur.

Myocarditis, pneumonitis, hepatitis, orchitis, and epididymitis may complicate adult infection, and aseptic meningitis or encephalitis may occur in up to 10% of childhood infections.

DIAGNOSIS

Clinical diagnosis is confirmed by demonstration of the Colorado tick fever viral genome or specific acute phase IgM antibody. The viral genome may be detected up to 6 weeks after infection by nucleic acid–based methods such as reverse transcription–polymerase chain reaction (RT-PCR) on blood or stored blood clots. Virions in circulating erythrocytes may be detected by immunofluorescent antibody labeling. Anti–Colorado tick fever virus IgM antibody is detected by antibody capture enzyme-linked immunosorbent assay (ELISA) or complement fixation. Neutralization assays using Vero or BHK-21 cells have been helpful.

Differentiating Colorado tick fever from Rocky Mountain spotted fever (Chapter 327) may be difficult before the appearance of the typical rash of the latter. However, Rocky Mountain spotted fever does not have a saddleback fever pattern and is 20 times less common than Colorado tick fever in the western endemic area.

TREATMENT

Rx

Treatment is supportive. Aspirin is contraindicated to avoid complicating thrombocytopenia.

PROGNOSIS

Extreme weakness and malaise may persist for weeks to months after final resolution of the fever. Older patients have a prolonged recovery. Seventy percent of patients older than 30 years may still have fatigue 3 weeks after the fever, whereas children and adolescents may recover completely within a week. Rare instances of maternal-fetal transmission have been reported. Full recovery eventually occurs, except when the disease course is complicated by neurologic insult. Patients should refrain from donating blood for 6 months.

DENGUE

DEFINITION

Dengue is an acute febrile illness characterized by severe muscle and joint pain, rash, malaise, and lymphadenopathy. The severity of the musculoskeletal complaints gave rise to the sobriquet *breakbone fever*. Dengue occurs in the tropical and subtropical climes of the Caribbean, Central and South America, Asia, and Africa. The mosquito range extends into the southeastern part of the United States, where dengue reemerged in the 1980s. After World War II, a spreading global pandemic has been associated with erosion of mosquito control programs, human population spread into rural settings, increased air travel, deterioration in public health infrastructure, and global warming. Each year, more than 200 million people worldwide are infected with dengue.[2]

The Pathogen

Dengue virus is a member of the Flaviviridae family, which consists of single-stranded RNA viruses with a lipid envelope approximately 50 nm in diameter. There are four serotypes of dengue: DEN-1, DEN-2, DEN-3, and DEN-4. No cross-protection is seen among the serotypes, so dengue can develop after infection with another serotype. Infection with a second serotype places the individual at risk for the development of hemorrhagic fever (Chapter 381).

EPIDEMIOLOGY

Dengue is transmitted to humans by the bite of female *Aedes aegypti* and *Aedes albopictus* mosquitoes. *A. albopictus* has become the dominant pest mosquito in many urban centers. Members of the two mosquito species acquire dengue virus by biting humans, typically during the day. The mosquitoes nest in stagnant water around human dwellings; they are not typically encountered in the forest. In the human host, dengue virus may reach a titer of greater than 10^8 median infectious doses per milliliter. The mosquito becomes infected when taking its meal from a viremic host. The virus continues replication in the midgut epithelium and salivary glands of female mosquitoes, which remain infectious for life. Within 8 to 12 days of the initial infection, the mosquito's salivary glands become infected, and virus is shed with saliva during the next blood meal. A given mosquito may infect multiple individuals, especially in view of its skittishness during feeding—slight movement of the host interrupts its meal, after which it returns to the original or another host. Zoonotic life cycles involving nonhuman primates (i.e., chimpanzees, gibbons, and macaques) and canopy-dwelling forest *Aedes* species have been demonstrated in western Africa and Malaysia.

The incubation period is typically 4 to 7 days but may range from 3 to 14 days. During outbreaks in the southeastern United States and Puerto Rico, the risk for infection may be as high as 79% in naïve hosts, and clinical disease may develop in up to 20%. Immunity against the infecting serotype is probably lifelong, but individuals remain susceptible to the remaining serotypes. Peak transmission occurs after increased rainfall, when rainwater collected in household containers allows expansion of mosquito populations. Epidemics tend to occur in 3- to 5-year cycles, but interepidemic cases occur regularly.

Dengue is a particular risk to visitors to the tropics and is a leading cause of pediatric morbidity and mortality in endemic areas.[3] Globalization and climate change have contributed to expansion of the geographic range. In one study of people who now live in the United States but who were born, lived

in, or traveled to dengue-endemic countries, 19% had IgG antibodies to dengue but 85% of them had no clinical history of dengue. Dengue accounts for approximately 2% of the febrile illnesses in travelers returning to the United States.

PATHOBIOLOGY

Dengue hemorrhagic fever (Chapter 381) and dengue shock syndrome are forms of dengue reinfection characterized by capillary leakage and hemorrhage. Previous infection with an alternative serotype allows antibody to the previously encountered serotype to combine with the newly infecting serotype. Although the first exposed serotype antibody is not neutralizing, it does allow enhanced antibody-mediated macrophage uptake, thereby leading to macrophage activation and increasing viral replication and viral load. Excretion of vasoactive inflammatory mediators by macrophages results in vascular leakage; severe vascular leak causes shock. Endothelial cell swelling and perivascular edema may occur. Rarely, dengue shock syndrome may occur with primary infection. Variation in a strain's ability to generate enhancing antibody, as well as differences in virulence, may account for differences in clinical behavior.

CLINICAL MANIFESTATIONS

Dengue infection is often subclinical. When it is symptomatic, dengue may be manifested as classic dengue, dengue hemorrhagic fever, or dengue shock syndrome. Patients may also have mild illness characterized by nonspecific fever, anorexia, and headache.

Classic dengue, which typically occurs in nonindigenous older children and adults, is characterized by sudden-onset fever, severe frontal headache, retro-orbital pain, myalgia, and, in many cases, nausea, vomiting, rash, lymphadenopathy, and arthralgia.[4] Patients may experience generalized weakness, altered taste, rigors, and cutaneous hyperesthesia. Classic dengue is self-limited, but some patients progress to dengue hemorrhagic fever or dengue shock syndrome, which is characterized by capillary leakage, hypotension, narrowed pulse pressure, and shock. Dengue in pregnancy may be severe.[5]

Physical examination demonstrates fever, relative bradycardia, scleral injection, ocular pressure tenderness, and pharyngeal injection. A transient macular rash appears on days 1 or 2 of illness. On days 2 and 3 of illness, fever and other symptoms may improve. The fever is typically but not consistently biphasic. After a hiatus of typically 2 days, fever and other symptoms recrudesce, although less severely. Generalized, nontender lymphadenopathy of the posterior cervical, epitrochlear, and inguinal regions may develop. Rash also recurs and appears as 2- to 5-mm speckles of pallor surrounded by erythema and occasionally accompanied by burning dysesthesia of the palms and soles. The rash may desquamate.

DIAGNOSIS

An adequate travel history and knowledge of occurrence of disease in the community can lead to consideration of dengue in the differential diagnosis. Viremia is of adequate intensity in infections with DEN-1, DEN-2, and DEN-3 to allow viral isolation. Viremia in DEN-4 infections is often less intense and more difficult to detect through inoculation of mosquito cells in vitro. Specific IgM antibody appears 3 to 5 days after infection. IgG antibody appears 9 to 10 days after infection. Cross-reactivity with other flaviviruses prevents serotype-specific diagnosis. Neutralization testing with hemagglutination inhibition is more specific, and complement fixation testing for IgG in paired sera is helpful. PCR-based assays are available.

Leukopenia develops by the second day of fever, falling to a low of 1000 to 2000 cells/mL by day 5 or 6, and is associated with granulocytopenia. In dengue hemorrhagic fever, thrombocytopenia of less than 100,000 cells/mL and a prolonged prothrombin time are characteristic.[6] Mild to moderate proteinuria and a few casts may be detected. Aspartate transaminase levels may be increased.

TREATMENT, PREVENTION, AND PROGNOSIS

Rx

Classic dengue resolves abruptly in 5 to 7 days, but fatigue and depression may linger for weeks; survival is uniform. The prognosis of patients with dengue hemorrhagic fever (Chapter 381) and dengue shock syndrome depends on early diagnosis and the introduction of supportive measures. Treatment is supportive and consists of antipyretics and analgesics. Initial resuscitation of patients with shock syndrome (Chapter 106) with crystalloid and colloidal solutions is indicated in those with moderately severe dengue shock syndrome. Fresh-frozen plasma and blood products are used as necessary.

A new tetravalent dengue vaccine can prevent about two-thirds of cases of dengue and about 95% of severe cases. Most infected patients recover fully, but the overall mortality rate is about 1% because of the poorer outcome of dengue shock and hemorrhagic fever (Chapter 381).

WEST NILE FEVER VIRUS

DEFINITION

West Nile fever is an acute febrile illness associated with malaise, rash, headache, myalgia, and lymphadenopathy. Infection involves a bird-mosquito-human cycle.[7] Viremia develops in all varieties of birds. Bats, cats, chipmunks, domestic rabbits, horses, skunks, squirrels, dogs, sheep, llamas, and alpacas may be infected.

The Pathogen

West Nile fever virus, which is the most widely distributed flavivirus, is transmitted by a variety of mosquito species. The mosquito vector varies: *Culex univittatus*, *Culex pipiens*, and *Culex molestus* in the Middle East and Africa; *Mansonia metallicus* in Uganda; and *Culex tritaeniorhynchus* in Asia. After introduction into the New York City area in 1999, *C. pipiens* became the most important vector in the United States. Other mosquito species may carry the virus.

EPIDEMIOLOGY

Viral transmission involves mosquitoes and wild birds, with mammals, including humans, being incidental end-stage hosts. In endemic areas, more than 60% of young adults have antibodies, thus suggesting a high prevalence of inapparent or undifferentiated febrile illness in children. There is no gender predominance. Between 0.5 and 1% of infected individuals experience a more severe illness. Incubation is typically 3 to 15 days but may be as short as 1 day. West Nile virus emerged in the United States in New York and has spread throughout the continental United States, Canada, Mexico, the Caribbean, and Central and South America. In America, birds of the Corvidae family (e.g., crows, jackdaws, ravens) are often infected, and recognition of increased death in crow populations continues to serve as a sentinel for the presence of West Nile virus. In addition to mosquito transmission, the virus has been transmitted by a transplanted organ, through blood transfusion, transplacentally, and in the laboratory. From 1999 to 2004, almost 17,000 neuroinvasive cases were reported to the Centers for Disease Control and Prevention.

Zika virus, a flavivirus related to dengue and West Nile virus, has emerged in Africa, Asia, and the Yap Islands of the southwestern Pacific. It causes outbreaks of fever, rash, arthralgia, and conjunctivitis.

PATHOBIOLOGY

West Nile virus grows in a variety of cells in vitro and produces cytopathic effects in *A. albopictus* cells. Individuals in whom encephalitis develops show evidence of diffuse brain inflammation and neuronal degeneration, with virus detected early in multiple sites. The virus initially replicates in keratinocytes and skin-resident dendritic cells, which then migrate to local lymph nodes, where replication generates viremia and organ dissemination. Either immune cell trafficking or disruption of the blood-brain barrier allows neuroinvasion.

CLINICAL MANIFESTATIONS

Approximately 80% of infections are asymptomatic, and most of the remaining infections are mild and manifested by fever, malaise, headache, nausea, anorexia, generalized lymphadenopathy, and myalgia.[8] Aseptic meningitis or encephalitis (Chapter 383) may occur in the elderly and, less commonly, in the very young. Severe neurologic disease, including meningitis, myelitis, encephalitis, and flaccid paralysis of the limbs and respiratory muscles, can develop. Like Colorado tick fever and dengue, West Nile fever may be biphasic. Nonpruritic, maculopapular, or roseolar rash occurs on the chest, back, and arms in half the patients, beginning during or with resolution of the fever. The rash persists for up to 1 week and then resolves with desquamation. Patients may experience vomiting, diarrhea, abdominal pain, and pharyngitis. Anterior myelitis or hepatitis may also occur. Disease is usually milder in children than in adults.

DIAGNOSIS

West Nile virus may be isolated from up to 77% of patients with West Nile fever on the first day of illness, but viral isolation is less common in patients with encephalitis (Chapter 383). Low-titer viremia may persist for the first 5 days of illness. Tests in acute and convalescent phase serum for virus-specific antibody using ELISA or immunofluorescence are diagnostic. However, virus-specific IgM may persist in the serum at 1 year after infection in a minority of patients. Detection of West Nile virus–specific IgM in cerebrospinal fluid is diagnostic of neuroinvasion because IgM normally does not cross the blood-brain barrier. Neutralization assays help distinguish cross-reactive antibodies to other flaviviruses. RT-PCR may detect viral RNA in human samples and in avian and insect specimens.

TREATMENT Rx

Treatment is supportive. The clinical value of antiviral agents is unknown. Infection is controlled by the endogenous development of neutralizing antibodies to protein E, the viral envelope protein.

PROGNOSIS

Illness generally persists 3 to 6 days before rapid recovery. The prognosis is excellent, but mortality rates of 10% or higher occur in patients with encephalitis (Chapter 383).

PHLEBOTOMUS FEVER

DEFINITION

Phlebotomus fever (i.e., sandfly fever, pappataci, and 3-day fever) is an acute, mild, self-limited febrile illness transmitted through the bite of *Phlebotomus* flies.

The Pathogen

Phlebotomus fever viruses are members of the genus Phlebovirus, family Bunyaviridae. The latter consists of a group of single-stranded RNA viruses that are 80 to 120 nm in diameter, possess a lipid envelope, and have three segments in the genome. A related virus, the Toscana virus hosted by *Phlebotomus perniciosus* and *Phlebotomus perfiliewi*, causes a similar illness in countries surrounding the northern Mediterranean basin and is emerging in western Europe. The related Punique, Granada, and sandfly fever Turkey viruses may cause similar febrile illnesses, acute meningitis, or meningoencephalitis.

EPIDEMIOLOGY

The virus's distribution parallels the distribution of *Phlebotomus* flies found throughout the Mediterranean basin, Middle East, and western India and Pakistan. In Central America, *Lutzomyia* fly species may transmit the virus. These tiny sandflies pass through mosquito netting to feed in the early evenings. Virus is maintained by transovarial and transstadial transmission. During outbreaks, humans may serve as a reservoir. Human infection is more common in rural areas during the summer months.[9] The incubation period is 2 to 6 days. Sandflies spread by hopping, thus limiting their travel range. Use of insect sprays locally is effective in decreasing risk.

CLINICAL MANIFESTATIONS

Sandfly fever virus causes an acute febrile illness associated with malaise, headache, photophobia, ocular pain, altered taste, myalgia, and arthralgia. The myalgias may be localized to specific regions (e.g., the chest) and simulate regional syndromes such as pleurodynia. A macular or urticarial rash may appear. Examination may show relative bradycardia after the first day, conjunctival injection, mild papilledema, or small palatal vesicles. Fever lasts 2 to 4 days and then subsides. Weakness and malaise may persist during convalescence. About 15% of patients experience recrudescence in 2 to 12 weeks. Aseptic meningitis may occur with mild cerebrospinal fluid pleocytosis. Peripheral leukopenia and lymphopenia may be present early in the illness. However, leukopenia may be delayed in some patients until the third day of illness, and a rebound relative lymphocytosis may be encountered.[10]

DIAGNOSIS

The diagnosis of phlebotomus fever is confirmed by isolation of virus after intracerebral inoculation of suckling mice, detection of the viral genome by RT-PCR, or detection of specific IgM antibody by ELISA.

TREATMENT AND PROGNOSIS Rx

Treatment is supportive, and recovery is complete. Ribavirin (Chapter 360) has been proposed as a therapeutic option.

RIFT VALLEY FEVER

Rift Valley fever, which is an acute-onset, febrile illness, is often associated with epizootic waves of spontaneous abortion in livestock.[11]

DEFINITION

The Rift Valley fever virus is a member of the family Bunyaviridae, genus Phlebovirus, but unlike other members of the genus, it is transmitted by *Aedes* mosquitoes.

EPIDEMIOLOGY

Rift Valley fever occurs throughout most of Africa, with the majority of epizootic outbreaks occurring in eastern and southern Africa, although outbreaks occurred in Saudi Arabia and Yemen in 2000 and Mauritania in 1998, 2003, 2010, and 2012. The principal initial vectors are probably the *Aedes* species associated with flooding, although *Stomoxys* flies have been shown to transmit virus as well. Shallow pools along rivers and streams play an important role as mosquito breeding sites. Feeding on nearby livestock allows a local epizootic outbreak and amplification of the virus in local mosquito populations, including *C. pipiens* in Egypt and *Culex theileri* in eastern Africa. Exposure to aborted livestock increases human risk of infection.

Hemorrhagic fever in humans is typically seen 1 to 2 weeks after a wave of abortion in livestock. Initial human cases usually occur in those who have close contact with livestock. The virus is highly transmissible through aerosolization. Although the risk for severe human infection is less than 1%, the extensive exposure associated with outbreaks can lead to significant morbidity and mortality. For example, in the 1977-1978 Egyptian outbreak associated with movement of camels from Sudan, an estimated 200,000 people were infected, with 600 deaths. Zinga virus, isolated in central Africa and Madagascar and shown to be responsible for mild human illness, is a strain of Rift Valley fever virus.

PATHOBIOLOGY

Rift Valley fever virus grows well in a variety of cell cultures and has cytopathic effects. After infection by a mosquito bite, virus is transported through the lymphatics to regional lymph nodes, where replication allows amplification of the input inoculum and development of viremia with systemic spread. Viral replication in liver, spleen, lymph node, adrenal, lung, and kidney tissues is highly cytopathic. In severe cases, hepatic necrosis and, rarely, focal brain necrosis may occur. Encephalitis is not associated with viremia, thus suggesting that this sequela is immune mediated rather than a direct viral effect. Inflammatory cell infiltration is associated with focal necrosis in the brain. Spontaneous abortion is common in livestock, but fetal loss in humans is not clearly correlated with viral infection.

CLINICAL MANIFESTATIONS

Most human infections are mild, with an abrupt onset of fever, chills, malaise, and arthralgia following a 2- to 6-day incubation. Despite the development of neutralizing antibodies, however, about 1 to 2% of infections progress to more severe disease, including a severe hemorrhagic fever associated with hepatic necrosis and disseminated intravascular coagulopathy. Recovery is complicated by retinal vasculitis or encephalitis, which occurs in less than 0.5% of patients 1 to 4 weeks after recovery and is associated with recurrent fever. In severe cases, focal brain necrosis and encephalitis may lead to hallucinations, stupor, coma, and death.

DIAGNOSIS

Intense viremia allows detection of virus by quantitative real-time RT-PCR. Specific IgM and IgG are detectable by ELISA applied to acute and convalescent (after 1 to 2 weeks) paired sera.

TREATMENT, PREVENTION, AND PROGNOSIS

Rx

Treatment is supportive. Ribavirin (see Table 381-5 and Chapter 360) has been proposed as a therapeutic option but exhibits limited penetration of the blood-brain barrier. Favipiravir, a selective inhibitor of RNA-dependent RNA polymerase, is also a candidate therapeutic under study. In endemic areas, vaccination of livestock is the most effective preventive measure.

The prognosis is good in the absence of retinitis or encephalitis. A high viral load at initial evaluation is a prognostic indicator for a poor outcome.

CHIKUNGUNYA FEVER

DEFINITION

Chikungunya fever is a febrile arthritis that occurs in sporadic cases and in epidemics.[12]

The Pathogen

Chikungunya, an enveloped, single-stranded RNA virus 60 to 70 nm in diameter, is a member of the family Togaviridae, genus Alphavirus. Chikungunya virus is transmitted by mosquitoes, principally *Aedes* species, but also by *Mansonia africana* and other genera. Known animal reservoirs are monkeys, baboons, and, in Senegal, *Scotophilus* bat species. During outbreaks, humans are the major reservoir.

EPIDEMIOLOGY

Chikungunya, which is endemic in sub-Sahara Africa, India, the Philippines, and Southeast Asia, spread in 2004-2005 to the Seychelles, Mauritius, and Mayotte islands with a genotype better adapted to *A. albopictus*. This genotype then spread to India, where the outbreak continues with millions being affected. The global emergence of this disease is exemplified by outbreaks in Réunion Island, Bhutan, Papua New Guinea, and Italy as well as by recently reported cases in several Caribbean islands.[13] Non-travel related cases have been reported in Florida, United States.[14] Outbreaks typically develop after heavy rains. In urban settings, outbreaks are explosive. In endemic areas, seroprevalence rates may be as high as 90%, thus suggesting that time required for loss of herd immunity is the reason for the prolonged absence of cases in a region after an outbreak. Globalization may contribute to increasing propensity for spread. After inoculation, the incubation period is typically 2 to 3 days but ranges from 1 to 12 days.

PATHOBIOLOGY

Intense viremia develops within 48 hours of the mosquito bite and wanes 2 to 3 days later. Onset of hemagglutination inhibition and neutralizing antibodies clears the viremia. Superficial capillaries in rash-involved skin demonstrate erythrocyte extravasation and perivascular cuffing. The virus adsorbs to human platelets and causes them to aggregate. Synovitis probably results from direct chikungunya viral infection of synovium.[15]

CLINICAL MANIFESTATIONS

Chikungunya fever is characterized by an explosive onset of fever and severe arthralgia. Constitutional symptoms, fever (temperature to 40° C), rigors, headache, photophobia, retro-orbital pain, conjunctival injection, pharyngitis, anorexia, nausea, vomiting, abdominal pain, tense lymphadenopathy, and myalgia are common. A maculopapular rash located on the torso, extremities, and occasionally the face, palms, and soles occurs in most patients 1 to 10 days after onset of the illness. Appearance of the rash is often associated temporally with initial defervescence; the rash may recur with fever and may be pruritic. Isolated petechiae and mucosal bleeding may occur, but significant hemorrhage is rare. Desquamation may take place when the rash resolves. The initial acute illness may last 2 to 3 days (range, 1 to 7 days). Fever may recrudesce after a 1- to 2-day hiatus. The polyarthralgia is migratory and predominantly affects the small joints of the hands, wrists, feet, and ankles, with less prominent involvement of the large joints.[16] Previously injured joints may be more severely affected. Stiffness and swelling may occur, but large effusions are uncommon. Synovial fluid shows decreased viscosity with poor mucin clot and 2000 to 5000 white blood cells per milliliter. Symptoms, including arthralgia, arthritis, and tenosynovitis, may persist for months to years. Maternal-fetal transmission may result in severe neonatal infection.

DIAGNOSIS

Chikungunya fever must be differentiated from dengue and o'nyong-nyong fever. Chikungunya virus may be isolated from blood during the initial 2 to 4 days of illness. In some patients, viral antigen may be detected in acute sera by hemagglutination assay as a result of the intensity of the viremia. Commercially available real-time RT-PCR assays on acute phase serum may be used to confirm the diagnosis. Specific IgM antibody may be detected for 6 months or longer. Hemagglutination inhibition and neutralization antibodies develop as the viremia is cleared. Complement fixation antibodies are positive by the third week and slowly decrease during the subsequent year.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonsteroidal anti-inflammatory agents are useful. During the acute arthritis, range of motion exercises lessen the stiffness. In most cases, mild joint symptoms may persist for months. Destructive arthropathy is rare and may be associated with low-titer rheumatoid factor, thus suggesting an unrelated, underlying inflammatory arthritis. Following the outbreak on Réunion Island in 2006, 70% of affected patients had episodic arthralgia, typically symmetric and incapacitating, with joint swelling in 63% at 3 years after infection.[17] In children, arthralgia and arthritis are milder and briefer in duration. A safe, immunogenic vaccine is currently under investigation.[18]

O'NYONG-NYONG FEVER

DEFINITION

O'nyong-nyong means "joint breaker" in the Acholi dialect of northwestern Uganda, where o'nyong-nyong fever first appeared in February 1959.

The Pathogen

O'nyong-nyong fever is clinically similar to chikungunya fever, and the viruses share antigenic similarity. O'nyong-nyong virus is also a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Within 2 years of its appearance in 1959, the o'nyong-nyong fever virus spread through Uganda and eastern Africa and affected 2 million people. Serologically determined attack rates ranged from 50 to 60%, with case rates of 9 to 78%. Disease spread at a rate of 2 to 3 km daily. After the epidemic, the virus was not detected again until it was isolated from *Anopheles funestus* mosquitoes in Kenya in 1978. *Anopheles gambiae* also serves as a vector. Serologic surveys suggested that o'nyong-nyong virus is endogenous, but cases were not detected again until 1996-1997, during an outbreak in south central Uganda. An outbreak in western Côte d'Ivoire occurred in 2003. The nonhuman vertebrate reservoir for o'nyong-nyong virus is not known. The incubation period lasts at least 8 days. O'nyong-nyong fever virus vectors include *A. funestus*, *A. gambiae*, and other species.

Igbo-ora (meaning "the disease that breaks your wings") virus is a variant of o'nyong-nyong, with 98.5% homology between the two at the genomic level. Igbo-ora is serologically similar to the chikungunya and o'nyong-nyong viruses. In 1984, an epidemic of fever, rash, arthralgia, and myalgia occurred in four villages on the Ivory Coast. The virus was isolated from *A. funestus* and *A. gambiae* mosquitoes and from affected individuals.

PATHOBIOLOGY

Little is known about the pathobiology of o'nyong-nyong fever.

CLINICAL MANIFESTATIONS

Illness begins with a sudden onset of polyarthralgia and polyarthritis. Between 4 and 7 days later, rash begins with improvement in joint symptoms. The rash is uniform in nature, begins on the face, and then spreads to the torso and extremities and occasionally to the palms. The rash lasts 4 to 7 days before fading. Fever is not prominent, but postcervical lymphadenopathy may be marked. Arthralgia is incapacitating in most patients for up to a week, but residual joint pain may persist for months.

DIAGNOSIS

O'nyong-nyong fever is difficult to differentiate from chikungunya fever and may also be mistaken for measles. Specific hemagglutination inhibition and

complement fixation tests are available. Mouse antisera raised against chikungunya virus react equally well with o'nyong-nyong virus, but o'nyong-nyong antisera do not react well with chikungunya virus. O'nyong-nyong–specific RT-PCR is available in reference laboratories.

TREATMENT AND PROGNOSIS

Rx

Treatment is symptomatic. Although residual joint pain often persists, there do not appear to be any long-term sequelae.

MAYARO FEVER

DEFINITION

Mayaro fever is an acute febrile illness characterized by fever, rash, arthralgia, and arthritis. Mayaro virus was first recognized in Trinidad in 1954. It has caused recorded outbreaks in Bolivia and Brazil and is endemic in the rain forest region where Bolivia, Brazil, and Peru share borders. Mayaro virus has a monkey reservoir and is transmitted to humans by *Haemagogus* mosquitoes dwelling in the tropical rain forest canopy.

The Pathogen

Mayaro virus is a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Mayaro virus was responsible for an outbreak in Belterra, Brazil, in 1988. Eight hundred of 4000 exposed latex gatherers became infected, with a clinical attack rate of 80%. Forest workers and hunters continue to be at greatest risk. Cases of imported Mayaro virus infection have been documented in the United States and in Europe after travel to the endemic Brazil-Bolivia-Peru interborder region.[19] The virus has been isolated from a bird in Louisiana, thus raising the specter of emergence in North America.

PATHOBIOLOGY

Viremia occurs during the first 1 to 2 days of illness.

CLINICAL MANIFESTATIONS

Illness is characterized by a sudden onset of fever, headache, dizziness, chills, and arthralgia in the small joints of the hands and feet. About 20% of patients have joint swelling. Unilateral inguinal lymphadenopathy is seen occasionally. Leukopenia is common. Fever resolves after 3 to 7 days, but a maculopapular rash then develops on the trunk and extremities of about two thirds of patients and lasts about 3 days.

DIAGNOSIS

Mayaro virus may be isolated from blood by growth in Vero or C6/36 cells. RT-PCR with ELISA is available. A specific IgM is also available as an antibody capture ELISA.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Recovery is complete, although some patients have persistent arthralgia 6 months later.

ROSS RIVER FEVER VIRUS (EPIDEMIC FEBRILE POLYARTHRITIS)

Ross River fever virus causes an acute-onset, febrile illness characterized by rash and arthralgia. Ross River virus is a member of the family Togaviridae, genus Alphavirus.

EPIDEMIOLOGY

Epidemics of fever and rash have been observed in Australia since 1928. Isolation of Ross River virus from mosquitoes, its serologic association with epidemic polyarthritis, and isolation of the virus from epidemic polyarthritis patients in Australia confirmed Ross River virus as the etiologic agent of epidemic polyarthritis. Seroprevalence has been observed in endogenous populations in Papua New Guinea, western New Guinea, the Bismarck Archipelago, Rossel Island, and the Solomon Islands. An outbreak in the Fiji Islands affected more than 40,000 individuals in 1979 to 1980. A similar epidemic occurred in the Cook Islands early in 1980. Antibodies to Ross River virus are not found in individuals west of Weber's line, a hypothetical line separating the Australian geographic zone from the Asiatic zone. Endemic cases and epidemics occur in tropical and temperate regions in Australia. Queensland and New South Wales have a particularly high annual incidence associated with higher rainfall. High rainfall usually precedes epidemic periods, with cases subsequently occurring from spring through fall. Seroprevalence may reach just 6 to 15% in temperate coastal zones but is 27 to 39% in the plains of the Murray Valley river system. In Queensland, annual rates of disease range from 31.5 to 288.3 per 100,000 person-years. From 1992 to 2006, 55,000 cases of Ross River virus infection were reported in Australia.

Aedes vigilax is the major vector on the eastern coast of Australia and *Aedes camptorhynchus* in the salt marshes of southern Australia. *Culex annulirostris* is a freshwater breeding vector. Other Australian *Aedes* species and *Mansonia uniformis* may also serve as vectors. In outbreaks on the Pacific islands, *Aedes polynesiensis*, *A. aegypti*, *A. vigilax*, and *C. annulirostris* may have contributed to transmission. Domestic animals, rodents, and marsupials may serve as intermediate hosts. Virus may persist in *Aedes* mosquitoes.

There is a predominance of women among infected individuals. Children have a case attack rate ratio lower than that of adults. The incubation period is 7 to 11 days.

Barmah Forest virus, another alphavirus found in Australia in 1986, may be manifested in a fashion similar to epidemic febrile polyarthritis. The number of cases reported annually has been increasing since its initial discovery.

PATHOBIOLOGY

Ross River viral antigen may be detected in monocytes and macrophages early in infection, but intact virus is not identifiable by electron microscopy or cell culture. Dermal vessels show mild perivascular mononuclear cell infiltrates, mostly T lymphocytic, in erythematous and purpuric areas. Vessels in purpuric areas also show erythrocyte extravasation. Antigen can be demonstrated in epithelial cells in erythematous or purpuric skin and in the perivascular zone in erythematous skin. However, viral antigens have not been found in normal skin. Synovium undergoes lining cell hypertrophy and sublining vascular proliferation and mononuclear cell infiltration. Viral RNA can be identified by RT-PCR. Synovial fluid cell counts range from 1500 to 13,800 cells/mL and consist of monocytes, vacuolated macrophages, and a few neutrophils. Animal models of infection indicate that Ross River virus targets bone, joint, and skeletal muscle and elicits an inflammatory response mediated by the innate immune system.

CLINICAL MANIFESTATIONS

Arthralgia typically occurs abruptly, followed in 1 to 2 days by a macular, papular, or maculopapular rash that may be pruritic.[20] Three fourths of patients have severe, incapacitating arthralgia in an asymmetrical and migratory distribution. Commonly affected joints are the metacarpophalangeal joints, finger interphalangeal joints, wrists, knees, and ankles. The shoulder, elbow, toe, spine, hip, and temporomandibular joints may also be affected. Arthralgias are worse in the morning and after periods of inactivity. A third of patients have synovitis. Polyarticular swelling and tenosynovitis are common. Up to a third of patients have paresthesias or palm or sole pain. Classic carpal tunnel syndrome may occur.

In some individuals, rash may precede or follow the joint symptoms by 11 or 15 days, respectively. On occasion, vesicles, papules, or petechiae are seen. The trunk and extremities are typically involved, but the palms, soles, and face may also be affected. The rash resolves by fading to a brownish discoloration or by desquamation. Fever tends to be mild to moderate and lasts 1 to 3 days. Headache, nausea, and myalgia are common. Mild photophobia, respiratory symptoms, and lymphadenopathy may occur.

DIAGNOSIS

In the Australian epidemics before 1979, patients were antibody positive at the time of initial evaluation. However, in the Pacific island epidemics of 1979 to 1980, patients remained viremic and serologically negative for up to a week after the onset of symptoms. Virus in serum is stable for up to a month at 0° to −10° C. Current testing in Australia is performed with an indirect ELISA. The presence of specific IgM or evidence of seroconversion to IgG positivity supports a recent infection.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonsteroidal anti-inflammatory drugs provide relief of joint pain. Half of all patients return to activities of daily living within 4 weeks despite residual polyarthralgia. Joint symptoms may recur, but episodes gradually resolve. In some patients, joint symptoms may persist for up to 3 years. Mild exercise tends to improve the joint symptoms.

SINDBIS

Sindbis virus causes a sudden-onset, febrile illness associated with arthralgia and rash. It is known as Ockelbo disease in Sweden, Pogosta disease in Finland, and Karelian fever in the Karelian Isthmus of Russia. *Aedes*, *Culex*, and *Culiseta* mosquitoes transmit the virus to humans, with birds serving as intermediate hosts.

EPIDEMIOLOGY

The virus was first isolated from *Culex* mosquitoes in the Egyptian village of Sindbis in 1952. Outbreaks frequently occur in the forested areas of Sweden, Finland, and the Karelian Isthmus, but sporadic cases and small outbreaks have occurred in Uganda, South Africa, Zimbabwe, central Africa, and Australia. Individuals involved in outdoor activities or occupations are at greatest risk. In northern Sweden, 2.9% of the population has Sindbis virus–specific serum IgG positivity indicative of prior infection.[21]

PATHOBIOLOGY

Skin lesions show perivascular hemorrhage, lymphocytic infiltrates, edema, and areas of necrosis. Virus has been isolated from skin lesions. Antiviral IgM may persist for years, thus raising the possibility that Sindbis virus arthritis is associated with viral persistence and a direct viral effect on the synovium. Autophagy, an evolutionarily conserved intracellular mechanism for recycling cytoplasmic material to lysosomes for degradation during times of stress, may be disrupted in neurons by Sindbis virus infection, thereby leading to programmed cell death or apoptosis.

CLINICAL MANIFESTATIONS

Arthralgia and rash are the initial symptoms, although one may precede the other by a few days. Arthralgia and arthritis involve the small joints of the hands and feet, wrists, elbows, ankles, and knees. On occasion, arthralgia affects the spine. Tendinitis is common and often involves the Achilles and hand extensor tendons. Fever, if present, tends to be mild to moderate. Constitutional symptoms, headache, fatigue, malaise, nausea, vomiting, pharyngitis, and paresthesias may be present but are not usually severe. Macular rash typically begins on the torso and then involves the arms, legs, palms, soles, and occasionally the head. Macules evolve to papules that have a tendency to vesiculate. Vesiculation is prominent on pressure points, including the palms and soles. As the eruption fades, a brownish discoloration is left. Vesicles on the palms and soles may become hemorrhagic. Rash may recur during convalescence.

DIAGNOSIS

Specific IgM detected by enzyme immunoassay supports a diagnosis of Sindbis virus infection. IgM titers may wane during a period of 3 to 4 years.

TREATMENT AND PROGNOSIS

Rx

Treatment is supportive. Nonerosive chronic arthropathy is common in Sweden and Finland, with up to half of all patients having joint symptoms 2.5 years after infection. In a few cases, symptoms may persist for up to 6 years.

REVIEW QUESTIONS

1. A 24-year-old woman presents with 3 weeks of arthralgia involving the fingers and toes. The illness began suddenly with fever and headache 2 weeks ago, about 1 week after returning from her 2-year tour in the Peace Corps in Peru teaching English to children of Amazon lumber workers. Fever and headache resolved after the first week of illness. During the second week of illness, she noticed a blotchy red rash on her torso and arms. She denies joint swelling. Examination was unremarkable. Laboratory testing excluded parvovirus B19, rubella, Epstein-Barr virus, hepatitis B virus, hepatitis C virus, and coxsackievirus infections. The most likely diagnosis is

A. Chikungunya virus infection
B. Dengue virus infection
C. Mayaro virus infection
D. Ross River virus infection
E. Sindbis virus infection

Answer: C The geographic exposure would eliminate chikungunya virus, Ross River virus, and Sindbis virus as causative agents. Mayaro virus and dengue have overlap in their geographic distribution. The history suggests a milder course with mild arthralgias, which would argue against dengue, also called breakbone fever. At this juncture, the diagnosis can be confirmed by finding a positive Mayaro virus–specific serum IgM.

2. A 67-year-old retired businessman from Greenwich, Connecticut, with a known history of insulin-dependent type 2 diabetes mellitus and chronic sinusitis was in fair health until August, when he had onset of fever, headache, nausea, and myalgia. He noticed a nonpruritic macular rash over his torso soon after the fever began; 4 days later, the involved skin began peeling. His headache then began to worsen. During the second week of illness, he developed nuchal rigidity and became obtunded, at which time he was hospitalized. A social history revealed a pigeon fancier hobby. Examination revealed somnolence with difficult arousal, nuchal rigidity, and flaccid paralysis. A differential diagnosis of West Nile virus infection was entertained. At this juncture, the best way to demonstrate that the neurologic presentation is due to West Nile virus infection is

A. Detect West Nile virus in peripheral blood by reverse transcription–polymerase chain reaction (RT-PCR)–based detection of viral RNA
B. Detect West Nile virus IgM antibody in serum
C. Detect West Nile virus IgM *and* IgG antibody in serum
D. Save a serum sample at this time and demonstrate a four-fold increase in West Nile virus IgG in a convalescent serum sample obtained 3 weeks later
E. Detect West Nile virus IgM antibody in cerebrospinal fluid

Answer: E At this time, during the second week of illness, detection of viremia is unlikely. Demonstrating West Nile virus IgM in the serum confirms a recent West Nile virus infection but does not definitively demonstrate that the neurologic involvement is caused by West Nile virus in this elderly man with diabetes and chronic sinusitis. Note that the IgM may persist for up to 1 year in a minority of patients; subclinical infection may have occurred more remotely in this man. Detecting a four-fold increase in West Nile virus IgG in convalescent serum confirms a recent infection but does not definitively demonstrate that the neurologic involvement is due to West Nile virus. IgM normally does not cross the blood-brain barrier, so detecting West Nile virus IgM in the cerebrospinal fluid demonstrates central nervous system infection with the virus, although leakiness in the blood-brain barrier from another cause with passive movement of serum IgM into the cerebrospinal fluid cannot be completely excluded.

3. A 20-year-old male premedical student from Chicago enjoyed his spring break rock climbing in the Rocky Mountains with his girlfriend. One week later, during his organic chemistry midterm, he developed headache and myalgia. He attributed his symptoms to the previous all-nighter studying for his examination. That evening he developed photophobia, eye pain, and weakness. The following morning, he noticed punctate red dots, which did not blanch on pressure, over his torso. In the Student Health Service, palatal petechiae, petechial rash on the torso, generalized lymphadenopathy, and mild splenomegaly were noted. Laboratory testing showed mild leukopenia and thrombocytopenia. A presumptive diagnosis of Rocky Mountain spotted fever was made by the Health Service Director, and the patient was started on doxycycline. However, you begin to doubt the diagnosis the following day when the patient fails to develop the classic spotted fever rash (see Chapter 327). Diagnostic tests are pending. The likely diagnosis is

A. Colorado tick fever
B. Dengue
C. Disseminated gonorrhea
D. Rocky Mountain spotted fever
E. None of the above

Answer: A The exposure and course are consistent with Colorado tick fever. Dengue is unlikely because the Rockies are outside of the geographic distribution for dengue, which is found in the southeast United States and other tropical and subtropical climates. Patients with disseminated gonorrhea present with an arthritis-dermatitis syndrome, in which generalized arthralgias and myalgias quickly settle into one or more locations with inflammatory arthritis or tenosynovitis; scattered 1- to 3-mm pustules may evolve necrotic centers. This patient lacked inflammatory arthritis or tenosynovitis; his exanthem consisted of multiple petechiae rather than pustules, and the lesions were more plentiful than the pustules typically seen in disseminated gonorrhea. The rash argues against Rocky Mountain spotted fever, in which the "spotted" rash of 1- to 5-mm macules classically becomes purpuric. The patient had petechiae that did not blanch on pressure. However, the Health Service Director was not incorrect in starting doxycycline. The classic rash can appear later or not at all in the course of Rocky Mountain spotted fever, and serologic diagnosis often requires acute and convalescent sera. Doxycycline can be life-saving when it is started early in suspected Rocky Mountain spotted fever.

4. An 18-year-old U.S. Marine stationed in Helmand Province, Afghanistan, flew home on emergency leave to see her sick father in Ottumwa, Iowa. Four days after arriving, she developed headache, stiff neck, eye pain, photophobia, arthralgia, and chest pain. Examination showed a macular rash measuring 2 × 4 cm with scattered papules within it on her left calf. Laboratory testing showed leukopenia and lymphopenia. Cerebrospinal fluid showed mild pleocytosis. The likely diagnosis is

A. Chikungunya fever
B. Dengue
C. O'nyong-nyong fever
D. Phlebotomus fever
E. Ross River fever

Answer: D In Afghanistan, the potential for exposure to the sandfly vector is significant. These small flies may pass through mosquito netting. Among British soldiers in Helmand Province, 52% of undifferentiated fever cases were attributed to phlebotomus fever. Myalgias may be sufficiently severe to be perceived as pleurodynia. Mild aseptic meningitis is common. Chikungunya fever is endemic in sub-Sahara Africa, India, the Philippines, and Southeast Asia and has spread to islands in the Indian Ocean and the Caribbean, but it is not found in the mountains of Afghanistan. Likewise, dengue is distributed in tropical and subtropical climates. Recent outbreaks of o'nyong-nyong fever have occurred in Uganda but not in Afghanistan. Ross River virus is limited to east of Weber's line, the virtual line that separates the Australian biogeographic zone from the Asian biogeographic zone. Furthermore, the rash in Ross River virus infection is a more widely distributed maculopapular rash with occasional vesicles, papules, or petechiae over the torso, extremities, face, palms, and soles; the rash also may desquamate. The rash described in this patient is more localized and is attributable to the sandfly bites.

5. A 26-year-old hipster born and living in Manhattan spends winters in Jamaica with friends. Shortly after returning to New York this year, she experienced sudden-onset fever, severe headache, eye pain, nausea, vomiting, myalgia, and arthralgia. By the next day, the joint and muscle pain became severe. Two days later, she sought medical attention. Examination showed an ill-appearing woman, alert but in apparent pain. Temperature was 100.5° F, pulse 104/minute, blood pressure 92/50 mm Hg, and respirations 28/minute. Multiple petechiae appeared on her left arm distal to where the blood pressure cuff was applied. Cervical and inguinal lymph nodes were palpable and nontender. Joint examination was unremarkable. Laboratory testing showed white cell count of 1500/μL and platelet count of 55,000/μL. Hemoglobin was 19 g/dL. Prothrombin time was 22 seconds. The pregnancy test was positive. A diagnosis of dengue virus infection was suspected. Dengue virus serology was positive for IgG antibody to serotype 1 as well as for IgM and IgG antibodies to serotype 2. The diagnosis is

A. Dengue virus infection, classic
B. Dengue virus infection, hemorrhagic fever
C. Dengue virus infection, shock syndrome
D. Dengue virus infection, classic with preeclampsia

Answer: B The patient began with classic dengue features but developed low-normal blood pressure, tachycardia, and hemoconcentration suggestive of volume loss. The positive tourniquet sign with the development of petechiae distal to the blood pressure cuff is a warning sign that hemorrhagic fever has developed. The presence of thrombocytopenia and prolonged prothrombin time provide laboratory support. The serologic evidence of a previous dengue virus infection with serotype 1 (IgM–, IgG+) supports the increased risk for development of hemorrhagic fever due to enhancement of immune response by preexisting antiviral antibodies. The patient has not yet developed hemorrhagic shock syndrome, but prompt intervention with supportive measures should improve prognosis. The patient is pregnant, which may worsen the clinical picture, but her low blood pressure argues against preeclampsia.

383

ARBOVIRUSES AFFECTING THE CENTRAL NERVOUS SYSTEM

THOMAS P. BLECK

Arboviruses, which are also termed *arthropod-borne viruses*, can affect the central nervous system (CNS). These viruses share a number of clinical and epidemiologic similarities and have an RNA genome, but they do not form a formal virologic taxonomic group. Arboviruses generally have avian or small mammalian reservoirs and are transmitted to humans and other large mammals incidentally when an infected mosquito or other arthropod obtains a blood meal.

EPIDEMIOLOGY

Most human disease is subclinical; a few patients have a brief febrile illness resembling influenza, and a small percentage, usually at the extremes of age, suffer meningitis or encephalitis. The diseases (Table 383-1) reflect the quotidian and seasonal characteristics of their insect vectors. Other viruses of the same genera cause hemorrhagic fever (Chapter 381), and other less frequently encountered arboviruses are also capable of producing encephalitis.

Many of these agents cause notifiable disease in the United States: St. Louis, West Nile, Powassan, eastern equine, western equine, and the California serogroup encephalitis viruses. Case definitions and additional information are available at http://www.cdc.gov/ncidod/dvbid/arbor/index.htm.

The diseases described here are zoonoses (Chapter 328), that is, illnesses caused by viruses transmitted from animals to humans. They are more prevalent in the tropics and subtropics and are usually localized because of ecologic restrictions on their transmission.

PATHOBIOLOGY

Two pathologic processes are common to the arboviral encephalitides: neuronal and glial damage mediated by intracellular viral infection; and migration of immunologically active cells into the perivascular space and brain parenchyma. Endothelial cell swelling and proliferation, destruction of myelin sheaths in deep white matter areas, and vasculitis are present in some arboviral encephalitides.

After a bite by an infected arthropod, viral replication occurs in local tissues and regional lymph nodes. Viremia, which seeds extraneural tissues, occurs and persists, depending on the extent of replication in extraneural sites, the rate of viral clearance by the reticuloendothelial system, and the appearance of humoral antibodies. The sites of extraneural infection vary among the viruses. Many alphaviruses and flaviviruses involve striated muscle and endothelium, whereas Venezuelan encephalitis virus is associated with myeloid and lymphoid tissue invasion. During viremia, the neural parenchyma may be invaded, but the mode of penetration of virus across the blood-brain barrier is not completely understood. Possible mechanisms include passive movement of virus across vascular membranes and viral replication in the cerebral capillary endothelium. Factors that increase vascular permeability or disrupt the blood-brain barrier promote invasion of the nervous system. Infected monocytes may also bring the virus into the CNS. In experimental animal infection, flaviviruses enter the CNS through the olfactory epithelium.

The immune response to flaviviruses starts with an innate interferon response to viral replication. Neurons then produce chemokines that recruit various components of the cellular immune response. The induced T-cell and monocyte trafficking is needed to clear the virus from the CNS, but it can also damage neurons.

The immature brain is more susceptible to damage by western equine, Venezuelan equine, and California serogroup encephalitis viruses (Table 383-2). St. Louis encephalitis and West Nile encephalitis principally affect the elderly, whereas Japanese encephalitis and eastern equine encephalitis have a bimodal incidence and strike both children and elderly persons. In endemic areas, immunity accumulated with increasing age may reduce the incidence of disease in older persons for some viruses; however, the reasons for the increased severity of illness with other viruses remain unknown.

TABLE 383-1 ARTHROPOD-BORNE VIRUSES ASSOCIATED WITH HUMAN ENCEPHALITIS

VIRUS	INSECT VECTOR	COMMON VERTEBRATE HOSTS	GEOGRAPHIC DISTRIBUTION
TOGAVIRIDAE			
Alphaviruses	Mosquitoes		
Eastern equine encephalitis	*Culiseta* spp, *Aedes* spp, *Coquillettidia* spp		Eastern United States and Gulf Coast, Caribbean region, South America
Western equine encephalitis	*Culiseta* spp, *Culex* spp		Western United States, Canada
Venezuelan equine encephalitis	*Aedes* spp, *Culex* spp, *Psorophora* spp, and *Mansonia* spp		South America, Central America, Florida and southwestern United States
FLAVIVIRIDAE			
Japanese serocluster	Mosquitoes		
Japanese encephalitis	*Culex* and *Aedes* spp		East and Southeast Asia, India, Australia
West Nile encephalitis	*Aedes* spp, *Culex* spp, and others		Africa, Middle East, North America
St. Louis encephalitis	*Culex* spp		Western Hemisphere
Murray Valley encephalitis	*Culex* spp		Australia
Tick-borne encephalitis complex			
Central European encephalitis	*Ixodes* spp	Goats, sheep	Europe, Russia
Russian spring-summer encephalitis	*Ixodes* spp		Europe, northern and central Asia
Kyasanur Forest disease	*Haemaphysalis spinigera*	Rodents, insectivores	India
Omsk hemorrhagic fever	*Dermacentor reticulatus*	Rodents	Central Asia
Powassan	*Ixodes* spp	Squirrels, groundhogs	North America, Russia
Louping ill	*Ixodes ricinus*	Small mammals, sheep, birds	British Isles
Langat	*Ixodes* spp	Rodents	Malaysia, Thailand, parts of former Soviet Union
BUNYAVIRIDAE			
California encephalitis	*Aedes melanimon, Aedes dorsalis*	Rodents, rabbits	California
La Crosse encephalitis	*Aedes triseriatus*	Chipmunks, squirrels	Eastern and Midwestern United States

TABLE 383-2 FEATURES OF ARBOVIRAL ENCEPHALITIDES IMPORTANT IN THE UNITED STATES

	EASTERN EQUINE ENCEPHALITIS	WESTERN EQUINE ENCEPHALITIS	VENEZUELAN EQUINE ENCEPHALITIS	WEST NILE ENCEPHALITIS	ST. LOUIS ENCEPHALITIS	CALIFORNIA SEROGROUP ENCEPHALITIS
Annual U.S. cases of symptomatic disease	10	0-2 cases, mostly infants and children	Rare, mostly children	Up to 3000, mostly >40 years	0-2000, mostly >50 years	10-50, mostly children
Time of year	Late summer, early fall	Early and mid summer	Summer	Summer, fall	Mid to late summer	July-September
Case-fatality rate	50-70%, highest in children <15 years and adults >55 years	3-5% in children	35% in children, <10% in older persons	14-19%, 30% in adults >70 years	9% overall; 0% <20 years, 30% >65 years	<1%

Cerebrospinal fluid findings (cells/μL)	500-2000 cells, predominantly neutrophils	<500 cells, predominantly lymphocytes	<500 cells, predominantly lymphocytes	<500 cells, predominantly lymphocytes	<500 cells, predominantly lymphocytes	<500 cells, predominantly lymphocytes

CLINICAL MANIFESTATIONS

Clinical symptoms and signs vary among the viral causes (see later), although all share common signs and symptoms of encephalitis (Chapter 414).

DIAGNOSIS

Diagnosis depends on a careful history that includes exposure to vertebrate animals and arthropod vectors, age, season, and travel, including the geographic site of exposure. Laboratory confirmation of infection is essential. The virus may be isolated from acute phase serum or whole blood in laboratory animals or in tissue culture. Neutralization, complement fixation (CF), hemagglutination inhibition (HI), fluorescent antibody, and enzyme-linked immunosorbent assay (ELISA) of acute and 3-week convalescent sera can also produce the correct diagnosis. Antigen detection and IgM capture ELISA often permit diagnosis on initial evaluation and within a week of the onset of illness in most cases. Sensitive nucleic amplification assays using reverse transcription–polymerase chain reaction (RT-PCR) are under development for a number of the arboviruses and may lead to earlier diagnosis.

Differential Diagnosis

The most important initial consideration is to differentiate arboviral encephalitides from other acute CNS infections, including infections other than encephalitis (Chapters 412 and 413), treatable causes of encephalitis (Chapter 414), and paraneoplastic and autoimmune encephalitis (Chapters 412 and 414). Anti–*N*-methyl-D-aspartate (NMDA) receptor encephalitis, which is as common as most viral causes of encephalitis in parts of the United States,[1] is an important part of the differential diagnosis, particularly in young women and especially because—unlike arboviral infections—it often responds to immunosuppressive treatment.

The early prodrome resembles influenza (Chapter 364). Bacterial meningitis (Chapter 412; especially early or partially treated), infective bacterial endocarditis (Chapter 76), brain abscess (Chapter 413), subdural empyema (Chapter 413), and cerebral thrombophlebitis may mimic viral encephalitis, and the cerebrospinal fluid (CSF) profile is sometimes similar. Other infections that occasionally cause meningoencephalitis that may resemble arthropod-borne viral encephalitis include tuberculosis (Chapter 324), cryptococcosis (Chapter 336), histoplasmosis (Chapter 332), coccidioidomycosis (Chapter 333), Rocky Mountain spotted fever (Chapter 327), leptospirosis (Chapter 323), falciparum malaria (Chapter 345), trichinosis (Chapter 357), *Naegleria* meningitis (Chapter 412), typhoid fever (Chapter 308), Lyme disease (Chapter 321), and *Mycoplasma* pneumonia (Chapter 317).

Acute meningoencephalitis may result from infections with other viruses, including herpesviruses (Chapter 374), human immunodeficiency virus (Chapter 386), mumps virus (Chapter 369), enteroviruses (Chapter 379), lymphocytic choriomeningitis virus (Chapter 412), rabies (Chapter 414), influenza (Chapter 364), and the exanthematous viral infections of childhood (Chapters 367 and 368). The exposure history, the presence of similar disease in the community, and the summer-fall occurrence are principal clues to an arboviral etiology. Enteroviruses (Chapter 379) also cause summer-fall outbreaks, but the predominant syndrome is aseptic meningitis, and the

concomitant occurrence of rash or pleurodynia is a helpful clue. Herpes simplex encephalitis (Chapter 414) presents an important diagnostic challenge because effective therapy is available and should be started quickly. The presence of localizing neurologic signs, localizing findings on computed tomography (CT) or magnetic resonance imaging (MRI), and detection of herpes simplex DNA in CSF by PCR help distinguish herpes simplex encephalitis from the arboviral encephalitides.

Noninfectious diseases of the CNS, such as stroke (Chapter 407), may rarely be confused with viral encephalitis. Subarachnoid hemorrhage (Chapter 408) produces meningismus, fever, headache, and neurologic signs that mimic an infectious etiology. Metabolic encephalopathies occasionally have features suggesting infectious encephalitis. Neoplastic or granulomatous diseases involving the CNS and a variety of diseases of uncertain etiology (Behçet disease [Chapter 270], Reye syndrome, acute multiple sclerosis [Chapter 411], and systemic lupus erythematosus [Chapter 266]) must be considered in the differential diagnosis as well.

PREVENTION

Control can be achieved by interruption of the cycle, including vaccination of reservoir animals, vector control, and education on vector avoidance. Practical measures include wearing long-sleeved clothing, using insect repellents, limiting outdoor activities during peak mosquito season, and eliminating standing pools of water. Vaccines are currently available for Japanese encephalitis.

TREATMENT Rx

Treatment is symptomatic and may include bedrest, antipyretics, and analgesics. Early empirical treatment of herpes simplex encephalitis (Chapter 374) may be appropriate while the diagnostic evaluation to document arboviral encephalitis proceeds. To date, no immunologic therapy has demonstrated a useful effect in humans.

EASTERN EQUINE ENCEPHALITIS

EPIDEMIOLOGY

Human disease is relatively rare, with fewer than 10 cases occurring each year in the Gulf Coast and Atlantic states, usually in association with an equine epizootic involving 100 to 300 animals. Outbreaks generally occur during the late summer and early fall. The occurrence of equine cases or outbreaks of fatal encephalitis in penned exotic birds precedes the appearance of human cases by several weeks or more. Epizootics of eastern equine encephalitis have been reported in the Caribbean (Hispaniola) and South America.[2]

In temperate areas, eastern equine encephalitis virus circulates between wild birds and *Culiseta melanura* mosquitoes in a freshwater swamp habitat. Equine epizootics and associated human cases result from extension of the transmission cycle to involve *Aedes* and *Coquillettidia* mosquitoes, which feed on horses and humans.[3]

PATHOBIOLOGY

The brain is grossly edematous and congested, and the inflammatory response is predominantly polymorphonuclear. The areas most affected are the basal ganglia, thalamus, hippocampus, and frontal and occipital cortices. Focal vasculitis, endothelial cell swelling, intravenous and arteriolar thrombus formation, demyelination, necrosis, neuronolysis, and neuronophagia are prominent. Eastern equine encephalitis virus appears to make use of host micro-RNAs to limit replication in myeloid cells, thereby restricting the host immune response and causing more severe neurologic damage.[4]

CLINICAL MANIFESTATIONS

Onset is abrupt, with high fever, vomiting, and somnolence. Stupor, coma, myoclonus, and generalized convulsions appear within 24 hours to as long as 10 days later. Autonomic disturbances (sialorrhea) may be prominent, and respiratory difficulty and cyanosis are frequent. In children, facial, periorbital, or generalized edema may be present.

A striking peripheral leukocytosis with immature neutrophils occurs frequently in patients with eastern equine encephalitis. CSF examination reveals 500 to 2000 white blood cells/μL (predominantly neutrophils). As the total cell count falls, neutrophils may persist as a significant fraction. Red blood cells may be present, protein concentration is elevated, and the glucose level is normal.

DIAGNOSIS

Brain CT and MRI are frequently abnormal and reveal lesions in the basal ganglia, thalami, and brain stem. The virus can rarely be isolated from blood or CSF. Serologic diagnosis by demonstration of a rise in antibody titer in appropriately timed paired sera is the most practical and available test. Because of the rapid course of the clinical disease, sera should be obtained at 2- to 3-day intervals during the acute phase of illness.

PREVENTION

An experimental formalin-inactivated chick embryo cell culture vaccine is used to protect laboratory and field workers. Reduction of mosquito populations by appropriate use of insecticides may be effective in threatened or established outbreaks.

TREATMENT Rx

Treatment is supportive. Control of fever, intracranial pressure, seizures, fluid and electrolyte disturbances, and the airway is critical. Although attempts at immunologic therapy have been reported, no controlled data are available.

PROGNOSIS

The case-fatality rate is 50 to 70%. Mortality, like incidence, is highest in children younger than 15 years and in persons older than 55 years, with no gender predilection. Death usually occurs during the first week; in surviving patients, recovery begins during the second week and may progress rapidly. Good functional recovery is associated with a long prodromal course and absence of coma. Residual damage, found in 30 to 50% of patients, is often severe, especially in children, and is characterized by mental retardation, spastic paralysis, and radiographic evidence of brain atrophy.

WESTERN EQUINE ENCEPHALITIS

EPIDEMIOLOGY

Few cases of western equine encephalitis have been reported in recent decades; the most recent epidemic occurred in Colorado in 1987. Epidemics occur in early or mid summer and may follow heavy snow melt or flooding, conditions favorable for breeding of mosquitoes. Cases of encephalitis in equines often precede the appearance of human disease. The illness principally affects residents of rural communities, and the incidence is higher in males than in females.

The ratio of inapparent to apparent infection is also age dependent and ranges from about 1 : 1 in infants younger than 1 year, to 58 : 1 in children 1 to 4 years old, to more than 1000 : 1 in persons older than 14 years. Western equine encephalitis virus also occurs in South America. Equine epizootics in Argentina have been associated with human cases.

Western equine encephalitis virus circulates between wild birds and *Culex tarsalis* mosquitoes. *Cx. tarsalis* is responsible for infection of humans and equines, which have low or undetectable viremia and do not perpetuate the chain of transmission. In temperate areas, transmission ceases during the winter months.

PATHOBIOLOGY

Pathologic examination of the brains of infants reveals massive parenchymal destruction; children dying months or years after the acute insult often have large cystic lesions in many areas of the brain. In older children and adults, acute western equine encephalitis is characterized by focal necrosis and perivascular cuffing, predominantly in the basal ganglia and thalami but also in deep cerebral white matter.

CLINICAL MANIFESTATIONS

The disease usually begins with an influenza-like illness consisting of fever, headache, malaise, and myalgia lasting 1 to 4 days. Somnolence, lethargy, photophobia, vomiting, and neck stiffness may follow; neurologic involvement may rapidly progress to stupor, coma, and seizures. Pareses, cranial nerve deficits, tremors, and abnormal reflexes may be present. In fatal cases,

patients die 1 to 2 days after coma develops. Congenital infections have been documented and result in severe and progressive neurologic deterioration.

Leukocytosis and a shift to the left are common. The CSF contains fewer than 500 white blood cells/μL (at first polymorphonuclear, then mononuclear) and an elevated protein concentration (usually 90 to 110 mg/dL).

DIAGNOSIS

Viral isolation from blood or CSF is almost never successful. Diagnosis is achieved by demonstration of a rise in HI, fluorescent antibody, CF, ELISA, or neutralizing antibody titers in appropriately timed (10 to 14 days apart) paired sera. Demonstration of IgM antibodies in serum or CSF by ELISA provides a presumptive diagnosis.

PREVENTION

An experimental formalin-inactivated vaccine grown in chick embryo cell culture has been used to protect laboratory workers but is not indicated for others. In threatened or ongoing epidemics, residents should be advised to use protective clothing, insect repellents, and window screens and to restrict outdoor activity in the early morning, late afternoon, and evening (times of greatest mosquito activity). Public health measures include spraying insecticides aimed at the adult *Cx. tarsalis* vector.

TREATMENT Rx

There is no specific therapy for western equine encephalitis. Supportive therapy is similar to that discussed earlier for eastern equine encephalitis.

PROGNOSIS

Western equine encephalitis is most severe in infants and young children. The case-fatality rate is between 3 and 5%. Survivors generally experience sudden and rapid recovery. However, about a third of surviving infants suffer mental retardation, cerebellar damage, choreoathetosis, and spastic paralysis. Children with protracted illnesses in whom convulsions develop during the acute stage are more likely to suffer long-term neurologic sequelae. Adults may have a prolonged convalescent syndrome, but objective residua are rare.

VENEZUELAN EQUINE ENCEPHALITIS

Six antigenic subtypes of Venezuelan equine encephalitis virus (I to VI) with several antigenic variants of subtypes I and III are recognized serologically. Subtypes IAB and IC are responsible for epidemics involving humans and equines. In Florida, subtype II is enzootic and produces sporadic human disease. Methods of transmitting Venezuelan equine encephalitis virus as a biologic warfare agent were developed in the 1960s; an epidemic of Venezuelan equine encephalitis, especially if humans and horses become ill simultaneously, could represent an attack rather than naturally occurring illness.

EPIDEMIOLOGY

Before 1973, large equine epizootics occurred at 5- to 10-year intervals in Venezuela, Colombia, Ecuador, and Peru and involved many thousands of animals with mortality rates as high as 40%. Associated human morbidity was also great (up to 32,000 clinical cases). The disease was quiescent for several years but has reemerged in the Gulf Coast region of Mexico in the past decade. The last major outbreak occurred in Venezuela and Colombia in 1995, with more than 85,000 human cases. Laboratory infections are common in unvaccinated persons who work with the virus or infected animals.

A large variety of mosquito vectors, including species of the genera *Aedes*, *Psorophora*, and *Mansonia*, transmit subtypes IAB and IC during epizootic epidemics. Equines are the principal viremic hosts. Virus may be present in the pharyngeal excretions of human patients; contact or aerosol person-to-person spread, although possible, is not epidemiologically important.

The other members of the Venezuelan equine encephalitis viral complex, including subtype II in Florida, have enzootic transmission cycles involving *Culex* mosquitoes and small forest rodents and marsupials. Human disease is sporadic and relatively uncommon.

PATHOBIOLOGY

Pathologic changes in the CNS include edema, congestion, meningeal and perivascular inflammation, intracerebral hemorrhage, neuronal degeneration, and vasculitis. In addition, hepatocellular degeneration and necrosis, widespread lymphoid depletion and follicular necrosis, and interstitial pneumonitis are frequent. Congenitally infected fetuses demonstrate massive and widespread necrosis of brain tissue, hemorrhage, and resorption of brain material resulting in hydranencephaly.

CLINICAL MANIFESTATIONS

The predominant syndrome is a self-limited influenza-like illness; encephalitis develops in only about 4% of infected persons, principally children younger than 15 years. Subclinical infections are rare.

After an incubation period of 2 to 5 days, there is a sudden onset of fever, chills, malaise, and headache, followed by myalgias, nausea, vomiting, and occasionally diarrhea. Physical examination reveals fever, tachycardia, conjunctival injection, and, in some cases, nonexudative pharyngitis. The acute illness generally subsides in 4 to 6 days, and convalescent symptoms may last up to 3 weeks. A biphasic course has sometimes been noted; acute symptoms can reappear after a brief remission, within a week after initial onset.

When it occurs, severe encephalitis is characterized by meningeal signs, seizures, tremor, stupor, coma, spastic paralysis, abnormal reflexes, cranial nerve palsies, and central respiratory failure. Residual neurologic damage occurs in severe cases. Infections of pregnant women acquired during the first and second trimester may result in fetal encephalitis and death.

The peripheral leukocyte count is often low, with a decrease in both lymphocytes and neutrophils, or normal with relative lymphopenia. In patients with CNS signs, the CSF contains up to 500 cells/μL, predominantly lymphocytes. Serum lactate dehydrogenase and aspartate aminotransferase concentrations may be elevated.

DIAGNOSIS

In contrast to the other arboviral encephalitides, Venezuelan equine encephalitis virus can be isolated from blood or from throat swabs or washings during the first 3 or 4 days of illness. Serodiagnosis is usually more practical and is achieved by testing appropriately timed paired sera by HI, CF, ELISA, neutralization, or IgM immunoassay.

PREVENTION

An experimental live attenuated vaccine made from subtype IAB is used for adult laboratory personnel. It provides solid immunity to subtypes IAB and IC but incomplete protection against heterologous Venezuelan equine encephalitis viruses. Epidemics and epizootics can be prevented by effective vaccination of equines. Spraying insecticides to reduce adult (infective) mosquito populations is the only means of immediate control in the face of an ongoing epidemic. Individual protection against mosquitoes is advised.

TREATMENT Rx

No specific therapy is available, and treatment of encephalitis cases is supportive.

PROGNOSIS

The case-fatality rate in children 5 years or younger with encephalitis is approximately 35%, but it is less than 10% in older persons.

JAPANESE ENCEPHALITIS

EPIDEMIOLOGY

Japanese encephalitis virus is a flavivirus that causes epizootics of clinical encephalitis in equines. The disease occurs throughout Asia, including Japan, China, the Korean peninsula, Taiwan, Okinawa, Vietnam, the Philippines, Burma, Malaysia, Bangladesh, east and south India, Sri Lanka, Thailand, and Indonesia. More than 30,000 clinical cases occur annually, about one third of which are fatal. Japanese encephalitis is a summertime disease in temperate areas but occurs sporadically year-round in the tropics. Several species of *Culex* mosquitos can transmit the virus, most notably *Cx. tritaeniorhynchus*.

Epidemics are most frequent at the northern fringe of the tropical zone, with a high incidence noted in southern China.[5] It is a predominantly rural disease, and the incidence in males is often higher than in females. In hyperendemic areas, more than 70% of adult populations surveyed have antibodies, and children younger than 15 years are principally affected by the disease.

In areas without a high prevalence of background immunity (e.g., northern India), however, all age groups are affected. In Japan, where schoolchildren have been protected by vaccination campaigns targeted at this age group, encephalitis has become prominent in the elderly. The ratio of clinically inapparent to apparent infection is higher than 500 : 1 in children and decreases with age; in Korea, the ratio in American servicemen was estimated at 25 : 1.

PATHOBIOLOGY

Neuropathologic changes and the distribution of lesions are similar to those described for St. Louis encephalitis (see later).

CLINICAL MANIFESTATIONS

Manifestations of Japanese encephalitis include abrupt fever, headache, and gastrointestinal symptoms. Meningeal irritation develops within 24 hours and is followed on the second or third day by the appearance of irritability, impaired consciousness, seizures (especially in children), muscle rigidity, parkinsonian findings, ataxia, coarse tremor, involuntary movements, cranial nerve deficits, paresis, hyperactive deep tendon reflexes, and pathologic reflexes. Weight loss and dehydration are often striking findings. In mild cases, fever subsides after the first week, and neurologic signs resolve by the end of the second week after onset. In severe cases, hyperpyrexia, progressive neurologic dysfunction, and coma result in death, usually between the seventh and tenth days. About 25% of patients undergo a prolonged recovery, with permanent sequelae often remaining. The occurrence of such sequelae correlates with severity of the acute stage of illness, and young children are most susceptible. Cardiorespiratory complications are frequent during the acute stage in these patients. A poor prognosis is associated with protracted high fever, frequent or prolonged seizures, high protein content in CSF, Babinski signs, and early respiratory depression. Fetal death from transplacental Japanese encephalitis infection has been reported.

DIAGNOSIS

Moderate peripheral leukocytosis and neutrophilia occur early in the disease. Pleocytosis (predominantly lymphocytic), protein elevation, and normal glucose concentration in CSF are usual findings.

MRI in Japanese encephalitis reveals edema in the basal ganglia, thalami, and focal areas of the cerebral cortex; evidence of hemorrhage in these areas may likewise be present. Enhancement may also be noted in the meninges, brain stem, and spinal cord.

Virus is rarely isolated from blood. Virus is also rarely recovered from the CSF of patients who live but may be recovered from the CSF of a third of patients who die. HI and neutralizing antibodies appear during the first week, and CF antibodies appear during the second week. Cross-reactions with other flaviviruses make serodiagnosis difficult. Specific IgM antibodies in serum or CSF are detectable by immunoassays in more than three fourths of patients at the time of hospital admission.

PREVENTION

Newer inactivated Vero cell culture–derived vaccines, including IC51 (marketed as Ixiaro and Jespect), CC-JEV (marketed as Encevac), and Jenvac, are available for use in persons older than 17 years and have recently been shown to be safe in children. They are more immunogenic than the older inactivated mouse brain–derived vaccine. A combined yellow fever–Japanese encephalitis vaccine (ChimeriVax-JE) is available in Australia and Thailand. A new chimeric vaccine, which is effective when it is administered concomitantly with measles-mumps-rubella vaccine, holds promise for children in endemic areas. In China, a live attenuated vaccine (SA14-14-2) is commonly used.

Ixiaro is licensed in the United States for individuals aged 2 months and older traveling to high-risk areas.[6] Generalized urticaria and angioedema may occur in 0.3%. Because two doses of the inactivated vaccine are used and approximately 1 month is required to confer protection, vaccination is not a practical measure in the event of an ongoing epidemic.[7]

Reduction of vector mosquito populations by the application of insecticides may help abort outbreaks. Immunization of swine is an ancillary control strategy.

TREATMENT

Rx

Treatment is supportive (see Eastern Equine Encephalitis). A randomized trial of interferon alfa showed no benefit.

PROGNOSIS

The case-fatality rate is probably about 25%. Sequelae such as mental impairment, emotional lability, choreoathetosis, tremor, parkinsonism, autonomic disturbances, paralysis, and psychiatric disturbances have been reported in up to 75% of patients.

WEST NILE FEVER AND ENCEPHALITIS

Before 1996, the predominant clinical manifestation of West Nile virus was a brief influenza-like illness, sometimes with a rash (Chapter 382) but infrequently with neurologic manifestations. Epidemics since then in Romania, Israel, and North America have added meningitis, meningoencephalitis, and myelitis to the list of disorders attributable to the virus.[8] Sequence analyses of various isolates of the virus indicate two lineages. The first includes viruses from North America, Europe, Israel, western Africa, India, Russia, and Australia; the second includes viruses from sub-Saharan Africa and Madagascar.

EPIDEMIOLOGY

See Chapter 382. The incidence of neuroinvasive West Nile disease varies in different parts of the United States but can be seen nearly everywhere (E-Fig. 383-1).[9] In a recent outbreak in Dallas, Texas, the incidence rate for West Nile encephalitis was 7.3 per 100,000 residents, with cases clustered in neighborhoods with high housing density.[10]

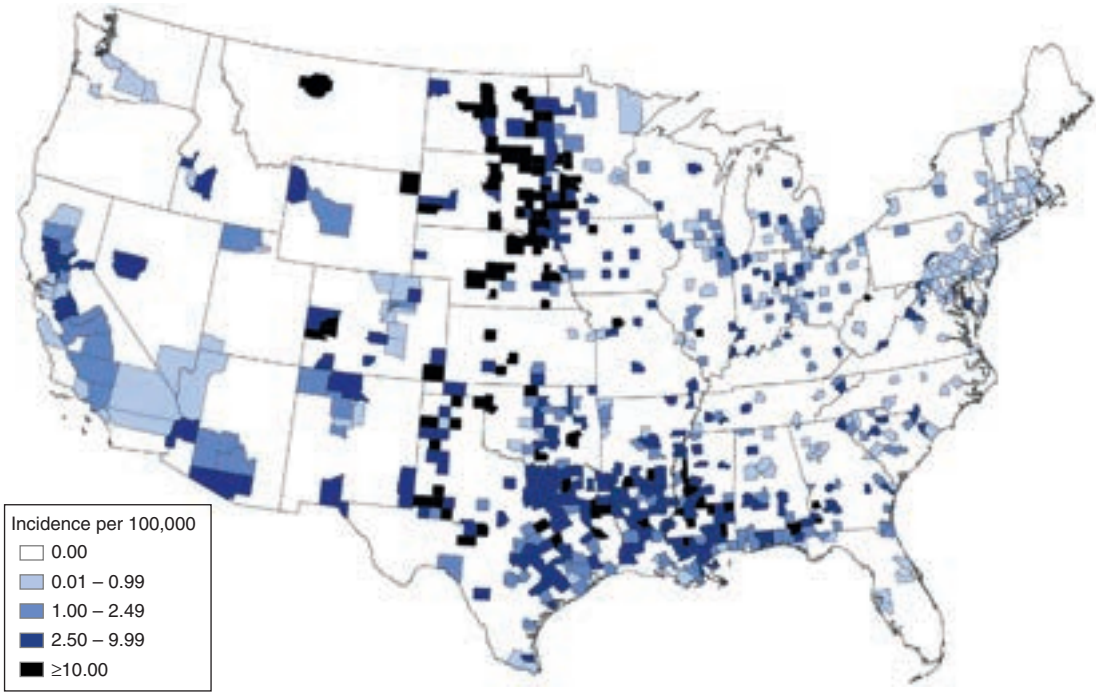
CLINICAL MANIFESTATIONS

The majority of infected people are asymptomatic. Fever develops in about 20%, and CNS manifestations are seen in less than 1%, although this percentage is higher in the elderly (Chapter 382). In those in whom clinical manifestations develop, an incubation period of 1 to 6 days is followed by the abrupt onset of symptoms, usually without a prodrome. The temperature rises quickly to 38.3° to 40.0° C, with rigors in a third of patients. Symptoms include drowsiness, severe frontal headache, ocular pain, myalgia, and pain in the abdomen and back. A small number of patients have dryness of the throat, anorexia, and nausea. Cough is common. Examination shows facial flushing, conjunctival injection, and coating of the tongue. Generalized lymphadenopathy had been a prominent feature in past epidemics but is no longer commonly reported. The spleen and liver are occasionally slightly enlarged. The temperature curve may be biphasic. A pale roseolar maculopapular rash, predominantly on the trunk and upper part of the arms, may appear from the second to fifth day but is now less common as well; it may be evanescent (several hours) or persist until defervescence, and it does not desquamate. Vesicular lesions occur rarely. The illness lasts 3 to 5 days in 80% of patients. Clinical manifestations appear to be more frequent in organ transplant recipients.

In the past decade, the incidence of CNS disease has increased in several epidemics, apparently because of a true increase in the invasiveness and neurovirulence of the virus. The virus causes a syndrome resembling poliomyelitis (Chapter 379), with prominent lower motor neuron dysfunction (acute flaccid paralysis with asymmetrical weakness and decreased deep tendon reflexes but preserved sensory function), which may be seen independently or with signs of meningoencephalitis. In some patients, prolonged, possibly permanent ventilatory failure requiring mechanical ventilation develops. About 95% of patients present with neuroinvasive disease and a significant neurologic defect; about 50% have weakness, 35% have tremor, and 15% have cranial neuropathies.[11] Some patients may have seizures, cranial nerve involvement, ataxia, tremors, or myoclonus. Acute inflammatory polyneuropathy (e.g., Guillain-Barré syndrome; Chapter 420) has also been reported. Other rare complications include myocarditis, pancreatitis, and hepatitis. Convalescence is often prolonged, lasting several weeks with prominent symptoms of fatigue. Lymph node enlargement requires several months to regress. Laboratory findings often include leukocytosis, whereas 10 to 15% of patients have leukopenia.

DIAGNOSIS

CSF examination may reveal a lymphocytic pleocytosis (<1800 cells/μL) with some increase in protein but a normal glucose concentration. Although West Nile virus may be isolated from the blood of three fourths of patients with West Nile fever on the first day of illness (Chapter 382), patients with West Nile encephalitis appear less likely to be viremic, and isolation of virus from CSF is infrequent. Viral RNA is detected in CSF by RT-PCR in about 50% of cases (Fig. 383-1). IgM antibody capture immunoassay, which is the test of choice, is more sensitive than RT-PCR. IgM antibodies may remain



E-FIGURE 383-1. West Nile virus neuroinvasive disease incidence map presenting data reported by state and local health departments to the Centers for Disease Control and Prevention's ArboNET surveillance system. This map shows the incidence of human neuroinvasive disease (e.g., meningitis, encephalitis, or acute flaccid paralysis) by county for 2012 with shading ranging from 0.01-0.99 to 1.0-2.49, 2.50-9.99, and greater than 10.0 per 100,000 population. (From http://www.cdc.gov/westnile/statsMaps/finalMapsData/data/2012CountyIncidenceMap.pdf. Accessed March 14, 2015.)

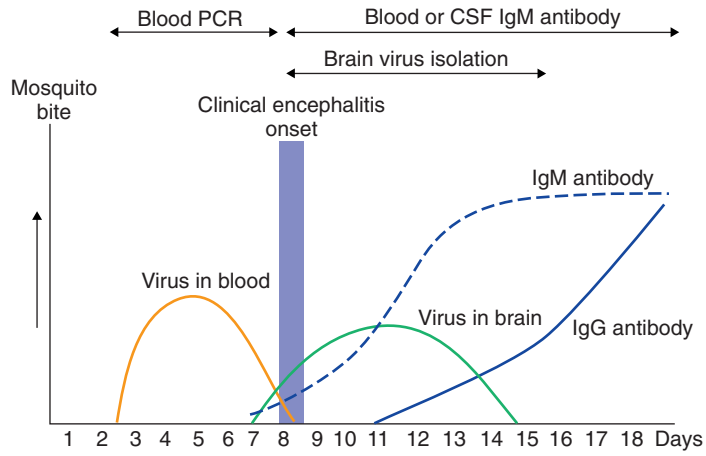


FIGURE 383-1. Typical time course for development of West Nile virus in blood and brain and occurrence of IgG and IgM antibodies in humans after West Nile virus infection. CSF = cerebrospinal fluid; PCR = polymerase chain reaction. (Reproduced from Davis LE, Beckham JD, Tyler KL. North American encephalitic arboviruses. *Neurol Clin.* 2008;26:727-757.)

detectable for up to 500 days after infection, so their presence should suggest acute infection only with compatible clinical manifestations. In some situations, cross-reactions with other flaviviruses, particularly St. Louis encephalitis virus, may complicate the interpretation of IgM immunoassays.

PREVENTION

Two phase II clinical trials of a live attenuated human chimeric vaccine (ChimeriVax-WN02) have demonstrated safety and both durable neutralizing antibody and cytotoxic T-cell responses.[12] A phase I trial of another chimeric vaccine (rWN/DEN4Δ30) also suggests promise. Because West Nile virus may be transmitted by organ transplantation, it is important to consider the possibility of this infection in organ donors.[13]

TREATMENT

Rx

Treatment is symptomatic and similar to that suggested for eastern equine encephalitis. Patients may require prolonged mechanical ventilation for either the polio-like syndrome or Guillain-Barré syndrome. The Guillain-Barré syndrome seen in West Nile patients does not appear to respond to plasma exchange. A trial of intravenous human immunoglobulin with high-titer anti–West Nile virus activity could not be completed because of the unpredictable annual geographic shifts in the activity of the disease. A recombinant humanized monoclonal antibody appeared safe in a phase I trial but has not been tested further. Ribavirin has activity against West Nile virus, but its clinical utility remains unknown.

PROGNOSIS

The overall case-fatality rate is 4 to 14%, but it is higher in the elderly. Risk factors for death include more severe weakness or coma, immunocompromise, and failure to produce virus-specific IgM. The prognosis for neurologic recovery is generally good; most U.S. patients regain physical and mental function by 1 year, but about half the patients in some series still report difficulties 1 year after the illness.

ST. LOUIS ENCEPHALITIS

ETIOLOGY

St. Louis encephalitis virus, a member of the family Flaviviridae,[14] shares close antigenic relationships with Japanese encephalitis, Murray Valley encephalitis, and West Nile viruses and is related to yellow fever (Chapter 381) and dengue (Chapter 382) viruses. Strains associated with *Culex pipiens*–borne epidemics in the northern United States are distinct from endemic strains transmitted by *Cx. tarsalis* in the western states.

EPIDEMIOLOGY

The virus is present in all parts of the Western Hemisphere, but epidemics occur only in North America and some Caribbean islands. During epidemic years, the virus has been responsible for up to 80% of all reported cases of encephalitis of known etiology in the United States. Epidemics of up to 2000 cases have taken place, mainly in urban-suburban localities of the Ohio-Mississippi River basin and in eastern and central Texas and Florida. Small outbreaks have also occurred in the western United States. Epidemics generally take place between July and September but may arise later in the year in warm areas such as Florida. Previous exposure and immunity to dengue may provide a degree of cross-protection against clinical St. Louis encephalitis. The ratio of inapparent to apparent infection is 800 : 1 in children up to 9 years of age, 400 : 1 in persons aged 10 to 49 years, and 85 : 1 in persons older than 60 years.

In most of the eastern United States, St. Louis encephalitis virus circulates between wild birds and *Cx. pipiens* mosquitoes, which breed in polluted water. In Florida and in parts of the Caribbean, *Cx. nigripalpus* is the principal vector. The cycle in the western United States also involves wild birds, but the vector is *Cx. tarsalis*, also that of western equine encephalitis. Because of the similar ecology of St. Louis encephalitis and western equine encephalitis viruses in the West, mixed outbreaks occur, mostly in rural, agricultural areas.

Above-average summer temperatures and conditions such as deficient rainfall, which create stagnant pools suitable for *Cx. pipiens* breeding, are associated with epidemics in the eastern United States. St. Louis encephalitis in the western states is favored by warm spring temperatures, heavy snow melt, and flooding.

PATHOBIOLOGY

Pathologic changes in fatal cases are limited to microscopic findings. Leptomeningitis is characterized by lymphocytic inflammation. Parenchymal changes consist of lymphocytic perivascular cuffing, cellular nodule formation, and neuronal degeneration.

CLINICAL MANIFESTATIONS

Three clinical syndromes are recognized: febrile headache, aseptic meningitis, and encephalitis. After an incubation period of 4 to 21 days, a variable period of nonspecific symptoms, including fever (temperature of 38° to 41° C), headache, malaise, drowsiness, myalgia, and sore throat, may be followed by an acute or subacute onset of meningeal or encephalitic signs, or both. Nausea, vomiting, and photophobia are common.

Neurologic abnormalities occur in up to 25% of patients. Extrapyramidal abnormalities and altered consciousness are the most significant findings. Other findings include meningismus, cranial nerve deficits (particularly the facial nerve), abnormal reflexes, tremors, myoclonic twitching, nystagmus, and ataxia. Motor abnormalities are infrequent, and sensory changes are extremely uncommon. Seizures occur in 10% of patients and are a poor prognostic sign, as is a persistent high temperature of 40° to 41° C. Signs of markedly increased intracranial pressure are unusual. A Guillain-Barré–like syndrome (Chapter 420) has occasionally been associated with St. Louis encephalitis, both as an acute manifestation and during the convalescent period.

In uncomplicated cases of St. Louis encephalitis, a moderate peripheral neutrophilic leukocytosis and shift to the left are noted. CSF pressure is elevated, protein level is mildly elevated, and glucose concentration is normal; a pleocytosis of up to 500 cells/μL is present, with an early neutrophilia predominance changing to lymphocytes within days. Serum creatine kinase, aspartate aminotransferase, and aldolase levels are frequently elevated. The electroencephalogram typically shows polymorphic delta activity, most prominently in the frontal and temporal regions; electrographic seizures are common. CT scans are normal, but MRI may show edema involving deep structures such as the substantia nigra. Hypo-osmolality, presumably as a result of the syndrome of inappropriate antidiuretic hormone secretion (Chapter 225), is noted in a third of patients.

Genitourinary tract symptoms (urgency, frequency, incontinence, and retention), microscopic hematuria, pyuria, proteinuria, and elevated blood urea nitrogen are frequent. St. Louis encephalitis viral antigen in cells of the urinary sediment has been detected by fluorescent techniques, and virus-like particles have been detected in urine by immunoelectron microscopy.

DIAGNOSIS

St. Louis encephalitis virus is rarely isolated from blood or CSF obtained during the acute phase of illness. Serologic diagnosis is achieved by demonstration of changing antibody titers; the HI, fluorescent, ELISA, and neutralizing tests demonstrate antibody within the first week after onset, and titers rise during the ensuing 2 weeks. CF antibodies appear 10 to 20 days after onset. Rapid, early diagnosis is possible by detection of IgM antibodies by ELISA in serum and CSF. Serologic cross-reactions may occur in persons

with previous exposure to dengue, West Nile, and other related flaviviruses. RT-PCR provides a more specific diagnosis, but its sensitivity is uncertain.

PREVENTION

No vaccine is available for St. Louis encephalitis. Surveillance of viral activity in vectors and avian hosts is used to define the risk for human infection and to initiate vector control efforts. In an established outbreak, avoidance of mosquito bites and spraying to reduce infected adult mosquitoes are the only effective means of control.

TREATMENT Rx

Treatment is supportive.

PROGNOSIS

A convalescent syndrome characterized by weakness, fatigue, nervousness, tremulousness, sleeplessness, irritability, depression, difficulty concentrating, and headaches occurs in 30 to 50% of older persons and clears in 80% of them within 3 years. The overall case-fatality rate is approximately 9%. Mortality is negligible in persons younger than 20 years but rises steeply after 55 years to approximately 30% in patients older than 65 years. Approximately 50% of the deaths occur during the first week, and 80% occur within 2 weeks after onset.

MURRAY VALLEY ENCEPHALITIS AND ROCIO ENCEPHALITIS

Murray Valley encephalitis and Rocio encephalitis, which are similar to Japanese encephalitis in their pathogenesis and clinical features, are caused by closely related flaviviruses. Murray Valley encephalitis has occurred in small epidemics in the Murray and Darling River valleys of Victoria and New South Wales, Australia. The virus is endemic in northern Australia and New Guinea, where it is maintained in a bird-mosquito cycle. Rocio encephalitis has caused epidemics of 1000 or more cases in São Paulo State, Brazil.

TICK-BORNE ENCEPHALITIS

PATHOGENS

A complex of six antigenically related tick-borne flaviviruses cause encephalitis: Powassan, tick-borne encephalitis, louping ill, Kyasanur Forest disease, Omsk hemorrhagic fever, and Langat viruses. The predominant syndrome is hemorrhagic fever (Chapter 381), but meningoencephalitis may be a component of the disease spectrum. Two subtypes of tick-borne encephalitis virus (central European encephalitis and Russian spring-summer encephalitis) are distinguished by serologic tests, are ecologically distinct, and differ in virulence for humans. Powassan and louping ill viruses are rare causes of encephalitis in North America and the British Isles, respectively. These viruses are easily distinguished serologically from mosquito-borne flaviviruses but induce cross-reactions within the complex.

EPIDEMIOLOGY

Tick-borne encephalitis occurs in Europe (including eastern Europe and Ukraine), southern Scandinavia, and far eastern Russia during the summer months, which corresponds to peak tick vector populations.[15] Several hundred to more than 2000 cases are reported annually, with morbidity rates of up to 20 per 100,000 inhabitants. Adults older than 20 years are mainly affected, and persons frequenting wooded areas that are heavily tick infested are at highest risk. In Europe, the disease is relatively mild (case-fatality rate of 1 to 2%), but in the Far East, it is severe (20 to 25%).

The vector of tick-borne encephalitis is *Ixodes ricinus* in Europe and *Ixodes persulcatus* in the Far East. The tick vector also serves as a reservoir for the virus. Larval ticks parasitize small rodents, which serve as amplifying viremic hosts during the spring and summer. Large vertebrates (goats, sheep, cattle) are hosts for nymphal and adult ticks. Outbreaks have occurred in families or groups of individuals ingesting unpasteurized milk or cheese from goats or sheep.

CLINICAL MANIFESTATIONS

Inapparent infections are common. Symptomatic tick-borne encephalitis in Europe typically (but not invariably) has a biphasic course beginning 7 to 14 days after exposure with an influenza-like illness that lasts 1 week, followed by a period of clinical remission for several days and then an abrupt onset of aseptic meningitis or meningoencephalitis. The meningoencephalitis is usually benign, although severe paralytic illness, myelitis, myeloradiculitis, and bulbar forms may occur.

In the Far East, tick-borne encephalitis begins suddenly with fever, headache, and gastrointestinal symptoms, followed rapidly by the appearance of depressed sensorium, coma, convulsions, and paralysis. Bulbar paralysis and cervical myelitis are frequent findings. In fatal cases, death occurs in the first week after onset. Aseptic meningitis and milder forms of encephalitis also occur. Chronic forms of tick-borne encephalitis have been described, with active clinical and pathologic abnormalities present a year or more after onset.

DIAGNOSIS

Brain MRI in patients with tick-borne encephalitis shows evidence of edema in the basal ganglia, thalami, and brain stem in about 20% of cases. MRI of the spinal cord may show anterior horn cell lesions corresponding to lower motor neuron weakness on examination.

Isolation of virus from blood is also possible during the early phase of illness. Serologic diagnosis is achieved by the HI, CF, neutralization, or ELISA techniques.

PREVENTION

In eastern Europe and the former Soviet Union, vaccines are used in high-risk groups (forestry and agricultural workers, military personnel). In Austria, immunization of the general population has resulted in a marked decline in incidence. Avoidance of tick exposure by wearing of protective clothing and use of repellents may be recommended in areas of high tick-borne encephalitis activity.

TREATMENT Rx

Treatment is supportive (see Eastern Equine Encephalitis).

PROGNOSIS

In European tick-borne encephalitis, convalescence is often prolonged, and residual paralysis may follow in severe cases. In the Far East, survivors frequently have residual paralysis, especially lower motor neuron paralysis of the upper extremities or shoulder girdle as a result of spinal cord involvement.

Louping Ill Encephalitis

Louping ill causes encephalitis in sheep (rarely in cattle, horses, and swine) in Scotland, northern England, and Ireland. Sporadic human cases have been recognized. Louping ill virus is maintained in nature by *I. ricinus* ticks and a variety of hosts, including small mammals, ground-dwelling birds (grouse), and probably sheep. The clinical features of louping ill resemble the European form of tick-borne encephalitis.

Powassan Virus Encephalitis

Powassan virus encephalitis has been documented in a small number of cases in the northeastern United States and eastern Canada. The virus is not associated with animal disease. The transmission cycle of Powassan virus involves *Ixodes cookei*, *Ixodes marxi*, and possibly other tick species along with mammals, particularly rodents and carnivores. Powassan encephalitis is characterized by fever and nonspecific symptoms, followed by encephalitic signs, which are frequently severe. Peripheral blood and CSF changes are similar to those described for other forms of flaviviral encephalitis. The case-fatality rate is about 50%, and residual paralysis may persist in survivors.

CALIFORNIA SEROGROUP ENCEPHALITIS

At least four members of the California serogroup of the Bunyaviridae family (Bunyavirus genus)—La Crosse, California encephalitis, Jamestown Canyon, and snowshoe hare viruses—cause encephalitis. California encephalitis virus occurs in the western United States (California, New Mexico, Utah, Texas) and has been implicated only rarely in human infections. In contrast, La Crosse virus, distributed more widely in the eastern half of the United States and southern Canada, is a major human pathogen. Jamestown Canyon and snowshoe hare viruses have also been implicated in sporadic cases of human encephalitis in the north central United States and Canada. California serogroup viruses have been implicated in human disease in China and the former Soviet Union.

EPIDEMIOLOGY

California serogroup encephalitis occurs as an endemic rather than an epidemic disease, with individual or small clusters of cases scattered across affected areas. Seventy to 120 cases are reported each year, generally between July and September, with a peak incidence in August. The virus primarily affects persons younger than 15 years living in rural and suburban areas characterized by deciduous hardwood forests. It is most prevalent in the north central states, where it is responsible for as many as 20% of cases of acute CNS infection in children. Focal "hot spots" (communities, even backyards) of recurrent summertime viral activity are recognized. The ratio of inapparent to apparent infection has been estimated variably at between 26 : 1 and 157 : 1.

The vector of La Crosse virus is *Aedes triseriatus*, which breeds both in forest tree holes and in artificial containers, notably discarded tires. This vector also serves as a reservoir for La Crosse virus. Wild rodents (squirrels, chipmunks) contribute to the cycle of transmission as viremic hosts. Humans acquire the disease by being bitten by an infected mosquito. *Aedes communis, Aedes stimulans, A. triseriatus,* and possibly anopheline mosquitoes are involved in transmitting Jamestown Canyon virus, and deer are the principal vertebrate hosts.

PATHOBIOLOGY

Histopathologic features in the CNS are qualitatively similar to those of other viral encephalitides. However, absence of inflammatory lesions in the cerebellum, medulla, and spinal cord may be a distinguishing feature of La Crosse infection.

CLINICAL MANIFESTATIONS

The clinical spectrum of California serogroup virus infection includes nonspecific febrile illness, aseptic meningitis, and meningoencephalitis. The disease begins with fever, headache, sore throat, and gastrointestinal symptoms. In mild cases, CNS signs appear on the third day after onset and subside within 7 to 8 days. In the more severe form, neurologic signs appear within 24 to 48 hours of onset, usually in the form of generalized seizures, elevated intracranial pressure, and altered consciousness, and persist longer. Encephalitis may be severe in the acute stage, but the disease is almost always self-limited; death is extremely rare.

The peripheral white blood cell count is elevated, with a predominance of polymorphonuclear cells and a shift to the left. CSF contains up to 500 lymphocytes/μL; the protein level is normal or mildly elevated, and the glucose concentration is normal. The electroencephalogram reveals generalized slowing in the delta and theta range; focal delta wave activity related to cortical destruction and focal seizures are also common findings.

DIAGNOSIS

In contrast to the other arboviral encephalitides, brain MRI in patients with California serogroup encephalitides may show lesions involving the temporal lobe in a pattern similar to that of herpes simplex encephalitis. The virus cannot be recovered from blood or CSF obtained during the acute phase. Diagnosis is best achieved by counterimmunoelectrophoresis, HI, CF, fluorescent, ELISA, and neutralization tests for antibody in paired acute and convalescent sera. The most practical, sensitive, and reliable methods are the HI test with La Crosse viral antigen and IgM antibody capture ELISA. Viral RNA can be detected in CSF or brain tissue by RT-PCR, although the sensitivity of the test remains to be determined.

PREVENTION

There is no vaccine for California encephalitis, although research involving DNA-based vaccines appears promising. Vector control methods are of uncertain usefulness in this disease. In defined hot spots of recurrent viral activity, breeding sites for *A. triseriatus* should be eliminated, particularly by draining or eliminating standing water (e.g., discarded tires or birdbaths) and filling holes in trees. Parents should protect children by limiting exposure and using mosquito repellents.

TREATMENT Rx

Treatment is supportive.

PROGNOSIS

The case-fatality rate is less than 1%. The risk for permanent neuropsychiatric sequelae is unclear, but hemiparesis and persistent seizure disorders have been reported.

384 EPIDEMIOLOGY AND DIAGNOSIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

THOMAS C. QUINN

GLOBAL STATISTICS

By 2014, approximately 80 million people had become infected with HIV since the beginning of the epidemic in 1981. Of these individuals, more than 45 million people had already died of AIDS, and it became ranked as one of the leading causes of death throughout the world.[1,2] According to estimates by the Joint United Nations Program on HIV/AIDS, 35 million people were living with HIV by 2013 (Fig. 384-1 and Table 384-1). In 2013 alone, 2.1 million people became newly infected, half of whom were young individuals between the ages of 15 and 24 years. The continuing rise in the population of people living with HIV infection reflects the combined effects of continued high rates of HIV infection and the beneficial impact of antiretroviral therapy (ART) resulting in fewer deaths[3] (Fig. 384-2).

The latest epidemiologic data indicate that globally, the spread of HIV appears to have peaked in 1996, when 3.5 million new HIV infections occurred.[4] In 2013, the estimated number of new HIV infections was approximately 35% lower than at the epidemic's peak about 15 years earlier. The epidemic appears to have stabilized in most regions, with new infections decreasing by 50% or more in 25 countries. Half of these reductions in the past 2 years have been among children. Despite these gains in some countries, prevalence continues to increase in Eastern Europe, Central Asia, and other parts of Asia because of the high rates of HIV infection. Sub-Saharan Africa remains the most heavily affected region and accounted for 72% of all new HIV infections in 2013.

Nearly 90% of all new infections occurred in developing countries; 50% occurred in women; and the major mode of transmission was heterosexual transmission, although infections continue to spread at high rates among men who have sex with men (MSM). Resurgence of the epidemic among MSM in high-income countries is increasingly well documented.[2] Differences are apparent in all regions, with some national epidemics continuing to expand even as the overall regional incidence of HIV infection stabilizes. Epidemic patterns have been changing over time. Perinatal transmission continues to occur in developing countries, where access to antiretroviral drugs to prevent mother-to-infant transmission is limited. In 2013, 240,000 children became newly infected, and 25 million children have been orphaned by the premature deaths of their parents from AIDS. In 2013, 1.5 million people died of AIDS, including 230,000 children.

DEMOGRAPHIC, SOCIAL, AND ECONOMIC IMPACT

For the first two decades of the epidemic, fatality rates from AIDS steadily increased and the average life expectancy in some countries in sub-Saharan Africa declined from 62 to 47 years of age. In Haiti, life expectancy was nearly 6 years less than it would have been in the absence of AIDS. Cambodia experienced a reduction in life expectancy of more than 4 years. However, the scaling up of antiretroviral therapy in low- and middle-income countries, as described later, has transformed national AIDS responses and generated broad-based health gains (Fig. 384-3). Since 1995, antiretroviral therapy has saved 14 million life-years in low- and middle-income countries, including 9 million in sub-Saharan Africa. As programmatic scale-up has continued, health gains have accelerated, with the number of life-years saved by antiretroviral therapy in Sub-Saharan Africa quadrupling in the last 4 years. Experience in the hyperendemic KwaZulu-Natal Province in South Africa illustrates the macroeconomic and household livelihood benefits of expanded treatment access, with employment prospects sharply increasing among individuals receiving antiretroviral therapy.[5,6]

THE GLOBAL RESPONSE

At a 2001 special session of the United Nations General Assembly on AIDS, 189 nations agreed that AIDS was a national and international security issue of the highest priority. The Global Fund for AIDS, Tuberculosis, and Malaria raised funds from private donations and industrialized countries to help support access to care and treatment in developing countries. This initiative was complemented by the U.S. government's Emergency Plan for AIDS Relief, now committed over a 10-year period through the Bush and Obama administrations to provide treatment and care for HIV-infected individuals, as well as additional resources for enhancing prevention efforts to prevent further transmission. As of 2014, approximately 13.6 million people in low- and middle-income countries were receiving antiretroviral therapy (ART)—a more than 25-fold increase since 2003 (see Fig. 384-3). The rapid expansion of antiretroviral therapy is one of the most remarkable achievements in recent public health history. ART coverage rose from 7% in 2003 to 54% in 2012 for individuals with CD4 counts less than 350 cells/mm^3, with especially high coverage achieved in Latin America (68%), the Caribbean (67%), Oceania (69%), and Eastern and Southern Africa (56%). Sixty-three percent of all people now receiving treatment in low- and middle-income countries are living in Sub-Saharan Africa, compared with 25% in late 2003. Coverage remains low in Eastern Europe and Central Asia (25%) and in the Middle East and North Africa (15%).

Unfortunately, not all have equal access to therapy, even within countries with middle to high prevalence. For example, an estimated 800,000 children younger than 15 years now require ART, but only 200,000 are receiving treatment. Children account for approximately 14% of AIDS deaths. Nearly 90% of children infected with HIV are African. The median proportion of HIV-infected children receiving treatment is just 28% in Sub-Saharan Africa. Similarly, less than 40% of HIV-infected pregnant women in low- and middle-income countries are benefiting from antiretroviral prophylaxis despite success in certain countries, such as Botswana, Brazil, and Thailand, and the virtual elimination of pediatric HIV disease in the industrialized world. Likewise, in Eastern Europe and Central Asia, injection drug use accounts for more than 70% of HIV-positive persons. However, only 25% of treatment recipients in this region are injection drug users. In years to come, additional resources will be required to reach the additional millions of HIV-infected people who require treatment with antiretroviral drugs, especially in light of recent recommendations to expand access to all HIV-infected adults who have a CD4+ count of less than 500/mm^3 based on the finding that early initiation of ART reduces mortality and incident tuberculosis.

REGIONAL EPIDEMICS

Sub-Saharan Africa

Sub-Saharan Africa represents the epicenter of the global HIV/AIDS pandemic (see Table 384-1). Studies in the late 1990s and early 2000s support the theory that HIV originated in Africa and that humans probably became infected sometime in the mid-20th century from a similar, related retrovirus in chimpanzees and sooty mangabey monkeys. For years, the infection remained limited to remote rural regions of Africa, but with urbanization, infected individuals migrated to major urban centers, where transmission was amplified and HIV spread to thousands of individuals within a relatively short period.

Seventy-five percent of all women infected with HIV live in Sub-Saharan Africa. In Côte d'Ivoire, home to the most serious epidemic in West Africa, HIV prevalence in females (6.4%) was more than twice as high than in males (2.9%). In Sub-Saharan Africa as a whole, women account for 60% of the estimated HIV infections. The risk for becoming infected is disproportionate for girls and young women. In Kenya, young women between 15 and 19 are three times more likely to be infected than their male counterparts, whereas 20- to 24-year-old women are 5.5 times more likely than men in their age cohort to be living with HIV infection. Among people aged 15 to 24 in Tanzania, females are four times more likely than males to be living with HIV. In the nine countries of Southern Africa most affected by HIV, the prevalence in young women 15 to 24 was on average three times higher than that in men of the same age.

Women's vulnerability to HIV in Sub-Saharan Africa stems not only from their greater physiologic susceptibility to heterosexual transmission but also from the severe social, legal, and economic disadvantages they often confront. HIV prevalence generally tends to peak at a younger age for women than for men. The very young are often at extremely high risk for infection through mother-to-child transmission.

HISTORICAL PERSPECTIVE

Three decades after initial recognition of acquired immunodeficiency syndrome (AIDS) in the United States, the disease has become epidemic in every country of the world. Initially reported as a disease primarily affecting homosexual men, AIDS was rapidly identified in many other risk groups, and it became evident that it was caused by an infectious agent transmitted through sexual activities, parentally through blood transfusions and injection drug use, and perinatally from mother to infant. Early investigations in the 1980s demonstrated that the etiologic agent of AIDS was the human immunodeficiency virus (HIV), which existed in two types, HIV-1 and HIV-2. After the development of diagnostic assays for HIV antibody, it became possible to track and monitor the escalating spread of HIV throughout the world, definitively define the modes and probabilities of transmission, and study the natural history of HIV infection. Within years of its recognition, HIV disseminated rapidly throughout the world, caused a massive epidemic, and became one of the leading causes of death worldwide. Efforts at prevention and treatment with antiretroviral drugs have tempered the spread and decreased the fatality rate in some countries, but in developing countries where the social, demographic, cultural, and economic impact of the AIDS epidemic has been the greatest, these gains were initially too limited and too slow to reverse the escalating trend of the epidemic. More recently, with the increased availability of antiretroviral drugs in many countries, the annual rate of increase in HIV infections may have peaked and mortality has declined.

From these epidemiologic trends it is projected that within the next decade, an additional 25 million people could become infected with HIV, unless the world succeeds in mounting a drastically expanded global prevention and treatment effort. It is anticipated that more than 40% of these new infections will occur in Asia, the Pacific, and Eastern Europe, although it is apparent that the epidemic will continue to devastate nearly all countries of the African continent. During the next decade, without full access to treatment and care in many countries, millions of individuals will join the ranks of the more than 45 million people who have already died of AIDS.

Globally an estimated 0.8% of adults 15 to 49 years of age are living with HIV, although the burden of the epidemic continues to vary considerably between countries and regions. AIDS is the leading cause of death in sub-Saharan Africa and the fourth largest killer worldwide. Sub-Saharan Africa remains the most severely affected region, with nearly 1 in every 20 adults (4.9%) living with HIV and accounting for more than two thirds of people living with HIV worldwide. Although the regional prevalence of HIV infection is nearly 25 times higher in Sub-Saharan Africa than in Asia, almost 5 million people are living with HIV in South, Southeast, and East Asia combined. After sub-Saharan Africa, the regions most heavily affected are the Caribbean, and Eastern Europe; and Central Asia, where 1.0% of adults were living with HIV in 2013.

Effective prevention of mother-to-child transmission depends on the simultaneous support of several strategies that work synergistically to reduce the odds that an infant will become infected as a result of exposure to the mother's virus. In ideal conditions, provision of antiretroviral prophylaxis and replacement feeding or continued antiretroviral treatment with breastfeeding can reduce transmission from an estimated 30 to 35% with no intervention to 1 to 2%. Unfortunately, most countries have not yet reached all pregnant women with these services, with estimates of only 30 to 60% of HIV-infected mothers receiving appropriate HIV care and prophylaxis for mother-to-child transmission (globally antiretroviral coverage for pregnant women reached 57% in 2013). Despite these limitations, it has been estimated that nearly 700,000 new HIV infections have been averted in the past decade because of provision of antiretroviral prophylaxis during pregnancy and to newborn infants.

Most HIV transmissions in Sub-Saharan Africa occur through sexual intercourse, with unsafe blood transfusions and unsafe injections accounting for a smaller fraction. Although sexual behavior is the most important factor influencing the spread of HIV in Africa, that behavior varies greatly across cultures, age groups, socioeconomic class, and gender. The interplay of multiple factors, biologic and behavioral, determines the spread of HIV. One study of four African cities (Cotonou, Kisumu, Ndola, and Yaounde) revealed that the most common behavioral and biologic factors in those cities with the highest HIV prevalence were young age at a woman's first sexual intercourse, young age at first marriage, age difference between spouses, the presence of herpes simplex type 2 infection and trichomoniasis, and lack of male circumcision. There is substantial evidence that sexually transmitted diseases (STDs) enhance the risk for sexual transmission of HIV, that the level of the HIV viral load in an individual enhances the probability of infectiousness, and that male circumcision is associated with a reduced risk for transmission. Although the complex interplay of factors makes it difficult to estimate the probable growth of the epidemic within the region, evidence from the past 30 years demonstrates that HIV can spread rapidly and widely from very low prevalence levels.

A little more than a 10th of the world's population lives in Sub-Saharan Africa, but it is home to 69% of all people infected with HIV in the world. In 2013, an estimated 1.5 million people living in Sub-Saharan Africa became newly infected with HIV, thus bringing the total number of people infected with HIV to 23.5 million. Sub-Saharan Africa accounted for 71% of all the world's AIDS-related deaths in 2013. Even though the rate of new HIV infections in sub-Saharan Africa has slowly declined, with the number of new infections in 2013 being approximately 25% lower than at the epidemic's peak in the region in 1995, the number of people infected with HIV has slightly increased in 2013, in part because of the increased longevity stemming from improved access to treatment.

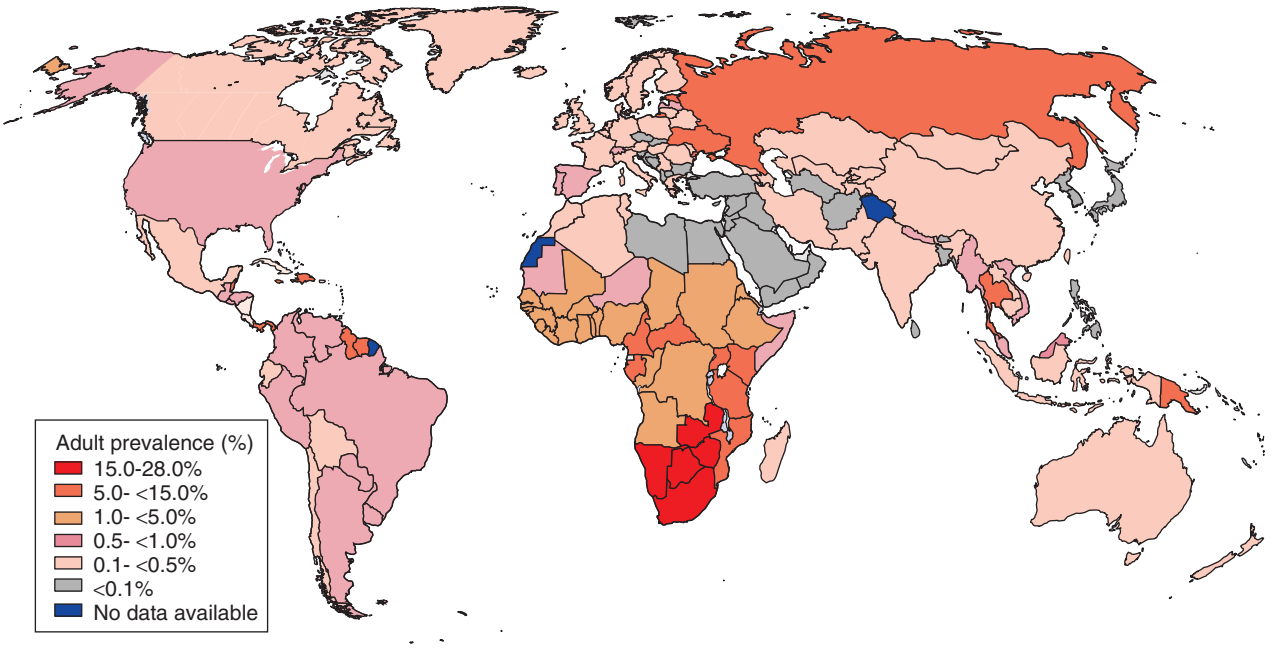

FIGURE 384-1. A total of 35.0 million people (33.2 to 37.2 million) were living with HIV infection in 2013. The adult prevalence of HIV infection is shown by country. (Data from UNAIDS GAP Report. UNAIDS; 2014.)

TABLE 384-1 REGIONAL HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME STATISTICS AND FEATURES AT THE END OF 2013

REGION	ADULTS AND CHILDREN LIVING WITH HIV/AIDS	ADULTS AND CHILDREN NEWLY INFECTED WITH HIV	ADULT PREVALENCE RATE* (%)	MAIN MODES OF TRANSMISSION FOR ADULTS LIVING WITH HIV/AIDS
Sub-Saharan Africa	24,700,000	1,500,000	4.9	Hetero
North Africa and Middle East	230,000	25,000	0.2	Hetero, IDU
Asia and the Pacific	4,800,000	350,000	0.3	Hetero, IDU
Latin America	1,600,000	94,000	0.4	MSM, IDU, Hetero
Caribbean	250,000	12,000	1.0	Hetero, MSM
Eastern Europe and Central Asia	1,100,000	110,000	1.0	IDU, Hetero, MSM
Western Europe	1,100,000	30,000	0.2	MSM, IDU, Hetero
North America	1,300,000	55,000	0.6	MSM, IDU, Hetero
Total	35,000,000	2,100,000	0.8	

*The proportion of adults (15 to 49 years of age) living with HIV infection or AIDS in 2013 using 2013 population numbers.
AIDS = acquired immunodeficiency syndrome; Hetero = heterosexual transmission; HIV = human immunodeficiency virus; IDU = transmission through injection drug use; MSM = sexual transmission among men who have sex with men.

Unfortunately, progress has been strikingly uneven in gaining access to ART in Sub-Saharan Africa, with coverage reaching or exceeding 50% in some countries (Botswana, Namibia, and Uganda) but remaining below 20% in most others.

Although some countries in Sub-Saharan Africa such as Kenya, Uganda, and Zimbabwe have shown recent declines in HIV prevalence, there is no evidence of any decline in Southern Africa, including the Republic of South Africa, Botswana, Namibia, and Swaziland, where exceptionally high infection levels continue. Southern Africa remains the area most heavily affected by the epidemic. The nine countries with the highest HIV prevalence worldwide are all located in this subregion, with each of these countries experiencing adult HIV prevalence greater than 10%; prevalence was as high as 26% in Swaziland, 24% in Botswana, and 23% in Lesotho. The Republic of South Africa is home to the world's largest population of people living with HIV (6.3 million), with a prevalence of 17.3%. Almost one in three pregnant women attending public antenatal clinics were infected with HIV. South Africa accounts for a large percentage of the treatment scale-up in sub-Saharan Africa, but as of 2013, antiretroviral therapy was only reaching 55% of South Africans eligible for treatment.

In Botswana, more than a third of pregnant women attending antenatal clinics and close to 50% of women 30 to 34 years of age were infected with HIV in 2013. Similarly, Lesotho has a national adult HIV prevalence of 23%, with 27% documented in women attending antenatal clinics. A third of pregnant women 25 to 34 years of age were infected. In Namibia, the prevalence of HIV infection is 13.4% in all adults, with an HIV prevalence of 42% in antenatal clinics in selected areas. In neighboring Mozambique, Malawi, and Zambia, HIV prevalence has been documented to be between 10% and 14%. There is wide geographic variation, however, with HIV infection rates in pregnant women ranging from less than 10% in some places to as high as 30% in others.

In the countries of Eastern Africa, HIV prevalence has either decreased or remained stable in the past several years. In Uganda, which saw a steep decline in HIV prevalence during the mid and late 1990s, adult HIV prevalence was estimated to be 6.7% in 2005. However, recent trends suggest that HIV prevalence may be increasing in selected areas (nationally at 7.2%), in part because of a decrease in mortality with access to ART but potentially also because of increasing incident rates as a result of decreasing condom use and an increased percentage of multiple partners. In neighboring Kenya, Eritrea, Tanzania,

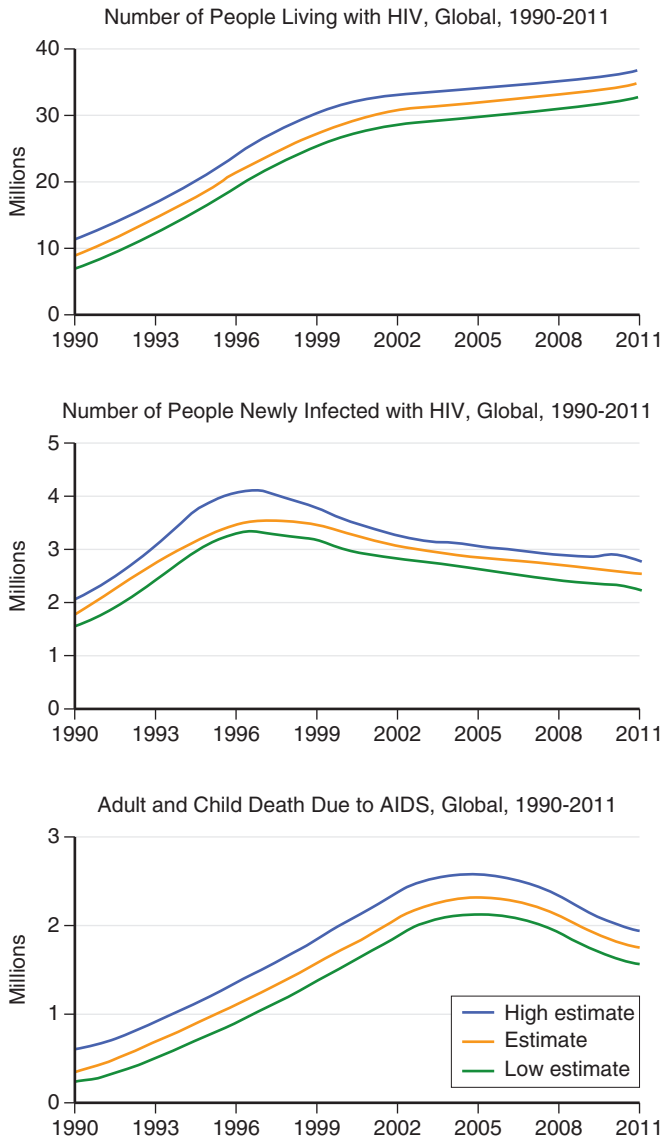

FIGURE 384-2. Global HIV trends in number of people living with HIV, new infections and fatalities, from 1990 to 2011. (Data from UNAIDS Global Report. *UNAIDS Report on the Global AIDS Epidemic 2012.* Geneva: UNAIDS; 2013.)

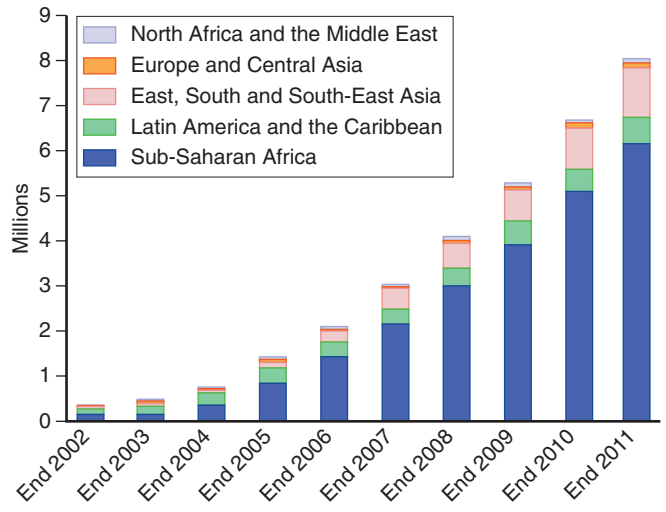

FIGURE 384-3. Estimated number of people receiving antiretroviral therapy in low- and middle-income countries from 2002 through 2011. (Data from UNAIDS Global Report. *UNAIDS Report on the Global AIDS Epidemic 2012.* Geneva: UNAIDS; 2013.)

Burundi, and Rwanda, the HIV epidemic has been stable in recent years, with prevalence rates ranging from 1% in Eritrea to 6% in Kenya, Tanzania, Burundi, and Rwanda. In Ethiopia, HIV prevalence (1.4%) has stabilized in urban areas but appears to be increasing in more distant rural areas, where access to treatment and care is more limited.

Western Africa is less severely affected than other parts of Sub-Saharan Africa, with national adult HIV prevalence rates of 2% in several countries. The highest rate in the region is in Côte d'Ivoire, at 3.0%. In Nigeria, infection levels vary radically across the country from 2.6% in the southwest to 6.1% in the north central zones (nationally 3.7%). HIV continues to spread rapidly among female sex workers and their clients, as well as in the general population. In some urban populations, more than 10% of adults are infected and the annual incidence is as high as 3%.

Despite the scale-up of treatment, AIDS is still one of the leading causes of death and years of productive life lost throughout the continent. Excess deaths attributable to HIV are highest in the 25- to 34-year-old group, usually a group with low mortality. Nearly 90% of deaths in this age group are in excess of background rates and were attributable to HIV. Because AIDS deaths are concentrated in childhood and young adult age groups, their effects are substantial, with life expectancy reduced markedly in several countries. HIV or AIDS cases will put an increasing strain on health care systems, which are already overburdened, and on individual households that are trying to manage with limited economic resources. Care and support for children orphaned by AIDS will become a growing concern throughout the region.

Asia and the Pacific

After Sub-Saharan Africa, Asia and the Pacific, home to 60% of the world's population, have the second largest number of HIV-infected individuals in the world, estimated at 4.8 million. In 2013, 350,000 adults and children became newly infected, in part because of growth of the HIV epidemic in China, India, and several other countries in Southeast Asia. With the exception of Thailand, national HIV prevalence levels remain comparatively low in most countries of Asia and the Pacific, with HIV prevalence being less than 1%, to some extent due to their large population base. Thus, because of the region's large population, Asia's comparatively low HIV prevalence translates into a substantial portion of the global HIV burden. India's national adult HIV prevalence rate of 0.3% offers little indication of the serious situation facing the country. An estimated 4.8 million people were living with HIV at the end of 2013—one of the highest figures in the world after South Africa.

Throughout the region, injection drug use remains one of the most prominent modes of transmission of HIV. More than 50% of injection drug users have already acquired HIV in Malaysia, Myanmar, Nepal, Thailand, Indonesia, Manipur, and Southern China. Very high rates of needle sharing have been documented among users in Bangladesh and Vietnam, along with evidence that a considerable proportion of sex workers in Vietnam also inject drugs. More recently, the epidemic in many parts of Asia is steadily expanding into lower risk populations through transmission to the sexual partners of those most at risk. In China, where the epidemic was previously driven by transmission through injection drug use, heterosexual transmission has become the predominant mode of HIV transmission.

China, with a fifth of the world's population, has also witnessed a dramatic escalation of the HIV epidemic in the past decade. A total of 780,000 Chinese individuals are estimated to be living with HIV. The HIV epidemic is particularly severe among injection drug users, who account for a quarter of all HIV infections. To compound the tragedy of the epidemic in China, reports from Henan province in Central China demonstrate that tens of thousands and possibly more rural villagers became infected by selling their blood to collecting centers that did not follow basic blood donation safety procedures. It has been estimated that 150,000 people have been infected through these practices. There are new signs of heterosexually transmitted HIV epidemics in at least three provinces—Guangdong, Guangxi, and Yunnan. Several other factors highlight the swift escalation of HIV infection in China. STDs quadrupled between 1997 and 2002, thus suggesting that unprotected sex with non-monogamous partners is increasing in China. There is massive population mobility. Approximately 100 million Chinese are temporarily or permanently away from their registered addresses, and increasing socioeconomic disparities add to the likelihood of the spread of HIV.

Indonesia, the world's fourth most populous country, is another example of how quickly the AIDS epidemic can emerge. After more than 10 years of negligible HIV prevalence, the infection rate in injection drug users, sex workers, and blood donors in some regions is rapidly increasing, with a 25% increase between 2001 and 2013. Papua New Guinea also has reported the

As of 2013, 48% of adults and children in need of ART in the region were estimated to be receiving such services. ART coverage is notably higher in eastern and southern Africa (56%) than in western and central Africa (35%). Treatment coverage for adults (50%) remains higher than that for children (38%). Children's access to ART is especially limited in Western and Central Africa.

AIDS-related deaths have fallen by 29% in Kenya, and a study in Uganda found that timely initiation of ART and cotrimoxazole prophylaxis reduced mortality by 95% and produced a 93% reduction in HIV-related orphans. In Botswana, where ART coverage exceeds 80%, the estimated annual number of AIDS-related deaths declined by more than half. More than 50% of all people in need of treatment are still not receiving such services.

highest HIV infection rates among the Pacific Island countries and territories. Even though the Philippines has maintained a low HIV prevalence, higher rates of STDs among Filipino sex workers, their clients, and MSM indicate low levels of condom use and the potential for rapid spread of HIV.

In some countries of Southeast Asia where HIV prevalence rose rapidly in the 1990s, strong prevention programs have limited the spread, most notably in Thailand, Cambodia, and Myanmar. Furthermore, the increased access to ART has coincided with a drastic drop in AIDS-related deaths. Despite these advances, AIDS is still a leading cause of death in Thailand and 1.2% of the country's population is infected with HIV. Although STDs and heterosexual transmission have declined as a result of the government's prevention programs, HIV continues to spread rapidly among injection drug users and MSM.

Treatment scale-up in Asia has been mixed. As of December 2013, 47% of those in South and Southeast Asia needing ART were receiving it, but only 18% were receiving it in East Asia, much lower than the global average (54%) for all low- and middle-income countries. In 2013, only one country in the Asia Pacific region (Cambodia) reached more than 80% coverage of antiretroviral therapy, whereas in Pakistan less than 20% of eligible infected persons received therapy. In Oceania, an estimated 69% received therapy.

Eastern Europe and Central Asia

The HIV epidemic has increased faster in Eastern Europe and Central Asia between 2000 and 2013 than in any other area of the world. In 2013 there were an estimated 1.1 million people living with HIV, a 20-fold increase in less than a decade. In recent years, the Russian Federation has experienced an exceptionally steep rise in reported HIV infections, 90% of which have been attributed to injection drug use. It is estimated that nearly 1% of the young people in Eastern Europe and Central Asia are injecting drugs, which places these individuals and their sex partners at high risk for becoming infected with HIV. In countries such as Azerbaijan, Georgia, Tajikistan, and Uzbekistan, HIV has experienced explosive growth. Similar explosive high rates of HIV are being documented in injection drug users and heterosexuals at risk for STDs in other countries of the Commonwealth of Independent States, in the Baltic States, and in Romania.

In Estonia, Latvia, and Lithuania, major HIV outbreaks are also occurring in selected populations, such as prison inmates. In one prison in Lithuania, 15% of the inmates were HIV positive, thus confirming the role of prisons in the spread of HIV in many countries of the region. The concentration of large numbers of young people in overcrowded prisons or juvenile justice facilities, often marked by an abundance of drugs but a scarcity of HIV information, clean needles, or condoms, provides fertile ground for the rapid spread of HIV among inmates and, on their eventual release, into the wider population.

Initially driven by injection drug use in young people, heterosexual transmission of HIV has become a prominent mode of spread in Belarus and Ukraine. With an estimated adult HIV prevalence rate of 0.8%, Ukraine is one of the most severely affected countries in the region. Three fourths of HIV infections in Ukraine are related to injection drug use, with a prevalence of 21.5% in injection drug users, and the proportion of sexually transmitted infection (STIs) is increasing, suggesting potential spread heterosexually and among MSM. Although many of these infections may occur in sex partners of injection drug users, the trend also may indicate spread into the wider population of these countries. In the Russian Federation and the Ukraine, up to 30% of female injection drug users are also involved in commercial sex work. In Odessa, 67% of sex workers who inject drugs were HIV positive. The public health efforts to stem the tide of the epidemic in these countries are limited and, in some cases, nonexistent. In contrast, HIV prevalence remains low in Poland, the Czech Republic, Hungary, and Slovenia, where well-designed national HIV/AIDS programs are in operation.

A number of countries in the region have expanded access to ART, although treatment coverage remains relatively low. By December 2013, only 25% of adults in need of therapy were receiving it—a level much less than the global average. Injection drug users, the population most at risk for HIV in Eastern Europe and Central Asia, are often least likely to receive ART when they are medically eligible. If effective interventions are not implemented in the more severely affected countries, it is likely that the situation will become dramatically worse over the next 5 years.

Latin America and the Caribbean

An estimated 1.6 million adults and children are living with HIV in Latin America and the Caribbean. Twelve countries in this region have an estimated HIV prevalence of 1% or greater in pregnant women. In several Caribbean countries, adult HIV prevalence rates are surpassed only by the rates experienced in sub-Saharan Africa, which makes this region the second most affected in the world. Haiti and the Bahamas remain the worst affected, with an estimated national prevalence higher than 1.8% in Haiti and a prevalence of 2.8% in the Bahamas. AIDS is the leading cause of death in some countries of the Caribbean basin. In Haiti, the Bahamas, and Guyana, the number of deaths in 15- to 34-year-olds is 2.5 times higher than it would have been in the absence of AIDS.

Homosexual and heterosexual transmission continues to be the major mode of transmission throughout the region, although there is evidence that spread of HIV is increasing through sharing of infected drug equipment. Population mobility, spurred by high rates of unemployment and poverty, is emerging as a significant factor in the epidemic's growth in this region. Central America's geographic position also makes it an important transit zone for people moving between the rest of the region and North American countries. Appropriately, protecting vulnerable populations on the move, including adolescent girls and young women, is now the focus of a regional prevention program in Central America. In Mexico, adult HIV prevalence in the wider population is still well under 1%, but prevalence rates are higher in specific population groups—6% in injection drug users and 15% in MSM. There is significant overlap between injection drug users and MSM, especially in Brazil and the southern Latin American countries, where injection drug use is a growing social phenomenon. Injection drug use is also a major route of HIV transmission in Argentina, Chile, and Uruguay.

Despite many constraints, the region has made progress in the provision of treatment and care. By reducing HIV-related morbidity through treatment, Brazil's treatment and care program is estimated to have avoided 234,000 hospitalizations in a 4-year period, thereby demonstrating a cost-effective approach to care. Argentina, Costa Rica, Uruguay, and Cuba now guarantee free and universal access to drugs through the public sector, and sharp reductions have recently been secured in Honduras and Panama. Treatment coverage has risen from 10% of those in need in 2004 to 68% in 2012. Similarly, pediatric antiretroviral coverage in the Caribbean was high (>60%) in comparison to the global average for children of 28%. Consistent with the evolving guidelines of HIV treatment, a growing number of people living with HIV in Latin America are starting treatment earlier at CD4+ cell counts of 350 or lower rather than waiting until the count drops below 200. Earlier initiation of therapy offers the possibility that medical outcomes in the region may improve further still and reduce the population-level viral load, which might result in lower transmission rates.

Western Europe

More than 1.1 million HIV-infected individuals reside in Western Europe, with trends similar to those witnessed in the United States, Australia, and New Zealand. Longer survival of people infected with HIV has led to a steady increase in the number of people living with the virus in high-income countries. In a multicountry study in Europe, Australia, and Canada, mortality rates in people living with HIV now approach those in the non–HIV-infected population, although excess mortality in HIV-infected people increases with the duration of infection. In the United Kingdom, half of all people living with HIV are receiving ART, with no appreciable increase in the number of patients with virologic failure or resistance to the drugs.

The HIV epidemic in Western Europe is a result of a multitude of epidemics that differ in their timing, scale, and effects on populations. A larger proportion of new HIV diagnoses in Western European countries occur through heterosexual intercourse. More than half of the new HIV infections in the United Kingdom in 2013 resulted from heterosexual sex, compared with 33% in 1998. In Ireland, a similar trend is visible, with numbers of heterosexually transmitted HIV infection increasing four-fold between 1998 and 2001. Unsafe sex between men remains an important factor for spread in most European countries, particularly in the United Kingdom, Germany, the Netherlands, and Spain. Injection drug use remains a major mode of transmission in Spain, France, and Portugal, but like in other countries in Europe, approximately a fourth of all HIV infections are now heterosexually transmitted. Most data from high-income countries demonstrate that the epidemic has shifted to the poor and marginalized sections of society. Underscoring the need for renewed prevention efforts, especially in young people, are findings of increases in high-risk behavior, less frequent condom use, and higher rates of STDs in several countries. In the United Kingdom, for example, rates of gonorrhea, syphilis, and chlamydial infections have more than doubled since 1995, and increases have been found in other Western European countries as well.

The United States

By 2013, more than 1.2 million people were living in the United States with HIV (see Table 384-1). Nationally, the adult HIV prevalence was estimated to be 0.6%. This increase reflects mixed results in the United States' effort to combat its epidemic. More people infected with HIV are living longer because of antiretroviral therapy, but unfortunately, the early gains made in prevention have not been sustained (Fig. 384-4). The number of newly recorded HIV cases in 46 states with confidential name–based reporting has varied only slightly since the late 1990s. In 2006, the annual incidence of HIV infection was estimated at 56,300, which was approximately 40% higher than previously estimated. The CDC estimates that approximately 50,000 people in the United States are newly infected with HIV each year. In 2011, there were an estimated 50,007 new HIV infections. Nearly two thirds of these new infections occurred in MSM; 18% were women who acquired HIV via heterosexual contact, 10% were men who also acquired HIV by heterosexual contact (Figs. 384-5 and 384-6), and 11% acquired HIV via injection drug use. The estimated rate of diagnosis of HIV infection for the United States was 16.1 in 100,000, with 31.4 in 100,000 in men and 8.0 in 100,000 in women.[7] In the United States, more than 620,000 people with AIDS have died since the epidemic began.

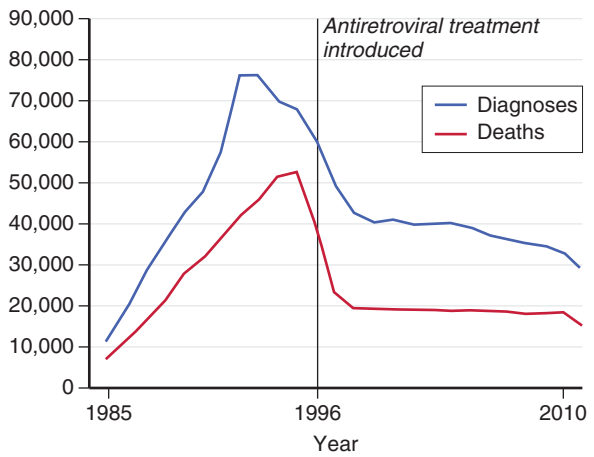

FIGURE 384-4. AIDS diagnosis and deaths in the United States from 1985 to 2010. (Data from Centers for Disease Control and Prevention. HIV Surveillance—United States, 1981-2008. *MMWR.* 2011;60:689-693.)

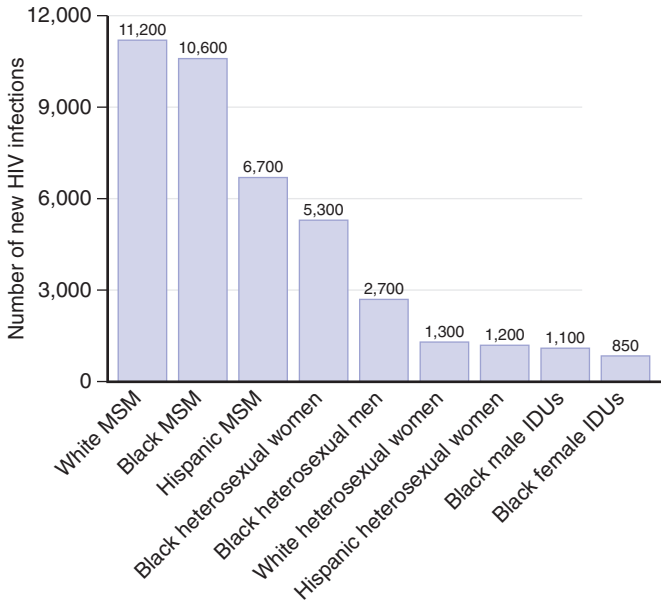

FIGURE 384-5. Estimated new HIV infections in the United States, 2010, for the most-affected subpopulations. IDUs = injection drug users; MSM = men who have sex with men. (Data from Centers for Disease Control and Prevention. Estimated HIV incidence in the United States, 2007-2010. *HIV Surveillance Suppl Rep.* 2012;17:4.)

More women are being infected with HIV through unprotected heterosexual exposure (86%) and injection drug use (14%).[8] The main risk factor for women who acquire HIV during sex is the risk behavior of their male partners, such as injection drug use, commercial sex, or sex with other men. As in Latin America, women living in impoverished and marginal circumstances appear to be at disproportionate risk for HIV infection. In North Carolina, HIV-positive women were considerably more likely to be unemployed, requiring public assistance, and exchanging sex for money and gifts.

As the U.S. epidemic evolves, it is becoming more an epidemic of African Americans and other minorities (see Fig. 384-5). African Americans make up 12% of the U.S. population but account for 47% of new HIV diagnoses. Hispanics represent 17% of the population but account for 21% of new HIV diagnoses. Among African Americans and Hispanics, most men infected with HIV were exposed during sex with other men (72% and 79%, respectively), whereas most women with HIV become infected heterosexually (89% and 86%, respectively). African American women are more than 10 times more likely to be infected with HIV than are white women. AIDS continues to be one of the leading causes of death in African American women aged 25 to 34 years and ranks in the top three causes of death in African American men aged 25 to 54 years. In the United States, the challenge of slowing the rate of new HIV infections overlaps with the need to provide diagnosis, treatment, and care services more equitably. The number of AIDS-related deaths was 69% lower than in 1994. However, further declines in mortality will require greater success in encouraging timely diagnosis of HIV infection. An estimated 21% of people living with HIV are unaware of their HIV status[9] (Fig. 384-7). Moreover, in 36% of people in whom HIV was diagnosed, AIDS was diagnosed within 12 months. With the aim of increasing the percentage of people who receive a timely diagnosis of HIV, the Centers for Disease Control and Prevention recommends routine voluntary HIV testing in all health care settings unless the patient "opts out," to not be tested.

With an epidemic that is nearly into its third decade, complacency has increased and prevention efforts have dwindled as a result of declining mortality. Multiple studies illustrate that prevention efforts are not reaching the large number of at-risk individuals who engage in unsafe sex. Increased rates of STIs among MSM have been documented in the United States, Australia, Great Britain, Canada, and other developed countries. Rates of gonorrhea, syphilis, and chlamydia have more than doubled in the past 5 years among MSM in selected U.S. and European cities. Renewed efforts to enhance prevention efforts, particularly in HIV care clinics, are being echoed throughout all these countries.

DIAGNOSIS

Screening for HIV Infection

The history and physical examination are of limited value in making the diagnosis of early HIV infection,[10] so laboratory testing is key to making the diagnosis. The U.S. Preventive Services Task Force on HIV screening recommends that clinicians screen for HIV infection in all adolescents and adults aged 15 to 65 years.[11] Younger adults and older adults who are at increased risk also should be screened.[12] In addition, they recommended that clinicians screen all pregnant women for HIV, including those who present in labor who are untested and whose HIV status is unknown. These updated recommendations were based on increasing evidence of the benefits of early antiretroviral therapy for HIV-infected persons and its effectiveness in preventing HIV transmission. This recommendation for increased screening was based on

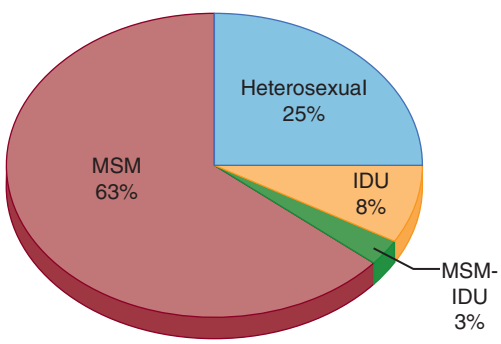

FIGURE 384-6. Estimated new HIV infections in 2010 in the United States by transmission category. IDUs = injection drug users; MSM = men who have sex with men. (Data from Centers for Disease Control and Prevention. Estimated HIV incidence in the United States, 2007-2010. *HIV Surveillance Suppl Rep.* 2012;17:4.)

HIV = human immunodeficiency virus; ART = antiretroviral therapy. (Data from Centers for Disease Control and Prevention. Vital signs: HIV prevention through care and treatment—United States. *MMWR.* 2011;60:1618-1623.)
*HIV-infected, n = 1,178,350; HIV-diagnosed, n = 941,950.
†Calculated as estimated number diagnosed (941,950) × estimated percentage linked to care (77%); n = 725,302
‡Calculated as estimated number diagnosed (941,950) × estimated percentage retained in care (51%); n = 480,395.
§Calculated as estimated number retained in care (480,395) × percentage prescribed ART in the Medical Monitoring Project (MMP) (88.8%); n = 426,590.
¶Calculated as estimated number on ART (426,590) × percentage with suppressed viral load in MMP (77.0%); n = 328,475 (28% of the estimated 1,178,350 persons in the United States who are infected with HIV).

the fact that over 20% of HIV-infected individuals have never been tested and are unaware of their infection, and based on evidence that identification and treatment of HIV infection are associated with a markedly reduced risk for progression to AIDS, AIDS-related events, and deaths in individuals with immunologically advanced disease. One randomized trial (HPTN 052) clearly demonstrated that the use of antiretroviral therapy is associated with substantially decreased risk for transmission from HIV-positive persons to uninfected sexual partners. Furthermore, evidence also demonstrates that the identification and treatment of pregnant women dramatically reduces rates of mother-to-child transmission. The overall benefits of screening for HIV infection in adolescents, adults, and pregnant women are substantial.

On the basis of HIV prevalence data, MSM and active injection drug users are at very high risk for new HIV infection and would qualify for increased HIV screening. Behavioral risk factors for HIV infection include having unprotected vaginal or anal intercourse; having sexual partners who are HIV infected, bisexual, or injection drug users; or exchanging sex for drugs or money. Other persons considered at high risk include those who have acquired or request testing for other STIs. Patients may request HIV testing in the absence of reported risk factors. Individuals not at increased risk for HIV infection include persons who are not sexually active, those who are sexually active in exclusive monogamous relationships with uninfected partners, and those who do not fall into any of the previously mentioned categories. It is recognized that these risk categories are not mutually exclusive, the degree of sexual risk is a continuum, and individuals may not be aware of their sexual partner's risk factors for HIV infection. For patients younger than 15 years and older than 65 years, it would be reasonable for clinicians to consider HIV risk factors on an individual basis, especially those with new sex partners. However, clinicians should bear in mind that adolescent and adult patients may also be reluctant to disclose having HIV risk factors even when asked.

The evidence is insufficient to determine optimum time intervals for HIV screening. One reasonable approach would be a one-time screening of adolescents and adult patients to identify persons who are already HIV positive with repeated screening of those who are known to be at risk for HIV infection, those who are actively engaged in risky behaviors, and those who live or receive medical care in a high-prevalence setting (HIV seroprevalence > 1%). High-prevalence settings include STD clinics, correction facilities, homeless shelters, tuberculosis clinics, clinics serving MSM, and adolescent health clinics with high prevalence of STDs. Currently, a reasonable approach may be to re-screen groups at *very high* risk for new HIV infection at least annually and individuals at *increased risk* at slightly longer intervals (3 to 5 years). Women screened for HIV during previous pregnancies should be re-screened for HIV at all subsequent pregnancies. The CDC also recommends that all persons aged 13 to 65 years be screened for HIV in health care settings located in areas where the prevalence of undiagnosed HIV infection is greater than 0.1% and that persons with increased risk for HIV be re-tested at least annually.

Laboratory Assays

Diagnosis of HIV infection is usually based on serologic detection of immunoglobulin G (IgG) antibodies to HIV-specific proteins. A conventional serum test for diagnosing HIV infection is the repeatedly reactive immunoassay followed by a confirmatory Western blot or immunofluorescence assay. The combined tests are highly accurate with sensitivity and specificity greater than 99.5%. Results are available within 1 to 2 days for most commercial laboratories. New and improved assays are now available for early detection and confirmation of acute HIV infection, including combination tests (p24 antigen and HIV antibodies) and qualitative and quantitative HIV-1 RNA assays.

The diagnostic accuracy of HIV infection has improved with each generation of serologic assays. Whereas the first-generation tests were based on whole viral lysate and an indirect enzyme immunoassay, second-generation tests use synthetic and recombinant peptide antigens that have improved sensitivity and specificity. Third-generation assays have used "sandwich" assay formats that allow simultaneous detection of IgM and IgG antibodies. Now, fourth-generation assays combine antibody and antigen testing within the same diagnostic test format. With increasing sensitivity of these diagnostic assays, the "window period" wherein HIV antibodies may not be detected because of acute or very recent infection has gradually shortened from 6 weeks to less than 3 weeks.[11] This shortening of the window is particularly important when acute infection may not be suspected. In patients with symptoms and signs of acute HIV infection, direct testing with sensitive assays such as nucleic acid testing for HIV RNA may be used.

Rapid tests represent a major advance in HIV serologic testing. Rapid HIV testing may use either blood or oral fluid specimens and can provide results in 5 to 40 minutes. The sensitivity and specificity of the rapid tests are also greater than 99.5%; however, initially positive results require confirmation with conventional methods. Rapid testing can be offered on site in a variety of settings, including clinics, mobile vans, health fairs, and places of worship. Rapid testing is becoming the test of choice for all patients who request screening for immediate feedback and opportunities for quick intervention and counseling. Rapid tests are particularly important in management decisions of occupational or nonoccupational exposures, when patients are unlikely to return for results and seroprevalence rates are high, such as STD clinics or emergency departments, and when patients with an acute illness in which HIV-related complication is being considered and serostatus is not known.

In 2012, the U.S. Food and Drug Administration (FDA) approved the OraQuick in-home HIV test, the first self-administered HIV test kit to detect antibodies to both HIV-1 and HIV-2. The test is available for consumers in drugstores, and individuals may obtain test results within 20 to 40 minutes after collecting an oral fluid sample by swabbing the upper and lower gums inside the mouth and placing the sample into a developer vial provided as part of the kit. As with all rapid HIV assays, positive test results are preliminary and need to be confirmed with a standard HIV antibody test. In clinical trials, self-testing with this rapid HIV assay had a sensitivity of 92% and a specificity of 99.98% compared with the standard enzyme immunoassay (EIA) screening assay. An alternative to home testing is the home access HIV test system, which allows blood samples to be taken at home using a fingerstick test strip that is mailed to a laboratory for screening and confirmation. Results are obtained by phone using an individual identifier code supplied with the product.

Other methods to establish HIV infection include viral isolation or qualitative or quantitative detection of HIV nucleic acid through polymerase chain reaction techniques, branch-chain DNA testing, or nucleic acid sequence–based amplification. Limitations of these assays include cost, the requirement for venipuncture and more laboratory technology, and the time interval between sample collection and test results. None of these tests is considered superior to routine serologic testing. However, viral detection is useful in specific situations such as diagnosis of neonatal HIV infection when maternal antibody is passively transferred to the fetus, potentially providing a false-positive serologic result in uninfected infants and in patients with indeterminate serologic results or in those who may be in the window period before HIV seroconversion.[14]

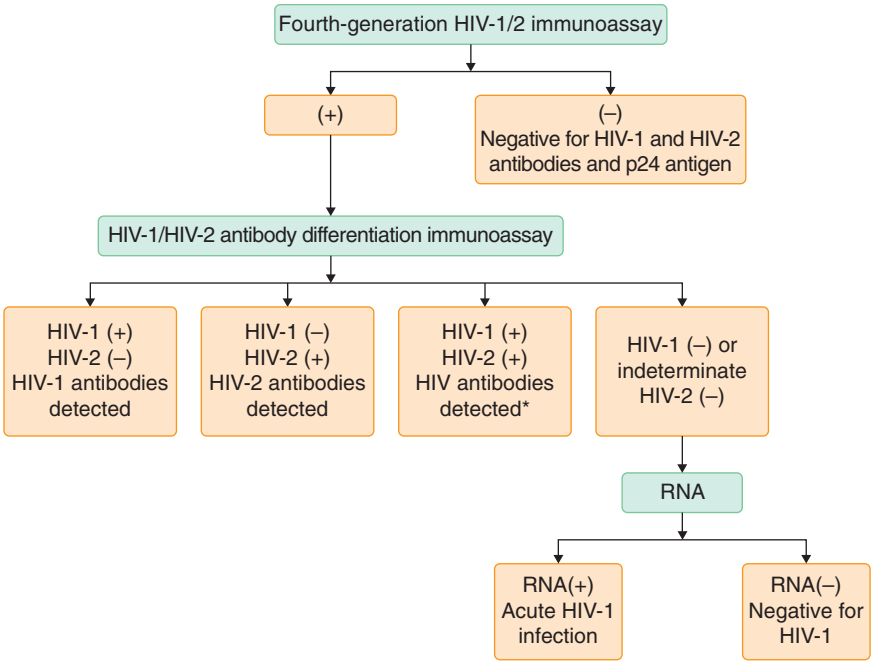

FIGURE 384-8. New HIV diagnostic testing algorithm evaluated in the United States, 2011-2013 HIV = human immunodeficiency virus. (From Centers for Disease Control and Prevention. Detection of acute HIV infection in two evaluations of a new HIV diagnostic testing algorithm—United States, 2011-2013. *MMWR.* 2013;62:489-494.
*Additional testing required to rule out dual infection with HIV-1 and HIV-2.

In 2013, the CDC evaluated and later offered an alternative-testing algorithm for the diagnosis of HIV infection[15] (Fig. 384-8). In this algorithm, all initial testing of serum is performed by an FDA-approved fourth-generation HIV-1/2 immunoassay. Specimens that are reactive on the fourth-generation assay should be re-tested/confirmed with an FDA-approved second-generation antibody assay that differentiates HIV-1 antibodies from other HIV antibodies, providing a definitive diagnosis of either HIV-1 or HIV-2. Seropositive individuals should initiate medical care that includes additional laboratory tests such as viral load, CD4 determination, and antiretroviral resistance assays to stage HIV disease and for the selection of initial antiretroviral drug regimens. Specimens that are reactive on the fourth-generation assay but negative on the HIV-1/HIV-2 antibody differentiation assay should be re-tested with an FDA-approved nucleic acid test for HIV-1 RNA. Under these circumstances a reactive nucleic acid test indicates the presence of acute HIV infection. A negative result would indicate the absence of HIV-1, and either a false-positive result on the initial fourth-generation assay or rarely recent HIV-2 infection. If HIV-2 infection is a possibility, a nucleic acid amplification test (NAAT) for HIV-2 DNA can be considered. However, HIV-2 infection is rare in the United States and there is no FDA NAAT for HIV-2. If a fourth-generation screening assay is not available, a third-generation HIV-1/2 immunoassay can be used as the initial test, followed by subsequent testing as specified in the algorithm. This alternative will miss some acute HIV infections in antibody-negative persons.

The previously described algorithm emphasizes high sensitivity during initial testing with the fourth-generation immunoassay, in which false-positive antibody-negative test results might occur, but these can be resolved during subsequent laboratory testing as recommended as part of initial clinical evaluation. The new diagnostic algorithm replaces the Western blot with an HIV-1/HIV-2 antibody differentiation assay as the supplemental test and includes an RNA test to resolve reactive immunoassays with negative supplemental test results. In retrospective studies, this algorithm performed better than Western blot at identifying HIV antibody-positive persons, detecting acute HIV infections, and diagnosing unsuspected HIV-2 infections.

REVIEW QUESTIONS

1. Which of the following statements is *incorrect:*

A. In 2013, 2.1 million people became newly infected, half of whom were young individuals between the age of 15 and 24 years.
B. By the end of 2013, 35 million people were living with HIV globally.
C. The epidemic has stabilized in many regions, with new infections decreasing by 50% or more in 25 countries.
D. HIV prevalence and incidence had declined sharply in 2013 in Eastern Europe and Central Asia.

Answer: D Prevalence and incidence have increased sharply over the past decade in Eastern Europe and Central Asia, partially driven by injection drug use and sexual transmission. In addition, treatment for those infected has also lagged behind in these regions.

2. Which of the following regions has yet to attain over 50% coverage of antiretroviral therapy for eligible individuals?

A. Latin America
B. The Caribbean
C. Oceania
D. Eastern Europe and Central Asia
E. Eastern and southern Africa

Answer: D Eastern Europe and Central Asia have reached coverage of only 25% of antiretroviral therapy for HIV-infected individuals eligible for treatment. The Middle East and North Africa have attained only a 15% coverage rate, whereas Latin America, the Caribbean, Oceania, and Eastern and southern Africa have all attained coverage rates over 56 to 69%.

3. Which of the following statements regarding the HIV epidemic in the United States is *false*?

A. The incidence of new HIV infections in 2012 has remained relatively stable over the past decade at approximately 50,000 new cases.
B. The incidence of HIV infection has declined in men who have sex with men (MSM), but has increased among injecting drug users.
C. HIV occurs at disproportionately higher rates among African Americans and Hispanics compared to white and other ethnicity groups.
D. Most women acquire HIV through unprotected heterosexual exposure.

Answer: B The frequency of new HIV infections among MSM continues to be relatively stable or in some areas slightly increased. There have been no observations within the last decade of any significant declines in HIV among this population. In contrast, HIV incidence has decreased among injection drug users.

4. The U.S. Preventive Services Task Force recently recommended that clinicians should screen for HIV in all adolescents and adults aged 15 to 65 years of age. This recommendation was based on which of the following facts?

A. There is increasing evidence of clinical benefit through early antiretroviral therapy for HIV-infected persons.
B. A recent randomized, clinical trial demonstrated that antiretroviral therapy is effective in reducing HIV transmission.
C. Approximately 20% of HIV-infected individuals have never been tested and are unaware of their infection.
D. Use of antiretroviral therapy during pregnancy has been shown to be effective in decreasing mother-to-child transmission of HIV.
E. All of the above.

Answer: E All of the above supporting statements for early diagnosis and treatment providing benefit to HIV infected persons provided the evidence for the USPSTF recommendations for routine screening for HIV.

IMMUNOPATHOGENESIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

JOEL N. BLANKSON AND ROBERT F. SILICIANO

Human immunodeficiency virus type 1 (HIV-1) infection results in a progressive state of immune system dysregulation that ultimately leads to the acquired immunodeficiency syndrome (AIDS), which is characterized by profound depletion of CD4+ T lymphocytes and the inability to control infections by opportunistic pathogens that do not cause disease in individuals with a normal immune system. Despite decades of research on this condition, the basic pathogenic mechanisms are still incompletely understood. This chapter reviews current understanding of the mechanisms involved in HIV-1 immunopathogenesis.

PRIMARY INFECTION

The natural history of HIV-1 infection is illustrated in Figure 385-1. During acute HIV-1 infection, massive viral replication occurs in CD4+ T lymphocytes in the absence of an adaptive immune response. CD4+ T cells in the gut-associated lymphoid tissue and other mucosal sites express high levels of the HIV coreceptor CCR5 and are thus particularly prone to infection and depletion by the commonly transmitted R5 variants of HIV-1. In animal models, it has been shown that approximately 30% of memory CD4+ T cells are infected and depleted by 4 days after infection. This is in contrast to chronic infection, in which less than 1% of all CD4+ T cells are productively

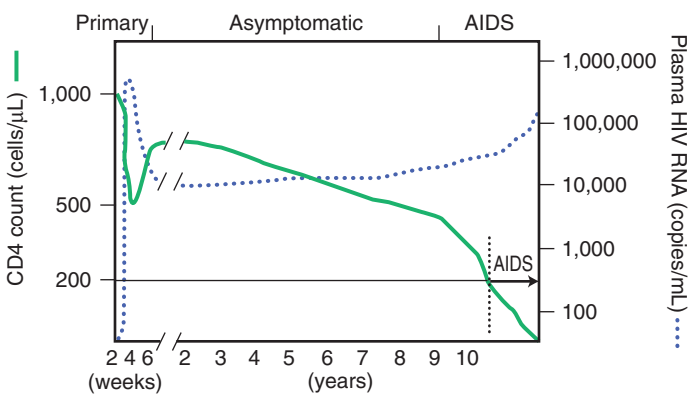

FIGURE 385-1. Natural history of HIV-1 infection. CD4 counts and viral load are shown in the three phases of infection. AIDS = acquired immunodeficiency syndrome.

infected at any given time. As a result of this massive early infection, plasma levels of virion-associated HIV-1 RNA of more than 1 million copies per milliliter are typically seen in plasma within 2 weeks of infection and patients tend to experience a constellation of signs and symptoms known as the *acute retroviral syndrome.* There can be significant declines in peripheral CD4+ T-cell counts in primary infection resulting in opportunistic infections. Within several weeks, the development of an effective HIV-1–specific cytolytic T-lymphocyte response results in the partial control of viral replication, and the plasma HIV-1 RNA level (commonly known as the viral load) falls and reaches a steady-state level known as the *set point.* The magnitude of the set point viral load during the second asymptomatic phase of the infection reflects a dynamic equilibrium between viral replication and the HIV-1–specific immune response. This set point determines the rate of progression to the final phase, clinical AIDS. The median set point is approximately 30,000 HIV-1 RNA copies per milliliter, and most patients who have this level of viremia will develop AIDS in a 5- to 10-year period if they are left untreated. Patients with much higher set point viral loads will tend to be rapid progressors who develop AIDS much more quickly; patients with much lower viral loads tend to be long-term nonprogressors.

SPECIFIC IMMUNITY FOR HUMAN IMMUNODEFICIENCY VIRUS

The host mounts a vigorous immune response to HIV-1 infection. The virus is thought to activate plasmacytoid dendritic cells through toll-like receptors, resulting in the secretion of type I interferons and other inflammatory cytokines. Whereas type I interferons have direct antiviral properties and enhance the HIV-1–specific immune response, excessive secretion may play a key role in pathogenic immune activation of CD4+ and CD8+ T cells (Fig. 385-2). Natural killer (NK) cells are important effector cells in the innate immune response that become activated when infection of target cells by HIV-1 or other viruses results in the downregulation of HLA molecules. Patients expressing certain NK receptor alleles are more likely to become long-term nonprogressors, suggesting that these cells may play a protective role possibly by controlling early HIV-1 replication, leading to the development of an effective adaptive immune response. Myeloid dendritic cells play a key role in the presentation of HIV-1 antigens to HIV-1–specific CD4+ and CD8+ T cells, which results in initiation of the adaptive immune response. They express CD4 molecules and have been shown to bind HIV-1. It is thought that in the process of presenting antigen, these cells may inadvertently transmit HIV-1 to clusters of activated CD4+ T cells.

The role of the humoral response in HIV-1 infection is not clear. HIV-1–specific antibodies, which are used to diagnose HIV-1 infection, do not develop until after peak viremia occurs. There is thus a window period in primary HIV-1 infection during which viremia is present in the absence of detectable antibodies. A subset of the antibodies that eventually appear are capable of preventing infection by blocking the interaction of the HIV-1 envelope protein gp120 with CD4 and coreceptor proteins on the surface of target cells. These so-called neutralizing antibodies are present at relatively low titers and have limited access to the critical regions of gp120. Recent studies suggest that the most effective neutralizing antibodies do not develop until 2 to 3 years after infection.[1] These broadly neutralizing antibodies may eventually form the basis of a vaccine by preventing new infections. However, although neutralizing antibodies in general can exert significant selective pressure on the virus, immunologic escape through rapid viral evolution is common, and the bulk of evidence suggests that these antibodies do not play a major role in the control of viral replication in most long-term nonprogressors.

The selective depletion of CD4+ T cells is the main reason that HIV-1 infection results in such profound immunosuppression; these so-called helper T cells play a major role in every facet of the adaptive immune response. The ability of HIV-1–specific CD4+ T cells to proliferate and to secrete key cytokines such as interleukin-2 (IL-2) is lost shortly after primary infection, setting up the entire HIV-1–specific response for failure.

CD8+ T cells contribute to the control of HIV-1 infection by the direct lysis of infected cells and by the secretion of soluble factors such as macrophage inflammatory protein 1β that bind to chemokine receptors, thereby preventing HIV-1 entry into target cells.[2] However, the HIV-1–specific CD8+ T-cell response that partially controls HIV-1 replication after peak viremia in primary infection does not achieve sterilizing immunity, partly because of a reservoir of latent virus in resting memory CD4+ T cells that develops shortly after infection. These quiescent cells probably do not make HIV-1 proteins and thus are not recognized by cytolytic T lymphocytes. Furthermore, the cytolytic T-lymphocyte response in patients with progressive disease is of poor quality with limited proliferative capacity. Most importantly, the low fidelity of HIV-1 reverse transcriptase results in the development of mutations with each round of replication. Mutations that lead to escape from cytolytic T-lymphocyte responses have a selective advantage and are thus selected for rapidly.

THE EFFECT OF HUMAN IMMUNODEFICIENCY VIRUS-1 REPLICATION ON THE IMMUNE SYSTEM

Whereas the HIV-1–specific immune response helps limit the rate of viral replication, sterilizing immunity is never achieved and ongoing viral replication has a negative impact on the immune system. Continuous viral replication results in chronic immune activation (see Fig. 385-2).[3] The mechanism is not understood. The chronic immune response to the virus may lead to nonspecific inflammation, and microbial translocation resulting from the depletion of CD4+ T cells in the gut-associated lymphoid tissue also may be important. Whatever the mechanism, immune activation appears to drive the depletion of CD4+ T cells. The level of immune activation markers on CD8+ T cells correlates better with the rate of CD4 decline than does the magnitude of the viral load in untreated patients.

Increased levels of activation markers are seen on NK cells, B cells, CD4+ T cells, and CD8+ T cells. Activation is accompanied by an increase in the turnover rate of these cells. The function of NK cells is compromised, which may predispose to the poor control of other viruses. B-cell defects result in hypergammaglobulinemia and the production of autoantibodies. Poor antibody responses to vaccines are also seen as CD4+ T cells decline.

Studies of viral dynamics make it clear that most productively infected cells live only a short time (~1 day) before succumbing to viral cytopathic effects or host cytolytic T lymphocytes or NK cells. Although the loss of infected CD4+ T cells contributes to CD4 depletion, there is marked depletion of $CD4^+$ T cells even though at any given time during chronic infection only 1% or less of these cells is productively infected. However, recent studies have suggested that non-productively infected CD4+ T cells are also susceptible to cell death by a pro-apoptotic and proinflammatory host response. Thus, it is currently thought that death of non-productively infected CD4+ T cells and chronic immune activation leading to the death of noninfected CD4+ T cells are the principle mechanisms for CD4 depletion.[4,5] Support for this idea comes from studies of the closely related simian immunodeficiency virus that replicates in natural simian hosts without causing immune activation or CD4 depletion. In addition to the quantitative loss of CD4+ T cells in HIV-1 infection, marked skewing of the CD4 T-cell repertoire is seen, and there is a diminished qualitative memory response to recall antigens long before the CD4+ T-cell count drops to 200 cells/μL. The chronic activation and high turnover rate of these cells eventually result in the progressive CD4 decline that is characteristic of HIV-1 infection.

There is evidence of immune exhaustion for both CD4+ and CD8+ T cells, and there is decline in the qualitative features of the CD8+ T-cell response to other chronic viruses such as cytomegalovirus and Epstein-Barr virus. This may be the result of anergy or depletion of the CD4+ T cells that are needed to sustain functional CD8+ T-cell responses.

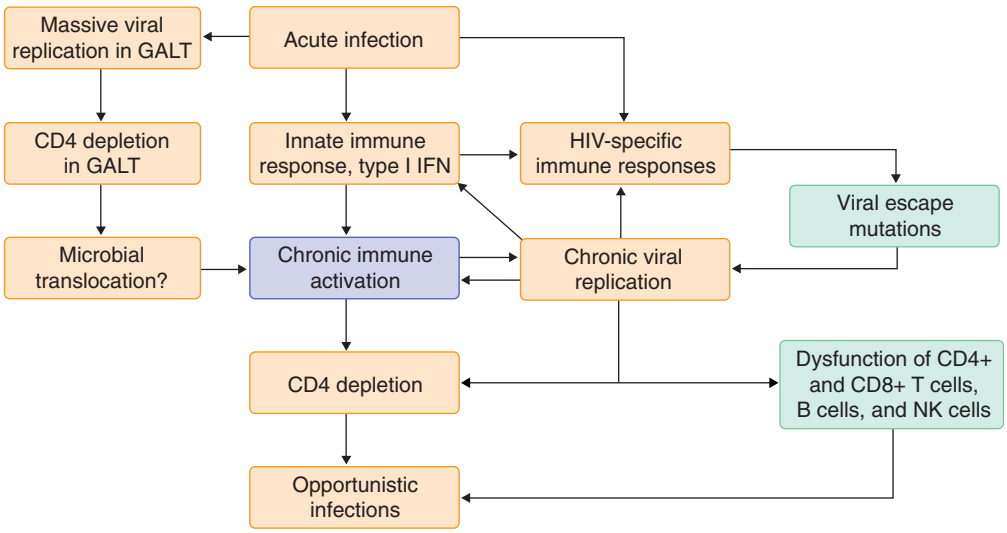

FIGURE 385-2. Parameters involved in chronic immune activation and CD4+ T-cell depletion. GALT = gut-associated lymphoid tissue; IFN = interferon; NK = natural killer.

CLINICAL CONSEQUENCES OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Clinical immunodeficiency is associated with the late stages of HIV-1 infection, when profound CD4+ T-cell depletion has occurred. However, some level of immunodeficiency may be present shortly after infection because of qualitative changes in the immune response related to ongoing viral replication. As a result, patients are more susceptible to infections such as *Mycobacterium tuberculosis* infection before the CD4 count reaches the 200 cells/μL threshold that defines AIDS. Patients are also much more susceptible to malignant neoplasms such as non-Hodgkin's lymphoma at any CD4+ T-cell count. Other opportunistic infections arise at fairly predictable CD4+ T-cell counts. *Pneumocystis jiroveci* infections occur at CD4 counts of lower than 200 cells/μL, *Cryptococcus neoformans* and *Toxoplasma gondii* infections occur at CD4 counts of lower than 100 cells/μL, and *Mycobacterium avium* complex and cytomegalovirus infections occur at CD4 counts below 50 cells/μL. Whereas these infections are a consequence of diminished cellular immunity, there is also a marked increase in invasive pneumococcal infections in HIV-1–infected patients, possibly because of defects in humoral immunity.

The Response to Antiretroviral Therapy

Treatment with selected combinations of antiretroviral drugs, which is known as highly active antiretroviral therapy (HAART), suppresses viral replication to below the limits of detection of current commercial assays (50 copies of HIV-1 RNA per milliliter of plasma). Current evidence suggests that HAART produces a complete or nearly complete arrest in viral replication in adherent patients, but trace amounts of viremia persist because of stable viral reservoirs, including the latent reservoir in resting CD4+ T cells. This suppression of viral replication is usually accompanied by a substantial increase in CD4+ T-cell counts. The initial rise in CD4+ T-cell counts occurs mostly as a consequence of migration of cells from lymph nodes (where 98% of all CD4 T cells reside) to the peripheral blood as inflammation diminishes in lymphoid tissue. Subsequently, there is an increase in the production of memory CD4+ T cells in most individuals. Naïve T-cell production is also sometimes seen at lower levels. Clinical studies have shown that patients who experience significant immune reconstitution[6] can safely discontinue prophylactic therapy for opportunistic infections. However, it is not clear whether patients who maintain undetectable viral loads while receiving HAART yet do not achieve significant CD4 T-cell immune reconstitution are still at risk for opportunistic infections. Two large studies have shown that although the use of IL-2 treatment in conjunction with HAART will cause a significant increase in CD4+ T-cell counts in these patients, the enhanced immune reconstitution is not associated with any clinical benefit.

Just as a decline is seen in the functional CD4+ T-cell response shortly after primary infection, there is a qualitative improvement in $CD4^+$ T-cell function shortly after HAART is initiated. In some cases, there are exaggerated immune responses to opportunistic infections leading to the immune reconstitution inflammatory syndrome (IRIS; Chapter 395), particularly when there is rapid control of viral replication after the initiation of HAART. IRIS usually presents as a paradoxical worsening of a disease process a few weeks after HAART is started and can occur even before there are significant changes in the absolute CD4+ T-cell counts. IRIS has been reported for virtually all known opportunistic infections, and in some cases it can occur in response to previously unrecognized infections. There have not been clinical trials looking at treatment of this condition, but nonsteroidal anti-inflammatory drugs and corticosteroids have been routinely used with varying degrees of success (Chapter 395).

REVIEW QUESTIONS

1. What is the most likely cause of CD4 depletion in HIV-infected patients?

A. Chronic immune activation
B. Direct killing of productively infected cells
C. Infection by opportunistic pathogens
D. Metabolic disturbances

Answer: A Chronic immune activation is thought to play the most significant role, although a recent study suggests that non-productively infected cells may die from a protective host response. Only 1% of cells are productively infected, and therefore it is felt that the death of these cells cannot explain the level of CD4 depletion seen.

2. At what CD4 count do patients become susceptible to *Pneumocystis jiroveci*?

A. 50 cells/μL
B. 100 cells/μL
C. 200 cells/μL
D. 500 cells/μL

Answer: C Clinical studies have shown that patients become susceptible to *Pneumocystis jiroveci* at a CD4 count of less than 200 cell//μL. *Cryptococcus neoformans* and *Toxoplasma gondii* infections occur at CD4 counts < 100 cells/μL; and *Mycobacterium avium* complex and CMV infections occur at CD4 counts < 50 cells/μL.

3. HIV-1–infected patients are highly susceptible to invasive pneumococcal disease because of:

A. Immune activation.
B. Dysfunction of B cells.
C. Apoptosis of CD8+ T cells.
D. Increased exposure to pneumococcus.
E. Hyposplenism.

Answer: B Although HIV-1 infection typically causes a defect of cellular immunity, humoral immunity is also affected because of a B-cell dysfunction and patients become susceptible to bacterial infections.

4. At what point after HIV infection do patients develop the acute retroviral syndrome?

A. 2 weeks
B. 6 weeks
C. 3 days
D. 3 months

Answer: A Patients typically develop the constellation of symptoms known as the acute retroviral syndrome 2 weeks after infection. At that point, as a result of the massive early infection, plasma levels of virion-associated HIV-1 RNA of more than 1 million copies/mL are typically seen in plasma.

5. What is the mechanism of the drop in HIV-1 RNA to the set point level in primary infection?

A. The development of an HIV-1–specific CD4+ T-cell immune response
B. The establishment of the latent reservoir
C. The development of neutralizing antibodies
D. The development of a an HIV-1–specific CD8+ T-cell immune response

Answer: D The development of the HIV-specific CD8+ T-cell response has been associated with partial control of viral replication in clinical studies and depletion of CD8+ T cells in an animal model abrogates this control of viremia.

6. Which of the following is the biggest barrier to the eradication of HIV-1?

A. The establishment of the latent reservoir
B. Chronic immune activation
C. B-cell dysfunction
D. Microbial translocation

Answer: A The quiescent memory CD4+ T cells of the latent reservoir probably do not express HIV antigens and thus are not targeted by the immune response. They are also not effectively targeted by antiretroviral therapy, thus preventing the eradication of HIV-1.

BIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUSES

FRANK MALDARELLI

Human immunodeficiency virus (HIV) causes progressive immune deficiency and death from opportunistic infections or neoplastic diseases. Over 34 million individuals worldwide are currently infected with HIV, and over 30 million have died since the disease was first recognized in 1981. Developments in diagnosis, prevention, and treatment have reduced morbidity and mortality from HIV, but the epidemic remains substantial; in 2012, 2.3 million new HIV infections occurred and 1.6 million people died from HIV and acquired immunodeficiency syndrome (AIDS).[1] Improvements in HIV care grew from an understanding of the discovery, characterization, and elucidation of replication of HIV. Continued research led to discoveries of cellular processes, mechanisms of pathogenesis, and new concepts of host antiviral immunity. Here we summarize basic concepts of HIV biology. Our understanding of HIV remains incomplete, and efforts are ongoing to improve testing, characterize viral replication and pathogenesis, identify novel antiviral targets, and develop innovative strategies to eradicate HIV infection.

CLASSIFICATION AND ORIGIN

HIV belongs to the lentivirus genus of the Orthoretrovirinae subfamily of Retroviridae; all retroviruses are defined by the presence of a specific enzyme, reverse transcriptase, that catalyzes the synthesis of DNA from an RNA

template, the central and unique event in retrovirus replication permitting integration of the viral DNA into the host genome. Retroviridae is a large family of viruses infecting diverse vertebrate hosts, mostly mammals and birds, and to a lesser degree, reptiles and fish. Retroviruses are responsible for a spectrum of diseases, including immunodeficiencies and neoplastic, neurologic, hematologic, encephalitic, and inflammatory disorders. Members of the lentivirus genus cause chronic, recurrent, or progressive diseases, including immunodeficiencies in various mammal species.

The origin of HIV variants currently circulating in humans has been traced by analyzing nucleic acid sequences of HIV and closely related viruses in primates; these analyses strongly indicate HIV emerged from zoonotic transmissions from primates to humans during the period 1890 to 1930 in Central and West Africa.[2] Zoonotic transmission requires close contact of blood and body fluid; scratches, bites, and butchery of captured infected animals provide ready mechanisms for transmission. Such opportunities for zoonotic transmission have likely taken place for thousands of years, and the reasons why an epidemic spread did not occur until recently are unclear. A number of factors may have contributed to epidemic spread during the late 19th and 20th centuries, including profound increases in human population density, habitat destruction forcing more contact between humans and other primates, malnutrition contributing to underlying immunodeficiency, population shifts due to political upheaval, and the development of infrastructure, such as roads, facilitating human travel over long distances.

The viral etiology of AIDS was first identified after intensive investigation of patients identified with AIDS. Cell cultures inoculated with plasma or co-cultured with lymphocytes from individuals with AIDS resulted in marked cytopathic effect; cell-free material transmitted the infection to fresh uninfected cultures and reproduced cytopathology; cultures contained both reverse transcriptase enzymatic activity and virions with morphology characteristic of lentiviruses. The virus was initially named HTLV-III because of its apparent relationship to the other human retroviruses HTLV-I and II; subsequent study demonstrated the virus responsible for AIDS was only distantly related to HTLV, and the new virus was renamed HIV. Molecular clones were constructed that reproduced cellular cytopathology. Plasma from infected individuals contained substantial antibodies to the virus, permitting development of robust new enzyme-linked immunosorbent assay (ELISA) and Western blot detection assays useful for patient diagnosis, epidemiologic surveillance, and blood product protection.

Following the development of the first tools for laboratory diagnosis of HIV infection, additional analysis identified individuals with symptomatic AIDS but who did not have serologic responses characteristic of HIV, leading to the identification of a second distinct immunodeficiency virus, denoted HIV-2. HIV-2 had a distribution restricted largely to West Africa and to countries having close economic, political, or cultural ties to West Africa.

Further genetic analysis and sampling of nonhuman primate species shed new light on sources of the HIV epidemic. HIV-1 can be classified using nucleic acid sequence analysis into four distinct groups: a large group of viruses found throughout the world (M, for "main"), a relatively small group of viruses in central Africa (O, for "other"), and two small groups in individuals with West African origin, comprising only fewer than 20 total infections, denoted N (not M, not O) and P. Phylogenetic reconstructions demonstrate distinct lineages for HIV-1 groups, indicating each is the result of a distinct zoonotic event (Fig. 386-1), which in the case of HIV-1 M, has spread worldwide. M viruses are closely related to a similar virus, simian immunodeficiency virus, present in chimpanzee species (denoted SIV_{cpz}, simian immunodeficiency virus, cpz to indicate the specific animal reservoir). Group O is most closely related to the SIV present in gorillas and in chimpanzees. In contrast, HIV-2 is highly related to SIV_{smm}, a lentivirus commonly present in the sooty mangabey, which has a geographic range including West and Central Africa, where HIV-2 was identified.

Group M viruses represent the great majority of infections in humans and are quite diverse, with at least nine subtypes, denoted A to D, F to H, J, and K. Analysis of the relationships of the nucleic acid sequences reveals an overall "starlike" phylogeny (see Fig. 386-1), indicating that, in general, all the current variants emerged from a common ancestor. Studies of the earliest viral sequences identified revealed it is likely that HIV underwent diversification early after transmission from animal reservoirs. Recombination among these subtypes may occur (see Fig. 386-1, *A/D*; and see later), yielding new recombinant viruses that are classified as circulating recombinant forms. Dual HIV-1/HIV-2 infections are also possible in geographic regions where viruses co-circulate, typically from West Africa.

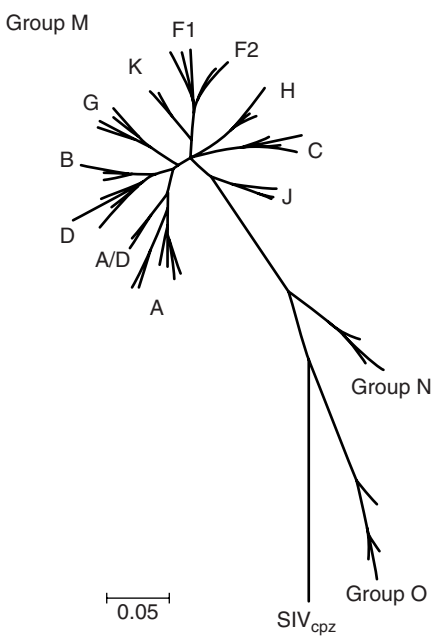

FIGURE 386-1. Phylogenetic relationships of HIV-1 groups and subtypes. Reference sequences of HIV RT were aligned in maximum likelihood phylogenetic trees constructed and rooted on the distant ancestor, SIV chimpanzee sequence (SIV_{cpz}). Group M viruses radiate in a starlike fashion, consistent with a common ancestor. An example of recombinant sequences (A/D) containing portions of parental subtypes A and D are identified as intermediate between the parental subtypes. Group O and N are distantly related to group M and likely represent independent zoonotic events. Marker = genetic distance depicting percent difference. HIV Sequence Database, http://www.hiv.lanl.gov/.

Once AIDS emerged, HIV spread rapidly throughout the world; while Africa maintained a highly diverse group of viruses, founder effects resulted in spread of one or a limited number of subtype viruses in countries outside Africa. The epidemic in the United States began with subtype B virus; although initially attributed to single case reports of individuals, careful and exhaustive analyses traced the HIV epidemic from Africa to the United States through Haiti. Importantly, current laboratory methods to detect HIV identify *all* HIV-1 and HIV-2 variants. In individuals from relevant geographic origin, especially West Africa, it is of paramount importance to characterize the infection precisely to target therapy appropriately; HIV-2 and group O HIV-1 are naturally resistant to non-nucleoside reverse transcriptase inhibitors and to fusion inhibitors.[3] As dual HIV-1/HIV-2 infections are possible, it is imperative that all individuals from endemic areas for these two viruses (especially West Africa) be tested for *both* HIV-1 and HIV-2.

STRUCTURE AND MOLECULAR BIOLOGY

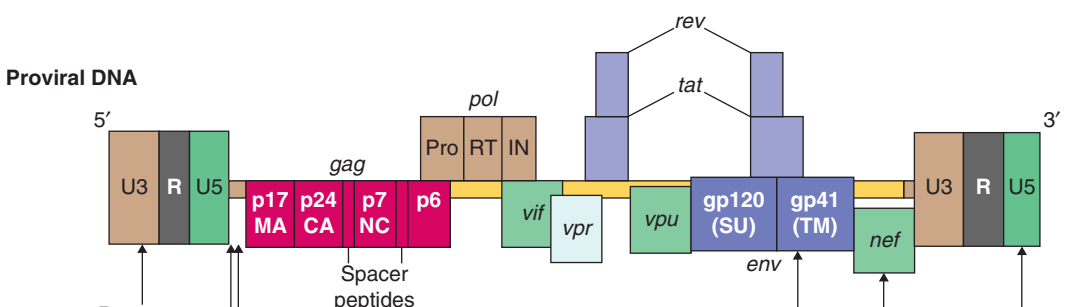
Genome Structure and Organization

Like all retroviruses, HIV replicates via a DNA intermediate. The virion contains two copies of single-stranded (+) sense RNA (denoted viral RNA), and the stably infected cell contains double-stranded viral DNA integrated into the host genome (denoted the provirus). As shown in Figure 386-4 and E-Figure 386-1, viral RNA and the provirus have distinct genomic organization in untranslated 3′ and 5′ regions. Untranslated regions at each end of the genome contain a short terminal repeat, as well as unique sequences at the 5′ (U5) and 3′ (U3) regions that are duplicated during replication, generating a longer duplicated sequence termed the *long terminal repeat* at each end of the provirus.

HIV encodes nine genes whose products are required for structural, enzymatic, regulatory, and innate immune neutralization functions (see E-Fig. 386-1). By convention, HIV genes are denoted in lower italics (*gag, pol,* etc.) with names that broadly reflect their function, location in the virion, or a historical vestige of prior viral classification (e.g., *gag,* "group antigen"). Additional genes were characterized that function in regulation or replication (*tat, rev, vpr*) or in blocking immune responses to HIV (*vif, vpu, nef*); all are critical for HIV infection in vivo.

Virion Structure

The HIV virion contains viral gene products and cellular components essential to transmit infection and establish the proviral state. HIV virions are



HIV gene	Function	Host binding partner	FDA approved inhibitor
***gag* ("group antigen")**			
p17 matrix MA	**Binds cellular membranes**	**Host membrane**	
p24 capsid CA	**Virion structure**	**TRIM5-alpha**	
pol ("polymerase")			
Protease	Processes gag/pol polyprotein		Yes
RT	Reverse transcription of viral RNA		Yes
RT-RNase H	Degrades RNA from RNA:DNA hybrid		
Integrase	Integrates linear HIV DNA into host genome		Yes
vpr ("viral protein R")	Uncertain		
vif ("viral infectivity factor")	Innate immune evasion	APOBEC family of proteins	
tat ("trans-activator of transcription")	Transcriptional regulation	Transcription factors	
rev ("regulator of expression of viral proteins")	Post-transcriptional RNA processing	CRM-1	
vpu ("viral protein U")	Adaptive immune evasion, facilitate Env trafficking	CD4	
	Innate and adaptive immune evasion	Tetherin	
***env* ("envelope")**			
gp120	**HIV attachment**	**CD4, coreceptor**	**Yes**
gp41	**HIV fusion**		**Yes**
nef ("negative regulatory factor")	Adaptive immune evasion	MHC1	
	Adaptive immune evasion	CD4	

E-FIGURE 386-1. HIV Genome organization and function. Proviral DNA with complete long terminal repeat (LTR) is depicted. HIV genes are lowercase *italics*. Gene products are capitalized Roman. Genes (not drawn to scale) are color coded, and the function of the corresponding gene product is summarized. Host components interacting with each gene product are noted, and gene products for which there are U.S. Food and Drug Administration–approved therapeutic drugs are indicated.

roughly spherical particles with a diameter of 80 to 120 nm and are composed of a viral core enveloped by a lipid membrane (Fig. 386-2).

The core of the mature virion is a conelike structure,[4] composed of the HIV p24 capsid (CA), which encapsidates components necessary for replication: two copies of HIV genomic RNA template complexed with HIV p6 nucleocapsid (NC); $tRNA^{lys}$ primer; HIV enzymes reverse transcriptase, protease, and integrase; and HIV Vif. The viral envelope, which is derived from the plasma membrane of the host cell as HIV undergoes budding, contains viral proteins Gp120 (SU) and Gp41 (TM), as well as a structural matrix protein, MA.

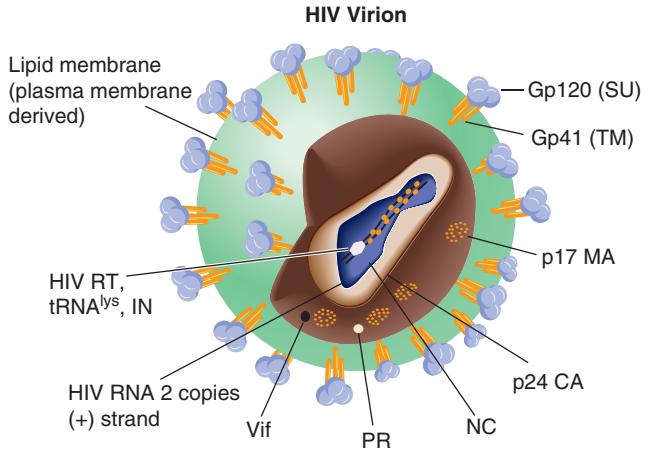


FIGURE 386-2. The HIV virion. HIV is an enveloped virus consisting of two (+) sense copies of viral RNA, enzymes required for replication contained in a viral core enveloped in a membrane derived by budding from the infected cell.

Replication Cycle

Early Events in Replication

Attachment and Fusion

Virus replication is initiated by direct contact of virions or infected cells with susceptible host cells (Fig. 386-3). Productive infection requires specific and essential interactions mediated by surface Env glycoprotein trimeric complexes consisting of HIV sp120 SU noncovalently bound to HIV gp41 TM.[5] The attachment phase is mediated exclusively by SU, which engages two distinct cell surface proteins for attachment, a receptor and a coreceptor (see Fig. 386-3). HIV initially binds CD4, resulting in conformational change in Env, which facilitates coreceptor binding. Typically, SU proteins use either the human chemokine receptor 5 (CCR5) or the human chemokine receptor 4 (CXCR4), to infect CD4+ T cells, but CCR5/CXCR4 dual tropic viruses circulate as well. Although virus infection can be propagated with either CCR5 or CXXCR4 as coreceptor, initial infection likely requires CCR5 tropic virus. Human populations have a significant population of individuals encoding a mutant CCR5 gene, who do not synthesize functional CCR5. HIV infection of individuals homozygous for CCR5 mutation is exceedingly rare, suggesting that initiation of infection virtually always requires interactions with CCR5. Inhibition of SU-coreceptor interactions has been achieved pharmacologically, and the U.S. Food and Drug Administration–approved coreceptor inhibitor maraviroc has potent anti-HIV activity.[6]

Engaging both receptor and coreceptor results in conformational change in Gp41, which reorganizes its structure and provides sufficient energy to drive membrane fusion. TM-mediated membrane fusion can be inhibited using specific peptide inhibitors that bind to Gp41; one such peptide fusion inhibitor, enfuvirtide, is in clinical practice.

Uncoating

Following entry into CD4 cells, HIV cores undergo uncoating (see Fig. 386-3) to release virion nucleic acid into the cytoplasm. Uncoating represents a critical checkpoint for innate antiviral activity that can strongly

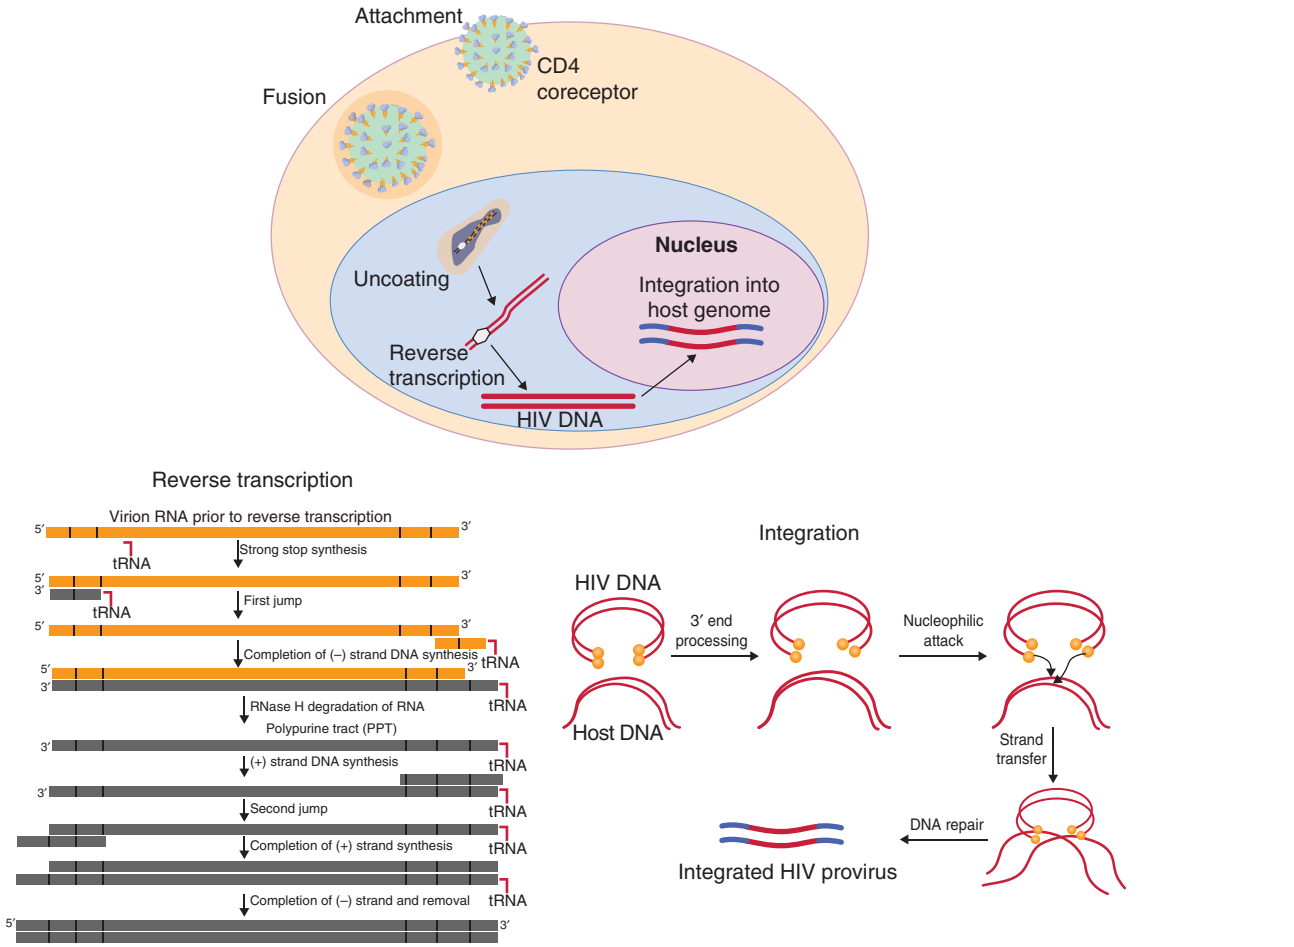

FIGURE 386-3. Early events in HIV replication include attachment, fusion, uncoating, reverse transcription, and integration into the host genome. Details of HIV reverse transcription and integration are depicted.

restrict infectivity.[7,8] An interferon-inducible host protein, TRIM5-alpha, can block uncoating of a number of viruses through interactions with the viral core; unfortunately, TRIM5-alpha cannot restrict either HIV-1 or HIV-2. TRIM5-alpha is under substantial genetic selection, with one of the fastest rates of positive selection of any human gene. Studies suggest that the current version of TRIM5-alpha present in human populations may have been selected during a previous epidemic to protect against an ancient retroviral infection. In this model, simply summarized as "generals are always fighting the last war, especially if they have won it," the current TRIM5-alpha was selected in the past to prevent a retroviral infection. Unfortunately, the current TRIM5-alpha is unable to restrict HIV and uncoating takes place unabated in human cells.

Reverse Transcription: Viral Genome Replication

Following uncoating, HIV has fresh access to nucleoside triphosphates, permitting reverse transcription to take place in the cytoplasm (see Fig. 386-3).[9] The (+)-strand template strands of HIV RNA are complexed with reverse transcriptase and a specific $tRNA^{lys}$ that functions as a primer located at a specific primer binding site (see E-Fig. 386-1) near the 5′ end of the template RNA and HIV RNA. Reverse transcription is a multistep process (see Fig. 386-3) that first synthesizes a DNA copy of the RNA genome and then excises the RNA from the RNA-DNA hybrid using an RNase H function of reverse transcriptase; RNA removal is incomplete, and residual RNA in a region denoted the polypurine tract (see Fig. 386-3) then serves to prime the next round of DNA synthesis. During reverse transcription a number of strand transfer events occur, permitting opportunities for frequent recombination. Reverse transcriptase is highly error prone, with only a rudimentary editing function. As a result, complete reverse transcription yields at least one mutation per virion synthesized per replication cycle. The replication cycle for HIV, estimated as 1 to 2 days, is relatively short, and the replicating population size is substantial. The combination of rapid and error-prone synthesis in a large replicating population results in a genetically diverse population that can respond rapidly to immune- or drug-selective pressure. Thus, rapid error-prone replication, combined with recombination, represents an important pathogenic determinant for HIV.

Reverse transcription was the first target for antiretroviral therapy, and a number of direct and allosteric inhibitors of reverse transcription have been developed. All reverse transcription inhibitors inhibit RNA-dependent DNA synthesis or DNA-dependent DNA synthesis. Nucleoside and nucleotide reverse transcriptase inhibitors are dideoxy analogues of deoxynucleotides that are incorporated as the template is copied and act as chain terminators, blocking additional nucleic acid synthesis. Non-nucleoside inhibitors of reverse transcription bind to reverse transcriptase in a hydrophobic domain proximal to the active site, deforming the enzyme structure and disrupting nucleic acid synthesis.

Nuclear Transport and Integration

Newly synthesized HIV DNA transports to the nucleus for integration into the host genome. A complex of the HIV protein integrase, newly synthesized HIV DNA, and associated proteins has been labeled an *intasome*. Structural studies have revealed a tetramer of integrase molecules bound to the ends of the retroviral DNA, bringing the DNA ends in close proximity, poised for integration into the genome in a multistep process (see Fig. 386-3). Integration is a highly successful target for antiretroviral therapy and inhibitors that block the transfer of HIV DNA strand into the host genome are now in clinical practice.

Early Evasion of Intracellular Immunity: Vif and Vpu

HIV infection triggers a complex set of immune responses, and several viral factors function to counteract innate and adaptive immunity. As described earlier, HIV is able to infect human cells because an otherwise effective restriction mechanism blocking uncoating by TRIM5-alpha is unable to detect the incoming virus. Infection results in activation of two additional interferon-induced genes, the ABOBEC family of nucleic acid editing enzymes and BST-2 (tetherin). HIV in turn encodes specific functions to counteract such antiviral mechanisms.

The interferon-induced APOBEC family (apolipoprotein B mRNA editing enzyme, catalytic polypeptide-like) of proteins are nucleic acid editing enzymes capable of catalyzing the removal of amino groups from the cytosine portion of cytidine; on copying, these deaminated cytidines base pair with adenosine, not guanine, and the net result is the introduction of multiple G-to-A mutations, resulting in hypermutation and complete viral inactivation. APOBEC can, in the absence of viral factors, be incorporated into new virions. As a result, during the next round of infection, after HIV enters a new host cell, APOBEC proceeds to hypermutate the newly reverse transcribed HIV genome. To block APOBEC-mediated inactivation of HIV, a viral gene product, Vif (see E-Fig. 386-1), directly binds to APOBEC proteins, redirecting it to degradation by ubiquitination pathways. Redirecting APOBEC for elimination rather than virion incorporation effectively neutralizes a potent innate immune response.

A second product of interferon induction is the bone marrow stromal antigen 2 (BST-2), CD317, or tetherin. BST-2 is tethered to the plasma membrane at both its amino and carboxy terminus and is enriched at virion budding. Tetherin can block the budding process directly; newly budding virions may contain one end of the tetherin molecule in the virion membrane, while the other end of tetherin remains on the cellular membrane, thereby effectively blocking virion release. To counter this host mechanism, the HIV-encoded protein Vpu effectively blocks tetherin by a number of mechanisms, including direct binding and redirecting the protein to intracellular degradation.

Late Steps in Replication

Transcription and Translation: Exploiting Cellular Processes to Balance Production of Viral Gene Products

Once the proviral state is established, HIV produces viral RNA and proteins using viral factors in concert with cellular mechanisms of transcription and translation. Thus, HIV replicates not by dismantling cell functions but rather by employing specific interactions between host factors, which ensures a balanced abundance of viral gene products.

Transcription

The integrated provirus is expressed in the context of host chromatin. The U3 portion of the HIV long terminal repeat contains binding sites for transcription factors common in lymphocytes and macrophage-monocyte lineages, including activator protein 1 (AP-1), specificity protein 1 (SP-1), nuclear factor kappa B (NF-κB), and nuclear factor of activated T cells (NFAT) binding sites. The presence of the viral transcription factor transactivator of transcription (Tat)[10,11] markedly stimulates transcription through binding to a specific RNA enhancer, denoted the transactivating region (TAR), and recruiting additional transcription factors (Fig. 386-4).

Post-transcriptional Processing

Retroviruses transcribe all of their genes from a single promoter. Full-length HIV RNA is processed for expression of all nine gene products and encapsidated as the viral genome into virions. To provide sufficient mRNA species to express all HIV proteins, RNA processing is highly regulated by alternative splicing and differential RNA transport (see Fig. 386-4).

Full-length RNA consists of a primary capped mRNA of approximately 9.2 kb that undergoes alternative splicing to produce three broad classes of RNA species: 9.2-kb unspliced RNA, responsible for translation of *gag/pol;* a number of distinct 4.5-kb singly spliced RNA species, responsible for translation of *vif, vpr,* and v*pu/env;* and 1.8-kb multiply spliced species, responsible for *tat, rev,* and *nef.* Multiply spliced 1.8-kb RNAs are constitutively expressed, but unspliced and singly spliced HIV mRNAs require specific transport out of the nucleus. The mechanism of retention in the nucleus is unclear, but the presence of cis regulatory sequences present in *gag/pol* and *env* result in nuclear retention. To export unspliced and singly spliced HIV RNAs, the viral protein Rev binds to a specific region in the *env* portion of the unspliced and singly spliced RNA, denoted as the Rev responsive element (RRE); the RRE is a sequence of c.240 nt that folds into a specific structure to which Rev binds. The Rev-RNA complex then engages the nuclear host CRM-1 transport apparatus, which transports RNA out of the nucleus. Engaging appropriate host elements therefore results in a balance of 9.2-, 4.5-, and 1.8-kb mRNA species.[12]

Translation of mRNA

All HIV RNAs are translated by cellular ribosomes on either smooth or rough endoplasmic reticulae. Abundance of several HIV proteins is regulated by translational mechanisms and post-translational modifications mediated by host mechanisms that are critical for viral protein function.

Full-length HIV RNA serves as RNA for encapsidation into the virion, and for Gag/Pol synthesis. Gag is synthesized as a 55-kd polyprotein precursor in relatively abundant amounts; Gag protein is N-myristoylated, permitting the protein to bind cellular membranes. The *pol* gene products are translated

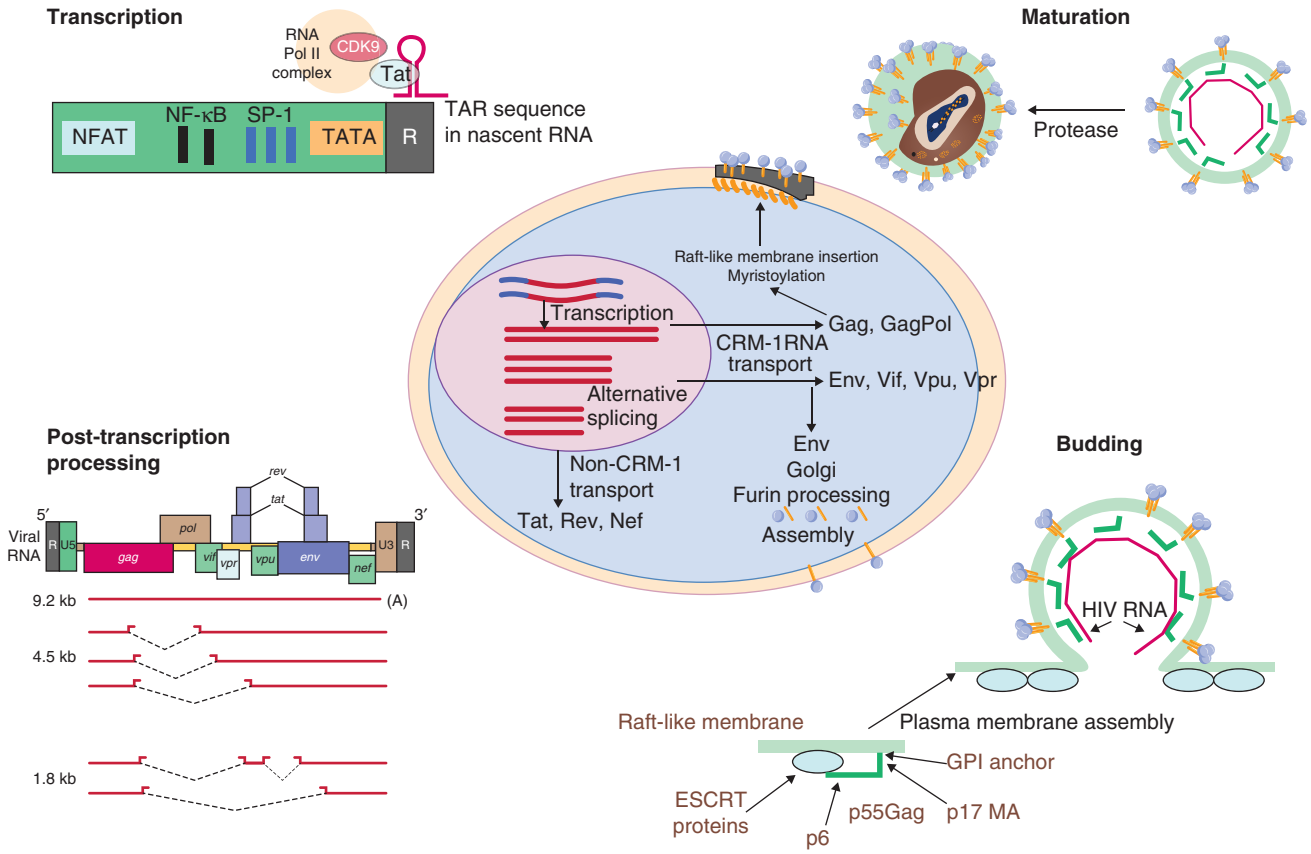

FIGURE 386-4. Late events in HIV replication. Following establishment of the provirus, transcription, post-transcriptional processing translation, virion assembly, budding, and virion maturation take place by co-opting cellular processes.

though frameshifting mechanisms.[13] Frameshifting is relatively inefficient, and the relative abundance of *pol* enzyme gene products is substantially lower than Gag proteins, effectively controlling the levels of enzymes in favor of an abundance of structural proteins.

HIV Vpu and Env proteins are translated from a 4.5-kb bicistronic mRNA, permitting effective production of both Vpu and Env proteins. As Vpu sequesters CD4 by direct protein-protein interactions on intracellular membranes (see later), it prevents CD4-Env interactions that would arrest Env within the cell. Thus, the coordinated expression of Vpu with Env ensures efficient expression of Env. Env is synthesized as a gp160 precursor of Env SU and TM, cotranslationally inserted into the lumen of rough endoplasmic reticulum membranes and glycoslylated predominantly at a number of canonical N glycosylation sites.

Multiply spliced mRNA species encoding *tat, rev,* and *nef* are translated earliest after infection; Tat and Rev are transported to the nucleus, where they activate transcription, and transport (see earlier). Nef serves a number of cytoplasmic functions in evasion of host immunity by binding MHC-1 and CD4, redirecting them away from plasma membranes. Thus, at an early time in the infectious cycle, immune molecules that help identify and target virus-infected cells are downregulated from the cell surface of infected cells, facilitating virus replication.

Transport and Assembly of Virion Components: An Elegant Dance

The late steps in virus replication are complex, but dissecting the individual steps has identified a number of critical interactions between host and virion components that represent active areas for development of useful therapeutics.

HIV virion proteins and virion RNA species traffic to the plasma membrane, where virion assembly takes place. Nascent Gag and GagPol polyprotein precursors undergo cotranslational modifications that target Gag to membranes.[14] Gag has self-assembly properties, but correct initial assembly of the virion core into a hexagonal lattice includes incorporation of virion RNA and additional factors. Virion RNA undergoes dimerization largely through direct RNA-RNA interactions that require specialized RNA sequences, denoted psi sequences, at the 5′ region of the genome favoring incorporation of only unspliced HIV RNA species. Gag polyprotein precursor can bind HIV RNA directly, providing a potential mechanism for transport to the cell membrane. Gag also accumulates in specialized membrane microdomains enriched with sphingomyelin-saturated phospholipids and cholesterol typical of lipid rafts and binds components of the endosomal sorting complexes required for transport (ESCRT) pathway (see Fig. 386-4). The ESCRT pathway is normally involved in intracellular membrane remodeling and scission events necessary for events such as organelle biogenesis, lysosome formation, and cytokinesis; by recruiting ESCRT to sites of HIV assembly on the plasma membrane, HIV engages a highly specialized pathway to execute budding. Elegant studies of HIV transmission have suggested these events may also participate in cell-cell transmission of HIV at "virologic synapses," specialized areas of cell-cell contact.

During the budding process, HIV undergoes several maturation events, including proteolytic processing of the Gag and GagPol precursor proteins by HIV protease (see Fig. 386-4). Protease is embedded as part of the GagPol precursor, cleaves itself from the precursor and then proceeds to process Gag and GagPol into component proteins. Processing is essential for virion infectivity, and protease inhibitors are highly effective agents in HIV therapy. During processing, the core lattice begins to bend by introducing pentamers of CA at critical points of the hexagonal lattice, effectively folding the structure into a fullerene-like cone that encapsidates dimeric HIV RNA-tRNA^{lys} and HIV enzymes. Proteolytic cleavage at the CA-SP1 site is critical; the development of maturation inhibitors that block cleavage by binding Gag instead of inhibiting protease represent a new antiviral target.

HIV Env precursor glycoprotein is processed by a cellular furin-like protease into mature products, gp120 (SU) and gp41, which traffic to plasma membranes through Golgi and post-Golgi membranes. Because the cellular receptor CD4 is also processed through similar mechanisms, intracellular Env-CD4 binding can effectively block Env from reaching the cell surface. The HIV Vpu protein, which directly binds and redirects CD4 to proteolytic degradation, thereby increases the proportion of Env reaching the cell surface and sites of HIV budding.

SUMMARY

By the completion of the infectious cycle, HIV has produced progeny for the next round of infection, obstructed adaptive and innate immune responses,

and established a proviral state in the infected cell. Despite multiple mechanisms of immune evasion, the majority of infected cells (>99.9%) die within 1 to 2 days of infection. Thus, the virus has a strikingly short period to engage critical cell pathways to complete replication, while the cells are undergoing destruction. A minority of cells survive infection and persist for prolonged periods. As a consequence, current antiretroviral therapy that targets active steps in HIV replication does not eradicate HIV infection. Mechanisms of persistence remain poorly understood, but likely include transcriptional and immunologic mechanisms.[15] Additional research will be essential to determine mechanisms of persistence and to identify new strategies to cure HIV infection.

REVIEW QUESTIONS

1. Which of the following animals represents the *most likely* source of HIV-1?

A. Sooty mangabey
B. Chimpanzee
C. Gorilla
D. Macaques
E. Mandrill

Answer: B HIV-1 is responsible for over 30 million infections worldwide and is closely related to a simian immunodeficiency virus (SIV) present in chimpanzee populations. Although gorillas have an SIV, that virus is more distantly related to HIV-1 than the chimpanzee virus. Sooty mangabeys have SIV that is very closely related to HIV-2 but not to HIV-1. Macaques and mandrills are species of monkeys with SIV variants that are only distantly related to HIV.

2. Which of the following inhibits HIV infection by introducing numerous G-to-A mutations in the HIV genome?

A. Tetherin
B. APOBEC
C. TRIM5-alpha
D. Vif

Answer: B APOBEC is a cytidine deaminase and one part of the innate immune system that inactivates virus by introducing multiple G-to-A changes, which result in multiple mutations and stop codons. Tetherin is a cell surface protein that retains virions at the cell surface and is antagonized by VPU. TRIM5-alpha is involved in blocking uncoating before reverse transcription, and Vif is a viral protein that abrogates Apobec activity by excluding it from incorporation into the virion.

3. HIV-2 is naturally resistant to which of the following agents?

A. Non-nucleoside reverse transcriptase inhibitors (NNRTI)
B. Nucleoside reverse transcriptase inhibitors (NRTI)
C. Protease inhibitors (PI)
D. Integrase inhibitors (INSTI)

Answer: A HIV-2 is only distantly related to HIV-1 and encodes a reverse transcriptase that is naturally resistant to non-nucleoside reverse transcriptase inhibitors. HIV-2 remains susceptible to NRTI, PI, and integrase inhibitors. It is critical that individuals with HIV-2 or HIV-1/2 *not* be treated with NNRTI, because mutants resistant to the other components of the regimen will emerge.

4. HIV virion assembly takes place:

A. At the plasma membrane.
B. Within the cytoplasm.
C. At the nuclear membrane
D. Within the nucleus.

Answer: A HIV assembles at the plasma membrane; no virus-like particles are seen in the cytoplasm or at or within the nucleus.

5. HIV protease inhibitors inhibit which of the following steps in HIV replication?

A. Proteolytic processing of HIV Gag and Gag/pol precursors
B. Proteolytic processing of Env precursor
C. Proteolytic processing of the HIV core during virion uncoating
D. Proteolytic processing of the intasome before integration

Answer: A Protease inhibitors are a key component of combination antiretroviral therapy. They block a late step in virus replication after virions have assembled. The immature virus is not infectious until after protease acts on Gag and Gag/Pol.

387 PREVENTION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

CARLOS DEL RIO AND MYRON S. COHEN

More than 30 years have passed since the first report of a case of human immunodeficiency virus (HIV) infection, and the pandemic has spread worldwide and infected more than 70,000,000 people, of whom approximately 35,000,000 have died as a consequence of acquired immunodeficiency virus (AIDS). HIV prevention efforts have been "front and center" since the virus was discovered as the cause of AIDS, as summarized in Figure 387-1. Behavioral interventions focused on HIV-negative persons have likely played a role in the falling population level incidence in some countries reported by the United Nations Program in HIV/AIDS (UNAIDS) in their 2012 report; however, approximately 2.7 million new infections still occur each year, and we have made little progress in reducing HIV incidence in the groups at highest risk. In the past few years, several promising new prevention strategies have demonstrated efficacy in clinical trials and are now being implemented,[1] leading President Obama to look toward an "AIDS-free generation." This chapter will provide a detailed view of HIV prevention approaches that are useful to the practicing clinician.

MODES OF TRANSMISSION AND PREVENTION

Sexual Transmission

The primary mode of HIV transmission throughout the world is sexual contact. However, the geographic distribution of cases attributable to homosexual or heterosexual transmission varies markedly. In the United States, most sexually transmitted cases of HIV are observed in men who have sex with men (MSM), and heterosexual transmission accounts for a smaller number of new infections except among women. However, heterosexual transmission is the leading mode of transmission worldwide and remains the primary mode of disease acquisition in Africa. Sexual transmission of HIV is relatively inefficient, but behavioral and biologic factors influence the likelihood of HIV transmission in a given sexual encounter. In particular, coinfection with classical sexually transmitted infections (STIs) (especially genital ulcerative diseases such as herpes simplex) greatly increases the infectiousness and the susceptibility of an individual. STIs increase the concentration of HIV in genital secretions, which increases the likelihood for transmission.

The risk for acquisition of HIV per coital act has been estimated to be 5 per 10,000 for insertive unprotected penile-vaginal intercourse to 50 per 10,000 for receptive unprotected anal intercourse. However, the risk is not stable and varies depending on the stage of infection and other amplifying cofactors. HIV transmission risk is highest in early HIV infection and in advanced infection (Fig. 387-2), demonstrating that the viral concentration in the genital secretions is the strongest predictor of the risk for transmission.

Prevention Strategies

Traditional strategies for the prevention of sexual transmission of HIV have focused on encouraging abstinence, reducing unsafe sexual behaviors (especially unprotected anal intercourse and concurrent relationships), encouraging proper condom use, and treating STIs. These interventions primarily focus on HIV-negative persons.

In situations in which a decision to engage in sexual activity has been made and the HIV status of the partner is positive, unknown, or in doubt, safe sexual practices ("safe sex") should be implemented. Consistent use of latex condoms has been shown to be effective in preventing HIV transmission at both individual and population levels. The condom should be made of latex and must be used properly. Natural skin condoms should not be used because they do not prevent transmission of HIV. Petroleum-based lubricants enhance the likelihood of rupture of latex condoms and should be avoided. If needed, water-based lubricants such as K-Y jelly should be used.

The effectiveness of condoms in preventing heterosexual transmission of HIV has been estimated to be 87%, but it may be as low as 60% or as high as 96%. The effectiveness of condoms during anal intercourse is probably lower because the frequency of condom breakage and slippage may be considerably higher than during vaginal intercourse. Circumcision represents an alternative strategy to protect men from HIV. Three randomized clinical trials have demonstrated a protective benefit of male circumcision, with the risk for acquisition of HIV infection through heterosexual intercourse decreasing by approximately 60%, with increasing reduction in HIV acquisition over time. However, this benefit has not been confirmed for MSM.

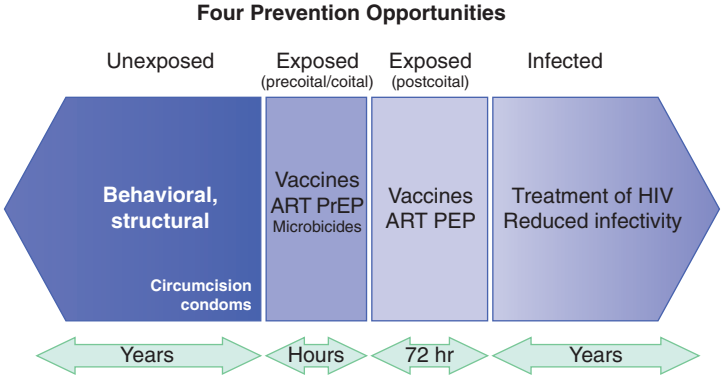

FIGURE 387-1. Opportunities for HIV prevention. ART = antiretroviral therapy; PEP = postexposure prophylaxis; PrEP = pre-exposure prophylaxis. (Modified from Cohen MS. Recent developments in HIV prevention. *AIDS* 2008, Abstract TUPL0102.)

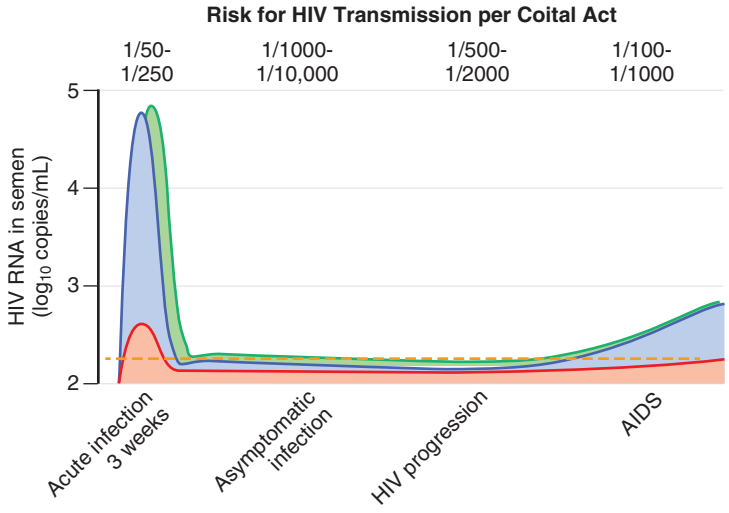

FIGURE 387-2. Prediction of the efficiency of HIV transmission according to HIV burden in the genital tract. Probability of male-to-female HIV transmission per coital act, as a function of HIV disease stage in the index case. Dashed line = a potential threshold for HIV transmission; orange = theoretical effect of a biologic intervention designed to reduce viral excretion; blue = expected distribution of viral burden in semen among men over time. (Modified from Cohen MS, Pilcher CD. Amplified HIV transmission and new approaches to HIV prevention. *J Infect Dis.* 2005;191:1391-1393.)

Antiretroviral therapy may influence infectivity and the subsequent risk for transmission through sexual contact. In the HPTN 052 study, early antiretroviral therapy of HIV-infected patients beginning at a CD4 count of 350 to 550 cells/mm^3 reduced sexual transmission of HIV-1 by 96%. Observational studies suggest that broader antiretroviral use at a population level can reduce HIV incidence. Antiretrovirals also are effective for the prevention of HIV when administered prophylactically to HIV-uninfected at-risk individuals as pre-exposure prophylaxis (PrEP). In a randomized trial, daily administration of co-formulated tenofovir plus emtricitabine as pre-exposure prophylaxis of MSM decreased the risk for HIV infection by 44%. Other studies using tenofovir with emtricitabine show a decrease of as much as two thirds in infections,[2] although findings have varied across studies dependings on adherence. Based on these studies, in 2013 the U.S. Food and Drug Administration approved the use of co-formulated tenofovir plus emtricitabine for pre-exposure prophylaxis to prevent sexual transmission of HIV. The Centers for Disease Control and Prevention (CDC) has issued guidelines for clinicians for pre-exposure prophylaxis with antiretroviral drugs for the prevention of HIV-infection in the United States.[3] Similarly, a tenofovir-containing vaginal gel led to a 39% reduction in the risk for HIV infection among women, but a tenofovir vaginal gel is not currently available commercially. In addition, antiretrovirals can be given after exposure to prevent HIV acquisition (postexposure prophylaxis [PEP]). The CDC and professional organizations have published guidelines for antiretroviral postexposure prophylaxis after sexual, injection drug use, and other nonoccupational exposures to HIV.[4] In these guidelines it is recommended that persons seek care 72 hours or sooner after nonoccupational exposure to the blood, genital secretions, or other potentially infected body fluids of a person known to have HIV infection be offered a 28-day course of antiretroviral therapy.

Transmission in Injection Drug Users

The primary mode of HIV transmission in injection drug users is sharing of contaminated needles and syringes. Sharing of injection paraphernalia ("works") is commonplace among injection drug users and is reinforced by the cultural, economic, and legal environment in that community. The risk for transmission of HIV is highest in injection drug users who share needles and use drugs that are injected more frequently, such as cocaine or methamphetamines.

Prevention Strategies

The primary mode of preventing HIV transmission in PWID is to stop the use of intravenous drugs. Education programs that are culturally sensitive and geared to young audiences have the best chance of preventing drug use. Access to treatment centers for injection drug users is the best approach. However, approximately 80% of active drug users in the United States are not in substance abuse treatment because of either choice or the unavailability of treatment centers. For injection drug users who do not wish to seek treatment or who are unable to gain access to treatment, the most effective way to prevent HIV infection is to avoid sharing needles and paraphernalia. Some communities have adopted programs that provide free needles and syringes for injection drug users, and there is strong evidence that these programs, when implemented properly, are effective in reducing HIV transmission and do not result in increased drug use among participants. Where supplies cannot be obtained, needles and syringes should be cleaned after each use, preferably with readily accessible virucidal cleansers such as chlorine bleach (diluted 1 : 10). As with sexual transmission, preliminary data from Vancouver, Canada, suggest that antiretroviral treatment of injection drug users decreases incidence of HIV among drug users. Most recently, a randomized controlled trial conducted in injection drug users in Thailand demonstrated a 49% reduction in HIV acquisition when tenofovir was given as PrEP. As a result the CDC issued guidance for the use of PrEP among injection drug users but has recommended the use of co-formulated tenofovir plus emtricitabine rather than tenofovir alone as the preferred PrEP regimen among injection drug users.[5] However, this is an off-label indication.

Transmission through Blood Products and Other Tissues

HIV has been transmitted through the transfusion of single-donor blood and blood products, including whole blood, fresh-frozen plasma, packed red blood cells, cryoprecipitate, clotting factors, and platelets. Confidential donor exclusion, as well as the institution of HIV antibody screening in 1985, followed by additional testing for antibodies to HIV-2 and p24 antigen in 1996 and nucleic acid testing in 2002, has reduced the risk for HIV infection through the transfusion of blood or blood products to approximately 1 in 2,135,000. Transmission of HIV by liver, heart, kidney, pancreas, bone, and possibly skin transplantation has been reported. In contrast, relatively avascular tissues such as corneas and processed tissues have not been associated with transmission.

Prevention Strategies

The institution of HIV antibody testing of donated blood and blood products in 1985 has had the most dramatic effect on lowering the incidence of transfusion-related transmission. When combined with voluntary self-deferral and nucleic acid testing, the blood supply in most countries has become virtually free of HIV. Heat inactivation processes for cryoprecipitate and clotting factor concentrates has eliminated transmission of HIV through use of these products. Other products, such as immunoglobulin preparations and hepatitis B vaccines, are produced by fractionation methods that remove HIV and have never been associated with transmission of HIV. Organ and tissue donors should be evaluated and serologically screened in a manner similar to blood donors. In addition, donations of semen and bone from a living donor may be quarantined until subsequent testing has definitively ruled out the possibility of delayed seroconversion in the donor.

Transmission to Health Care Workers

Detailed studies examining the risk associated with specific exposures to health care workers, such as needlestick injuries and mucous membrane exposure, have demonstrated low risk for acquisition of disease in the workplace. More than 3628 health care workers have been prospectively examined in carefully designed surveillance studies at 10 high-incidence medical centers. The overall risk for seroconversion after a percutaneous needlestick from a known HIV-infected source is 0.3% per exposure. A retrospective study conducted by the CDC found that the risk for transmission of HIV to health care workers is increased when the device causing the injury is visibly contaminated with blood, when the device has been used for insertion into a vein or artery, when the device causes a deep injury, or when the source patient dies within 2 months after the exposure. Exposure of mucous membranes to HIV-infected blood has resulted in seroconversion only rarely, and the risk for transmission is estimated to be 0.09% per exposure.

Prevention Strategies

In August 1987, the CDC published guidelines recommending that the principles of "universal precautions" be incorporated into health care settings to minimize exposure of health care workers to blood and body fluids that may be infected with blood-borne pathogens such as HIV. Universal precautions are based on the premise that any patient may be infected with blood-borne infectious agents and it may be difficult, if not impossible, to differentiate those with infection from their uninfected counterparts. All specimens containing blood or blood-tinged fluids obtained from *any* patient should be considered hazardous and handled as such. The use of universal precautions helps minimize the transmission of many transmissible diseases in addition to HIV.

Gowns, protective eyewear, and masks are not usually needed except in circumstances in which splattering or splashing of blood-containing fluids is likely to occur. Health care workers with denuded skin, open lesions, or active dermatitis should avoid direct patient contact and should not process contaminated equipment or materials. Handling of sharp instruments ("sharps") represents the greatest risk for transmission of HIV to health care workers. Although injuries from sharps cannot be eliminated entirely, the number of exposures can be reduced substantially by adhering to guidelines put forth in universal precautions. Before a sharp instrument is used, thought should be given to where the instrument will be disposed after use. Impervious containers should be readily available in all patient care areas and identified by the health care worker *before* the use of sharps. These containers should be checked frequently and should not be allowed to overfill. Used needles should never be manipulated, bent, broken, or recapped. Recapping of needles is the single most common activity that results in needlestick injuries. Technologic developments that do not rely on health care worker compliance, such as self-sheathing needles, also have been important in decreasing the risk for needlestick injury.

Antiretroviral agents are also used for PEP in health care workers. A case-control study suggested that risk for HIV seroconversion after occupational exposure was decreased by approximately 81% with the use of zidovudine alone. Subsequent recommendations have incorporated the newer antiretroviral drugs, as well as risk stratification for the type of exposure, in the management of occupational exposure to HIV. In 2013, the CDC issued revised

recommendations for the use of PEP after exposure to HIV among health care workers.[6] The essential elements of management of a health care worker after a needlestick or mucous membrane exposure include appropriately evaluating the donor (patient) and recipient (health care worker) at the time of exposure, counseling of the health care worker, and providing follow-up HIV testing. There is no longer the need to determine the severity of exposure to direct the number of antiretroviral drugs to be used; a regimen containing three or more drugs is now recommended with co-formulated tenofovir/emtricitabine plus raltegravir as the preferred regimen. Antiretroviral drugs for PEP should be initiated within 72 hours of exposure and continued for 4 weeks. The U.S. Public Health Service has established a National Clinicians' Post-Exposure Prophylaxis Hotline (PEPline) to provide expert consultation about the management of health care workers with potential HIV exposure. The PEPline can be accessed at 1-888-448-4911 or through the Internet at http://www.ucsf.edu/hivcntr/Hotlines/PEPline.

PREVENTION INTERVENTIONS FOR INFECTED INDIVIDUALS

Antiretroviral therapy administered to HIV-infected individuals decreases the risk for HIV transmission by over 96%, and thus suppression of HIV replication to undetectable levels is the most effective intervention to decrease HIV transmission from an HIV-infected person. As a result, the U.S. Department of Health and Human Services Antiretroviral treatment guidelines now recommend initiation of antiretroviral treatment regardless of the CD4 cell count and monitoring for viral suppression.

In addition, the CDC, Health Resources and Services Administration, National Institutes of Health, and Infectious Diseases Society of America have published joint recommendations for incorporating HIV prevention into the HIV medical care setting. These guidelines reflect four basic priorities: (1) screening for risky behavior and STIs; (2) providing general and tailored risk reduction messages to patients; (3) when indicated, referring patients for additional risk reduction services and other services that may affect risk reduction (e.g., substance abuse treatment); and (4) ensuring that patients are provided with partner counseling and referral services. HIV-infected persons should be screened and treated for STIs. The CDC's 2010 sexually transmitted disease treatment guidelines recommend that all patients with newly diagnosed HIV infection undergo screening for gonorrhea, chlamydial infection, hepatitis B and C virus infection, and syphilis. Screening for curable STIs (gonorrhea, chlamydial infection, and syphilis) should be performed at least annually in sexually active patients. More frequent screening for STI's might be appropriate depending on individual risk behaviors, the local epidemiology of STIs and whether incident STIs are detected by screening or by presence of symptoms.

PREVENTION IN DEVELOPMENT

As shown in Figure 387-1, many prevention strategies are available, and some are in development. Vaccine strategies are increasingly focused on the generation of different types of antibodies. Broad neutralizing antibodies offer almost compete protection in macaques from infection for several months, suggesting the feasibility of a protective vaccine.[7] Injectable antiretroviral agents in different classes may serve as an advance for PEP and PreP, and such agents are in phase 2 testing. Delivering of slow-release topical tenofovir from a cervical ring is being examined in two clinical trials.

REVIEW QUESTIONS

1. After occupational exposure by a health care worker to HIV through a needlestick injury, management should include which of the following?

A. The HIV status of the exposure source patient should be determined.
B. Postexposure prophylaxis should contain no more than two antiretrovirals.
C. Antretroviral therapy should be started within 72 hours of exposure and continued for 4 weeks
D. All of the above are correct.
E. Only a and c and correct.

Answer: E In managing health care personnel who experience occupational exposure to blood and/or body fluids that might contain HIV, the USPHS guidelines published in 2013 recommend that after occupational exposure to HIV occurs the HIV status of the exposure source be determined (if possible). Postexposure prophylaxis should be started as soon as possible (within 72 hours) and continued for 4 weeks and three or more antiretrovirals should be prescribed.

2. The most effective strategy for the prevention of sexual transmission of HIV from an infected to an uninfected partner is:

A. Voluntary HIV counseling and testing.
B. Antiretroviral therapy of the infected partner.
C. Antretroviral therapy of the uninfected partner.
D. Prompt treatment of sexually transmitted infections.
E. Avoidance of oral sex.

Answer: B Antiretroviral therapy to bring HIV replication below the limits of detection has proved to be an effective strategy to decrease by 96% the risk for HIV transmission among serodiscordant couples.

3. Confidential donor exclusion, HIV antibody screening, testing for antibodies to HIV-2 and p24 antigen, and nucleic acid testing has reduced the risk for HIV infection through the transfusion of blood or blood products to:

A. Approximately 1 in 20,000.
B. Approximately 1 in 200,000.
C. Approximately 1 in 2,000,000.
D. Approximately 1 in 20,000,000.

Answer: C HIV has been transmitted through the transfusion of single-donor blood and blood products, including whole blood, fresh-frozen plasma, packed red blood cells, cryoprecipitate, clotting factors, and platelets. Confidential donor exclusion, as well as the institution of HIV antibody screening in 1985, followed by additional testing for antibodies to HIV-2 and p24 antigen in 1996 and nucleic acid testing in 2002, has reduced the risk for HIV infection through the transfusion of blood or blood products to approximately 1 in 2,135,000.

4. The effectiveness of condoms in preventing heterosexual transmission of HIV has been estimated to be:

A. As low as 60% and as high as 96% (~87%).
B. Higher for anal than for vaginal sex.
C. Equal for latex and natural skin condoms.
D. Enhanced by petroleum-based lubricants.

Answer: A The effectiveness of condoms in preventing heterosexual transmission of HIV has been estimated to be 87%, but it may be as low as 60% or as high as 96%. Consistent use of latex condoms has been shown to be effective in preventing of HIV transmission at both individual and population levels. The condom should be made of latex and must be used properly. Natural skin condoms should not be used because they do not prevent transmission of HIV. Petroleum-based lubricants enhance the likelihood of rupture of latex condoms and should be avoided. If needed, water-based lubricants such as K-Y jelly should be used.

5. HIV transmission risk is highest in:

A. Patients taking antiretrovirals.
B. Patients with a sexually transmitted infection such as genital wart.
C. Early HIV infection and advanced infection.
D. An episode of a concomitant viral infection such as influenza.

Answer: C The risk for HIV transmission is highest in early HIV infection and in advanced infection, demonstrating that the HIV viral concentration in the genital secretions is the strongest predictor of the risk for transmission.

ANTIRETROVIRAL THERAPY OF HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

ROY M. GULICK

The development of effective antiretroviral therapy (ART) for human immunodeficiency virus (HIV) infection is one of the most notable achievements in modern medicine. The first cases of acquired immunodeficiency syndrome (AIDS) were reported from Los Angeles in 1981. In the early to mid-1980s, without any available antiretroviral treatments, the life expectancy of an individual diagnosed with AIDS was only approximately 6 to 12 months. The first antiretroviral drug, zidovudine (azidothymidine, AZT) was approved by the U.S. Food and Drug Administration (FDA) in 1987 on the basis of a short-term survival benefit. Triple-drug therapy was first introduced in the mid-1990s and resulted in a two-thirds decrease in HIV-related deaths within 2 years in developed countries. Today, there are a total of 28 antiretroviral drugs that are approved by the FDA and three-drug combination regimens are the standard of care. The benefits of ART were extended to developing countries, and an estimated over 14 million people currently are taking ART worldwide. The life expectancy of an HIV-infected individual appropriately treated with ART is now estimated to be nearly that of the general population, both in developed[1] and developing countries.[2]

WHEN TO START ART?

The rationale for starting ART early in someone with HIV infection is based on several principles: (1) untreated infection causes progressive immunodeficiency resulting in opportunistic diseases and death; (2) current ART regimens decrease plasma HIV RNA (viral load) levels and the risk for the emergence of drug resistance, as well as increase CD4+ T-lymphocyte counts and general immune function; and (3) current treatment results in years of virologic suppression. In addition, it is now appreciated that ART reduces inflammation and immune activation that leads to end-organ diseases (cardiac, hepatic, neurologic, oncologic, and renal) and that ART reduces HIV transmission. The rationale for delaying ART traditionally centered on practical factors: medication adherence can be challenging; drug toxicities occur, and the long-term side effects of antiretroviral drugs are not known; and the risk for clinical progression is low in early disease. Additionally, although ART can prevent HIV transmission, drug-resistant virus can be transmitted in the community. In fact, the U.S. Centers for Disease Control and Prevention estimates at least 15% of Americans newly diagnosed with HIV are infected with drug-resistant virus.[3]

Whereas before 2008, U.S. treatment guidelines recommended waiting to start antiretroviral treatment, current guidelines from both the U.S. Department of Health and Human Services and the International Antiviral Society–USA recommend starting ART in *all* HIV-infected patients, regardless of CD4 cell count number, because of both clinical benefits to the patient and reduction in HIV transmission to others.[4,5] This recommendation is supported by the fact that current ART regimens are potent, convenient, and generally well-tolerated, as well as by supportive clinical cohort data[6] and randomized controlled clinical trials. There are no randomized clinical trial data to support starting ART in patients with CD4 counts greater than 550 cells/μL, and thus some controversy in the field remains, as evidenced by British, European, and World Health Organization treatment guidelines that do not routinely recommend ART in patients with CD4 cell counts greater than 500/μL (Table 388-1).

WHAT TO START?

Since 1987, the FDA has approved 28 antiretroviral drugs from six mechanistic classes (Table 388-2). The goal of ART is to suppress viral replication, prevent the emergence of drug-resistant viral strains, enhance immunologic responses, decrease clinical events, and prolong healthy life. Antiretroviral drugs interfere with individual steps in the HIV replication cycle (Fig. 388-1). The first step of the life cycle is HIV entry, a three-step process

starting with binding of the HIV external membrane glycoprotein (gp120) to the CD4 receptor on the surface of the T lymphocyte. This binding induces a conformational change in gp120 permitting the second step of HIV entry, binding to a second cellular receptor, the chemokine receptor, either CCR5 (bound by R5 viruses) or CXCR4 (bound by X4 viruses). Some HIV strains are dual-tropic and can bind to either the CCR5 or CXCR4 receptor, and some individuals are infected with a mixed population of R5 and X4 viral strains. Binding to the chemokine receptor induces an additional conformational change allowing the viral protein gp41 to pierce the target cell membrane and then fold in on itself in a coil-on-coil interaction, leading to fusion of the viral and cellular membranes and extrusion of the viral particle contents (viral RNA, viral proteins) into the cytoplasm of the cell.

Inside the cell, viral RNA is transcribed to viral DNA by a viral-specific enzyme called *HIV reverse transcriptase*. Following transcription, two strands of viral DNA form a double-stranded complex catalyzed by a second viral-specific enzyme called *HIV integrase,* which also promotes transport of the viral DNA complex into the nucleus of the cell and strand transfer—the random integration of the viral DNA into the cellular genome. At the point of viral DNA integration, the cell is infected for life. It may enter a latent period, with a cellular lifespan as long as 60 years, or may be activated to transcribe both cellular and viral DNA into RNA and then translate RNA into proteins, including viral proteins, which assemble at the surface of the cell and then bud off into new viral particles. After budding, a third viral-specific enzyme, *HIV protease,* cleaves viral precursor proteins, a step that is necessary

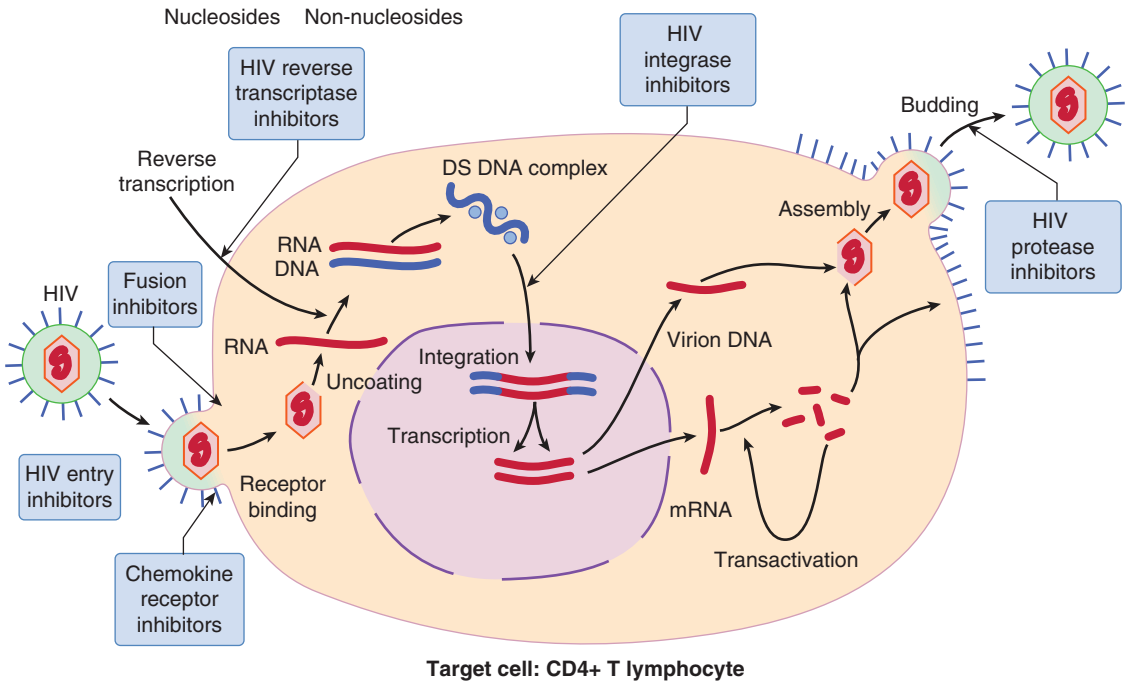

FIGURE 388-1. Life cycle of human immunodeficiency virus (*HIV*) and mechanisms of action of the six antiretroviral drug classes. See text (What to Start? section) for details.

for viral maturation and infectivity. One infected cell can produce hundreds to thousands of viral particles, and many will be capable of starting the process again on encountering another CD4+ T lymphocyte.

Antiretroviral drugs inhibit different steps of the HIV replication cycle (see Fig. 388-1). Two kinds of HIV entry inhibitors target the first step in the HIV life cycle, viral entry, by inhibiting either CCR5 chemokine receptor binding (CCR5 antagonists) or membrane fusion (fusion inhibitors). The nucleoside analogue reverse transcriptase inhibitors (NRTIs) target the viral-specific enzyme *HIV reverse transcriptase.* A second class of HIV reverse transcriptase inhibitors are the non-nucleoside analogue reverse transcriptase inhibitors (NNRTIs), which bind to a different part of the same enzyme. The integrase strand transfer inhibitors (INSTIs) inhibit the viral-specific enzyme *HIV integrase* by specifically targeting the transfer of viral DNA to the host cell genome. The HIV protease inhibitors (PIs) bind to the active site of the *HIV protease* enzyme and prevent precursor protein cleavage, viral maturation, and infectivity.

Initially, single nucleoside analogue therapy was studied for the treatment of HIV infection. However, virologic suppression, immune enhancement, and clinical benefits were only transient and drug-resistant virus emerged (Fig. 388-2). When more than one drug was available, dual nucleoside analogue therapy was studied and found to be better than single-drug therapy, but virologic, immunologic, and clinical benefits again were only temporary. A three-drug regimen was superior to two-drug therapy and led to essentially complete virologic suppression, preventing the emergence of drug-resistant viral strains and increasing CD4 cell counts, and resulted in durable effects. With potent virologic suppression and immunologic recovery came dramatic decreases in HIV-related illnesses and prolonged survival.

Despite their life-saving potential, early antiretroviral drug regimens had significant associated side effects and toxicities and were complicated to take. Some early drugs were associated with anemia and leukopenia (zidovudine), peripheral neuropathy (didanosine, zalcitabine, stavudine), pancreatitis (didanosine, stavudine), kidney stones (indinavir), nausea and vomiting (ritonavir), diarrhea (nelfinavir), and Stevens-Johnson syndrome (nevirapine). A common three-drug regimen in 1996 consisted of 20 pills, divided for dosing every 8 hours. Whereas the first decade of ART developed effective regimens that controlled viral replication, the second decade was about developing potent, well-tolerated, and convenient regimens to enable long-term use. Use of low-dose ritonavir or the newer drug cobicistat inhibits the cytochrome P450 3A4 isoenzyme, decreasing the metabolism of most protease inhibitors and the integrase inhibitor elvitegravir, allowing once- or twice-daily dosing; this strategy is known as pharmacokinetic boosting. Additional antiretroviral drugs were approved, and co-formulations (more than one

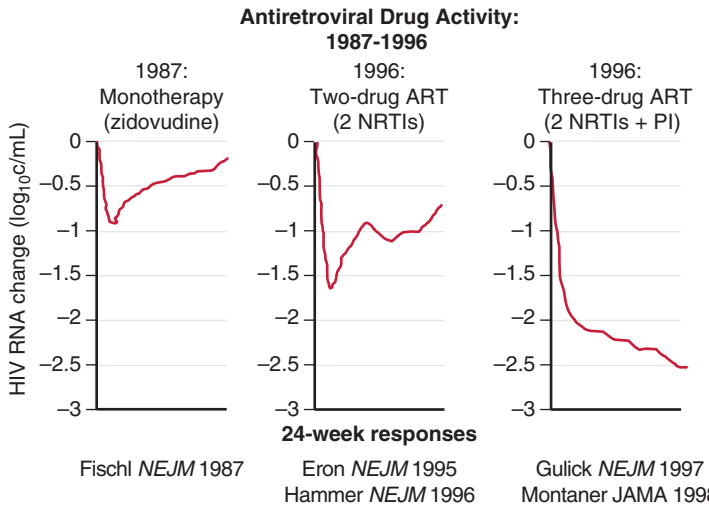

FIGURE 388-2. Antiretroviral drug (*ART*) activity: 1987 to 1996. Major clinical trials leading to finding of sustained efficacy of three-drug antiretroviral therapy. NRTI = nucleoside analogue reverse transcriptase inhibitors; PI = protease inhibitor. (1987: Fischl MA, et al. *N Engl J Med.* 1987;317:185-191; 1994: Eron JJ, et al. *N Engl J Med.* 1995;333:1662-1669 and Hammer SM, et al. *N Engl J Med.* 1996;335:1081-1090; 1996: Gulick RM, et al. *N Engl J Med*. 1997; 337:734-739 and Montaner JS, et al. 1998;279: 930-937.)

medicine in a single pill) were developed such that one-pill, once-daily HIV treatment was possible (Table 388-3).

Currently, there are four FDA-approved, one-pill, once-daily regimens; these are popular with providers and patients and lead to excellent adherence, with virologic suppression rates over 85% in some groups. Potency, convenience, and tolerability are essential qualities of current antiretroviral drug regimens and account for the durable clinical benefits. Current recommended initial regimens in the U.S. ART guidelines (Table 388-4) are combinations of two nucleoside analogues together with a third drug (non-nucleoside reverse transcriptase inhibitor, protease inhibitor, or integrase inhibitor). Globally, the most widely used antiretroviral regimen is two nucleoside analogues combined with a non-nucleoside analogue (NNRTI). A study from Denmark estimated that the life expectancy of someone with HIV infection who is appropriately treated and is free from comorbidities (hepatitis C infection, injection drug use) is now that of the age-matched general population.

TABLE 388-3 ANTIRETROVIRAL FIXED-DOSE COMBINATIONS

DRUG CLASS(ES)	GENERIC NAMES	ABBREVIATION(S)	TRADE NAMES	DOSING	YEAR OF U.S. FDA APPROVAL
2 NRTI	zidovudine + lamivudine	ZDV/3TC	Combivir	Twice daily	1997
3 NRTI	abacavir + zidovudine + lamivudine	ABC/ZDV/3TC	Trizivir	Twice daily	2000
Boosted PI	lopinavir + ritonavir	LPV/RTV	Kaletra	Once or twice daily	2000
2 NRTI	tenofovir + emtricitabine	TDF/FTC	Truvada	Once daily	2004

WHEN TO CHANGE ANTIRETROVIRAL THERAPY?

In a stable patient on ART, HIV RNA should be monitored every 3 to 6 months. Even with virologic suppression rates of over 85%, some patients will experience antiretroviral treatment failure, most commonly presenting as virologic failure, with a once-suppressed viral load level now being detectable above the limit of the HIV RNA assay (20, 40, or 50 copies/mL). The reasons for regimen failure can include suboptimal adherence, baseline drug resistance or cross-resistance, prior use of ART, use of less potent antiretroviral drug regimens, drug levels and drug-drug interactions, penetration into tissue reservoirs (e.g., genital tract, central nervous system [CNS]), suboptimal provider experience, and other, unknown reasons. Also, more than one factor may play a role in an individual patient. One of the challenges with treatment failure is to try to determine the cause of failure and then select the next regimen that can address and overcome the reason for failure.

U.S. ART guidelines suggest focusing on virologic failure and changing antiretroviral regimens promptly when failure is confirmed. Virologic failure can be defined as repeated detection of HIV RNA levels in a drug-adherent patient. HIV RNA levels suppressed below the level of detection of the assay are unlikely to result in the emergence of drug-resistant viral strains. Levels greater than 200 copies/mL (and certainly 500 copies/mL) will lead to the selection of drug-resistant viral strains and result in treatment failure. More controversial are HIV RNA levels between the level of detection and 200 copies/mL that may represent a higher virologic set point rather than ongoing viral replication and may not necessitate treatment change.

HIV is prone to errors in gene replication, and thus an individual is infected not with just one virus but a "swarm" of related viral strains with distinct genetic mutational patterns. Drug resistance is conferred by viral strains with specific amino acid substitutions in viral proteins (HIV reverse transcriptase, HIV protease, HIV integrase) that are selected for in the presence of an antiretroviral drug. For example, with ongoing replication in the presence of the nucleoside analogue emtricitabine or lamivudine, a viral strain with the substitution of valine for methionine at amino acid position 184 (M184V) of HIV reverse transcriptase will be selected and confer complete resistance to these drugs. Drugs with which single substitutions confer resistance are considered to have a low barrier to resistance and include the nucleoside analogues emtricitabine and lamivudine, the NNRTIs efavirenz and nevirapine, and the integrase inhibitors elvitegravir and raltegravir. Drugs that require multiple substitutions are considered to have a high barrier to resistance, including the nucleoside analogue zidovudine and most of the HIV protease inhibitors. Drugs with overlapping resistance patterns lead to cross resistance. For example, a patient who develops resistance to emtricitabine with the M184V substitution will have complete cross resistance to lamivudine, even though the patient never took lamivudine. Drug resistance can be assessed by an HIV genotype (that identifies amino acid substitutions that must be correlated with drug resistance) or an HIV phenotype (that assesses viral growth in the presence of each of the drugs).[7]

Another common clinical conundrum is immunologic failure—a patient taking ART who achieves virologic suppression but fails to increase the CD4 cell count. The causes of immunologic failure are not clear, but associations with various factors, including CD4 count less than 200 cells/μL at the time of ART initiation, older age, coinfections, medications (e.g., zidovudine; the combination of didanosine and tenofovir), persistent immune activation, and loss of regenerative potential have been reported. There is no accepted treatment for immunologic failure. Neither changing nor adding antiretroviral drugs results in an improved CD4 cell response. Immune-based therapies have been studied but are not effective. In two large randomized clinical trials, interleukin-2 was associated with increased CD4 cell counts, but failed to demonstrate associated clinical benefits. Current management is to continue antiretroviral therapy, optimize opportunistic infection prophylaxes, and follow the patient closely.

WHAT ANTIRETROVIRAL THERAPPY TO CHANGE TO?

The current goal for all HIV-infected patients taking ART, regardless of treatment experience, is to maximally suppress the viral load level below the level of assay detection.[4] In a treatment-experienced patient, this is done by reviewing the ART history with a focus on adherence, tolerability, and possible drug-drug interactions; conduct drug-resistance testing (HIV genotype for first or second failure; HIV genotype and phenotype for more advanced failure); identify susceptible drugs and drug classes and, ultimately, design a subsequent regimen with at least two (and preferably three) fully active antiretroviral agents.[4]

In the last 10 years, a number of newer antiretroviral drugs have made this goal possible, including drugs in existing mechanistic classes with activity against class-resistant virus (the HIV protease inhibitors darunavir and tipranavir and the HIV NNRTI etravirine) and drugs with new mechanisms of action (the fusion inhibitor enfuvirtide; the CCR5 antagonist maraviroc; and the HIV integrase inhibitors raltegravir, elvitegravir, and dolutegravir). Several recent studies in treatment-experienced patients show that new active antiretroviral regimens result in virologic suppression rates that are nearly the same as those for treatment-naïve patients.[8] A recent study found that including nucleoside analogues in subsequent regimens is not necessary if the regimen contains more than two active antiretroviral drugs.

SIDE EFFECTS AND TOXICITY

Antiretroviral drugs (like all drugs) are associated with side effects and toxicity.[4] Probably the most common side effect of ART as a group is gastrointestinal (nausea, vomiting, diarrhea), although some drugs are more associated than others (e.g., zidovudine, ritonavir). Toxicities may be divided according to seriousness and drug classes. Life-threatening toxicities occur and include drug-related hepatitis associated with NNRTIs and protease inhibitors. Of these, the NNRTI nevirapine is unique in causing drug-related hepatitis more frequently in patients with higher CD4 counts (>250 cells/μL in women and > 400 cells/μL in men), likely due to an immunologic mechanism. A hypersensitivity reaction characterized by rash and constitutional symptoms is associated with the nucleoside analogue abacavir and the NNRTIs etravirine and nevirapine. An elegant study linked the abacavir-associated hypersensitivity reaction to a genetic locus that can be screened for in patients (HLA-B*5701, at a cost of approximately $50); if the drug is avoided in patients with the genetic marker, the risk for HSR is minimized. Lactic acidosis has been associated with the nucleoside analogue class (particularly stavudine and zalcitabine). The NNRTIs, although structurally unrelated, all are associated with rash; Stevens-Johnson syndrome is rarely described with etravirine or nevirapine. Teratogenicity is described with efavirenz (FDA pregnancy category D); however, newer U.S. recommendations allow continuing the drug in a pregnant woman with maximal virologic suppression, although the drug should not be started in a pregnant woman.[9]

Acute side effects can be troubling to the patient and can lead to suboptimal adherence. Providers should be in close contact with a patient starting a new antiretroviral regimen and have a low threshold to substitute offending drugs for side effects or toxicities. As noted, probably the most common side effect of antiretroviral drugs is gastrointestinal toxicity, though this often can be managed by taking ART with food. Zidovudine causes anemia, neutropenia, and fatigue. Efavirenz causes CNS side effects (e.g., vivid dreams, somnolence) in up to 50% of people and should be dosed at bedtime. Atazanavir causes increased indirect bilirubin by inhibiting uridine 5′-diphosphoglucuronosyltransferase, which can be associated with frank jaundice but is not associated with other liver test abnormalities.

With the current expectation that ART is life-long, chronic and cumulative toxicities also are important. Increased cardiovascular events are associated with some protease inhibitors[10] and controversially with abacavir. Indinavir and atazanavir cause renal stones. Metabolic changes, including hyperglycemia and frank diabetes, hyperlactatemia, and/or hyperlipidemia, are associated with stavudine and some protease inhibitors. Morphologic changes occur and can be very distressing for patients, including lipoatrophy (loss of fat in the face and extremities) associated with stavudine and zidovudine, and lipoaccumulation (gain of fat in the breasts, abdomen, and dorsocervical fat bad [buffalo hump]) associated with some protease inhibitors. Some NRTIs, including didanosine and stavudine, cause a progressive toxic peripheral neuropathy. Tenofovir is associated with proximal renal tubular dysfunction characterized by hypophosphatemia, proteinuria, glycosuria, and eventually, elevated creatinine. Tenofovir also has been associated with loss of bone mineral density over the first year of treatment that appears to stabilize thereafter. Newer antiretroviral drugs and investigational antiretroviral agents often are developed and selected for less toxicity.

SPECIAL POPULATIONS

Acute Infection

Previously debated, it is now recommended that an individual identified with acute HIV infection start three-drug ART. ART reduces signs and symptoms of acute HIV and also prevents ongoing HIV transmission. Because of the risk for acquiring drug-resistant HIV, ART should be started while awaiting the results of the HIV genotype. Many experts would start a protease inhibitor–containing regimen and then adjust when the genotypic results are available.

Acute Opportunistic Infection

A patient presenting with an acute opportunistic infection who was not previously known to have HIV infection prompts the question of the optimal time to start ART. Despite prior concerns of drug-drug interactions and precipitating the immune reconstitution inflammatory syndrome (IRIS) (Chapter 395), ART demonstrates benefits in patients with acute opportunistic infections. One study of patients with a treatable opportunistic infection diagnosed in the prior 2 weeks (the majority with *Pneumocystis* pneumonia) randomized them to start ART within 48 hours or to wait at least 4 weeks. There were significantly fewer clinical events (disease progression and death) in the group that started ART earlier. Additional studies of patients with tuberculosis also demonstrated clinical benefits to starting ART earlier, particularly in patients with CD4 counts less than 50 cells/μL. Starting ART within 2 weeks of an opportunistic infection is now considered the standard of care. An exception is CNS opportunistic infections (e.g., cryptococcal or tuberculous meningitis) in which studies demonstrated increased mortality in patients who started ART earlier.[11,12]

Coinfection with Hepatitis B

If treatment is started for either infection, both need to be treated optimally: two active drugs for hepatitis B and three active drugs for HIV. The antiretroviral drugs emtricitabine, lamivudine, and tenofovir have activity against both viruses; thus, a suitable regimen to treat both infections would be tenofovir, emtricitabine (or lamivudine), and a third antiretroviral drug. Stopping drugs with activity against hepatitis B may result in a serious hepatitis flare.

Coinfection with Hepatitis C

The optimal time to treat hepatitis C infection in a patient with HIV infection is not known. The hepatitis C drug ribavirin has significant interactions with the antiretroviral drugs didanosine, stavudine, and zidovudine, and these combinations should be avoided. The newer hepatitis C protease inhibitors are unrelated to the HIV protease inhibitors and have no activity against HIV but may have significant drug interactions with HIV NNRTIs and protease inhibitors, and this is an active area of research.

Pregnancy

The recently updated U.S. Perinatal Treatment Guidelines recommend ART for prevention of mother-to-child transmission of HIV for all pregnant women, regardless of CD4 cell count or HIV RNA level. Based on their safety records, recommended drugs in pregnancy include the NRTIs lamivudine and zidovudine; the NNRTI nevirapine; and the PIs atazanavir, lopinavir, and ritonavir. Other drugs are considered alternatives (e.g., the NRTIs abacavir and tenofovir and the PI darunavir), although insufficient data are available on newer drugs (the NNRTIs etravirine and rilpivirine, and the CCR5 antagonist maraviroc). Efavirenz is teratogenic and should not be started in pregnant women; however, updated guidelines recommend continuing efavirenz in a women found to be pregnant if she is maximally virologically suppressed.

ANTIRETROVIRAL THERAPY FOR PREVENTION

One of the most successful HIV prevention strategies is the use of ART, both in HIV-infected and HIV-uninfected people. The first example of this was the prevention of HIV-infected mother-to-child transmission by giving the mother ART. In a classic study, the use of a single drug, zidovudine, in an HIV-infected mother reduced the risk for transmission to her infant from 25 to 8%. Current standard of care is to treat the mother with three-drug ART, with a resultant reduction in the risk for transmission to less than 1%.

A recent study randomized HIV-infected individuals with CD4 counts of 350 to 550/μL who were members of a committed couple with an HIV-uninfected individual to start ART immediately or to wait until the CD4 count decreased to less than 250 cells/μL and followed the seronegative partners for HIV seroconversion. Of 28 linked cases, 27 occurred in the group not on ART versus only 1 in an individual on ART (who had only recently started); thus, treating the infected individual with ART was associated with a 96% reduction in transmission to the HIV-uninfected partner.

Giving ART to at-risk HIV-uninfected individuals to avoid infection also is a strategy that has been explored. Postexposure prophylaxis is recommended on the basis of an older case-control study of health care workers exposed to HIV in which taking zidovudine was associated with an 81% decrease in the risk for seroconversion compared to no prophylaxis. The U.S. Centers for Disease Control and Prevention (CDC) recommends administering three-drug ART for 4 weeks following significant exposure (occupational or nonoccupational) to HIV.[13,14]

Pre-exposure prophylaxis (PrEP)[15] is a newer strategy in which one- or two-drug ART is given to HIV-uninfected individuals who are at risk for acquiring HIV infection on the basis of published studies in men who have sex with men,[A12] serodiscordant heterosexual couples,[A13] sexually active heterosexuals,[A14] and, most recently, injection drug users.[A15] Notably, two other PrEP studies in African women failed to show a benefit, although this may have been due to suboptimal adherence.[A16] Current U.S. CDC guidance recommends PrEP for high-risk individuals with two-drug ART with tenofovir-emtricitabine (coformulated) following exclusion of acute or chronic HIV infection, ongoing monitoring of HIV status and renal function, screening for sexually transmitted diseases, and risk reduction counseling and condom distribution.

CURE

Although current ART is highly effective, it is not curative. Soon after infection, HIV establishes a latent-CD4+ T-lymphocyte cell reservoir that can persist for an estimated 60 years. Even with years of ART-induced prolonged virologic suppression, the latent-cell reservoir does not decrease significantly. Strategies of intensification of ART by changing or adding additional antiretroviral drugs have not been successful in decreasing the reservoir. In 2009, the first known cure of HIV infection was reported: a 40 year-old man with HIV infection well controlled on ART developed acute myelogenous leukemia and underwent radiation, cytotoxic chemotherapy, and ultimately a bone marrow transplant from a donor with a deletion in the gene that codes for the CCR5 receptor that is required for HIV entry.[16] The patient's course was complicated by transplant rejection, administration of antirejection medications, cessation of ART, and a second bone marrow transplant. Ultimately, his HIV RNA remained suppressed below detection in the plasma in the absence of ART, his CD4 cell count returned to normal levels, and additional intensive investigations failed to identify replication-competent virus. After more than 5 years off of ART, he is considered to be cured. This case report is intriguing in that the cause of the cure is not clear (radiotherapy, chemotherapy, the CCR5-negative transplants, graft rejection, antirejection medications, or a combination of these), but the fact that it occurred is stimulating an intense research agenda for HIV cure.

REVIEW QUESTIONS

1. Which CD4 cell count should prompt starting antiretroviral therapy in an HIV-infected individual?

A. <200/μL.
B. <350/μL.
C. <500/μL.
D. Treatment should be started regardless of CD4 cell count.

Answer: D.

2. Which treatment strategy is *not* recommended for first-line antiretroviral therapy?

A. Two nucleoside analogue reverse transcriptase inhibitors (NRTIs) + a non-nucleoside reverse transcriptase inhibitor (NNRTI)
B. Three NRTIs
C. Two NRTIs + a protease inhibitor (PI)
D. Two NRTIs + an integrase strand transfer inhibitor (INSTI)

Answer: B.

3. When should you change an antiretroviral regimen for treatment failure?

A. HIV RNA repeatedly 50 to 200 copies/mL
B. HIV RNA repeatedly over 500 copies/mL
C. Any confirmed HIV RNA above the limit of detection
D. CD4 cell count < 200 cells/μL

Answer: B.

4. What is the best regimen to treat both HIV and HBV infections?

A. zidovudine/lamivudine + darunavir/ritonavir
B. abacavir/lamivudine + raltegravir
C. tenofovir/emtricitabine + zidovudine
D. tenofovir/emtricitabine/efavirenz

Answer: D.

5. HIV pre-exposure prophylaxis (PrEP) should be offered to all *except:*

A. An active heroin user.
B. An HIV-negative partner of an HIV-positive individual with an HIV RNA of 250,000 copies/mL.
C. A heterosexual woman with several sexual partners who "doesn't always use condoms."
D. A gay man in a monogamous relationship with an HIV-negative partner.

Answer: D.

389

INFECTIOUS AND METABOLIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS AND ACQUIRED IMMUNODEFICIENCY SYNDROME

HENRY MASUR, LETHA M. HEALEY, AND COLLEEN HADIGAN

INFECTIOUS COMPLICATIONS

The initial cases of the acquired immunodeficiency syndrome (AIDS) were identified when unusual infectious diseases occurred in patients who had no prior diagnosis of an immunodeficiency. *Pneumocystis* pneumonia (PCP), toxoplasma encephalitis, cytomegalovirus (CMV) retinitis, and *Mycobacterium avium* bacteremia, as well as Kaposi sarcoma and central nervous system (CNS) lymphoma were so unusual in previously healthy patients that suspicion was quickly raised that the patients must have had some new form of immune deficit, especially when individual patients manifested several such infections either serially or concurrently, and when the number of such patients rapidly increased. The specific infectious syndromes were so characteristic of this new syndrome that their occurrence in previously healthy patients was soon considered as "AIDS defining" until the retroviral etiology of the syndrome was discovered and diagnostic tests for human immunodeficiency virus (HIV) became available for widespread clinical testing.

Despite the widespread availability of effective antiretroviral regimens in the United States since the late 1990s, AIDS-related opportunistic infections are still seen frequently at many health care facilities, especially those serving populations with poor access to health care. In the United States, opportunistic infections occur in two distinct populations: those who are not under effective care and those in whom effective antiretroviral therapy (ART) has recently been started.[1]

At least 25% of HIV-infected patients in the United States are unaware of their retroviral infection. This group often presents to health care facilities with opportunistic infections as their initial clue that they have HIV infection. A substantial number of patients, additionally, are aware of their HIV

The first few years of the AIDS epidemic were devoted to learning how to recognize and treat these infectious diseases and tumors. At the onset of the epidemic, clinicians were hampered by a dearth of available and accurate diagnostic tools for many of these pathogens. There was also a dearth of therapeutic and preventive therapies for some of the common causative organisms. As better diagnostic techniques were developed, and effective drug therapies were discovered and tested, patients survived their opportunistic infections with increasing frequency. The demonstration that specific chemoprophylaxis could prevent many of these infectious diseases also improved the quality and duration of patient survival. However, patient survival did not improve dramatically until antiretroviral regimens were developed that provided durable HIV viral suppression with immunologic reconstitution, which thus substantially reduced or eliminated the occurrence of subsequent opportunistic infections.

infection but are not in care as a result of economic, behavioral, or social factors. These patients also present with initial or serial opportunistic infections because they are not benefitting from stable and effective ART.

A second population who develop opportunistic infections includes patients who have access to care and are durably suppressed virologically. In this group, opportunistic infections develop when the initiation of ART unmasks the presence of opportunistic pathogens, creating symptomatic clinical syndromes. In addition, immune reconstitution inflammatory syndromes occur in the first few weeks or months after initiation of ART, representing exaggerated immune responses to viable organisms or to antigen (Chapter 395).

In addition to the relatively acute opportunistic infections that have been traditionally associated with AIDS, as patients live longer they are developing increasing morbidity and mortality due to certain latent viruses such as hepatitis C virus (HCV), and hepatitis B virus (HBV) (Chapter 149), as well as human papillomavirus (HPV) (Chapter 373).[2] HCV and HBV progression is accelerated in HIV-infected patients compared to HIV-uninfected patients, leading to earlier development of cirrhosis, liver failure, and hepatoma.[3,4] HPV is associated with cervical carcinoma and anal carcinoma, as well as oral cancers.

In addition to opportunistic infections and malignant neoplasms, an unexpected complication of chronic HIV disease in patients who have suppressed HIV viral loads has been a persistent inflammatory state that appears to be related to low-level HIV viremia. This viremia is usually below the level of detection of standard clinical assays for blood and may be related to viral replication in poorly understood reservoirs. The persistent inflammatory state appears to accelerate atherosclerotic cardiovascular and cerebrovascular disease, renal disease, and hepatic disease. This persistent inflammatory state interacts with the AIDS-related metabolic dysfunctions, including dysglycemias and dyslipidemias, which exacerbate and complicate the inflammation-induced accelerated atherosclerosis.[5,6]

PATHOBIOLOGY

HIV infection causes cellular immune dysfunction by multifaceted mechanisms that include reducing the number and function of CD4 lymphocytes. The immune defect in patients with HIV infection is unique: in no other population do PCP, toxoplasma encephalitis, CMV retinitis, cryptococcal meningitis, cryptosporidiosis, microsporidiosis, and Kaposi sarcoma occur so frequently and with such characteristic presentations. The opportunistic infections that occur in patients with HIV infection differ substantially in their prevalence and natural history compared with patients with other immunodeficiencies. They differ in subtle ways in terms of response to therapy and prevention from the syndromes and causative organisms that occur in patients with other immunologic disorders due to corticosteroids or calcineurin inhibitors, for instance, or from immunologic and inflammatory defects associated with neutropenia or antibody deficiency or complement disorders.

The number of circulating CD4 cells is an excellent indicator of patient prognosis and of susceptibility to opportunistic infection for patients with HIV/AIDS (Fig. 389-1). Monitoring CD4 counts prospectively has thus become a cornerstone of patient management. The blood HIV viral load is also an independent predictor of host susceptibility to opportunistic infection, but is not nearly as sensitive and specific for estimating survival or for assessing susceptibility to opportunistic infection as are CD4 counts.[7] Although CD4 cells are enormously important to host defenses in all persons, the circulating CD4 count is not nearly as specific and sensitive a predictor of opportunistic infection susceptibility in any other patient population as they are in patients with HIV infection.

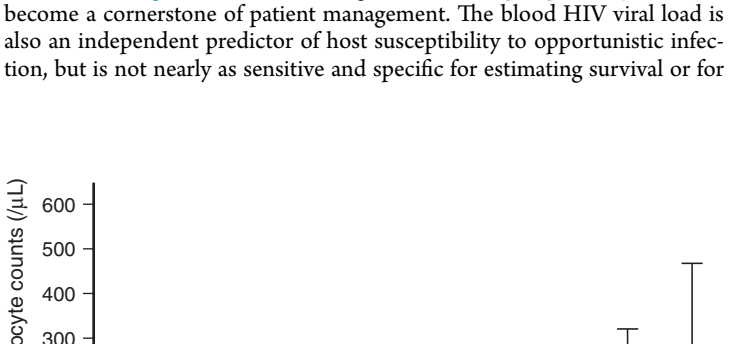

FIGURE 389-1. Distribution of CD4+ lymphocyte counts at diagnosis of opportunistic infection

The specific opportunistic infections that an HIV-infected patient develops are influenced not only by the patient's specific immunologic defects but also by environmental and behavioral factors. For instance, in areas of the world where exposure to *M. tuberculosis* is common, tuberculosis is a major cause of morbidity and mortality in patients with AIDS regardless of CD4 count, although the incidence of disease increases as the CD4 count declines. In contrast, however, in areas of the world such as the United States where tuberculosis exposure is relatively uncommon, tuberculosis is rarely seen except in immigrants and persons exposed to special populations, such as those in prisons or homeless shelters. Other mycobacteria, such as the environmental pathogen *Mycobacterium avium,* have become much more common than tuberculosis. Similarly, in many areas of the developing world, salmonellosis is a common complication of HIV infection and often causes diarrhea and life-threatening bacteremic disease. In the developed world, however, salmonella exposure is much less frequent and thus enteric disease is more likely to be caused by microsporidia, cryptosporidia, or nonopportunistic pathogens such as *Clostridium difficile* than by *Salmonella.*

Behavioral factors are also important determinants of which opportunistic infections occur. Patients with a history of intravenous drug abuse are more likely to be infected with HCV and HBV than matched patients without substance abuse histories. They are also more likely to develop nonopportunistic processes such as *Staphylococcal* sepsis because of their parenteral exposures. Men who have sex with men who develop proctitis or colitis are more likely to have lymphogranuloma venereum proctitis or gonococcal proctitis than patients with different risk factors.

The pathogens that cause active disease in patients with HIV infection may be organisms that were acquired recently or may represent reactivation of latent organisms acquired months or years previously. *Mycobacterium tuberculosis, Pneumocystis jiroveci, Trypanosoma cruzi, Leishmania donovani, Histoplasma capsulatum,* and *Coccidioides immitis* are examples of pathogens that can cause acute disease either soon after exposure or after many months or years of latency as assessed by molecular typing or clinical epidemiology. Thus, many pathogens need to be considered as possible etiologic agents despite exposure that may have occurred in the distant past.

CLINICAL MANIFESTATIONS

One of the early observations about clinical disease in patients with AIDS was that the clinical manifestations of opportunistic infections were not identical to the presentations in other immunosuppressed patients. In patients with AIDS, for instance, PCP is much more likely to manifest with subacute symptoms over weeks or months than in HIV-uninfected patients with cancer or transplant recipients who most often present acutely over a few days. When patients are diagnosed with PCP, those with AIDS are usually less hypoxemic and have less impressive radiographic infiltrates despite the longer duration of symptoms before diagnosis. The number of organisms found in sputum or bronchoalveolar lavage specimens is also greater in patients with AIDS than in other immunosuppressed individuals, such as patients with cancer or transplant recipients, despite the less severe symptoms. Patients with AIDS also are more likely to develop treatment-limiting toxicity associated with trimethoprim-sulfamethoxazole than patients with cancer or transplant recipients. Patients with AIDS are also more likely to have multiple recurrences if they are not treated with chemoprophylaxis than other immunosuppressed populations.

For infections due to *Toxoplasma gondii,* patients with HIV/AIDS characteristically develop toxoplasma encephalitis. Other immunosuppressed populations more often develop disseminated visceral disease involving the liver, spleen, or kidneys. Similarly, CMV in patients with HIV/AIDS causes retinitis and colitis. In patients with stem cell transplants, however, retinitis is relatively uncommon and pneumonia is frequent.

Some pathogens that have been recognized to cause frequent disease among patients with HIV/AIDS, such as *M. avium, Cryptosporidium, Microsporidium,* and *Bartonella,* were rarely recognized as causes of life-threatening human disease before the HIV/AIDS epidemic. Even as diagnostic studies have improved for these pathogens, they are far more often recognized among patients with HIV/AIDS than among other highly immunosuppressed patient populations. Conversely, some pathogens that were deemed likely to be AIDS associated based on the mechanisms for host

immune response, such as *Listeria monocytogenes* and disseminated *Strongyloides stercoralis,* are rarely seen in patients with HIV/AIDS. The reasons why some pathogens are unexpectedly frequent, or unexpectedly unusual despite similar environmental exposures, have not been fully elucidated.

DIAGNOSIS

For any infection in any patient population, management is likely to be more effective and to be associated with fewer complications if the specific cause is conclusively identified, the appropriate therapy is started quickly, and unnecessary drugs are avoided. For patients with HIV infection, such an approach is especially appropriate given the broad range of opportunistic and nonopportunistic infections that could cause a particular syndrome, as well as the noninfectious causes, including drug toxicities, that can masquerade as infections.

Although the diagnostic approach always should be individualized to the specific patient considering the current CD4 count, past and current exposures, prior infections, the history, physical findings, and routine laboratory tests of the current illness, certain tests are consistently useful. Blood cultures for routine bacteria and fungi, a serum cryptococcal antigen test, or a syphilis serologic test often provide useful information. If the patient has pulmonary dysfunction, Gram stain and routine culture of expectorated or induced sputum is usually useful. If a history of appropriate geographic exposure is present, serum and urine histoplasma antigen and Coccidioides antibodies also can be useful, as can a *Toxoplasma* IgG test.

The utility of specific tests needs to be validated in each patient population to determine their positive and negative predictive value. Certain tests that are useful in other patient populations or for research purposes are not necessarily useful to clinically diagnose opportunistic infections. For instance, serum polymerase chain reaction (PCR) for CMV is very useful for managing patients who have received stem cell transplants, because their positive and negative predictive values are high. However, serum CMV PCR in patients with HIV infections correlates mainly with the degree of immunosuppression and does not have sufficient positive and negative predictive value to be useful for assessing the cause of end organ disease. Serum PCR for Epstein-Barr virus (EBV), varicella zoster virus (VZV), or herpes simplex virus (HSV) also would not be useful in most circumstances for similar reasons. An increasing number of laboratories are offering other molecular tests for opportunistic pathogens, but care must be taken to be certain that the predictive value of these tests is proved. For instance, PCR for *Pneumocystis* in bronchoalveolar lavage may have excellent negative predictive value, but its positive predictive value is very low because many immunosuppressed patients appear to be colonized with *Pneumocystis* and thus a positive result does not prove with any confidence that *Pneumocystis* is the cause of the pulmonary dysfunction.

Imaging is an important aspect of patient evaluation. Patients with HIV infection may have pathologic processes despite a paucity of symptoms or normal readings on routine chest radiographs, for example. Thus, computerized tomography (CT) of the lungs may reveal unexpected pathologic findings such as diffuse interstitial infiltrates suggestive of PCP despite the absence of cough, shortness of breath, or oxygen desaturation. Such a finding could lead to an induced sputum or bronchoalveolar lavage diagnosis of the process at a time when disease is mild and the likelihood of successful treatment is high. CT of the abdomen also should be considered in patients with low CD4 counts even in the absence of abdominal symptoms, because such a study may reveal unexpected adenopathy or organ infiltration that could be readily biopsied more feasibly than other more obvious clinical manifestations. Positron emission tomography and nuclear scans have roles for identifying the etiology of infectious syndromes.

TREATMENT

Empirical Management

For the initial management of a presumed infectious syndrome in a patient with HIV infection or AIDS, clinicians need to determine the urgency of starting therapy before the specific causative process is definitively identified. Given the range of processes that can cause disease in patients with HIV infection or AIDS, the optimal approach is to establish the specific cause before starting therapy. However, some patients will be too sick or deteriorating too quickly to permit withholding therapy until a diagnosis can be established. Thus, for some patients, empirical therapy may be the best management strategy, with careful monitoring of the patient to determine if the therapy is effective.

When assessing an HIV-infected patient with any clinical syndrome, especially a syndrome associated with fever, opportunistic infections are immediate considerations. However, the likelihood of an opportunistic infection depends on the current CD4 count: if the patient's current CD4 count is greater than 200 to 300 cells/μL, the likelihood of most opportunistic infections (other than tuberculosis) is low (but not zero). For any patient, regardless of CD4 count, common community-acquired, nonopportunistic infections also must be considered because HIV-infected patients are equally susceptible to these as their HIV-uninfected counterparts. In addition, noninfectious syndromes must be considered, especially as the patient population ages and congestive heart failure, cerebrovascular disease, or chronic renal disease occur, potentially accelerated by the HIV-related inflammatory state. Patients also may have more than one process occurring concurrently. A familiar scenario, for instance, for a patient with documented PCP, would be the failure to recognize that the reason for pulmonary deterioration is not progressive PCP, but superimposed congestive heart failure, pulmonary hypertension, pulmonary emboli, or secondary lung infection due to methicillin-resistant *Staphylococcus aureus* (MRSA), *Streptococcus pneumoniae,* or *Cryptococcus neoformans*.

For some syndromes, empirical therapy is appropriate in most patients, with response to therapy providing a presumptive diagnosis. For instance, an empiric 2-week course of pyrimethamine plus sulfadiazine would be appropriate for a patient with AIDS with a CNS mass lesion, CD4 count less than 100 cells/μL, and positive antitoxoplasma serum immunoglobulin G (IgG), before a brain biopsy would be performed. Given the potential morbidity of a brain biopsy, and the high probability that a patient with AIDS with cerebral toxoplasmosis would demonstrate clinical and radiologic improvement within 14 days, such an approach has been considered preferred compared to immediate brain biopsy or even, in some circumstances, lumbar puncture. Similarly, for a patient with a CD4 count less than 200 cells/μL who presents with fever, cough, shortness of breath, severe hypoxemia, and diffuse bilateral interstitial pulmonary infiltrates, empirical therapy with ceftriaxone or vancomycin, plus azithromycin, plus trimethoprim-sulfamethoxazole to adequately provide coverage against common causes of community-acquired pneumonia as well as PCP would often be appropriate if the patient were too unstable to tolerate bronchoscopy without a high risk for intubation.

Definitive Therapy

The NIH-CDC-HIVMA Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents and other chapters in this text provide details on the diagnostic, therapeutic, and preventive approaches to specific syndromes. The drugs of choice are also listed in Table 389-1, adapted from the CDC-NIH-IDSA Guideline on Management of Opportunistic Infections in Adults and Adolescents, which is updated regularly online throughout the year (http://www.aidsinfo.nih.gov).

The treatments for opportunistic infections change as new drugs and new data become available.[8] Thus major AIDS guidelines are now updated promptly on-line (www.aidsinfo.nih.gov). For hepatitis-C, recommendations are changing so rapidly that the on-line site should be consulted before therapy is initiated unless the provider is very familiar with current data (www.hcvguidelines.org).

The institution of therapeutic or preventive drugs requires careful considerations of pharmacokinetics and drug-drug interactions. Patients with HIV infection often have organ dysfunction that may alter absorption or excretion of drugs. These patients are also often on multiple drugs (both AIDS related and AIDS unrelated) that can interact with clinically important consequences for drug effectiveness or toxicity. Such therapy thus requires considerable experience and consultation with up-to-date references for guidance.

When a patient with HIV/AIDS who has not been receiving ART develops an opportunistic infection, prospective studies demonstrate that the patient will have longer survival and fewer AIDS-defining complications if the patient is put promptly on ART. The definition of "prompt," that is, the decision as to how soon to start ART, is a complex analysis that must factor in the patient's willingness and ability to take ART, the evolution of the opportunistic infection if ART is not initiated, access to medical care and drugs after hospitalization, ability to absorb the drugs, potential interactions of ART with other drugs, including those used to treat the opportunistic infection, the patient's ability to tolerate potential drug toxicities, and the possible consequences if immune reconstitution inflammatory syndrome occurs.[9] The general principle is to start ART as soon as possible, but each patient will require individual assessment to determine the optimal interval between recognition of an opportunistic infection and initiation of ART.

When patients who are already receiving ART develop an opportunistic infection or any other complication not directly related to the drug itself, ART should be continued. The regimen should be reassessed to ensure that it is optimal in terms of antiviral activity, tolerability, potential toxicity and drug interactions, and the patient's ability to attain adequate serum levels given their ability to absorb oral drugs.

TABLE 389-1 PROPHYLAXIS TO PREVENT FIRST EPISODE OF OPPORTUNISTIC DISEASE

OPPORTUNISTIC INFECTIONS	INDICATION	PREFERRED	ALTERNATIVE
Streptococcus pneumoniae	For individuals who have not received any pneumococcal vaccine, regardless of CD4 count, followed by:	PCV13 0.5 mL IM × 1	PPV23 0.5 mL IM × 1
	• If CD4 count ≥ 200 cells/μL	PPV23 0.5 mL IM at least 8 wk after the PCV13 vaccine	
	• If CD4 count < 200 cells/μL	PPV23 can be offered at least 8 wk after receiving PCV13 or can wait until CD4 count increased to > 200 cells/μL	
	For individuals who have previously received PPV23	One dose of PCV13 should be given at least 1 yr after the last receipt of PPV23	
	Revaccination		
	• If age 19-64 yr and ≥ 5 yr since the first PPV23 dose	PPV23 0.5 mL IM × 1	
	• If age ≥ 65 yr and if ≥ 5 yr since the previous PPV23 dose	PPV23 0.5 mL IM × 1	
Influenza A and B virus	All HIV-infected patients	Inactivated influenza vaccine annually (per recommendation for the season) Live-attenuated influenza vaccine is contraindicated in HIV-infected patients	
Syphilis	For individuals exposed to a sex partner with a diagnosis of primary, secondary, or early latent syphilis within past 90 days *Or* For individuals exposed to a sex partner > 90 days before syphilis diagnosis in the partner, if serologic test results are not available immediately and the opportunity for follow-up is uncertain	Benzathine penicillin G 2.4 million U IM for 1 dose	*For penicillin-allergic patients:* • Doxycycline 100 mg PO q12h for 14 days *Or* • Ceftriaxone 1 g/day IM or IV for 8-10 days *Or* • Azithromycin 2 g PO for 1 dose; not recommended for MSM or pregnant women
Histoplasma capsulatum	CD4 count ≤ 150 cells/μL and at high risk because of occupational exposure or lives in a community with a hyperendemic rate of histoplasmosis (>10 cases/100 patient-years)	Itraconazole 200 mg/day PO	

(Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents. *http://aidsinfo.nih.gov/guidelines*.)
HIV = human immunodeficiency virus; IM = intramuscularly; IV = intravenously; MSM = men who have sex with men; PO = orally.

PREVENTION

Soon after the initial recognition of AIDS, before the era of ART or pathogen specific chemoprophylaxis, clinicians recognized that PCP ultimately occurred in 60 to 80% of patients in North America. Moreover, many of the patients who survived their first episode of PCP had one or more subsequent episodes. One of the first interventions demonstrated to prolong life was the institution of anti-*Pneumocystis* prophylaxis for patients who had oral thrush, oral hairy leukoplakia, a prior episode of PCP, or a CD4 count less than 200 cells/mm^3. Subsequently, the concept of primary and secondary chemoprophylaxis was extended to other pathogens such as *M. avium* complex (MAC) and toxoplasma.

These observations about *Pneumocystis,* MAC, and toxoplasma led to the development of a comprehensive preventive strategy to minimize the impact of opportunistic infections on those HIV-infected individuals who are immunologically vulnerable as measured by their CD4 count and viral load or by prior experience with an opportunistic infection (CDC-NIH-IDSA Guideline on Management of Opportunistic Infections in Adults and Adolescents, http://www.aidsinfo.nih.gov). Specific chemotherapy for primary prevention is indicated for the duration of immunosuppression, with the CD4 count thresholds depending on the pathogen. Chronic suppressive therapy should be continued for durations that depend on the pathogen and the patient's CD4 count. Recommendations for primary prophylaxis are summarized in Table 389-2; more complete information on primary and secondary prophylaxis is available in the CDC-NIH-IDSA Guideline on Management of Opportunistic Infections in Adults and Adolescents (http://www.aidsinfo.nih.gov).

Although immune reconstitution with ART is the most effective method to prevent opportunistic infections, many patients with low CD4 counts and uncontrolled viremia will continue to benefit from chemoprophylaxis. These efforts should be modified when patients have had a durable suppression of their viremia and increase in their circulating CD4 counts.

Preventive strategies focus not only on chemoprophylaxis but also on immunization and reducing exposure to opportunistic pathogens. Examples of exposure reduction interventions likely to be effective would be reducing exposure of patients to puppies and kittens from commercial breeders and reducing consumption of untreated surface water to prevent cryptosporidiosis. Other useful interventions would include precautions in travel to the Southwest United States to avoid coccidioidomycosis and avoiding exposure to outdoor cats and rare meat to reduce the likelihood of toxoplasmosis.

Immunizations such as pneumococcal vaccine, HPV vaccine, and hepatitis B vaccine also can be important, although host response to vaccines is reduced when patients are immunosuppressed. Live virus vaccines must be avoided in patients with low CD4 counts.

METABOLIC DISORDERS

With effective and well-tolerated ART, HIV-infected patients have a survival that is almost as long as HIV-uninfected persons.[10] It has become clear that patients with HIV infection experience increased incidence of cardiovascular and cerebrovascular disease; metabolic diseases, including diabetes mellitus; chronic kidney and liver disease; and perhaps accelerated neurocognitive decline, compared to HIV-uninfected patients. The proposed etiology for these disorders appears to be multifactorial and includes various ART-associated toxicities, immune dysregulation, and chronic inflammation related to chronic retroviral disease, even in the context of durable viral suppression.

Text continued on p. 2302

TABLE 389-2 TREATMENT OF ACQUIRED IMMUNODEFICIENCY VIRUS–ASSOCIATED OPPORTUNISTIC INFECTIONS (INCLUDES RECOMMENDATIONS FOR ACUTE TREATMENT AND SECONDARY PROPHYLAXIS/CHRONIC SUPPRESSIVE/MAINTENANCE THERAPY)

OPPORTUNISTIC INFECTION	PREFERRED THERAPY	ALTERNATIVE THERAPY	OTHER COMMENTS
Pneumocystis pneumonia (PCP) infection	Patients who develop PCP despite TMP-SMX prophylaxis usually can be treated with standard doses of TMP-SMX. Duration of PCP treatment: 21 days *For moderate-to-severe PCP:* • TMP-SMX: (TMP 15-20 mg and SMX 75-100 mg)/kg/day q6h or q8h IV; can switch to PO after clinical improvement *For mild-to-moderate PCP:* • TMP-SMX: (TMP 15-20 mg and SMX 75-100 mg)/kg/day, given PO in three divided doses *Or* • TMP-SMX: (160 mg/800 mg or DS) 2 tablets q8h PO *Secondary prophylaxis, after completion of PCP treatment:* • TMP-SMX DS: 1 tablet/day PO *Or* • TMP-SMX (80 mg/400 mg or SS): 1 tablet/day PO	*For moderate-to-severe PCP:* • Pentamidine 4 mg/kg/day IV infused over ≥ 60 min; can reduce dose to 3 mg/kg/day IV because of toxicities *Or* • Primaquine 30 mg (base)/day PO + (clindamycin 600 mg q6h IV or 900 mg q8h IV) or (clindamycin 300 mg q6h PO or 450 mg q8h PO) *For mild-to-moderate PCP:* • Dapsone 100 mg/day PO + TMP 5 mg/kg q8h PO *Or* • Primaquine 30 mg (base)/day PO + (clindamycin 300 mg q6h or 450 mg q8h PO) *Or* • Atovaquone 750 mg q12h PO with food *Secondary prophylaxis, after completion of PCP treatment:* • TMP-SMX DS: 1 tablet PO three times weekly *Or* • Dapsone 100 mg/day PO *Or* • Dapsone 50 mg/day PO + (pyrimethamine 50 mg + leucovorin 25 mg)/wk PO *Or* • (Dapsone 200 mg + pyrimethamine 75 mg + leucovorin 25 mg)/week PO *Or* • Aerosolized pentamidine 300 mg/mo via Respirgard II nebulizer *Or* • Atovaquone 1500 mg/day PO *Or* • (Atovaquone 1500 mg + pyrimethamine 25 mg + leucovorin 10 mg)/day PO	*Indications for adjunctive corticosteroids:* • PaO_2 < 70 mm Hg at room air *Or* • Alveolar-arterial O_2 gradient > 35 mm Hg *Prednisone doses (beginning as early as possible and within 72 hours of PCP therapy):* • Days 1-5: 40 mg q12h PO • Days 6-10: 40 mg/day PO • Days 11-21: 20 mg/day PO IV methylprednisolone can be administered as 75% of prednisone dose. Benefit of corticosteroid if started after 72 hr of treatment is unknown, but some clinicians will use it for moderate-to-severe PCP. Whenever possible, patients should be tested for G6PD before use of dapsone or primaquine. Alternative therapy should be used in patients found to have G6PD deficiency. Patients who are receiving pyrimethamine/sulfadiazine for treatment or suppression of toxoplasmosis do not require additional PCP prophylaxis. If TMP-SMX is discontinued because of a mild adverse reaction, reinstitution should be considered after the reaction resolves. The dose can be increased gradually (desensitization) or reduced or the frequency modified. TMP-SMX should be permanently discontinued in patients with possible or definite Stevens-Johnson syndrome or toxic epidermal necrosis.

Toxoplasma gondii encephalitis	*Treatment of acute infection:* • Pyrimethamine 200 mg PO 1 time, followed by weight-based therapy as follows: • If < 60 kg, pyrimethamine 50 mg/day PO + sulfadiazine 1000 mg q6h PO + leucovorin 10-25 mg/day PO • If > 60 kg, pyrimethamine 75 mg/day PO + sulfadiazine 1500 mg q6h PO + leucovorin 10-25 mg/day PO • Leucovorin dose can be increased to 50 mg q12h or q24h *Duration for acute therapy:* • At least 6 wk; longer duration if clinical or radiologic disease is extensive or response is incomplete at 6 wk *Chronic maintenance therapy:* • Pyrimethamine 25-50 mg/day PO + sulfadiazine 2000-4000 mg/day PO (in two to four divided doses) + leucovorin 10-25 mg/day PO	*Treatment of acute infection:* • Pyrimethamine (leucovorin)* + clindamycin 600 mg q6h IV or PO *Or* • TMP-SMX (TMP 5 mg/kg and SMX 25 mg/kg) q12h IV or PO *Or* • Atovaquone 1500 mg q12h PO with food + pyrimethamine (leucovorin)* *Or* • Atovaquone 1500 mg q12h PO with food + sulfadiazine 1000-1500 mg q6h PO (weight-based dosing, as in preferred therapy) *Or* • Atovaquone 1500 mg q12h PO with food *Or* • Pyrimethamine (leucovorin)* + azithromycin 900-1200 mg/day PO *Chronic maintenance therapy:* • Clindamycin 600 mg q8h PO + (pyrimethamine 25-50 mg + leucovorin) *Or* • TMP-SMX DS 1 tablet q12h *Or* • Atovaquone 750-1500 mg q12h PO + (pyrimethamine 25 mg + leucovorin 10 mg)/day PO *Or* • Atovaquone 750-1500 mg q12h PO + sulfadiazine 2000-4000 mg/day PO (in two to four divided doses) *Or* • Atovaquone 750-1500 mg q12h PO with food • Pyrimethamine and leucovorin doses are the same as for preferred therapy.	Adjunctive corticosteroids (e.g., dexamethasone) should be administered only when clinically indicated to treat mass effect associated with focal lesions or associated edema; discontinue as soon as clinically feasible. Anticonvulsants should be administered to patients with a history of seizures and continued through acute treatment, but should not be used as seizure prophylaxis. If clindamycin is used in place of sulfadiazine, additional therapy must be added to prevent PCP.
Mycobacterium tuberculosis (TB) disease	After collecting specimen for culture and molecular diagnostic tests, empirical TB treatment should be started in individuals with clinical and radiographic presentation suggestive of TB. Initial phase (2 mo, given daily, 5-7 times/wk by DOT): • INH + [RIF or RFB] + PZA + EMB, Continuation phase: • INH + (RIF or RFB) daily (5-7 times/wk) or three times weekly Total duration of therapy (for drug-susceptible TB): • Pulmonary TB: 6 mo • Pulmonary TB and culture- positive after 2 mo of TB treatment: 9 mo • Extrapulmonary TB with a CNS infection: 9-12 mo • Extrapulmonary TB with bone or joint involvement: 6-9 mo • Extrapulmonary TB in other sites: 6 mo Total duration of therapy should be based on number of doses received, not on calendar time.	*Treatment for Drug-Resistant TB* Resistant to INH: • (RIF or RFB) + EMB + PZA + (moxifloxacin or levofloxacin) for 2 mo; followed by (RIF or RFB) + EMB + (moxifloxacin or levofloxacin) for 7 mo Resistant to rifamycin + 1 other drug: • Regimen and duration of treatment should be individualized based on resistance pattern, clinical and microbiologic responses, and in close consultation with experienced specialists.	Adjunctive corticosteroid improves survival for TB meningitis and pericarditis. RIF is ***not recommended*** for patients receiving HIV PI because of its induction of PI metabolism. RFB is a less potent CYP3A4 inducer than RIF and is preferred in patients receiving PIs. Once weekly rifapentine can result in development of rifamycin resistance in HIV-infected patients and is ***not recommended***. Therapeutic drug monitoring should be considered in patients receiving rifamycin and interacting ART. Paradoxical IRIS that is not severe can be treated with NSAIDs without a change in TB or HIV therapy. For severe IRIS reaction, consider prednisone and taper over 4 wk based on clinical symptoms. For example: • If receiving RIF: prednisone 1.5 mg/kg/day for 2 wk, then 0.75 mg/kg/day for 2 wk • If receiving RFB: prednisone 1 mg/kg/day for 2 wk, then 0.5 mg/kg/day for 2 wk A more gradual tapering schedule over a few months may be necessary for some patients.

TABLE 389-2 TREATMENT OF ACQUIRED IMMUNODEFICIENCY VIRUS–ASSOCIATED OPPORTUNISTIC INFECTIONS (INCLUDES RECOMMENDATIONS FOR ACUTE TREATMENT AND SECONDARY PROPHYLAXIS/CHRONIC SUPPRESSIVE/MAINTENANCE THERAPY)—cont'd

OPPORTUNISTIC INFECTION	PREFERRED THERAPY	ALTERNATIVE THERAPY	OTHER COMMENTS
Disseminated *Mycobacterium avium* complex (MAC) disease	*At least two drugs as initial therapy with:* • Clarithromycin 500 mg q12h PO + ethambutol 15 mg/kg/day PO *Or* • Azithromycin 500-600 mg + ethambutol 15 mg/kg)/day PO if drug interaction or intolerance precludes the use of clarithromycin Duration: • At least 12 mo of therapy, can discontinue if no signs and symptoms of MAC disease and sustained (>6 mo) CD4 count>100 cells/μL in response to ART	Addition of a third or fourth drug should be considered for patients with advanced immunosuppression (CD4 counts < 50 cells/μL), with high mycobacterial loads (>2 log CFU/mL of blood), or in the absence of effective ART. *Third or fourth drug options may include:* • RFB 300 mg/day PO (dosage adjustment may be necessary based on drug interactions) • Amikacin 10-15 mg/kg/day IV *Or* • Streptomycin 1 g/day IV or IM *Or* • Moxifloxacin 400 mg/day PO or levofloxacin 500 mg/day PO	Testing of susceptibility to clarithromycin and azithromycin is recommended. NSAIDs can be used for patients who experience moderate-to-severe symptoms attributed to IRIS. If IRIS symptoms persist, short-term (4-8 wk) systemic corticosteroids (equivalent to 20-40 mg prednisone) can be used.
Salmonellosis	All HIV-infected patients with salmonellosis should be treated because of high risk for bacteremia. • Ciprofloxacin 500-750 mg q12h PO (or 400 mg q12h IV) if susceptible *Duration of therapy:* For gastroenteritis without bacteremia: • If CD4 count ≥ 200 cells/μL: 7-14 days • If CD4 count < 200 cells/μL: 2-6 wk For gastroenteritis with bacteremia: • If CD4 count ≥ 200/μL: 14 days; longer duration if bacteremia persists or if the infection is complicated (e.g., if metastatic foci of infection are present) • If CD4 count < 200 cells/μL: 2-6 wk *Secondary prophylaxis should be considered for:* • Patients with recurrent *Salmonella* gastroenteritis ± bacteremia *Or* • Patients with CD4 < 200 cells/μL with severe diarrhea	• Levofloxacin 750 mg q24h PO or IV *Or* • Moxifloxacin 400 mg q24h PO or IV *Or* • TMP, 160 mg, SMX 800 mg q12h (PO or IV) *Or* • Ceftriaxone 1 g q24h IV *Or* • Cefotaxime 1 g q8h IV	Oral or intravenous rehydration if indicated. Antimotility agents should be avoided. The role of long-term secondary prophylaxis in patients with recurrent *Salmonella* bacteremia is not well established. Must weigh benefit against risks for long-term antibiotic exposure. Effective ART may reduce the frequency, severity, and recurrence of *Salmonella* infections.
Mucocutaneous candidiasis	*For oropharyngeal candidiasis; initial episodes (for 7-14 days):* Oral therapy: • Fluconazole 100 mg/day PO *Or* Topical therapy: • Clotrimazole troches, 10 mg PO five times daily *Or* • Miconazole mucoadhesive buccal 50-mg tablet—apply to mucosal surface over the canine fossa once daily (do not swallow, chew, or crush) *For esophageal candidiasis (for 14-21 days):* • Fluconazole 100 mg (up to 400 mg)/day PO or IV *Or* • Itraconazole oral solution 200 mg/day PO *For uncomplicated vulvovaginal candidiasis:* • Oral fluconazole 150 mg for 1 dose *Or* • Topical azoles (clotrimazole, butoconazole, miconazole, tioconazole, or terconazole) for 3-7 days *For severe or recurrent vulvovaginal candidiasis:* • Fluconazole 100-200 mg/day PO for ≥ 7 days *Or* • Topical antifungal ≥ 7 days	*For oropharyngeal candidiasis; initial episodes (for 7-14 days):* Oral therapy: • Itraconazole oral solution 200 mg/day PO *Or* • Posaconazole oral solution 400 mg q12h PO for 1 day, then 400 mg/day Topical therapy: • Nystatin suspension 4-6 mL q6h 1-2 flavored pastilles four or five times daily *For esophageal candidiasis (for 14-21 days):* • Voriconazole 200 mg q12h PO or IV *Or* • Posaconazole 400 mg q12h PO *Or* • Anidulafungin 100 mg IV 1 time, then 50 mg/day IV *Or* • Caspofungin 50 mg/day IV *Or* • Micafungin 150 mg/day IV *Or* • Amphotericin B deoxycholate 0.6 mg/kg/day IV *Or* • Lipid formulation of amphotericin B 3-4 mg/kg/day IV *For uncomplicated vulvovaginal candidiasis:* • Itraconazole oral solution 200 mg/day PO for 3-7 days	Chronic or prolonged use of azoles may promote development of resistance. Higher relapse rate for esophageal candidiasis seen with echinocandins than with fluconazole use. Suppressive therapy usually not recommended unless patients have frequent or severe recurrences. *If decision is to use suppressive therapy:* Oropharyngeal candidiasis: • Fluconazole 100 mg/day PO or three times weekly • Itraconazole oral solution 200 mg/day PO Esophageal candidiasis: • Fluconazole 100-200 mg/day PO • Posaconazole 400 mg q12h PO Vulvovaginal candidiasis: • Fluconazole 150 mg PO once weekly

Cryptococcosis	*Cryptococcal meningitis:* Induction therapy (for at least 2 wk, followed by consolidation therapy): • Liposomal amphotericin B 3-4 mg/kg/day IV + flucytosine 25 mg/kg PO QID (*Note:* Flucytosine dose should be adjusted in patients with renal dysfunction.) Consolidation therapy (for at least 8 wk, followed by maintenance therapy): • Fluconazole 400 mg/day PO (or IV) Maintenance therapy Liposomal: • Fluconazole 200 mg/day PO for at least 12 mo *For non-CNS, extrapulmonary cryptococcosis and diffuse pulmonary disease:* • Treatment same as for cryptococcal meningitis *Non-CNS cryptococcosis with mild-to-moderate symptoms and focal pulmonary infiltrates:* • Fluconazole, 400 mg/day PO for 12 mo	*Cryptococcal meningitis:* Induction therapy (for at least 2 wk, followed by consolidation therapy): • Amphotericin B deoxycholate 0.7 mg/kg/day IV + flucytosine 25 mg/kg q6h PO *Or* • Amphotericin B lipid complex 5 mg/kg/day IV + flucytosine 25 mg/kg q6h PO *Or* • Liposomal amphotericin B 3-4 mg/kg/day IV + fluconazole 800 mg/day PO or IV *Or* • Amphotericin B deoxycholate 0.7 mg/kg/day IV + fluconazole 800 mg/day PO or IV *Or* • Fluconazole 400-800 mg/day PO or IV + flucytosine 25 mg/kg q6h PO *Or* • Fluconazole 1200 mg/day PO or IV *Consolidation therapy (for at least 8 wk, followed by maintenance therapy):* • Itraconazole 200 mg q12h PO for 8 wk—less effective than fluconazole *Maintenance therapy:* • No alternative therapy recommendation	Addition of flucytosine to amphotericin B has been associated with more rapid sterilization of CSF and decreased risk for subsequent relapse. Patients receiving flucytosine should have either blood levels monitored (peak level 2 hr after dose should be 30-80 µg/mL) or close monitoring of blood counts for development of cytopenia. Dosage should be adjusted in patients with renal insufficiency. Opening pressure should always be measured when an LP is performed. Repeated LPs or CSF shunting are essential to effectively manage increased ICP. Corticosteroids and mannitol are ineffective in reducing ICP and are **not recommended**. Some specialists recommend a brief course of corticosteroid for management of severe IRIS symptoms.
Histoplasmosis	*Moderately severe to severe disseminated disease:* Induction therapy (for at least 2 wk or until clinically improved): • Liposomal amphotericin B 3 mg/kg/day IV Maintenance therapy: • Itraconazole 200 mg q8h PO for 3 days, then 200 mg q12h PO *Less severe disseminated disease:* Induction and maintenance therapy: • Itraconazole 200 mg q8h PO for 3 days, then 200 mg q12h PO Duration of therapy: • At least 12 mo *Meningitis:* Induction therapy (4-6 wk): • Liposomal amphotericin B 5 mg/kg/day Maintenance therapy: • Itraconazole 200 mg q8h to q12h PO to for ≥ 1 yr and until resolution of abnormal CSF findings Long-term suppression therapy: For patients with severe disseminated or CNS infection after completion of at least 12 mo of therapy and those who relapse despite appropriate therapy: • Itraconazole 200 mg/day PO	*Moderately severe to severe disseminated disease:* Induction therapy (for at least 2 wk or until clinically improved): • Amphotericin B lipid complex 3 mg/kg/day IV *Or* • Amphotericin B cholesteryl sulfate complete 3 mg/kg/day IV Alternatives to itraconazole for maintenance therapy or treatment of less severe disease: • Voriconazole 400 mg q12h PO for 1 day, then 200 mg q12h *Or* • Posaconazole 400 mg q12h PO • Fluconazole 800 mg/day PO *Meningitis:* • No alternative therapy recommendation Long-term suppression therapy: • Fluconazole 400 mg/day PO	Itraconazole, posaconazole, and voriconazole may have significant interactions with certain ARV agents. These interactions are complex and can be bi-directional. Therapeutic drug monitoring and dosage adjustment may be necessary to ensure triazole antifungal and ARV efficacy and reduce concentration-related toxicities. Random serum concentration of itraconazole + hydroxy itraconazole should be > 1 µg/mL. Clinical experience with voriconazole or posaconazole in the treatment of histoplasmosis is limited. Acute pulmonary histoplasmosis in HIV-infected patients with CD4 counts > 300 cells/µL should be managed as in nonimmunocompromised host.

TABLE 389-2 TREATMENT OF ACQUIRED IMMUNODEFICIENCY VIRUS–ASSOCIATED OPPORTUNISTIC INFECTIONS (INCLUDES RECOMMENDATIONS FOR ACUTE TREATMENT AND SECONDARY PROPHYLAXIS/CHRONIC SUPPRESSIVE/MAINTENANCE THERAPY)—cont'd

OPPORTUNISTIC INFECTION	PREFERRED THERAPY	ALTERNATIVE THERAPY	OTHER COMMENTS
Cytomegalovirus (CMV) disease	*CMV retinitis:* Induction therapy: For immediate sight-threatening lesions (adjacent to the optic nerve or fovea): • Intravitreal injections of ganciclovir (2 mg) or foscarnet (2.4 mg) for one to four doses over a period of 7-10 days to achieve high intraocular concentration faster • Plus one of the listed preferred or alternative systemic therapy: Preferred systemic induction therapy: Valganciclovir 900 mg q12h PO for 14-21 days For peripheral lesions: Administer one of the preferred or alternative systemic therapy Chronic maintenance (secondary prophylaxis): Valganciclovir 900 mg/day PO *CMV esophagitis or colitis:* • Ganciclovir 5 mg/kg q12h IV; may switch to valganciclovir 900 mg q12h PO once the patient can tolerate oral therapy • Duration: 21-42 days or until symptoms have resolved • Maintenance therapy is usually not necessary, but should be considered after relapses *Well-documented. histologically confirmed CMV pneumonia:* • Experience for treating CMV pneumonitis in patients with HIV is limited. Use of IV ganciclovir or IV foscarnet is reasonable (doses same as for CMV retinitis) • The optimal duration of therapy and the role of oral valganciclovir have not been established *CMV neurologic disease:* (***Note:* Treatment should be initiated promptly.**) • Ganciclovir 5 mg/kg q12h IV + (foscarnet 90 mg/kg q12h IV or 60 mg/kg q8h IV) to stabilize disease and maximize response, continue until symptomatic improvement and resolution of neurologic symptoms • The optimal duration of therapy and the role of oral valganciclovir have not been established	*CMV retinitis:* Alternative systemic induction therapy: • Ganciclovir 5 mg/kg q12h IV for 14-21 days *Or* • Foscarnet 90 mg/kg q12h IV or 60 mg/kg q8h for 14-21 days *Or* • Cidofovir 5 mg/kg/wk IV for 2 wk; saline hydration before and after therapy and probenecid, 2 g PO 3 hr before dose, followed by 1 g PO 2 hr and 8 hours after the dose (total of 4 g). (*Note:* This regimen should be avoided in patients with sulfa allergy because of cross sensitivity with probenecid.) Chronic maintenance (secondary prophylaxis): • Ganciclovir 5 mg/kg IV 5-7 times weekly *Or* • Foscarnet 90-120 mg/kg IV once daily *Or* • Cidofovir 5 mg/kg IV every other week with saline hydration and probenecid as above *CMV esophagitis or colitis:* • Foscarnet 90 mg/ kg q12h IV or 60 mg/kg q8h for patients with treatment-limiting toxicities to ganciclovir or with ganciclovir resistance *Or* • Valganciclovir 900 mg q12h PO in milder disease and if able to tolerate PO therapy *Or* • For mild cases, if ART can be initiated without delay, consider withholding CMV therapy. • Duration: 21-42 days or until symptoms have resolved	The choice of therapy for CMV retinitis should be individualized, based on location and severity of the lesions, level of immunosuppression, and other factors (e.g., concomitant medications and ability to adhere to treatment). The ganciclovir ocular implant, which is effective for treatment of CMV retinitis is no longer available. For sight-threatening retinitis, intravitreal injections of ganciclovir or foscarnet can be given to achieve higher ocular concentration faster. The choice of chronic maintenance therapy (route of administration and drug choices) should be made in consultation with an ophthalmologist. Considerations should include the anatomic location of the retinal lesion, vision in the contralateral eye, the patients' immunologic and virologic status and response to ART. Patients with CMV retinitis who discontinue maintenance therapy should undergo regular eye examinations—normally every 3 mo—for early detection of relapse IRU, and then annually after immune reconstitution. IRU may develop in the setting of immune reconstitution. *Treatment of IRU:* • Periocular corticosteroid or short courses of systemic steroid Initial therapy in patients with CMV retinitis, esophagitis, colitis, and pneumonitis should include initiation or optimization of ART.

Herpes simplex virus (HSV) disease	*Orolabial lesions (for 5-10 days):* • Valacyclovir 1 g q12h PO *Or* • Famciclovir 500 mg q12h PO *Or* • Acyclovir 400 mg q8h PO *Initial or recurrent genital HSV (For 5-14 days):* • Valacyclovir 1 g q12h PO *Or* • Famciclovir 500 mg q12h PO *Or* • Acyclovir 400 mg q8h PO *Severe mucocutaneous HSV:* • Initial therapy acyclovir 5 mg/kg q8h IV • After lesions begin to regress, change to PO therapy, as above. Continue until lesions are completely healed. *Chronic suppressive therapy:* For patients with severe recurrences of genital herpes or patients who want to minimize frequency of recurrences: • Valacyclovir 500 mg q12h PO • Famciclovir 500 mg q12h PO • Acyclovir 400 mg q12h PO • Continue indefinitely regardless of CD4 cell count.	*For acyclovir-resistant HSV:* Preferred therapy: • Foscarnet 80-120 mg/kg/day IV in two or three divided doses until clinical response Alternative therapy: • IV cidofovir (dosage as in CMV retinitis) *Or* • Topical trifluridine *Or* • Topical cidofovir *Or* • Topical imiquimod • Duration of therapy: 21-28 days or longer	Patients with HSV infections can be treated with episodic therapy when symptomatic lesions occur or with daily suppressive therapy to prevent recurrences. Topical formulations of trifluridine and cidofovir are not commercially available. Extemporaneous compounding of topical products can be prepared using trifluridine ophthalmic solution and the IV formulation of cidofovir.
Varicella zoster virus (VZV) disease	*Primary varicella infection (chickenpox):* Uncomplicated cases (for 5-7 days): • Valacyclovir 1 g q8h PO *Or* • Famciclovir 500 mg q8h PO Severe or complicated cases: • Acyclovir 10-15 mg/kg q8h IV for 7-10 days • Can switch to oral valacyclovir, famciclovir, or acyclovir after defervescence if no evidence of visceral involvement. *Herpes zoster (shingles):* Acute localized dermatomal: • For 7-10 days; consider longer duration if lesions are slow to resolve • Valacyclovir 1 g q8h PO *Or* • Famciclovir 500 mg q8h Extensive cutaneous lesions or visceral involvement: • Acyclovir 10-15 q8h mg/kg IV until clinical improvement is evident • Can switch to PO therapy (valacyclovir, famciclovir, or acyclovir) after clinical improvement (i.e., when no new vesicle formation or improvement of signs and symptoms of visceral VZV), to complete a 10-14 day course. Progressive outer retinal necrosis (PORN): • (Ganciclovir 5 mg/kg ± foscarnet 90 mg/kg) q12h IV + (ganciclovir 2 mg/0.05 mL ± foscarnet 1.2 mg/0.05 mL) intravitreal injection twice weekly • Initiate or optimize ART Acute retinal necrosis (ARN): • (Acyclovir 10-15 mg/kg q8h IV) + (ganciclovir 2 mg/0.05 mL intravitreal injection twice weekly × 1-2 doses) for 10-14 days, followed by valacyclovir 1 g q8h PO for 6 wk	*Primary varicella infection (chickenpox):* Uncomplicated cases (for 5-7 days): • Acyclovir 800 mg PO 5 times per day *Herpes zoster (shingles)* Acute localized dermatomal: • For 7-10 days; consider longer duration if lesions are slow to resolve • Acyclovir 800 mg PO 5 times per day	In managing VZV retinitis, consultation with an ophthalmologist experienced in management of VZV retinitis is strongly recommended. Duration of therapy for VZV retinitis is not well defined, and should be determined based on clinical, virologic, and immunologic responses and ophthalmologic responses. Optimization of ART is recommended for serious and difficult-to-treat VZV infections (e.g., retinitis, encephalitis).

ART = antiretroviral therapy; ARV = antiretroviral; CNS = central nervous system; DOT = directly observed therapy; EMB = ethambutol; ICP = intracranial pressure; IRIS = immune reconstitution inflammatory syndrome; IRU = immune recovery uveitis; NSAIDs = nonsteroidal antiinflammatory drugs; PI = protease inhibitor; PZA = pyrazinamide; RFB = rifabutin; RIF = rifampicin; TMP-SMX = trimethoprim/sulfamethoxazole.

Numerous studies have now demonstrated an increased risk for coronary heart disease (CHD) among HIV-infected populations compared to uninfected contemporaries.[11] Although much of this increased risk is attributable to traditional CHD risk factors, such as diabetes, hypertension, dyslipidemia, and smoking, HIV-specific factors such as ART exposure, chronic inflammation, and immune dysfunction are also likely to be contributory. ART-associated increases in lipids as well as nonspecific ART toxicities account for a portion of the observed increased CHD in HIV. Some of the more compelling data on this topic were obtained from the Strategies for Management of Antiretroviral Therapy (SMART) study, which was designed to test whether CD4 T-cell guided reductions in exposure to ART would result in decreased cardiovascular events. Unexpectedly, there was an apparent increase in cardiovascular events observed with drug conservation. A subsequent nested case-control analysis of these data showed strong associations between elevated markers of inflammation at baseline, such as interleukin 6 and D-dimer and all-cause mortality,[12] highlighting the contribution of inflammation and immune activation in the context of chronic viral infection.

Careful identification and management of CHD risk factors is warranted in HIV care. Smoking, which is often enriched in populations with HIV infection, is an important modifiable risk factor that may be addressed to provide CHD risk reduction. As in the general population, smoking cessation in HIV-infected patients is accompanied by a reduction in incident CHD.[13] Dyslipidemia, a commonly identified condition among HIV-infected patients, caused in part by certain protease inhibitors and non-nucleoside reverse transcriptase inhibitors, is another target for CHD reduction. Selection of ART agents with limited effects on dyslipidemia is one potential approach to optimize lipid levels, but use of direct lipid-lowering therapy is often indicated. However, observational data suggests that standard therapy with 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) may be less effective for preventing cardiovascular disease[14] in the context of HIV despite their demonstrated ability to reduce markers of inflammation.[15] In addition, careful attention to potential drug-drug for preventing cardiovascular disease interactions is required when coadministering various protease inhibitors and statins due to effects on CYP3A4 activity that can lead to increased levels of statins.

Diabetes, insulin resistance, kidney injury, and neurocognitive dysfunction are also increased in HIV-infected populations. Similar to in the general population, the presence of chronic HCV infection is associated with an increased risk for diabetes and the development of chronic kidney disease[16] among individuals with HIV. However, immune dysfunction and toxicities associated with certain ART medications also increase the risk for diabetes and kidney injury in HIV.[17] Finally, the risk for developing HIV-associated neurocognitive dysfunction (HAND) has declined in the era of widespread ART use; however, longer survival and the increasing age of the HIV-infected population has led to a rise in the overall prevalence of HAND.[18] Indeed, with increased life expectancy, attentive care directed toward the recognition and management of metabolic, cardiovascular, and neurodegenerative conditions will become increasingly important in the health care approach to individuals living with HIV infection.

REVIEW QUESTIONS

1. Which of the following opportunistic infections is most typical of HIV infection with a CD4 count less than 50 cells/mm^3?

A. Mucormycosis
B. BK virus nephropathy
C. Nocardiosis
D. *Mycobacterium avium* complex disease
E. *Listeria monocytogenes* meningitis

Answer: D Patients with HIV infection and low CD4 counts (<50 cells/mm^3) characteristically develop pneumocystosis, toxoplasmosis, CMV retinitis, tuberculosis, cryptococcal meningitis, cryptosporidiosis, and disseminated *Mycobacterium avium* complex infection. Mucormycosis is typically seen in patients with neutropenia or diabetes mellitus and is rare in patients immunosuppressed because of HIV infection. Listeria, surprisingly, does not appear to occur with enhanced frequency among patients with HIV infection although it is an intracellular pathogen. Nocardiosis can occur in patients with HIV infection, but is unusual. BK virus causes disease in transplant recipients, with nephropathy seen in renal transplant patients. BK virus is most unusual in patients with HIV infection.

2. Which of the following peripheral blood assays is the best indicator of susceptibility to opportunistic infections for patients with HIV infection?

A. CD4 lymphocyte count
B. CD8 lymphocyte count
C. Total lymphocyte count
D. Total neutrophil count
E. Total leukocyte count

Answer: A For HIV-infected patients, CD4 T cell counts in the peripheral blood are excellent indicators of susceptibility to opportunistic infections. There is a tight correlation between the counts and susceptibility to AIDS-defining illnesses. Counts under 200 cells/mm^{3}are a good estimate of susceptibility to pathogens such as *Pneumocystis* pneumonia. Counts under 100 cells/mm^3 are indicators of susceptibility to CMV, *Toxoplasma,* and *Mycobacterium avium.* The total lymphocyte count also can be used, but is not nearly so specific and sensitive. CD8 suppressor cells are related to immune response, but also are not tightly correlated with infectious susceptibility. Patients with HIV infection become neutropenic only with very-late-stage disease, when their marrow is involved by certain infections or tumors, or if they have marrow suppression resulting from a drug effect or a nutritional deficiency. Neutropenia in this population is not as ominous as in patients who have had chemotherapy and who have eroded mucosal barriers.

3. For HIV-infected patients on long-term antiretroviral therapy, and viral loads less than 50 copies and CD4 counts greater than 300 cells/mm^3, which of the following groups of problems are the major cause of HIV-related morbidity and mortality?

A. *Candida,* herpes zoster, and herpes simplex
B. Kaposi's sarcoma and multicentric Castleman's disease
C. Progressive multifocal leukoencephalopathy and central nervous system lymphoma
D. Accelerated liver, heart, and kidney disease
E. Sepsis and septic shock

Answer: D For patients with HIV infection well controlled on antiretroviral therapy, accelerated liver disease, coronary atherosclerosis, renal disease, and neurocognitive disorders are emerging as major causes of morbidity. At CD4 counts greater than 300, Kaposi's sarcoma occurs, but it is not common in the United States. Similarly, at such counts progressive multifocal leukoencephalopathy and CNS lymphoma are uncommon. Septic shock does not occur with substantially increased frequency in patients with HIV infection. They are susceptible at all CD4 counts to increased incidence of pneumococcal disease, but most cases of sepsis in this population come from predictable sources such as intravenous catheters or intravenous drug abuse.

4. For a patient with HIV infection whose CD4 count is 50 cells/mm^3 and who is going to start antiretroviral therapy in the next few weeks, which of the following prophylactic drugs would be most beneficial pending sustained HIV viral suppression?

A. Fluconazole
B. Valganciclovir
C. Valacyclovir
D. Trimethoprim-sulfamethoxazole
E. Caspofungin

Answer: D Patients with CD4 counts below 200 cells/mm^3 are susceptible to *Pneumocystis* pneumonia (PCP), and the susceptibility increases as the CD4 count decreases. In the pre-antiretroviral era, 70 to 80% of HIV-infected patients ultimately developed PCP if they did not take anti-pneumocystis prophylaxis. Azithromycin to prevent disseminated *Mycobacterium avium* complex infection would also be appropriate, although this option was not offered as an answer. Antiviral prophylaxis with valacyclovir would reduce the frequency of herpes simplex and herpes zoster, but this prophylaxis is not recommended in preference to treating episodes caused by these pathogens when they occur. Similarly, fluconazole could be used to reduce the likelihood of mucosal candidiasis, but the recommendation is not to give prophylaxis but to treat episodes when they occur. Caspofungin, a parental antifungal, would have no role for prophylaxis. Some drugs that are effective for prophylaxis, such as fluconazole and acyclovir, are not recommended for routine use because of potential drug interactions, drug toxicities, cost, and the fact that episodes of the targeted diseases are usually not life-threatening and can be treated when they occur acutely.

5. Which of the following vaccines would be appropriate to give to a patient with newly diagnosed HIV infection (CD4 count = 100 cells/mm^3, viral load = 1 million copies) who had childhood immunizations but none since then and who will be starting on antiretroviral therapy plus chemoprophylaxis with trimethoprim-sulfamethoxazole and azithromycin in 1 week?

A. Herpes zoster vaccine
B. Herpes simplex vaccine
C. Pneumococcal vaccine (conjugated)
D. Attenuated influenza vaccine
E. Measles-mumps-rubella vaccine

Answer: C For patients with low CD 4 counts (<200 cells/mm^3) it is not prudent to administer live virus vaccines such as the zoster vaccine or measles-mumps-rubella or the live attenuated influenza virus vaccine. There is no licensed vaccine for herpes simplex. Pneumococcal vaccine is important to administer. CDC guidelines and guidelines at http://www.aidsinfo.nih.gov provide information on the vaccine products to use. Pneumococcal vaccines are effective in reducing the morbidity of pneumococcal disease in this patient population. It may be wise to readminister this when the CD4 count has risen substantially if the initial immunization was administered when the CD4 count was below the 100 to 200 range.

390 GASTROINTESTINAL MANIFESTATIONS OF HIV AND AIDS

TAMSIN A. KNOX AND CHRISTINE WANKE

INTRODUCTION

Gastrointestinal (GI) diseases were among the leading causes of morbidity and mortality in persons infected with human immunodeficiency virus (HIV) before the advent of highly active antiretroviral therapy (HAART) in 1996. Profound wasting and chronic diarrhea are still manifestations of end-stage acquired immunodeficiency syndrome (AIDS) in persons who are not receiving or are resistant to antiretroviral therapy (ART). However, the common GI problems found today in persons receiving effective ART have shifted away from the enteric and hepatobiliary infections associated with low $CD4^+$ counts. Current GI issues are mainly due to side effects of antiretroviral medications, to nutritional and metabolic disorders associated with chronic HIV disease and therapy, and to liver disease from coinfection with hepatitis B virus (HBV) and hepatitis C virus (HCV).

The degree of immunosuppression, measured by the $CD4^+$ count, is the most important determinant of the likelihood of a GI illness, the type of disease, and its severity. The more profound the $CD4^+$ count suppression, the more likely a GI disease will be present.

The route of transmission of HIV may affect GI function; men who have sex with men (MSM) have higher rates of diarrhea and Kaposi sarcoma than do those who acquired HIV from intravenous drug use (IVDU). Alcohol abuse or IVDU predisposes to liver disease. Regional exposures may increase the risk for disease. In resource-limited settings, lack of ART, increased exposure to pathogens, lack of clean water, poverty, and hunger are associated with increased prevalence and severity of GI disease. In contrast, nutritional and metabolic diseases such as obesity, metabolic syndrome, and fatty liver are seen in HIV populations with high caloric and fat intake and lack of exercise. GI complications of HIV infection and recommendations for their treatment are summarized in Table 390-1.

GASTROINTESTINAL DISEASES FOUND WITH $CD4^+$ COUNTS GREATER THAN 200 TO 500 CELLS/μL

The GI diseases discussed in this section may also be seen with more advanced HIV infection.

Side Effects of Medications

Adverse effects of medications are frequently seen in the course of HIV treatment and may be due to ART or to the medications required for treatment or prevention of opportunistic infections. Gastric effects, including nausea, vomiting, loss of appetite, and dyspepsia, may occur as a symptom of the HIV infection itself or in response to ART regimens, particularly those with zidovudine, didanosine, ritonavir, amprenavir, or indinavir. Hypersensitivity reactions to ART, such as occurs in persons with the HLA-B5701 haplotype who take abacavir, may also be manifested as fever, abdominal pain, and rash. Didanosine, stavudine, and pentamidine may cause acute pancreatitis.

Lactic acidosis is a life-threatening condition caused by mitochondrial toxicity from nucleoside reverse transcriptase inhibitors (NRTIs), particularly stavudine, didanosine, and zidovudine. Early discontinuation of NRTIs and supportive care are key to recovery, but the syndrome may be difficult to diagnose because of nonspecific findings such as fatigue, nausea, muscle aches, weight loss, or abdominal pain. Blood lactate levels are usually greater than 5 mmol/mL. Nevirapine has been associated with liver toxicity when used in men and women with $CD4^+$ counts higher than 250 and 400 cells/μL, respectively. One of the most common adverse effects of atazanavir has been asymptomatic elevation in indirect bilirubin. Some ART agents have also been associated with the development of significant elevations in triglycerides (to levels > 1000 mg/dL) and the associated development of pancreatitis.

Although all antiretrovirals have been associated with diarrhea, nelfinavir is particularly known to cause a secretory form of diarrhea. Although antiretroviral therapy is now likely the most common cause of diarrhea in treated HIV-infected patients, intestinal pathogens should still be sought in stool examinations, despite a normal $CD4^+$ count or low HIV load.

Nutritional and Metabolic Disorders

With the advent of effective ART and the conversion of HIV to a chronic manageable disease, overnutrition and obesity have become frequent complications of HIV infection. Lifestyle factors and poor dietary choices may help promote the development of overweight/obesity, but some weight gain and increases in visceral fat may be related to the use of specific ART agents. HIV-associated lipodystrophy syndrome,[1] which was recognized after the introduction of effective triple ART regimens, is a complex of four distinct components: visceral fat accumulation, subcutaneous fat atrophy, atherogenic lipid profiles, and glucose intolerance. The pathogenesis remains unclear, but nutritional intake probably contributes to all components except fat atrophy. Chronic inflammation caused by long-term HIV infection and selected antiretrovirals has been implicated as well, particularly the protease

TABLE 390-1 RELATIONSHIP OF GASTROINTESTINAL DISEASES TO CD4⁺ COUNTS IN HIV-INFECTED PATIENTS

CD4⁺ COUNT	SYSTEM	SYMPTOMS AND DISEASES	TREATMENT
>200-500 cells/μL	GI and pancreas	**Nausea, vomiting, abdominal pain**	Changes in antiretroviral regimen
		Side effects of medications	Lipid-lowering agents, low-fat diet, no alcohol
		Pancreatitis	Treat specific pathogens, if present
		Diarrhea	Antimotility agents and fiber
	Nutritional and metabolic	**Lactic acidosis**	Stop nucleoside reverse transcriptase inhibitors
		Stavudine, didanosine, zidovudine	
		Changes in body shape	
		Obesity	Diet, exercise
		Metabolic syndrome	Diet, exercise, lipid-lowering agents, insulin-sensitizing agents
		Visceral obesity	hGH/GHRH in clinical trials
	Liver	**Liver function abnormalities, cirrhosis**	
		Chronic hepatitis with HCV	Combination of direct-acting agents against HCV
		Chronic HBV infection	Nucleosides/-tides for HBV infection
		Hepatotoxicity	Stop implicated antiretrovirals
	Oral lesions (≈400-500 cells/μL)	**Plaques, pain**	
		Oral thrush	Clotrimazole troche, nystatin, oral azoles
		Hairy leukoplakia	Acyclovir
		Herpes simplex-1	Acyclovir, famciclovir, valacyclovir
		Idiopathic ulcers	Corticosteroids, thalidomide (men)
		Gingivitis	Topical chlorhexidine, oral metronidazole
		Kaposi sarcoma	Radiation, intralesional injection, systemic chemotherapy
	Anorectal lesions	**Anorectal pain, mass, discharge, tenesmus**	
		Anal fissure, fistula, or perirectal abscess	Local care, surgery
		Foreign body in rectum	Endoscopic or surgical removal
		Sexually transmitted disease:	
		Gonorrhea, *Chlamydia trachomatis*, syphilis	Specific antibiotic therapy
		Herpes simplex infection	Acyclovir, famciclovir, valacyclovir
		Condyloma	Podophyllin, surgical excision, or ablation
		Anal cancer	Surgery, chemoradiation therapy
<200 cells/μL	Esophagus	**Dysphagia, odynophagia**	
	<200 cells/μL	*Candida*	Fluconazole, itraconazole, (voriconazole)
	<50 cells/μL	CMV	Ganciclovir
		Idiopathic ulcers	Oral corticosteroids, thalidomide (men)
		HSV	Acyclovir, famciclovir, valacyclovir
<100 cells/μL	Intestine	**Diarrhea**	
		Bacterial, viral, or protozoal infection	Treat specific pathogens
		AIDS enteropathy	Antimotility agents, nutritional support, ART
		Abdominal pain, fever	
		CMV	Treat specific pathogens
		Mycobacterium tuberculosis, MAC, *Histoplasma* *Cryptosporidium*	Surgery if perforation or dead bowel
	Malignancy	**GI bleeding, weight loss, or abdominal pain**	
		Kaposi sarcoma	As above
		Lymphoma	Systemic chemotherapy
<50 cells/μL	Wasting	**Weight loss**	
		Increased metabolic demands (infection, HIV)	Treat HIV and underlying infections
		Decreased oral intake	Appetite stimulants
		Malabsorption	Anabolic steroids, hGH
	Hepatobiliary	**Hepatomegaly, elevated liver function test results**	
		Opportunistic infections—MAC, fungal	Consider liver biopsy
		Lymphoma	
		Jaundice, RUQ pain, elevated liver function test results	
		AIDS cholangiopathy	ERCP and sphincterotomy
		Acalculous cholecystitis	Laparoscopic cholecystectomy

AIDS = acquired immunodeficiency syndrome; ART = antiretroviral therapy; CMV = cytomegalovirus; ERCP = endoscopic retrograde cholangiopancreatography; GHRH = growth hormone–releasing hormone; GI = gastrointestinal; HBV = hepatitis B virus; HCV = hepatitis C virus; hGH = human growth hormone; HIV = human immunodeficiency syndrome; HSV = herpes simplex virus; MAC = *Mycobacterium avium* complex; RUQ = right upper quadrant.

inhibitors. Host factors (e.g., genetics) also probably play a role in producing these syndromes. The co-occurrence of visceral fat accumulation, atherogenic lipid profiles, and glucose intolerance defines metabolic syndrome, the diagnosis of which requires three of the following factors: high triglyceride levels, low high-density lipoprotein levels, hypertension, elevated waist circumference, and glucose intolerance. The prevalence of metabolic syndrome has increased dramatically in HIV-infected individuals, and there is concern that it may contribute to the increased risk for cardiovascular disease in persons infected with HIV.[1,2]

Liver Disease

Liver disease is now the second leading cause of death in those with HIV infection, owing to the prevalence of coinfection with chronic viral hepatitis (Chapter 149). Coinfection with HCV is present in approximately 25%, depending on the HIV transmission category: 50 to 90% of IVDUs and hemophiliacs, 10 to 20% of heterosexuals, and 5 to 10% of MSM.[3] Chronic HBV infection, defined by the presence of hepatitis B surface antigen (HBsAg), is found in approximately 10% of persons with HIV, and some have more than one viral coinfection. Hepatic fibrosis progresses more rapidly in HIV-infected individuals and leads to cirrhosis, decompensated liver disease, or hepatic failure (Chapter 154). This may be further accelerated by alcohol use, steatosis, or fatty liver disease and by hepatotoxicity from ART. Coinfection with HCV or HBV increases the risk for death by four- to six-fold over HIV infection alone and increases the risk of hepatic decompensation.[4] Mortality from liver disease increases as CD4⁺ cells decline, more markedly with CD4⁺ counts lower than 100 cells/μL. Early diagnosis and treatment of HCV

and HBV may arrest or slow the progression of hepatic fibrosis and reduce the hepatotoxicity associated with antiretroviral treatment.

All persons with HIV infection should be screened for coinfection with HBV and HCV.[5] A positive serologic test for HBsAg indicates chronic HBV infection and should be followed by tests for HBV DNA and hepatitis B e antigen. Those without chronic HBV infection and with no protective antibody to HBV surface antigen (negative anti-HBs) should be vaccinated against HBV. If treatment of hepatitis B is to be initiated in the absence of ART, a dual regimen of telbivudine and adefovir is appropriate because these agents will not select for HIV resistance. A positive test for HCV antibody should prompt testing for HCV RNA, which determines whether chronic HCV infection is present. Noninvasive markers of hepatic fibrosis, serum biomarkers, and hepatic elastography (to measure hepatic stiffness) are being developed to replace liver biopsy. The prevalence of hepatocellular carcinoma (HCC) (Chapter 196) is increased in those with HIV coinfection; it is found at a younger age and is more aggressive in HIV-infected patients. Regular 6-month screening for HCC by serum α-fetoprotein levels and ultrasound imaging of the liver in persons with cirrhosis may help identify lesions earlier.

Randomized clinical trials have shown that anti-HCV therapy can induce a sustained virologic response (SVR)—that is, undetectable levels of HCV RNA measured 6 months after the end of treatment. However, SVR rates are approximately 60 to 80% of those achieved in persons with HCV monoinfection. Newer drug regimens in development with direct-acting antivirals hold promise for improved SVR rates without the side-effects of pegylated interferon.[6] To avoid drug interactions, neither didanosine (lactic acidosis) nor zidovudine (anemia) should be given with ribavirin.

Hepatotoxicity from ART occurs in up to 12% of patients started on a new ART regimen. Risk factors for hepatotoxicity include chronic HCV or HBV infection, female sex, and the use of ritonavir or nevirapine in the regimen. Effective ART has been associated with reduced hepatic inflammation, less progression of hepatic fibrosis, and decreased mortality from liver disease.

Oral Lesions

New oral lesions should raise suspicion for HIV disease. The lesions may be unsightly but asymptomatic or cause discomfort and difficulty eating. Thrush appears as white plaques, usually on the buccal mucosa. Oral hairy leukoplakia (Figure 425-5 in Chapter 425), which is associated with Epstein-Barr virus, consists of raised shaggy, dirty white patches on the sides of the tongue but is not premalignant.

Oral ulcers (Chapter 425) are caused by infection with herpes simplex virus type 1 (HSV-1) and tend to be more severe and persistent than ulcers in immunocompetent hosts. Idiopathic ulcers similar to those found in the esophagus are found in patients with advanced HIV disease. These deep necrotic ulcers are most commonly found on the buccal and pharyngeal mucosa. They respond to systemic corticosteroids or thalidomide. Gingivitis and periodontal disease appear as linear or diffuse erythema of the gums. With declining $CD4^+$ counts, they may progress to necrotizing gingivitis with pain and hemorrhage. There is increasing concern that these bacterial diseases may contribute to systemic inflammation and more rapid progression of HIV disease.

Kaposi sarcoma (Chapter 393), a multicentric malignancy of endothelial cells caused by human herpesvirus 8 infection, is more common in MSM with HIV infection in the United States but is also prevalent in Africa. Oral lesions are found in half of persons with other sites of Kaposi sarcoma and appear on the palate or gums as raised reddish or bluish nodules.

Anorectal Diseases

Anorectal disorders in HIV-infected individuals are more prevalent in MSM. Anal fissures, fistulas, abscesses, and foreign objects may be found on anal examination as a consequence of receptive anal intercourse or manipulation. Proctitis caused by gonorrhea *(Neisseria gonorrhoeae)* (Chapter 299) is characterized by mucopurulent discharge from the anus, tenesmus, and bleeding. *Chlamydia trachomatis* infection (Chapter 318) also causes proctitis and inguinal lymphadenopathy. Cultures and swabs of the discharge are diagnostic.

Primary syphilis (Chapter 319) is manifested as an anal chancre or ulcer that may be tender because of its location. Secondary syphilis appears 2 to 6 months later as condylomata lata, or warty masses around the anus. Perianal shallow, painful ulcers caused by HSV (Chapter 374) evolve as the initial vesicles rupture. These ulcerations may be cultured for HSV, or scrapings will show viral inclusions. Patients may have concurrent herpes proctitis.

Anal condylomata or warts are caused by infection with human papillomavirus (HPV) (Chapter 373) and appear as white, pink, or gray painless lesions around the anus and in the anal canal. HPV types 16 and 18 are associated with the development of dysplasia and squamous cell cancer of the anus, which is manifested as bleeding or a mass. The prevalence of anal dysplasia may be as high as 50% in HIV-positive MSM, and the incidence of anal cancer has increased more than six-fold in the past two decades. Screening via anal cytology is being pioneered for high-risk individuals.

GASTROINTESTINAL DISEASES MORE COMMONLY SEEN WITH $CD4^+$ COUNTS LESS THAN 200 CELLS/μL

GI illness increases in prevalence and severity as the $CD4^+$ count declines. With marked immunosuppression, there may be multiple concurrent infections. Although specific antimicrobial therapy may control the infection, HAART is the most effective therapy.

Esophageal Diseases

Candidal esophagitis (Chapter 338) is the most common esophageal infection in HIV-infected individuals. The combination of oral thrush and dysphagia has a positive predictive value of 90% for esophageal candidiasis. If the symptoms do not resolve with treatment in 7 days, endoscopy is indicated.[7] Cytomegalovirus (CMV) (Chapter 376) and idiopathic esophageal ulcerations may appear when the $CD4^+$ count falls below 50 cells/μL. Odynophagia, or severe pain on swallowing, is the initial symptom. Endoscopy shows large ulcerations with elevated margins, and CMV inclusions are seen in biopsy samples. HSV infections are much less common and appear as confluent shallow ulcerations in the esophagus. Idiopathic ulceration is diagnosed by the absence of viral inclusions on biopsy specimens.

Diarrhea

Diarrhea remains a common illness in HIV-infected individuals, even in the era of effective ART. Infections of the small intestine are accompanied by large-volume watery diarrhea. Colonic disease may be manifested as bloody, inflammatory, or small-volume diarrhea and tenesmus. Routine bacterial pathogens, including *Salmonella*, *Campylobacter*, and *Shigella*, have all been documented to cause diarrhea in HIV-infected patients. Enteroaggregative *Escherichia coli* has been identified as a cause of persistent diarrhea in HIV-infected individuals. The use of multiple antibiotics in HIV-infected patients has led to the frequent occurrence of *Clostridium difficile* colitis (Chapter 296). Mycobacterial infections with either *Mycobacterium tuberculosis* or atypical mycobacteria, most commonly *Mycobacterium avium* complex (MAC), may infiltrate the small bowel in HIV-infected patients. Although *M. tuberculosis* infection occurs with exposure in individuals with moderate $CD4^+$ cell depletion, disseminated MAC disease occurs only in individuals with $CD4^+$ counts lower than 50 cells/μL.

Most often, viral diarrheas are similar in manifestation to those in the general population, pathogens are not routinely identified in the clinical setting, and disease is self-limited. However, CMV may cause disease throughout the length of the GI tract in HIV-infected patients with $CD4^+$ counts lower than 50 cells/μL. In the small bowel, CMV may cause a watery diarrhea, and in the colon, a colitis with blood and signs of inflammation on endoscopy. Biopsy with identification of virus in tissue is required to make the diagnosis of CMV enteric disease.

Parasitic causes of diarrhea are common in HIV-infected individuals.[8] Opportunistic parasitic pathogens include *Cryptosporidium parvum*, the microsporidial organisms *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*, and *Cyclospora cayetanensis*. Persistent diarrhea caused by cryptosporidiosis (Chapter 350) occurs when the $CD4^+$ count is less than 200 cells/μL, and the most effective control of this pathogen is treatment of HIV.

Pathogens are not found in up to half of cases of diarrhea in HIV-infected patients, even after a full diagnostic evaluation. This condition has been called AIDS enteropathy and is associated with chronic diarrhea, malnutrition, and wasting.[9] It is possible that some of the chronic diarrhea is caused by pathogens that are not yet recognized or by noninfectious causes such as lymphoma. It is also likely that some of these pathogen-negative diarrheas are caused by HIV itself, which may infect the enterocyte as well as lymphoid tissue within the gut.

Malignancy

Kaposi sarcoma (Chapter 393) may develop at any location in the GI tract. Kaposi lesions appear endoscopically as raised reddish nodules that may bleed spontaneously. Non-Hodgkin lymphomas may involve any portion of

the GI tract, as well as the liver, and are manifested as bleeding, obstruction, weight loss, or abdominal pain.

Wasting

Wasting in HIV-infected individuals is defined by the World Health Organization as a body mass index of less than 18.5 kg/m^2. Weight loss and wasting are still seen in patients with treated HIV infection, and even modest weight loss of 3% or greater increases mortality.

In uncontrolled HIV infection, multiple factors contribute to wasting. Caloric requirements are increased by the metabolic demands of HIV replication, concurrent opportunistic infections, and fever. Oral intake may be poor because of nausea, anorexia, dysphagia, odynophagia, or chronic diarrhea or as a result of food insecurity, depression, or dementia.[10] Weight loss is exacerbated by malabsorption of nutrients from small intestinal or pancreatic disease. HIV-infected persons may not be able to increase caloric intake to overcome the loss of nutrients in stool and meet the metabolic demands of their illness. Targeted approaches to wasting and weight loss include treatment of HIV or opportunistic infections, frequent small meals, and use of appetite stimulants (megestrol acetate, dronabinol), anabolic steroids (testosterone, oxandrolone, nandrolone), or recombinant human growth hormone, as indicated. With control of HIV replication, nutritional status and weight generally improve, although they may not return to premorbid levels if the wasting was severe.

Hepatobiliary Disease

Hepatobiliary disease is associated with very low CD4$^+$ counts, often less than 20 cells/μL. Evaluation of abnormalities in liver function should initially exclude HBV and HCV infection and drug-induced hepatotoxicity, particularly that involving antiretroviral or sulfa-containing medications. The presence of hepatomegaly suggests an infiltrative process such as MAC or fungal infection or lymphoma. Alkaline phosphatase is disproportionately elevated. Liver imaging often does not show a localized lesion but determines whether biliary dilation is present, a finding suggestive of extrahepatic disease. Liver biopsy with special stains and cultures may be definitive.

In contrast, the presence of right upper quadrant pain with or without jaundice indicates biliary tract disease (Chapter 155). AIDS cholangiopathy[11] includes a sclerosing cholangitis–like process with diffuse biliary strictures and dilations and papillary stenosis with narrowing of the distal common bile duct at the entrance to the duodenum. In papillary stenosis, the common bile duct is dilated proximal to the stenosis. Acalculous cholecystitis may also be seen. These changes are caused by infection of the biliary tree with *Cryptosporidium*, microsporidia, *Isospora belli*, or CMV in the setting of profound immunosuppression. Endoscopic retrograde cholangiopancreatography can be performed to establish the diagnosis, obtain brushings for examination, and treat papillary stenosis by sphincterotomy. Treatment of the specific organism seldom eradicates infection because of the degree of immunosuppression. However, treatment with ART can result in marked improvements in biliary findings.

APPROACH TO GASTROINTESTINAL DISEASES

The GI tract is host to a myriad of infectious and infiltrative diseases in HIV-infected persons. Even so, routine GI diseases such as diverticulitis, choledocholithiasis, or peptic ulcer disease must be considered, particularly in those treated with ART. The clinician is guided by the symptom complex, as laid out in Table 390-1, to identify the probable organisms or tumors by clinical findings. The CD4$^+$ count influences the likelihood of the type of GI infection. It is important to remember that multiple illnesses may occur simultaneously with HIV infection and that finding one cause of a symptom or complaint may not be sufficient.

With diarrhea, careful stool evaluations should include cultures for *Salmonella*, *Shigella*, and *Campylobacter*; assay for *Clostridium difficile* toxin; and at least three examinations for parasites, including acid-fast stains for MAC and *Cryptosporidium*. If these measures are unrevealing, upper GI endoscopy with biopsy of the small intestine is indicated to diagnose protozoal infections with *Cryptosporidium*, *Isospora belli*, or microsporidia. Signs of colitis are best evaluated by flexible sigmoidoscopy or colonoscopy with biopsy and cultures. Examination and biopsy of the terminal ileum with acid-fast stain is necessary to confirm the diagnosis of pathogens such as *M. tuberculosis* or MAC.

All persons with HIV should be screened for coinfection with HBV and HCV and vaccinated against hepatitis A and B if not immune. Finally, close attention to serial measurement of weight and calculation of the body mass index is crucial to identify those who may have poor outcomes as a result of weight loss or excessive weight gain.

REVIEW QUESTIONS

1. A 47-year-old man with poorly controlled HIV infection complains of pain on swallowing both liquids and solids. His HIV viral load is 157,468 copies/mL and his CD4 count is 152 cells/mm^3. He admits to poor adherence to antiretroviral therapy. On exam, he is wasted. There are white patches on his buccal mucosa. His abdominal exam is unremarkable. You recommend:

A. Upper gastrointestinal (GI) endoscopy with biopsies and brushings of the esophagus
B. Empirical treatment with fluconazole
C. Ophthalmic exam for cytomegalovirus (CMV) involvement of the retina
D. Empirical treatment with ganciclovir
E. Oral corticosteroids for idiopathic HIV related esophageal ulcers

Answer: B The most likely diagnosis is *Candida* esophagitis causing odynophagia. Esophageal infections do not cause obstruction, so there is no dysphagia, but the esophageal contractions with swallowing cause pain in an inflamed esophagus with either liquids or solids. Oral thrush and dysphagia are 90% predictive of esophageal candidiasis. An empirical trial of an antifungal medication directed at *Candida* is an appropriate treatment, reserving upper GI endoscopy for patients who do not quickly respond to treatment. CMV, herpes, and idiopathic ulcerations of the esophagus generally occur in patients with CD4 counts below 50 cells/mm^3. GI endoscopy with biopsies of the ulcers is the best way to make these diagnoses.

2. On initial laboratory reports, a 55-year-old man living with HIV/AIDS who is new to the clinic is found to have the following biochemical tests of liver function. He feels generally well. He is on a stable antiretroviral regimen with good control of HIV infection. He takes a multivitamin and Percocet for knee pain. His abdominal exam shows no hepatosplenomegaly. His CD4 count is 410 cells/mm^3, and his HIV viral load is undetectable.

Laboratory Measurement	Value	Normal Range
Bilirubin	1.0	0.2-1.3 mg/dL
Alkaline phosphatase	120	38-126 UL
AST	80	5-34 UL
ALT	90	0-55 UL
Total protein	7.8	6.3-8.2 g/dL
Albumin	4.0	3.5-5.0 g/dL

The most appropriate next step would be:

A. A liver biopsy to determine whether he has cirrhosis
B. Stop all medications and see if the biochemical tests return to normal.
C. Test for autoimmune hepatitis with a panel including antinuclear antibody and serum protein electrophoresis.
D. Weight reduction diet and exercise for fatty liver
E. Test for hepatitis B and C with hepatitis B surface antigen and anti–hepatitis C antibody.

Answer: E Biochemical tests of liver function are frequently abnormal in HIV/AIDS, with mild to moderate abnormalities in the aminotransferases (AST, ALT) being the most frequent abnormalities seen. The differential diagnosis includes drug-related hepatotoxicity, fatty liver, alcohol, and overuse of acetaminophen, but autoimmune hepatitis is uncommon in a male with HIV/AIDS. Over 25% of persons with HIV infection are coinfected with hepatitis C or hepatitis B virus. Chronic hepatitis B can be diagnosed by a positive hepatitis B surface antigen (which is also seen transiently in acute infection). Chronic hepatitis C infection is diagnosed by a positive anti–hepatitis C antibody (anti-HCV), and chronic infection is confirmed by testing for virus in the blood with an HCV-RNA. National recommendations (Health Resources and Services Administration) are to screen all persons with HIV/AIDS for chronic hepatitis B and C infection. Those who are negative should have repeated screening yearly.

3. A 51-year-old man with HIV/AIDS comes to clinic complaining of weight gain. He has a body mass index (BMI) of 31 kg/m^2. Control of his HIV infection is documented with a CD4 count of 520 cells/mm^3 and an undetectable HIV viral load. On exam, there is a fat deposit (buffalo hump) over his upper dorsocervical spine, abdominal obesity, but slender-appearing arms and legs. Clinical considerations should include:

A. Uncontrolled HIV infection causing wasting
B. Normal aging
C. Lipodystrophy with evidence of metabolic syndrome
D. An eating disorder
E. An inherited metabolic disorder

Answer: C HIV-associated lipodystrophy syndrome has four components: visceral fat accumulation (abdominal obesity), subcutaneous fat atrophy (slender arms and legs), atherogenic lipid profile, and glucose intolerance. The etiology of HIV-associated lipodystrophy has not been fully elucidated. However, dietary excess, chronic inflammation due to long-standing HIV infection, genetic predisposition, and the role of certain antiretrovirals may all play a role. The prevalence of metabolic syndrome has markedly increased in persons with HIV/AIDS and may predispose to accelerated cardiovascular disease. This patient should have fasting glucose and lipids checked and should be counseled on weight control and exercise.

4. A 42-year-old woman with HIV/AIDS presents with diarrhea. This has been going on for at least 2 months and is associated with mild abdominal cramping and weight loss because eating increases her cramps and diarrhea. She denies fevers or vomiting. What information is most helpful in planning her evaluation?

A. A family history of inflammatory bowel disease
B. The presence of blood in the stool
C. Obtaining a history of recent travel in the United States
D. Her most recent CD4 cell count
E. A history of lactose intolerance

Answer: D Diarrhea is very frequent among persons living with HIV/AIDS. The etiology of diarrhea is best predicted by a person's CD4 count. In those with a normal CD4 count, diarrhea is often related to medications, lactose intolerance, or irritable bowel syndrome. Usually, weight loss is not a significant component. When the CD4 count declines, opportunistic infections are more likely. At CD4 counts below 100 cells/mm^3, enteric pathogens are common, including bacterial pathogens (*Salmonella*, *Shigella*, *Campylobacter*, *Clostridium difficile*, and enteroaggregative *Escherichia coli*) and parasites (*Cryptosporidium*, microsporidia). At CD4 counts below 50 cells/mm^3, CMV, disseminated *Mycobacterium avium* complex (MAC), or AIDS enteropathy may cause diarrhea. The diagnosis can be made by stool cultures and smears for parasites, but both upper and lower GI endoscopy may be needed to obtain biopsies if stool examinations are negative.

5. A 52-year-old man with HIV/AIDS is seen in HIV clinic complaining of fatigue. When pressed, he admits to intermittent diarrhea and occasional fevers. He is on antiretrovirals. He is slender with a BMI of 20.3 kg/m^2. His examination is otherwise unremarkable except for a few raised cherry-colored nodules on his arms and chest. Which of the following could contribute to HIV-related wasting?

A. Excessive exercising
B. Inadequate dietary intake
C. An opportunistic infection or uncontrolled HIV infection increasing his energy requirements
D. AIDS enteropathy causing malabsorption
E. All of the above

Answer: E HIV-associated wasting is multifactorial. A careful dietary history and evaluation by a nutritionist is important to ensure adequate caloric intake. Dietary energy requirements are increased in persons who exercise regularly or who have increased metabolic demands due to an opportunistic infection and/or uncontrolled HIV infection from resistant virus. Malabsorption due to disease of the small intestine or pancreatic insufficiency also increases dietary caloric requirements because a percentage of nutrients are not being absorbed. Symptoms of nausea, vomiting, or anorexia may further decrease needed caloric intake.

PULMONARY MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME

KRISTINA CROTHERS AND ALISON MORRIS

INTRODUCTION

Pulmonary disease has historically been a leading cause of morbidity and mortality in patients with human immunodeficiency virus (HIV) and the acquired immunodeficiency syndrome (AIDS). Case reports of the previously rare *Pneumocystis* pneumonia (PCP) were the first harbingers of the AIDS epidemic in the 1980s, and in the early era of HIV, pulmonary infections such as bacterial pneumonia, PCP, and tuberculosis (TB) were frequently encountered. Pulmonary malignancies such as Kaposi sarcoma and lymphoma were also common. Prognosis for persons with HIV has changed dramatically with introduction of chemoprophylaxis for common infections such as PCP and with combination antiretroviral therapy (ART). The range of pulmonary diseases encountered in the HIV-infected patient has also changed over the course of the HIV epidemic and now includes fewer opportunistic infections with potential increases in diseases such as chronic obstructive pulmonary disease (COPD).

Pathobiology of HIV and Effects on Pulmonary Immunity

HIV infection in the absence of ART is characterized by immune dysfunction, dysregulation, and progressive immunodeficiency that results in a substantially increased risk for infections and other complications (Fig. 391-1). Early after initial infection, CD4 lymphocytes are depleted from mucosal-associated lymphoid tissue. During the chronic phase of untreated HIV, generalized immune activation and systemic CD4 lymphocyte depletion occurs, and remaining T cells may mount abnormal responses to antigens. Accompanying B-cell dysfunction results in abnormal polyclonal activation, hypergammaglobulinemia, and lack of specific antibody responses. Although ART decreases opportunistic infections and mortality in HIV-infected patients, persistent immune activation, dysfunction, and chronic low-level inflammation can persist and may contribute to the increased risk of several chronic comorbid diseases among HIV-infected individuals. The contribution of this chronic immune activation to pulmonary diseases such as COPD is currently unknown.

Within the lung parenchyma, HIV infection results in impaired innate and adaptive immune responses to pathogens.[1] Alveolar macrophages and lung CD4 T cells from HIV-infected individuals have deficiencies and impaired responses in pathogen recognition (e.g., influenza, *Mycobacterium tuberculosis*).[2] HIV can also lead to other abnormalities in host defense of the lung, including mucociliary function and soluble defense molecules within respiratory secretions. Among individuals who initiate ART, lung HIV viral levels and inflammation generally decrease, mirroring responses in the systemic

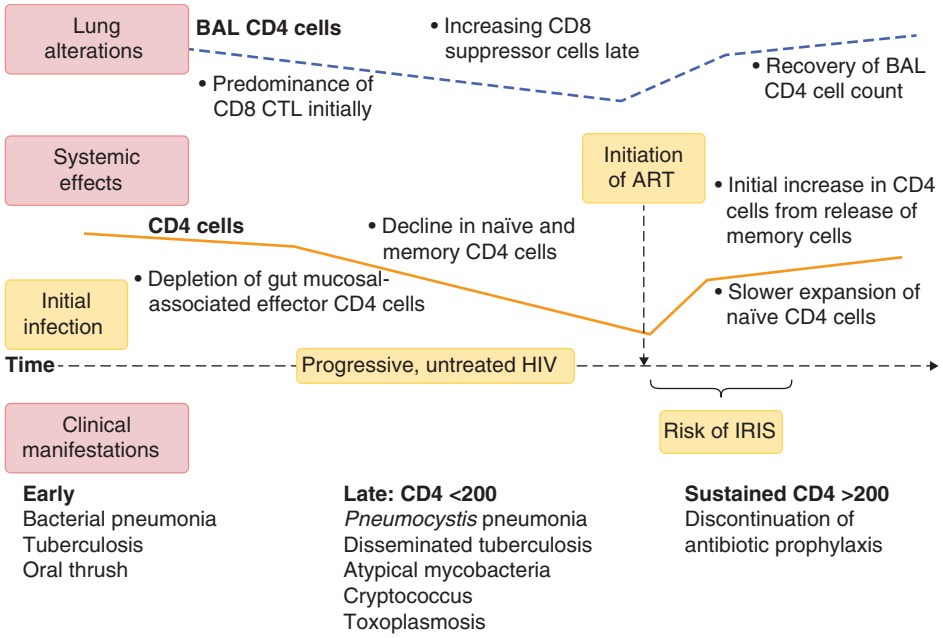

FIGURE 391-1. Systemic and lung alterations in T lymphocytes with HIV infection and initiation of antiretroviral therapy (ART). After initial HIV infection, CD4 lymphocytes of the effector memory type are depleted from mucosal-associated lymphoid tissue; the CD4 cells within the alveolar space appear to be spared but gradually decrease over time with progressive untreated HIV. During the chronic phase of HIV infection, there is progressive decline in the systemic CD4 cell count owing to decreased naïve and memory T cells. Within the alveolar space, HIV-specific cytotoxic CD8 T lymphocytes (CTL) predominate, although in late-stage disease these are replaced with CD8 suppressor lymphocytes. As discussed in the text, HIV infection is also associated with abnormal function of T cells, B-cell dysfunction, and within the lung, abnormalities in several other lines of host defense. With initiation of ART, CD4 cell counts increase systemically and in the lung. ART, antiretroviral therapy; BAL = bronchoalveolar lavage; IRIS, immune reconstitution inflammatory syndrome.

circulation. Nonetheless, HIV-infected individuals appear to have an increased risk of chronic lung diseases, although the mechanisms by which this increased risk occurs are not yet well understood.

EVALUATION OF THE HIV-INFECTED PATIENT WITH LUNG DISEASE

Respiratory disease is a common cause of both outpatient and inpatient visits in HIV-infected individuals. Pulmonary disease in this population can result from both infectious and noninfectious causes that are related to HIV infection or HIV medications, or that are unrelated to HIV. These pulmonary diseases often have characteristic clinical and radiographic manifestations, but there is also variability and overlap among them. In addition, HIV-infected patients often have more than one condition. For these reasons, definitive diagnosis of HIV-associated pulmonary diseases is encouraged when possible. The diagnostic evaluation should be guided by the constellation of the clinical signs and symptoms, laboratory testing, and radiographic appearance, as well as the severity of disease (Fig. 391-2A and 2B).

Clinical Findings

Often, the clinical history, physical examination, and laboratory testing can provide clues for a specific diagnosis (Table 391-1). For example, injection drug users have a greater risk of bacterial pneumonia and TB, whereas men who have sex with men have an increased risk of Kaposi sarcoma. As in the HIV-uninfected population, cigarette smoking is associated with bacterial pneumonia as well as COPD. In general, patients with a history of a previous opportunistic infection such as PCP are at increased risk of recurrence, although use of prophylaxis decreases disease incidence. Travel or place of residence also influences the risk of endemic fungal infections and TB. Certain extrapulmonary symptoms can also implicate specific diseases. For example, complaints of headache or altered mental status in a person with respiratory symptoms should prompt a search for *Cryptococcus* pneumonia and meningitis. Many diseases such as TB, malignancies, and fungal infections can cause extrapulmonary signs and symptoms such as lymphadenopathy, hepatic dysfunction, and bone marrow infiltration.

The CD4 cell count is one of the most critical pieces of information in determining the differential diagnosis of HIV-associated pulmonary disease (Table 391-2). Some diseases such as TB and bacterial pneumonia can occur at any CD4 cell count but are more common at lower counts, with a more atypical presentation of disease that is more likely to be disseminated. In contrast, disease such as pulmonary Kaposi sarcoma, *Toxoplasma gondii* pneumonia, and *Mycobacterium avium* complex are usually only seen if the CD4 cell count is below 100 cells/μL, and more often below 50 cells/μL. PCP is uncommon above a count greater than 200 cells/μL and less common if the CD4 cell count is between 100 and 200 cells/μL in a person receiving ART. If available, the most recent CD4 cell count *prior to* hospitalization is often more useful in HIV-infected inpatients to guide decision making, because the CD4 count can fall in the setting of acute illness.

Radiographic Studies

The radiographic picture also provides important clues to the diagnosis of HIV-associated pulmonary disease (Table 391-3). Certain radiographic findings are "classic" for certain diseases such as bilateral perihilar diffuse infiltrates in PCP (Fig. 391-3), but atypical presentations of pulmonary disease are not uncommon. The radiographic presentation also varies with the CD4 cell count. For example, TB presents with upper lung zone infiltrates that are often cavitary in patients with CD4 cell counts above 200 cells/μL (Fig. 391-4), but cavitation is uncommon with TB in patients with low CD4 cell counts, and lower lobe consolidation mimicking bacterial pneumonia can be seen (Fig. 391-5).

PULMONARY INFECTIONS

Pulmonary infections remain a major cause of morbidity and mortality in HIV-infected populations. Although pulmonary infections are more common in individuals without access to ART, a study of over 9000 HIV-infected and HIV-uninfected individuals found incident pulmonary infections remained more common in the era of combination ART.[3] The CD4 cell count has significant impact on the epidemiology of pneumonia, and HIV-infected individuals with advanced immunosuppression are at risk of a large spectrum of infectious causes of pneumonia (Fig. 391-6). Individuals with higher CD4 cell counts also remain at increased risk of bacterial pneumonia and TB when compared to HIV-uninfected populations. The general approach to the HIV-infected patient with pneumonia is described above, and we discuss the three most common HIV-associated pulmonary infections in further detail below.

Bacterial Pneumonia

EPIDEMIOLOGY

Recurrent bacterial pneumonia, defined as two or more episodes within 12 months, is an AIDS-defining illness. The risk for bacterial pneumonia is substantially increased among HIV-infected individuals, and in contrast to other opportunistic infections, this elevated risk persists in the combination ART era. For example, in a study of HIV-infected veterans in the ART era, the incidence rate of bacterial pneumonia in HIV-infected individuals was 28.0

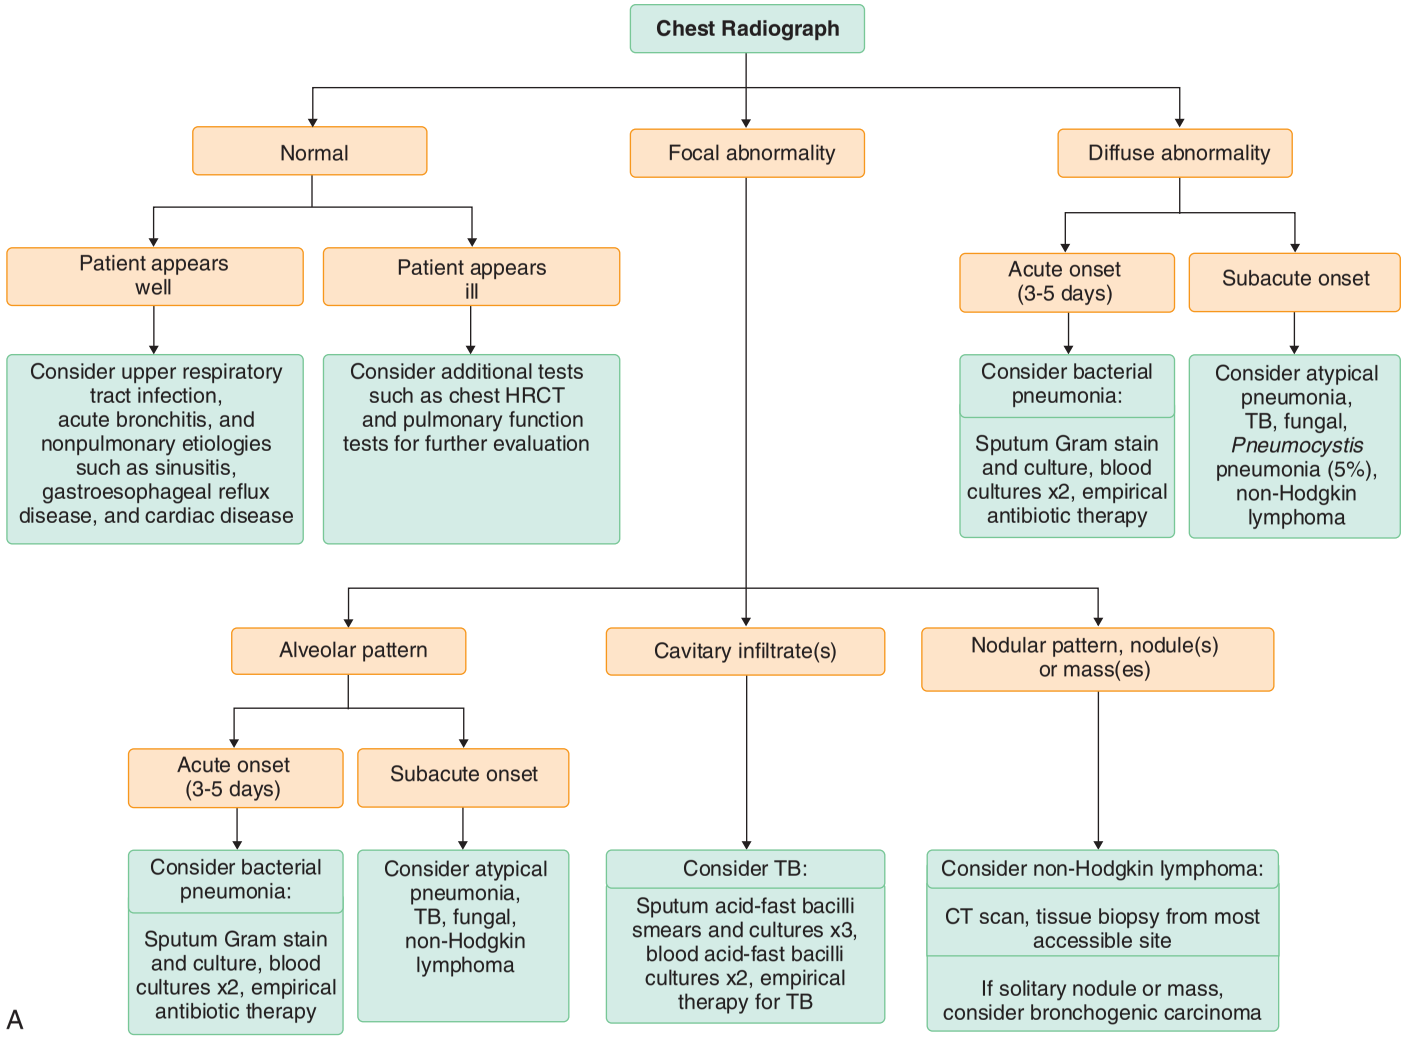

FIGURE 391-2. **Diagnostic approach to the HIV-infected patient with clinical manifestations of possible pulmonary disease and a CD4 cell count greater than 200 cells/μL (A) and a CD4 cell count below 200 cells/μL (B).** HRCT = high-resolution computed tomography; TB = tuberculosis.

B

FIGURE 391-2, cont'd.

TABLE 391-1 DIAGNOSTIC CLUES TO ETIOLOGY OF HIV-ASSOCIATED PULMONARY DISEASES

CLINICAL SETTING

Ambulatory: URI > acute bronchitis > bacterial pneumonia > *Pneumocystis* pneumonia
Hospital: bacterial pneumonia > *Pneumocystis* pneumonia > TB > pulmonary KS
Intensive care unit: *Pneumocystis* pneumonia > bacterial pneumonia; non–AIDS associated conditions > AIDS-associated conditions

CD4 CELL COUNT (see Table 391-2)

PATIENT BACKGROUND

HIV transmission category: MSM—increased incidence of KS; IDU—increased incidence of bacterial pneumonia, TB
Habits: cigarettes—increased incidence of bacterial bronchitis, bacterial pneumonia, COPD, bronchogenic carcinoma
Travel and residence: assess risk for endemic fungal diseases, TB, NTM

MEDICAL BACKGROUND AND USE OF PROPHYLAXIS

Previous disease: increased incidence of recurrence of bacterial pneumonia, *Pneumocystis* pneumonia, fungal pneumonias
Prophylaxis/maintenance: decreased incidence of disease—*Pneumocystis* pneumonia, fungal pneumonias, TB (if PPD positive or positive interferon-γ release assay)

SYMPTOMS AND SIGNS

Respiratory symptoms: especially cough (productive or nonproductive) and symptom duration
Symptoms suggesting extrapulmonary or disseminated disease
Physical examination of the chest: focal or nonfocal findings
Signs suggesting extrapulmonary or disseminated disease

LABORATORY TESTS

WBC count: elevated or, if normal, elevated relative to baseline—bacterial pneumonia
Serum LDH: elevated—nonspecific but classically seen in *Pneumocystis* pneumonia
Arterial blood gas: nonspecific but useful for prognosis, management decisions (e.g., admission and whether corticosteroids are indicated for *Pneumocystis* pneumonia)

CHEST RADIOGRAPHY (see Table 391-3)

AIDS = acquired immunodeficiency syndrome; COPD = chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; IDU = injection drug user; KS = Kaposi sarcoma; LDH = lactate dehydrogenase; MSM = men who have sex with men; NTM, nontuberculous mycobacteria; PPD = purified protein derivative (in an HIV-infected person, PPD is considered positive if ≥ 5-mm induration); TB = tuberculosis; URI = upper respiratory tract infection; WBC = white blood cell.

TABLE 391-2 CD4 CELL COUNT RANGES FOR HIV-ASSOCIATED PULMONARY DISEASES

ANY CD4 CELL COUNT

Bacterial pneumonia (most often *Streptococcus pneumoniae*, *Haemophilus* species)
Mycobacterium tuberculosis pneumonia
Influenza
Non-Hodgkin lymphoma
Lung cancer
Nonspecific interstitial pneumonitis
Lymphocytic interstitial pneumonitis
Pulmonary arterial hypertension
Chronic obstructive lung disease

CD4 CELL COUNT < 200 CELLS/μL

Pneumocystis pneumonia
Cryptococcus neoformans pneumonia

CD4 CELL COUNT < 100 CELLS/μL

Bacterial pneumonia caused by *Pseudomonas aeruginosa*
Toxoplasma gondii pneumonia
Pulmonary Kaposi sarcoma

CD4 CELL COUNT < 50 CELLS/μL

Mycobacterium avium complex—usually associated with disseminated disease
Histoplasma capsulatum—usually associated with disseminated disease
Coccidioides immitis—usually associated with disseminated disease
Aspergillus species (most often *Aspergillus fumigatus*) pneumonia
Cytomegalovirus pneumonia—usually associated with disseminated disease

TABLE 391-3 COMMON RADIOGRAPHIC FEATURES OF HIV-ASSOCIATED PULMONARY DISEASES

CONDITION	COMMON RADIOGRAPHIC FINDINGS
Pneumocystis pneumonia	Bilateral perihilar infiltrates Pneumatoceles, pneumothorax Ground-glass opacities Normal (chest radiograph) Upper lobe or asymmetrical infiltrates (less common)
Bacterial pneumonia	Focal infiltrates Pleural effusions Cavitary lesions
Mycobacterium tuberculosis	Focal infiltrates Normal (in extrapulmonary disease) Diffuse infiltrates/miliary pattern Nodules Cavitary lesions Intrathoracic adenopathy Pleural effusions Upper lobe involvement if high CD4 cell count
Mycobacterium kansasii	Consolidation Nodules Diffuse infiltrates Intrathoracic adenopathy Cavitary lesions Pleural effusions
Mycobacterium avium complex	Normal Intrathoracic adenopathy Focal pneumonia (rare)
Fungal pneumonia	Multifocal or diffuse infiltrates Focal infiltrate Normal Cystic lesions Nodules Intrathoracic adenopathy Pleural effusions (especially *Cryptococcus neoformans*)
Cytomegalovirus	Multifocal or diffuse infiltrates Reticular pattern Ground-glass opacities
Toxoplasma gondii	Bilateral infiltrates Pleural effusions
Non-Hodgkin lymphoma	Single or multiple nodules Focal infiltrates Diffuse interstitial infiltrates Pleural effusions Intrathoracic adenopathy
Kaposi sarcoma	Multifocal or diffuse infiltrates Bilateral central opacities Nodules Peribronchial cuffing, tram-track Kerley B lines Pleural effusions Intrathoracic adenopathy
Lung cancer	Masses Nodules Intrathoracic adenopathy Pleural effusions
COPD	Large lung volumes Flattened diaphragms Bullae Emphysema (chest CT)
Interstitial lung diseases	Normal (chest radiograph) Increased interstitial markings Small lung volumes Fibrosis Traction bronchiectasis Peribronchovascular nodules (sarcoidosis, LIP) Intrathoracic lymphadenopathy (sarcoidosis, rarely LIP)
Pulmonary hypertension	Normal Enlarged pulmonary arteries Vascular pruning Right heart enlargement

COPD = chronic obstructive pulmonary disease; CT = computed tomography; LIP = lymphocytic interstitial pneumonia

FIGURE 391-3. **Chest radiograph of an HIV-infected person, CD4 cell count less than 200 cells/μL, demonstrating characteristic bilateral reticular-granular opacities of *Pneumocystis* pneumonia.** Bronchoscopic alveolar lavage demonstrated *Pneumocystis* on Giemsa stain. Courtesy Laurence Huang, MD. Used with permission.

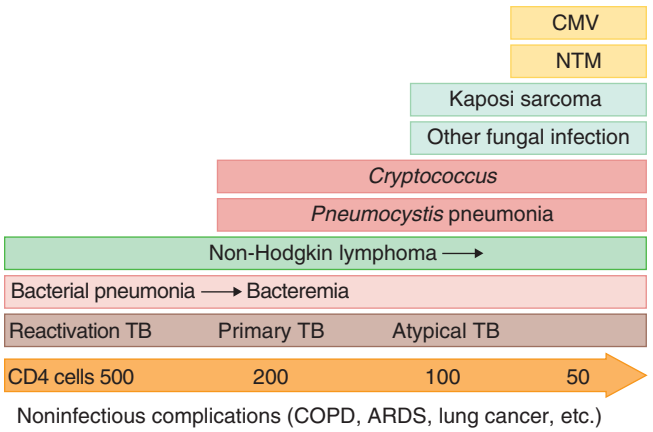

FIGURE 391-6. **Risk of pulmonary complications by CD4 cell count.** ARDS = acute respiratory distress syndrome; CMV = cytomegalovirus; COPD = chronic obstructive pulmonary disease; NTM = nontuberculous mycobacteria; TB = tuberculosis.

FIGURE 391-4. **Chest radiograph of an HIV-infected person, CD4 cell count greater than 200 cells/μL, demonstrating a right upper lobe infiltrate with areas of cavitation.** Sputum acid-fast bacillus stain was positive, and multiple sputum cultures grew *Mycobacterium tuberculosis*. Courtesy Laurence Huang, MD. Used with permission.

FIGURE 391-5. **Chest radiograph of an HIV-infected person, CD4 cell count less than 200 cells/μL, revealing right lower lung zone consolidation with air bronchograms.** Sputum culture grew *Mycobacterium tuberculosis* that was resistant to rifampin. Courtesy Laurence Huang, MD. Used with permission.

per 1000 person-years compared with 5.8 per 1000 person-years in the HIV-uninfected group.[4] Bacterial pneumonia can occur throughout the course of HIV infection and at any CD4 lymphocyte count, although the incidence increases as the CD4 lymphocyte count declines. Additional risk factors for bacterial pneumonia include injection drug use and cigarette smoking.

PATHOBIOLOGY AND PATHOGENS

Immunodeficiency as reflected by circulating CD4 T-cell counts, as well as local abnormalities within the host defenses of the lung, confer increased risk for bacterial pneumonia. Numerous bacteria may cause pneumonia in HIV. *Streptococcus pneumoniae* is the most commonly isolated cause of community-acquired bacterial pneumonia in HIV-infected populations and is often complicated by bacteremia and invasive disease. Other frequent causes of pneumonia in HIV-infected persons include *Haemophilus* species and *Staphylococcus aureus*, the latter of which can cause community-acquired pneumonia in patients both with and without a history of injection drug use. More unusual bacterial organisms that can cause pneumonia in HIV-infected persons include *Rhodococcus equi* and *Nocardia* species. Atypical causes of community-acquired bacterial pneumonia such as *Mycoplasma* or *Legionella* species do not seem to occur with increased frequency in HIV-infected compared to uninfected patients.

CLINICAL MANIFESTATIONS

Patients typically present with acute onset of symptoms over a few days, often with cough productive of purulent sputum, fever, systemic malaise, and leukocytosis with a neutrophilic predominance. Typical radiographic findings consist of segmental, lobar, or multilobar consolidation on chest radiograph, although more diffuse reticular or interstitial patterns can occur as well. Cavitary infiltrates may result from a number of different causes, including bacteria such as *S. aureus*, *Pseudomonas*, and *Nocardia* species. Numerous cavitary infiltrates, particularly from staphylococcal species, should prompt consideration of septic pulmonary emboli. The risk of invasive disease secondary to *S. pneumoniae* is increased in those who are not on ART and who have not received pneumococcal vaccine. Other risk factors for bacteremia secondary to *S. pneumoniae* include low CD4 cell count, alcohol abuse, current smoking, recent hospitalization, and other comorbid illnesses.

DIAGNOSIS

Blood cultures should be obtained, particularly in individuals with low CD4 cell counts, and sputum cultures considered. Thoracentesis should be considered for patients with pleural effusion, particularly if they are not responding appropriately to antimicrobial therapy.

TREATMENT

Rx

The treatment of HIV-infected patients with community-acquired bacterial pneumonia should follow published guidelines.[5] Initial empirical therapy should include coverage against frequently identified organisms (e.g., *S. pneumoniae* and *Haemophilus* species) and should target both typical and atypical causes of bacterial pneumonia. Local drug resistance patterns should be taken into account, and monotherapy with a macrolide should be avoided if patients are already on macrolide prophylaxis. Macrolides should also be avoided if TB is in the differential, because resistance can develop. For patients with CD4 lymphocyte counts below 100 cells/μL or with recent hospitalization, neutropenia, broad-spectrum antimicrobial use, or underlying structural lung disease, consideration should be given to including coverage against *Pseudomonas aeruginosa*. For patients with recent health care contact, consideration should be given to antimicrobial therapy directed against microorganisms

associated with health care–associated pneumonia (e.g., more resistant gram-positive and gram-negative organisms). Empirical coverage for methicillin-resistant *S. aureus* with vancomycin should also be considered in injection drug users and other high-risk populations.

PREVENTION

Pneumococcal vaccine should be given to HIV-infected patients. Current recommendations are for the 13-valent pneumococcal conjugate vaccine (PCV13) to be given first, followed by 23-valent pneumococcal polysaccharide vaccine (PPV23) at least 8 weeks or more later (Chapter 18). For those who have already received the PPV23, the PCV13 should be given at least 1 year later. Prevention of bacterial pneumonia also includes yearly administration of inactivated influenza vaccine to all HIV-infected individuals.

PROGNOSIS

Time to clinical stability and length of stay for HIV-infected patients with community-acquired bacterial pneumonia are generally similar to HIV-uninfected patients. Although 90-day mortality has overall improved among HIV-infected patients after an episode of pneumonia when comparing the early ART era to the current era, mortality rates remain substantially higher in patients during the 1 year following pneumonia. Risk factors for increased mortality following pneumonia include a CD4 cell count below 200 cells/μL, no ART use, older age, and greater burden of comorbid illness.

Mycobacterium Tuberculosis

EPIDEMIOLOGY

TB is the most common opportunistic infection seen in HIV infection worldwide (Chapter 324). A global explosion in TB cases has resulted from the AIDS epidemic, especially in low-income countries. In contrast to many other HIV-associated infections, TB can be transmitted from person to person via an airborne route, leading to disease in HIV-uninfected individuals as well. TB is often the first manifestation of HIV and is the leading cause of death. In the United States, although TB cases have declined, TB remains an important infectious complication in HIV-infected patients, particularly in high-risk groups such as those living in communal settings or who are incarcerated, foreign-born individuals, or those with a history of TB exposure. Multidrug-resistant (defined as resistance to at least isoniazid and rifampin) and extensively drug-resistant TB (defined as multidrug-resistant TB plus resistance to any fluoroquinolone and at least one second-line injectable drug) are increasing in the HIV population, and some studies find that HIV is an independent risk factor for drug resistance. Drug resistance is associated with decreased survival, especially in HIV-infected individuals with low CD4 cell counts or those not receiving ART. ART use significantly decreases the risk of TB.

CLINICAL MANIFESTATIONS

Although HIV-infected patients may present with characteristic symptoms of TB including fever, sweats, weight loss, and cough, individuals with more advanced immunosuppression (CD4 cell counts < 350 cells/μL) often have an atypical presentation with minimal symptoms. Patients with more advanced HIV are more likely to present with disseminated disease with risk increasing the lower the CD4 cell count. Other clinical history that is suggestive of TB is a history of recent or remote TB exposure or of latent TB without adequate treatment. On physical examination, patients may have signs of lung consolidation, lymphadenopathy, or hepatosplenomegaly. Laboratory testing is often nonspecific, but may reflect underlying organ involvement. The radiographic presentation depends on the degree of immunosuppression. Patients on ART with preserved CD4 cell counts usually have a chest radiographic pattern similar to that in the HIV-uninfected population with reactivation of TB, with upper lung zone infiltrates, often with cavitation (see Fig. 391-4). In patients with more advanced immunosuppression, the chest radiograph pattern is more consistent with primary TB (see Fig. 391-5). There are diffuse infiltrates, often in the middle and lower lung zones. Cavitation is uncommon in patients with a low CD4 cell count. A normal radiograph, miliary disease, or lymphadenopathy are also seen in HIV-infected patients with low CD4 cell counts. Pleural effusions may also be seen.

DIAGNOSIS

Definitive diagnosis by either culture of *M. tuberculosis* from an affected body site or identification by nucleic-acid amplification testing (NAA) is considered the gold standard. Visualization of acid-fast bacilli (AFB) on sputum smear may be the only feasible test in some resource-poor settings; however, HIV-infected individuals are more likely to have negative smears despite active disease. Current recommendations support obtaining three sputum specimens for AFB smear and culture with NAA testing of at least one sputum specimen. Use of NAA allows for rapid identification of the mycobacterial species in smear-positive specimens, allowing determination of TB versus nontuberculous mycobacteria. It is also able to identify *M. tuberculosis* in smear-negative patients more rapidly than culture. Because NAA testing does not provide information on drug sensitivity, it should always be paired with culture. Genotype testing can also be used and rapidly identifies drug resistance mutations, but it is not available in many settings. If three spontaneous sputum samples cannot be obtained, induced sputum or bronchoscopy should be performed. Specimens from other body sites such as cerebrospinal fluid, pleural fluid, and bone marrow aspirates can be evaluated. In patients with isolated pleural effusion where TB is suspected, pleural biopsy should be considered to obtain samples for culture and sensitivity. Mycobacterial blood cultures should be obtained, particularly in individuals with CD4 cell counts below 200 cells/μL.

TREATMENT Rx

To prevent transmission of TB, empirical treatment should be started in any HIV-infected person suspected of having TB, even if smears are negative (Chapter 324). Patients with AFB detected on smears or culture should also be started on therapy directed against TB while waiting for identification of the mycobacterial species. The recommended regimen for HIV-infected individuals with suspected TB is isoniazid, rifampin, pyrazinamide, and ethambutol with pyridoxine (Table 391-4). Consultation with an expert in TB treatment is recommended in cases of drug resistance. Directly observed therapy is recommended for HIV-infected individuals with TB.

ART is an important adjunctive therapy in HIV-infected individuals with TB. Concurrent ART treatment is shown to decrease mortality, prolong AIDS-free survival, and decrease time to sputum conversion.[A] Patients receiving ART should be continued on it during TB treatment. In patients with a CD4 cell count below 50 cells/μL, randomized trials have shown that starting ART within 2 weeks of TB therapy is of benefit.[B] In individuals with higher CD4 cell counts and severe clinical disease, ART should be initiated within 2 to 4 weeks. In all other individuals (except those with TB meningitis [who should have delayed ART]), ART should be started within 8 to 12 weeks. Initiation of ART can be difficult during TB treatment because there are a myriad of drug interactions. Immune reconstitution inflammatory syndrome (IRIS) can also be seen in about one third of individuals (Chapter 395). IRIS is a paradoxical reaction that presents with a temporary worsening of clinical symptoms or radiographic findings, resulting from increased immunity against TB (see later).

PREVENTION

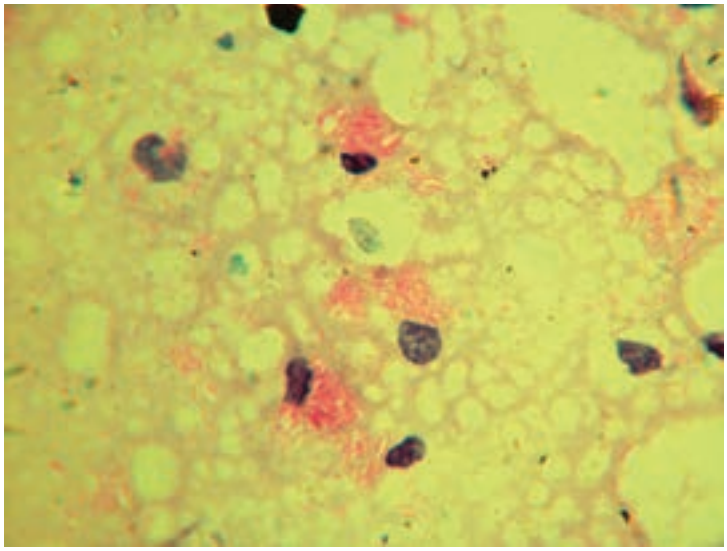
Prevention of primary infection with TB consists of avoiding exposure. Prevention of transmission of drug-resistant TB is of particular importance. To decrease transmission to other patients or health care workers, HIV-infected patients with any suspicion of TB should be placed in isolation until three sputum smears are negative for AFB. Improved ventilation, rapid initiation of therapy and sensitivity testing, mask use, and shifts to outpatient therapy can help decrease nosocomial transmission.

HIV-infected individuals exposed to TB who develop latent infection are at high risk of reactivation, but this risk can be significantly decreased with appropriate prophylaxis. Prevention of reactivation disease involves testing for latent TB infection (LTBI) with either a tuberculin skin test or an interferon-γ release assay (IGRA). HIV-infected persons should be tested when first diagnosed and depending on the clinical situation (Table 391-5). Individuals testing positive (≥5 mm of induration on skin test or a positive IGRA) should receive a course of prophylaxis once active infection has been ruled out. Isoniazid (300 mg daily or 900 mg twice weekly) combined with pyridoxine should be given for 9 to 12 months.[A] A recent randomized study demonstrated similar efficacy of a 3-month regimen of directly observed rifapentine and INH, with better completion rates.[B] Other regimens can also be used (see Table 391-4).

Secondary prevention of TB after treatment of active infection is not generally recommended in the United States. Some studies have found that continuation of isoniazid after completion of 6 months of TB therapy decreases risk of recurrence in high-burden countries.

PATHOBIOLOGY

Mycobacterium tuberculosis is an acid-fast bacillus that often has a characteristic beaded appearance (E-Fig. 391-1). The organism enters the lung, where it is ingested by alveolar macrophages. Defects in alveolar macrophage function in HIV can increase TB susceptibility. After entry, the host may clear the organism, become latently infected, or progress to active disease. Bacilli can also disseminate via the lymphatics and blood stream, producing disease in other organs. Typical lung pathology consists of necrotic and caseating granulomas made up of macrophages and other inflammatory cells. In individuals with HIV, classic granulomas may not be seen, particularly in those who are more immunocompromised.



E-FIGURE 391-1. Stain of sputum sample demonstrating multiple acid-fast bacilli shown to be *Mycobacterium tuberculosis*. Courtesy Derek Armstrong, QBC Diagnostics, and Richard Chaisson.

TABLE 391-4 TREATMENT AND PREVENTION REGIMENS FOR TUBERCULOSIS IN THE HIV-INFECTED PATIENT

	DRUGS	TOTAL DURATION	COMMENTS
Drug-susceptible pulmonary tuberculosis (TB)	*Initial phase (2 months):* Isoniazid + Rifampin or rifabutin + Pyrazinamide + Ethambutol *Continuation phase (4-7 months):* Isoniazid Rifampin or rifabutin	• 6 months • 9 months if culture positive after 2 months of TB therapy	• Give isoniazid with supplemental pyridoxine • Rifabutin preferred if patient is receiving protease inhibitor • Directly observed therapy 5-7 days/week recommended
Isoniazid-resistant pulmonary TB	*Initial phase (2 months):* Rifampin or rifabutin + Pyrazinamide + Ethambutol + Moxifloxacin or levofloxacin *Continuation phase (7 months):* Rifampin or rifabutin + Ethambutol + Moxifloxacin or levofloxacin	• 9 months	• Rifabutin preferred if patient is receiving protease inhibitor • Directly observed therapy recommended
Rifamycin-resistant or other drug-resistant pulmonary TB	Regimen per resistance pattern, clinical and microbiological responses		Consultation with experts recommended
Latent TB: preferred regimens	Isoniazid 300 mg PO daily *Or* Isoniazid 900 mg PO twice weekly	• 9 months	Latent TB defined as: 1. Screening test positive with no active disease and no previous history of treatment for active or latent TB *Or* 2. Close contact of person with infectious TB and no evidence of active disease • Give isoniazid with supplemental pyridoxine • Twice-weekly isoniazid regimen should be given by directly observed therapy
Latent TB: alternative regimens	Rifampin 600 mg PO daily or rifabutin (dose adjusted based on ART agents)	• 4 months	• Rifabutin preferred if patient receiving protease inhibitor

For detailed dosing and additional information, please see Reference 5.
ART = antiretroviral therapy.

TABLE 391-5 INDICATIONS FOR TESTING FOR LATENT TUBERCULOSIS IN HIV INFECTION

INDICATION	COMMENTS
When HIV first identified	Can use either tuberculin skin test or interferon-γ release assay to diagnose latent tuberculosis
Annually if patient at continuing risk of exposure to tuberculosis	Active disease should be ruled out before starting therapy
When individuals with a negative test have an increase in CD4 cell count to > 200 cells/μL with antiretroviral therapy	

PROGNOSIS

Response to therapy and time to negative cultures depends on the setting and the immunologic state of the patient. In the United States, response to therapy and time to convert sputum cultures in HIV-infected and HIV-uninfected individuals are similar. In contrast, the risk of death and relapse in sub-Saharan Africa is higher in HIV-infected individuals than in HIV-uninfected persons. HIV-infected patients with drug-resistant TB have decreased survival, particularly those with extensively drug-resistant TB, whose mortality may be as high as 90%.

Pneumocystis Pneumonia

EPIDEMIOLOGY

PCP was the first opportunistic infection described in the AIDS epidemic and was responsible for almost two thirds of AIDS-defining diagnoses (Chapter 341). With the widespread use of PCP prophylaxis followed by the introduction of ART, PCP incidence has decreased dramatically, although it remains the most common serious opportunistic infection in the United States. Some areas of the developing world such as Asia and South America have a high incidence of PCP, but the frequency of PCP in Africa may be lower, potentially because of geographic variations in *Pneumocystis* distribution, decreased susceptibility to PCP, lack of resources to detect *Pneumocystis*, or from competing risk of death from other infections (e.g., TB, bacterial pneumonia) that occur before HIV-infected individuals reach a CD4 cell count where they are susceptible to PCP.

Most cases of PCP occur in HIV-infected individuals who are not on ART, do not adhere to PCP prophylaxis, or are unaware of their HIV status. The primary risk factor is a CD4 cell count below 200 cells/μL, with the risk increasing as the CD4 cell count falls to lower levels. Risk of PCP is also higher in individuals with oropharyngeal candidiasis or a previous history of PCP. This risk can be reversed with successful ART. Individuals on ART also have a decreased risk of primary PCP if they have a suppressed HIV viral level with a CD4 cell count between 101 and 200 cells/μL.[6]

CLINICAL MANIFESTATIONS

The classic presentation of PCP in an HIV-infected patient is fever, a nonproductive cough, and dyspnea on exertion. The course of PCP in HIV infection may be subacute with duration of symptoms of 2 weeks or more, in contrast to the often fulminant disease in patients immunocompromised for reasons other than HIV, or in contrast to the acute course of bacterial pneumonia. Pleuritic chest pain and purulent sputum are much less common in PCP than in bacterial pneumonia. Complaints of hemoptysis should prompt investigation of other diagnoses. Physical examination in PCP is usually nonspecific, and the lungs are often normal on auscultation. Crackles are the most common abnormality, and signs of focal consolidation are less often seen. Patients are often hypoxic or desaturate with exertion, but this finding is nonspecific. A CD4 cell count below 200 cells/μL is usually seen. Serum lactate dehydrogenase (LDH) is often increased in patients with PCP, but an elevated serum LDH is not sufficiently specific to establish the diagnosis of PCP, nor is a normal LDH sufficiently sensitive to rule it out. A room air arterial blood gas should be measured if feasible to determine severity of disease, and an increase in the alveolar-arterial (A-a) oxygen gradient is common. The classic radiographic presentation is bilateral reticular or granular infiltrates (see Fig. 391-3). The infiltrates start in the perihilar region and extend toward the periphery with progressive disease. The opacities are

PATHOBIOLOGY

Pneumocystis is a fungal organism that exists in trophic and cystic forms. After inhalation, the organism attaches to alveolar epithelial cells. Progression to acute pneumonia is marked by development of a foamy alveolar exudate, damage to the alveolar-capillary membrane, and inflammation. Macrophages, dendritic cells, neutrophils, and B lymphocytes all play a role in *Pneumocystis* clearance, but CD4 T lymphocytes are critical in clearance. Colonization, in which the organism or its DNA is detected in an individual without clinical pneumonia, can occur.

PCP was historically thought to result from reactivation of latent infection acquired during childhood, but it now seems likely that person-to-person transmission and de novo infection from environmental sources occur as well. Airborne transmission has been demonstrated in laboratory animals, and infection can be passed to immunosuppressed hosts via a nonimmunosuppressed carrier. The environmental niche for the organism is unknown, but its DNA has been detected in air, soil, and water samples.

FIGURE 391-7. Close-up of the left lung from a chest radiograph of an HIV-infected person, CD4 cell count less than 200 cells/μL with *Pneumocystis* pneumonia. Two thin-walled cysts (*arrows*) are present. Courtesy Laurence Huang, MD. Used with permission.

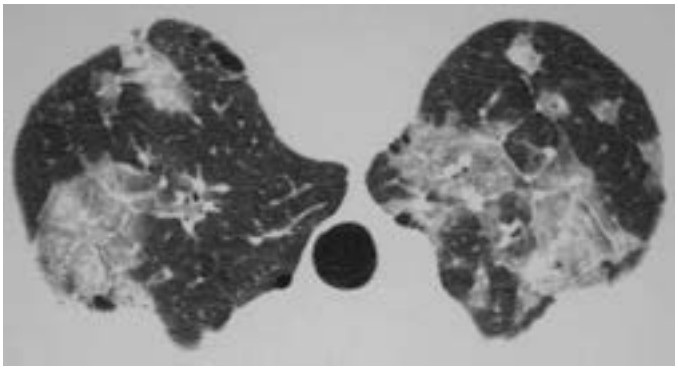


FIGURE 391-8. Chest high-resolution computed tomography (HRCT) in an HIV-infected person, CD4 cell count less than 200 cells/μL, whose chest radiograph showed normal findings. Because of clinical suspicion of *Pneumocystis* pneumonia (PCP), the patient underwent HRCT demonstrating characteristic patchy ground-glass opacities consistent with PCP. Courtesy Laurence Huang, MD. Used with permission.

typically symmetrical, but unilateral or asymmetrical disease can occur. Chest radiographs may also be normal, and atypical radiographic manifestations can occasionally be seen, including focal lobar consolidation, nodules, cavitary lesions, or miliary disease. In patients receiving aerosolized pentamidine for prophylaxis, upper lung infiltrates are more common owing to enhanced drug deposition in the lower lobes, and this presentation can be confused with TB. Pneumatoceles (thin-walled cysts) and pneumothoraces are common (Fig. 391-7). Pleural effusions and intrathoracic adenopathy are rare. Chest computed tomography (CT) can be a useful diagnostic study in patients who are suspected of having PCP, but present with a normal chest radiograph. In these patients, ground-glass opacities (Fig. 391-8) can suggest—but do not confirm—the diagnosis, because this finding is nonspecific; however, a normal high-resolution chest CT essentially rules out the diagnosis of PCP.

DIAGNOSIS

Empirical diagnosis is sometimes necessary in resource-limited settings, but definitive diagnosis with microscopic visualization of *Pneumocystis* in respiratory specimens is preferable. Because *Pneumocystis* culture cannot be performed, staining of respiratory samples is used to visualize organisms. Methenamine silver or toluidine blue O will stain the cyst wall. Giemsa and Diff-Quik staining will demonstrate both cystic and trophic forms. Immunofluorescence stains are also used and are more sensitive.

Spontaneously expectorated sputum cannot generally be used for PCP diagnosis, but induced sputum is often the first sample obtained in patients. Sensitivity of induced sputum varies by the clinical setting and experience of the institution. Repeated sputum samples are generally not obtained as they are in TB. Because a negative induced sputum cannot rule out PCP, bronchoscopy with bronchoalveolar lavage (BAL) should be performed if the initial induced sputum is negative (Chapter 341). BAL has excellent sensitivity (>90%) in the HIV-infected population, and transbronchial biopsy is rarely needed to diagnose PCP.

Newer diagnostic techniques are being investigated and may become more widespread. Polymerase chain reaction (PCR) of respiratory specimens can be used to detect *Pneumocystis* DNA in various respiratory samples, including oral washes. It is very sensitive and specific for *Pneumocystis*, but it may be difficult to distinguish between colonization and disease and is not widely available. Tests to detect elevated levels of serum 1→3, β-D-glucan (a component of fungal cell walls) can be used to support a diagnosis of PCP, but levels can also be elevated in other fungal infections.[7]

TABLE 391-6 TREATMENT REGIMENS FOR *PNEUMOCYSTIS* PNEUMONIA IN HIV INFECTION*

TREATMENT REGIMEN	DOSE(S), FREQUENCY	TOXICITIES
MILD PCP† (ARTERIAL Po_2 > 70 mm Hg *AND* ALVEOLAR-ARTERIAL O_2 DIFFERENCE < 35 mm Hg)		
Trimethoprim-sulfamethoxazole (TMP-SMX)	15-20 mg/kg (TMP component) daily (q6-8h or TMP-SMX 2 double strength tablets q8h)	Fever, dermatologic, gastrointestinal (GI), hematologic
TMP *plus* Dapsone	15 mg/kg daily (q8h) 100 mg once daily	Dermatologic, GI, hematologic
Clindamycin *plus* Primaquine	1800 mg daily (q6-8h) 30 mg (base) once daily	Dermatologic, GI, hematologic
Atovaquone	750 mg bid (with food)	Dermatologic, GI
MODERATE-SEVERE PCP‡ (ARTERIAL Po_2 < 70 mm Hg *OR* ALVEOLAR-ARTERIAL O_2 DIFFERENCE > 35 mm Hg)		
TMP-SMX	15-20 mg/kg (TMP component) daily (q6-8h)	Fever, dermatologic, GI, hematologic
Pentamidine	3-4 mg/kg once daily	Renal, pancreatic
Clindamycin *plus* Primaquine	1800-2400 mg (q6-8h) 30 mg (base) once daily	Dermatologic, GI, hematologic

*Recommended duration of therapy = 21 days.
†Oral route is preferred for patients with mild PCP who are treated as outpatients.
‡IV route is preferred (at least until clinical improvement) for patients with moderate-severe PCP. Adjunctive corticosteroids (prednisone 40 mg PO twice daily for 5 days, then 40 mg PO once daily for 5 days, then 20 mg PO once daily for 11 days or potency-equivalent methylprednisolone IV) should also be administered.
For detailed dosing and additional information, please see Reference 5.

TREATMENT

Anti-*Pneumocystis* Therapies

The first-line agent for treating PCP, regardless of severity, is trimethoprim-sulfamethoxazole (TMP-SMX) (Table 391-6). It is as effective as intravenous (IV) pentamidine but less toxic. Clinical resistance testing is not possible in PCP, but TMP-SMX can be used even if patients have been taking this agent for prophylaxis. Patients with mild PCP (Pao_2 > 70 mm Hg and A-a oxygen gradient < 35 mm Hg) who are able to tolerate oral medications can receive TMP-SMX by mouth. Patients who have moderate or severe PCP or who are unable to tolerate oral therapy should be given IV TMP-SMX. Therapy should be continued for a total duration of 21 days and may be switched to an oral regimen when the patient has clinically improved. Side effects of TMP-SMX are common in HIV-infected individuals. Frequent adverse effects include rash, nausea and vomiting, abnormal liver function tests, hyperkalemia, fever, and myelosuppression. Some toxicities of TMP-SMX can be life threatening, including Stevens-Johnson syndrome, toxic epidermal necrolysis, and a distributive shock syndrome that presents similarly to anaphylaxis, but these toxicities are rare. If side effects are mild, continuing treatment is recommended along with symptomatic treatment for adverse effects.

If patients cannot take TMP-SMX or if they develop a treatment-limiting side effect, several alternative regimens are available (see Table 391-6). IV pentamidine, clindamycin with primaquine, trimethoprim with dapsone, or atovaquone may be used. IV pentamidine is associated with a host of toxicities, including renal dysfunction, dysglycemias, pancreatitis, and torsades de pointes. Renal function and glucose levels need to be monitored during therapy; renal dysfunction and hypo- and hyperglycemia commonly occur. Clindamycin with primaquine has comparable efficacy to TMP-SMX or TMP-dapsone in mild to moderate disease. It may also be more effective than IV pentamidine in patients with severe disease. Because primaquine is administered orally, this regimen is less desirable if there is concern about effective

gastrointestinal absorption. Dapsone with trimethoprim is recommended only in mild or moderate PCP. Oral atovaquone should not be given in moderate or severe PCP and is less effective than other regimens for mild disease.

Adjunctive Corticosteroids

Randomized studies have demonstrated an increase in survival when corticosteroids are used as adjunctive therapy in PCP. Patients with an initial room air Po_2 below 70 mm Hg or an A-a gradient above 35 mm Hg should receive corticosteroids (see Table 391-6). Corticosteroids should be started at the time of PCP treatment, or at least within 72 hours of starting treatment, because they work to decrease the inflammation produced by killing of *Pneumocystis*, thus preventing deterioration in oxygenation. Corticosteroids should not be held during treatment while awaiting confirmation of the diagnosis of PCP.

Antiretroviral Therapy

Many patients with PCP are not receiving ART at the time of diagnosis. Early initiation of ART during treatment for acute PCP is supported by a randomized trial demonstrating a decrease in the end-point of progression to AIDS or mortality when ART was started within 2 weeks of diagnosis of an opportunistic infection.■ This study did not include PCP patients with respiratory failure who required mechanical ventilation. Given the risk of IRIS in these patients, optimal timing of ART is not well-defined (see "Intensive Care of the HIV-Infected Patient").

Treatment Failure

Patients with PCP often show an initial clinical worsening during treatment, with worsening oxygenation, increased radiographic infiltrates, and fever as the host reacts to dying organisms. If the patient fails to demonstrate improvement after 4 to 8 days of therapy, treatment failure should be considered. Other causes of clinical worsening, such as fluid overload, development of a pneumothorax, or presence of another infection, should be sought before deciding to change treatment.

PREVENTION

Evidence of airborne transmission and clusters of PCP outbreaks suggest that isolation of patients with PCP might prevent transmission of infection, but current guidelines do not find sufficient evidence to support recommending respiratory isolation for HIV-infected individuals with PCP. Primary prophylaxis is instituted in HIV-infected individuals with a CD4 cell count below 200 cells/μL or in those with oral candidiasis. TMP-SMX is the preferred agent for prophylaxis (Table 391-7). Dapsone, atovaquone suspension, or aerosolized pentamidine can also be used. Secondary prophylaxis should be instituted in individuals after they complete PCP treatment. In general, secondary prophylaxis of PCP is similar to primary prophylaxis, except that aerosolized pentamidine has been associated with more breakthrough PCP when used as secondary prophylaxis in individuals with a CD4 cell count below 100 cells/μL. Prophylaxis should be continued for life unless individuals experience immune reconstitution with ART. If the CD4 cell count is sustained above 200 cells/μL for at least 3 months, primary and secondary prophylaxis can be discontinued.

TABLE 391-7 PREVENTION REGIMENS FOR *PNEUMOCYSTIS* IN HIV INFECTION

PREVENTION REGIMEN	ALTERNATIVE DOSING	COMMENTS
Trimethoprim-sulfamethoxazole 1 double-strength (DS) tablet daily	1 single-strength tablet daily 1 DS tablet thrice weekly	Also effective prophylaxis against *Toxoplasma gondii* and many bacterial pathogens
Dapsone 100 mg daily		Combine with pyrimethamine and leucovorin in persons who are *T. gondii* immunoglobulin G antibody positive. Consider combining with pyrimethamine and leucovorin when used for secondary prophylaxis.
Atovaquone suspension 1500 mg daily		Improved bioavailability compared to tablets
Aerosolized pentamidine 300 mg monthly via RespirGard II nebulizer		May be associated with increased risk of extrapulmonary disease

PROGNOSIS

Prognosis for persons with PCP has improved dramatically from the beginning of the AIDS epidemic. Improvements resulted first from use of corticosteroids in more severe disease. Whether use of ART has improved short-term prognosis from PCP is debated. Changes in intensive care unit (ICU) care (e.g., use of low-tidal-volume ventilation) have also improved outcomes of severe PCP. Overall mortality from PCP is around 10%, with mortality in patients requiring mechanical ventilation approximately 30%.[8] Studies have found that survival correlates with degree of hypoxemia, underlying comorbidities, younger patient age, higher albumin, and first episode of PCP.

Other Infections

FUNGAL INFECTIONS

Although *Pneumocystis* is the most common fungal cause of pneumonia in HIV-infected patients, other endemic and nonendemic fungi may cause disease, particularly in those who are more severely immunosuppressed (e.g., CD4 cell counts < 200 cells/μL, and more often when < 100 cells/μL). Histoplasmosis can be encountered in patients who have been to the U.S. Midwest, and coccidioidomycosis in patients from the Southwest. *Cryptococcus neoformans* is found throughout the world. Of note, although invasive aspergillosis is a well-documented complication of various immunosuppressive disorders, it is uncommon in patients with HIV disease. Risk factors for the development of aspergillosis in HIV-infected individuals include use of corticosteroids, neutropenia, marijuana, and broad-spectrum antimicrobial drugs.

In more severely immunodeficient HIV-infected patients, fungal infection is often disseminated. For example, the most commonly encountered manifestation of cryptococcal disease is meningitis. Coccidioidomycosis in HIV-infected persons can present with focal or diffuse pneumonia, as well as cutaneous disease, meningitis, liver or lymph node involvement, or disseminated disease. Disseminated histoplasmosis most often presents as a febrile wasting illness in HIV-infected persons. Isolated pulmonary disease secondary to fungal infection tends to be more rare but can occur, particularly with histoplasmosis and coccidioidomycosis; isolated or focal pulmonary disease is more likely in those with CD4 cell counts above 250 to 300 cells/μL. The most commonly encountered chest radiographic findings of cryptococcal, coccidioidal, and histoplasmosis infection consist of diffuse bilateral interstitial infiltrates that are often reticular or reticulonodular. Focal consolidation, nodular opacities, cavitation, pleural effusion, and hilar adenopathy are less frequent, but may also be seen (Fig. 391-9). Radiographic findings can mimic other diseases, particularly PCP and atypical bacterial infections.

Diagnosis of pulmonary fungal infection is usually established by culture of sputum or BAL fluid and occasionally of pleural fluid; however, serologic and antigen testing can aid in the diagnosis of a variety of fungal infections. Cryptococcal antigen is a sensitive and specific test performed on serum, cerebrospinal fluid, urine, BAL fluid, or pleural fluid. The *Histoplasma* antigen test is also a sensitive method for rapid diagnosis of disease and can be obtained on urine, serum, cerebrospinal fluid, or BAL fluid. Serologic tests are useful in evaluation of suspected coccidioidomycosis, with an estimated 80 to 90% sensitivity of complement fixation and tube precipitin test for diagnosis.

VIRAL INFECTIONS

Viral pneumonias are not frequently encountered in HIV-infected patients. Although often isolated in the BAL, cytomegalovirus (CMV) is a less common cause of pneumonia (Chapter 376). Most cases of CMV disease occur in patients with a CD4 lymphocyte count less than 50 cells/μL. Symptoms of CMV pneumonia are nonspecific; chest radiograph findings include reticular or ground-glass opacities, alveolar infiltrates, and nodules or nodular opacities. The diagnosis of CMV pulmonary disease can be challenging because BAL fluid culture is not specific. Definitive diagnosis requires biopsy and demonstration of widespread specific cytopathic changes in the lungs, but biopsies may not be feasible. Patients suspected of having CMV pneumonitis should undergo a careful evaluation for evidence of disseminated disease, particularly ocular involvement. Treatment of CMV pneumonia is the same as currently recommended for disseminated disease.

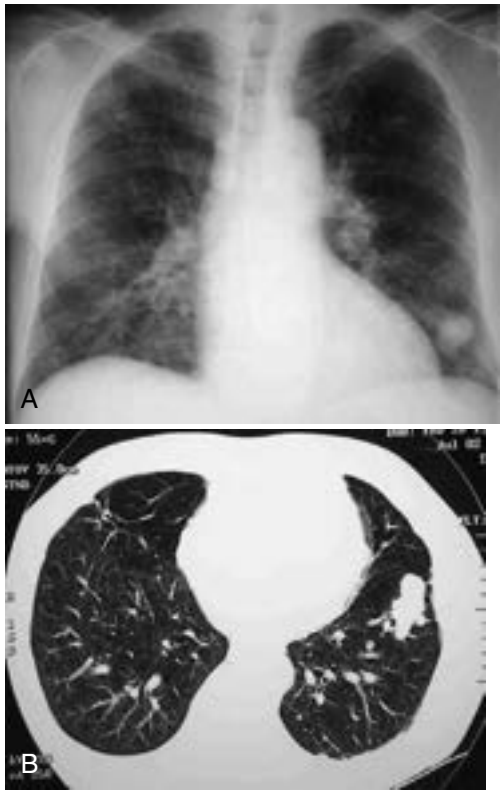

FIGURE 391-9. **Chest radiograph (A) and chest computed tomography (CT) scan (B) of an HIV-infected individual, CD4 cell count less than 200 cells/μL. A multilobulated noncalcified mass measuring 4.6 × 2.4 cm is present in the left lower lobe, with multiple adjacent satellite nodules. Culture from CT-guided transthoracic needle aspiration revealed *Cryptococcus neoformans*. Courtesy Laurence Huang, MD. Used with permission.**

Influenza generally presents similarly and has a comparable clinical course in HIV-infected as in HIV-uninfected adults (Chapter 364). HIV infection does not appear to increase the risk for influenza, although influenza-related mortality may be greater in those with AIDS compared to the general U.S. population. Prompt initiation of antiviral therapy directed against influenza is recommended. All HIV-infected persons should receive the inactivated influenza vaccine annually.

NONTUBERCULOUS MYCOBACTERIA

TB is the most common mycobacterial lung disease seen in HIV, but other nontuberculous mycobacterial pulmonary infections may occur. The two most common causes in HIV are *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii* (Chapter 325). Although the lungs may be a portal of entry for MAC, patients usually present with disseminated disease, and isolated pulmonary MAC in HIV is rare. When isolated pulmonary MAC is seen, it has been reported in patients receiving ART and thus may be a manifestation of immune reconstitution inflammatory syndrome. The chest radiograph is most often normal in MAC infection, even when cultures of respiratory specimens grow MAC. Focal infiltrates are rare. Endobronchial lesions containing MAC can sometimes be seen. MAC treatment consists of at least ethambutol and a macrolide. Additional agents can be considered in advanced immunosuppression, high mycobacterial burden, or inability to use ART. Primary MAC prophylaxis with azithromycin or clarithromycin is recommended in HIV-infected individuals with a CD4 cell count below 50 cells/μL. Secondary prophylaxis is recommended after a minimum of 12 months of treatment and can be discontinued when the CD4 cell count is above 100 cells/μL for at least 6 months.

M. kansasii is most common in the southern and central United States, with clusters of disease also reported in Europe, Asia, and Africa. It can occur at any CD4 cell count, but is most common in individuals with CD4 cell counts below 100 cells/μL. The clinical presentation and radiographic appearance of *M. kansasii* is similar to TB. Diagnostic work-up is also similar to that of TB, with the exception that identification of *M. kansasii* does not always indicate disease, because colonization can occur. Treatment consists of isoniazid, rifampin, and ethambutol with pyridoxine for a minimum of 12 months after cultures become negative. Rifabutin or a macrolide can be substituted for rifampin in patients taking a protease inhibitor or non-nucleoside reverse transcriptase inhibitor.

NONINFECTIOUS PULMONARY DISEASES

Chronic Obstructive Lung Disease

EPIDEMIOLOGY

HIV infection has been associated with several different manifestations of obstructive lung disease, including features of emphysema and chronic bronchitis, which together comprise COPD, as well as bronchial hyperresponsiveness, which characterizes asthma. Bronchiectasis causes an obstructive ventilatory defect and has been described in patients with HIV. COPD and bronchiectasis are known sequelae of severe or repeated opportunistic infection; however, evidence suggests that HIV infection is associated with an increase in COPD apart from the effects of opportunistic infections and after controlling for other traditional risk factors for COPD such as smoking and illicit drug use (Chapter 88).[9]

PATHOBIOLOGY

The pathogenesis of COPD in HIV infection is incompletely understood and likely involves multiple pathways. Respiratory tract infections, prior bacterial pneumonia or PCP, and colonization with microorganisms likely play an important role. The association of lung function with HIV specific markers suggests a potential pathogenic role for the virus itself. In comparison to HIV-uninfected persons, HIV-infected persons with poor viral control or greater degree of immunodeficiency have more severe diffusing capacity impairment.[10] Furthermore, a high viral load or low CD4 T-cell count (<100 cells/μL) have been associated with accelerated decline in airflow over time in a longitudinal cohort study of injection drug users.

CLINICAL MANIFESTATIONS

In general, the clinical presentation of chronic obstructive lung diseases is similar in HIV-infected as in uninfected persons. The majority of patients with COPD are cigarette smokers. HIV-infected individuals may be more likely to experience respiratory symptoms such as chronic cough, phlegm production, and dyspnea on exertion, for a given degree of impairment in pulmonary function, compared to HIV-uninfected individuals.

TREATMENT

Rx

In general, treatment of asthma and COPD in patients with HIV infection is similar to that for the HIV-uninfected population, although no studies have specifically examined these treatments in persons with HIV. Smoking cessation should be prioritized. Protease inhibitors, particularly ritonavir, have been reported to increase systemic levels of inhaled or intranasal fluticasone. The use of high-dose inhaled corticosteroids for COPD in patients with HIV also requires careful monitoring for oral candidiasis and pneumonia.

PROGNOSIS

No studies have specifically addressed whether the prognosis for COPD in HIV-infected patients is similar to that in HIV-uninfected patients. COPD is likely to be a major cause of morbidity and mortality as HIV-infected patients are aging.

Lung Cancer

EPIDEMIOLOGY

Whereas AIDS-defining cancers such as Kaposi sarcoma and non-Hodgkin lymphoma have decreased, non-AIDS-defining cancers in HIV-infected patients have increased, primarily among those aged 50 years and older. Lung cancer is now the most common infection-unrelated non-AIDS-defining cancer and is a leading cause of mortality in HIV-infected persons. The incidence of lung cancer is greater among HIV-infected persons than among HIV-uninfected persons.[11]

PATHOBIOLOGY

Although lung cancer can develop at any CD4 lymphocyte count, immunodeficiency is postulated as a mechanism for the enhanced risk of lung cancer associated with HIV. Prior lung disease and infections, particularly bacterial pneumonia and TB, are also risk factors in epidemiologic studies. HIV viral

load, CD4 cell count, and use of ART do not appear associated with lung cancer risk.

CLINICAL MANIFESTATIONS

Most HIV-infected patients who develop lung cancer are cigarette smokers. Although all pathologic types are seen, adenocarcinoma is the most frequent pathologic type reported; squamous cell carcinoma is the second most frequently observed pathologic type. The distribution of tumor stage at diagnosis and histologic type appear similar in HIV-infected as in uninfected patients. Radiographic appearance is also similar to that in the HIV-uninfected population (E-Fig. 391-2).

TREATMENT

Rx

Surgical resection should be considered for any patient who meets criteria based on stage of cancer and underlying medical condition. Chemotherapy and radiation may also be indicated. Significant decreases in CD4 cell counts and hematologic toxicity can occur with chemotherapy.

PROGNOSIS

Studies have been conflicting on the impact of HIV infection on survival for patients with lung cancer. Some studies suggest that survival is overall no different when stratified by stage of disease and propensity score adjustment, with an overall median survival for all stages of 7 months for HIV-uninfected controls versus 8 months for HIV-infected patients. Other studies have shown that when controlling for confounders and competing risks, HIV infection was associated with a greater risk of lung cancer–specific death, with an overall median survival of 6 months among non–small cell lung cancer patients with HIV compared to 20 months in patients without evidence of HIV. HIV-infected patients may less frequently receive lung cancer treatments, potentially accounting for survival differences. Whether lung cancer screening with an annual low-dose CT scan will have a beneficial effect on mortality in HIV-infected smokers, as it has in older HIV-uninfected heavy smokers, is not yet known.[12,13]

Other Thoracic Malignancies

The most common HIV-associated malignancy is Kaposi sarcoma (KS), although its incidence has decreased dramatically with combination ART. KS is an angioproliferative tumor and most commonly presents with mucocutaneous involvement. The lymph nodes, gastrointestinal tract, and lungs can also be involved. HIV-associated KS is substantially more likely in men who have sex with men than in other HIV risk groups. Human herpesvirus 8 (HHV-8) has been found in all forms of KS and appears to play a central role in pathogenesis.

Pulmonary KS presents in most patients when their CD4 T-cell counts are below 200 cells/μL. Respiratory symptoms typically are nonspecific and include nonproductive cough, dyspnea, and fever. Most but not all patients with pulmonary KS have concomitant mucocutaneous disease. Typical chest radiograph findings of pulmonary KS consist of bilateral perihilar or central opacities, as well as linear densities, nodular opacities, pleural effusions, and intrathoracic lymphadenopathy (Fig. 391-10A). The diagnosis of pulmonary KS can often be established by visualization of characteristic lesions on bronchoscopy. Endobronchial lesions from KS are flat or slightly raised, red or violaceous lesions (see Fig. 391-10B), and their presence is often sufficient to establish a presumptive diagnosis without requiring biopsy. HHV-8 may be detected in BAL. Tumors can regress in size and number in response to ART, and therefore all patients with KS should receive combination ART if no other contraindications exist. Treatment of more advanced systemic disease also includes chemotherapy. Of malignancies, KS is the most likely to be associated with IRIS in patients who initiate ART.

Almost all HIV-associated non-Hodgkin lymphomas (NHL) are of B-cell origin (Chapter 185). The majority are associated with Epstein-Barr virus (EBV) infection. As with KS, the incidence of NHL has declined dramatically in the era of combination ART. Most HIV-infected patients with NHL present with disseminated disease and extranodal involvement at diagnosis. Clinically apparent pulmonary involvement occurs in up to 30% of patients with AIDS-related NHL. Occasionally, the lung is the only site involved. Although NHL can present at a wide range of CD4 lymphocyte counts, most patients have advanced HIV infection, with median CD4 T-cell counts around 100 cells/μL.

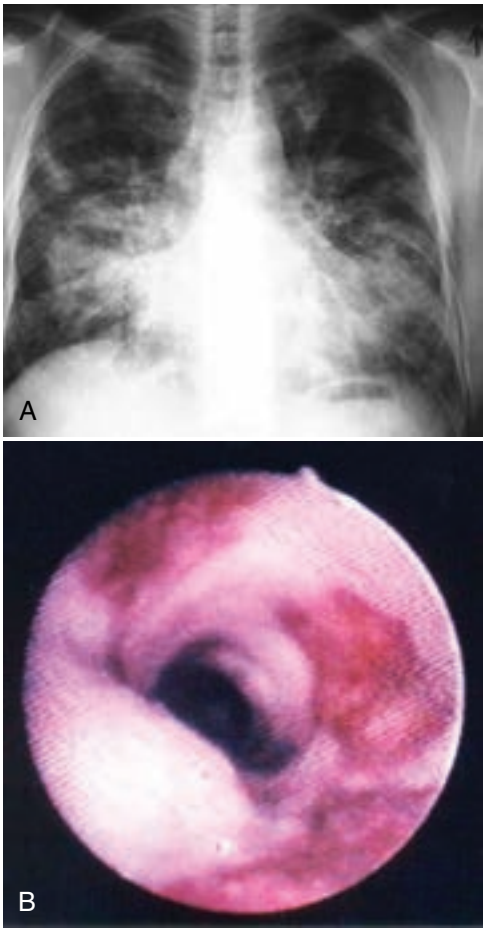

FIGURE 391-10. Chest radiograph (A) of an HIV-infected patient, CD4 cell count less than 100 cells/μL, with characteristic bilateral middle and lower lung zone, predominantly central, distribution of abnormalities of Kaposi sarcoma. The patient had no evidence of mucocutaneous disease, and the diagnosis was made by visualization of characteristic erythematous violaceous Kaposi sarcoma throughout the airways on bronchoscopy (**B**). **B**, courtesy Laurence Huang, MD. Used with permission.

Common presenting features of thoracic involvement with NHL are nonspecific and include cough and dyspnea. Systemic symptoms such as fever, sweats, and weight loss are common. Chest radiograph findings typically include single or multiple nodules, nodular opacities or masses, lobar infiltrates, and diffuse interstitial infiltrates; pleural effusions and intrathoracic lymphadenopathy are common accompanying findings. The diagnosis of NHL requires demonstration of malignant lymphocytes on cytology or biopsy specimens. Most often, the diagnosis is made by biopsy of an extrathoracic site. The yield of pleural cytology is significantly higher in HIV-associated pulmonary lymphoma as opposed to HIV-uninfected cases. Pulmonary involvement in NHL is treated as part of the systemic disease (Chapter 185).

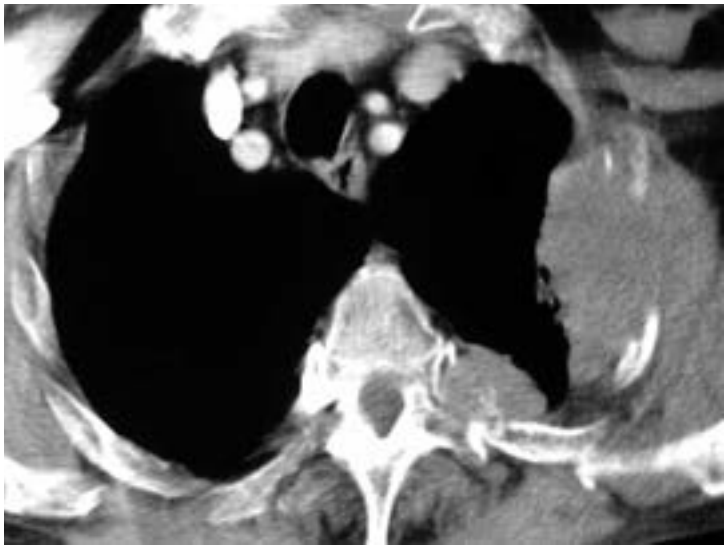
Interstitial Lung Disease

EPIDEMIOLOGY

Interstitial lung disease is a less common cause of pulmonary disease than infections, malignancies, or obstructive lung diseases. HIV-infected individuals may develop a number of diagnoses seen in the general population such as nonspecific interstitial pneumonitis (NSIP), sarcoidosis, and hypersensitivity pneumonitis. Sarcoidosis is sometimes associated with initiation of ART, and it is debated whether it is a manifestation of IRIS. Lymphocytic interstitial pneumonia (LIP) is a disease entity that is more common in HIV-infected children than adults, and its incidence has decreased significantly since introduction of ART.

PATHOBIOLOGY

Causes of interstitial lung diseases are poorly understood. Pathology is similar to that seen in the HIV-uninfected population (Chapter 92). It is unclear whether LIP represents a unique pathologic disorder or results from multiple



E-FIGURE 391-2. Chest computed tomography (CT) in an HIV-infected smoker with a CD4 cell count of 200 cells/μL and HIV viral level below 50 copies/mL, with chronic obstructive pulmonary disease. CT-guided biopsy demonstrated squamous cell cancer. Courtesy Laurence Huang, MD. Used with permission.

causes that lead to similar lung pathology. Lung biopsy in LIP demonstrates interstitial lymphocytes with spreading into the alveolar septae.

CLINICAL MANIFESTATIONS

Manifestations vary depending on the specific diagnosis, but symptoms often include progressive shortness of breath and nonproductive cough. Patients may be febrile. Physical examination may reveal crackles on lung examination. Systemic findings such as lymphadenopathy in sarcoidosis can provide clues to specific etiologies. Radiographic manifestations vary with the disease. Pulmonary function testing generally shows a pattern consistent with restrictive lung disease, and diffusing capacity for carbon monoxide is often impaired.

DIAGNOSIS

BAL is a useful initial procedure for ruling out infectious causes of lung disease, but definitive diagnosis of interstitial lung disease generally requires a lung biopsy. In most cases, a video-assisted thoracoscopic lung biopsy is preferred to transbronchial biopsy, although in the case of sarcoidosis, transbronchial biopsies are useful in establishing a diagnosis.

TREATMENT Rx

There have been no treatment trials of interstitial lung diseases in HIV-infected patients, and treatment should generally follow guidelines for the HIV-uninfected population (Chapter 92). In LIP, initiation of ART is recommended, with consideration of corticosteroids depending on the clinical severity.

PROGNOSIS

Prognosis is generally the same as that in the HIV-uninfected population. In a small number of cases, LIP may be a precursor to lymphoma, which carries a worse outcome, however LIP usually has a better prognosis in HIV infection because it may respond to initiation of ART.

Pulmonary Hypertension

EPIDEMIOLOGY

HIV is recognized as a cause of World Health Organization (WHO) Group 1 pulmonary arterial hypertension (PAH). PAH has been reported to occur with a prevalence of 0.5% in the HIV-infected population, compared to 1 to 2 cases per million in HIV-uninfected individuals.[14] HIV-infected individuals also may have additional risk factors for PAH, including IV drug use or liver disease.

PATHOBIOLOGY

The hallmark pathologic manifestation of HIV-PAH is the plexiform lesion. More subtle changes such as medial hypertrophy and intimal hyperplasia of pulmonary arterioles can also be seen. The exact causes of PAH in HIV are not well understood, but may involve genetic or environmental insults in addition to HIV.

CLINICAL MANIFESTATIONS

PAH in the HIV-infected patient presents similarly to PAH in the HIV-uninfected individual, although patients are often younger and have a better New York Heart Association functional class at presentation. Initial symptoms are often nonspecific, but patients eventually may report symptoms of dyspnea with exertion, syncope, or exertional chest pain. Physical examination can be normal or suggestive of right-sided heart failure.

DIAGNOSIS

The gold standard for diagnosis of PAH is right heart catheterization. Echocardiography is often performed as a screening test, but pulmonary arterial pressures on echocardiography may not correlate with pressures on catheterization. Other causes of pulmonary hypertension such as underlying lung disease, left-sided heart failure, or cirrhosis should be evaluated as well.

TREATMENT Rx

There have been few trials of standard PAH agents in HIV-infected populations, but in general, guidelines for PAH treatment in the HIV-uninfected population should be followed (Chapter 68). Epoprostenol may be associated with a higher risk of intravascular infections in HIV-infected individuals, especially those who are active IV drug users. Sildenafil levels can increase when used in combination with antiretrovirals, particularly with regimens that include ritonavir. Tadalafil appears to have less interaction with ritonavir. Treatment with warfarin can also be used in addition to PAH-specific therapies. Although results of studies are conflicting, there may be some benefit to ART in this disease, and patients should be started on ART if they are not already receiving it.

PROGNOSIS

One-year survival for HIV-infected individuals with PAH is 58 to 88% and varies with the cohort studied. Lower CD4 cell count and higher HIV viral levels are associated with worse survival.

Intensive Care of the HIV-Infected Patient

The epidemiology of ICU care for HIV-infected ICU patients has shifted multiple times over the course of the AIDS epidemic. A recent study of HIV-infected veterans with a first ICU admission between 2002 and 2010 found that 15% of HIV-infected individuals had a medical or cardiac ICU admission, compared to 10% of HIV-uninfected individuals.[15] HIV-infected patients were also younger, had a longer length of stay, and were more likely to require mechanical ventilation. Another study of over 2500 HIV-infected individuals found that 4.2% required ICU admission over a median of 2.2 years of follow-up from an AIDS diagnosis; a diagnosis of HIV after the CD4 cell count had fallen below 350 cells/μL and low CD4 cell count were associated with increased incidence of ICU admission.[16] ART use was protective for ICU admission.

HIV-infected patients may be admitted to the ICU with conditions related to their HIV, with side effects of ART, or for reasons unrelated to HIV. Currently, about half of ICU admission diagnoses in this population are directly related to HIV (e.g., opportunistic infections, malignancies). HIV-infected individuals may also be admitted with common conditions such as myocardial infarction, the risk for which may be increased in HIV-infected individuals on ART. Life-threatening complications of ART such as lactic acidosis or severe IRIS can also precipitate ICU admission. In recent series, respiratory failure is still the most common cause of ICU admission, with PCP, TB, and bacterial pneumonia causing varying degrees of disease depending on the population. The outcome of HIV-infected ICU patients with acute respiratory distress syndrome (Chapter 104) now is similar to HIV-negative patients.[17] In about 20 to 40% of cases, HIV infection is not known at the time of ICU admission, and providers need to consider HIV infection in their differential even if HIV infection has not been confirmed.

Antiretroviral Therapy Use

Among HIV-infected patients admitted to the ICU, clinicians need to be aware of numerous antiretroviral drug toxicities, drug-drug interactions, and concerns regarding absorption and metabolism of specific medications. Side effects of ART are numerous. Several toxicities secondary to ART that may require ICU admission include acute liver failure, lactic acidosis, pancreatitis, and hypersensitivity reactions.

In HIV-infected ICU patients, clinicians need to decide whether to continue or initiate ART. In general, expert opinion is that ART should be continued in the ICU for critically ill HIV-infected patients already on ART, if ART can be safely administered with minimal drug-drug interactions or risk of toxicities while receiving ICU medications. For patients admitted to the ICU for AIDS-related diseases, initiation of ART should be strongly considered in consultation with an infectious disease specialist. Survival is improved when ART is started concurrently with or in close proximity to treatment of opportunistic infection, but existing data do not include critically ill patients with respiratory failure that is severe enough to require mechanical ventilation. Nevertheless, HIV-infected patients admitted for non-AIDS-related conditions but with prolonged ICU hospitalizations or severely decreased CD4 T-cell count should also be considered for ART initiation.

HIV-infected patients who initiate ART, particularly in close proximity to treatment for an opportunistic infection, are at risk for development of IRIS. IRIS is a paradoxical worsening of clinical status typically related to recovery of the immune system after immunosuppression (Chapter 395). IRIS occurs as a result of host inflammatory responses to previously recognized or subclinical infections, or to cancer or self-antigens. Manifestations of IRIS that can result in critical illness include pneumonitis, meningitis, hepatitis, and pericarditis. Respiratory failure secondary to IRIS is most often associated

with TB and PCP. Other causes of clinical worsening such as a new infection, treatment failure, or drug reaction should be ruled out. IRIS is usually self-limited, and ART should be continued. Nonsteroidal anti-inflammatories can provide symptomatic relief.■

Prognosis for HIV-infected ICU patients has improved dramatically over the course of the AIDS epidemic. Many studies demonstrate mortality comparable to the HIV-uninfected population, although a study of HIV-infected veterans found that 30-day mortality was higher in those with HIV infection. Factors that predict increased mortality include an AIDS-associated diagnosis, need for mechanical ventilation, low serum albumin, and a diagnosis of PCP. In PCP patients, specific mortality risks include mechanical ventilation and development of a pneumothorax.

REVIEW QUESTIONS

1. Which of the following pulmonary complications is most likely in an HIV-infected person with a CD4 lymphocyte count above 500 cells/μL?

A. *Streptococcus pneumoniae* pneumonia
B. Disseminated *Mycobacterium tuberculosis*
C. *Pneumocystis* pneumonia
D. Pulmonary Kaposi sarcoma
E. Lung cancer

Answer: A At a CD4 lymphocyte count above 500 cells/μL, HIV-associated complications such as *Pneumocystis* pneumonia (PCP) and pulmonary Kaposi sarcoma are unlikely. Among the remaining choices, *S. pneumoniae* pneumonia is more frequent than either disseminated *M. tuberculosis* (which less commonly presents with disseminated disease at a CD4 count above 500 cells/μL) or lung cancer.

2. *Pneumocystis* pneumonia may present with which of the following chest radiographic findings?

A. Normal chest radiograph
B. Focal consolidation
C. Bilateral reticular or granular opacities
D. Pneumatoceles
E. All of the above

Answer: E PCP can present with a wide range of chest radiographic findings, including all of the abnormal findings listed, as well as a normal radiograph.

3. A 40-year-old HIV-infected man presents to the emergency room with cough productive of purulent sputum and fevers for 2 days. He is homeless, smokes cigarettes, and has a history of alcohol abuse. He denies injection drug use and has never had pneumonia previously. He has not been on antiretroviral therapy (ART) nor antibiotic prophylaxis; his most recent CD4 T-cell count 3 months ago was 310 cells/μL. He has not been in health care contact since that time. He has no known drug allergies. On examination, he is alert and in no acute respiratory distress. His temperature is 38.4° C, blood pressure is 130/80, heart rate 95, respirations 15, and oxygen saturation of 96% on room air. His chest x-ray shows a right middle lobe consolidation. Which of the following should be recommended initially:

A. Obtain a chest computed tomography (CT) scan with IV contrast.
B. Initiate treatment with ceftriaxone and azithromycin.
C. Initiate treatment with vancomycin and piperacillin/tazobactam.
D. Initiate treatment with IV trimethoprim-sulfamethoxazole.
E. Initiate treatment with isoniazid, rifampin, ethambutol, and pyrazinamide.

Answer: B The acute onset of illness with a focal opacity on chest radiograph is consistent with bacterial pneumonia, and the patient's history of cigarette smoking and alcohol abuse in addition to HIV infection increase his risk for bacterial pneumonia. The results of a chest CT are unlikely to influence initial treatment decisions in this case. Although opportunistic infections are possible, they are less likely because his CD4 count recently was over 200, and etiologies such as PCP or tuberculosis (TB) are less likely, given the acuity of symptoms and radiographic findings. He does not have risk factors for health care–associated pneumonia or known underlying lung disease, thus coverage for community-acquired pneumonia with ceftriaxone and azithromycin would be an appropriate first regimen.

4. You are asked to evaluate a 58-year-old HIV-infected man who was initially admitted to the hospital 15 days ago with fevers, chills, night sweats, weight loss, and cough. He has a history of TB treated 30 years ago. On admission, he was not on ART and was found to have a CD4 T-cell count of 10 cells/μL and an HIV viral load of over 100,000 copies/mL. A sputum induction was negative for acid-fast bacilli but positive for *Pneumocystis*. He was treated with trimethoprim-sulfamethoxazole, and after 8 days was improving. He was not given corticosteroids. He was then started on highly active antiretroviral therapy (ART) and discharged. He now presents with recurrent fever and increased dyspnea. His chest x-ray on admission showed faint bilateral, hazy air space opacities. Now 15 days later at his second hospitalization, his chest x-ray reveals increased dense bilateral air space opacities. What is the next most appropriate step in this patient's management:

A. Start rifamycin, isoniazid, pyrazinamide, and ethambutol.
B. Switch from trimethoprim-sulfamethoxazole to pentamidine.
C. Stop HAART.
D. Start Solu-Medrol.
E. Bronchoscopy with bronchoalveolar lavage

Answer: E The differential diagnosis to consider in this patient who presents with worsening of respiratory symptoms and air space opacities includes inadequately treated or nonresponding PCP, a new opportunistic infection, a noninfectious process such as congestive heart failure, or immune reconstitution inflammatory syndrome (IRIS). Because his initial diagnosis of PCP was based on sputum induction, a bronchoscopy would be indicated to assess for other infections before diagnosing IRIS, which is ultimately what this patient was thought to have. He improved with the addition of a brief course of corticosteroids, completion of 21 days of trimethoprim-sulfamethoxazole, and continuation of his ART.

5. When should ART be started in an HIV-infected person with a new diagnosis of TB and a CD4 cell count below 50?

A. After completion of TB treatment
B. Within 2 weeks of starting TB treatment
C. After 1 month of TB treatment
D. When sputum cultures are no longer positive for TB
E. When patient is no longer febrile

Answer: B Although initiation of ART used to be delayed until after TB therapy, owing to drug interactions and the concern for the immune reconstitution syndrome, several randomized studies have shown decreased mortality, greater AIDS-free survival, and more rapid conversion of sputum smears and culture with early initiation of ART. Thus, all HIV-infected individuals with TB should receive ART. If the patient is naïve to ART, it is recommended that ART be initiated within 2 weeks of TB treatment initiation in individuals with CD4 cell counts below 50 cells/μL and within 8 to 12 weeks in all others. Individuals receiving ART should continue its use during TB therapy.

SKIN MANIFESTATIONS IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

TOBY MAURER

From the beginning of the epidemic, skin disease has often been the initial feature of infection with human immunodeficiency virus (HIV). Cutaneous manifestations are often predictive of the stage of immunosuppression and long-term prognosis.[1] Morbidity from skin diseases, particularly from opportunistic infections, has decreased with the advent of antiretroviral therapy (ART), although there are still significant dermatologic problems for patients in the post-ART era (Table 392-1). Cutaneous manifestations seen in patients with HIV may be categorized as infectious, neoplastic, inflammatory, or related to ART.

INFECTIOUS MANIFESTATIONS

HIV Seroconversion Exanthem

Acute retroviral syndrome (ARS) is an infectious mononucleosis–like illness consisting of fever, lymphadenopathy, pharyngitis, and neurologic symptoms.[2] It can be the presenting sign of primary HIV infection in 40 to 90% of patients. The rash typically presents as a nonspecific morbilliform eruption affecting the upper part of the trunk and face, with relative sparing of the peripheries. It is often accompanied by aphthous and penile ulcerations. There is evidence that very early after infection, HIV goes to dendritic cells in skin and causes an inflammatory response, which may explain the rash. Patients with primary HIV infection may be highly infectious because of the presence of a high viral burden in blood and genital secretions. The HIV antibody test, however, is likely to be negative because ARS precedes seroconversion by 2 to 6 weeks. Confirmation of ARS can be made by finding positive plasma HIV RNA in the setting of a negative HIV antibody. The potential benefits to public and individual health may now justify treatment of patients with acute HIV infection, particularly those who are symptomatic.[3] Initiation of ART in this phase may decrease disease severity, alter the initial viral set point, and decrease viral replication so as to reduce the risk HIV transmission.

TABLE 392-1 SKIN CONDITIONS COMMON IN PATIENTS WITH CD4$^+$ COUNTS LESS THAN 200 CELLS/μL AND NOT RECEIVING ANTIRETROVIRAL THERAPY

Photodermatitis
Psoriasis, difficult to control or involving more than 50% of the body
Pruritic papular eruption associated with HIV infection
Prurigo nodularis
Oral hairy leukoplakia
Molluscum contagiosum
Eosinophilic folliculitis

Viruses

HERPES ZOSTER

Herpes zoster is 10 times more common in HIV patients than in the general population.[4] Because varicella virus (VZV) reactivation can be observed even at relatively normal CD4$^+$ counts, herpes zoster may be the first feature of HIV infection. Herpes zoster in the setting of HIV may affect more than one dermatome, involve unusual locations, or become disseminated. Cutaneous dissemination often presents with multiple and monomorphic vesicular skin lesions in a generalized distribution. These can affect a number of distinct dermatomes and often cross the midline. Complications such as blindness (when the cranial nerve V1 distribution is affected), post-herpetic neuralgia, myelitis, encephalitis, and visceral involvement can cause significant morbidity. HIV patients with limited disease usually respond well to oral antiviral therapy, and antiviral treatment should be started at any time during the disease course (not only within the first 48 hours, as with herpes zoster not associated with HIV). Intravenous acyclovir should be considered for disseminated disease or for lesions involving the eye. There have been a few reports of a verrucous chronic form of zoster occurring in severely immunosuppressed patients; this form of zoster is usually associated with acyclovir resistance. Zoster has been one of the more commonly reported diseases in the immune reconstitution inflammatory syndrome (IRIS) (Chapter 395) and typically appears during the second stage (≈3 months after initiation of ART). The zoster vaccine is not recommended in patients with CD4 counts below 200 cells/μL. Use of the vaccine in patients with CD4 counts above 200 cells/μL is controversial because the safety and efficacy of zoster vaccination in this population has not been demonstrated.[5]

HERPES SIMPLEX VIRUS

Infection with herpes simplex virus (HSV) should always be considered in HIV patients with mucocutaneous ulcerations (Fig. 392-1), particularly when localized to the anogenital area. The presentation is generally typical and characterized by multiple tiny vesicles, punched-out erosions, or crusts. Atypical or extensive ulcerative, vegetative, or tumor-like lesions may also occur. Patients with CD4$^+$ counts below 200 cells/μL may require higher doses of acyclovir to treat the infection. Patients who fail to respond may have HSV with acyclovir resistance, and alternative agents such as foscarnet or cidofovir may be required. In those unable to tolerate the toxicity profile of

FIGURE 392-1. Chronic herpes simplex infection.

these agents, topical or intralesional cidofovir has been reported to be beneficial.[6]

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) infection (Chapter 373) is very common in all stages of HIV infection. Common, flat, genital, and plantar warts are all seen with increased frequency. Lesions are often more extensive and more difficult to treat than in immunocompetent patients. The warts themselves are rarely symptomatic unless they are on the soles of the feet or around the fingernails, where they may cause excruciating pain. Severely immunosuppressed patients may have extensive warts that are recalcitrant to standard treatment. Although the advent of ART has not reduced the number or severity of warts, most patients commencing on ART often notice considerable improvement or resolution of existing lesions. Some patients receiving ART will not clear their warts despite improvement in the $CD4^+$ count, suppression of viral load, and resolution of all other opportunistic infections. The reasons for this observation remain obscure. Treatment modalities include cryotherapy, surgery, laser, topical salicylic acid preparations, podophyllin, intralesional bleomycin, and contact sensitization immunotherapy. Immunomodulatory therapy in the form of imiquimod has had less promising results in HIV patients. Topical cidofovir has been used, but the high cost of formulation limits its use. Owing to the frequent presence of high-risk HPV types, there is a risk of malignant transformation in HIV-infected patients. Anal carcinoma and anal intraepithelial neoplasia (AIN) are frequent (men and women) and may develop more rapidly in this population. Regular screening for cervical neoplasia should be performed in HIV-infected women, and screening anal pap smears may be helpful in identifying anal dysplasia in men. HPV vaccination appears to be safe and immunogenic in the presence of HIV and is reasonable to consider in persons aged 9 to 26 years (as is suggested in the HIV-uninfected population). Investigations are ongoing as to whether HPV vaccination will demonstrate benefit in the broad group of HIV-infected patients older than 26.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a poxvirus that causes a self-limited papular umbilicated eruption commonly seen in children. It is rarer to see in adults, and when on the face, persistent, or severe, it raises the possibility of HIV coinfection. It tends to occur when the $CD4^+$ count falls below 200. First-line treatment is ART because molluscum contagiosum is invariably cleared with rising $CD4^+$ counts. Ablative treatments such as cryotherapy or curettage will treat individual lesions more expeditiously; however, without ART the lesions are likely to recur.

EPSTEIN-BARR VIRUS (ORAL HAIRY LEUKOPLAKIA)

Oral hairy leukoplakia (OHL) is characterized by nonpainful white plaques with a feathered edge, particularly on the lateral border of the tongue. It is associated with Epstein-Barr virus and is very rare in immunocompetent hosts. OHL can occur at any $CD4^+$ count and may therefore be the initial feature of HIV infection. Table 392-2 lists diseases not affected by the $CD4^+$ count. The appearance of OHL was a poor prognostic indicator before ART. There is no specific treatment of OHL, although it tends to resolve when patients are taking ART. Superinfection with *Candida* species should be considered if the lesions are painful.

Bacteria

STAPHYLOCOCCUS AUREUS

Infections with *Staphylococcus aureus* are commonly seen in HIV disease. Staphylococcal folliculitis (Fig. 392-2) tends to be more severe or refractory to treatment than in patients who are HIV negative. Other cutaneous manifestations of staphylococcal infection include cellulitis, bullous impetigo, abscesses, ecthyma (necrotic plaques), or rarely, botryomycosis. HIV-infected persons are at a heightened risk of infection with methicillin-resistant *S. aureus* (MRSA) and appear to have increased susceptibility for recurrence.[7] Choice of treatment is dictated by location and severity of infection. The use of antiseptic washes such as benzoyl peroxide or chlorhexidine solution may have a role in the treatment of *S. aureus* folliculitis, but these agents can dry out the skin and lead to eczematous eruptions prone to secondary bacterial infections. Systemic antibiotics can be used, and susceptibility testing (or knowledge of local resistance patterns) should guide antibiotic selection. The use of topical mupirocin to reduce MRSA carriage is controversial because it does not appear to reduce infection rates. Abscesses should be incised and drained. Rifampin can be used in combination with other antibiotics to reduce carriage rates of *S. aureus*, but caution should be used in patients receiving ART, because rifampicin is a potent inducer of cytochrome P-450 and will therefore interfere with protease inhibitors. More severe infections may require intravenous antibiotics.

BARTONELLA

Bacillary angiomatosis (BA) is caused by *Bartonella* species (most commonly *Bartonella henselae* and *Bartonella quintana*). The cutaneous lesions appear as angiomatous lesions that can present in papular, nodular, or verrucous forms. Clinically, they may resemble lesions of Kaposi sarcoma (KS) and may also be confused with pyogenic granuloma or cutaneous lymphoma. Systemic involvement is common; visceral disease may present as osseous lesions, hepatic and splenic tumors, lymph node disease, pulmonary lesions, brain lesions, bone marrow infiltration, and widespread fatal systemic involvement. BA can present with unexplained fever, bacteremia, or endocarditis and should be considered in any HIV-infected patient with fever of unknown origin. Suspicious cutaneous lesions should always be biopsied and examined with hematoxylin, eosin, and Warthin-Starry silver staining. Blood and tissue cultures should be obtained, and indirect fluorescent antibody testing is useful when available. Polymerase chain reaction (PCR)-based tests play an important role and can be performed on biopsy and serum samples. Immunohistochemical staining for anti-HHV8 can be used to differentiate KS from BA. Bacillary angiomatosis responds to antibiotics such as erythromycin or doxycycline. Although cutaneous lesions resolve in 3 to 4 weeks, the treatment should be continued for at least 3 months. Severely ill patients should be treated with intravenous doxycycline combined with either gentamicin or rifampin for at least 3 months.

SYPHILIS

Syphilis (Chapter 319) is frequently seen in patients with HIV infection. Given the increasing number of reported syphilis cases, regular screening for syphilis, even in asymptomatic HIV-infected patients, is recommended. Its cutaneous manifestations are protean, and therefore syphilis should be

TABLE 392-2 SKIN CONDITIONS THAT CAN OCCUR AT ANY $CD4^+$ COUNT

Eczema

Tinea/onychomycosis
Kaposi sarcoma
Warts
Syphilis

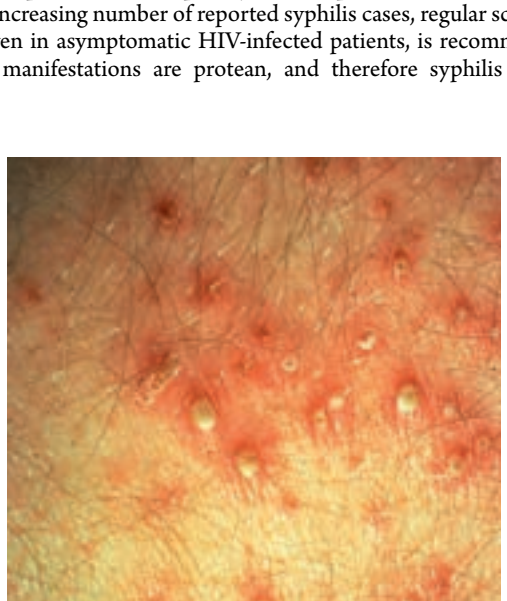

FIGURE 392-2. Staphylococcal folliculitis.

FIGURE 392-3. Secondary syphilis.

considered in any patient infected with HIV who has a new cutaneous eruption. An example of a secondary syphilis exanthem is shown in Figure 392-3. Primary, secondary, and tertiary forms of syphilis may be manifested clinically as they are in HIV-negative individuals, although atypical findings are not uncommon. Central nervous system (CNS) involvement may occur early in HIV patients, and relapse in the CNS may be more common after standard treatment. In most HIV patients, serologic tests are accurate and reliable for the diagnosis of syphilis and to monitor response to treatment. Atypical results can occur, and the use of other tests (biopsy and darkfield microscopy) should be considered when results do not match clinical findings.[8] First-line treatment is with benzathine penicillin G, 2.4 million units in a single dose. Azithromycin resistance is becoming more common. Close follow-up is essential, and titers of syphilis serology should be documented to ensure adequate treatment and CNS clearance. HIV-infected patients who meet criteria for treatment failure should be managed in the same manner as HIV-uninfected patients, because serologic clearance of syphilis appears largely unaffected by the use of ART. CSF examination and retreatment should be strongly considered for patients whose non-treponemal test titers do not decrease appropriately within 6 to 12 months of treatment.

Fungi

CANDIDA

Oral candidiasis is a common and localized infection caused by the yeast *Candida albicans*. It is commonly seen in patients with immunodeficiency, including HIV infection. It is characterized by white cheesy plaques and papules, loosely adherent to the tongue and oropharynx. Topical therapies include clotrimazole troches and nystatin oral suspension. Fluconazole is recommended for moderate to severe disease, but resistance has been noted in the setting of advanced HIV with extensive prior triazole use. Second-line treatment is with oral itraconazole, although it is unclear whether pulsed therapy is preferable.

DERMATOPHYTES

Cutaneous dermatophyte infections are common in HIV-infected patients, but it is not clear if these are any more frequent than in the non–HIV-infected population. Tinea infections follow a normal pattern and can involve the hands, feet, lower trunk, groin, and buttocks. The dermatophyte can spread to hair-bearing areas and present with plaques of folliculitis known as Majocchi granuloma. In those with advanced HIV, tinea infections can be atypical, diffuse, and severe. Tinea of the palms, soles, and other areas can be treated with topical imidazoles or terbinafine. If extensive areas are involved, oral antifungals are usually a more effective alternative and should be continued for approximately 1 month in cases of Majocchi granuloma. Treatment of onychomycosis with oral antifungals is standard but should be used selectively after risks and benefits of treatment are considered.

OTHER FUNGI

Cryptococcus neoformans is an encapsulated yeast that is a well-recognized opportunistic infection in advanced HIV ($CD4^+$ count < 200 cells/μL). Clinical manifestations most commonly involve the lungs and CNS, but cutaneous dissemination can be seen in approximately 10% of patients.[9] Skin lesions can occur anywhere on the body and present as pearly 2- to 5-mm

FIGURE 392-4. Kaposi sarcoma.

molluscum-appearing papules. Unlike molluscum, however, they develop over a short period of time. Large gelatinous plaques with umbilicated areas may also occur. Diagnosis is established by skin biopsy and culture. *Cryptococcus* on the skin in HIV is always associated with systemic cryptococcal infection and a serum cryptococcal antigen will be positive. *Histoplasma capsulatum* and *Penicillium marneffei* may morphologically resemble molluscum. Patients who have had these diseases should be evaluated for long-term suppressive doses of antifungal medications.

Infestations

SCABIES

Scabies is caused by infestation with the mite *Sarcoptes scabiei* and is commonly seen in HIV infection. It can be manifested as the classic rash of scabies, with burrows affecting the finger and toe webs and widespread excoriated papules with a predilection for the axillae, nipples, and genitalia. With advancing immunosuppression, the infestation can become more widespread and refractory to treatment. Crusted scabies can develop with advanced HIV and presents with thick crusts that are teeming with mites. Combination treatment with a topical agent such as permethrin or benzoyl benzoate and systemic treatment with ivermectin tablets is recommended for crusted scabies. Topical agents may be sufficient for classic scabies. Lindane lotion is often used to treat scabies, but there have been reports of lindane-resistant scabies and neurologic side effects attributed to this treatment.

TUMORS

Kaposi Sarcoma

KS is the most common HIV-associated malignancy, but since the introduction of ART, there has been a significant decrease in its incidence. It is characterized by dusky purple nodules and plaques with a predilection for the extremities and oral mucosa (Fig. 392-4). Poor prognostic factors include lymphedema and internal organ involvement. It is caused by HHV8, also known as Kaposi sarcoma–associated virus. The virus may be transmitted vertically, sexually, or casually, and its presence is necessary for the development of KS. Immune reconstitution with ART is the first-line treatment for early disease. Chemotherapy can be added for aggressive or unresponsive KS.

Malignant Melanoma

Malignant melanoma occurs with increased incidence in HIV-positive patients. Melanoma behavior can be more aggressive because HIV patients are more likely to present with metastases and have worse outcomes. High-risk patients should be screened annually, and those with a history of malignant melanoma should be followed closely for recurrence or early evidence of metastasis.[10]

Nonmelanoma Skin Cancer

Persons with AIDS have a three- to five-fold increased risk of developing a nonmelanoma skin cancer. The clinical manifestations of squamous cell carcinoma (SCC) and basal cell carcinoma (BCC) are identical to those seen in the uninfected population. Cutaneous SCC may be dangerous in the context of HIV infection, because lesions can present at a younger age and are associated with a high risk for local recurrence, metastasis, and increased mortality. Management of SCC is surgical excision, whereas curettage and electrodessication may be appropriate for BCC lesions on the extremities or trunk. Surgical excision should be the treatment of choice for BCC on the face.

INFLAMMATORY MANIFESTATIONS

Immune Reconstitution Inflammatory Syndrome

Most patients benefit substantially after the commencement of ART with a large reduction in morbidity and mortality. However, a subset of patients experience unmasking of new skin disease or paradoxical worsening of existing dermatologic conditions, attributable to IRIS (Chapter 395). Risk factors for developing IRIS include starting ART with a low CD4 nadir (<200 cells/μL) and the presence of subclinical opportunistic or other infections at the time of ART initiation. The most common skin manifestations of early IRIS include varicella-zoster reactivation and eosinophilic folliculitis. KS can present with organ involvement during IRIS. Other cutaneous manifestations include HPV (presenting as genital, flat, or common warts), reactivation of HSV or cytomegalovirus, cutaneous mycobacterial infection, or molluscum contagiosum. Leprosy, fungal infections, and parasitic infections such as leishmaniasis have also been reported. IRIS is most effectively treated by identifying and treating any underlying infection.

Seborrheic Dermatitis

Seborrheic dermatitis is a common dermatosis in the general population, but it has a strikingly increased prevalence in HIV-infected patients. Although more common in those with advanced HIV, the condition can be seen in all stages of immunosuppression. It appears as orange-red scaly patches affecting the scalp, eyebrows, nose, and cheeks. Seborrheic dermatitis can also affect the central portion of the chest and genitalia. ART appears to make seborrheic dermatitis more responsive to the standard therapy consisting of combinations of topical antifungals (econazole or ketoconazole) and low-potency corticosteroids.

Atopic Dermatitis

Atopic dermatitis (AD) is common in HIV-infected patients. The condition is characterized by pruritic scaly plaques that are classically localized to flexural areas. The distribution, however, can vary with ethnicity; AD in black Africans often involves the extensor surfaces. Treatment for AD is the same in the non–HIV-infected population. Frequent application with emollients should be emphasized. Topical steroids and sedating antihistamines are useful for flares. Topical pimecrolimus and tacrolimus are licensed for the treatment of atopic dermatitis, but their safety has not been demonstrated in HIV infection. As with other dermatoses, AD improves with ART, but in patients who had a $CD4^+$ nadir less than 200 cells/μL it tends to be more persistent even with ART.

Psoriasis

Psoriasis may appear early in HIV infection. The severity ranges from mild to severe, with more severe disease correlating with worsening immunosuppression. This observation is paradoxical because psoriasis is thought to be a T-cell-mediated disease but may be explained by immune dysregulation. All psoriasis subtypes occur in the setting of HIV, but inverse (flexural), guttate, and erythrodermic forms are seen most often. Psoriatic arthritis is more common and severe than in the non-HIV population. Treatment should be tailored to disease severity. First-line therapy for mild to moderate psoriasis includes topical steroids, calcipotriol, and retinoids (tazarotene). In those with moderate to severe disease, ultraviolet therapy (UVB, PUVA) and ART are the first-line treatments. Oral retinoids are an appropriate second-line agent. Immunosuppressive agents such as methotrexate and cyclosporine can be used for severe or refractory disease. Patients on these agents should be followed closely, and concomitant prophylaxis for opportunistic infections should be considered. Given the limited evidence and risks associated with their use (particularly in the HIV-infected population), tumor necrosis factor (TNF)-α inhibitors should be reserved for patients with very refractory psoriasis and those with debilitating arthritis. ART invariably reduces the severity of psoriasis and is considered a first-line treatment in those with moderate to severe disease.

Papular Pruritic Eruption of HIV

Papular pruritic eruption (PPE) is commonly seen in Africa and Asia in association with HIV. The condition presents with excoriated papules that initially appear on the extensor extremities but subsequently extend to involve the trunk and face. Pruritus can be severe. Because its presentation is nondescript, other itchy skin diseases such as eczema or eosinophilic folliculitis should be considered in the differential diagnosis. Skin biopsies have been considered to be important to distinguish between PPE and other itchy papular eruptions.[11] When present, PPE is highly predictive of HIV infection and is often the presenting sign. It has been hypothesized that this condition represents a hyperactive immune response to arthropod bites. Treatment is difficult, but potent topical corticosteroids and UVB may be of some benefit. Because PPE presents at CD4 counts of 350 cells/μL or less, it may be an indication for ART initiation. The condition has been reported to improve dramatically with effective ART.

Eosinophilic Folliculitis

Eosinophilic folliculitis is characterized by urticarial follicular-based papules and pustules located primarily on the scalp, face, neck, and upper chest (Fig. 392-5). These lesions are intensely itchy, and skin biopsy is helpful in ruling out other causes of folliculitis. Eosinophilic folliculitis tends to be seen when $CD4^+$ counts are less than 200 cells/μL. It can also be seen as part of the immune reconstitution syndrome within the first 16 weeks of starting ART. Treatments include topical corticosteroids, antihistamines, itraconazole, metronidazole, oral retinoids, and UV light therapy. If immune reconstitution is implicated, these agents can be given for an 8- to 12-week period while immune restoration stabilizes.

Prurigo Nodularis

Prurigo nodularis is characterized by pruritic dome-shaped nodules that initially develop on photoexposed areas of the extremities but eventually extend to involve the trunk. Development of prurigo nodularis is associated with background skin pigment and CD4 counts below 100 cells/mm^2. Standard treatment options include emollients, potent topical steroids, and sedating antihistamines such as chlorpheniramine or hydroxyzine. Thalidomide is often effective in recalcitrant cases but requires careful monitoring for peripheral neuropathy, and women of childbearing potential require effective contraception. Immune reconstitution and reduction of viremia with ART are helpful. Regimens that include raltegravir may be useful in refractory cases.[12]

Photodermatitis

HIV-infected patients have a tendency toward photosensitivity, a phenomenon that is poorly understood. Patients are commonly on photosensitizing medications like trimethoprim-sulfa and dapsone for prophylaxis and treatment of concomitant infections. But even in the absence of classic photosensitizing drugs, HIV itself and pigmented skin are risk factors for photodermatitis. Photodermatitis presents with pruritic plaques or indurated plaques in photoexposed areas of the skin like the cheeks, ears, lower lip, tip of the nose, and dorsal hands. Sunscreen and sun avoidance are the treatments.

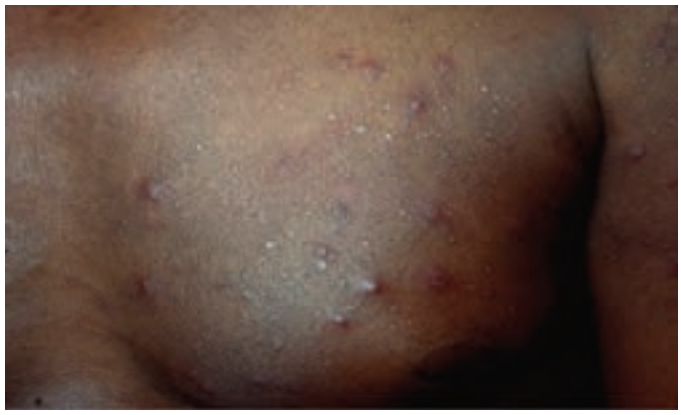

FIGURE 392-5. Eosinophilic folliculitis.

FIGURE 392-6. HIV-associated facial lipoatrophy.

METABOLIC MANIFESTATIONS

HIV Lipodystrophy Syndrome

Lipodystrophy syndrome was first described in 1998 and consists of peripheral lipoatrophy, central lipohypertrophy, lipid abnormalities, and insulin resistance. It is likely that it is caused by a number of factors, including ART, although it is unlikely that a single agent is responsible. Cutaneous facial lipoatrophy tends to be the most problematic dermatologic aspect, with significant associated psychological morbidity (Fig. 392-6). Currently, no treatments are effective for lipodystrophy syndrome, although surgical correction with dermal fillers may improve the cosmetic appearance.

REVIEW QUESTIONS

1. All of the following skin conditions are increased in frequency and/or severity in patients with HIV/AIDS. Which one of them is clearly exacerbated (or unmasked) by initiation of antiretroviral therapy (ART) as an immune reconstitution manifestation?

A. Seborrheic dermatitis
B. Papular pruritic eruption (PPE) of HIV
C. Malignant melanoma
D. Atopic dermatitis
E. Herpes zoster

Answer: E Herpes zoster has been one of the more commonly encountered diseases in the immune reconstitution inflammatory syndrome (IRIS) and typically appears during the second stage (≈3 months after initiation of ART). Other skin disorders in HIV-positive patients that manifest with worsening that is attributed to immune reconstitution include: human papillomavirus, reactivation of herpes simplex and cytomegalovirus, cutaneous mycobacterial infection, and molluscum contagiosum. The other choices listed are not known to be significantly exacerbated by initiation of ART; in fact, some of them show marked improvement with it.

2. Which of the following pruritic eruptions is ***not*** a skin disorder that is known to be increased in frequency and/or severity in AIDS patients?

A. Secondary syphilis
B. Prurigo nodularis
C. Pityriasis rosea
D. Seborrheic keratosis
E. PPE

Answer: C Pityriasis rosea is an acute self-healing exanthem of unknown etiology for which many infectious agents have been incriminated. It is not known to be definitively associated with HIV/AIDS. Syphilis is frequently seen in patients with HIV infection: primary, secondary, and tertiary forms of syphilis may be manifested clinically as they are in HIV-negative individuals, but atypical findings are not uncommon. Prurigo nodularis is characterized by pruritic dome-shaped nodules that particularly develop in persons with background skin pigment and CD4 counts below 100 cells/mm^2. Seborrheic dermatitis and keratosis have a strikingly increased prevalence in HIV-infected patients. PPE is commonly seen in Africa and Asia in association with HIV. Skin biopsies are indicated to distinguish between PPE and other itchy papular eruptions in patients with HIV/AIDS. When present, PPE is highly predictive of HIV infection and is often the presenting sign.

3. Oral hairy leukoplakia is associated with which of the following infectious organisms?

A. Epstein-Barr virus (EBV)
B. *Candida*
C. Herpes simplex
D. Cytomegalovirus (CMV)
E. *Cryptococcus*

Answer: A Oral hairy leukoplakia is characterized by nonpainful white plaques with a feathered edge, especially on the lateral borders of the tongue. It is associated with EBV and is very rare in immunocompetent hosts. There is no specific treatment for it, but it tends to resolve when patients are taking ART. Superinfection with *Candida* species should be considered if the lesions are painful.

HEMATOLOGY AND ONCOLOGY IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

THOMAS S. ULDRICK AND ROBERT YARCHOAN

Patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) have a substantially increased risk of developing a number of cancers. Three of these cancers, Kaposi sarcoma (KS), certain non-Hodgkin lymphomas (NHLs), and cervical cancer, confer a diagnosis of AIDS when they arise in an HIV-infected patient and are referred to as AIDS-defining malignancies (ADMs). HIV increases the risk for a number of other tumors, including classic Hodgkin lymphoma (cHL), lung cancer, anal cancer, oropharyngeal cancer, hepatocellular carcinoma, and nonmelanoma skin cancer. These other HIV-associated tumors are referred to as non–AIDS-defining malignancies (NADMs) (Table 393-1).[1] Cytopenias and coagulation abnormalities are also common in patients with AIDS.

Effective combination antiretroviral therapy (cART) for HIV became broadly available in 1996. Its widespread use dramatically reduced opportunistic infections (OIs) and increased the longevity of patients with HIV infection. In part for these reasons, the number of persons living with HIV in the United States has approximately doubled since 1996. The use of cART also decreased the incidence of KS and NHL in the HIV-infected population. Nonetheless, these tumors remain important causes of morbidity and mortality. However, as the HIV-infected population ages, NADM, as well as other cancers not associated with HIV, are becoming increasingly common, and cancer is now a leading cause of death in HIV-infected persons. Cytopenias are also less common with cART, and management of neutropenia and anemia has shifted from growth factor support to effective treatment of HIV. Still, HIV increases the risk of hematologic abnormalities, which continue to cause diagnostic and therapeutic challenges. With more than 1 million people in the United States and 30 million people globally infected with HIV, management of HIV-infected patients with cancers and blood disorders is increasingly important.

CANCERS IN HIV-INFECTED PATIENTS

Care of the HIV-infected patient with cancer requires integration of oncologic and infectious disease expertise, including evaluation of comorbidities, planning of timing and selection of cART, and OI prophylaxis. Although patients with advanced AIDS may tolerate chemotherapeutic regimens poorly, patients whose HIV is controlled with cART can often receive full-dose regimens and do as well as their HIV-negative counterparts. There are 30-plus approved antiretroviral agents. Consideration of potential pharmacokinetic interactions between antiviral drugs and cancer therapy is required.

EPIDEMIOLOGY

The standardized incidence ratios of KS and certain aggressive B-cell NHLs are markedly increased in patients with HIV, especially those with low CD4 counts. KS, certain NHLs, cervical cancer, and a number of other NADMs are directly or indirectly caused by oncogenic viruses, especially Kaposi sarcoma herpesvirus (KSHV, also called human herpesvirus 8 [HHV-8]), Epstein-Barr virus (EBV), human papillomavirus (HPV), hepatitis C virus (HCV), and hepatitis B virus (HBV) (see Table 393-1). Many of these viruses are prevalent in various HIV-infected populations and are poorly controlled in the setting of immunosuppression. HIV-infected individuals also often have increased exposure to other cancer risk factors, such as cigarette smoke.

Substantial changes in the patterns of cancer in the U.S. AIDS epidemic have been noted since the introduction of cART. The incidence of KS and NHL have decreased relative to their peak, while the burden of NADMs, most of which develop over a longer period of time, is rising. Whereas most cancers developing in HIV patients were ADMs early in the epidemic, these cancers are now divided approximately evenly between ADM and other cancers (Fig. 393-1).[2] Overall, cancer is one of the leading causes of death in HIV-infected patients in countries where cART is widely available, in part because fewer patients are dying from other causes, such as OIs associated with low CD4 counts or AIDS itself. Also, HIV-associated cancers, especially ADMs, are a major public health concern in many resource-limited regions, such as sub-Saharan Africa.

PREVENTION AND SCREENING

Several chemopreventive strategies and behavioral interventions should be used to prevent HIV-associated malignancies. The risk of KS and NHL in patients with HIV is decreased with cART. Some studies show that improved immunity with cART also can reduce the prevalence of premalignant HPV-associated cervical[3] and anal squamous intraepithelial neoplasia and lesions. Vaccination against HBV and antiviral therapy against HBV and HCV decrease the risk of hepatocellular carcinoma in HIV-uninfected populations and are warranted. Smoking is prevalent in many HIV-infected populations, and smoking cessation interventions are advised. Nonmelanoma skin cancer is increased with HIV, and reduction of exposure to ultraviolet radiation is prudent.

HPV vaccines can reduce the risk of HPV-associated cancers and premalignant conditions. They should optimally be administered in early adolescence before the onset of sexual activity and exposure to HPV infection. A concern in this area is that the rate of uptake of the HPV vaccine is now low in the United States, especially in boys. Recent studies suggest that there may also be value in vaccination after the onset of sexual activity, in part to prevent reinfection after clearance of high-risk strains. The HPV vaccine has been shown to be safe in HIV-infected children and adults, and those with relatively preserved immune function can develop antibodies to the vaccine; however, it has not been shown whether the vaccine is protective in this population. Women with HIV infection, squamous intraepithelial lesions (SIL), and/or poor control of oncogenic HPV subtypes need more frequent gynecologic evaluation than low-risk women (see section on cervical cancer). Given the markedly increased risk of anal cancer in women and men with HIV (see Table 393-1), programs have been developed employing cytologic examination of anal mucosa to screen for and treat high-grade squamous intraepithelial lesions (HSIL).[4] A National Cancer Institute (NCI)-funded prospective study is planned to evaluate whether this approach is effective in preventing anal cancer.

TABLE 393-1 AIDS-DEFINING MALIGNANCIES AND COMMON NON–AIDS-DEFINING MALIGNANCIES IN PERSONS WITH HIV IN THE COMBINED ANTIRETROVIRAL THERAPY ERA

MALIGNANCIES	STANDARD INCIDENCE RATIO (HIV ONLY / AIDS)	ESTIMATED % OF ALL CANCERS 2004-2007 IN HIV/AIDS IN UNITED STATES	VIRAL ASSOCIATIONS	OTHER IMPORTANT RISK FACTORS
AIDS-DEFINING MALIGNANCIES				
Non-Hodgkin lymphoma				
Systemic	10-15 / 30-60	25.9%	EBV, KSHV*	
Primary CNS lymphoma	250 / 1020	3%	EBV
