Host defenses against *S. aureus* infection primarily consist of an intact, normal skin barrier and the innate immune system. Conditions in which these defenses are impaired are associated with increased risk of *S. aureus* infection. Among these conditions are injection drug use, presence of vascular access devices, burns, chronic skin diseases, use of systemic steroids, traumatic wounds, minor skin abrasions or trauma, surgical procedures, insulin-dependent and non–insulin-dependent diabetes, peritoneal dialysis, hemodialysis, subcutaneous and intramuscular injections, acupuncture, prosthetic implants, and congenital or acquired neutrophil disorders (e.g., chronic granulomatous disease, Job's syndrome). If the cutaneous barrier is breached, the next line of defense is the innate immune system. Neutrophils recruited to the site of infection ingest and kill staphylococci. Staphylococci elaborate numerous virulence factors specifically designed to thwart each step of the host response. If large numbers of organisms are present, the host response is overwhelmed, infection is not contained, and dissemination occurs. Endothelial cell injury and invasion can also occur. Intracellular organisms and small colony variants within phagocytes and endothelial cells may play a role in relapse and persistent bacteremia. High tissue burdens of organisms and bacteremia are usually but not always accompanied by fever, tachycardia, and other signs of the systemic inflammatory response syndrome, including frank septic shock.

The three toxin-mediated syndromes, which can occur in the absence of invasive disease, are staphylococcal food poisoning, staphylococcal toxic shock syndrome, and staphylococcal scalded skin syndrome. Staphylococcal food poisoning is caused by the ingestion of a preformed heat-stable enterotoxin. The emetogenic activity of enterotoxin is mediated by the intestinal release of 5-hydroxytryptamine and the stimulation of receptors present on afferent vagal neurons. Toxic shock syndrome is caused by a specific toxin, TSST-1, or other staphylococcal enterotoxins acting as superantigens that bind to major histocompatibility complex class II molecules of antigen-presenting cells and T-cell receptors, stimulating the massive release of cytokines from T cells and resulting in septic shock and death. Staphylococcal scalded skin syndrome and bullous impetigo are caused by either of two exfoliative toxins, A or B. These toxins are serine proteases that specifically cleave desmoglein 1, a desmosomal protein that anchors the overlying superficial epidermis to the stratum granulosum.

CLINICAL MANIFESTATIONS

Skin and Soft Tissue Infections

Skin and soft tissue infections are by far the most common infections caused by *S. aureus*; millions of cases occur annually in the United States (Chapter 441). Community MRSA strains have been associated with a 50% increase in the rates of skin and soft tissue infections in the United States. This heterogeneous group of skin diseases includes impetigo, folliculitis, furuncle, abscess, erysipelas and cellulitis, mastitis (cellulitis of the breast), necrotizing fasciitis, and wound infections.

E-TABLE 288-1 COMPARISON OF COMMUNITY AND HOSPITAL CLONES OF METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA)

PROPERTY	COMMUNITY MRSA	HOSPITAL MRSA
Methicillin-resistance gene cassette	*SCCmecIV*[*]	*SCCmecI, II, III*
Common genotypes[†]	USA300 (ST8) USA400 (ST1)	USA100 (ST5) USA500 (ST8) USA800 (ST5)
Panton-Valentine leukocidin	Present in ≈95%	Present in <5%
Antimicrobial resistances	β-Lactams, macrolides, fluoroquinolones	β-Lactams, macrolides, clindamycin, tetracycline, fluoroquinolones, aminoglycosides
Doubling time[‡]	30 minutes	45-60 minutes
agr Mutants	Uncommon	Common

*Staphylococcal chromosomal cassette type; this element contains the methicillin resistance gene *mecA*.
[†]Pulsed field gel electrophoresis type with the sequence type (ST) in parentheses.
[‡]Time for the number of cells to double in broth culture.

E-TABLE 288-2 EXAMPLES OF VIRULENCE FACTORS PRODUCED BY *STAPHYLOCOCCUS AUREUS*

ACTIVITY	GENES	PROTEIN OR MOLECULE
Inhibition of antimicrobial peptides	*icaA, icaD, icaB, icaC, icaR*	Polysaccharide intercellular adhesin (PIA)
	isdA, isdB	Iron-regulated surface determinants of *S. aureus* (IsdA and IsdB)
	mprF	Multiple peptide resistance factor (MprF)
	Sak	Staphylokinase
Inhibition of chemotaxis	*chp*	Chemotaxis inhibitory protein of *S. aureus* (CHIPS)
	ecb	Extracellular complement-binding protein (Ecb)
	efb	Extracellular fibrinogen-binding protein (Efb; inhibitor of C5a generation)
	scn	Staphylococcal inhibitor of complement (SCIN)
Inhibition of oxygen-mediated bacterial killing	*crtM, crtN*	Carotenoid pigment, staphyloxanthin (*S. aureus* golden pigment; promotes resistance to reactive oxygen species)
	isdA, isdB	Iron-regulated surface determinants of *S. aureus*, IsdA and IsdB (promote resistance to neutrophil reactive oxygen species)
	sodA, sodM	Superoxide dismutase, SodA, SodM IsdB (promotes resistance to neutrophil reactive oxygen species)
Inhibition of neutrophil function	*cap5* or *cap8*	Capsular polysaccharide (inhibits phagocytosis)
	clfA	Clumping factor A (ClfA; inhibits phagocytosis)
	eap	Extracellular adherence protein (Eap; inhibits leukocyte adhesion)
	hlgA, hlgB, hlgC	Gamma hemolysin subunits A, B, and C; HlgA, HlgB, HlgC (causes cell lysis)
	lukS-PV, lukF-PV	Panton-Valentine leukocidin (causes cell lysis)
	psm	Phenol-soluble modulin-like peptides (PSMs; causes cell lysis)
Perturbation of T-cell function	*sea, seb, sec$_n$, sed, see, seg, seh, sei, sej, sek, sel, sep*	Staphylococcal enterotoxins: SEA, SEB, SEC$_n$, SED, SEE, SEG, SEH, SEI, SEJ, SEK, SEL, SEP (superantigens)
	tst	Toxic shock syndrome toxin 1 (TSST-1; superantigen)
Perturbation of B-cell function	*spa*	Protein A (B-cell superantigen)
Adhesion	*cna*	Collagen-binding protein
	fnA, fnB	Fibronectin-binding proteins A and B
	clfA, clfB	Clumping factors A and B (binds platelets and fibrinogen)

Impetigo, folliculitis, and furuncle are superficial infections; fever and other systemic signs of infection are not present. Impetigo is a focal infection of the epidermis that occurs most commonly in children (Fig. 441-1). The typical lesion, which may be multiple or in clusters, is about 1 cm in diameter, with erythema surrounding a bulla or bullae (caused by the production of exfoliative toxin) containing cloudy fluid or with a crusty or scabbed-over appearance. Gram stain of the fluid or drainage from the lesion shows the organism. Folliculitis is a superficial infection with tender, erythematous, maculopapular or pustular lesions centered around hair follicles. Both impetigo and folliculitis readily respond to local measures, such as application of soap and water, topical antibiotics, or antiseptics; systemic antimicrobial therapy may be indicated for extensive or refractory infections.

A furuncle is simply a boil, an erythematous, suppurative infection measuring 1 to 2 cm that extends through the dermis into the subcutaneous tissue (Fig. 441-2). It may drain spontaneously with application of hot compresses or can be surgically drained with simple incision and drainage. Antimicrobial therapy is not needed. The distinction between a furuncle and an abscess is somewhat arbitrary. Abscesses tend to be larger and deeper and may be associated with systemic signs of infection and bacteremia. Furuncles may extend to fascia or deeper tissues and coalesce into carbuncles, a more severe form of infection that may be accompanied by bacteremia. Large abscesses and carbuncles, particularly in the presence of fever and the systemic inflammatory response syndrome, require surgical drainage and systemic antimicrobial therapy.

Erysipelas (Fig. 441-4) and cellulitis, which are similar in appearance, are painful, warm, indurated, erythematous, nonlocalized infections that may be accompanied by lymphangitis. Cellulitis extends into the dermis and subcutaneous fat; erysipelas is more superficial. Surrounding cellulitis is often associated with an obvious cutaneous abscess, but it may also overlie a deeper abscess, in which case the primary therapy is surgical drainage. Cellulitis without an associated abscess should be treated with systemic antimicrobial therapy. Cellulitis due to streptococci (Chapter 290) cannot reliably be distinguished from that caused by *S. aureus* owing to their similar appearance. The presence of an associated purulent lesion suggests staphylococcal infection.

Necrotizing fasciitis is an infection of the deep layers of skin and subcutaneous tissues, extending to muscle and along fascial planes. It is associated with systemic toxicity, leukocytosis, and severe pain often out of proportion to the physical findings. The overlying skin may appear to be uninvolved, belying the serious nature of this infection, which requires immediate surgical intervention for débridement of involved tissue. Necrotizing fasciitis, which is more typically caused by group A streptococci (Chapter 290) or occurs as a mixed infection, has been associated with community MRSA infection.

Pyomyositis (also termed tropical myositis) is an infection of the skeletal muscle; *S. aureus* is the most common cause. The patient presents with fever, pain, and swelling and induration that can be felt on deep palpation. The overlying skin and soft tissue may appear normal. There is often a history of trauma to the infected area. Although it can occur in otherwise normal children and adults, acquired immunodeficiency syndrome and other immunocompromising conditions are predisposing factors. This infection is thought to occur as a consequence of metastatic seeding from a subclinical bacteremia, and blood cultures may not be positive at the time of diagnosis. The diagnosis is established by culture of pus collected by needle aspirate. Surgical or percutaneous drainage should be performed, and systemic antimicrobial therapy is indicated.

S. aureus causes 30% of surgical site infections overall in the United States, and approximately 50% of those follow neurosurgical or orthopedic procedures. These infections occur at the site of incision, typically after the second or third postoperative day. Signs and symptoms are fever accompanied by erythema, edema, induration, drainage, pain, and tenderness at the surgical site. Superficial infections respond to removal of stitches, débridement of devitalized tissue, opening of the wound to allow drainage, and a short course of antimicrobial therapy. Deeper infections may require more extensive débridement and longer courses of therapy (4 to 6 weeks), particularly if bone or a prosthetic device is involved. Removal of infected prosthetic material or a foreign body greatly increases the chance of cure.

Bacteremia

Bacteremia, the presence of bacteria in the blood stream, exemplifies the pathogenicity of *S. aureus*. It is present in approximately 75% of cases of invasive, deep tissue infections. The most common sources of bacteremia are skin and soft tissue infections, central venous catheters and other intravascular devices, bone and joint infections, pneumonia, and endocarditis. Bacteremia can emanate from any source, which may not be obvious in 25% of cases. Invasion of the blood stream allows the organism to disseminate widely throughout the body, establishing multiple metastatic sites of infection and thereby perpetuating bacteremia. Fever is usually but not always present. Sepsis syndrome and septic shock are common, and death occurs in 10 to 20% of cases. Patients with occult *S. aureus* bacteremia have high rates of organ failure, septic shock, and intensive care unit (ICU) admissions, prolonged ICU stays, and high mortality.[3]

The presence of bacteremia dictates the approach to the diagnosis, management, and therapy of *S. aureus* infection. When blood cultures are positive, even if the primary source is known, there is always the possibility of endocarditis or other secondary foci of infection. Echocardiography has been generally recommended in cases of *S. aureus* bacteremia to look for valvular vegetations or other signs of endocarditis, although its role is evolving.[4] If it is available, transesophageal echocardiography is preferable to transthoracic echocardiography because it has better sensitivity. An echocardiogram should be obtained in cases of complicated bacteremia, defined by the presence of any one of the following: positive blood cultures for 3 days or more, presence of an intracardiac device (e.g., pacemaker, prosthetic valve), presence of a secondary or metastatic focus of infection, relapse or recurrence of *S. aureus* bacteremia, or clinically suspected endocarditis.

Source control is the cornerstone of management and therapy. Both primary and secondary foci of infection should be identified and eliminated whenever possible because these may lead to treatment failure or relapse once therapy is discontinued. Computed tomography or magnetic resonance imaging should be considered if signs and symptoms point to deep tissue abscesses or osteomyelitis. Follow-up blood cultures should be obtained to document clearance. Persistent bacteremia is suggestive of endovascular infection, and failure to clear blood cultures after 3 to 4 days of appropriate therapy is a strong predictor of complicated bacteremia, necessitating a longer course of therapy. Antimicrobial therapy should always be administered. A shorter duration of therapy (i.e., 14 days) is appropriate for uncomplicated bacteremia (Table 288-1). Longer courses of 4 to 6 weeks are recommended for the treatment of endocarditis or bacteremia complicated by slow resolution or the presence of metastatic infection.

Endocarditis

S. aureus is the leading cause of both native valve and prosthetic valve endocarditis (Chapter 76), accounting for approximately 30% or more of all cases. Most are community-acquired infections, often occurring as a complication of injection drug use. The number of health care–associated infections has been increasing in recent years.[5] Risk factors are diabetes mellitus, hemodialysis, and presence of a prosthetic valve. The presentation is that of an acute febrile illness with high fever developing during a few days. The patient may appear toxic and septic. The intracardiac source of infection may not be evident at first because a pathologic murmur may not be evident when the patient first presents. A quarter or more of patients have an associated infection of bone, joint, or skin and soft tissue. The aortic and mitral valves are most commonly involved in native valve infection except in injection drug users (discussed later). Systemic embolization to the brain, kidneys, spleen, gut, or other large vessels is clinically evident in about one third of cases. Peripheral manifestations, including Roth's spots, Osler's nodes, Janeway's lesions, and petechiae, occur with a similar frequency. Morbidity and mortality are high, in part due to the occurrence of this infection in older patients,

TABLE 288-1 CRITERIA FOR DIAGNOSIS OF UNCOMPLICATED *STAPHYLOCOCCUS AUREUS* BACTEREMIA*

Resolution of fever and systemic signs of infection by day 3 of therapy
Sterile blood cultures within 2 or 3 days of initiation of antimicrobial therapy
Presence of an identifiable and easily removable focus of infection
Prompt removal of the primary focus of infection
No echocardiographic or clinical signs of endocarditis
No osteomyelitis
No hematogenous secondary foci of infection
No preexisting valve abnormalities predisposing to endocarditis (e.g., prosthetic valve, rheumatic heart disease, bicuspid aortic valve)
No implanted prosthetic device (e.g., prosthetic hip)

*Uncomplicated *S. aureus* bacteremia can be treated with a shorter course of antibiotics (see text).

FIGURE 288-1. Chest radiograph shows multiple nodular pulmonary lesions, suggestive of septic embolization, in a patient with tricuspid valve *S. aureus* endocarditis. The *red circle* shows a lesion with signs of cavitation.

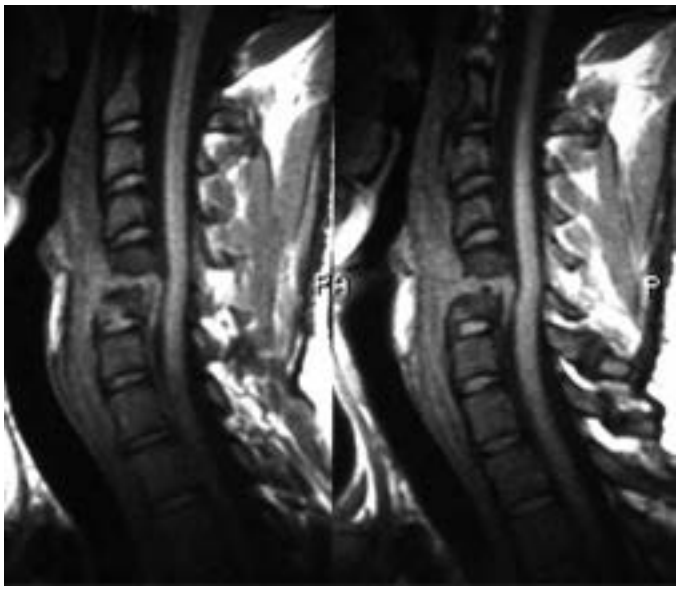

FIGURE 288-2. Noncontrast, non–fat-saturated, T1-weighted, sagittal sequence shows discitis, osteomyelitis, prevertebral and epidural abscess, and cord compression in a patient with *S. aureus* infection of the cervical spine.

many of whom have medical comorbidities. Strokes occur in approximately 20% of patients, and congestive heart failure occurs in 40 to 50%. Twenty-five percent to 30% of patients do not survive the initial hospitalization.

Native valve endocarditis in injection drug users involves the tricuspid valve in approximately three quarters of cases. Patients typically have fever, cough, hemoptysis, and pleuritic chest pain as a consequence of hematogenous seeding of the lung and septic emboli from the valve. The chest radiograph may show pulmonary infiltrates, signs of consolidation or pleural effusion, or multiple, often peripheral nodular pulmonary infiltrates with cavitation, hallmark features of septic embolization (Fig. 288-1). Patients tend to be young and otherwise healthy, so mortality is relatively low, 5% or less. Injection drug users can also have aortic valve or mitral valve endocarditis, in which case the presentation is similar to that described earlier. Conversely, patients who are not injection drug users may have tricuspid valve endocarditis with pulmonary findings.

S. aureus prosthetic valve endocarditis is associated with a 40% or higher in-hospital mortality. Although prosthetic valve endocarditis can be managed medically in some cases, outcomes tend to be worse, and surgery and valve reimplantation are usually required to cure the infection or to manage its complications.[6]

Pericarditis

S. aureus is the most common cause of purulent pericarditis in children and following cardiac surgery in adults. It may occur by contamination at the time of surgery; by bacteremic seeding from another site of infection; as a complication of endocarditis, paravalvular abscess, or myocardial abscess; or by direct extension of infection from pneumonia, lung abscess, or empyema. The presentation is that of acute pericarditis (Chapter 77), with fever and severe chest pain, tachycardia, and hemodynamic instability. The clinical course may be extremely rapid, terminating in septic shock or cardiac tamponade. Immediate drainage of the infected pericardial space and administration of systemic antimicrobial therapy are indicated. Needle pericardiocentesis is useful for confirming the diagnosis and providing temporary decompression of the pericardial space, but definitive therapy requires surgical or continuous tube drainage.

Osteomyelitis

S. aureus is the most common cause of osteomyelitis, both acute and chronic (Chapter 272). The primary mode of infection is hematogenous seeding. Up to a quarter of cases of bacteremia are complicated by osteomyelitis, and concurrent bacteremia is present in 50% or more of osteomyelitis cases. Acute osteomyelitis—defined as an initial episode with a clinical course of days to weeks, but not months—is manifested with fever and pain at the site of infection. Long bones are more commonly infected in children, whereas vertebrae are more commonly infected in adults.[7] Adults can also have long bone osteomyelitis, usually from a contiguous focus of infection or at a site of fracture or prior trauma. Vertebral osteomyelitis is frequently accompanied by paravertebral or epidural abscess (Fig. 288-2). Back pain accompanied by signs of cord compression, such as radicular pain, sensory loss, lower extremity weakness, urinary retention, and bowel or bladder incontinence, is an emergency. Magnetic resonance imaging should be performed as soon as possible to define the location and extent of infection, and neurosurgical consultation should be obtained in anticipation of surgical decompression and drainage.

Septic Arthritis

S. aureus is the most common cause of septic arthritis (Chapter 272), usually as a consequence of bacteremic seeding, trauma, or a surgical procedure. Risk factors include diabetes, recent joint surgery or joint prosthesis (Chapter 276), and rheumatoid arthritis (Chapter 264). Cardinal features are joint pain, history of joint swelling, and fever. The diagnosis is established by analysis of synovial fluid, in which the white blood cell count typically exceeds 25,000/mm^3, with 90% neutrophils. Blood cultures are positive in 30 to 50% of cases, organisms are seen on Gram stain of synovial fluid in about 50% of cases, and synovial fluid culture is almost always positive. Hip, knee, ankle, and wrist are most commonly affected. *S. aureus* also has a predilection for infecting the sternoclavicular, sacroiliac, and symphysis pubis joints. Multiple joints are involved in 5% of cases. Both antimicrobial therapy and drainage of the infected joint (by repeated needle aspiration, by arthrotomy, or arthroscopically) are required to prevent destructive arthritis.

Central Nervous System Infections

S. aureus is an uncommon cause of community-acquired central nervous system infections, such as bacterial meningitis, primary brain abscess, or subdural empyema. These infections are often associated with endocarditis or a contiguous focus of infection, such as cavernous sinus thrombosis. Mortality of these infections is as high as 30 to 50%. *S. aureus* is an important cause of nosocomial meningitis after head trauma, craniotomy, or implantation of intraventricular or extraventricular catheters.

Pulmonary Infections

S. aureus is an uncommon cause of community-acquired pneumonia (Chapter 97), accounting for 1 to 5% of cases. It is typically a severe, often fatal, fulminant necrotizing pneumonia accompanied by evidence of cavitation on chest radiographs. Production of Panton-Valentine leukocidin has been associated with severe pneumonia. Community-acquired staphylococcal pneumonia should be considered, and coverage for MRSA strains should be included in the empirical regimen, in two clinical settings: severe pneumonia requiring admission to an ICU and pneumonia in a patient with influenza.

Hospital-acquired and ventilator-associated pneumonias often are caused by *S. aureus* and MRSA in particular. Mortality can be as high as 40 to 50%, reflecting the virulence of the organism and the comorbid conditions that contribute to poor outcomes. The diagnosis is readily established by

examination of a Gram stain and culture of sputum, tracheal aspirate, or lavage fluid (obtained to avoid oropharyngeal contamination), which typically shows organisms and numerous neutrophils. The culture is less specific than the Gram stain because it can be positive in colonized patients, but it is highly sensitive. Coverage for *S. aureus* can be discontinued if the organism is not isolated in culture.

Lung abscess and pleural empyema, infections most commonly caused by oral anaerobic bacteria, are occasionally caused by *S. aureus*. The clinical course may be subacute or even indolent. Empyema occurs as a complication of prior chest tube placement, surgery, trauma, staphylococcal pneumonia, or tricuspid valve endocarditis. These infections are treated with drainage and antimicrobial therapy.

Orthopedic Device–Associated Infections

Prosthetic joint and implant-associated infections occurring within the first 12 weeks of surgery are most commonly caused by *S. aureus*. *S. aureus* is second only to coagulase-negative staphylococci as a cause of later infections. The presentation may be acute, with joint pain, evidence of arthritis, fever, and systemic signs of infection. Alternatively, the infection may run a more chronic course, with pain and loosening of the prosthesis but little or no fever. Formation of biofilm makes treatment of these infections a challenge. Intraoperative inspection, débridement, and hardware retention may be appropriate for infections of less than 3 weeks in duration or occurring within the first month of implantation.[8] Otherwise, débridement and removal of the prosthesis or implant in conjunction with antimicrobial therapy offer the best chance of cure. This can be accomplished either as a one-stage procedure, in which the infected prosthesis or implant is removed and immediately replaced, or as a two-stage procedure, in which the device is removed and replaced after completion of a 4- to 6-week course of antimicrobial therapy.

Genitourinary Infections

Genitourinary infections arise by hematogenous dissemination or as an ascending infection, usually as a result of instrumentation, urinary catheterization, or surgery. These infections include cystitis, pyelonephritis, microabscess, perinephric abscess, prostatitis, and prostatic abscess. *S. aureus* can also be a contaminant introduced during the collection of urine from a patient with asymptomatic vaginal or perineal colonization. Contamination should be suspected if the urine colony counts are low, repeated urine cultures are negative, pyuria is absent, and there are no signs or symptoms of urinary tract infection. If contamination seems unlikely and there is no well-documented history of an event that could lead to ascending infection, hematogenous dissemination should be suspected. Blood culture samples should be obtained to determine whether there is ongoing bacteremia and appropriate imaging studies performed to identify a deep focus of infection and the presence of renal and perinephric abscesses.

Toxin-Mediated Diseases

These diseases are caused by the ingestion of preformed toxin or the elaboration of toxin by *S. aureus* from a site of colonization or infection. Staphylococcal food poisoning is a gastroenteritis caused by the ingestion of a preformed enterotoxin produced in food contaminated with *S. aureus* from an infected or colonized food handler. When contaminated food is kept at room temperature for several hours, organisms replicate and produce a heat-stable toxin that is not inactivated by cooking or digestive enzymes. Nausea, vomiting, abdominal pain, and diarrhea occur within 2 to 6 hours of eating the contaminated food. There is no fever, and the illness is self-limited, generally lasting about a day. Antibiotics have no role in therapy, which consists of fluid replacement to prevent dehydration. Infants, small children, and the elderly are more severely affected and may require intravenous fluids.

Toxic shock syndrome is caused by colonization or infection with a strain that elaborates a specific toxin, TSST-1, or certain staphylococcal enterotoxins. TSST-1 is responsible for 100% of menstrual cases due to its ability to cross the vaginal mucosa and to achieve systemic concentrations. TSST-1 and the staphylococcal enterotoxins SEA, SEB, and SEC are responsible for nonmenstrual toxic shock syndrome, which is characteristically associated with an identifiable focus of infection, usually of the skin. The diagnosis is clinical, defined by fever, erythroderma, hypotension, involvement of three or more organ systems (renal, hematologic, hepatic, pulmonary, gastrointestinal, muscle, central nervous system, mucous membranes), and desquamation, especially of the palms and soles, 1 to 2 weeks after the onset of illness. Bacteremia is present in only 5% of cases. The case fatality rate is about 5%. Treatment consists of systemic antimicrobial therapy, removal of the source of toxin production, and treatment of septic shock. Streptococcal toxic shock syndrome is discussed in Chapter 290.

FIGURE 288-3. Scalded skin–type lesions with multiple ruptured bullae and desquamation in a patient with aortic valve endocarditis caused by an exfoliative toxin–producing strain of *S. aureus*.

Colonization or infection with an *S. aureus* strain that produces exfoliative toxin A or B may cause staphylococcal scalded skin syndrome, a disease primarily of infants but occasionally seen in adults (Fig. 288-3), and bullous impetigo, a pustular skin lesion. The appearance is that of a scald, burn, or blister. The differential diagnosis of staphylococcal scalded skin syndrome includes drug reaction (Chapter 440), toxic epidermal necrolysis (Chapter 439), Kawasaki disease (Chapter 439), and pemphigus foliaceus (Chapter 439).

DIAGNOSIS

S. aureus infection is diagnosed by isolating the organism in culture specimens of blood, tissue, or pus. Non–culture-based methods, such as nucleic acid amplification tests, are becoming available, but their utility is still being defined.[9] Culture remains the "gold standard." Gram stain is useful for making a presumptive diagnosis of staphylococcal infection and should be performed whenever possible to look for gram-positive cocci in tetrads or clusters in pus, bone or tissue samples, respiratory secretions, or body fluids such as cerebrospinal fluid, pleural or pericardial fluid, synovial fluid, or urine. Failure to isolate the organism in culture is strong evidence against *S. aureus* infection unless a patient is being actively treated with an antibiotic; even then, infected sites may remain culture positive for several days. The specificity of isolating *S. aureus* from blood or other sterile body sites is essentially 100%. Because of nasopharyngeal colonization in some uninfected individuals, isolation of *S. aureus* from culture of a respiratory specimen lacks specificity; however, if Gram stain also shows gram-positive cocci in tetrads and clusters and many neutrophils, this is suggestive of *S. aureus* pneumonia.

Susceptibility Testing

Susceptibility testing should be performed for clinically significant isolates to guide antimicrobial therapy. The critical determination is whether the isolate is methicillin resistant (i.e., resistant to β-lactam antibiotics). Resistance to macrolides and fluoroquinolones is common, and these drugs should not be used to treat suspected staphylococcal infection without confirmation of in vitro susceptibility. Clindamycin is usually active, although macrolide-resistant strains that produce a ribosomal methylase, inducibly or constitutively, are cross-resistant. Tetracyclines and trimethoprim-sulfamethoxazole are active against 80 to 90% of strains. Resistance to vancomycin, daptomycin, telavancin, or linezolid, although rare, may occur, particularly when there has been prior exposure to the drug, making susceptibility testing important for these antibiotics.

TREATMENT

Rx

The two principles of therapy for *S. aureus* infections are (1) source control by elimination of focal infection and infected foreign material whenever feasible and (2) administration of systemic antimicrobial therapy. For boils and cutaneous abscesses, incision and drainage may be all that is required. Antimicrobial therapy is indicated if the infection is not amenable to removal (e.g., cellulitis, pneumonia), drainage is impossible or inadequate, systemic signs

and symptoms of infection are present, or there is invasive disease (i.e., metastatic sites of infection; involvement of deep tissues, vital organs, sterile sites) and in all cases of bacteremia. An undrained focus of infection or retention of an infected foreign body is the most common reason for unsatisfactory clinical response, treatment failure, or relapse.

The most important consideration in selecting an antibiotic is susceptibility of the *S. aureus* isolate to β-lactams. A penicillinase-resistant penicillin, such as nafcillin (1 to 2 g every 4 to 6 hours IV, depending on the severity of the infection), oxacillin, or flucloxacillin, or a cephalosporin (e.g., cefazolin 1 to 2 g every 8 hours IV) is the agent of choice for the treatment of methicillin-susceptible *S. aureus* (MSSA) infections; no other antibiotic is as safe or as effective as a β-lactam. An orally administered β-lactam (e.g., dicloxacillin 500 mg four times daily or cephalexin 500 mg four times daily) is appropriate for most cutaneous infections; a parenteral agent is recommended, at least initially, for invasive infections. Only if the patient is allergic or has a serious reaction is an agent other than a β-lactam preferred for the treatment of infection caused by an MSSA strain.

Methicillin-resistant strains are cross-resistant to all currently available β-lactams, except for ceftaroline (dose of 600 mg IV every 12 hours), which is indicated for treatment of skin and skin structure infections caused by methicillin-resistant strains. Otherwise, a β-lactam should not be used for treatment of infection known or suspected to be caused by a methicillin-resistant strain. The prevalence of methicillin resistance in *S. aureus* isolates from hospital-acquired and health care–associated infections in the United States and in many European countries is 25 to 50% or higher. MRSA also causes a substantial proportion of community-onset infections in individuals lacking other risk factors, especially in the United States. Trimethoprim-sulfamethoxazole (one or two 80/160-mg tablets twice a day), clindamycin (300 mg three times a day), and doxycycline or minocycline (100 mg twice a day) are active in vitro against most community-acquired MSSA and MRSA strains and are effective when administered orally for the treatment of skin and soft tissue infections in outpatients. Fluoroquinolones should not be used because most methicillin-resistant strains are also fluoroquinolone resistant.

For invasive infections, vancomycin is still a drug of choice.[10] It must be administered intravenously; doses of 30 to 60 mg/kg/day, adjusted on the basis of creatinine clearance, are recommended to achieve trough serum concentrations of 15 to 20 μg/mL for patients with bacteremia, endocarditis, or other serious infections. Treatment failures are not uncommon with bacteremia or endocarditis. Patients can remain persistently bacteremic (≥3 days or longer) or relapse, even when the strain is susceptible (minimal inhibitory concentration [MIC] ≤2 μg/mL) in vitro. Other than the presence of an undrained focus of infection, the reasons for this are unclear. Possible explanations include vancomycin's slowly bactericidal activity; tolerance, in which the isolate is inhibited at low concentrations but not killed; or so-called heteroresistance, in which a small fraction of the population of organisms has a higher MIC. Vancomycin MIC of 2 μg/mL has been associated with treatment failure in some retrospective studies but not in others.[11-13] Strains with intermediate susceptibility to vancomycin (MICs of 4 or 8 μg/mL), which account for 1 to 3% of MRSA isolates, should be considered resistant because this is highly predictive of vancomycin treatment failure. Vancomycin-resistant strains (MIC >8 μg/mL), which express the *vanA* gene, are rare. Alternatives to vancomycin include quinupristin-dalfopristin (7.5 mg/kg every 8 to 12 hours, rarely used because of poor tolerability and limited efficacy data), linezolid (600 mg every 12 hours, Food and Drug Administration [FDA] approved for pneumonia and skin and soft tissue infection), daptomycin (FDA-approved doses of 4 mg/kg once daily for complicated skin and soft tissue infections and 6 mg/kg once daily for bacteremia), telavancin (10 mg/kg once daily, approved for skin and soft tissue infection and pneumonia when alternative treatments are not suitable), and ceftaroline (skin and soft tissue infection). These alternative agents have been shown to be noninferior to vancomycin in high-quality, randomized controlled trials, and none has demonstrated superiority.

Some authorities recommend higher doses of daptomycin (e.g., 10 mg/kg/day) for treatment of bacteremia or endocarditis, particularly when the infection has failed to respond to vancomycin. Daptomycin should not be used to treat primary staphylococcal pneumonia because it is inactivated by pulmonary surfactant, although it is indicated for treatment of hematogenous pneumonia, as occurs in tricuspid valve endocarditis or septic pulmonary embolization.

The role of combination therapy is ill defined. Aminoglycoside combination regimens have not been shown to improve outcomes, but there are good data demonstrating increased toxicity and adverse events with aminoglycoside combinations. Aminoglycoside combinations should not be used routinely, and if used at all, they should be reserved for patients who have failed to respond to first-line therapy. Rifampin combination therapy is recommended for the treatment of osteomyelitis, device-related bone infection and prosthetic joint infection, or prosthetic valve endocarditis, particularly that caused by methicillin-resistant strains of staphylococci. Rifampin (300 to 450 mg twice daily) must always be administered in combination with a second active agent because resistance emerges rapidly during therapy.

PREVENTION

The emergence of community MRSA and the large burden of hospital-acquired and health care–associated staphylococcal infections have stimulated renewed interest in prevention strategies. The organisms that cause these infections are usually resident flora (either *S. aureus* or coagulase-negative staphylococci), or they are acquired by direct contact with a contaminated source, such as a wound or dressing, the skin or hands of an asymptomatically colonized individual, or a contaminated health care provider. The most effective strategy is adherence to principles of basic infection control, the key component of which is hand hygiene, whether it is handwashing or use of an alcohol-based hand rub. This disrupts transmission of organisms by the hands of care providers, a well-documented source of bacterial contamination. Barrier precautions (gloves and gowns) are important for minimizing contact with infected wounds, contaminated secretions, and dressings. Isolation precautions and screening for asymptomatic carriage are more controversial and less well documented in terms of their efficacy. For patients undergoing surgical procedures, surgical hand and surgical site antisepsis, aseptic surgical technique, and antimicrobial prophylaxis are important preventive measures.

Another potentially effective means of preventing infection is screening and decolonization of *S. aureus* carriers. Studies to determine whether screening, decolonization, and isolation actually prevent MRSA infection have had mixed results. In the ICU setting, universal decolonization with 2% chlorhexidine bath cloths and 2% intranasal mupirocin ointment was found to be more effective than targeted screening and decolonization in reducing MRSA rates. This approach has yet to be widely adopted, and one concern is emergence of resistant strains.

Decolonization may be considered in two other settings: prevention of recurrent infection in individuals who have had several prior episodes and prevention of surgical site infections. The best-studied regimens are topically applied mupirocin nasal ointment (0.5 g twice daily in each nostril for 5 days), with or without bathing with chlorhexidine soap, and orally administered rifampin (600 mg in one or two divided doses) in combination with another active agent (e.g., a fluoroquinolone if the isolate is susceptible, trimethoprim-sulfamethoxazole, doxycycline). In a randomized, double-blind, placebo-controlled, multicenter trial, the number of surgical site *S. aureus* infections acquired in the hospital was reduced by the rapid screening of nasal carriers by a real-time polymerase chain reaction assay and the decolonization of carriers with mupirocin nasal ointment and chlorhexidine soap. Several antistaphylococcal vaccine candidates are currently in phase I and phase II clinical trials; the availability of an effective vaccine would be an important tool in preventing staphylococcal infections.

PROGNOSIS

Prognosis of *S. aureus* infections and outcomes depend on the site of infection, adequacy of source control, presence of comorbidities (e.g., diabetes; immunosuppression; underlying cardiac, renal, or liver disease), presence of bacteremia, presence of secondary foci of infection, presence of severe sepsis or septic shock, antibiotic effectiveness, and duration of therapy for complicated disease. Methicillin resistance is a risk factor for poorer outcome largely because of its health care association, and thus occurrence in a population that is elderly and in which comorbid medical illnesses are prevalent, and possibly because less effective antibiotics (non–β-lactams) are used to treat these infections. Historically, untreated *S. aureus* bacteremia was lethal in 85% or more of cases. Antibacterial therapy, 4 to 6 weeks or longer for complicated bacteremia or infections of deep tissues, and recognition of the importance of source control have dramatically improved outcome. Mortality remains high, in the range of 20 to 40%, in patients with severe sepsis, septic shock, or endocarditis.

COAGULASE-NEGATIVE STAPHYLOCOCCI

More than 30 different species of coagulase-negative staphylococci have been identified, and about half of these colonize humans. *Staphylococcus epidermidis* is the species that most commonly causes infection. Coagulase-negative staphylococci infrequently cause infection unless there is a foreign body in place, and although bacteremia occurs, metastatic seeding of secondary sites of infection is distinctly uncommon. Coagulase-negative staphylococci are typically resistant to methicillin and multiple other antibiotics, and they are an important reservoir of drug resistance elements that are horizontally transferrable to *S. aureus*. They are the most common cause of health care–associated infections overall in the United States (Chapter 282); they account

for one third of central line–associated blood stream infections; and they are the second most common cause of surgical site infections, particularly when a prosthetic device or other foreign material has been implanted. Infections are often indolent, causing little in the way of fever or systemic signs of infection, but they may also be acute and life-threatening, as in the case of prosthetic valve endocarditis. Coagulase-negative staphylococci are proficient biofilm producers; consequently, débridement and removal of the infected prosthetic device or foreign body are paramount. Prosthetic joint infections occurring more than 1 month after device implantation are best managed with removal of the prosthesis and reimplantation in a one-stage or two-stage procedure. Antimicrobial therapy for these infections is similar to that for *S. aureus*, except that hematogenous seeding rarely occurs, so attention is focused primarily on source control.

Coagulase-negative staphylococci, because they are normal skin flora, are the most common blood culture contaminant. In approximately 75% of cases, when the blood culture is positive for coagulase-negative staphylococci, this reflects contamination rather than infection. Sorting out whether a positive culture represents contamination or true infection can be a challenge. A single positive blood culture or blood cultures in which more than one strain is present are likely to be due to contamination. Time to blood culture positivity, quantitative blood cultures, and the presence of multiple positive cultures can be useful in determining whether a positive blood culture represents true infection. Isolation of coagulase-negative staphylococci from the blood of a patient with a prosthetic valve, intravenous pacemaker, or vascular graft can be especially problematic because these patients are at high risk for true infection. Unless the patient is hemodynamically unstable or otherwise seriously ill, it is advisable to withhold antibiotics until additional culture specimens are obtained to document the presence of true bacteremia. Isolation of coagulase-negative staphylococci from culture specimens of deep tissue, bone, prosthetic devices, or other normally sterile sites, especially if multiple cultures are positive, strongly suggests true infection.

Staphylococcus lugdunensis, in contrast to other coagulase-negative staphylococci, is pathogenic and causes infections in the absence of a foreign body and in otherwise normal hosts that clinically resemble *S. aureus* infections. These include prosthetic valve and native valve endocarditis, bacteremia, skin and soft tissue infection, septic arthritis, prosthetic joint infection, and osteomyelitis. It lacks free coagulase, but some strains produce a membrane-bound form that can lead to its misclassification as *S. aureus*. *S. lugdunensis* lacks protein A and is positive for ornithine decarboxylase and pyrrolidonyl arylamidase, differentiating it from *S. aureus*. *S. lugdunensis* is susceptible to most antibiotics, including penicillin (approximately 75% of isolates), and resistance to nafcillin and oxacillin is rare. The management of these infections is similar to that of *S. aureus* infections.

REVIEW QUESTIONS

1. Ms. A is a 53-year-old woman admitted 1 week ago for fevers to 102.3° F and right flank pain. A computed tomography scan showed findings consistent with a 6-cm psoas abscess. Three blood culture samples were drawn, and empirical therapy was begun with vancomycin and piperacillin-tazobactam. All three blood culture samples grew methicillin-resistant *Staphylococcus aureus* (MRSA) with a vancomycin minimal inhibitory concentration (MIC) of 2 μg/mL. Treatment was de-escalated to vancomycin alone with documented trough concentrations of 15 μg/mL. One of two blood culture samples obtained on day 5 of therapy because of recurrent fever now is reported as positive for gram-positive cocci in clusters. Which of the following is the *most likely* explanation for the persistently positive blood culture?

A. Vancomycin-nonsusceptible MRSA strain
B. Failure to obtain a transesophageal echocardiogram
C. Undrained psoas abscess
D. Subtherapeutic levels of vancomycin
E. Contamination of the blood culture sample with coagulase-negative staphylococci

Answer: C An isolate with a vancomycin MIC of 2 μg/mL is considered to be susceptible. Vancomycin-intermediate strains have low prevalence, 1 to 3%, and the MIC of these strains is 4 to 8 μg/mL. Vancomycin-resistant strains (MIC > 8 μg/mL) are rare. Thus, vancomycin nonsusceptibility is very unlikely. The vancomycin trough is in the therapeutic range, and although an echocardiogram is recommended for patients with complicated bacteremia, failure to obtain this study has not been shown to affect outcome. It is a mistake to attribute a positive blood culture to a contaminant in a patient with known *S. aureus* bacteremia. Poor source control with an undrained abscess, a well-known cause of persistent bacteremia, is the best answer.

2. Ms. B is a 58-year-old patient with degenerative arthritis who had a right hip replacement performed 3 weeks ago. She presents with about a week of slowly worsening hip pain with breakdown of the surgical site, cultures of which grew methicillin-susceptible *S. aureus*. Blood cultures are negative, and she has no fevers. She is adamant that she does not want the hardware removed. What is the best course of action in this situation?

A. Begin oral cephalexin and discharge the patient for follow-up in 2 weeks to see if she improves.
B. Begin a 2 week course of once-daily IV daptomycin and discharge the patient for follow-up in 2 weeks to assess need for further therapy.
C. Treat her with cefazolin for a week, and if she does not get better, perform incision and drainage.
D. Tell her that with incision, drainage, and debridement and a course of IV and oral antibiotics, she should do well without removal of the hardware.
E. Try to convince her to have the hardware removed because if it is left in place, the infection cannot be cured.

Answer: D The patient is likely to have a methicillin-susceptible infection of the prosthesis. Because the infection is within a month of implantation and she has had less than 3 weeks of symptoms, she should do well with incision and drainage and a prolonged course of IV and oral antibiotics (3 to 6 months). Because hardware removal is probably not necessary, trying to threaten her into a procedure she has already said she does not want is unwise. Empirical therapy with an oral (A) or parenteral (C) β-lactam is ill-advised because it is important to document whether the joint is involved and to perform incision and drainage to minimize the possibility of progression of infection and a worse outcome. Empirical therapy with daptomycin is a poor choice for the same reasons, and moreover, a β-lactam is the preferred initial therapy for methicillin-susceptible *S. aureus* (MSSA).

3. Mr. C is a previously healthy 23-year-old man who is admitted with a 1-week illness characterized by a dry cough, fever, and myalgias. Yesterday he noticed that the cough became productive of yellow sputum, and last night be noticed shortness of breath. On examination, his temperature is 104° F, pulse is 128, respiratory rate is 22, blood pressure is 100/60, and pulse oximetry is 80% saturation on room air. He has rales at the right base, and a chest radiograph shows a fluffy right lower lobe infiltrate. A rapid influenza test result is positive, and sputum Gram stain shows numerous polymorphonuclear leukocytes and a few gram-positive cocci in clusters. Two blood culture samples are obtained. Which one of the following antibiotics is the worst choice to treat this suspected pneumonia?

A. Clindamycin
B. Ceftaroline
C. Daptomycin
D. Linezolid
E. Vancomycin

Answer: C This patient has *S. aureus* pneumonia as a complication of influenza. The susceptibility of the organism is unknown, but he is at risk for MRSA infection. Either linezolid or vancomycin would be an appropriate choice as both are first-line agents. Of the three other antibiotics, all have issues, but daptomycin is the worst choice of the three because it is inactivated by pulmonary surfactant, resulting in treatment failure, and it is not indicated for treatment of pneumonia. Clindamycin could be used because most community MRSA and MSSA strains are susceptible, and although it is not a first-line agent in adults, it has been used to treat children with staphylococcal pneumonia. Ceftaroline, although not approved by the Food and Drug Administration for staphylococcal pneumonia, has an indication for treatment of community-acquired pneumonia, and it is active against both MRSA and MSSA. Thus, in a pinch, either clindamycin or ceftaroline would be preferred to daptomycin.

4. Mr. T is a 38-year-old diabetic patient who presents with a 2-day history of worsening pain and swelling of his left upper arm and subjective fevers. He tells you that he is penicillin allergic. His temperature is 99.8° F, and other vital signs are normal. On physical examination, there is a 5-cm-diameter tender, red, indurated lesion with central fluctuance over the triceps area. You perform incision and drainage, which yields about 3 mL of pus. Which one of the following antibiotics should *not* be used as empirical therapy for this community-acquired skin abscess?

A. Clindamycin
B. Doxycycline
C. Levofloxacin
D. Minocycline
E. Trimethoprim-sulfamethoxazole

Answer: C Clindamycin, doxycycline, minocycline, and trimethoprim-sulfamethoxazole are active in vitro against both MRSA and MSSA strains and have been recommended and used to treat skin and soft tissue infections in areas with high prevalence of MRSA. Many MRSA strains and some MSSA strains are fluoroquinolone resistant, and therefore fluoroquinolones should not be used in the absence of documented in vitro susceptibility.

5. Which one of the following measures is probably the most effective means of preventing MRSA transmission?

A. Chlorhexidine bath
B. Good hand hygiene
C. Isolation
D. Mupirocin nasal ointment
E. Screening for colonization

Answer: B Although randomized, controlled trials are lacking, on the basis of the known mechanisms of *S. aureus* transmission, whether MRSA or MSSA, good hand hygiene is probably the most effective strategy to prevent spread of the organism. Chlorhexidine baths alone have not proved effective. Screening and isolation of patients have had variable success. Mupirocin nasal ointment alone may reduce the risk of perioperative infection in colonized individuals but has not been shown to prevent transmission. The study of Huang and colleagues[A6] found that in an intensive care unit setting, screening and isolation and targeted MRSA decolonization were relatively ineffective in reducing MRSA rates, whereas universal decolonization did reduce rates.

STREPTOCOCCUS PNEUMONIAE INFECTIONS

LIONEL A. MANDELL

DEFINITION

The term *pneumococcal pneumonia* refers to infection of the pulmonary parenchyma and its associated structures by *Streptococcus pneumoniae*. There are an estimated 5 million cases annually worldwide, and community-acquired pneumonia (CAP) of all etiologies is the commonest cause of death from infection in the United States and Europe.[1]

The Pathogen

S. pneumoniae is a gram-positive coccus that typically grows in pairs or short chains. Careful examination of the diplococcal form reveals slightly tapered ends that give rise to its lancet-shaped appearance. It is a facultative anaerobe that grows best on blood agar plates in a 5% carbon dioxide ambient environment. The colonies are typically surrounded by a greenish zone of hemolysis resulting from degradation of hemoglobin by a pneumococcal toxin. The organism can be distinguished from other streptococci by its susceptibility to ethyl hydrocupreine (Optochin) and bile solubility.

The surface of the pneumococcus consists of a capsule and a cell wall. The capsule, which helps prevent phagocytosis, is composed of polysaccharides that define at least 92 different pneumococcal serotypes. The cell wall is a dynamic structure composed of more than a dozen distinct glycopeptides.

EPIDEMIOLOGY

The pneumococcus is one of the most common causes of CAP and can cause hospital-acquired and health care–associated pneumonia as well.[2] The false impression that *S. pneumoniae* is uncommon has arisen because at least one third of patients with CAP are unable to produce sputum and, even if they do, often provide an inadequate sample. Moreover, if the patient has recently taken just one dose of a drug to which the pneumococcus is susceptible, it may not be possible to isolate the organism.

The ecologic niche of the pneumococcus is the nasopharynx, and up to 80% of infants and 20% of healthy adults may be colonized. Colonizing and invasive strains of pneumococci have developed adaptive mechanisms allowing them to escape host responses. Simultaneous colonization with more than one capsular type has been reported. The horizontal transfer of genes that can occur can expand the gene pool of the colonizing pneumococci, thereby enhancing their adaptive abilities and virulence properties. Asymptomatic colonization is an immunizing experience because homologous anticapsular antibodies may be demonstrated in individuals after colonization with a specific serotype.

A particular serotype may colonize the nasopharynx for varying periods, but the average duration in infants is 7 weeks. Carriage rates are highest during the late fall, winter, and early spring. Although each of the 92 serotypes is potentially pathogenic, the most frequently encountered are types 3, 4, 6, 7, 9, 12, 14, 18, 19, and 23.

Person-to-person transmission results from close interpersonal contact. Although pneumococcal pneumonia is typically a sporadic illness, epidemics can occur in crowded settings such as daycare centers, barracks, nursing homes, and prisons.

The incidence of pneumococcal pneumonia is about 18 per 100,000 people per year. For persons 5 years or younger and 75 years or older, rates are about 23 and 35.8 per 100,000 people, respectively. For pneumococcal bacteremia, the incidence is about 7.5 per 100,000 people per year and increases with age; the case-fatality rate is 21%.

Risk factors for pneumococcal pneumonia include dementia, seizure disorders, heart failure, cerebrovascular disease, chronic obstructive pulmonary disease (COPD), human immunodeficiency virus (HIV) infection, previous viral respiratory illness, alcoholism, malnutrition, diabetes, cirrhosis, and renal insufficiency.

Certain ethnic groups such as Native Americans, particularly Alaskan natives, and Australian Aboriginals, appear to be particularly susceptible to

invasive pneumococcal infection. Any individual who has a defect in immunoglobulin G (IgG) synthesis (Chapter 250) or phagocyte function (Chapter 169) or who has undergone splenectomy is also at increased risk for invasive pneumococcal infection.

PATHOBIOLOGY

Pneumonia is the result of a breakdown in the interplay between colonizer and host as well as pneumococcal virulence factors that can influence both colonization and invasion. In pneumococcal pneumonia, the microorganism first colonizes the nasopharynx. Aspiration of small amounts of oropharyngeal contents occurs in deep sleep, even in normal individuals, but if the oropharyngeal material includes pneumococcal serotypes associated with invasive infection and if normal clearance mechanisms fail, the colonizers may become pathogens. Whether or not a particular pneumococcus results in active infection is related to a number of virulence factors that allow it to avoid or mitigate host defenses and to attack host cells. These include capsular polysaccharides, which allow avoidance of opsonophagocytosis; exoglycosidases, which enable access to cell receptors and choline-binding proteins; and divalent metal-ion binding lipoproteins, which can act as adhesins. Autolysins can cause lysis of host cells and pneumolysin, and choline-binding proteins may enable the pathogen to gain access to the vascular system, potentially resulting in bacteremia and metastatic infection.[3] The risk for infection is increased by any process or condition that exposes the host to the pathogen, that allows oropharyngeal secretions to bypass upper airway defenses, or that interferes with the host's ability to ingest and kill the pneumococci (Table 289-1).

It appears that aspirated pneumococci adhere to type II cells in the alveolus if they are not cleared by normal defense mechanisms. Attachment to resting cells is mediated by two classes of glycoconjugates, but local inflammatory mediators upregulate host cell receptors, such as those for platelet-activating factor (PAF), and provide a site of attachment for the bacteria. This interaction between PAF receptor and pathogen appears to be an important step in internalization of the bacteria by means of an endocytic vacuole and may promote invasion. Expression of pili by certain pneumococcal strains facilitates binding to epithelial cells and results in a more vigorous tumor necrosis factor (TNF)–dependent inflammatory response, which can cause further tissue damage.

In the lung, the pneumococci are able to activate complement and stimulate the cytokine response. Initially, the alveoli fill with fluid exudate (Fig. 289-1), which allows the infection to spread to adjacent uninfected alveoli. In healthy lungs, polymorphonuclear leukocytes (PMNs) constitute less than 1% to 2% of alveolar cells and normally reside in the interstitial areas of the lung and in adjacent capillaries. Recruitment of PMNs into alveoli depends on the generation of chemoattractants necessary for the directed migration of neutrophils.

Ultimately, the signs and symptoms of disease are both attributable to the pathogens themselves and to the body's response to them. The bacterial cytotoxin pneumolysin and various pneumococcal cell wall components are able to induce a variety of effects that initiate and then enhance the inflammatory response, thereby resulting in the various signs and symptoms of pneumonia.

The effects of pneumococcal infection are ultimately manifested as changes in lung mechanics secondary to reductions in lung volumes and lung compliance, as well as gas exchange problems resulting from intrapulmonary shunting and subsequent arterial hypoxemia. If severe enough, death may ensue.

Antibiotic Resistance

The phenotypic expression of antibiotic resistance corresponds to genetic alterations resulting from horizontal acquisition of foreign genetic information or from mutations in the microbial genome. The impact of antibiotic resistance as documented in vitro is not as straightforward as one might imagine, and there is not a direct relationship between resistance and clinical outcomes.

With *S. pneumoniae,* resistance may be acquired by direct DNA incorporation and remodeling from closely related oral commensal bacteria by the process of natural transformation. Pneumococcal resistance to β-lactams such as penicillin is solely attributable to the presence of low-affinity penicillin-binding proteins (PBPs). Increasing the concentration of the β-lactams can usually overcome such resistance. Revision of the break points for resistance in nonmeningeal isolates has resulted in a lower prevalence of penicillin resistance than was previously reported.[4] The PBPs themselves are *trans* and carboxypeptidase enzymes that are involved in bacterial cell wall synthesis and represent the primary sites of action for β-lactam drugs.

Resistance to macrolides, in contrast, can occur through multiple mechanisms, including target site modification or an efflux pump. Target site modification is caused by a ribosomal methylase encoded by the *ermB* gene. A change in 23S recombinant RNA mediated by this gene can result in resistance to macrolides, lincosamides, and streptogramin B–type antibiotics (MLS_B phenotype). The efflux mechanism is encoded by the *mefA* gene, which results in an M phenotype. The former is typically associated with high-level resistance with minimal inhibitory concentrations (MICs) of 64 µg/mL or higher, but the latter is usually associated with low-level resistance with MICs of 1 to 32 µg/mL. These two mechanisms account for approximately 45% and 55%, respectively, of resistant isolates. Clonal dissemination is important in the spread of macrolide resistance. Some pneumococcal isolates have been found with both the *erm* and *mef* genes, but the significance of such a finding is unknown.

Resistance to fluoroquinolones may be mediated by changes in one or both target sites (topoisomerase II and IV) of the pneumococcus, which usually result from mutations in the *gyrA* and *parC* genes, respectively. Low-level resistance may result from changes in one site, but high-level resistance can result when dual mutations occur. An efflux pump may have a role as well. Also of concern is the fact that the incidence of multidrug-resistant isolates is increasing.

TABLE 289-1 PREDISPOSING FACTORS FOR PNEUMOCOCCAL PNEUMONIA

INCREASED EXPOSURE TO *STREPTOCOCCUS PNEUMONIAE*
Prisons
Military barracks
Daycare centers
Shelters for the homeless
DECREASED HOST DEFENSES
Complement deficiency
Antibody deficiency
Functional or anatomic asplenia
Decreased numbers or function of phagocytes
SPECIFIC DISEASE ENTITIES
Multiple myeloma
Lymphoma
Chronic lymphocytic leukemia
Human immunodeficiency virus infection
RESPIRATORY AND PULMONARY PROBLEMS
Chronic obstructive pulmonary disease
Smoker
Allergies
Previous viral infection

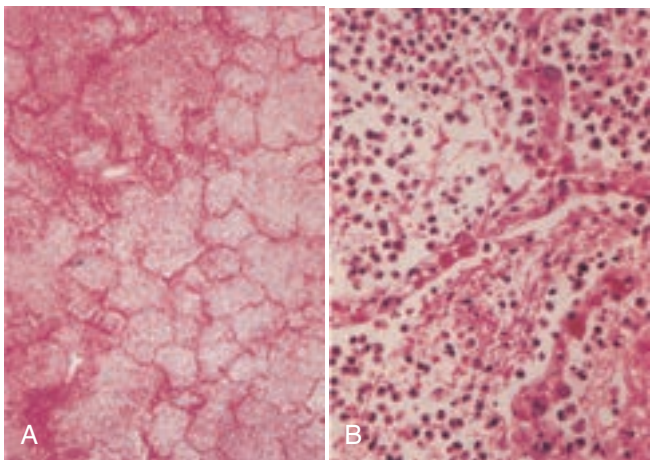

FIGURE 289-1. Pneumonia. A, Low-power magnification (×100) of hematoxylin and eosin (H&E) stain of tissue section from the left lower lobe of the lung. Note the intact alveolar walls and alveoli filled with edema and thick cellular exudates. **B,** Higher magnification (× 500) H&E stain of the same section shown in **A.** Note the heavy infiltrate of polymorphonuclear cells and the intact alveolar walls.

CLINICAL MANIFESTATIONS

The clinical features of pneumococcal pneumonia depend on factors such as whether the patient is immunocompetent or immunosuppressed, the severity of illness, and whether the patient has taken antibiotics. Temperatures can vary from 101° F to higher than 103° F (38° to 39.5° C), can be accompanied by chills and rigors, and are usually associated with a tachycardic response. A cough, typically productive of purulent and occasionally blood-tinged sputum, is often present, and as many as 46% of patients report chest pain. About 20% have gastrointestinal symptoms such as nausea, vomiting, or diarrhea. In elderly people, symptoms and signs may be more subtle; for example, older patients may have predominantly confusion.

On examination, the patient is often listless and may be cyanotic. The respiratory rate is increased; if pleuritic pain is marked, the patient may be splinting the affected side. Whereas dullness to percussion over a lung segment suggests consolidation, a flat percussion note is typically associated with a pleural effusion. Breath sounds may be "distant" if there is an overlying effusion, but they are bronchial in nature if the underlying lung is consolidated. Rales may be noted. If the patient has pleurisy without much pleural fluid, a friction rub may be heard.

No radiographic appearance is characteristic of pneumococcal pneumonia (Chapter 97). Typically, however, involvement is limited to one or more segments within a single lobe. Involvement is unilateral approximately 80% of the time, and the presence of cavitation or lung abscess is uncommon. Among patients with pneumococcal pneumonia, necrotizing changes in the lungs were seen in 6.6% of cases in a large series but were often overlooked on initial readings of chest radiographs or computed tomography (CT) scans. Forty-five percent of patients have an associated pleural effusion, but only 15% have an effusion of sufficient size to warrant drainage (>10 mm on lateral decubitus views). Purulent pericarditis can also be seen (Chapter 77).

Patients with lobar consolidation are more likely to be bacteremic, but there are no consistently significant differences in the radiologic manifestations of bacteremic and nonbacteremic pneumococcal pneumonia. Bacteremic pneumococcal pneumonia may seed distant sites and cause meningitis (Chapter 412), endocarditis (Chapter 76), or septic arthritis (Chapter 272).

With sepsis, sepsis syndrome, or septic shock (Chapter 108), the patient may be hypotensive, and the findings of organ failure vary depending on the target organ(s) involved. For example, oliguria, anuria, and acidosis suggest renal failure; myocardial impairment suggests heart failure; and jaundice is consistent with hepatic failure. Systemic activation of coagulation together with consumption of clotting proteins can result in simultaneous clotting and bleeding (Chapter 175). In some cases, peripheral gangrene and purpura fulminans may be seen.

DIAGNOSIS

Despite extensive testing, a specific etiologic agent is not found in 50% or more of patients with CAP. The history, physical examination, chest radiograph, sputum Gram stain, and blood and sputum cultures are insensitive and lack specificity, but more invasive methods (e.g., endotracheal aspirate, bronchoscopy techniques, pleural fluid aspiration, and lung biopsy) require special expertise and are infrequently indicated. As a general rule, routine diagnostic tests to identify a pathogen are optional for outpatients with CAP, but more extensive testing is recommended for hospitalized patients (Table 289-2).[5]

Ultimately, the diagnosis should be based on suggestive clinical features and a chest radiograph with or without corroborating microbiologic data. Because *S. pneumoniae* is the most common etiologic agent of CAP, virtually any recommended treatment regimen must provide adequate coverage for it, so documentation of its presence has little or no effect on ultimate clinical outcomes. From the point of view of epidemiology and antimicrobial susceptibility, however, documentation of a pathogen is desirable.

The sputum Gram stain is a relatively simple and inexpensive procedure to document the presence of certain pathogens. The adequacy of the specimen is based on the relative number of neutrophils and squamous epithelial cells (SECs). There should be at least 25 neutrophils and fewer than 10 SECs per low-power field (×100 magnification). The sensitivity of sputum Gram stain for *S. pneumoniae* is 55%, but the specificity is higher than 80%. Unfortunately, approximately 30% of patients overall are unable to produce an appropriate sputum sample. In elderly patients, this figure reaches almost 70%. Overall, only 28% at best of sputum samples are of good quality. Sputum cultures are neither sensitive nor specific, particularly when dealing with relatively fastidious pathogens such as *S. pneumoniae.*

Blood cultures are positive in only 5% to 14% of patients with CAP. If patients have taken a previous dose of antibiotic, culture results are even less useful. As a result, sputum Gram stain, sputum culture, and blood cultures are generally recommended only in patients with selected clinical indications (see Table 289-2). In patients with severe CAP, an expectorated sputum sample should be replaced by an endotracheal aspirate sample if the patient is intubated.

Pneumococcus can also be detected by polymerase chain reaction (PCR), but this is not done routinely and there currently is no evidence that such testing will change clinical outcomes. Nevertheless, an increased pneumococcal bacterial load demonstrated by real-time PCR is associated with an increased risk for septic shock, need for mechanical ventilation, and death, suggesting that such a test may be of help in identifying patients suitable for care in the intensive care unit.[6] Pneumococcal capsular polysaccharide can be detected in urine, and this may occasionally be helpful for diagnosis after antibiotic therapy has been started. The overall sensitivity of the pneumococcal urinary antigen test is less than 80% but can reach 90% or higher in patients with pneumococcal bacteremia and those with high-risk pneumonia. The specificity in adult patients with CAP can exceed 95%. Detection of antibody to pneumococcal polysaccharide is not useful.

Newer methods which may help in the diagnosis of pneumococcal pneumonia include real-time polymerase chain reaction (RT-PCR) to detect pneumococcal DNA in blood and the use of host biomarkers such as C-reactive protein (CRP) and procalcitonin (PCT).[7] These are acute phase reactants which increase in the presence of an inflammatory response, particularly to bacterial pathogens. CRP may help to identify worsening disease, and PCT may help in determining the need for antibacterial therapy.

TABLE 289-2 INDICATIONS FOR MORE EXTENSIVE DIAGNOSTIC TESTING IN COMMUNITY-ACQUIRED PNEUMONIA

Intensive care unit admission for community-acquired pneumonia
Failure of outpatient treatment
Radiographic appearance of cavities on initial evaluation
Infection resulting in neutropenia
Alcohol abuse
Chronic severe liver disease
Severe chronic obstructive lung disease
Asplenia (anatomic or functional)
Recent travel (within 2 weeks)
Positive rapid *Legionella* spp. or pneumococcal urinary antigen test result
Pleural effusion

PREVENTION

Two types of pneumococcal vaccines are available, each with its own particular advantages and disadvantages.[8]

Polysaccharide Vaccine

A polysaccharide vaccine contains 25 μg of each of the 23 capsular polysaccharides that account for 90% of invasive infections (Chapter 18). Polysaccharide vaccines stimulate B-cell responses, thereby resulting in type-specific antibody production that enhances ingestion and killing of the pathogens by phagocytes. The antigens, however, are T-cell independent and therefore do not result in long-lasting immunity. Two types of polysaccharide vaccine have been available, Pneumovax (Merck) and Pnu-Imune (Lederle).

The effectiveness of the pneumococcal polysaccharide vaccine ranges from 56% to 81%. Data suggest that it is effective in preventing both pneumococcal and all-cause pneumonia. A randomized trial demonstrated that the immunogenicity of the 23-valent polysaccharide vaccine is comparable to that of the 7-valent pneumococcal conjugate vaccine (see later) in frail, hospitalized, elderly patients. It is not effective in immunocompromised patients, such as those with sickle cell disease, chronic renal failure, immunoglobulin deficiency, Hodgkin's disease, non-Hodgkin's lymphoma, leukemia, and multiple myeloma.. The vaccine is recommended for (1) persons 65 years or older; (2) persons 2 to 64 years old with chronic illnesses such as cardiovascular disease, chronic pulmonary disease (not asthma), diabetes mellitus, alcoholism, chronic liver disease, or cerebrospinal fluid leaks; (3) persons 2 to 64 years old with functional or anatomic asplenia; and (4) persons 2 to 64 years old living in special environments or social settings (Alaskan natives, certain Native American populations, residents of long-term care facilities).

Although the effectiveness of the vaccine is less in these subgroups, the following immunocompromised patients 2 years or older should also be immunized: (1) persons with HIV infection, leukemia, lymphoma, or Hodgkin's disease and (2) those with multiple myeloma, generalized malignancy,

chronic renal failure, nephrotic syndrome, or organ or bone marrow transplants and individuals being treated with immunosuppressive chemotherapy, including steroids.

The lack of an anamnestic response with polysaccharide vaccines means that antibody levels decrease over time, and revaccination is required. Although the exact timing is unclear, most experts suggest revaccination at 5 years. For immunocompetent persons 65 years or older, a second dose is suggested if the patient was given the first vaccine 5 years earlier at an age younger than 65 years. For persons 2 to 64 years of age with asplenia, a single revaccination is suggested 5 years after the initial dose if the patient is older than 10 years. However, if the patient is younger than 10 years, revaccination should be given 3 years after the first dose. For immunocompromised patients, revaccination should be given 5 years after the first dose if the patient is older than 10 years and 3 years after the first dose if the patient is younger than 10 years.

Conjugated Vaccine

This vaccine contains capsular polysaccharide from 13 of the most frequent pneumococcal pathogens affecting children linked to an immunogenic protein, thereby producing T cell–dependent antigens, which results in long-term immunologic memory. A heptavalent vaccine was effective in reducing the risk of pneumonia in young children. Use of a 7-valent vaccine resulted in an overall decrease in the prevalence of antimicrobial resistant pneumococci and in the incidence of invasive pneumococcal disease in both children and adults and with replacement with nonvaccine serotypes such as 19A and 35B. As a result, in 2010, the U.S. Food and Drug Administration licensed a new 13-valent pneumococcal conjugate vaccine to replace the 7-valent vaccine. Overall data demonstrate a superior antibody response in adults vaccinated with the 13-valent pneumococcal conjugate vaccine compared with the pneumococcal polysaccharide vaccine, whether or not they were previously vaccinated with the latter.[9] This vaccine is recommended for children, elderly adults, and younger immunocompromised patients.[10]

TREATMENT

A number of prediction rules have been developed to help determine the appropriate site of care. This step, together with optimal antimicrobial therapy and supportive measures, can help to maximize chances for a satisfactory outcome.[11]

Empirical therapy is usually used for CAP. If pneumococcal infection can be documented, however, antibiotic therapy can be targeted against this specific pathogen.

Treatment Regimens

Directed Therapy Against Known *S. pneumoniae*

S. pneumoniae can be treated with a number of antimicrobials, including various β-lactams, macrolides, and selected fluoroquinolones (Table 289-3). Resistance has been described for virtually all of these agents, and the prevalence of resistant serotypes has risen since the introduction of the 13-valent conjugate vaccine.[12] For nonmeningeal infections such as pneumonia, susceptibility is now defined by a penicillin MIC of 2 μg/mL or less, intermediate as an MIC of 4 μg/mL, and resistant as an MIC of more than 8 μg/mL. Multidrug-resistant pathogens, which are resistant to three or more antimicrobial agents with different mechanisms of action, have been seen in a number of countries. Risk factors for drug-resistant pneumococcal infection include recent antimicrobial therapy, age younger than 2 years or older than 65 years, attendance at a daycare center, recent hospitalization, and HIV infection.

If a good-quality Gram stain of sputum reveals sheets of PMNs with lancet-shaped gram-positive diplococci as the only organism, if the patient has no risk factors for infection with resistant *S. pneumoniae,* and if the patient is not living in an area endemic for penicillin-resistant *S. pneumoniae,* it is reasonable to initiate parenteral treatment with penicillin G, 2.4 million U/day. For outpatients, oral therapy is usually given in the form of amoxicillin, 500 mg three times daily. For infection with *S. pneumoniae* with penicillin MICs of up to 1 μg/mL, penicillin is still an appropriate agent. For strains with penicillin MICs of 2 to 4 μg/mL, data regarding efficacy are conflicting, and higher doses may be better. If the patient is allergic to penicillin, a macrolide such as azithromycin (500 mg on day 1; then 250 mg/day) or clarithromycin (500 mg twice daily) may be used. Monotherapy with a macrolide should not be used in areas where there is a high prevalence of macrolide-resistant pneumococci.

Five days is the minimal recommended duration of treatment of CAP that is not complicated, severe, or associated with bacteremia.

For patients who are hospitalized because of CAP, higher doses of parenteral antibiotics are generally used, including penicillin in the range of 12 million U (2-3 million every 4 hours) or ampicillin, 4 g/day (1 g every 6 hours). Third-generation cephalosporins such as ceftriaxone (1-2 g every 24 hours) and cefotaxime (1-2 g every 8 hours) are other alternatives.

TABLE 289-3 ANTIMICROBIAL DOSES AND FREQUENCY OF ADMINISTRATION

ANTIMICROBIAL	DOSE AND ROUTE	FREQUENCY
MACROLIDES		
Azithromycin	500 mg × 1; then 250 mg PO	q24h
Clarithromycin	500 mg PO	q12h
Erythromycin	500 mg PO	q6h
TETRACYCLINE		
Doxycycline	100 mg PO	q12h
FLUOROQUINOLONES		
Moxifloxacin	400 mg PO or IV	q24h
Gemifloxacin	320 mg PO	q24h
Levofloxacin	750 mg PO or IV	q24h
β-LACTAMS		
Amoxicillin	1 g PO	q8h
Amoxicillin–clavulanate	2 g PO	q12h
Ampicillin–sulbactam	2 g IV	q6h
Cefepime	1-2 g	q12h
Cefixime	400 mg PO	q12h
Cefotaxime	1-2 g IV	q8h
Ceftriaxone	1-2 g IV	q24h
Cefpodoxime	100-200 mg	q12h
Cefuroxime	500 mg PO	q12h
Ertapenem	1 g IV	q24h
Imipenem	500 mg IV	q6h
Meropenem	1 g IV	q8h
Piperacillin–tazobactam	3.375 g IV	q6h
MISCELLANEOUS		
Linezolid	600 mg PO or IV	q12h
Vancomycin	0.75-1 g IV	q12h

IV = intravenous; PO = oral; q = every. Five days is the minimal recommended duration of treatment of community-acquired pneumonia that is not complicated, severe, or associated bacteremia.

The patient can be switched to an oral regimen when cough and shortness of breath are improving, the white blood cell count is normalizing, and oral intake and gastrointestinal tract absorption are adequate. Febrile patients are frequently treated outside the hospital, so absence of a fever is not a prerequisite for switching to an oral regimen.

Some studies have suggested that initial combination antimicrobial treatment of bacteremic pneumococcal pneumonia that includes a macrolide is associated with lower mortality rates possibly because of an immunomodulatory effect of the macrolides.

Empirical Treatment

This is discussed in the chapter dealing with CAP (Chapter 97). The body of evidence supporting the positive effects of guidelines on outcomes in CAP patients is compelling, particularly for those ill enough to require hospitalization.[13]

PROGNOSIS

In an otherwise well, relatively young patient with no comorbid conditions and with mild to moderate infection, the elevated temperature and white blood cell count usually resolve by days 2 to 4 and 4, respectively. The patient looks and feels better within a few days, but it is important to keep in mind that even in patients younger than 50 years, only 60% of cases will have resolved radiologically by 1 month. In patients older than 50 years or those with more severe infection or COPD, only 25% may clear radiographically by 1 month.

A patient who fails to respond or deteriorates after initial treatment must be carefully reassessed with a detailed review of the history and treatment course plus appropriate radiographic studies and cultures.[14] If the diagnosis is incorrect, other infectious causes of pneumonia, such as *Haemophilus influenzae* (Chapter 300) or the atypical agents (Chapter 97), must be considered. Noninfectious illnesses must also be considered; these include heart failure (Chapter 58), pulmonary embolism (Chapter 98), pulmonary neoplasm (Chapter 191), radiation injury (Chapter 20), drug reaction (Chapter 254), and inflammatory lung disease, to name a few. If the original diagnosis was correct, metastatic infection, lung abscess (Chapter 90) or empyema, and unsuspected drug resistance must be considered. Drug factors such as errors

in selection, dose, or route of administration are possible explanations, especially in patients who receive oral medication.

There also appears to be an increased risk of cardiovascular events after certain respiratory infections, including pneumococcal pneumonia. This may be attributable to an enhanced inflammatory state and its effects on coronary arteries.[15]

REVIEW QUESTIONS

1. Pneumonia can be caused by a variety of mechanisms. The pathobiology of pneumococcal pneumonia initially depends on

A. colonization and inhalation of the organisms.
B. inhalation of the organisms.
C. colonization and aspiration of the organisms.
D. aspiration of the organisms.
E. spread from adjacent pleural spaces.

Answer: C The pathobiology of pneumococcal pneumonia initially depends on colonization and aspiration of the organisms. The "ecologic niche" of *Streptococcus pneumoniae* is the nasopharynx, and 20% of even healthy adults may carry the organism. Carrier rates are highest in late fall to early spring. Pathogens such as bacteria, viruses, and fungi can gain access to the lower respiratory tract and the distal airways by a number of mechanisms, including inhalation, aspiration (both gross and silent), spread from adjacent sites, and rarely by direct instillation as may occur with penetrating trauma. After colonization is established, the most common means of gaining access to the lower airways is by aspiration of the pneumococcus. This can occur even during deep sleep in normal individuals. One does not have to have a seizure or be drunk and vomiting for this to happen. Pneumococcal virulence factors can influence both the colonization process and any subsequent bacterial invasion that may occur.

2. Mr. S is a 46-year-old man in excellent general health. He has no known medical problems and is a nonsmoker, a social drinker, and an avid jogger. He noted the onset of a cough productive of purulent sputum with occasional traces of blood, some right-sided pleuritic type chest pain, and shortness of breath even while walking over the past several days. He has also experienced some chills and sweats in the last day or 2. On examination, he is febrile, his respiratory rate is 24 breaths/min, and his chest radiograph shows a right middle lobe lobar consolidation without an effusion. His white blood cell count is 16,000 with a left shift, and a Gram stain of sputum showed classic gram-positive lancet-shaped diplococci with numerous polymorphonuclear leukocytes in the field. No other organisms were noted. A decision is made to admit him to the hospital. He has no drug allergies. Treatment should be started with

A. a macrolide.
B. penicillin.
C. a fluoroquinolone.
D. ceftriaxone.
E. macrolide plus ceftriaxone.

Answer: B Treatment should start with penicillin. Unfortunately, the information gained from the history, physical examination, and chest radiograph are not necessarily definitively helpful in accurately predicting the etiologic pathogen. In this case, it certainly sounds as though a diagnosis of pneumonia is correct (if pulmonary embolism has been ruled out), there are no obvious risk factors for pathogens such as *Legionella* spp., and gram-negative rods would be quite unlikely. The finding of gram-positive cocci consistent with the pneumococcus and the absence of any other pathogen seen on Gram stain argues for a pneumococcal etiology. Given his overall presentation and the results obtained so far, it would be reasonable to begin treatment with a penicillin. He does not have risk factors for drug-resistant *Streptococcus pneumoniae* (DRSP), such as recent antibiotic treatment, age older than 65 years, HIV infection, or recent hospitalization, and he does not live in an area where DRSP is endemic.

Having said this, some would argue that overall, it might be safer to initiate treatment with a macrolide and a nonpseudomonal third-generation cephalosporin or a fluoroquinolone alone for a patient requiring admission to the hospital, but not the intensive care unit. As soon as specific culture data become available (e.g., blood or sputum), treatment could be changed to penicillin. Given the specifics of this case, however, it certainly is reasonable to initiate treatment with penicillin alone.

Mandell LA, Wunderlink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007; 44(Suppl):S27-S72.

3. A 20-year-old ,am who is in excellent health with no prior medical illnesses is involved in an accident while riding his motorcycle. He fractures his left femur and requires open reduction and internal fixation plus a splenectomy for his ruptured spleen. What would be the best way to prevent pneumococcal infection in this young man for the future?

A. Daily low doses of penicillin orally
B. Monthly intramuscular benzathine penicillin
C. Pneumococcal polysaccharide vaccine
D. Pneumococcal conjugate vaccine
E. Pneumococcal conjugate vaccine followed by pneumococcal polysaccharide vaccine

Answer: E Pneumococcal conjugate vaccine followed by pneumococcal polysaccharide vaccine would be used to prevent pneumococcal infection. There are currently two types of pneumococcal vaccines, a polysaccharide vaccine (PSV) and a protein conjugate vaccine (PCV). A vaccine would be the preferred method of protection by inducing immunity as opposed to relying on the use of prophylactic antibiotics. The problem is that in the case of a PSV, those who are immunosuppressed because of illness such as myeloma or lymphoma, immunosuppressing drugs, or transplantation are less likely to benefit from it. This includes patients who are either functionally or anatomically asplenic. For this 20-year-old accident victim who has never been given a pneumococcal vaccine before and is now at risk of pneumococcal infection because of his asplenic condition, he should be given a single dose of PCV13 followed at least 2 months later by a dose of PSV.

Musher D. How effective is vaccination in preventing pneumococcal disease? *Infect Dis Clin North Am*. 2013;27:229-241.

4. To diagnose pneumonia in general and pneumococcal pneumonia specifically, the best test is

A. bronchoscopy.
B. chest radiography.
C. urinary antigen.
D. biomarkers.
E. none of the above.

Answer: E Unfortunately, there is no one specific test that is definitively diagnostic of pneumonia and pneumococcal pneumonia. The diagnosis is made by taking a careful history, doing a physical examination, and then supplementing this with additional tests depending on the severity of illness and whether or not admission to the hospital is being considered. Chest radiography is usually the most helpful because if the results are negative, it usually tends to rule out pneumonia. The constellation of findings obtained from the history, physical examination, and radiography can certainly suggest pneumonia versus some other process such as pulmonary embolism, but they are not foolproof, and the pattern of infiltrate on radiographs does not signify a particular pathogen. Initial treatment can be started with broader spectrum agents and then modified depending on any additional information that becomes available (e.g., cultures of blood or sputum, urinary antigen test results).

5. Pneumococcal resistance to penicillin is the result of

A. a change in penicillin-binding proteins (PBPs).
B. an antibiotic pump mechanism.
C. an alternative metabolic pathway for the bacteria.
D. mutations in the *gyrA* or *parC* genes.
E. impaired access to the bacteria because of porin closure.

Answer: A Bacteria can protect themselves from antibiotics in a number of ways. To be effective, the antibiotic must be able to reach the target site within the pathogen, but this can be prevented by several mechanisms. These include:

1. An enzyme that inactivates the antibiotic
2. Decreased access to the bacterium via porin channels
3. Altered target sites so the antibiotic cannot recognize the target
4. Alternate metabolic pathways for the bacteria
5. Efflux pumps

In the case of β-lactam drugs such as the penicillins and the pneumococcus, the target sites are the penicillin-binding proteins, which are trans and carboxypeptidase enzymes involving bacterial cell wall synthesis. As the affinity of the drug for the target site decreases, it becomes harder for the drug to interact with the target and to induce any damage in the bacterial pathogen.

290 NONPNEUMOCOCCAL STREPTOCOCCAL INFECTIONS AND RHEUMATIC FEVER

DONALD E. LOW

THE PATHOGENS

The *Streptococcus* genus contains a number of species that inhabit a broad range of hosts, including humans and domesticated animals, where they often colonize as part of the normal flora and cause infection. They are gram-positive cocci that grow in chains. The two most useful methods of classifying streptococci are by the type of hemolytic reaction displayed on blood agar on which they are grown and the serologic reactivity of the cell wall polysaccharide antigens as originally described by Rebecca Lancefield (Table 290-1). On blood agar plates, streptococci may cause complete (β), incomplete (α), or no (γ) hemolysis. Hemolytic streptococci from humans can be classified into Lancefield groups A, B, C, F, G, and L on the basis of carbohydrate antigens of the cell wall and can be subdivided into large- and small-colony (<0.5 mm in diameter) formers. The β-hemolytic group A and group B streptococci (GBS) are considered the major pathogenic β-hemolytic streptococci. The β-hemolytic large-colony–forming species, *Streptococcus dysgalactiae* subspecies *equisimilis,* may possess Lancefield group A, C, G, or L antigens. The small-colony–forming β-hemolytic strains with Lancefield group A, C, F, or G or no group antigens belong to the *anginosus* (or previously termed *Streptococcus milleri*) group. Members of the *anginosus* group (*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*) are considered part of the viridans group streptococci (VGS), most of which display α-hemolytic or nonhemolytic reactions.

TABLE 290-1 IDENTIFICATION OF THE β-HEMOLYTIC STREPTOCOCCI

SPECIES	LANCEFIELD GROUP	COLONY SIZE	ORIGIN
S. pyogenes	A	Large	Human
S. agalactiae	B	Large	Human, bovine
S. dysgalactiae subsp. *equisimilis*	A, C, G, L	Large	Human, animals
S. equi subsp. *zooepidemicus*	C	Large	Animals, human
S. canis	G	Large	Dog, human
S. anginosus (group)*	A, C, G, F, none	Small	Human

*Group carbohydrate antigen.

STREPTOCOCCUS PYOGENES (GROUP A STREPTOCOCCUS)

The most clinically significant of the streptococcal human pathogens are *Streptococcus pyogenes* (also referred to as group A streptococci [GAS]), which contain the Lancefield group A antigen on their cell surface. GAS causes primarily infections of the upper respiratory tract and the skin. It is also responsible for a toxic shock–like syndrome; necrotizing fasciitis; and delayed nonsuppurative sequelae, including acute rheumatic fever and poststreptococcal glomerulonephritis. The major virulence factor of the organism is the M protein. This protein, a stable dimer, is anchored to the cell membrane and traverses and penetrates the cell wall. Whereas the proximal portion of the molecule is highly conserved among GAS, the distal portions contain type-specific epitopes localized on the tips that protrude from the cell surface. This variation in the distal region of the M proteins provides the basis of widely used epidemiologic typing schemes that use serologic methods (M type) or nucleotide sequence analysis of the M protein gene (*emm* type). There are more than 150 distinct *emm* and *emm*-like genes recognized. Epidemiologic studies have revealed that certain disease manifestations are commonly associated with particular M types, such as M1 and M3 types, which are associated with the most severe invasive manifestations such as toxic shock syndrome and necrotizing fasciitis. Humans are the natural host, and there is no animal or environmental reservoir. The throat and skin of the human host are the principal reservoirs for GAS. GAS is transmitted primarily person to person by either contact or droplet transmission.

EPIDEMIOLOGY

All GAS infections have the highest incidence in children younger than 10 years. The asymptomatic prevalence is also higher (15%-20%) in children than in adults. Age is not the only factor; crowded conditions in temperate climates during the winter months are also associated with epidemics of pharyngitis in school children as well as in military recruits. The peak incidence for streptococcal pharyngitis and impetigo varies with season and locale. In many temperate regions of the world, the incidence of pharyngitis peaks in winter; impetigo, although less common, peaks during the summer months. In contrast, for many tropical host populations, impetigo is hyperendemic year round, but throat infection, whether pharyngitis or asymptomatic carriage, ranges from very low to moderate levels.

CLINICAL MANIFESTATIONS

Respiratory Tract Infections

Pharyngitis

Group A streptococci are a major cause of pharyngitis and remains the only agent of this syndrome requiring etiologic diagnosis and treatment. The burden and economic costs of GAS pharyngitis are great. It has been estimated that in the United States alone, more than 7 million cases of acute pharyngitis are diagnosed by pediatricians annually. *S. pyogenes* is the cause in only 15% to 30% of them, but antibiotics are prescribed in 55% to 75% of the cases. Although a major consequence of GAS pharyngitis, acute rheumatic fever (see later), is much less common now than in the past, it is still a considerable problem in the developing world. The World Health Organization (WHO) estimates that there are about half a million cases of acute rheumatic fever worldwide annually. On clinical grounds, streptococcal pharyngitis (Fig. 290-1) is strongly suggested by the presence of fever, tonsillar exudate, tender enlarged anterior cervical lymph nodes, and absence of cough.

Because these findings are nonspecific and are also commonly found in cases of viral origin, however, even experienced physicians may accurately diagnose streptococcal pharyngitis based on the clinical findings alone in no more than 75% of the cases. Treatment of suspected GAS pharyngitis at the time of initial clinical evaluation has only a modest effect on relieving acute symptoms and perhaps on preventing suppurative complications. However, antibacterial treatment may be delayed for several days and still achieve the goal of preventing rheumatic fever and spread of disease. Prospective studies to compare the impact of various pharyngitis management strategies on clinically relevant outcomes have been recommended. A particular focus of recent guidelines has been to reduce overall use of antibiotics for treatment of pharyngitis in both children and adults in order to limit antibiotic resistance (Table 290-2).

FIGURE 290-1. Acute streptococcal pharyngitis. Pus is present in the tonsillar crypts, and some palatal petechiae are seen. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003).

TABLE 290-2 SCORE FOR USE IN BOTH CHILDREN AND ADULTS WITH SORE THROAT TO ESTIMATE PROBABILITY OF POSITIVE CULTURE AND GUIDE MANAGEMENT APPROACH

DIAGNOSTIC CRITERIA		*MANAGEMENT*		
FINDINGS	**POINTS**	**SCORE**	**RISK FOR STREPTOCOCCAL INFECTION (%)**	**RECOMMENDATION**
Temperature >38°C	+1	≤0	1-2.5	No culture or antibiotics
Absence of cough	+1	1	5-10	
Swollen, tender anterior cervical nodes	+1	2	11-17	Culture: antibiotics only if culture positive
Tonsillar swelling or exudate	+1	3	18-35	
Age		≥4		Antibiotics
3-14 yr	+1			
>44 yr	−1			

Adapted from McIsaac WJ, Kellner JD, Aufricht P, et al. Empirical validation of guidelines for the management of pharyngitis in children and adults. *JAMA*. 2004;291:1587-1595.

Throat culture is the conventional method for establishing the diagnosis of GAS pharyngitis. In an untreated patient with GAS pharyngitis, results of a properly obtained throat culture (by vigorous swabbing of both tonsils and posterior pharynx) are almost always positive; however, a positive throat culture may reflect chronic colonization by GAS, and the acute illness may be caused by another agent. Quantitation of GAS from the throat swab culture cannot be used to differentiate carriage from infection because sparse growth may be associated with true infection. A negative throat culture result permits the physician to withhold antibiotic therapy from most patients with sore throats.

Many GAS antigen detection tests are available commercially. These tests vary in method. Most of these tests have a high degree of specificity, but their sensitivity in clinical practice can be unacceptably low. Therefore, treatment is indicated for patients with acute pharyngitis who have a positive rapid antigen detection test result.

Otitis Media and Rhinosinusitis

During the past several decades, a number of studies have reported isolation of GAS from 2% to 5% of cultures of middle ear fluid specimens obtained from children with acute otitis media. Thus, in contrast to the very striking role of GAS as the major bacterial agent of acute pharyngitis, GAS has been fairly consistently the fourth most predominant pathogen causing pediatric acute otitis media, after *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* GAS acute otitis media is associated with increased risk for development of mastoiditis. Although the risk is small (<1%), it is much greater than with acute otitis media caused by *S. pneumoniae, H. influenzae,* or *M. catarrhalis.* GAS is the etiologic agent of acute bacterial rhinosinusitis in 2% to 7% of cases.

Pneumonia

The occurrence of pneumonia has increased with the resurgence of invasive GAS disease during the past several decades, with 10% of patients with invasive GAS disease presenting with pneumonia. Small outbreaks of GAS pneumonia have been described in chronic care facilities and within families, as well as sporadic cases occurring in the community. GAS pneumonia now occurs with a frequency similar to that of other well-recognized causes, such as *Staphylococcus aureus* or *Klebsiella pneumoniae*. A Canadian population-based surveillance program of invasive GAS disease confirmed that GAS pneumonia is a severe illness of sudden onset frequently associated with local and systemic complications, particularly empyema (19%), toxic shock (32%), and death (38%).

Skin and Soft Tissue Infections

Scarlet Fever

Scarlet fever is a diffuse erythematous eruption that generally occurs in association with pharyngitis, most commonly in children 5 to 15 years of age. The development of the scarlet fever rash requires prior exposure to *S. pyogenes* and occurs as a result of delayed-type skin reactivity to pyrogenic exotoxin (erythrogenic toxin, usually types A, B, or C) produced by the organism. The rash of scarlet fever is a diffuse erythema that blanches with pressure, with numerous small (1-2 mm) papular elevations, giving a sandpaper quality to the skin. It usually starts on the head and neck and is accompanied by circumoral pallor and a strawberry tongue. Subsequently, the rash expands rapidly to cover the trunk followed by the extremities and then ultimately desquamates; the palms and soles are usually spared. The rash is most marked in the skinfolds of the inguinal, axillary, antecubital, and abdominal areas and about pressure points. It often exhibits a linear petechial character in the antecubital fossae and axillary folds, known as Pastia's lines.

Erysipelas

Erysipelas is an acute, superficial, non-necrotizing dermal or hypodermal infection that is mainly caused by streptococci. The definitive diagnosis is based on clinical findings that usually include a sharply demarcated shiny erythematosus plaque associated with pain, swelling, and fever (see Fig. 441-1). Erysipelas affects predominantly adult patients in the sixth or seventh decade of life and is located on the lower limb in more than 80% of cases. A female predominance exists, except in young patients. Risk factors include disruption of the cutaneous barrier (leg ulcer, wound, fissured toe-web intertrigo, and pressure ulcer), lymphedema, chronic edema, or local surgical operations (lymph node dissection, saphenectomy). Toe-web intertrigo appears to be a major portal of entry whether or not due to dermatophytes. Erysipelas is less commonly caused by group B, C, or G streptococci and rarely by staphylococci. Bulla formation is considered as a relatively severe but frequent local complication of the disease. Although most cases of erysipelas are caused by β-hemolytic streptococci, many other bacteria can produce non-necrotizing cellulitis, which can often occur in particular circumstances, such as *Pasteurella multocida* after cat or dog bites, *Aeromonas hydrophila* after immersion in fresh water, *Vibrio* spp. after saltwater exposure, or *H. influenzae* in periorbital cellulitis in children. Recurrence is the main complication of erysipelas; it occurs in about 20% of cases. Measures to reduce recurrences of erysipelas include treatment of any predisposing factor, such as toe-web intertrigo or wound, and reducing any underlying edema. If frequent infections occur despite such measures, prophylactic antibiotics may be warranted.

Impetigo

Impetigo is a highly contagious infection of the superficial epidermis that most often affects children 2 to 5 years of age (see Fig. 441-1), although it can occur in any age group. Impetigo is classified as bullous or nonbullous impetigo; the latter is the most common form. Bullous impetigo simply means that the skin eruption is characterized by bullae (blisters). The infection usually heals without scarring, even without treatment. *S. aureus* is the most important causative organism, especially in bullous impetigo. GAS causes fewer cases, either alone or in combination with *S. aureus,* and is more often found in nonbullous impetigo. The diagnosis usually is made clinically

and can be confirmed by Gram stain and culture, although this is not usually necessary. Culture may be useful to identify patients with nephritogenic strains of GAS during outbreaks of poststreptococcal glomerulonephritis. Impetigo usually is transmitted through direct contact. Patients can further spread the infection to themselves or others after excoriating an infected area. Infections often spread rapidly through schools and daycare centers.

The Cochrane Collaboration reviewed interventions for impetigo. There was little evidence found for the use of disinfecting measures, such as chlorhexidine. There was good evidence that topical mupirocin and topical fusidic acid are equally or more effective than oral antibiotics for people with limited disease. Fusidic acid and mupirocin were of similar efficacy. It was found to be unclear whether oral antibiotics are superior to topical antibiotics for people with extensive impetigo.

Cellulitis

Bacterial cellulitis refers to a diffuse, spreading skin infection. Associated regional lymphadenopathy and lymphatic streaking are variable, and local complications (abscesses, necrosis) are more frequent than in erysipelas. Petechiae and ecchymoses with frequent bullae may develop in inflamed skin, resulting in hemorrhagic cellulitis. *Cellulitis* usually refers to a more deeply situated skin infection than erysipelas. However, the distinction between these entities is not clear-cut, and the two conditions share the typical clinical features, including sudden onset, usually with a high fever, and the tendency to recur. GAS has been considered the main causative agent of cellulitis, although groups B, C, and G streptococcus and *S. aureus* can also be a cause.

The predominant infection site for cellulitis is on the lower extremities. Lymphedema and disruption of the cutaneous barrier, which serves as a site of entry for the pathogens, are risk factors for infections. About 20% to 30% of patients have a recurrence during a 3-year follow-up period. Blood cultures are positive for β-hemolytic streptococci in fewer than 5% of cases.

Invasive Group A Streptococcus Disease

Invasive disease is defined as the isolation of GAS from an otherwise sterile site. GAS is capable of producing a variety of bacterial exotoxins, including a family of toxins known as superantigens (SAg). Severe invasive GAS disease includes streptococcal toxic shock syndrome and necrotizing fasciitis. *S. anginosus* plays a significant role as a reservoir of antimicrobial resistance genes, transferring different resistance traits to more pathogenic organisms such as *S. pneumoniae* and *S. pyogenes*. Both manifestations are associated with high morbidity and mortality.

Toxic Shock Syndrome

Streptococcal *toxic shock syndrome* is defined as hypotension accompanied by multiple organ failure, indicated by two of the following signs: renal impairment, coagulopathy, liver involvement, acute respiratory distress syndrome, a generalized rash, and soft tissue necrosis. In contrast to the other major form of toxic shock syndrome that is caused by toxin-producing *S. aureus* (Chapter 288), in which blood cultures are positive in fewer than 5% of cases, most (60%) patients with streptococcal toxic shock syndrome have positive blood cultures. In the late 1980s, patients with severe GAS infections were characterized and reported. Most patients were younger than 50 years old and otherwise healthy. All had invasive GAS infections characterized by signs that included shock; multiorgan system involvement; and rapidly progressive, destructive soft tissue infection (necrotizing fasciitis). The case-fatality rate was 30% even though most patients received appropriate antimicrobial therapy. M-types 1 and 3 were the most common type, and 80% of the isolates produced pyrogenic exotoxin A.

A focus of infection in staphylococcal toxic shock syndrome, if present at all, tends to be superficial, a complication of surgical wounds or burns or a foreign body (e.g., tampons). Streptococcal toxic shock syndrome can originate from an unknown focus or from a deep-seated soft tissue infection (e.g., necrotizing fasciitis, myositis, and cellulitis). Mortality rates are much higher with streptococcal than staphylococcal toxic shock, reported at up to 80% when associated with myositis.[1]

Necrotizing Fasciitis

Necrotizing fasciitis is defined by infection of the subcutaneous tissue and fascia that often results in necrosis with relative sparing of the underlying muscle. Histopathology demonstrates both necrosis of superficial fascia and polymorphonuclear infiltrates as well as edema of the reticular dermis, subcutaneous fat, and superficial fascia. GAS organisms in this disorder secrete proteases that disrupt host tissue and exotoxins that can cause local tissue injury or systemic manifestations as the result of an excessive and inappropriate inflammatory response, leading to a life-threatening infection.

In the early stages of necrotizing fasciitis caused by GAS, the clinical findings can be nondescript, with as many as one third of patients initially being given a diagnosis other than necrotizing fasciitis. The only feature that might alert the clinician is a complaint of pain out of proportion to that expected on examination, even for patients who report previous trauma to the area. Necrotizing fasciitis has been found to occur more frequently during the winter months and in older men. More then half of patients give a history of an antecedent skin lesion or injury at the site of infection. In adults, most cases occur in persons with at least one chronic underlying illness, and in children, the most frequent underlying illness is an infection caused by varicella-zoster virus (Chapter 375). The most common primary site of infection is the lower extremity followed by the upper extremity, trunk, and groin or perineum.

Streptococcal exotoxins, which are superantigens, have been recognized as central mediators of the systemic effects associated with severe GAS infections.[2] Superantigens interact with antigen-presenting cells and T cells to induce T-cell proliferation and massive cytokine production, which leads to fever, rash, capillary leak, and subsequent hypotension, the major symptoms of severe GAS disease (Fig. 290-2). Twelve distinct superantigens produced by GAS have been identified, and many GAS strains harbor genes encoding four to six different superantigens. The magnitude of the inflammatory response is determined by the patient's human leukocyte antigen class II type. Another important risk factor for invasive GAS infections is lack of opsonic anti-M1 protein and neutralizing antisuperantigen antibodies.

Treatment of either streptococcal toxic shock or necrotizing fasciitis has not been critically studied because of the low incidence of disease and difficulty in patient recruitment for clinical trials. The dogma for the management GAS necrotizing fasciitis is that when necrotizing fasciitis is suspected, early surgical debridement is warranted. Despite the lack of clinical or scientific evidence to support this approach, it is widely endorsed in standard textbooks and treatment guidelines. The published studies are all based on retrospective chart review of patients with necrotizing fasciitis from multiple etiologies, including mixed aerobic and anaerobic organisms.

The finding that lack of protective antibodies against streptococcal M protein and superantigens correlates with risk for developing invasive streptococcal diseases, highlights the importance of antibodies in protection against these infections and suggests that intravenous immunoglobulin (IVIG) might be a potential adjunctive therapy. IVIG exhibits high polyspecificity generated by antibodies pooled from several thousands of donors and has been shown to contain broad-spectrum antibodies against streptococcal superantigens and M proteins. In addition, IVIG has a general anti-inflammatory effect that is largely attributable to Fc receptor–mediated mechanisms. The documentation of clinical efficacy of IVIG includes several case reports and two observational cohort studies, one case-control study, and one multicenter placebo-controlled trial.

Nonsuppurative Sequelae of Streptococcal Infections

Acute Rheumatic Fever

Acute rheumatic fever is a delayed, nonsuppurative sequela of a pharyngeal infection with the GAS. After the initial pharyngitis, a latent period of 2 to 3 weeks occurs before the first signs or symptoms of acute rheumatic fever appear. The disease presents with various manifestations that may include arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum. In developing areas of the world, acute rheumatic fever and rheumatic heart disease are estimated to affect nearly 20 million people and are the leading causes of cardiovascular death during the first five decades of life. The story is much different in developed countries. In the latter half of the 20th century, rheumatic fever receded as an important health problem in almost all wealthy countries. Today, most physicians in these countries are unlikely ever to see a case of acute rheumatic fever. Most of the reduction is attributable to improved living conditions, which have resulted in less overcrowding and better hygiene, with consequent reductions in transmission of group A streptococci. In other words, rheumatic fever is now a disease of poverty.

Worldwide, at least 350,000 deaths are attributable to rheumatic fever or rheumatic heart disease each year; most occur in developing countries and among indigenous groups.[3] The observation in some studies that only a few M serotypes (types 3, 5, 6, 14, 18, 19, 24, and 29) were implicated in outbreaks of rheumatic fever suggested a particular "rheumatogenic" potential of certain strains of GAS. The decrease in the incidence of acute rheumatic fever in developed countries with the replacement of rheumatogenic types by

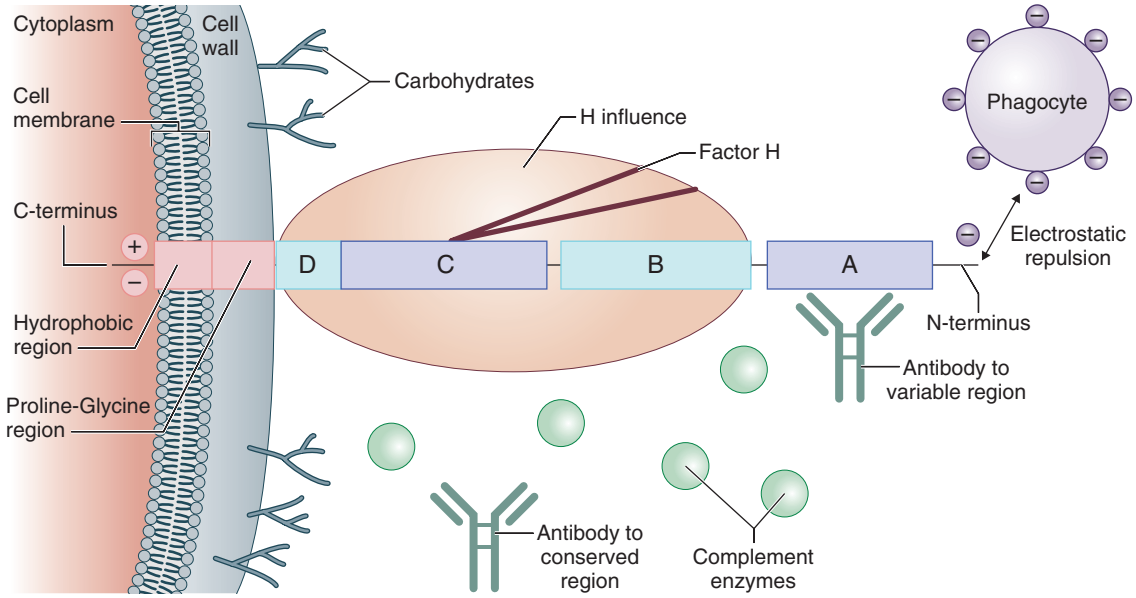

FIGURE 290-2. Thwarting the immune system is the primary job of the M protein. Negative charges at the N-terminus may repel phagocytic white blood cells. By binding with factor H—a regulatory protein produced by the human host—the M protein protects its most conserved regions from antibodies and complement enzymes. Only antibodies against the antigenically shifting hypervariable region can clear an established streptococcal infection from the host's body. (Reprinted from Fischetti VA. Streptococcal M protein. *Sci Am*. 1991;264(6):58-65; with permission from Mr. Tomoyuki Narashima from Tane+1 LLC for reproduction of illustration).

nonrheumatogenic types is not solely responsible for the decrease in acute rheumatic fever, and the issue of potential rheumatogenic strains remains unresolved. A streptococcal strain capable of causing a well-documented pharyngitis almost always is potentially capable of causing rheumatic fever. The lack of specific rheumatogenic strains also can explains the relatively high risk for recurrent disease with new streptococcal infections, in contrast to poststreptococcal glomerulonephritis, in which only a few "nephritogenic" strains appear to be capable of inducing the disease (e.g., type 12 with pharyngitis and type 49 with impetigo), and recurrent disease is uncommon.

Modified Jones criteria were first published in 1944 to be able to define persons with acute rheumatic fever. They have been periodically revised by the American Heart Association in collaboration with other groups.[4] According to revised Jones criteria, the diagnosis of rheumatic fever can be made when two of the major criteria or one major criterion plus two minor criteria are present along with evidence of streptococcal infection. Exceptions are chorea and indolent carditis, each of which by itself can indicate rheumatic fever. Major criteria include the following:

1. Migratory polyarthritis: a temporary migrating inflammation of the large joints, usually starting in the legs and migrating upward
2. Carditis: inflammation of the heart muscle, which can manifest as congestive heart failure, pericarditis with a rub, or a new heart murmur
3. Subcutaneous nodules: painless, firm collections of collagen fibers over bones or tendons, commonly appearing on the back of the wrist, the outside elbow, and the front of the knees
4. Erythema marginatum: a long-lasting rash that begins on the trunk or arms as macules and spreads outward to form a snakelike ring while clearing in the middle. This rash never starts on the face, and it is made worse with heat.
5. Sydenham's chorea (St. Vitus' dance): a characteristic series of rapid movements of the face and arms without purpose, generally occurring late in the disease

Minor criteria include the following:

1. Fever
2. Arthralgia: joint pain without swelling
3. Raised erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)
4. Leukocytosis
5. Electrocardiogram showing features of heart block, such as a prolonged PR interval
6. Supporting evidence of streptococcal infection: elevated or rising antistreptolysin O titer or anti-DNAse B
7. Previous episode of rheumatic fever or inactive heart disease

The pathogenic mechanisms that lead to the development of acute rheumatic fever remain incompletely understood. Clearly, streptococcal pharyngeal infection is required, and genetic susceptibility may be present. On the other hand, evidence is sparse that toxins produced by the streptococcus are important. Molecular mimicry is thought to play an important role in the initiation of the tissue injury. As a result of molecular mimicry, antibodies directed against GAS antigens cross-react with host antigens. In addition to the role of antibody, observations suggest a role for cellular immunity in molecular mimicry.

Primary prevention of acute rheumatic fever is accomplished by proper identification and adequate antibiotic treatment of GAS tonsillopharyngitis.[5,6] The diagnosis of GAS pharyngitis is best accomplished by combining clinical judgment with diagnostic test results, the criterion standard of which is the throat culture. Penicillin (either oral penicillin V or injectable benzathine penicillin) is the treatment of choice because it is cost effective, has a narrow spectrum of activity, and has long-standing proven efficacy. In addition, GAS resistant to penicillin has not been documented. For penicillin-allergic individuals, acceptable alternatives include a narrow-spectrum oral cephalosporin, oral clindamycin, or various oral macrolides. An individual who has had an attack of rheumatic fever is at very high risk of developing recurrences after subsequent GAS pharyngitis and needs continuous antimicrobial prophylaxis to prevent such recurrences (secondary prevention). The recommended duration of prophylaxis depends on the number of previous attacks, the time elapsed since the last attack, the risk for exposure to GAS infections, the age of the patient, and the presence or absence of cardiac involvement. Penicillin is again the agent of choice for secondary prophylaxis, but sulfadiazine or a macrolide is an acceptable alternative in penicillin-allergic individuals.

Poststreptococcal Reactive Arthritis

The term *poststreptococcal reactive arthritis* (PSRA) was first used to describe patients with arthritis after documented GAS infection but who failed to meet the Jones criteria for the diagnosis of acute rheumatic fever. Since then, the differentiation of PSRA from acute rheumatic fever has remained unsettled.[7] Compared with acute rheumatic fever, the arthritis of PSRA is more likely to occur within 10 days after infection, be symmetrical and nonmigratory, last longer than 3 weeks, and be poorly responsive to aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs). Periarticular findings, such as tenosynovitis, have not been considered to be part of the clinical spectrum of acute rheumatic fever but have been described with PSRA. However, some studies have reported that an additive and prolonged pattern of arthritis, as well as aspirin unresponsitivity, may be seen in 19% to 36% of patients with acute rheumatic fever. Some have suggested that patients with higher ESR and CRP, a shorter duration of joint symptoms after NSAID therapy, and without relapse when NSAIDs were stopped were diagnosed as having acute rheumatic fever rather than PSRA. Although all patients with PSRA have

serologic evidence of a recent GAS infection, no more than half of these patients who have a throat culture performed have GAS isolated. Because a small proportion of patients with PSRA have been reported to develop subsequent valvular heart disease, these patients should be observed carefully for several months for clinical evidence of carditis. If valvular disease is detected, the patient should be classified as having had acute rheumatic fever and should continue to receive secondary prophylaxis.

Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (PSGN) is a disease characterized by the sudden appearance of edema, hematuria, proteinuria, and hypertension (Chapter 121).[8] It is now known to follow infection by nephrogenic strains of GAS, which are M types 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60. These may cause skin or throat infections, but specific M types, such as 49, 55, 57, and 60, are most commonly associated with skin infections. In addition, nontypeable GAS is frequently isolated from the skin or throats of patients with glomerulonephritis, representing presumably unclassified nephritogenic strains. The overall risk of developing acute PSGN after infection by these nephritogenic strains is about 15%. The risk for nephritis may also be related to the M type and the site of infection. The risk of developing nephritis infection by M type 49 is 5% if it is present in the throat. This risk increases to 25% if infection by the same organism is present in the skin. The time lapse between infection and onset of PSGN symptoms is typically 1 to 3 weeks after a throat infection and 3 to 6 weeks after a skin infection.

The pathogenic mechanism of PSGN remains largely unknown (Chapter 121). Diffuse glomerular hypercellularity, C3 and immunoglobulin G (IgG) deposition, and proteinuria and hematuria are cardinal features. However, it can occur without all of these signs present concurrently. For a reliable diagnosis of PSGN, clear evidence that a streptococcal infection preceded the glomerulonephritis is required. However, streptococcal infection has often cleared by the time the patient appears in the clinic because the symptoms generally arise 1 to 3 weeks after the patient was infected. Acute PSGN most often follows upper respiratory tract GAS infections in colder climates and skin infections in warmer climates. Occasionally, it may also be seen after group C or G streptococcal infections. A high incidence of PSGN is noted in other parts of the world, especially in areas with tropical climates where skin infections are common. Epidemic episodes tend to occur in highly populated areas where poor hygiene, malnutrition, anemia, and parasites are common, and episodes are separated by periods of 5 to 7 years in certain communities. Epidemics occur also in the Western world, especially in closed communities. Acute PSGN affects all age groups but most commonly children and young adults. Males are affected more often than females, often in the ratio of 2 : 1. Acute PSGN rarely strikes the same individual twice. Thus, it appears likely that protective immunity is acquired as a result of an infection with a nephritogenic strain.

Although penicillin treatment of the antecedent streptococcal infections is highly efficacious in preventing acute rheumatic fever, it does not appear to be the case in PSGN. Studies carried out during epidemics of nephritis found that prior antibiotics had little, if any, effect in preventing PSGN. Penicillin is, nevertheless, effective in epidemiologic attempts to eradicate nephritogenic strains by treatment of acute glomerulonephritis patients and their colonized family contacts. Because recurrent episodes of acute glomerulonephritis are so rare, continuous antibiotic prophylaxis, such as is used in the secondary prevention of rheumatic fever, is unnecessary.

The ultimate prognosis in persons with acute glomerulonephritis depends largely on the severity of the initial insult. In an extremely small proportion of patients, the initial injury is so severe that either persistent renal failure or progression to renal failure occurs. However, in most patients, histologic regression of the disease is the rule, and the ultimate prognosis is good.

DIAGNOSIS

Streptococcal Antibody Tests

Ant streptococcal antibody titers reflect past and not present immunologic events and therefore cannot be used to determine whether an individual with pharyngitis and GAS in the pharynx is truly infected or merely a streptococcal carrier. When present, elevated or rising antistreptococcal antibody titers provide reliable confirmation of a recent GAS infection and are of value in identifying a preceding GAS infection in a patient suspected of having rheumatic fever. The most commonly used and commercially available antibody assays are antistreptolysin O and anti-DNAse B. These tests are valuable in patients who have possible nonsuppurative complications of GAS infections (acute rheumatic fever or acute glomerulonephritis). The antistreptolysin O test is usually obtained first, and if the result is not elevated, an anti-DNAse B test may be performed. Antistreptolysin O titers begin to rise approximately 1 week and peak 3 to 6 weeks after the infection. Anti-DNAse B titers begin to rise 1 to 2 weeks and peak 6 to 8 weeks after the infection. Elevated titers for both tests may persist for several months after even uncomplicated GAS infections.

It is not uncommon for laboratory personnel and physicians to misinterpret streptococcal antibody titers because of a failure to appreciate that the normal levels of these antibodies are higher among school-aged children than among adults. Single antibody titers are often misleading. Sequential samples more accurately define infection, allowing correlation of titer increases with temporal confirmation of GAS acquisition.

TREATMENT Rx

Antimicrobial Susceptibility

Penicillin and the cephalosporins continue to be the drugs of first choice for the treatment of most GAS infections. The continued susceptibility of *S. pyogenes* to β-lactams is remarkable, especially compared with the emergence of resistance to β-lactams among pneumococci and VGS over the past decade. A limited ability to acquire foreign DNA and a physiologic fitness cost associated with β-lactam resistance are possible explanations for this organism's continued susceptibility to penicillin. The macrolides are the second-line drug of choice and are used in penicillin-hypersensitive patients. Clindamycin is also the drug of choice for chronic, recurrent pharyngitis. However, resistance has emerged in this organism. Elevated rates of macrolide resistance (>25%) among GAS reported in Korea, Taiwan, Spain, and Italy are causes of concern. Limited surveillance data suggest that the overall rate of macrolide-resistant GAS in North America is 3% to 9%. There are two primary mechanisms of macrolide resistance in GAS: efflux (encoded by *mefA*) and target modification caused by ribosomal methylation (encoded by *ermB* or *ermA*). Isolates with the *mefA* gene have a pattern of resistance known as the M phenotype: they are macrolide resistant but clindamycin susceptible. GAS isolates with the *ermB* gene are usually resistant to macrolides and clindamycin. Isolates with the *ermA* gene typically have an inducible phenotype that requires exposure to a macrolide inducer before clindamycin resistance becomes evident. There are rare reports of L4 ribosomal protein and 23S recombinant RNA mutations in macrolide-resistant GAS isolates.

Fluoroquinolones are a useful therapeutic alternative for the treatment of skin and soft tissue infections in adults. Although strains of GAS nonsusceptible to the fluoroquinolones have been reported, they are rare. The mechanisms of decreased susceptibility to the fluoroquinolones among *Streptococcus* spp. are mainly mediated by point mutations in the quinolone resistance–determining region of the bacterial topoisomerase II enzymes, namely, DNA gyrase and topoisomerase IV. DNA gyrase and topoisomerase IV enzymes are homologs, with each enzyme consisting of a tetramer with two subunits (two *gyrA* and two *gyrB* molecules in DNA gyrase, two *parC* and two *parE* molecules in topoisomerase IV). *S. pyogenes* isolates that are resistant or have reduced susceptibility to fluoroquinolones have been reported, but isolates with a high level of resistance have been detected very infrequently.

Tetracycline resistance in GAS is quite common. In gram-positive organisms, resistance to tetracycline is typically conferred by ribosome protection genes, such as *tet*(M) and *tet*(O). Tetracycline resistance is usually acquired by GAS through horizontal gene transfer. A global sample of GAS revealed 80 or more separate acquisitions of tetracycline resistance. Of 244 clones, 38% and 25% displayed resistance to tetracycline and erythromycin, respectively; a relatively high proportion (15%) were resistant to both classes of drugs. *tet*(M) displayed a highly significant association with *erm*(B). Trimethoprim–sulfamethoxazole is not active against GAS and therefore should not be used as monotherapy for infections potentially caused by GAS.

STREPTOCOCCUS AGALACTIAE (GROUP B STREPTOCOCCUS)

EPIDEMIOLOGY

Group B streptococci, also known as *Streptococcus agalactiae*, was once considered a pathogen of only domestic animals, causing mastitis in cows. Although asymptomatic vaginal carriage of GBS was described in 1935, the first report of GBS sepsis in a neonate was not reported until 1964. Since the 1970s, GBS is recognized as one of the most common causes of neonatal infectious morbidity and mortality in developed countries. GBS causes significant maternal and perinatal morbidity, asymptomatic bacteriuria in pregnancy, and urinary tract and other infections in the adult nonpregnant population. The virulence of *S. agalactiae* is related to the polysaccharide

toxin it produces. Immunity is mediated by antibodies to the capsular polysaccharide and is serotype specific. Several serotypes are known, including Ia, Ib, Ic, II, III, IV, V, VI, VII, and VIII.

CLINICAL MANIFESTATIONS

Neonatal Group B Streptococcus Disease

Group B streptococci colonizes the vaginal and gastrointestinal (GI) tracts in healthy women, with carriage rates ranging from 15% to 45%. Neonates can acquire the organism vertically in utero or during delivery from the maternal genital tract. Although the transmission rate from mothers colonized with *S. agalactiae* to neonates delivered vaginally is approximately 50%, only 1% to 2% of colonized neonates go on to develop invasive GBS disease. Neonatal GBS disease is divided into early and late disease. Early GBS neonatal sepsis often presents within 24 hours of delivery but can become apparent up to 7 days postpartum. Pneumonia with bacteremia is common, but meningitis is less likely. Late GBS neonatal sepsis is defined as infection that presents between 1 week postpartum and age 3 months. Late disease commonly involves GBS serotype III, typically characterized by bacteremia and meningitis.

PREVENTION

The current approach to the prevention of early-onset GBS infection in pregnancy is to provide intrapartum antimicrobial prophylaxis in women at term with culture evidence of recent vaginal or rectal GBS infection.■ Women without a known GBS status delivering before 37 weeks' gestation with premature rupture of the membranes or intrapartum fever are also candidates for intrapartum antimicrobial prophylaxis. Penicillin or ampicillin is the initial approach. Clindamycin and macrolides are standard in individuals with penicillin allergy, but GBS infections are no longer always sensitive to these two drugs. Despite these recommendations, there is lack of evidence from well-designed and well-conducted trials to recommend intrapartum antibiotic prophylaxis to reduce neonatal early-onset GBS disease.

Invasive Group B Streptococcus Disease

S. agalactiae infection is extremely rare in healthy adults and is almost always associated with underlying abnormalities. Bacteremia with an unknown source accounts for approximately 25% of all cases of invasive GBS disease. Diabetes mellitus and malignancy are the most common underlying diseases associated with infection. Urinary tract infections are a common manifestation of GBS disease and are observed in both pregnant and nonpregnant adults. Other presentations of GBS infection include pneumonia, skin and soft tissue infections, septic arthritis, osteomyelitis, meningitis, peritonitis, and endo-ophthalmitis.

Invasive GBS disease is a major cause of illness and death in older adults and is even more frequent among long-term care facility residents, possibly because of concurrent conditions such as advanced age, diabetes, cirrhosis, and stroke, which are known risk factors for GBS infection.[9] Case-fatality rates are about 13% for persons 65 years and older. An increased prevalence of serogroup V has been reported in adult populations. Serotype V has been associated with higher rates of antimicrobial drug resistance.

TREATMENT Rx

Although β-lactams remain the preferred therapy for GBS infections, strains with elevated penicillin minimal inhibitory concentrations have been reported but are rare.

STREPTOCOCCUS DYSGALACTIAE SUBSPECIES *EQUISIMILIS* (HUMAN GROUP C AND G STREPTOCOCCI)

EPIDEMIOLOGY

Non–group A or B β-hemolytic streptococci that are frequently normal inhabitants of the oropharynx, skin, and GI and genitourinary (GU) tracts are also capable of causing significant disease. These include groups C, G, F, and L, of which the most common are groups G and C (see Table 290-1). Large-colony-forming human groups C and G streptococci are currently classified as *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE). Infections caused by SDSE are transmitted person to person; an animal reservoir for these strains has not been reported. Zoonotic group C or G streptococcal infections are comparatively rare and are mostly caused by other streptococcal species after animal contact or are associated with the consumption of unpasteurized dairy food products. Nonhuman large-colony-forming β-hemolytic group G streptococci usually belong to *Streptococcus canis,* an animal pathogen that has been found only rarely in humans.

CLINICAL MANIFESTATIONS

A population-based study carried out in North America demonstrated a substantial morbidity and mortality associated with infections caused by SDSE, comparable to that caused by invasive GAS infection during the same study period. Both SDSE and GAS affected similar adult populations, tended to be community acquired, and affected primarily persons with underlying medical conditions. The mortality rate was similar to that (8%-21%) reported in other studies. Whereas SDSE primarily presented as skin and soft tissue infection in older patients, individuals with invasive *S. anginosus* group infections were more likely to be younger patients with intra-abdominal infections; these were typically polymicrobial and represented sequelae of perforated appendicitis and associated peritonitis. This finding is supported by the fact that *S. anginosus* group isolates have been recovered from 20% to 40% of healthy appendices.

Pharyngitis is a classic presentation in adult patients, and SDSE has clearly been responsible for epidemic outbreaks of pharyngitis in children. The etiologic role of SDSE in pharyngitis is supported by reports on acute poststreptococcal glomerulonephritis and, more recently, on acute rheumatic fever after SDSE isolation from the upper respiratory tract.

In a 1-year study of 90 patients presenting with 98 disease episodes of acute bacterial cellulitis in Finland, SDSE instead of GAS was strikingly the most common finding. Some patients and household members also carried SDSE in the pharynx; it was not detected in the control participant. Whereas SDSE was isolated either from skin lesions or blood from 22% of patients, GAS was isolated from 7% of patients.

TREATMENT Rx

The non–group A or B β-hemolytic streptococci are typically susceptible to penicillins and cephalosporins, although α-hemolytic VGS have shown increasing resistance to penicillin and other β-lactams. In contrast, the resistance to erythromycin and tetracycline among SDSE is similar to rates found in GAS.

VIRIDANS GROUP STREPTOCOCCI

Streptococcus anginosus Group (*Streptococcus milleri* Group)

The *S. anginosus* group includes three distinct species and more subspecies. *S. anginosus*, *S. constellatus*, and *S. intermedius* have all been collectively known as either *S. anginosus* or *S. milleri*. Members of the *S. anginosus* group are nonmotile, facultative anaerobes that demonstrate variable hemolysis patterns (α, β, or γ) on sheep blood agar. Colonies are typically small (colony < 0.5 mm). A caramel or butterscotch smell is useful for identifying the *S. anginosus* group when present but is not a sufficiently sensitive screening test. There are β-hemolytic strains of each of the three species, and the strains may possess one of four different Lancefield group antigens (group A, C, F, or G) or no group antigen. Non-–hemolytic varieties of each of the three species are grouped into the general classification of viridans streptococci.

The organisms, although normal flora of the human oral cavity and GI tract, have the ability to cause abscesses and systemic infections, unlike *S. pyogenes* and *S. agalactiae*. The *S. anginosus* group should be considered true pathogens when isolated from humans. *S. anginosus* often presents as part of a polymicrobial infection in patients with oral, head and neck, and abdominal infections. Copathogens in such infections may include other bacteria such as *Eikenella corrodens* and *Fusobacterium nucleatum*. This group is less commonly the cause of endocarditis than other viridans streptococci. Whereas *S. intermedius* has an apparent tropism for the brain and liver, *S. anginosus* and *S. constellatus* have been isolated from a wider range of sites and infections.

Thoracic infections caused by *S. anginosus* group are largely pleural. They are polymicrobial in one third of cases and in most patients are associated with major surgery or surgical procedures of the respiratory or digestive tract. The empyema frequently requires thoracotomy for complete resolution. In the chest, infections tend to cause loculated empyemas that are not conducive to tube thoracostomy drainage or to antibiotic treatment. About 75% of infections of the chest require surgical intervention. The optimal method and timing of intervention for thoracic empyema remains debated, likely because of the presentation of pleural space disease in one of three stages: exudative effusions, fibrinopurulent collections, and organized loculations. In the fibrinopurulent stage, the lung can be thoracoscopically dissected off the chest wall without much difficulty.

Members of the *S. anginosus* group are largely susceptible to β-lactam agents. Minimal inhibitory concentrations (MICs) to penicillin G are usually 0.125 mcg/mL or less. Some strains with penicillin G MICs between 0.25 and 2 mcg/mL have been reported; rare strains have penicillin MIC 4 mcg/mL or greater. Penicillin-intermediate or -resistant strains have altered penicillin-binding proteins; these are more likely to be *S. anginosus* or *S. intermedius* than *S. constellatus*. Vancomycin is an appropriate alternative agent for penicillin-allergic patients. A parental third-generation cephalosporin is recommended for brain abscesses and bacteremia caused by members of the *S. anginosus* group.

Fluoroquinolone MICs among *S. anginosus* group members are high but in the susceptible range (0.5-1.0 mcg/mL); resistance tends to develop easily, and therefore fluoroquinolones are not appropriate first-line antimicrobial agents. Macrolide resistance appears to be emerging among the *S. anginosus* group. Most strains of the *S. anginosus* group are resistant to aminoglycosides. Sulfonamides have no activity against *S. anginosus* group isolates.

S. anginosus plays a significant role as a reservoir of antimicrobial resistance genes, transferring different resistance traits to more pathogenic organisms such as *S. pneumoniae* and *S. pyogenes*.

Other Viridans Group Streptococci

There are now at least 30 recognized species of VGS, including those discussed earlier. Although often found as commensals whose pathogenic abilities appear to be much more subtle than those of the pyogenic streptococci, they may also participate in various infections such as subacute bacterial endocarditis; catheter-related and neutropenia-related bloodstream infections; and purulent abdominal, hepatobiliary, brain, and dental infections. Antimicrobial resistance is substantial in the viridans streptococci as a group. Penicillin resistance is from 30% to 50% in strains isolated from patients in North America. *S. mitis* and *S. oralis* are the most common strains found in blood cultures of cancer patients and are commonly resistant to β-lactam antimicrobials. *S. sanguinis*, *S. oralis*, and *S. gordonii*, in descending order, are the most common strains isolated from cultures of blood of endocarditis patients.

ZOONOTIC STREPTROCOCCI

Streptococcus suis

S. suis is a pathogen in pigs that can cause severe infection in humans.[10] *S. suis* was first reported by veterinarians in 1954 after outbreaks of meningitis, septicemia, and purulent arthritis occurred among piglets. Fourteen years later, the first human *S. suis* cases were diagnosed in Denmark, and subsequently, other cases were reported in more than 30 countries, including Canada, the United States, Japan, Vietnam, and Thailand. It can be clinically manifested with meningitis, arthritis, and sepsis. *S. suis* is the name assigned to streptococci that were formally called Lancefield groups R, S, and T. Of the 35 known serotypes, the most frequent serotype identified from humans has been serotype 2 (group R). Human *S. suis* infections are most often reported from countries where pig rearing is common. The relatively high mean patient age (47-55 years) and almost complete absence of children in case series, as well as the high male-to-female patient ratio (3.5 : 1 to 6.5 : 1), support the notion that infection with *S. suis* is generally an occupational disease. The annual risk of developing *S. suis* meningitis among abattoir workers and pig breeders has been estimated to be 3 cases per 100,000 population; the risk is lower for butchers, at 1.2 cases per 100,000 population in developed countries. The incubation period of *S. suis* is from hours to 14 days (median, 2.2 days). A very short incubation time is consistent with direct entry of *S. suis* into the blood through skin wounds. Patients have generally been healthy before infection with *S. suis,* although predisposing factors, such as splenectomy, diabetes mellitus, alcoholism, malignancy, and structural heart diseases, have been reported. An outbreak in China was associated with an overall case-fatality rate of 18%, but this reached 63% among patients with severe sepsis and septic shock.

Data from Vietnam show that *S. suis* is susceptible to penicillin, ceftriaxone, and vancomycin. Resistance was seen to tetracycline (83%), erythromycin (20%), and chloramphenicol (3%). In a European study, 384 *S. suis* strains from diseased pigs were susceptible to penicillin, but resistance was detected to gentamicin (1.0%), trimethoprim–sulfamethoxazole, (6.0%), and tetracycline (75%). There may be a role for the use of dexamethasone as an adjunctive treatment to reduce mortality and improve the outcome of bacterial meningitis caused by infection with *S. suis*. In a randomized, double-blind, placebo-controlled clinical trial in Vietnam, dexamethasone (0.4 mg/kg twice daily for 4 days) resulted in a significant reduction in the risk for death at 1 month and in the risk for death and disability at 6 months in patients with confirmed bacterial meningitis; *S. suis* accounted for 25% of pathogens.

Currently, a human vaccine is not available, but simple preventive measures, such as wearing gloves during processing pig meat or slaughtering, handwashing after handling raw pork meat, and thorough cooking of pork, should prevent most cases. Travelers should be aware that dietary habits in some countries may pose a risk for infectious diseases, including *S. suis* infection.

Streptococcus canis

S. canis is an organism that was described in 1986 as having the Lancefield group G antigen and was isolated from animals, most frequently dogs. Extensive phenotypic testing of isolates from dogs was described in 1994, and the isolation of *S. canis* from a human with sepsis was reported in 1997. Despite its name, *S. canis* has also been isolated from animals other than dogs, including cats, harbor porpoises, cows, mice, rats, and rabbits. In healthy dogs, *S. canis* is found as commensal flora of the skin, oropharynx, GU tract, and anus. Rare cases of *S. canis* infection in humans have been reported in the literature. Resistance to erythromycin and tetracycline is common. In the clinical laboratory, group G streptococci are not usually identified to the species level. In addition, laboratory tests have only recently been able to identify *S. canis* accurately. Thus, the true incidence of *S. canis* infection is unknown.

Streptococcus bovis Group

Members of the *Streptococcus bovis* group have long been regarded as opportunistic pathogens in humans, causing up to 11% to 14% of all endocarditis cases and 24% of streptococcal endocarditis. *S. bovis* group isolates from human infections are divided into three biotypes, designated biotypes I, II/1, and II/2. Most *S. bovis* group endocarditis isolates belong to biotype I, for which a reclassification as *Streptococcus gallolyticus* subspecies *gallolyticus* has been proposed. The human intestinal tract is a major natural reservoir of *S. bovis* group strains with a reported carriage rate of about 10%. There is a strong association between the presence of malignant or premalignant lesions in the GI tracts of patients and isolation of *S. bovis* as a causative agent of bacteremia or endocarditis.

Streptococcus iniae

S. iniae is a β-hemolytic streptococcus without a group antigen. It is a major fish pathogen in many regions of the world. These bacteria are also zoonotic, with infections in humans associated with the handling and preparation of infected fish. The first human infections were reported in 1996. Most cases of human *S. iniae* infections have been in persons of Asian descent, who are elderly and commonly have underlying conditions such as diabetes mellitus, chronic rheumatic heart disease, cirrhosis, or other conditions.

Carrier fish have been implicated in fish-to-fish transmission of *S. iniae*, and these carriers may be responsible for human infection because fish with overt signs of disease are unmarketable. Soft tissue injuries that occur during the preparation of fresh fish from wet markets usually result in bacteremic cellulitis of the hand followed by one or more of the following conditions: endocarditis, meningitis, arthritis, sepsis, pneumonia, osteomyelitis, and toxic shock. *S. iniae* is susceptible to penicillin and other antimicrobials. The expression of a suite of virulence factors, many of them similar to those found in GAS, is responsible for successful entry, propagation, and evasion of immune defenses of the host by this bacterium. Underreporting of human cases is likely because identification of *S. iniae* is based on biochemical testing of isolates with commercial kits; the use of kits is associated with problems because *S. iniae* is not listed in commercial or clinical databases, and many atypical strains are assigned low matches.

REVIEW QUESTIONS

1. Group A streptococcus (GAS) is a major cause of pharyngitis and reasons for visits to health care facilities and for the prescription of antibiotics. Which of the following statements is correct?

A. The treatment of GAS pharyngitis is an important strategy for the prevention of rheumatic heart disease in developed countries.
B. Periarticular findings, such as tenosynovitis, have not been considered to be part of the clinical spectrum of acute rheumatic fever but have been described with poststreptococcal reactive arthritis.
C. Penicillin treatment of the antecedent streptococcal infections is highly efficacious in preventing acute rheumatic fever and post-streptococcal glomerulonephritis (PSGN).
D. Quantitation of GAS from the throat swab culture can be used to differentiate carriage from infection.
E. On clinical grounds, streptococcal pharyngitis cannot be strongly suggested by the presence of fever, tonsillar exudate, tender enlarged anterior cervical lymph nodes, and presence of cough without laboratory confirmation.

Answer: B The term *poststreptococcal reactive arthritis* was first used to describe patients with arthritis after documented GAS infection but who failed to meet the Jones criteria for the diagnosis of acute rheumatic fever. Since then, the differentiation of PSRA from acute rheumatic fever has remained unsettled. In the latter half of the 20th century, rheumatic fever receded as an important health problem in almost all wealthy countries. Most of the reduction is attributable to improved living conditions, which have resulted in less overcrowding and better hygiene, with consequent reductions in transmission of GAS, not the widespread use of antibiotics. In other words, rheumatic fever is a disease of poverty. Studies carried out during epidemics of nephritis found that prior antibiotics had little, if any, effect in preventing acute PSGN. Penicillin is, nevertheless, effective in epidemiologic attempts to eradicate nephritogenic strains by treatment of acute glomerulonephritis patients and their colonized family contacts. Quantitation of GAS from the throat swab culture is unable to differentiate at presentation between a child who is acutely infected and one who is a chronic carrier presenting with acute nonstreptococcal pharyngitis. The methods for making that discrimination (testing for serological response and strain typing) require time and the aid of reference or research laboratories. A position paper by the American College of Physicians–American Society of Internal Medicine/American Academy of Family Physicians/U.S. Centers for Disease Control and Prevention recommends a departure from the principle of laboratory confirmation of all adult cases with recommendations to use a clinical prediction rule.

2. Acute rheumatic fever is a delayed, nonsuppurative sequela of a pharyngeal infection with group A streptococci (GAS). Which of the following statements is correct?

A. Only "rheumatogenic" strains have been associated with acute rheumatic fever.
B. According to revised Jones criteria, the diagnosis of rheumatic fever can only be made when two of the major criteria or one major criterion plus two minor criteria are present along with evidence of streptococcal infection.
C. Penicillin (either oral penicillin V or injectable benzathine penicillin) is the treatment of choice.
D. Poststreptococcal reactive arthritis (PSRA) is an entity in patients who had arthritis after an episode of GAS pharyngitis but lacked other major criteria of acute rheumatic fever. However, they frequently go on to develop acute rheumatic fever.

Answer: C Penicillin is cost effective, has a narrow spectrum of activity, and has long-standing proven efficacy. In addition, GAS resistant to penicillin has not been documented. For penicillin-allergic individuals, acceptable alternatives include a narrow-spectrum oral cephalosporin, oral clindamycin, or various oral macrolides. Although the observation in some studies that only a few M serotypes (types 3, 5, 6, 14, 18, 19, 24, and 29) were implicated in outbreaks of rheumatic fever suggested a particular "rheumatogenic" potential of certain strains of GAS, the issue of potential rheumatogenic strains remains unresolved. A streptococcal strain capable of causing a well-documented pharyngitis almost always is potentially capable of causing rheumatic fever. Exceptions are chorea and indolent carditis, each of which by itself can indicate rheumatic fever. Compared with acute rheumatic fever, the arthritis of PSRA is more likely to occur within 10 days after infection, be symmetrical and nonmigratory, last longer than 3 weeks, and be poorly responsive to aspirin or other nonsteroidal anti-inflammatory drugs. Periarticular findings, such as tenosynovitis, have not been considered to be part of the clinical spectrum of acute rheumatic fever but have been described with PSRA. Because a small proportion of patients with PSRA have been reported to develop subsequent valvular heart disease, these patients should be observed carefully for several months for clinical evidence of carditis.

3. The current recommendations for the surgical treatment of group A streptococci (GAS) necrotizing fasciitis are based on

A. Prospective randomized controlled trials comparing immediate surgical intervention (<24 hours from time of admission) versus delayed therapy (>24 hours from time of admission).
B. Retrospective reviews of studies comparing the outcomes of patients treated early in their disease versus those who had delayed therapy.
C. Retrospective reviews of studies of patients with a diagnosis of necrotizing fasciitis from multiples etiologies.
D. Prospective studies of patients with GAS necrotizing fasciitis.

Answer: C All of the reports of outcomes of necrotizing fasciitis have been studies that have included necrotizing fasciitis from multiple causes. There have been no prospective studies comparing immediate surgical intervention (<24 hours from time of admission) versus delayed therapy (>24 hours from time of admission). The published studies are all based on retrospective chart review of patients with necrotizing fasciitis from multiple etiologies, including mixed aerobic and anaerobic organisms.

4. Since the 1970s, group B streptococcus (GBS) is recognized as one of the most common causes of neonatal infectious morbidity and mortality in developed countries. Which of the following statements is correct?

A. Although the transmission rate from mothers colonized with *S. agalactiae* to neonates delivered vaginally is approximately 50%, only 1% to 2% of colonized neonates go on to develop invasive GBS disease.
B. Late GBS neonatal sepsis is defined as infection that presents between 1 week postpartum and age 3 months. Late disease commonly involves transmission of GBS from mother to baby after discharge.
C. The current approach to the prevention of early-onset GBS infection in pregnancy requires prepartum antimicrobial prophylaxis in women in their last trimesters of pregnancy with culture evidence of recent vaginal or rectal GBS infection.
D. Early-onset GBS disease can still occur in infants whose mothers screened negative for GBS colonization. Therefore, all women should receive intrapartum antibiotic prophylaxis regardless of screening results.

Answer: A The ability of the organism to cause invasive disease is related to the virulence and preexisting immunity from the mother. Virulence of *S. agalactiae* is related to the polysaccharide toxin it produces. Immunity is mediated by antibodies to the capsular polysaccharide and is serotype specific. Several serotypes are known, including Ia, Ib, Ic, II, III, IV, V, VI, VII, and VIII. A minority of infants with GBS late-onset disease are born to GBS-colonized mothers. Intrapartum prophylaxis does not appear to prevent late-onset GBS disease, implicating infected breast milk and nosocomial or community sources in these cases.

Multiple clinical trials have demonstrated that the use of intrapartum penicillin or ampicillin significantly reduces the rate of neonatal colonization with GBS and the incidence of early-onset neonatal GBS disease. Even in the setting of a maternal GBS screening program, efforts to evaluate and treat infants with intrapartum clinical risk factors for early-onset sepsis remain important. Results of studies have demonstrated that prompt intrapartum antibiotic treatment of women with signs and symptoms of chorioamnionitis regardless of their GBS screening results and the evaluation of well-appearing infants for possible sepsis because of intrapartum clinical risk factors remain imperative.

5. The *S. anginosus* group includes three distinct species and more subspecies. *S. anginosus, S. constellatus,* and *S. intermedius* have all been collectively known as *S. anginosus*. Characteristics of this group include

A. Being part of the normal flora of the genitourinary tracts.
B. The *S. anginosus* group should be considered true pathogens when isolated from humans.
C. *S. milleri* is a closely related viridans group streptococci that is more frequently a cause of endocarditis.
D. Lung infections caused by the *S. anginosus* group are largely confined to the right middle lobe.

Answer: B Although part of the normal flora, the group has the ability to cause abscesses and systemic infections, unlike *S. pyogenes* and *S. agalactiae*. The *S. anginosus* group is a heterogeneous group of organisms that can be human commensals, colonizing the gastrointestinal tract and the oral mucosa. The *S. anginosus* group is generally considered to be of low pathogenic potential in immunocompetent individuals. The *S. anginosus* group is one that has been the source of much controversy and confusion regarding taxonomy and classification. The group includes *S. anginosus, S. constellatus,* and *S. intermedius*. However, each of these species has been known as *S. anginosus* or *S. milleri* at one time. *S. milleri* has never been accepted as a confirmed taxonomic entity, although historically, it has been widely used interchangeably with the *S. anginosus* group. Thoracic infections caused by *S. anginosus* group are largely pleural. They are polymicrobial in one third of cases, and in most patients, are associated with major surgery or surgical procedures of the respiratory or digestive tract. The empyema frequently requires thoracotomy for complete resolution. In the chest, infections tend to cause loculated empyemas that are not conducive to tube thoracostomy drainage or to antibiotic treatment alone. About 75% of infections of the chest require surgical intervention.

291 ENTEROCOCCAL INFECTIONS

TRISH M. PERL

DEFINITION

Enterococci, formerly called group D streptococci, are endogenous human gut flora that had been considered pathogens with low virulence in the past. However, more recently, they have emerged as increasingly important health care–associated pathogens. This emergence is primarily because of their inherent resistance to commonly used antimicrobials, acquisition of high-level resistance to vancomycin and aminoglycosides, persistence in the environment, and transmission from patient to patient by way of the contaminated hands of health care workers. Hence, the emergence of vancomycin-resistant enterococci (VRE) has limited therapeutic options in confirmed enterococcal infections and in empirical therapy for infections in severely ill hospitalized patients and it represents a challenge for infection control in the health care setting. This chapter reviews the most important clinical manifestations of enterococci and their diagnosis and the importance of infection prevention.

The Pathogen

Members of the genus *Enterococcus* were long classified within group D of the genus *Streptococcus*. However, in the past 30 years, they have been reclassified based on new molecular and genetic analyses. Enterococci are catalase-negative gram-positive cocci that can appear singly or in pairs or short chains. They are facultative anaerobes that grow optimally at 35° to 37° C and are usually α-hemolytic or nonhemolytic on sheep blood agar. Enterococci can grow in broth containing 6.5% NaCl and hydrolyze esculin in the presence of 40% bile salts (bile-esculin medium) that can distinguish them from most streptococci. *Enterococcus faecalis,* the most common cause of enterococcal infections in humans, is the causative agent for 80% to 90% of the enterococcal infections followed by *Enterococcus faecium,* which is found in 5% to 10% of the infections. *Enterococcus casseliflavus, Enterococcus gallinarum,* and *Enterococcus raffinosus* are less frequently associated with infections, but clusters of infections have been reported. Other species isolated from different sources in humans include *Enterococcus avium, Enterococcus caccae, Enterococcus cecorum, Enterococcus dispar, Enterococcus durans, Enterococcus gilvus, Enterococcus italicus, Enterococcus hirae, Enterococcus malodoratus, Enterococcus mundtii, Enterococcus pallens, Enterococcus pseudoavium,* and *Enterococcus sanguinicola.*

EPIDEMIOLOGY

Enterococci are part of the normal human gut flora, and infections in both hospitalized and nonhospitalized patients can arise from either an endogenous or exogenous source. The proportion of infections caused by enterococci in hospitalized patients has been increasing over the past several decades. Overall, urinary tract infections (UTIs) are the most common clinical condition caused by enterococci. Based on data reported to the Centers for Disease Control and Prevention (CDC), enterococcal species are now the second most common isolates for any health care–associated infection and prominent causes of catheter-associated bloodstream, UTIs, and surgical site infections, causing approximately 15% of these infections in North America. Enterococci are the second most common cause of catheter-associated UTIs and cause both complicated and uncomplicated UTIs. They are also the second most common cause of central line–associated blood stream infections and are involved in approximately 5% to 15% of all cases of infective endocarditis. They are also the third most frequent pathogen recovered in surgical site infections. Outside of the United States, these organisms are less common but increasingly important causes of infections.

In the 1970s, *E. faecalis* accounted for up to 95% of isolates and was associated with the introduction of third-generation cephalosporins. Increasingly, hospitalized patients, if they are colonized or infected with an *Enterococcus* species, tend to have a strain resistant to vancomycin and sometimes ampicillin (i.e., VRE).[1] *E. faecium* is the most common strain to acquire vancomycin resistance. VRE was first reported in Europe in 1986. Since the mid-, the proportion of enterococcal strains resistant to vancomycin, primarily *E. faecium,* has risen steadily. According to the CDC's National Healthcare Safety Network (NHSN), 62% to 82.6% of *E. faecium* isolates and 6.2% to 9.5% of *E. faecalis* isolates were resistant to vancomycin in 2009 to 2010.[2] Also, according to a recent report by the CDC on antimicrobial resistance in the United States, 66,000 *Enterococcus* health care–associated infections are reported yearly, and 20,000 of them are caused by VRE. There are two major genotypes for acquired vancomycin resistance, VanA and VanB. The genes encoding the VanA phenotype result in high-level resistance to vancomycin and teicoplanin and are carried on a transposon usually found on a plasmid that is transferable to other gram-positive cocci, including *Staphylococcus aureus*. VanA is mostly found in *E. faecium* and, less frequently in *E. faecalis*. VanB is associated with variable resistance to vancomycin, but isolates are usually susceptible to teicoplanin. VanB is usually recovered from *E. casseliflavus* and *E. gallinarum*. Importantly, these genetic elements have been integrated into the genome of *S. aureus* that is resistant to vancomycin. The vancomycin-resistant *S. aureus* (VRSA) acquired a vancomycin resistance gene (*VanA*) from a VRE isolate that colonized a patient coinfected with methicillin-resistant *S. aureus*.

The epidemiology of VRE differs between Europe and North America. In Europe, VRE is often detected in farm animals, likely because of the use of the antibiotic avoparcin in animal feeds until it was banned in 1997. The proportion of VRE among enterococcal clinical isolates in hospitalized Europeans has been historically lower than in the United States; however, these rates are increasing. In the United States, avoparcin was never used in animal feeds, and therefore VRE is not usually found in farm animals or healthy humans. In contrast, the proportion of enterococcal isolates resistant to vancomycin is higher in U.S. hospitals than European hospitals. The proportion of enterococcal isolates from hospitalized European patients that are highly resistant to vancomycin varies by geographic region from less than 1% to up to 35%.

Most VRE infections are associated with health care and result from an exogenous source, meaning transmission from the environment, another patient, or on the hands of a health care worker. Nearly all infections are preceded by a period of colonization, primarily in the gastrointestinal (GI) tract. A study of hospitalized patients found that the most sensitive predictor of VRE colonization was previous admission to an acute care hospital in the past year. Importantly, after being colonized with VRE, patients may harbor the strain in their GI tract for years. Similarly, a study among hemodialysis patients demonstrated that the primary risk factor for VRE colonization was hospitalization in the prior year. Although many colonized patients do not develop infections, they are still able to contaminate the environment and shed and transmit bacteria to other hospitalized patients. The organism has a predilection to contaminate the hospital environment and equipment and has been associated with outbreaks.

Apart from preexisting GI colonization, risk factors for enterococcal infections, particularly VRE infections, include severe underlying conditions such as renal failure, previous solid organ or bone marrow transplantation, solid and hematologic malignancy, diabetes mellitus, and neutropenia. Other factors associated with infection include prior surgical or GI procedures, presence of a vascular or urinary indwelling catheter, hospital factors such as location in the intensive care unit (ICU) or oncology ward, proximity to colonized patients, prolonged length of hospitalization, and recent antimicrobial exposure.

Numerous epidemiologic investigations have revealed that most classes of antimicrobials have been associated with VRE infections. In particular, vancomycin, cephalosporins, and drugs with anaerobic organism coverage use have been linked to VRE acquisition. However, measuring the attributable impact of a particular antibiotic on VRE acquisition is difficult. Increasingly, an association between VRE colonization and *Clostridium difficile*

infection is reported in high-risk patients such as those with hematologic malignancies.

PATHOBIOLOGY

Enterococci are commensal organisms that colonize the human GI tract and female genital tract. Although they are not as intrinsically virulent as other gram-positive pathogens, under certain conditions, the commensal relationship is disrupted, and serious infections occur. Several adhesion factors have been identified, including aggregation substance, which allow binding to epithelial surfaces and enhance the ability for colonization. The ability to adhere to heart valves and urinary tract epithelium enables enterococci to cause endocarditis and UTIs. Enterococci are also known to secrete potential virulence factors. These include cytolysin–hemolysin, which is a bacterial toxin that is produced in a higher proportion of infecting strains compared with stool-colonizing strains. Infecting strains also possess the ability of intestinal translocation, although the exact mechanisms of this process have yet to be determined. In addition, some cell surface determinants that are encoded may mediate adherence to host tissues that may be important in this organism's role in endocarditis. To this point, little is known about the host defense mechanisms in enterococcal infections. In addition, the exact role of capsular polysaccharides in colonization or infection is unknown. Strains have been shown to survive within phagocytic cells, yet it is unclear whether this represents successful host defense or evasion by the enterococci. The intrinsic resistance to multiple antimicrobials that enterococci possess, along with their ability to acquire new resistance mechanisms through mutation or acquisition of new genes, enhances their ability to survive and multiply in the many hospitalized patients treated with broad-spectrum antimicrobials.

CLINICAL MANIFESTATIONS

No specific clinical manifestations can help distinguish enterococcal infections from infections caused by other bacteria. Enterococci are not thought to cause lower respiratory tract infections or ventilator-associated pneumonia and, if found in these settings, likely represent colonization and not infection. Enterococci act as opportunistic pathogens in severely ill and compromised patients. They are known to cause UTIs, intra-abdominal abscesses, wound infection, bacteremia (including catheter-associated blood stream infections), and endocarditis.

Urinary Tract Infections

Urinary tract infections are the most frequent type of infection caused by enterococci.[3] Most infections are nosocomial in origin and include uncomplicated cystitis, pyelonephritis, prostatitis, and perinephric abscess. These infections are typically secondary to urinary catheterization or instrumentation. In contrast to nosocomial UTI, enterococci cause fewer than 5% of uncomplicated cystitis or pyelonephritis cases in otherwise healthy nonhospitalized women. Patients with diabetes mellitus appear to be at increased risk for enterococcal UTI. Bacteremia is only infrequently associated with enterococcal UTI.

Bacteremia

Importantly, enterococci can cause infection or contaminate cultured blood via contaminated catheter hubs and contaminated skin. Determining a true bacteremia versus a blood culture that is not clinically significant can be a challenge. Given this backdrop, the incidence of bacteremia caused by enterococci continues to increase. Specific risk factors include prolonged hospitalization, preexisting urethral catheters or intravascular lines, recent surgery, malignancy, neutropenia, and biliary pathology. Secondary bacteremia without endocarditis usually arises from the urinary tract, hepatobiliary tract, or soft tissue infection. Bacteremia secondary to an intra-abdominal source carries a high mortality rate. Risk factors for VRE bacteremia parallel those mentioned previously but additionally include severe preexisting comorbid conditions, including hematologic malignancy, human immunodeficiency virus (HIV) infection, chronic renal insufficiency, and liver transplantation. Prior exposure to broad-spectrum antimicrobials, including those with antianaerobic activity such as clindamycin or metronidazole, and exposure to multiple and prolonged antimicrobial therapy are consistent risk factors. Enterococcal bacteremia is frequently polymicrobial, and the clinical picture is often influenced by whether it is isolated alone or with other bacteria. When enterococci are isolated alone, the course is typically indolent, and frequently fever is the only sign. In contrast, polymicrobial bacteremia is more severe, often presenting with shock or disseminated intravascular coagulation. VRE bacteremia is associated with higher mortality rates than bacteremia caused by vancomycin-susceptible strains, and early treatment with an appropriate antibiotic within the first 48 hours of presentation has been associated with improved outcomes.

Endocarditis

Enterococci, particularly *E. faecalis*, are an increasingly frequent cause of endocarditis even though most enterococcal bacteremias are not complicated by endocarditis. The disease occurs most frequently in older patients, with a male predominance. Most cases appear to arise in the community. Patients with preexisting valvular heart disease, including prosthetic valves, are at highest risk, yet many patients lack underlying heart disease. Enterococci more commonly cause left-sided endocarditis primarily affecting the mitral valve. Clinically, these patients present with symptoms that closely resemble a subacute bacterial endocarditis caused by viridans streptococci. Many patients have symptoms for weeks or months before seeking medical care.

Intra-abdominal Infections

In intra-abdominal infections, enterococci are often detected as part of a polymicrobial process.[4] These infections typically arise from a hepatobiliary source, including postoperative infection in liver transplantation, and are complicated by secondary bacteremia.

Skin and Soft Tissue Infections

Enterococci rarely cause cellulitis or other soft tissue infections alone but are often isolated in mixed surgical site infections, diabetic foot infections, and decubitus ulcers along with other gram-negative bacilli, gram-positive cocci, and anaerobic bacteria. Their clinical significance in these situations has not been adequately determined. Enterococci are not thought to be primary pathogens in chronic osteomyelitis. When they are identified, it is thought they may solely represent superinfection, and thus adequate therapy may not require antibiotics directed at enterococcal eradication.

DIAGNOSIS

The diagnosis of an *Enterococcus* infection is made by isolating the organism through culture of a sterile site, such as blood or urine. Recently, molecular techniques have been developed to identify *Enterococcus* more quickly. The diagnosis and differential diagnosis of specific conditions are the same as discussed for UTIs (Chapter 284) and endocarditis (Chapter 76).

TREATMENT

Rx

Therapy for enterococcal infections is complicated by the fact that strains exhibit inherent resistance to many commonly used antibiotics, including cephalosporins.[5] In addition, enterococci can acquire resistance to a wide range of antibiotic classes, including aminoglycosides (high-level resistance), β-lactams, fluoroquinolones, and vancomycin. Thus, effective directed therapy for any severe enterococcal infection requires susceptibility testing by experienced microbiology laboratories, with therapy adjusted based on the results. Optimal therapy for most infections includes intravenous ampicillin, penicillin, or vancomycin. Given the resistance or tolerance to cell wall–targeting antibiotics, including penicillins and vancomycin, standard therapy with these antibiotics, except in UTIs, should include the addition of a synergistic aminoglycoside (i.e., gentamicin or streptomycin), as long as high-level resistance is not detected. This strategy of two-drug therapy has been associated with improved outcomes. This is particularly important in the setting of suspected endocarditis. Even when enterococcus appears susceptible to trimethoprim–sulfamethoxazole in vitro, it should not be used in therapy because clinical failures have been reported secondary to the ability of enterococci to use exogenous folate. Similarly, *E. faecalis* is intrinsically resistant to quinupristin–dalfopristin, which therefore should not be used in therapy for infections caused by this species. Recently, there has been increasing isolation of *E. faecium* strains with intrinsic resistance to penicillins. Still, most *E. faecalis* strains remain susceptible to ampicillin and the related piperacillin, in contrast to most *E. faecium* strains, which are resistant to ampicillin.

If the VRE strains are known to be susceptible, potential therapy in these infections includes linezolid, tigecycline, and daptomycin. Linezolid is commonly the drug of choice,■ although its use is associated with bone marrow suppression, including thrombocytopenia, and has only bacteriostatic activity against the enterococci. Linezolid, when used in combination with selective serotonin reuptake inhibitors, can be associated with serotonin syndrome (Chapter 434). Although daptomycin is not approved by the U.S. Food and Drug Administration (FDA) to treat VRE, it treats skin and soft tissue infections and bacteremia.[6] Tigecycline is FDA approved to treat complicated skin and soft tissue infections and complicated intra-abdominal infections caused by vancomycin-susceptible isolates of *E. faecalis,* but a recent black box warning

by the FDA limits its use. Nitrofurantoin remains an option for VRE UTIs. Given the complexity of enterococcal infections, an infectious disease consult should be considered for therapeutic guidance.

Urinary Tract Infections

A single agent can usually be used to treat enterococcal UTIs, including ampicillin, amoxicillin, penicillin, quinolones, fosfomycin, or vancomycin (E-Table 291-1). Vancomycin is typically reserved for penicillin-allergic patients or if the strain has high-level penicillin resistance. β-Lactam–β-lactamase inhibitor combinations are usually reserved for polymicrobial infections. Nitrofurantoin is also occasionally used because most strains remain susceptible. Fosfomycin is also indicated for UTIs caused by susceptible *E. faecalis*.

Bacteremia without Endocarditis

Many cases of enterococcal bacteremia are transient or self-limited, yet antibiotic therapy with penicillin or ampicillin has been shown to improve outcomes (see E-Table 291-1). Unlike in endocarditis therapy, it is not known whether patients benefit from combination therapy (penicillin or ampicillin or vancomycin plus an aminoglycoside), except perhaps when an indwelling intravascular catheter is present. In the setting of an indwelling intravascular catheter, especially for VRE, removal of the catheter is indicated. If the bacteremia is secondary to another site such as an intraabdominal abscess, drainage of the source is critical to cure.

Endocarditis

Combination therapy (intravenous penicillin, ampicillin, or vancomycin plus an aminoglycoside) is the standard therapy for enterococcal endocarditis. Various combinations have been tried with varying success depending on the species and susceptibilities of the organisms. Doses and durations are found in Chapter 76 and E-Table 291-1, but in general, consultation with infectious diseases experts is indicated. Importantly, the aminoglycoside is used to provide synergistic killing of the organism. The duration of therapy is typically 4 to 6 weeks with longer therapy given to patients who had prolonged symptoms before seeking therapy, prosthetic valve infection, or relapsed after initial treatment. If the causative enterococcal strain is highly resistant to both gentamicin and streptomycin, then alternative agents and durations must be explored, and surgery to excise infected valves should be considered. Optimal therapy of VRE strains that are resistant to ampicillin is not known but includes combination therapy under the guidance of an infectious diseases consultant. Several newly approved agents, including linezolid, and daptomycin could be considered if the strain is found to be susceptible. VRE endocarditis may require early surgery because outcomes with antibiotic therapy alone can be poor. Careful microbiologic and clinical assessment of all patients with enterococcal endocarditis and VRE in particular is helpful in deciding when surgery is necessary. If repeated blood cultures grow for more than 7 days after the initiation of medical therapy or other signs of uncontrolled infection (persistent fever or leukocytosis) are present, surgical repair of the valve or valve replacement should be considered early in the treatment course if there are no absolute contraindications for surgery.

Of note, linezolid resistance is increasingly reported even in patients without previous exposure to the antibiotic. Daptomycin resistance is also reported in both *E. faecalis* and *E. faecium* after prolonged courses of therapy.

PRIMARY PREVENTION

Optimal infection prevention for VRE, similar to many multidrug-resistant bacteria, includes proper use and compliance with hand hygiene, use of contact precautions, proper management and timely removal of urinary and vascular catheters, reduction of antibiotic selective pressure through antimicrobial stewardship, and environmental cleaning of equipment and patient rooms. The latter is particularly important for VRE. A study in a U.S. hospital's medical ICU found that the number of patients already colonized with VRE in a defined geographic area ("colonization pressure") was the most significant variable in predicting new acquisition of VRE. Hence, decontamination of patients' skin, called source control, may broadly control transmission of resistant pathogens and reduce device-related infections such as central venous catheter–associated blood stream infections. Source control using daily bathing of patients with chlorhexidine gluconate-saturated cloths has been associated with reduced VRE contamination of patients' skin and health care workers' hands. A multicenter cluster randomized, cross-over clinical study in ICUs found daily bathing with chlorhexidine gluconate (CHG) solution reduced VRE acquisition by 25% and decreased the risk for VRE bacteremia in known VRE-colonized patients,[A2] although a subsequent trial has cast doubt on the efficacy of such an approach.[7]

The methods for VRE-specific prevention are directed at preventing incident colonization in high-risk hospitalized patients. Nearly all enterococcal infections, including VRE infections, are preceded by GI colonization, and although most colonized patients do not develop infections, they are still able to shed and transmit bacteria to other hospitalized patients. At least with VRE, a colonization-to-infection ratio of 10 : 1 has been reported, suggesting for every one clinical infection in an ICU, there may be 10 colonized patients lurking undetected in the unit. Thus, the unrecognized colonized patients represent the target population for infection prevention and control efforts such as active surveillance. Active surveillance programs use rectal or perirectal surveillance swabs to detect previously unrecognized, colonized patients and isolate them to prevent further transmission. Currently, surveillance cultures are recommended at the time of hospital admission for patients at high risk for carriage of VRE, and colonized patients or infected patients should be placed in isolation using contact precautions. Contact precautions typically entail private rooms, dedicated equipment such as stethoscopes, and gloves and gowns for all patient contact, although in a recent randomized trial in medical and surgical ICUs, the use of gloves and gowns for all patient contact compared with usual care did not result in a difference in the acquisition of VRE (or methicillin-resistant *S. aureus*).[A3] Implicit in this is the continued use of standard precautions that requires cleaning and disinfection of equipment that is used in patient rooms. Many hospitals do use active surveillance in the ICU and other wards with a high prevalence of VRE, although the overall adoption of this strategy has been hindered by the perceived high costs of surveillance programs and lack of available randomized control trial data.

PROGNOSIS

Enterococcal bacteremia is associated with prolonged hospitalization and added costs compared with similar patients without enterococcal bacteremia. Still, apart from enterococcal endocarditis, the attributable mortality of enterococcal infections is difficult to quantify owing to its predilection to infect patients with preexisting comorbid conditions and high levels of illness severity. In certain patient populations, including those with liver and bone marrow transplants, studies have suggested increased morbidity, length of stay, and mortality associated with vancomycin resistance. Furthermore, a recent meta-analysis reported that the odds of dying from a vancomycin-resistant enterococcal blood stream infection were 2.5 times higher than dying from an infection caused by a susceptible enterococcus. The unadjusted mortality in susceptible enterococcal bacteremia was 20%. It is unclear why resistance is associated with higher mortality, although it is thought that delayed adequate empirical therapy may play a role. These studies should be interpreted cautiously because the clinical impact of resistance in enterococci was assessed before the availability of newer antimicrobials with activity against VRE.

REVIEW QUESTIONS

1. Which of the following is a characteristic of the growth of Enterococci?

A. The ability to grow in NaCl broth
B. The β-hemolytic reaction on sheep blood agar
C. The lack of growth on media containing bile
D. The lack of esculin hydrolysis

Answer: A Enterococci are facultative anaerobes that grow optimally at 35°-37 °C and are usually β-hemolytic or nonhemolytic on sheep blood agar. Enterococci can grow in broth containing 6.5% NaCl and hydrolyze esculin in the presence of 40% bile salts (bile-esculin medium) which can distinguish them from most streptococci.

2. Vancomycin-resistant enterococci (VRE) are the result of

A. the acquisition of VanA gene from VRSA (vancomycin-resistant *Staphylococcus aureus*).
B. the selective pressure of antimicrobials on enterococci, including vancomycin.
C. an efflux pump highly active on vancomycin.
D. a porin loss limiting the vancomycin action on the cell wall

Answer: B An example of selective pressure was demonstrated in Europe when the use of specific antimicrobials in animals led to the development of resistance.

3. Among the following antimicrobials, which one is not a treatment of enterococci?

A. Daptomycin
B. Ampicillin
C. Vancomycin
D. Clindamycin

Answer: D (See section on Treatment.)

4. Enterococci are commonly associated will all of these clinical manifestations except

A. wound infection.
B. urinary tract infection.
C. bacteremia.
D. osteomyelitis.

Answer: D Enterococci are known to cause urinary tract infections, intra-abdominal abscesses, wound infections, bacteremia, including catheter-associated bloodstream infections, and endocarditis; less commonly, they cause osteoarticular infections and meningitis.

5. All of the answers below are needed to control the transmission of VRE among hospitalized patients except

A. hand hygiene.
B. contact precaution.
C. screening and treatment of colonized patients with effective antimicrobials.
D. antimicrobial stewardship programs.

Answer: C Screening or surveillance is important to identify the colonized patient and to assure isolation in contact precautions but treatment of colonization is not recommended. Limiting antimicrobial use will help decrease the selective pressure.

DIPHTHERIA AND OTHER *CORYNEBACTERIUM* INFECTIONS

ROLAND W. SUTTER

DEFINITION

Diphtheria is an acute infectious disease caused by toxigenic *Corynebacterium diphtheriae,* a gram-positive bacillus. The hallmark of the disease is the presence of a thick, firmly adherent pseudomembrane at the site of infection. The organism primarily infects the mucosa of the nose, pharynx, tonsils, or larynx

(respiratory diphtheria). Rarely, other mucosal sites may be infected (e.g., conjunctiva, genitals, or ear). In developing countries, a variety of indolent skin lesions (cutaneous diphtheria) are common. Absorption of toxin can result in severe complications such as life-threatening myocarditis or polyneuritis.

The Pathogen

C. diphtheriae is a member of a group of aerobic, nonmotile, unencapsulated, nonsporulating, pleomorphic gram-positive bacilli.[1] Its name comes from the Greek *korynee* (meaning "club"), which describes the shape of the organism on stained smears with one end usually being wider, and *diphtheria* (meaning "leather hide"), for the characteristic adherent membrane.[2] The genus *Corynebacterium* is characterized by bacilli that line up in parallel groups and bend when dividing to create "Chinese character" arrangements. Both nontoxigenic and toxigenic *C. diphtheria* strains exist. Toxigenicity is conferred when a nontoxigenic organism is infected with a β-phage carrying the gene for the toxin (*tox*). *C. diphtheriae* has four biotypes—*gravis, mitis, intermedius,* and *belfanti*—that are distinguished by colonial morphology and varying biochemical and hemolytic reactions. Strains may be distinguished for epidemiologic purposes by molecular techniques. Diphtheria toxin-producing strains of *Corynebacterium ulcerans* can produce classic respiratory diphtheria-like disease, including distal toxic complications.

EPIDEMIOLOGY

Humans are the only natural reservoir of *C. diphtheriae,* although the organism has occasionally been isolated from a variety of domestic and other animals, including horses. Spread occurs in close-contact settings through respiratory droplets or by direct contact with respiratory secretions or skin lesions. The organism may survive for weeks and possibly months on environmental surfaces and in dust, and fomite transmission can occur. The majority of nasopharyngeal *C. diphtheriae* infections may abort or result in asymptomatic carriage, with clinical disease developing in only about one in seven individuals. However, asymptomatic carriers are important in maintaining transmission.

In the prevaccine era, respiratory disease dominated in temperate climates, with a fall and winter peak in incidence. Most individuals acquired natural immunity by the midteen years. Cutaneous disease is more common in tropical countries, but the contribution of cutaneous diphtheria in inducing or maintaining diphtheria immunity in tropical countries is unknown. Over the past 3 decades, outbreaks of cutaneous diphtheria have occurred in the United States and Europe, typically in homeless and alcoholic inner-city adults.

Diphtheria immunization protects against disease but does not prevent carriage. Vaccination with diphtheria toxoid (formalin-treated toxin) was introduced in the 1920s. Immunization of children in an era when the majority of older individuals had natural immunity resulted in a dramatic drop in the incidence of diphtheria and an even more rapid decline in the proportion of toxigenic strains isolated, presumably because the selective advantage of the *tox* gene—promotion of greater replication and spread of the organism—is lost in an immune host. In the postvaccine era, the respiratory diphtheria has virtually been eliminated from developed countries with excellent childhood vaccination coverage.[3] In the United States, reported cases fell from 147,991 in 1920, to 15,536 in 1940, to a total of 55 cases from 1980 to 2012. The absence of reported diphtheria cases in the United States in recent years, however, does not indicate that circulation of toxigenic *C. diphtheriae* has ceased. Investigations in a Northern Plains Indian community in North Dakota and First Nations communities in Ontario, Canada, suggested that *C. diphtheriae* strains might have circulated independently for more than 2 decades in these communities despite the absence of reported respiratory diphtheria cases.

In the absence of natural environmental boosting, vaccine-induced immunity wanes with increasing age and duration since a previous vaccination dose. There is a growing cohort of individuals with no natural diphtheria immunity. Serosurveys indicate that 20% to 60% of adults in industrialized countries have diphtheria antitoxin levels below minimal protective levels. A level of 0.01 IU/mL from an in vitro neutralization assay, the "gold standard" test, is considered the lower limit of protection. Long-term protection against diphtheria requires a level of greater than 0.1 IU/mL. As long as a high proportion of the population remains susceptible, the danger of reintroduction or reemergence of toxigenic strains exists.

Large outbreaks of diphtheria have occurred in the vaccine era. In the 1990s, there was a major resurgence of diphtheria in several countries of the former Soviet Union. In Russia, the number of reported cases rose from 593 in 1989 to 39,582 in 1994, with more than two thirds of cases occurring in adults. Large-scale campaigns of mass administration of diphtheria toxoid to virtually the entire population in the affected new independent states of the former Soviet Union have since led to significant decreases in the incidence of diphtheria, from a peak of 50,449 cases in 1995, to 7197 cases in 1997, to preresurgence levels by the late 1990s (Fig. 292-1). A large outbreak occurred in Indonesia from 2010 to 2012 and in Thailand in 2012.[4] Low vaccination coverage, and non- or inadequate vaccination have been the underlying causes. In general, outbreaks of diphtheria may occur in a suceptible population caused by clonal spread of the organism or transfer of the bacteriophage to nontoxigenic strains of *C. diphtheriae*. Although the reported diphtheria cases have declined globally in the past decade, some countries (e.g., India) continue to have endemic foci.

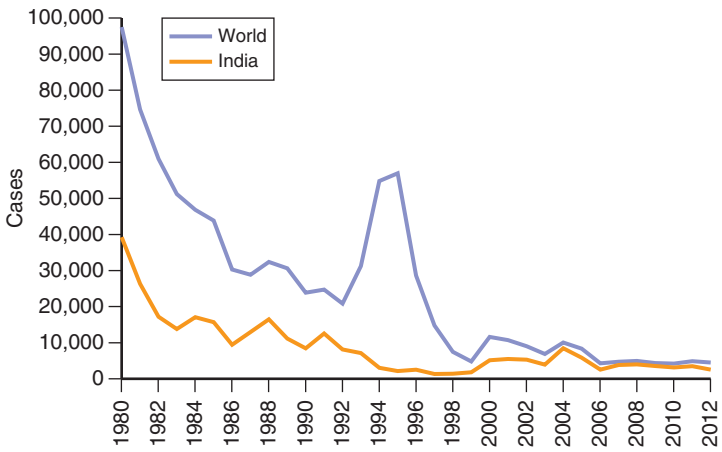

FIGURE 292-1. Reported diphtheria cases, worldwide, 1980 to 2012. (Data from the World Health Organization.)

PATHOBIOLOGY

In classic respiratory diphtheria, *C. diphtheriae* colonizes the mucosal surface of the nasopharynx or larynx and multiplies locally without blood stream invasion.[5] The symptoms and signs of diphtheria are attributable to toxin production. Diphtheria toxin is an extremely potent inhibitor of protein synthesis, and the estimated human lethal dose is 0.1 mg/kg. Released toxin causes local tissue necrosis with the formation of a tough pseudomembrane composed of a mixture of fibrin, dead cells, and bacteria that is firmly adherent to the underling submucosal tissue. The membrane usually begins on the tonsils, on the posterior pharynx, or in the nose. In more severe cases, it progressively extends over the pharyngeal wall, fauces, and soft palate and into the larynx and may result in respiratory obstruction. Toxin entering the blood stream causes tissue damage at distant sites, particularly the heart (myocarditis), nerves (demyelination), and kidney (tubular necrosis). The extent of toxin absorption varies with the site of infection, being much less from the skin or nose than from the pharynx. Nontoxigenic strains may cause mild local respiratory disease and rarely a membrane.

CLINICAL MANIFESTATIONS

Respiratory Diphtheria

Infection limited to the anterior nares (nasal diphtheria) is manifested as a chronic serosanguineous or seropurulent discharge without fever or significant toxicity. A whitish membrane may be observed on the septum. The faucial (pharyngeal) form is most common. After an incubation period of 1 to 7 days, the illness begins with a sore throat, malaise, and mild to moderate fever. Initially, there is mild pharyngeal erythema, usually followed by progressive formation of a whitish tonsillar exudate, which over a period of 24 to 48 hours consolidates into a firmly adherent grayish membrane that bleeds on attempted removal. In more severe cases, the patient appears toxic, and the membrane is more extensive. Cervical lymphadenopathy and soft tissue edema may occur and result in the typical bull neck appearance and stridor. Laryngeal involvement (laryngeal diphtheria), which may develop on its own or as a result of membrane extension from the nasopharynx, is manifested as hoarseness, stridor, and dyspnea. The following clinical classification has been proposed by the World Health Organization: (1) catarrhal form (erythema of pharynx, no membrane), (2) follicular form (patches of exudate,

no pharynx or tonsillar involvement), (3) spreading form (membranes covering the tonsils and the posterior pharynx), and (4) combined form (more than one anatomical site involved, e.g., throat and skin). The more severe clinical manifestations are associated with increasing toxin absorption levels.

The likelihood of toxic complications depends primarily on the interval between disease onset and administration of antitoxin. The severity of disease at initial evaluation closely predicts the likelihood of a severe clinical course, complications, and death. Myocarditis typically occurs in the first or second week after the onset of respiratory symptoms and develops either suddenly or insidiously with signs of low cardiac output and congestive failure. Conduction disturbances, which may occur without other signs of myocarditis, include ST-T wave abnormalities, arrhythmias, and heart block. Neurologic impairment is manifested as cranial nerve palsies and peripheral neuritis.[6] Palatal or pharyngeal paralysis (or both) occurs during the acute phase; peripheral neuritis, symmetrical and predominantly motor, occurs 2 to 12 weeks after onset of the disease. Motor deficit may range from minor proximal weakness to complete paralysis. Complete recovery is the rule. In fulminant, sometimes called "hypertoxic," diphtheria, toxic circulatory collapse with hemorrhagic features occurs.

Cutaneous Diphtheria

Cutaneous diphtheria lesions are classically indolent, deep, punched-out ulcers that may have a grayish-white membrane. However, the lesions may be indistinguishable from impetigo, or *C. diphtheriae* may infect chronic dermatoses such as stasis dermatitis. Coinfection with *Streptococcus pyogenes, Staphylococcus aureus,* or both occurs frequently. Toxic complications of only cutaneous diphtheria are rare.

DIAGNOSIS

A high index of suspicion is required. Specimens for culture should be taken from beneath the membrane, from the nasopharynx, and from any suspicious skin lesions. Because special media are required, the laboratory should be alerted to the concern about diphtheria. *C. diphtheriae* is best isolated on selective media that inhibit the growth of other nasopharyngeal organisms; one containing potassium tellurite is generally used. Based on colonial morphology and Gram stain appearance, a presumptive diagnosis may be possible within 18 to 24 hours. Culture results may be negative if the patient previously received antibiotics. Toxigenicity testing should be performed on all *C. diphtheriae* isolates. Because both nontoxigenic and toxigenic strains may be isolated from the same patient, more than one colony should be tested. Traditional testing methods include guinea pig inoculation and the modified Elek test, in which the isolate and appropriate controls are streaked on a culture plate in which a filter strip soaked with antitoxin has been embedded; toxin production is confirmed by an immunoprecipitation line in the agar. Identification of the diphtheria tox gene allowed the development of rapid and accurate polymerase chain reaction–based methods for identification of toxigenic strains.

Differential Diagnosis

The differential diagnosis includes streptococcal and viral tonsillopharyngitis, infectious mononucleosis, Vincent's angina, candidiasis, and acute epiglottitis. A history of travel to a region with endemic diphtheria or a history of contact with a recent immigrant from such an area increases the suspicion of diphtheria, as does a pre-antitoxin treatment serum antitoxin level of less than 0.01 IU/mL.

TREATMENT

Rx

The decision to initiate therapy should be based on clinical grounds because delayed treatment, especially delays in antitoxin administration, is associated with worse outcomes. The goals of treatment are to neutralize the toxin rapidly, eliminate the infecting organism, provide supportive care, and prevent further transmission (Table 292-1). The mainstay of therapy is equine diphtheria antitoxin. Because only unbound toxin can be neutralized, treatment should commence as soon as the diagnosis is suspected, and each day of delay in administration increases the likelihood of a fatal outcome. A single dose ranging in quantity from 20,000 units for localized tonsillar diphtheria up to 100,000 units is given for extensive disease with severe toxicity. Antitoxin may be administered intramuscularly or intravenously; particularly for more severe cases, the intravenous route is preferred. Tests for sensitivity to antitoxin should be performed according to package insert instructions before administering it and desensitization carried out if necessary. Antibiotic therapy, by eliminating the organism, halts toxin production, limits local infection, and prevents transmission. Parenteral penicillin (4-6 million U/day) and erythromycin (40 mg/kg/day in four divided doses; maximum of 2 g/day, usually orally if the patient can swallow) are the drugs of choice. General supportive care includes ensuring a secure airway (with tracheotomy, if necessary), electrocardiographic monitoring for evidence of myocarditis, treating heart failure and arrhythmias, and preventing secondary complications of neurologic impairment such as aspiration pneumonia. The patient should be in strict isolation until follow-up culture results are negative. Convalescing patients should receive diphtheria toxoid.

The local health department must be notified. Close contacts should have cultures performed and be administered prophylactic antibiotics and brought up to date with an age-appropriate diphtheria toxoid-containing vaccination. A positive culture result in a contact may confirm the diagnosis if the patient is culture negative. All contacts without full primary immunization and a booster within the preceding 5 years should receive diphtheria toxoid.

The availability and access to diphtheria antitoxin has become problematic in recent years. Currently, very few manufacturers exist. In the United States, because manufacturers discontinued diphtheria antitoxin production in 1997, no licensed product is available. However, diphtheria antitoxin for therapeutic purposes can be obtained from the Centers for Disease Control and Prevention (CDC; 770-488-7100), which distributes a Brazilian-produced antitoxin (Instituto Butantan, Sao Paulo, Brazil) under an Investigational New Drug protocol.

TABLE 292-1 GOALS AND PROPOSED INTERVENTIONS FOR THE MANAGEMENT OF SUSPECTED DIPHTHERIA CASES

GOALS	PROPOSED INTERVENTIONS
Neutralize toxin as soon as possible to reduce severe complications, including death.	After a presumptive diagnosis of diphtheria, immediately obtain and administer antitoxin, initiate antimicrobial treatment, and arrange for appropriate supportive care.
Prevent further spread of *Corynebacterium diphtheriae* to close contacts, including hospital staff.	Isolate the patient; strictly observe respiratory barrier procedures. Notify the health department. Review the vaccination status of the family and other close contacts and initiate postexposure prophylaxis.
Confirm the diagnosis.	Collect appropriate specimens for culture (alert the laboratory to ensure that it can prepare specific culture media).
Induce long-term protection against *C. diphtheriae* in case and close contacts.	Complete the primary series with diphtheria toxoid as needed.

PREVENTION

Immunization with diphtheria toxoid is the only effective means of primary prevention. The primary series is four doses of diphtheria toxoid (given with tetanus toxoid and pertussis vaccine) at 2, 4, 6, and 15 to 18 months; a preschool booster dose is given at 4 to 6 years of age. Thereafter, boosters should be given as part of the adolescent immunization visit (i.e., between 11 and 13 years of age) followed by doses administered every 10 years.

For additional protection against pertussis during adolescence, the CDC recommends the routine use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, adsorbed (Tdap), in adolescents 11 to 18 years of age in place of tetanus and diphtheria toxoid (Td) vaccines. Similarly, for adults who have never received a dose of Tdap, the CDC recommends routine use of a single dose of Tdap for adults older than 19 years of age to replace the next booster dose of Td (Chapter 18), although a second dose five years later may be needed to protect against diphtheria.[7]

Genetically altered, fully immunogenic mutants of diphtheria toxin have been created (e.g., CRM197) CRM197 is used as a protein carrier in several polysaccharide–protein conjugate vaccines. However, the role of CRM197 in contributing to or maintaining immunity has not been evaluated.

PROGNOSIS

Diphtheria, at the beginning of the 21st century, remains a serious disease associated with a high case-fatality rate. In the United States, the diphtheria

TABLE 292-2 CORYNEBACTERIA AND RELATED ORGANISMS ASSOCIATED WITH HUMAN DISEASE

SITE OF INFECTION	PATHOGEN	CLINICAL SYNDROME	COMMENTS
Respiratory tract	*Corynebacterium diphtheriae*	Classic diphtheria	
	Corynebacterium ulcerans	Diphtheria	Zoonotic infection; may produce diphtheria toxin
	Corynebacterium pseudodiphtheriticum	Pharyngitis Rarely, pneumonia in patients with advanced AIDS	
	Arcanobacterium haemolyticum	Pharyngitis, tonsillar abscess, rash	Clinically indistinguishable from streptococcal pharyngitis
Skin and soft tissue	*Corynebacterium pseudotuberculosis*	Granulomatous lymphadenitis	Zoonotic infection, especially in sheep; occupational risk for veterinarians and butchers
	Corynebacterium minutissimum	Erythrasma	
	Corynebacterium kroppenstedtii	Granulomatous breast abscess	
Genitourinary tract	*Corynebacterium glucuronolyticum*	UTIs in men; chronic prostatitis	
	Corynebacterium urealyticum	Chronic and recurrent UTIs	More common in elderly, chronically ill, and immunosuppressed patients and in those with indwelling catheters
	Corynebacterium riegelli	Encrusted cystitis	
Health care–associated infections	*Corynebacterium jeikeium* and less commonly many others, including *Corynebacterium amycolatum, Corynebacterium striatum,* and *Corynebacterium urealyticum*	Catheter- and device-associated infections Postprocedure wound and soft tissue infections Prosthetic valve joint infections Nosocomial pneumonia CSF shunt infections	*C. jeikeium* is the most common corynebacterial pathogen in hospitals and causes severe infections in immunosuppressed patients and those with indwelling devices

CSF = cerebrospinal fluid; UTI = urinary tract infection.

case-fatality rate has remained virtually unchanged (between 5% and 10%) over recent decades.

OTHER *CORYNEBACTERIUM* SPECIES

Corynebacteria other than *C. diphtheriae* are ubiquitous in the environment and are among the normal flora colonizing humans and animals. The pathogenic potential of many of these organisms was not appreciated in the past, but many are now known to be associated with specific and often serious infectious diseases, especially in immunosuppressed, chronically ill, and hospitalized patients (Table 292-2). In general, these organisms remain susceptible to vancomycin, but resistance to other classes of antimicrobials is common and varies among species.

REVIEW QUESTIONS

1. A 61-year-old Vietnam veteran with a low socioeconomic status (SES) in Seattle is brought to the emergency department (ED) because of difficulties breathing. On radiography, a lobar pneumonia is demonstrated, and appropriate treatment with antibiotics is initiated. The attending ED physician also notes a rash on the lower extremity. The lesions are deep punched-out non-itching ulcers that are indolent. On culture, *Staphylococcus aureus* is grown. What is the likely diagnosis of the skin rash?

A. Impetigo
B. Cutaneous diphtheria
C. Chronic dermatitis superinfected by *S. aureus*
D. Cat scratch disease
E. Scabies.

Answer: B Cutaneous lesions caused by *Corynebacterium diphtheriae* are typically deep punched-out ulcers in a patient of risk (low SES, probably alcohol abuse, poor hygiene). The isolation *S. aureus* (or other skin bacteria) occurs frequently. *C. diphtheriae* may not be cultured initially because of the need for special media. Impetigo and chronic dermatitis are possible diagnoses but are unlikely given the typical appearance of the lesions (usually honey-colored scabs). Similarly, cat scratch disease is unlikely in the absence of a supporting history of contact with cats. Scabies causes a papular rash with intense itching.

2. A 23-year-old Peace Corps volunteer returns from a 2-year assignment in the rural East Java Province of Indonesia. She presents with sore throat, malaise, and mild to moderate fever for 3 days. Before leaving Indonesia, the patient received erythromycin. On examination, a whitish membrane adheres tightly to the right tonsil. During the swapping of the tonsil for culture, the membrane cannot be removed and starts to bleed at the edge. What is the most likely diagnosis?

A. Streptococcal tonsillitis
B. Plaut Vincent angina
C. Respiratory diphtheria
D. Primary syphilis lesion
E. Infectious mononucleosis (MN) caused by Epstein-Barr virus (EBV)

Answer: C A greyish white pseudomembrane on a tonsil should lead to a high suspicion for diphtheria, as does the history of an extended stay in a developing country where diphtheria is endemic. None of the other diagnoses are associated with the formation of a pseudomembrane.

3. Given a high index of suspicion of respiratory diphtheria in this 23-year-old patient (see question 2), what is the immediate priority?

A. Report the suspected case to the local health department.
B. Inform the laboratory to use special media for culturing (potassium tellurite media).
C. Contact the Centers for Disease Control and Prevention and order equine diphtheria antitoxin.
D. Check the patient's diphtheria toxoid vaccination history.
E. Isolate the patient.

Answer: E In order of priority, it is essential to ensure that the airways are patent. In this case, we have no indication that these are compromised. After the diagnosis of suspected diphtheria is established, the patient needs to be isolated to prevent spread to contacts. The isolation of *Corynebacterium diphtheriae* requires a special media, so the laboratory has to be alerted. Given that the patient has been taking antibiotics for several days, it is unlikely the culture result will be positive. However, because of the potential complications of diphtheria, treatment with equine diphtheria antitoxin should be initiated on the basis of suspicion as soon as possible. Then the local health department should be contacted.

4. Which one is not a likely complication of diphtheria toxin?

A. Myocarditis
B. Kidney (tubular necrosis)
C. Neuropathy (caused by demyelination)
D. Encephalitis
E. Respiratory insufficiency

Answer: D Encephalitis is not a likely complication of diphtheria. Myocarditis occurs up to several weeks after the onset of acute respiratory diphtheria and is associated with a high fatality rate. The kidneys may be affected but recover. The most common form of neuropathy is palatal paralysis or peripheral neuropathy in the lower extremity; both are reversible. Extension of diphtheric membranes into the respiratory tree can lead to respiratory stress and even insufficiency.

5. What recommendations for diphtheria antitoxin vaccination would you make to a 26-year-old oil worker going to the Middle East for several months? The man had received two doses of diphtheria, tetanus, and pertussis (Tdap) vaccine as a child and is leaving the United States in 6 weeks.

A. Give a dose of diphtheria toxoid-containing vaccine (d).
B. Administer a dose of tetanus and diphtheria toxoid (Td).
C. Complete the vaccination schedule with adult-formulation Tdap vaccine before departure.
D. Given the possible adverse events and the unlikely exposure to diphtheria in the oil fields, no further immunization is recommended.
E. Complete the schedule with infant-formulation Tdap vaccine before departure.

Answer: C To have protective antitoxin levels, a full primary series of diphtheria toxin–containing vaccine is needed. In this instance, administer a dose now and a second dose 4 weeks later. A single dose of diphtheria toxoid would be suboptimal and would be a missed opportunity for vaccinating against tetanus and pertussis.

6. Which of the following statements about diphtheria immunization is correct?

A. DTP (diphtheria and tetanus toxoid and pertussis vaccine) should not be administered to pregnant women because of the risk of adverse pregnancy outcomes.
B. Diphtheria-specific IgG levels are higher in infants when their mothers were immunized with DTP 2 years before delivery than when their mothers received DTP in midpregnancy.
C. Adults require boosters of diphtheria toxoid every 10 years even after completing a full series of infant immunizations plus preschool and adolescent boosters.
D. A single booster administration in an adult who had never received DTP immunizations in childhood will provide adequate protection.

Answer: D For adults older than 19 years of age who have never received a dose of DTP, the U.S. Centers for Disease Control and Prevention still recommends the routine use of a single dose of DTP to replace the next booster dose. The Vaccine Adverse Event Reporting System has not identified any concerning events in maternal, infant, or fetal outcomes in pregnant women who received DTP. It has been demonstrated that protective IgG levels in the infants of women immunized with DTP within the past 2 years before delivery is the same as those in infants whose mothers were immunized in the second or third trimester. In fact, it is now suggested that vaccinating mothers in the late second or third trimester of pregnancy is safe and would more likely allow maternal antibody production to reach higher protective levels (to be transferred across the placenta to the fetus) by the time of delivery. The diphtheria prevention protocol involves a primary series of 4 doses of diphtheria toxoid (in the form of DPT) to be administered at 2, 4, 6, and 15 to 18 months; a preschool booster dose to be given at 4 to 6 years of age, and subsequent boosters to be given as part of adolescent immunization visits (between 11 and 13 years of age) followed thereafter by doses administered every 10 years. (See section on Prevention and Kao CM, Schneyer RJ, Bocchini JA. Child and adolescent immunizations: selected review of recent US recommendations and literature. *Office Pediatr*. 2014;26:383-395.)

7. Which of the following statements about diphtheria is correct?

A. Outbreaks of diphtheria can be caused either by clonal spread of toxigenic strains or by transfer of the gene for the toxin via bacteriophage to nontoxigenic strains.
B. The case-fatality rate for diphtheria has decreased dramatically since the advent of childhood immunization for the disease.
C. The extent of diphtheria toxin absorption into the circulation is not dependent on the primary site of infection.
D. Nontoxigenic strains of *Corynebacterium diphtheriae* do not cause clinical illness in humans.
E. Cutaneous diphtheria in North America and Europe occurs almost exclusively in severely immunocompromised individuals.

Answer: A Outbreaks of serious illness can be caused by either toxigenic strains or nontoxigenic strains that have been made toxigenic by transfer of the toxin gene by phages. Infection by nontoxigenic strains of *C. diphtheriae* can cause symptoms, although typically much milder than those caused by toxigenic strains. Although the incidence of diphtheria has plummeted throughout most of the world since the advent of childhood immunization, the case-fatality rate has not changed much; it remains a very serious disease (with case-fatality of 5% to 10% in the United States). The extent of toxin absorption varies with the site of infection, being much less from the skin or nose than from the pharynx. Outbreaks of cutaneous diphtheria have occurred in the United States and Europe typically in homeless and alcoholic inner-city adults, not necessarily those who are severely immunocompromised.

293

LISTERIOSIS

BENNETT LORBER

DEFINITION

Listeriosis is a food-borne infection caused by the gram-positive rod *Listeria monocytogenes*. Most patients have impaired cell-mediated immunity and are seen with life-threatening bacteremia or meningitis. However, a self-limited, febrile gastroenteritis in healthy persons also occurs.

The Pathogen

Widely distributed in nature, *L. monocytogenes* may be found in soil, on vegetation, and in the stool of healthy mammals, including humans. It causes disease in animals, especially herd animals, and in humans. The organism has been isolated from many foods, including raw vegetables, raw milk, fish, poultry, and meat. Unlike most food-borne pathogens, *L. monocytogenes* can grow at refrigerator temperatures.

EPIDEMIOLOGY

Non-perinatal listeriosis is almost always the result of food-borne infection.[1,2] Listeriosis is a relatively rare food-borne illness (≈1% of U.S. cases) but is associated with a case-fatality rate of 16 to 20% (second only to *Vibrio vulnificus* at 35 to 39%) and causes approximately 19 to 28% of all food-borne disease–related deaths.[3] Outbreaks have been documented in association with coleslaw, milk, soft cheeses, pâté, ready-to-eat pork products, deli counter meats, hot dogs, smoked fish, butter, sprouts, taco or nacho salads, and cantaloupes. In 2011, *L. monocytogenes*–contaminated cantaloupes were responsible for the deadliest food-borne disease outbreak in U.S. history, with 28 states reporting illness in 146 persons and death in 30 (21% mortality).[4]

Listeriosis was made a nationally reportable disease in 2000. The Centers for Disease Control and Prevention has established PulseNet (http://www.cdc.gov/pulsenet/), a network of public health and food regulatory laboratories that use pulsed-field gel electrophoresis to subtype food-borne pathogens to detect promptly disease clusters that may have a common source. Presently, the annual incidence of listeriosis is 3 cases per million population, and it accounts for 1800 cases per year and about 400 deaths. Neonates and adults older than 60 years have the highest infection rates. Pregnant women represent 20% of all affected individuals[5]; other adults at increased risk for invasive listeriosis (bacteremia, meningitis) include those with hematologic malignant disease, advanced acquired immunodeficiency syndrome (AIDS), a solid organ transplant, or iron overload and anyone treated with corticosteroids or an anti–tumor necrosis factor agent. However, as many as a fourth of all cases of invasive listeriosis occur in apparently healthy persons, particularly those older than 60 years.

PATHOBIOLOGY

L. monocytogenes enters the human body through the intestine, most often after the ingestion of contaminated food.[6] The bacterium induces its own uptake by gastrointestinal cells and macrophages. Mother-to-child transmission occurs transplacentally or through an infected birth canal. Within the host cell, the bacterium is enclosed in a phagolysosome, but through the production of an exotoxin called listeriolysin O, it destroys the phagolysosome membrane and gains access to the cytoplasm. All pathogenic strains of *L. monocytogenes* produce listeriolysin O, the major virulence factor. Listeriae actively divide in the cytoplasm, migrate to the periphery of the cell by polymerization of host cell actin, and then push out the cell membrane to form pseudopods, which are taken up by adjacent host cells. The bacteria move from cell to cell in this fashion and repeat their life cycle without exposure to antibodies or complement.

After invasion through the gastrointestinal tract, listeriae may disseminate hematogenously to any body site but show a particular tropism for the central nervous system (CNS). Less commonly, listeriae may spread intra-axonally through cranial nerves to reach the CNS; this mode of CNS invasion may result in rhombencephalitis (brain stem infection).

Immunity to listerial infection is handled chiefly through the cell-mediated arm of the immune system. Persons who have had splenectomy or have abnormalities solely of humoral immunity or leukocytes are not at increased risk for infection.

CLINICAL MANIFESTATIONS

The incubation period for invasive listeriosis (time from ingestion of contaminated food to illness) averages about 30 days. Invasive listeriosis in an immunocompromised adult is most often manifested as bacteremia without an obvious focus. In such cases, patients have nonspecific complaints, such as fever, malaise, myalgia, and back pain. Bacteremia is the form of invasive listeriosis that complicates pregnancy; CNS infection is extremely rare in the absence of other risk factors. Listeriosis during pregnancy may lead to spontaneous abortion or neonatal sepsis, but early antimicrobial therapy may result in the birth of a healthy child.[7] Endocarditis with *L. monocytogenes* can occur on both native and prosthetic valves and carries a high rate of septic complications. Endocarditis, but not bacteremia per se, may be a clue to underlying colon cancer; colonoscopy should be considered in all cases of listerial endocarditis.

Persons in whom *L. monocytogenes* bacteremia develops may progress to CNS infection, most commonly manifested as meningitis. *Listeria* has a predilection for infecting brain tissue as well as the meninges, and unlike other common bacterial causes of meningitis, it not infrequently causes encephalitis or brain abscess. Brain abscess as a result of infection by *L. monocytogenes* exhibits unusual features compared with other bacteria: listerial brain abscess coexists with bacteremia in nearly all cases and with meningitis in a fourth; in addition, abscesses are often subcortical.

L. monocytogenes is the most common cause of bacterial meningitis in patients with lymphomas, organ transplant recipients, and patients treated with corticosteroids for any reason. Affected persons usually have the classic acute symptoms of meningitis, but the presentation is subacute (>24 hours) in 60% of cases. Nuchal rigidity is absent in 20%. Focal neurologic findings, including ataxia, tremors, myoclonus, and seizures, may be seen, consistent with the tropism of *Listeria* for brain parenchyma. Gram stain of cerebrospinal fluid (CSF) reveals small gram-positive rods in only about one third of cases. The glucose content in CSF is normal in more than 60% of cases; mononuclear cells predominate in 30%.

Listerial rhombencephalitis[8] is an unusual form of listerial encephalitis that involves the brain stem and, unlike other listerial CNS infections, usually occurs in healthy adults. The typical clinical picture is one of a biphasic illness with a prodrome of fever, headache, nausea, and vomiting lasting about 4 days, followed by the abrupt onset of asymmetrical cranial nerve deficits, cerebellar signs, and hemiparesis or hemisensory deficits or both. Respiratory failure develops in about 40% of patients. Nuchal rigidity is present in about half, and CSF findings are only mildly abnormal, with a positive CSF culture in about 40%. Almost two thirds of patients are bacteremic. Magnetic resonance imaging is superior to computed tomography for demonstrating rhombencephalitis. Mortality is high, and serious sequelae are common in survivors.

Localized infection may occur after hematogenous seeding (e.g., liver abscess, septic arthritis) or, rarely, after direct inoculation (e.g., papulopustular rash, conjunctivitis). Osteoarticular listeriosis[9] primarily involves prosthetic joints, occurs in immunocompromised patients, and requires implant removal for cure.

Well-documented reports of food-borne outbreaks have demonstrated that ingestion of *L. monocytogenes* in a sufficiently large inoculum can result in a self-limited illness consisting of fever, chills, diarrhea, abdominal cramps, and sometimes nausea and vomiting. Symptoms follow exposure by 1 to 2 days and last for about 2 days.

DIAGNOSIS

Differential Diagnosis

Clinical situations in which a diagnosis of listeriosis should be considered include the following:

- neonatal sepsis or meningitis;
- meningitis or parenchymal brain infection in patients with subacute presentations, hematologic malignant neoplasms, AIDS, organ transplantation, corticosteroid immunosuppression, treatment with anti–tumor necrosis factor agents, or age older than 50 years;
- simultaneous infection of the meninges and brain parenchyma;
- subcortical brain abscess;
- fever during pregnancy;
- blood, CSF, or other normally sterile specimen reported to have "diphtheroids" on Gram stain or culture; and
- food-borne outbreak of febrile gastroenteritis when routine cultures fail to identify a pathogen.

The differential diagnosis of listerial CNS infection includes the more common causes of bacterial meningitis and brain abscess; indolent listerial meningitis or rhombencephalitis may mimic CNS tuberculosis.

Laboratory Findings

The diagnosis of listeriosis is made by routine bacterial culture of specimens from usually sterile sites, such as blood or CSF. The laboratory must exercise caution because *L. monocytogenes* may be mistaken for diphtheroids, streptococci, or enterococci. Specific stool culture is recommended only when routine stool cultures are negative in the setting of an outbreak of gastroenteritis; many people have enteric colonization with *L. monocytogenes* without invasive disease. The laboratory must be advised that listerial infection is suspected because the organism is unlikely to be identified with routine stool culture media.

Serologic testing (antibody to listeriolysin O) is not useful for invasive disease but may be helpful in the retrospective identification of food-borne outbreaks of febrile gastroenteritis when routine cultures are negative. Real-time polymerase chain reaction analysis of CSF for the *hly* gene, which encodes listeriolysin O, has been useful in diagnosing CNS listeriosis, including cases in which routine bacterial cultures were negative, but this test is not yet commercially available.[10]

PREVENTION

Guidelines for preventing listeriosis are similar to those for preventing other food-borne illnesses. In general, one should thoroughly cook raw food from animal sources; wash raw vegetables thoroughly before eating; keep uncooked meats separate from vegetables and from cooked and ready-to-eat foods; avoid raw (unpasteurized) milk or foods made from raw milk; and wash hands, knives, and cutting boards after each handling of uncooked foods.

People at high risk for listeriosis (those immunocompromised by illness or medications, pregnant women, and the elderly) may choose to avoid soft cheeses such as feta, Brie, Camembert, blue veined, and Mexican-style cheese such as queso fresco. Hard cheeses, processed cheeses, cream cheese, cottage cheese, and yogurt are safe. Leftover foods or ready-to-eat foods such as hot dogs should be cooked until steaming hot. It is best to avoid foods from delicatessen counters, such as prepared salads, meats, and cheeses, or at least to reheat cold cuts thoroughly until they are steaming hot before eating.

Listeriosis is effectively prevented by trimethoprim-sulfamethoxazole given as *Pneumocystis* prophylaxis to organ transplant recipients, those receiving corticosteroid immunosuppression, or individuals infected with human immunodeficiency virus. Second episodes of neonatal listerial infection are virtually unheard of, and intrapartum antibiotics are not recommended for women with a history of perinatal listeriosis.

Except for transmission from infected mother to fetus, human-to-human transmission of listeriosis does not occur; patients do not need to be isolated.

TREATMENT

Rx

Recommendations for the treatment of infection with *L. monocytogenes* derive from in vitro data, animal models, and clinical experience with small numbers of patients; no controlled trials have been performed to prove the efficacy of one drug over another. Many antimicrobials show in vitro activity against *L. monocytogenes*. Clinical utility is more relevant than in vitro susceptibility test results because cephalosporins and other drugs to which the bacterium appears to be susceptible are inadequate to treat infection.

Twenty percent of cases of bacterial meningitis in those older than 50 years are due to *L. monocytogenes*. Therefore, empirical therapy for bacterial meningitis in all adults older than 50 years should include either ampicillin or trimethoprim-sulfamethoxazole, especially in the absence of associated pneumonia, otitis, sinusitis, or endocarditis, which would suggest a cause other than *L. monocytogenes*. Cephalosporins, commonly used for the treatment of bacterial meningitis, should not be used alone when *Listeria* is a diagnostic consideration.

Ampicillin is generally considered the drug of choice for treating confirmed cases of listeriosis. In cases of meningitis and endocarditis and in patients with severely impaired T-cell function, many authorities recommend the addition of gentamicin to ampicillin for synergy on the basis of in vitro testing and animal models. For meningitis, therapy should be continued for at least 3 weeks; bacteremic patients without CNS involvement may be treated for 2 weeks. Endocarditis and brain abscess should be treated for at least 6 weeks. Meningitis doses should be used to treat all cases of invasive listeriosis, even in the absence of CNS or CSF abnormalities.

In patients with penicillin hypersensitivity, trimethoprim-sulfamethoxazole is the preferred agent. It is bactericidal and appears to be as effective as the combination of ampicillin and gentamicin. Drugs that should be avoided because of treatment failure and relapse include cephalosporins, chloramphenicol, tetracycline, vancomycin, and erythromycin.

Corticosteroids appear to be important adjunctive agents in treating the most common forms of bacterial meningitis. Their role in the treatment of listerial CNS infection is unknown.

Iron is a virulence factor for *L. monocytogenes*, and clinically, iron overload states are risk factors for listerial infection. Therefore, in patients with listeriosis and iron deficiency, it may be prudent to withhold iron replacement until antimicrobial therapy is complete.

PROGNOSIS

Listeria meningitis carries a mortality of about 25%,[11] and mortality is higher in those with underlying malignant disease. Mortality from brain abscess and endocarditis is about 50%; survivors of brain abscess commonly have significant neurologic residua.

REVIEW QUESTIONS

1. Which one of the following individuals is at the highest risk for invasive listeriosis?

A. A 25-year-old with common variable hypogammaglobulinemia
B. A 45-year-old being treated with an anti–tumor necrosis factor agent
C. A 38-year-old with a splenectomy
D. A 52-year-old who has had leukemia and neutropenia
E. A 72-year-old on hemodialysis

Answer: B Invasive listeriosis occurs most often in those with impaired cell-mediated immunity due to underlying disease or due to treatment with drugs such as corticosteroids or anti–tumor necrosis factor agents. Splenectomy, disorders of white blood cell numbers or function, and immunoglobulin disorders are not associated with an increased risk.

2. A 66-year-old man presents with fever and altered consciousness. The findings on examination of his cerebrospinal fluid (CSF) are consistent with bacterial meningitis, and CSF Gram stain shows small, gram-positive rods. He had an anaphylactic reaction to amoxicillin 2 years ago. Which one of the following is the best treatment for this patient?

A. Ceftriaxone
B. Vancomycin
C. Imipenem
D. Trimethoprim-sulfamethoxazole
E. Aztreonam

Answer: D Gram-positive rods in the CSF of a patient with meningitis most likely represent *Listeria monocytogenes*. In those with severe penicillin allergy, trimethoprim-sulfamethoxazole is the recommended agent to treat listerial meningitis. No cephalosporin should be used to treat listeriosis. Vancomycin and imipenem are active in vitro, but treatment failures have been reported. Aztreonam has no anti-listerial activity.

3. An elderly woman is hospitalized with meningitis due to *Listeria monocytogenes*. Which one of the following types of isolation is appropriate for this patient?

A. No isolation required
B. Contact isolation
C. Airborne isolation
D. Droplet isolation

Answer: A Except for transmission from mother to fetus or newborn, human-to-human transmission of listeriosis has not occurred. No isolation is required for those infected with *L. monocytogenes.*

4. Which one of the following is the mechanism by which *Listeria monocytogenes* avoids being killed by phagocytic cells?

A. Inhibition of chemotaxis
B. Inhibition of attachment
C. Inhibition of ingestion
D. Suppression of the metabolic burst
E. Escape from the phagosome

Answer: E The exotoxin, listeriolysin O, is the major virulence factor of *L. monocytogenes* and enables the bacterium to escape from the phagocytic vacuole, whereupon it multiplies in the phagocytic cell cytoplasm.

5. An elderly man is found to have a brain abscess. Which one of the following features is strongly suggestive of *Listeria monocytogenes* as the abscess etiology rather than a more common pathogen?

A. Absence of fever
B. Absence of leukocytosis
C. Location in the pons
D. Focal neurologic findings
E. Presence of seizures

Answer: C Unlike the usual causes of brain abscess, *Listeria* has a particular tropism for the brain stem. Subcortical brain abscesses due to other pathogens are rare; the presence of a subcortical brain abscess should always raise the possibility of listerial infection.

ANTHRAX

DANIEL R. LUCEY AND LEV M. GRINBERG

DEFINITION

Anthrax is caused by *Bacillus anthracis*, a spore-forming, gram-positive rod that is aerobic or facultatively anaerobic. Its name derives from a Greek word for "coal," in reference to the black color of the eschar that forms in cutaneous anthrax. Although it is primarily a disease of animals (zoonosis), anthrax was developed as a biowarfare weapon by several nations in the 20th century and used for bioterrorism in the United States in 2001 when spores were mailed in letters.

The Pathogen

The bacterium is a large (1 to 1.5 by 3 to 5 μm), gram-positive rod. It has a ground-glass appearance of growth on sheep blood agar, with 2- to 5-mm, nonhemolytic, tenacious ("beaten egg white") colonies within 24 hours of culture; oval, central to subterminal spores; and a capsule that can be visualized by India ink staining.

EPIDEMIOLOGY

Human infection with *B. anthracis* is often linked to a zoonotic source, such as cattle, sheep, goats, water buffalo, and other animals. Meat, bones, hides, and hair have been reported to transmit infection. Spores can persist in soil for many years. Spores infect animals or humans, then germinate into the vegetative form of *B. anthracis* and cause disease. The World Health Organization provides an online global epidemiology database for anthrax along with guidelines for management of the disease in animals, humans, and the environment.

A systematic review of the worldwide medical literature found that between 1900 and 2005, at least 82 patients with inhalational anthrax were reported in clinical detail.[1] These 82 cases included 18 patients from the United States with naturally acquired, animal-related disease in the 20th century and 11 patients with inhalational anthrax due to the bioterrorism-related events of 2001. The dozens of patients with inhalational anthrax from the 1979 outbreak in Sverdlovsk that was linked to an accidental release of spores downwind from a military facility, however, were not included in these 82 cases because of unavailability of their clinical records. Only the autopsy records from 1979 were preserved by the pathologists (Abramova and Grinberg), and these were published first in Russian in 1993 and then in English for the 41 cases confirmed by histopathology or microbiology.[2,3]

Between 2006 and 2013, an additional five patients with naturally acquired inhalational anthrax were diagnosed, three in the United Kingdom and two in the United States. In 2009, the first human case in the United States of culture-confirmed gastrointestinal anthrax was diagnosed.[4] At least three of these six sporadic cases, including the gastrointestinal case, were linked to exposure to spores contaminating drums made from animal hides. The source of exposure was uncertain for the others. More typically, gastrointestinal anthrax is linked to consumption of meat from infected animals.

Importantly, *B. anthracis* is not transmitted from person to person through the air. Moreover, only one quarter of the 41 autopsy-confirmed inhalational cases in 1979 had any evidence of pneumonia, specifically an acute hemorrhagic pneumonia. All had the characteristic hemorrhagic mediastinal adenopathy, edema, and pleural effusions caused by the primary inhalation of spores. Infection by reaerosolization was suspected in a small number of these patients in 1979.

In support of this reaerosolization hypothesis, a detailed review of the experimental literature found evidence that spores from *Bacillus* species could reaerosolize under outdoor conditions.[5] Moreover, a study of the spores in a contaminated U.S. Senate Office concluded that spores used in a terrorist incident reaerosolized under common office activities.

The most common form of anthrax is the cutaneous form. Direct contact with infected animals or contaminated animal products is the usual mode of transmission. One of the lessons from the 2001 bioterrorist attacks in the United States, however, is that spores in the mailed letters caused cutaneous anthrax in 11 persons, none of whom had inhalational anthrax. Of note, therefore, unexplained cutaneous anthrax cases could be an early clue to an intentional release of spores, especially given that the shortest part of the incubation period in humans for cutaneous anthrax (1 to 12 days) is less than that for laboratory-documented inhalational anthrax (4 to 43 days).

In 2009-2010, at least 80 confirmed or probable cases of anthrax occurred in persons who injected heroin in Europe, primarily in the United Kingdom.[6] In 2012-2013, at least another 14 cases occurred, again in the United Kingdom[7] but also in Denmark, France, and Germany. A new term, *injection anthrax*, was applied to this novel route of infection and distinct clinical syndrome that involved severe soft tissue infection at the site of the injection and sometimes systemic disease. The single strain of *B. anthracis* in these outbreaks most closely matched that reported from a goat in Turkey, suggesting that heroin originating in Afghanistan or Pakistan and smuggled overland in an animal skin may have been the source of these spores in Europe.

PATHOBIOLOGY

Major virulence factors of *B. anthracis* include its two binary toxins, edema toxin and lethal toxin, and also its antiphagocytic poly-D-glutamic acid capsule. Edema toxin consists of edema factor bound to a third anthrax toxin component, protective antigen. Similarly, lethal toxin consists of lethal factor bound to protective antigen. These three toxin components, edema factor, lethal factor, and protective antigen, are encoded on one plasmid (pX-01). The antiphagocytic capsule is encoded on a second plasmid (pX-02). Both plasmids are necessary to cause disease.

The pathogenesis of anthrax has been attributed primarily to its two binary toxins. However, more recently, key roles for both nontoxin and toxin components have been implicated in the pathogenesis of the characteristic cardiac and endovascular abnormalities,[8] bleeding, and shock. Nontoxin components include the peptidoglycan part of the bacterial cell wall and nontoxin metalloproteinases. Moreover, inhibition of both innate and adaptive immune responses occurs by the activities of both toxins and the antiphagocytic capsule.

Similarly, the sepsis model has been proposed to explain the high lethality of inhalational anthrax, rather than the toxin model.[9] In this sepsis model, the primary role of anthrax toxin is to inhibit the immune response against the vegetative form of the bacteria, thus allowing the typically high levels of bacteremia to develop and subsequent shock, multiorgan failure, and death to occur.

Lethal toxin[10] is a metalloproteinase and inhibitor of the mitogen-activated protein kinase intracellular signal transduction pathway. It contributes to the coagulation disorder, hemolysis, and hemorrhage seen with inhalational anthrax. Whether lethal toxin contributed to the vasculitis lesions reported in the 1979 outbreak in Sverdlovsk is uncertain. Edema toxin contributes to the typical "gelatinous" fluid in the mediastinum and abdomen as well as the marked edema seen in both cutaneous anthrax and injection anthrax. The

mechanism is attributed to excessive production of cyclic adenosine monophosphate from adenosine triphosphate, by edema toxin acting as an adenylate cyclase enzyme. The result is water and calcium dysregulation with marked edema.

CLINICAL MANIFESTATIONS

Major clinical manifestations of anthrax infection—inhalational, cutaneous, gastrointestinal, injection, and meningeal—are related to the routes through which *B. anthracis* can enter the body: inhalation, contact, ingestion, or injection (e.g., by contaminated heroin).[11]

Inhalational anthrax[12] almost always causes hemorrhagic mediastinitis, gelatinous edema, and mediastinal adenopathy, resulting in mediastinal widening, as well as pleural effusions due to blockage and reversal of normal lymphatic flow and drainage within the mediastinum. These pleural effusions can be large, bloody, and recurring unless repeatedly drained by thoracentesis or chest tube. Such effusions were found to contribute to respiratory failure in the 1979 outbreak in Sverdlovsk, in part due to compression of lung parenchyma and impaired gas exchange. During the outbreak, the pleural fluid was drained by thoracentesis, rather than by chest tube, and antibiotics were injected into the pleural space. Nevertheless, nearly every patient with inhalational anthrax who underwent autopsy in this outbreak was found to have large (average, 1776 mL) pleural effusions. Although it was not known in 1979 or in 2001, these pleural effusions can serve as a reservoir for toxin. Pleural fluid toxin levels were not tested until the two U.S. patients in 2006 and 2011. High levels of lethal factor were reported.

Radiography demonstrated pulmonary infiltrates in 7 of the 11 patients in 2001 in the United States as well as in both U.S. patients in 2006 and 2011. Thus, although inhalational anthrax has been stated by some not to cause pneumonia, these radiologic findings serve to emphasize the important diagnostic point for clinicians that not only mediastinal widening and pleural effusions but also pulmonary infiltrates are often seen. Moreover, in the 1979 outbreak in Sverdlovsk, one quarter of the 41 autopsy-confirmed cases had a hemorrhagic pneumonia. Thus, pulmonary infiltrates on radiologic imaging, whether or not interpreted as pneumonia, do not rule out the diagnosis of inhalational anthrax.

In 2005, a new three-part clinical staging system for inhalational anthrax (Table 294-1) was published, adding an intermediate progressive stage based on clinical, microbiologic, and radiologic information acquired from the 11 patients in 2001. Previously, these patients would have been included in the late stage, for whom death was considered almost certain. Importantly, all six of the patients who survived the anthrax attacks in 2001 had rapid therapy initiated, including pleural drainage, during this intermediate progressive stage. This three-part symptomatic clinical staging system is cited at www.cidrap.umn.edu/idsa/bt/anthrax/biofacts/anthraxfactsheet.html.

Although in 2001 none of the five patients in the late fulminant stage survived, the two U.S. patients in 2006 and 2011 both survived even though they required mechanical ventilation, placing them in the late fulminant stage. One additional treatment they received was anthrax antitoxin, which was not available in 2001.

The shortest incubation period that has been *documented* microbiologically or histopathologically is 4 days. The range is 4 to 43 days. Although shorter incubation periods may have occurred, none have been documented in the English literature by these laboratory criteria.

Cutaneous anthrax accounts for about 95% of patients with anthrax. The incubation period ranges from 1 to 12 days. Like the three clinical stages of symptomatic inhalational anthrax, three stages of cutaneous anthrax can be delineated: (1) an initial pruritic papule progressing to (2) a central vesicular or bullous lesion with surrounding nonpitting edema and finally (3) a necrotic and hemorrhagic central lesion that evolves into the classic painless eschar with surrounding edema. Resolution can take up to 2 months. This three-stage progression can occur even if appropriate antibiotics are given. During the anthrax letter attacks of 2001, some of the cutaneous lesions were initially considered to be due to brown recluse spider bites. These lesions are usually painful, unlike the painless lesions of anthrax.

In contrast to cutaneous anthrax, injection anthrax[13] described from Europe in persons injecting spore-contaminated heroin does not typically develop a black crusted eschar, can be painful, and can present with severe gastrointestinal or central nervous system manifestations that can rapidly lead to death. The 2011 official report from Health Protection Scotland on outbreaks of this novel form of anthrax advises physicians to suspect injection anthrax in heroin users who demonstrate any of three presentations: (1) severe soft tissue infection including necrotizing fasciitis and cellulitis/abscess, especially if marked edema is present (Fig. 294-1); (2) signs of sepsis even if no soft tissue infection is evident; and (3) meningitis or subarachnoid hemorrhage/intracranial bleed.

Gastrointestinal anthrax is divided into an oropharyngeal form and an intestinal form. The oropharyngeal form has painful cervical adenopathy and an incubation period between 2 hours and 6 days. The oral lesions can ulcerate. They also can progress to cause a white pseudomembrane with dysphagia and hoarseness. The intestinal form has been described to have three clinical phases, much like the three-part progressive clinical stages of inhalational anthrax and cutaneous anthrax: (1) a prodromal phase with fever, malaise, and sometimes syncope; followed by (2) a progressive phase with abdominal

TABLE 294-1 CLINICAL STAGING SYSTEM FOR INHALATIONAL ANTHRAX

I. EARLY PRODROMAL STAGE

Nonspecific illness sometimes described as "flulike" and including any of the following: fever, cough, headache, chills, nausea, chest pain, or abdominal pain. Laboratory tests and radiographs are nondiagnostic. The prognosis for cure is good with appropriate therapy, but the diagnosis is difficult to confirm acutely in this stage.

II. INTERMEDIATE PROGRESSIVE STAGE

Any of the following findings are defining inclusion criteria for this stage:
1. Positive blood cultures (typically positive in <24 hours)
2. Mediastinal adenopathy
3. Pleural effusions: bloody, often large, require drainage, and may recur

Findings in this stage may include high fever, dyspnea, confusion or syncope, or increasing nausea and vomiting. Exclusion criteria for this stage include the following:
1. Meningitis
2. Respiratory failure requiring intubation and mechanical ventilation or
3. Shock

Importantly, patients in the intermediate progressive stage can still be cured with appropriate antibiotics and drainage of pleural effusions by repeated thoracentesis or preferably chest tube to keep the pleural space dry in order to reduce the adverse mechanical effect on respiration by large-volume effusions and to remove potentially toxin-producing *Bacillus anthracis* from the pleural space.

III. LATE FULMINANT STAGE

Inclusion criteria include any one of the following findings:
1. Meningitis
2. Respiratory failure requiring intubation and mechanical ventilation
3. Shock: end-organ hypoperfusion

Findings in this stage may also include any of those from previous stages, so there are no exclusion criteria. The probability of survival is lowest in this stage. Novel therapeutics that safely and effectively neutralize anthrax toxin may be needed to increase survival.

FIGURE 294-1 An example of the lesions due to injection anthrax.

pain, nausea, vomiting, abdominal distention, ascites, and severe weakness; and finally (3) a fulminant phase with rapidly increasing abdominal girth and expanding ascites, paroxysmal abdominal pain, and shock. Of note, the U.S. patient with gastrointestinal anthrax in 2010 who survived had more than 50 liters of ascitic fluid drained as part of her therapy along with antibiotics and anthrax antitoxin.

Anthrax meningoencephalitis can occur in association with any of the other forms of anthrax, inhalation, cutaneous, gastrointestinal, or injection, and rarely without a known portal of entry. Cerebral edema, parenchymal brain hemorrhage, vasculitis, and subarachnoid hemorrhage can occur. The cerebrospinal fluid is often bloody with anthrax meningitis. At autopsy, the extensive bleeding gives a characteristic macroscopic appearance termed the cardinal's cap. This form of anthrax remains fatal in more than 95% of cases.

DIAGNOSIS

If anthrax is suspected, blood should be obtained immediately before any antibiotics are given, primarily for microbiologic culture and possibly for newer assays for anthrax toxins whenever available. Notably, blood cultures from patients with inhalational anthrax will grow the large, gram-positive rods within 24 hours. Given such high levels of bacteremia, it is surprising that even one dose of an effective antibiotic has been reported to turn blood cultures negative, hence the need to draw blood culture samples before antibiotics are given. Toxin assays could still be positive after initial antibiotics, but these assays are still investigational at this time. Nasal cultures should not be performed as a routine clinical diagnostic test for individual patients because a negative result does not rule out inhalation of spores. Nasal cultures could be epidemiologically useful, however, as part of an investigation to help estimate the perimeter of exposure to spores.

In the microbiology laboratory, if the initial culture is suggestive of *B. anthracis*, three tests can be performed with a biosafety cabinet. These are assays for motility (nonmotile), catalase (positive), and hemolysis (negative). If these characteristics are found, identification is still not proved until a sample is sent to a reference laboratory where polymerase chain reaction analysis can identify *B. anthracis* and gamma-phage lysis of the encapsulated bacteria can provide confirmation. One or more antibody tests also are available, although results are unlikely to be positive during the earliest part of the disease. In contrast, a number of investigational anthrax toxin tests (e.g., for lethal factor, edema factor, or protective antigen) are being developed that should have positive results early in the disease, even if antibiotics have been given, and may also have prognostic value. At the time of this writing, these assays are available in the United States only through the Centers for Disease Control and Prevention (CDC).

A noncontrast computed tomography scan of the chest can be a valuable adjunctive diagnostic tool for inhalational anthrax. It is more sensitive than a chest radiograph for demonstrating the characteristic hyperattenuating mediastinal adenopathy causing the mediastinal widening and pleural effusions. The hyperattenuation is consistent with bleeding into lymph nodes and thus helps differentiate inhalational anthrax from tularemia, histoplasmosis, tuberculosis, sarcoidosis, and most other causes of mediastinal or hilar adenopathy.

Anthrax meningitis is typically neutrophilic and bloody. Very large gram-positive rods in the cerebrospinal fluid distinguish anthrax meningitis from other causes of gram-positive meningitis, such as the smaller *Listeria monocytogenes*. In the February 2014 *Emerging Infectious Diseases* online journal, the CDC published its first formal updated guidelines on anthrax since 2001, including diagnostic tests, prophylaxis, treatment, and monitoring.[14] New diagnostic recommendations include a lumbar puncture at admission unless it is contraindicated because new treatment recommendations will be based in part on whether meningitis has been excluded.

TREATMENT

Rx

Treatment of symptomatic anthrax includes antibiotics and, in the case of inhalational anthrax, pleural fluid drainage. In addition, in December 2012, the Food and Drug Administration (FDA) licensed the first anthrax antitoxin for treatment of inhalational anthrax. The CDC recommendations for prevention and treatment were updated in 2014, and the reader is referred to their webpage for complete details.[14]

Treatment with three intravenous antibiotics is recommended in the 2014 CDC recommendations if meningitis is possible or confirmed. These include a bactericidal fluoroquinolone (ciprofloxacin is the preferred drug), a bactericidal β-lactam (meropenem is the preferred drug), and a protein synthesis inhibitor (linezolid is the preferred drug). If meningitis is excluded, a bactericidal drug (ciprofloxacin is preferred) and a protein synthesis inhibitor (either clindamycin or linezolid) is preferred.

A total 60-day course of antibiotic therapy, of at least 2 weeks intravenously with more than one drug followed by the remainder with one oral drug, is recommended for inhalational anthrax because of concern that spores may germinate into vegetative bacteria if therapy is stopped sooner.

An essential treatment modality for inhalational anthrax is pleural drainage. The CDC 2014 guidelines state: "Drainage of pleural fluid and ascites is believed to improve survival by reducing the toxin level and by decreasing mechanical lung compression. These data support the need for early and aggressive drainage of any clinically or radiographically apparent pleural effusions; chest tube drainage is recommended over thoracentesis because many effusions will require prolonged drainage. Thoracotomy or video-assisted thoracic surgery might be required to remove gelatinous or loculated effusions."

As of 2014, there are two types of anthrax toxin antibodies in the Strategic National Stockpile. One is polyclonal, called intravenous anthrax immune globulin, and is derived from the plasma of persons who have received the anthrax vaccine. It is still investigational, and the investigational new drug protocol is held by the CDC in Atlanta. Intravenous anthrax immune globulin has been given as adjunctive therapy to several patients, including three in the United States in 2006, 2009, and 2011 as well as several patients in the United Kingdom. The other antitoxin is a humanized monoclonal antibody called raxibacumab that was licensed by the FDA in December 2012 for treatment of inhalational anthrax in both adults and children.[15] It has not been given to any patients with anthrax as of February 2015 but was licensed by the FDA on the basis of efficacy in animal models of inhalational anthrax plus human safety data in healthy volunteers. It does not cross the blood-brain[16] barrier. It is given intravenously during 2 hours and 15 minutes, after a single dose of the antihistamine diphenhydramine.

PREVENTION

Clinical anthrax can be prevented by preexposure vaccination or by postexposure prophylaxis with antibiotics. Moreover, in December 2012, the monoclonal antibody antitoxin (raxibacumab) was licensed by the FDA for postexposure prophylaxis in both adults and children "when alternative therapies are not available or not appropriate."

The current FDA-licensed anthrax vaccine (as of 1970) contains protective antigen as the vaccine antigen and alum as an adjuvant.[17] It requires five injections during an 18-month period when it is given before exposure. In contrast, postexposure prophylaxis, which is an off-label use of this same vaccine and thus needs an investigational new drug or emergency use authorization protocol, requires only three injections given during a 1-month period. This vaccine is in limited supply and is dedicated primarily for use by the military; however, it is available to civilian populations through at least one commercial travel clinic.

Antibiotics that are approved by the FDA for postexposure prophylaxis include ciprofloxacin, doxycycline, and procaine penicillin G as well as levofloxacin. Either doxycycline or ciprofloxacin is recommended as the preferred drug by the CDC for initial prophylaxis when the antibiotic susceptibility of an anthrax strain is unknown. During pregnancy, however, ciprofloxacin is preferred to doxycycline according to 2014 CDC guidelines. The CDC website on anthrax (at http://www.bt.cdc.gov/agent/anthrax) has detailed recommendations regarding the choice of antibiotics, doses, and durations for both prevention and treatment of anthrax.

Prevention of anthrax due to bioterrorism remains a national priority. A suspicion of clinical anthrax or exposure to spores warrants immediate involvement of law enforcement authorities because of the possibility of a criminal act. Evolving approaches for detecting and responding to any future bioterrorism attacks with anthrax include the BioWatch system to detect aerosolized threats and the Autonomous Detection System in postal facilities. The Cities Readiness Initiative was initially described on the CDC website in June 2004 as a program for multiple U.S. cities to help prepare for large-scale public health emergencies, including bioterrorism attacks (e.g., with aerosolized anthrax or another organism). Large volumes of medical supplies, including but not limited to antibiotics, can be delivered rapidly from the Strategic National Stockpile to one or more cities followed by local distribution. The 2012 Institute of Medicine report titled *Prepositioning Antibiotics for Anthrax* discusses the Strategic National Stockpile, Cities Readiness Initiative, BioWatch, and antibiotic issues including defining multidrug-resistant and extremely drug-resistant strains.

PROGNOSIS

The inhalational anthrax of all six patients who survived the attacks of 2001 was diagnosed during the intermediate progressive stage, and prompt therapy prevented progression beyond this stage. The 45% case-fatality rate in 2001 was much improved over the 88% rate seen in the United States from 1900 to 1976. Survival is more likely in patients who undergo pleural drainage, receive multidrug antibiotic regimens, do not require intubation or tracheotomy, and do not progress to anthrax meningoencephalitis. Of note, two patients with inhalational anthrax in the United States (in 2006 and 2011) with respiratory failure requiring mechanical ventilation have survived. Whether the addition of antitoxin to their intensive care, multiple antibiotics, and pleural drainage played a causal role in their survival is uncertain. Their survival emphasizes, however, that even patients in the late fulminant stage can sometimes survive.

The mortality from cutaneous anthrax is approximately 20% if it is untreated, particularly in patients in whom upper airway compression develops from a lesion on the neck or in whom secondary bacteremic anthrax meningitis develops. Anthrax meningitis remains fatal in more than 95% of victims, and thus better therapies are needed. The FDA licensure of the first anthrax antitoxin for both children and adults, as therapy and also as postexposure prophylaxis when alternative therapies are not available or not appropriate, may improve clinical outcome in systemic forms of anthrax. An antitoxin is still needed, however, that can treat anthrax meningitis.

FUTURE DIRECTIONS

A rapid test is still needed for the diagnosis of infection with *B. anthracis* in the early prodromal stage of the illness or in later clinical stages if the patient received antibiotics before blood culture samples were obtained. Such a test is likely to be based on a toxin or a toxin component. Ideally, it should be available at the point of care.

Anthrax toxin inhibitors, in conjunction with antibiotics, could be particularly useful in treating patients who have progressed into the systemic stages of anthrax as a result of inhalational, gastrointestinal, or injection anthrax causing serious soft tissue infection. In addition, antitoxin could be useful in the setting of infection with an engineered form of multidrug-resistant or extremely drug-resistant anthrax. New anthrax vaccines are still being tested. A shorter series of primary and booster doses for the only licensed vaccine was reported in December 2013. Criteria have been established for approval by the FDA of this vaccine specifically in the setting of postexposure prophylaxis. Meeting these criteria and obtaining licensure of the vaccine for postexposure prophylaxis will be a major advance.

REVIEW QUESTIONS

1. A 56-year-old man is diagnosed with inhalational anthrax. His blood cultures are positive for *Bacillus anthracis*. His noncontrast chest computed tomography scan shows mediastinal adenopathy and moderate-sized bilateral pleural effusions. He is receiving several appropriate antibiotics. According to the 2014 anthrax management guidelines from the Centers for Disease Control and Prevention (CDC), what is recommended to be done with regard to the pleural effusions?

A. Follow closely on a daily basis to be sure they decrease in size with antibiotics.
B. Drain by thoracentesis only if they enlarge after 48 hours with antibiotics.
C. Drain immediately by thoracentesis but without chest tube drainage.
D. Perform thoracentesis on one side and send fluid for anthrax toxin levels.
E. Perform bilateral chest tube drainage at this time.

Answer: E Retrospective analysis of the 1979 inhalational anthrax outbreak in Sverdlovsk, USSR, the 2001 outbreak in the United States, and the recent findings of high levels of anthrax toxin in the pleural fluid support the CDC's 2014 guidelines on aggressive management of pleural effusions. The CDC now advises: "Drainage of pleural fluid and ascites is believed to improve survival by reducing the toxin level and by decreasing mechanical lung compression. These data support the need for early and aggressive drainage of any clinically or radiographically apparent pleural effusions; chest tube drainage is recommended over thoracentesis because many effusions will require prolonged drainage."

2. In December 2012, the Food and Drug Administration (FDA) licensed the first anthrax antitoxin. This product is a humanized monoclonal antibody. Which of the following choices is *not* included in the FDA licensure of this antitoxin?

A. Treatment of children during any stage of inhalational anthrax
B. Treatment of adults during any stage of inhalational anthrax
C. Treatment of children with only early-stage inhalational anthrax
D. Postexposure prophylaxis when alternative therapies are unavailable
E. Postexposure prophylaxis when alternative therapies are not appropriate.

Answer: C This monoclonal anthrax antitoxin was licensed by the FDA in December 2012 for treatment of inhalational anthrax in both children and adults at any stage of the disease (early prodromal, intermediate progressive, or late fulminant). In addition, this antitoxin was licensed for postexposure prophylaxis in both children and adults "when alternative therapies are not available or not appropriate." (See discussion in the Prevention and Treatment sections.)

3. The CDC recommendations for use of the anthrax vaccine specifically for postexposure prophylaxis, in addition to an antibiotic, is for which of the following number of vaccine doses and schedules?

A. One dose of vaccine as soon as possible after exposure to spores
B. Two doses of vaccine during a 1-month period
C. Three doses of vaccine during a 1-month period
D. Three doses of vaccine during a 12-month period
E. Five doses of vaccines during an 18-month period

Answer: C Anthrax vaccine is recommended by the CDC in their 2014 guidelines specifically for postexposure prophylaxis as three doses of vaccine given during a 1-month period. In contrast, the FDA-licensed anthrax vaccine for the traditional preexposure use requires five injections given during an 18-month period. (See discussion in the Prevention section.)

4. Antibiotics that are approved by the FDA for postexposure prophylaxis include all of the following except

A. Levofloxacin
B. Ciprofloxacin
C. Procaine penicillin G
D. Clindamycin
E. Doxycycline

Answer: D Ciprofloxacin, doxycycline, levofloxacin, and procaine penicillin G are all approved by the FDA for postexposure prophylaxis use to prevent symptomatic anthrax. Clindamycin is not approved for postexposure prophylaxis; however, it is included in the 2014 CDC recommendations for treatment of some patients with symptomatic anthrax infection. (See discussion in the Prevention section.)

5. Blood culture samples drawn before antibiotics are administered typically will start growing *Bacillus anthracis* in patients with inhalational anthrax within what time frame?

A. 6 hours
B. 24 hours
C. 48 hours
D. 1 week
E. Will not grow in standard culture media

Answer: B A striking and consistent finding in all patients since the 2001 U.S. outbreak of inhalational anthrax is the growth within 24 hours of *Bacillus anthracis* from blood cultures of patients who were not already receiving antibiotics when the blood culture samples were drawn. This crucial observation emphasizes the diagnostic importance of drawing blood culture samples in any patient suspected of having inhalational anthrax before antibiotics are started. (See discussion in the Diagnosis section.)

ERYSIPELOTHRIX INFECTIONS

ANNETTE C. REBOLI

DEFINITION

Erysipelothrix rhusiopathiae causes three well-defined patterns of human infection: (1) erysipeloid, a cellulitis of the fingers and hands (also known as whale finger or pork finger), which is the most common manifestation of infection with *E. rhusiopathiae*; (2) a diffuse cutaneous form; and (3) a bacteremic form, with or without cutaneous involvement, usually complicated by endocarditis.

The Pathogen

E. rhusiopathiae is a thin, pleomorphic, nonsporulating, microaerophilic gram-positive rod. It may be confused with other gram-positive bacillary organisms, particularly *Listeria monocytogenes* (Chapter 293) and *Corynebacterium* species (Chapter 292). It can be differentiated from *L. monocytogenes* by its lack of motility, lack of catalase and coagulase production, and resistance to neomycin. Most strains of *E. rhusiopathiae* produce hydrogen sulfide on triple sugar iron agar slants, a feature that distinguishes *E. rhusiopathiae* from *L. monocytogenes* and from corynebacteria. Because α-hemolysis may be seen after 48 hours of incubation of *E. rhusiopathiae*, confusion with streptococci may also occur. The term *erysipeloid* refers to cutaneous infection by *E. rhusiopathiae* and should not be confused with erysipelas (see Fig. 441-4), which is a superficial cellulitis caused by streptococci or staphylococci.

EPIDEMIOLOGY

E. rhusiopathiae is found worldwide as a commensal or as a pathogen in a variety of wild and domestic animals, including swine, sheep, cattle, horses, dogs, cats, rodents, chickens, ducks, turkeys, penguins, and parrots, as well as in flies, ticks, mites, and lice. The greatest commercial impact of *E. rhusiopathiae* infection is due to disease in swine, but infection of sheep and poultry is also important economically. Environmental surfaces in contact with infected animals or their products are potential sources of *E. rhusiopathiae.* It can persist for prolonged periods in contaminated soil. *E. rhusiopathiae* is killed within 15 minutes by heating to 55° C and by several commercially available home disinfectants.

The incidence of cutaneous infection in humans seems to be decreasing because of technologic advances in animal industries. Infection is usually the result of contact with infected animals or their products. Persons at greatest risk for infection include fishers, fishmongers, farmers, butchers, slaughterhouse workers, and veterinarians.[1] The organism gains entry through cuts and abrasions on the skin. The seasonal incidence of erysipeloid parallels that of swine erysipeloid and is highest in the summer and early fall. The rare instances of systemic infection that do not have an occupational link tend to occur in immunocompromised hosts, suggesting that oropharyngeal or gastrointestinal colonization with the organism may occur. Chronic alcoholism has been acknowledged as a common underlying condition. Erysipeloid and erysipeloid with bacteremia have been reported rarely after cat and dog bites, suggesting that *E. rhusiopathiae* may be part of the oral flora of these animals.

PATHOBIOLOGY

The virulence of *E. rhusiopathiae* is associated, at least in part, with resistance to phagocytosis by polymorphonuclear leukocytes. This antiphagocytic ability results from the organism's possession of a capsule. In the absence of specific antibodies, *E. rhusiopathiae* evades phagocytosis, but even if it is phagocytosed, it is able to replicate intracellularly in these cells. Other virulence factors include enzymes (neuraminidase and hyaluronidase) and surface proteins.

CLINICAL MANIFESTATIONS

Because of the mode of acquisition (contact with infected animals or their products, with organisms inoculating abrasions on the skin), lesions are usually confined to the fingers and hands (Fig. 295-1). A well-defined, slightly elevated, violaceous lesion accompanied by a very painful, throbbing, burning, or itching sensation develops within 2 to 7 days of traumatic dermal inoculation. The infected area is swollen. Vesicles may be present, but suppuration is absent. The lesion spreads slowly to other fingers but rarely involves the fingertips or the skin above the wrist. As the lesion spreads peripherally, the central area clears.[2] Systemic signs and symptoms are rare. There may be sterile arthritis of an adjacent joint. Regional lymphadenopathy or lymphadenitis occurs in about 20% of cases, and low-grade fever develops in approximately 10%. Lesions usually resolve within 3 weeks without treatment. Relapse occurs in 1% of cases.

The diffuse cutaneous form is rare. The cutaneous lesion progresses proximally from the site of inoculation or appears at remote areas. Patients often have fever and arthralgias, but blood cultures are generally negative.

Systemic infection with *Erysipelothrix* is uncommon. More than 90 cases of bacteremia have been reported; most of the patients had endocarditis. Although cases of prosthetic valve endocarditis have been reported, most cases have involved native valves. In 60% of cases, infection developed on apparently normal heart valves. One third of patients had an antecedent or concurrent skin lesion of erysipeloid. The clinical manifestations of endocarditis secondary to *E. rhusiopathiae* and other microorganisms are similar. *E. rhusiopathiae* endocarditis correlates highly with occupation, exhibits a tropism for the aortic valve, affects more males than females, and is associated with high mortality.[3] The high mortality may reflect a delay in appropriate therapy because of the empirical use of vancomycin, which is not an effective treatment of *E. rhusiopathiae.* Cases of *E. rhusiopathiae* endocarditis have been

FIGURE 295-1. Erysipeloid with its characteristic purple, nonpurulent swelling of the finger. Also known as whale finger or pork finger, this form of cellulitis caused by *Erysipelothrix rhusiopathiae* should not be confused with streptococcal or staphylococcal erysipelas (see Fig. 441-4). (From Farrar WE, Wood MJ, Innes JUA, Tubbs H. *Infectious Diseases: Text and Color Atlas*. 2nd ed. New York: Gower Medical Publishing; 1992.)

complicated by paravalvular and myocardial abscess formation, cerebral emboli, congestive heart failure, valve perforation, and acute renal failure. *E. rhusiopathiae* bacteremia without endocarditis occurs more frequently than was previously believed. Bacteremia is occurring with increased frequency in immunocompromised patients, whereas endocarditis usually occurs in immunocompetent patients. Focal infections, including brain abscess, meningitis, endophthalmitis, osteomyelitis, septic arthritis, epidural and paravertebral abscesses, liver abscess, necrotizing fasciitis, intra-abdominal abscess, and peritonitis, have been reported. Some of these infections were complications of bacteremia. Septic arthritis has occurred in native joints, in prosthetic joints, and after arthroscopic surgery.[4] Peritonitis has complicated peritoneal dialysis.

DIAGNOSIS

E. rhusiopathiae grows on routine laboratory media. Because *E. rhusiopathiae* is located only in deeper parts of the skin in cases of erysipeloid, biopsy of the entire thickness of the dermis from the edge of the lesion yields maximal recovery of the organism. Definitive diagnosis by skin biopsy is rarely necessary because of the classic clinical presentation and the rapid response to therapy. Routine blood culture techniques are adequate for growth and isolation of the organism in suspected cases of bacteremia or endocarditis. Various selective media have been used to improve the isolation of *E. rhusiopathiae* from contaminated specimens. Molecular techniques, such as polymerase chain reaction with primers specific for *E. rhusiopathiae*, have been developed and improve the efficiency of detection and identification.[5]

TREATMENT

Rx

Most isolates of *E. rhusiopathiae* are susceptible to penicillin, cephalosporins, imipenem, clindamycin, ciprofloxacin, ofloxacin, and daptomycin. Some resistance has been observed with erythromycin, tetracycline, and chloramphenicol. *E. rhusiopathiae* is resistant to vancomycin, aminoglycosides, trimethoprim-sulfamethoxazole, and sulfonamides. Penicillin G is the treatment of choice. Uncomplicated cutaneous lesions generally respond well to a 5- to 7-day course of oral penicillin. Treatment hastens healing, although relapse may still occur. Bacteremia should be treated with intravenous penicillin; cases of endocarditis should be treated with 12 million to 20 million units of penicillin G daily or ceftriaxone 1 g daily for 4 to 6 weeks. Two weeks of intravenous therapy followed by 2 weeks of oral therapy has been successful. The use of quinolones or daptomycin may be considered for *Erysipelothrix* infections when the patient is allergic to β-lactams. Oral linezolid was used to complete therapy in a case of bacteremia complicated by endophthalmitis. Valve replacement may be necessary in patients with endocarditis. Infected prosthetic devices should be removed.

PREVENTION

Proper cleaning and disinfection of work surfaces and attention to hygienic work practices, including the use of gloves and hand hygiene, reduce the risk for infection. Vaccines are available for commercial use in animals only.

4. Hocqueloux L, Poisson DM, Sunder S, et al. Septic arthritis caused by *Erysipelothrix rhusiopathiae* in a prosthetic knee joint. *J Clinc Microbiol.* 2010;48:333-335.
5. Pal N, Bender JS, Opriessnig T. Rapid detection and differentiation of *Erysipelothrix* spp. by a novel multiplex real-time PCR assay. *J Appl Microbiol.* 2010;108:1083-1093.

REVIEW QUESTIONS

1. A 56-year-old fisherman, who has no significant medical problems, presents with a 2-week history of a well-defined, elevated, painful, reddish purple plaque on the dorsum of his right hand. The lesion has been slowly expanding during the course of 2 weeks and appeared approximately 1 week after his last fishing trip. He is afebrile, and there is no evidence of regional lymphadenopathy or lymphadenitis. Which of the following is the most appropriate recommendation?

A. Aspirate the leading edge and send any material for Gram stain and culture.
B. Begin oral penicillin.
C. Refer for a biopsy of the lesion.
D. Begin intravenous vancomycin.
E. No treatment

Answer: B This patient has classic erysipeloid, caused by *Erysipelothrix rhusiopathiae*. It is a zoonosis that is linked to certain occupations, including fishermen. The lesion is a cellulitis that is generally found on the hands or fingers, and the organism is introduced through cuts and abrasions of the skin. Systemic signs of infection are rare. Although uncomplicated skin lesions may resolve spontaneously during a period of 3 weeks, a short course of oral penicillin G hastens healing and is the treatment of choice. The organism is resistant to vancomycin. Because the organism is located in deeper parts of the skin and there is not any suppuration, in cases of erysipeloid, aspiration is unlikely to lead to recovery of the organism. A biopsy of the entire thickness of the dermis at the edge of the lesion would yield maximum recovery of the organism but is not indicated because of the classic presentation and the ease of treatment with penicillin. (Veraldi S, Girgenti V, Dassoni F, et al. Erysipeloid: a review. *Clin Exp Dermatol*. 2009;34:859-862.)

2. A 47-year-old man with a history of chronic liver disease, secondary to alcohol use, presents with a 3-day history of fever, chills, and generalized arthralgias. He works in a slaughterhouse that processes pigs. Approximately 3 weeks ago, he developed a cellulitis of his finger that resolved spontaneously without therapy. Blood culture samples are obtained and yield gram-positive bacilli that are identified as *Erysipelothrix rhusiopathiae*. An echocardiogram is normal, and follow-up blood cultures are negative. The antibiotic therapy of choice is

A. Vancomycin
B. Intravenous penicillin G
C. Tetracycline
D. Ampicillin and gentamicin
E. Trimethoprim-sulfamethoxazole

Answer: B This patient has bacteremia without infective endocarditis. *Erysipelothrix rhusiopathiae* bacteremia without endocarditis occurs more frequently than was previously believed and is occurring with increased frequency in immunocompromised patients, including those with liver disease. The treatment of choice for systemic infections is intravenous penicillin G. *E. rhusiopathiae* is resistant to vancomycin, aminoglycosides, tetracycline, and trimethoprim-sulfamethoxazole. (Wang Q, Chang BJ, Riley TV. *Erysipelothrix rhusiopathiae*. *Vet Microbiol*. 2010;140:405-417.)

3. A 45-year-old veterinarian presents with a 2-week history of fever, chills, and sweats. On physical examination, he is noted to have a 3/6 diastolic murmur, consistent with aortic regurgitation. Three sets of blood cultures are positive for *Erysipelothrix rhusiopathiae*, and an echocardiogram reveals a vegetation on the aortic valve. He has an allergy to penicillin, which is manifested as hives. The most appropriate alternative antibiotic therapy is

A. Vancomycin
B. Ceftriaxone
C. Daptomycin
D. Ampicillin and gentamicin
E. Tetracycline

Answer: C This patient has infective endocarditis of the aortic valve caused by *Erysipelothrix rhusiopathiae*. *E. rhusiopathiae* endocarditis correlates highly with occupation, exhibits a tropism for the aortic valve, and affects more males than females. Penicillin is the treatment of choice; daptomycin and quinolones are alternative therapies when the patient is allergic to β-lactams. For a patient with an immediate hypersensitivity reaction to penicillin, cephalosporins are contraindicated because of possible cross-reactivity. *E. rhusiopathiae* is resistant to vancomycin, tetracyclines, aminoglycosides, and trimethoprim-sulfamethoxazole. Even if there was not a concern for resistance, tetracyclines are bacteriostatic, and it is necessary to administer bactericidal agents for the treatment of endocarditis. (Piper KE, Steckelberg JM, Patel R. In vitro activity of daptomycin against clinical isolates of gram-positive bacteria. *J Infect Chemother*. 2005;11:207-209.)

4. A 60-year-old man with a history of rheumatoid arthritis, who is being treated with prednisone chronically, presents to his physician to discuss prevention of infection with *Erysipelothrix rhusiopathiae*. He has a friend who works in the slaughterhouse with him who recently was treated for endocarditis caused by *E. rhusiopathiae*. The physician should recommend the following:

A. Vaccination
B. Chronic low-dose therapy with oral penicillin while he is receiving prednisone
C. Good hand hygiene and use of protective gloves
D. Use of a gown, mask, and gloves while at work

Answer: C *Erysipelothrix rhusiopathiae* is an occupational pathogen that is transmitted through traumatic contact with infected animals or animal products. Occupations at risk include fishermen, farmers, veterinarians, and slaughterhouse workers. Immunocompromised hosts are at risk for infection. The transmission of *Erysipelothrix* generally occurs by traumatic inoculation through abrasions or cuts in the skin of the hands and rarely through consumption of contaminated meat or fish products. Proper cleaning and disinfection of work surfaces and attention to hygienic work practices, including good hand hygiene and the use of gloves, reduce the risk of infection. Vaccines are available for commercial use in animals only, and there are currently no known vaccines that are available for humans. There is no documentation of transmission by droplets or aerosols, and therefore masks are not indicated. (Wang Q, Chang BJ, Riley TV. *Erysipelothrix rhusiopathiae*. *Vet Microbiol*. 2010;140:405-417.)

5. A 63-year-old woman with a history of chronic eczema and alcoholism underwent a right knee arthroplasty for degenerative joint disease. She lived on a farm that raised swine. Six months after the arthroplasty, she developed pain and swelling of the right knee, with subsequent drainage of purulent material from a pustule in the incision. Plain radiographs revealed loosening of the prosthesis and osteomyelitis. She underwent removal of the prosthesis, and multiple operative samples of fluid and bone revealed gram-positive rods. Cultures were positive for *Erysipelothrix rhusiopathiae*. Blood cultures were negative. She was treated with intravenous imipenem for 2 weeks. Which of the following is the most appropriate recommendation for outpatient oral therapy?

A. Clarithromycin
B. Tetracycline
C. Trimethoprim-sulfamethoxazole
D. Ciprofloxacin

Answer: D Most isolates of *Erysipelothrix rhusiopathiae* are susceptible to penicillin, cephalosporins, imipenem, clindamycin, ciprofloxacin, ofloxacin, and daptomycin. Resistance has been observed with erythromycins, tetracyclines, and chloramphenicol. *E. rhusiopathiae* is also resistant to vancomycin, aminoglycosides, trimethoprim-sulfamethoxazole, and sulfonamides. An oral fluocinolone, such as ciprofloxacin, has excellent efficacy in the treatment of osteomyelitis and septic arthritis. Although arthritis is one of the most common features of *E. rhusiopathiae* infection in animals, this type of infection is relatively rare in humans. There are about 12 cases of bone and joint infection reported in the medical literature. Most patients had a skin lesion at the site of the infected joint and have an occupational or recreational exposure to an animal reservoir of infection. (Hocqueloux L, Poisson DM, Sunder S, et al. Septic arthritis caused by *Erysipelothrix rhusiopathiae* in a prosthetic knee joint. *J Clin Microbiol*. 2010;48:333-335.)

CLOSTRIDIAL INFECTIONS

DALE N. GERDING AND STUART JOHNSON

Clostridial infections are characterized by disease produced by toxins. They include tetanus and botulism, both caused by neurotoxins, and clostridial myonecrosis or gas gangrene, caused by the toxins of *Clostridium perfringens* as well as those of other clostridial species. Although these clostridial infections remain important clinically, their frequency has declined markedly with the advent of vaccines and better public health measures. Several previously little known species of clostridia that produce very large clostridial cytotoxins (LCCs) varying in size from 250 to 308 kD have become increasingly prominent. They include, in particular, *Clostridium difficile*, which is responsible for one of the most common health care–associated infections and for increasing mortality among elderly patients. Another LCC-producing organism, *Clostridium sordellii*, has caused devastating infections in young women in association with pregnancy and medical abortion, in injection drug users, and in patients with traumatic wounds. *Clostridium novyi* type A is a third LCC organism that has also caused severe infections in injection drug users.

CLOSTRIDIUM DIFFICILE INFECTION

DEFINITION AND PATHOGEN

C. difficile infection (CDI) is a gastrointestinal infection characterized by diarrhea (three or more loose or unformed stools in ≤24 hours) and a positive test result for *C. difficile* toxin A or toxin B in stool, evidence of a toxin-producing strain of *C. difficile* in stool, or evidence of pseudomembranous colitis on direct visualization of the colon. *C. difficile* is a spore-forming, anaerobic, gram-positive organism that survives well in water, soil, and animals and has a worldwide distribution.

EPIDEMIOLOGY

CDI occurs most frequently in health care settings, particularly in long-term care facilities and acute care hospitals, and is most frequent and lethal among the elderly, especially those older than 75 years. Rates in U.S. hospitals have nearly tripled in the decade since 2000, and it is now estimated that there are 500,000 to 750,000 CDIs each year. A specific strain of *C. difficile*—identified as the restriction endonuclease group BI, pulsed-field gel type NAP1, polymerase chain reaction ribotype 027 (BI/NAP1/027) strain—is thought to be responsible for much of the epidemic that has extended to Canada and Europe. Rates of community-onset CDI have also increased during the past decade, in association with the rising rates in hospitals and nursing homes.[1] However, 94% of community-onset cases in this population-based study were associated with receiving some kind of recent health care, including outpatient visits, recently discharged patients, and nursing home residents. It is unlikely that community-associated cases (with no health care exposure) account for more than 10 to 15% of all CDIs. Risk factors for CDI include antimicrobial use, advanced age, and stay in an acute or chronic care facility. Hospitals are considered a particularly high-risk environment because patients are elderly, antibiotic use is frequent, the environment is contaminated with *C. difficile* spores (which are difficult to eradicate), asymptomatic patients carry *C. difficile* in their stools, and health care workers carry *C. difficile* on their hands if they do not practice good hand hygiene. In about 2 to 3% of healthy adults, *C. difficile* can be cultured from their stools, but the frequency in asymptomatic hospitalized patients increases with the duration of hospitalization and may reach 20% or more. Exposure to nearly all

antimicrobials has been associated with subsequent CDI, but those with the highest risk are clindamycin, the cephalosporins, and the fluoroquinolones. CDI is rare in children and young adults, despite their frequent exposure to antimicrobials. However, children younger than 1 year are commonly colonized with *C. difficile* but remain asymptomatic, an observation that remains largely unexplained.

PATHOBIOLOGY

CDI risk appears to be minimal in the absence of antimicrobial therapy. When antimicrobials are administered, they have the unintended consequence of disrupting the normal protective bowel microbiota, which may persist for days to weeks after the antimicrobial is stopped. If *C. difficile* is ingested during this time, the spores germinate in the gut, and the vegetative form of the organism multiplies and begins to make toxins. At this point, whether the patient will develop diarrhea is dictated by the status of his or her immunity to the toxins, which is best correlated with serum immunoglobulin G antibodies directed at toxin A and toxin B of *C. difficile*. Those with good antibody responses will be asymptomatic but will remain colonized with *C. difficile*, whereas those with little or no antibody response will develop diarrhea and CDI. Toxin A is primarily an enterotoxin, and toxin B is a cytotoxin. Both act by glucosylation that disrupts the cell cytoskeleton, resulting in colonic epithelial cell rounding, fluid leakage, and cell death. In the presence of pseudomembranous colitis, the colon appears to be covered in yellow to white pseudomembranes that vary in size from punctate to completely confluent and covering the entire colon in advanced cases. On histologic evaluation, the colon demonstrates a marked neutrophil infiltration throughout the colon wall, with mucosal necrosis and volcano-like lesions from which the pseudomembrane is seen to "erupt." The pseudomembrane is composed of proteinaceous material and cellular debris.

CLINICAL MANIFESTATIONS

Clinical symptoms of CDI range from asymptomatic carriage to severe and sometimes life-threatening pseudomembranous colitis complicated by major fluid losses and systemic complications. With mild CDI, patients may simply have "nuisance diarrhea" that resolves when the implicated drug is discontinued. Others with more severe CDI have substantial fluid and protein losses combined with fever, cramps, hypoalbuminemia, leukocytosis, and hypotension. Leukocytosis is common (occurring in up to 50% of patients) and is a marker of severe CDI when it exceeds 15,000/mm^3. Extremely high levels (>50,000/mm^3) are an indication of fulminant and potentially fatal illness. Other factors that may be indicative of severe or late-stage disease include toxic megacolon, high fever, renal failure, hypotension, and a lactic acidosis greater than 5.0 mmol/L.

DIAGNOSIS

The diagnosis should be suspected in any patient who has otherwise unexplained diarrhea (three or more loose or unformed stools in ≤24 hours) in association with recent or concurrent antibiotic use. Only about 10 to 20% of patients in this category actually have CDI, but this is the group of patients that should be tested. The standard test to establish the diagnosis is to detect toxins A and B in stool or to detect a toxin-producing strain of *C. difficile* in stool. Tests that detect only toxin A are not acceptable because about 1 to 3% of strains that cause CDI produce toxin B but not toxin A. The most common laboratory method has been an enzyme immunoassay, but its sensitivity is only 50 to 80%. Repeated testing does not improve the diagnostic accuracy because enzyme immunoassays also have specificity deficiencies that increase the rate of false-positive test results with repeated testing. Polymerase chain reaction tests for *C. difficile* in stool are widely available commercially and markedly improve test sensitivity to 90 to 95% (compared with the "gold standard" of culture for a toxigenic strain). The polymerase chain reaction tests are more expensive, but their use by clinical laboratories is increasing rapidly. They increase the sensitivity of CDI diagnosis, but some studies have shown that a positive test result for stool toxin should also be present to confirm the diagnosis.[2] The standard cell cytotoxin assay is little used but more sensitive than enzyme immunoassay, but it has the disadvantages of a 24- to 48-hour turnaround and the requirement for tissue culture facilities. Stool culture for *C. difficile*, which is the most sensitive test available, is likewise slow and requires confirmation of toxin production by the organism before reporting. Testing of stools for glutamate dehydrogenase, or "common antigen," can be used as a rapid screening test, but it is only about 50% specific and requires confirmation with a toxin test, which can increase the turnaround time for reporting positive results. CDI can also be diagnosed by observing pseudomembranous colitis directly through sigmoidoscopy or colonoscopy or at surgery. When a negative test result does not confirm the diagnosis in a patient whose clinical symptoms are highly suggestive of CDI, empirical treatment of CDI should be given rather than repeating the test. The cause of infectious diarrhea in an adult patient with an onset longer than 48 hours after hospital admission is almost always CDI because other infectious enteric pathogens (with the exception of norovirus) are extremely rare in the hospital setting. Also common in the differential diagnosis are noninfectious causes of diarrhea, such as antibiotic or other drug-associated diarrhea, ischemic colitis, and idiopathic inflammatory bowel disease. For patients with antibiotic-associated diarrhea and no evidence of colitis, the cause of diarrhea with a negative *C. difficile* toxin assay is usually not defined.

PREVENTION

Two major prevention strategies are employed. The first is traditional infection control, in which barriers to transmission (gowns, gloves, isolation, hand hygiene, environmental cleaning) are used to prevent the spores of *C. difficile* from reaching the patient. The second strategy is to reduce the likelihood of infection if the patient does encounter *C. difficile* while in the hospital. The most efficacious strategy, also known as antimicrobial stewardship, is to avoid or to minimize exposure to antimicrobials, especially those with a high CDI risk, such as clindamycin, cephalosporins, and fluoroquinolones. Interventions to restrict exposure to clindamycin and to cephalosporins have been highly effective in interrupting outbreaks of CDI in hospitals.[3]

TREATMENT

Rx

Treatment of CDI begins with discontinuation of the implicated antibiotic, supportive care, and avoidance of antiperistaltic agents. Mildly ill patients may recover with these simple conservative measures, but most require specific treatment. Continuation of the offending antibiotics while CDI is being treated with vancomycin and other agents results in lower cure rates and higher CDI recurrence rates in patients. Metronidazole, at a dose of 500 mg orally three times a day for 10 to 14 days, has been the recommended treatment for patients with mild CDI because it is much less expensive and it avoids some of the concern about vancomycin-resistant enterococcus colonization. However, a large randomized prospective trial of vancomycin versus metronidazole has placed the recommendation into question as it showed vancomycin to be statistically superior to metronidazole for all patients with CDI (P = .02). Patients with severe CDI (variously defined as a white blood cell count >15,000 or a creatinine increase to >1.5-fold above baseline) should be treated with vancomycin 125 mg orally four times a day for 10 days.[4] Vancomycin can be substituted for metronidazole if there is a delayed response in patients with mild illness. A newer option is fidaxomicin (200 mg orally twice daily), a narrow-spectrum macrocycle that is as efficacious as vancomycin and reduces recurrent infection. The anticipated response to these drugs is rapid defervescence, with gradual normalization of bowel habits. Mean time to resolution of diarrhea is about 3 days; if symptoms have not resolved by day 5 or day 6 of treatment, a change in therapy should be considered. However, there are no data to support the use of more than one drug at a time to treat CDI. Failure to respond often means that either the disease has progressed too far or another condition is causing the symptoms. For patients with severe complicated or fulminant CDI, medical management includes vancomycin at a higher dose (500 mg four times a day) orally or by nasogastric tube; if ileus is present, metronidazole (500 mg IV every 8 hours) is added, with vancomycin also administered by enema. If symptoms progress with this therapy, colectomy may be life-saving and should be performed before the white blood cell count reaches 50,000/mm^3 or lactate concentration reaches 5.0 mmol/L. A colon-sparing loop ileostomy procedure followed by infusion of polyethylene glycol and vancomycin has demonstrated reduced mortality compared with historic colectomy controls and may be a preferred procedure to colectomy.[5]

Other antibiotic options include oral fusidic acid, teicoplanin, nitazoxanide, rifaximin, and bacitracin, but most of these drugs have been evaluated in only a small number of patients, and none (like metronidazole) has Food and Drug Administration approval for the treatment of CDI. There is no convincing evidence that toxin-binding agents, such as cholestyramine and probiotics, are useful in treating CDI. About 20 to 25% of patients treated with either vancomycin or metronidazole have a recurrence of symptoms when treatment is stopped because of the persistence of *C. difficile* spores or acquisition of a new strain. Treatment with vancomycin, fidaxomicin, or metronidazole is recommended, depending on the severity of the recurrence. Patients with multiple recurrences of CDI are extremely difficult to treat and may benefit from consultation with an infectious disease specialist or gastroenterologist. Observational data and one prospective randomized controlled trial suggest that fecal microbiota transplantation might be an effective treatment for recurrent *C. difficile* infection.

PROGNOSIS

The majority (≈80%) of patients respond to simple withdrawal of the implicated antibiotic combined with a single course of metronidazole, vancomycin, or fidaxomicin. Some patients with fulminant disease eventually require colectomy. The attributable mortality rate is as high as 7% in large series, and the majority of lethal cases occur in patients older than 65 years. Patients with multiple recurrences require repeated courses of antibiotics, usually vancomycin with tapering and pulse-dose regimens that may need to be continued for weeks to months, or may require resorting to fecal microbiota transplantation.

NECROTIZING CLOSTRIDIAL TISSUE INFECTION

Clostridium sordellii

DEFINITION AND PATHOGEN

C. sordellii is another clostridial species that produces LCCs, and it has become more common as a cause of septic shock and necrotizing fasciitis in association with trauma, childbirth, medical abortion, and injection drug use. *C. sordellii* antitoxin cross-neutralizes the cytotoxic effect of *C. difficile* toxins, indicating the similarity of these LCCs.

EPIDEMIOLOGY

The organism is commonly found in soil and in the intestines of animals and occasionally humans worldwide. Soil contamination of wounds is the usual suspected route of infection. Infections have been described after traumatic wounds, childbirth, medical abortion, and intramuscular or subcutaneous injection drug use.

PATHOBIOLOGY

C. sordellii produces up to seven identified toxins; of these, hemorrhagic toxin (TcsH) and lethal toxin (TcsL), which are both LCCs and analogous to TcdA and TcdB of *C. difficile*, are considered major virulence factors. TcsL has been shown to be essential for virulence.[6] The toxins produce local necrosis, progressive edema, and shock that results in high mortality. The toxins are glucosyltransferases that glucosylate the Rho, Rac, or Ras proteins, causing impaired cytoskeletal organization and massive capillary leakage, leading to the progressive edematous state.

CLINICAL MANIFESTATIONS

Initial symptoms are nonspecific and include nausea, lethargy, dizziness, and tenderness at the infection site. Tachycardia and hypotension follow within hours. Laboratory tests show a marked leukocytosis or leukemoid reaction. Hypotension and tachycardia are refractory to treatment. Edema secondary to capillary leakage is prominent, resulting in hemoconcentration but little or no fever. Peritoneal and pleural effusions are common. White blood cell elevations greater than 75,000/mm^3 are associated with a fatal outcome.

Infection Associated with Childbirth and Medical Abortion

This is a rare infection in which patients present 4 to 7 days after the administration of oral mifepristone and vaginal misoprostol for medical abortion with nausea, vomiting, weakness, abdominal pain, hypotension, and tachycardia but little or no fever and, often remarkably, a lack of findings on pelvic examination. The presentation is similar to toxic shock syndrome. There is rapid progression to vascular collapse and cardiac arrest. Leukocytosis is dramatic, with white blood cell counts near 100,000/mm^3 in most patients. After delivery, the presentation is similar, but localized swelling and discoloration of the labia and perineum may be evident if the episiotomy site is infected. All patients to date have died.

Infection Associated with Injection Drug Use

Black tar heroin (a dark, gummy, less refined and cheaper form of heroin) has been associated with necrotizing fasciitis at the subcutaneous or intramuscular injection site, presumably a result of the contaminants mixed with the heroin. Patients present with 2 to 7 days of symptoms of necrotizing fasciitis of the upper or lower extremity where they injected heroin, in some cases accompanied by hypotension. Aggressive surgical débridement is required at the infection site, together with fluids and pressors. Cultures of débrided tissue reveal multiple organisms in addition to *C. sordellii*. Mortality in these patients is 50%.

DIAGNOSIS

Diagnosis is difficult because of the lack of specific symptoms, but it is usually made by identifying the likely source of infection and isolating *C. sordellii* from the infection site or blood cultures. Polymerase chain reaction analysis for *C. sordellii* in infected tissues may be required to make the diagnosis when cultures are negative. Other bacteria are also commonly found at the infection site. Computed tomography or magnetic resonance imaging may be helpful in identifying localized infections, which can then be excised or drained surgically, providing material for microbiologic diagnosis.

PREVENTION

C. sordellii infections are very rare, and the exact mechanism of infection, especially after medical abortion, is not known. However, careful attention to wound cleansing, avoidance of injecting drugs into skin or muscle, and good hygiene during childbirth are likely to help prevent *C. sordellii* infection.

TREATMENT Rx

Definitive treatment information is lacking. The infection progresses so rapidly that therapeutic interventions are rarely successful. Surgery to remove necrotic sites of infection and administration of intravenous fluids and pressors to treat hypotension and tachycardia are supportive. Antibiotic susceptibility suggests that β-lactams, clindamycin, tetracyclines, and chloramphenicol are active, but no clinical treatment efficacy data are available. Theoretically, use of an antibiotic such as clindamycin to suppress toxin synthesis could be a useful adjunct to treatment. At present, there is no antitoxin available.

PROGNOSIS

Infections after childbirth or medical abortion have been uniformly fatal. Mortality in injection drug users or patients after trauma or surgery is about 50%.

Clostridium novyi Infection in Injecting Drug Users

C. novyi α-toxin causes an LCC-producing disease in humans. *C. novyi* has long been recognized as a cause of fatal toxemia in animals with contaminated wounds. An extended outbreak of human infections occurred in Scotland, Ireland, and elsewhere in the United Kingdom in 2000 to 2009 among persons injecting heroin extravascularly (skin or muscle popping).[7] A localized necrotizing infection with painful edema, sepsis, and significant mortality was recognized. The findings include soft tissue inflammation, edema and necrosis at the injection sites, circulatory collapse, marked leukocytosis, and pleural effusions. Treatment usually involves débridement and antibiotic administration (gentamicin, flucloxacillin, penicillin, metronidazole, and clindamycin were used during this outbreak because infections are typically polymicrobial in origin).

Clostridial Myonecrosis (Gas Gangrene)

DEFINITION

Clostridial myonecrosis, or gas gangrene, can be caused by several *Clostridium* species, most commonly *C. perfringens* after trauma or tissue injury and *Clostridium septicum* after dissemination from a colonic source.[8]

EPIDEMIOLOGY

Gas gangrene has historically been a complication of battlefield injuries and of trauma in noncombat settings. The estimated number of cases in the United States is about 1000 per year. Traumatic injuries account for about 50% of cases, with vehicular accidents accounting for the majority; the remaining cases develop in patients after crush injuries, industrial accidents, gunshot wounds, and burns. Minor injuries such as puncture wounds, intramuscular injections, simple lacerations, and subcutaneous injections with epinephrine may occasionally precipitate clostridial myonecrosis. Postoperative complications account for about 30% of cases and are most frequently associated with surgery on the appendix, biliary tract, or intestine. Approximately 20% are "spontaneous" or nontraumatic and are invariably associated with an occult colonic malignant neoplasm.

PATHOBIOLOGY

Clostridia are widely distributed in nature and can be cultured from nearly all soil samples, from environmental sites in the hospital, and from the human

intestine. A critical factor is a physiologic state of the wound with conditions that support germination and toxin production by toxigenic clostridia. Particularly critical are a low oxidation-reduction potential, hypoxia, appropriate substrates, and calcium ions. The probability of infection is substantially increased by devitalized muscle and the presence of foreign material such as soil. *C. perfringens* elaborates at least 12 recognized toxins, most importantly α-toxin and θ-toxin of *C. perfringens* type A. Although the interaction is complex, good evidence supports a central role for α-toxin, a phospholipase C, and θ-toxin or perfringolysin O, a cholesterol-dependent cytolysin, in the extensive cell death and disruption of microvascular perfusion that are characteristic of clostridial myonecrosis. The vascular perfusion changes are likely mediated by toxin-induced platelet aggregation and leukocyte margination. The α-toxin of *C. septicum*, a pore-forming cytolysin unrelated to α-toxin of *C. perfringens*, also causes cell death and microvascular perfusion changes.

CLINICAL MANIFESTATIONS

Initial symptoms of traumatic myonecrosis usually occur 1 to 4 days after the precipitating event, although the range is 8 hours to 3 weeks. The initial symptom is pain that is often sudden and severe at the site of surgery or trauma. The involved skin has intense edema and is initially pale before progressing to a bronze or magenta color, followed by the formation of bullae. The bullae contain fluid that may be clear or hemorrhagic. The discharge has an odor that is described as "foul-sweet."

Circulatory collapse and hypotension unresponsive to fluid challenge are common and may reflect the effect of α-toxin, which suppresses cardiac contractility. About 15% of patients have bacteremia that is usually complicated by rapid hemolysis with a dramatic drop in the hematocrit, which may even decrease to 0%. Common complications include jaundice, hypotension, hepatic failure, and renal failure. The renal failure is often due to hemoglobulinuria and myoglobulinuria, but it may also be due to acute tubular necrosis from hypotension. Despite the severity of the illness, the patient's mental status is usually remarkably good until very late in the disease. Surgical intervention shows necrotic muscle that does not contract with stimulation. Deeper dissection reveals beefy red necrotic muscle that becomes black and extremely friable in the late stages.

Uterine gas gangrene, which was once common after septic abortions, is now rare but may complicate normal delivery, amniocentesis, cesarean section, or abortion. The onset is usually sudden, with fever, tachycardia, hypotension, renal failure, and jaundice. Radiography may show gas in the uterine wall. The urine is often "port wine" in color as a result of hemoglobulinuria, and there is often jaundice because of massive intravascular hemolysis. The usual causes are *C. perfringens* and *C. sordellii.*

Spontaneous myonecrosis occurs in the absence of trauma and is usually caused by *C. septicum*. One distinctive association is with colon cancer and neutropenic enterocolitis, which represent portals of entry for hematogenous seeding of *C. septicum*. This infection is also seen with acute leukemia and is most common with chemotherapy for solid tumors and after stem cell transplantation. The usual portals of entry are the terminal ileum, cecum, and ascending colon, hence the term *typhlitis*. The usual manifestation is a necrotizing infection in an extremity or in the abdominal wall, accompanied by hypotension and renal failure. Examination shows spreading crepitations with rapid clinical deterioration during a period of hours, and imaging reveals gas.

DIAGNOSIS

The diagnosis of gas gangrene is usually based on a constellation of characteristic clinical features, including myonecrosis, shock, and renal failure. The patient typically complains of severe pain. Early recognition is important because early institution of treatment may strongly influence the prognosis. The diagnosis is established by examination of skin and muscle, which shows putrid discharge, characteristic bullae, and crepitations. Gram stain demonstrates abundant gram-positive bacilli and no inflammatory cells. Histopathologic examination of the lesion shows myonecrosis without polymorphonuclear leukocytes, a finding that is remarkably different from most soft tissue infections, which do not feature necrosis and have abundant inflammatory cells. Gas is present in the tissue and may be detected by physical examination, radiography, or other imaging methods.

PREVENTION

The basic principle of prevention is adequate management of traumatic wounds—establishing adequate drainage, removing foreign bodies, draining hematomas, and ensuring good hemostasis.

TREATMENT

Rx

The most important facet of treatment is prompt surgical débridement. Many cases require extensive, often mutilating surgery. Penicillin and clindamycin are recommended but are rarely adequate without radical surgery, except in patients with neutropenic enterocolitis, who can often be managed with antibiotics. The rationale for penicillin combined with clindamycin is that some strains of clostridia are resistant to clindamycin, but clindamycin is probably the superior drug for reducing toxin formation. Other antibiotics that are generally effective include metronidazole and chloramphenicol. The use of hyperbaric oxygen is controversial, in part because the therapeutic trials have been either of poor quality or not convincing.

PROGNOSIS

Factors associated with a poor prognosis include advanced age, location on the trunk, association with severe underlying disease, leukopenia, renal failure, hemolysis, and shock. The best results are seen in young patients with involvement of a single extremity. Management plays an important role, particularly the use of early and aggressive surgery as well as antibiotics. The overall mortality rate of patients with traumatic gas gangrene in tertiary centers is about 25%.

NEUROTOXIC CLOSTRIDIAL INFECTIONS

Botulism

DEFINITION

Botulism is a severe neuroparalytic disease characterized by a descending flaccid motor neuron paralysis. It is caused by botulinum toxin produced by *Clostridium botulinum.*

The Pathogen

C. botulinum is a gram-positive, spore-forming obligate anaerobe that is widely distributed in nature and is frequently found in soil, marine environments, and agricultural products. Each strain produces one of seven toxins designated by the letters A to G. A new botulism toxin designated H, the first new neurotoxin identified in more than 40 years, was recently isolated from a patient with infant botulism.[9] Botulinum toxin may also be produced by the related clostridial species *Clostridium baratii* and *Clostridium butyricum*. All these neurotoxins produce the same syndrome; the usual causes of disease in humans are types A, B, and E, with rare cases caused by type F.

EPIDEMIOLOGY

Botulism in humans is generally one of three types: food-borne botulism, infant botulism, or wound botulism. Rarely, botulism may be acquired as a result of iatrogenic misadventures with botulinum toxin, which is a potential bioterrorism agent if it is inhaled or ingested.

Food-borne botulism is the most common form of botulism in the world but is a distant second to infant botulism in the United States. Nevertheless, 20 cases from ingestion of prison-made alcohol (pruno) and the first eight cases in more than 30 years from ingestion of a commercially canned product (hot dog chili sauce) have occurred recently.[10,11] Foods most frequently implicated are home-canned vegetables or fermented foods, and most cases are sporadic single cases occasionally involving two or three people. Commercially preserved and restaurant-prepared foods are also rare causes of food-borne botulism. Type A toxin is predominant in the United States. Alaska has the highest rate of any state, with approximately 35% of all cases; 80% of events and cases in Alaska are caused by type E and are most often associated with fermentation methods used to prepare fish and marine mammals by native Alaskans.[12] Meat and meat products are frequently implicated in Europe, where the predominant toxin is type B. In China, the most frequent vehicle is a vegetable product, and type A predominates.

Infant botulism is the most frequently recognized form in the United States and is the most recently discovered type of botulism, first described in 1976. It is caused by production of botulinum toxin in the intestine after presumed spore ingestion and colonization in 2- to 36-week-old infants. Honey has been identified as the source of *C. botulinum* spores, but in most cases the source is never identified. Nearly all cases are caused by type A or type B toxin. The symptoms usually begin with constipation followed by poor feeding, weak cry, lethargy, and generalized weakness characterized as the

"floppy baby syndrome" because of loss of head control. This form of botulism is rare in adults, occurring most often in patients with anatomic or functional abnormalities of the intestines.

Wound botulism, first described in 1943, is the least frequent form of the disease and is usually caused by either type A or type B toxin. Sporadic cases in traumatic wounds contaminated by soil are rarely reported. Outbreaks have been described in black tar heroin users in the western United States, particularly if they inject the drug intramuscularly or subcutaneously (skin popping). These drug users also develop other clostridial infections, including necrotizing fasciitis caused by *C. sordellii* and *C. novyi* and tetanus caused by *Clostridium tetani.*

Inhalation or ingestion of botulinum toxin is considered one of the top six bioweapon agents in terms of probability of use. The presumed method would be contamination of the food supply, water supply, or commercial beverages or aerosolization in a highly populated area to cause inhalational botulism. It is estimated that a point-source aerosol release of the toxin could incapacitate or kill 10% of people within a 0.5-km radius.

Iatrogenic botulism results from the misuse of botulinum toxin for cosmetic or therapeutic purposes. Cosmetic treatment doses are far too low to cause systemic disease, but the use of unlicensed products with high concentrations of botulinum toxin can cause systemic symptoms. Higher doses used for the management of muscle movement disorders have caused occasional cases with systemic botulism-like symptoms.

PATHOBIOLOGY

Pathologic findings are due to absorption of toxins from the intestine (ingested preformed toxin in foods or in situ production in the intestine in infants), inhalation (aerosol from bioterrorism), absorption from cutaneous infection sources (wounds), or iatrogenic injection. The toxin is disseminated by the systemic circulation and causes flaccid paralysis by binding presynaptic motor neuron terminals and blocking acetylcholine transmission across the neuromuscular junction. The estimated lethal doses of purified botulinum toxin A for a 70-kg human are 0.09 to 0.15 μg when given intravenously, 0.8 to 0.9 μg when inhaled, and 70 μg when given orally.

CLINICAL MANIFESTATIONS

In contrast to Guillain-Barré syndrome (Chapter 420), which is an ascending paralysis, botulism is characterized by generalized weakness and a descending paralysis. Symptoms are due to absorption of botulinum toxin from the gut, the lung, or a wound. Clinical symptoms consist of highly distinctive and usually symmetrical cranial nerve palsies, followed by a symmetrical descending flaccid paralysis. Prominently involved cranial nerves III, IV, and VI cause blurred vision and diplopia; involvement of cranial nerve VII causes the characteristic expressionless facies and dysphagia; and involvement of cranial nerve IX causes dysarthria. Thus, the initial symptoms include the "four *d*'s"—diplopia, dysarthria, dysphagia, and dysphonia—although the last is rarely reported, and blurred vision is reported more commonly than diplopia. These findings are followed by a descending upper extremity paralysis and respiratory paralysis. Neurologic examination shows bilateral cranial nerve VI paresis, ptosis, dilated pupils with a sluggish reaction, and diminished gag reflex, followed by descending involvement of motor neurons. Deep tendon reflexes are diminished or absent. Mentation remains clear, vital signs are normal, and the neurologic findings are symmetrical. The most common cause of death is respiratory failure. The tempo of the disease and the extent of paralysis in the absence of treatment are highly variable. The symptoms may be restricted to a few cranial nerves, or there may be complete paralysis of all voluntary muscles. Progression may occur during a period of hours or days. The timing and extent of neurologic deficits depend on the size of the botulinum toxin inoculum.

DIAGNOSIS

Botulism should be suspected in patients with an acute flaccid paralysis involving the cranial nerves, particularly in the presence of bilateral cranial nerve VI dysfunction, associated neurologic findings, and a 10-hour to 5-day history of consuming suspect food, such as preserved or home-canned foods. Nausea, vomiting, abdominal pain, and diarrhea are common early in the illness, with constipation present when paralysis develops. The finding of two or more cases that are epidemiologically linked is virtually diagnostic of food-borne botulism because other causes of paralysis are rare and sporadic. In the absence of a history of suspect food ingestion, potentially infected wounds should be sought, including injection sites in users of black tar heroin. With bioterrorism, the epidemiology may reflect a common source exposure, such as a local water supply or an aerosolized toxin, but it could also be widely distributed with a contaminated food source, such as the milk supply.

Laboratory tests for suspected food-borne botulism include analysis of serum, stool, gastric contents, or food for botulinum toxin and culture of stool and suspect food or wounds for *C. botulinum.* Toxin assay specimens should be collected before treatment with antitoxin. With wound botulism, recovery of *C. botulinum* from wound cultures or detection of toxin in serum is diagnostic. The toxin assays are generally available only at public health laboratories. The standard is a mouse bioassay for detection and quantification of toxin. Toxin type is determined by type-specific antibody neutralization. In general, adult patients with clinical evidence of food-borne botulism have detectable toxin in sera in a third of cases and detectable toxin in stool in a third of cases, but the organism is recovered from stool in about 60%.

The differential diagnosis includes myasthenia gravis, Guillain-Barré syndrome, tick paralysis, cerebrovascular accident, trichinosis, Eaton-Lambert syndrome, hypocalcemia, hypermagnesemia, organophosphate poisoning, atropine poisoning, and paralytic poisoning by shellfish or puffer fish. Electromyography using repetitive stimulation at 2 to 50/second may be helpful in distinguishing causes of flaccid paralysis. Electromyography patterns with slow and rapid supramaximal stimulation show similar responses in botulism and Eaton-Lambert syndrome. Findings on cerebrospinal fluid analysis and cranial imaging are normal in botulism.

PREVENTION

The disease can be prevented by destroying spores in the original food source, inhibiting germination, or destroying preformed toxin.

TREATMENT

Rx

Clinicians who suspect botulism should immediately seek clinical consultation, notify public health authorities, and administer antitoxin. The agency to contact in the United States is the state health department, which will contact the Centers for Disease Control and Prevention (CDC) if needed. Additional emergency consultation is available from the CDC botulism duty officer through the CDC Emergency Operations Center (telephone: 770-488-7100); similar public health agencies should be contacted in other countries. Treatment consists of supportive care and passive neutralization with equine botulinum antitoxin.

The standard treatment of adults since 2010 in the United States is heptavalent botulinum antitoxin (HBAT) through a CDC-sponsored Food and Drug Administration investigational new drug protocol.[13] HBAT contains equine-derived antibody to the seven known botulinum toxin types (A to G) with the following nominal potency values: 7500 U anti-A; 5500 U anti-B; 5000 U anti-C; 1000 U anti-D; 8500 U anti-E; 5000 U anti-F; and 1000 U anti-G. BabyBIG (botulism immune globulin) is a human-derived treatment of infant botulism types A and B and is available for infant botulism through the California Infant Botulism Treatment and Prevention Program. The antitoxin should be given as early as possible and should not be delayed while awaiting microbiologic results. This treatment does not reverse paralysis or neutralize toxin already bound to nerve endings, but it does neutralize unbound toxin in the circulation to prevent progression. The HBAT antitoxin is derived from horses, and as a result, hypersensitivity reactions may occur.

Respiratory failure is a major risk, and patients must be monitored carefully with liberal criteria for ventilatory support. The requirement for mechanical ventilation varies from about 20% in adults with food-borne disease to 60% in patients with infant botulism. Other forms of supportive care include enteral or parenteral feeding and positioning in the reverse Trendelenburg position.

Toxin can be removed from the gastrointestinal tract by gastric lavage, cathartics, and enemas early in the course. Antibiotic treatment is unnecessary, except for wound botulism.

PROGNOSIS

The case-fatality rate for untreated food-borne botulism was once 60 to 70% but is currently 3 to 5% with treatment. Infant botulism in the United States now has a mortality rate of less than 1%; the use of human antitoxin has reduced the median duration of hospitalization from 6 to 3 weeks. Patients who survive any form of botulism generally have a complete recovery.

Tetanus

DEFINITION

Tetanus is a neurologic syndrome characterized by generalized rigidity and convulsive spasm of skeletal muscles caused by a neurotoxin elaborated at the site of injury by *Clostridium tetani.*

The Pathogen

C. tetani is an anaerobic, gram-positive, slender, motile bacillus. When it sporulates, the terminal spore gives the organism a characteristic "drumstick" or "tennis racket" shape. The vegetative form produces tetanospasmin, a protein neurotoxin with a molecular mass of approximately 151 kD, including a heavy chain (100 kD) that binds neuronal cells and a light chain that blocks the release of neurotransmitters.

EPIDEMIOLOGY

C. tetani can be found in 2 to 23% of soil samples, with the highest yield in manure-treated soil. The organism can also be found in stool from a variety of domestic and farm animals and poultry. Tetanus is most common in warm climates and in highly cultivated rural areas. The greatest problem occurs in resource-limited countries because of high numbers of unimmunized mothers and unhygienic practices. The estimated annual toll from neonatal tetanus in developing countries is greater than 257,000, mostly secondary to inadequate passive immunity caused by absence of immunity in the mother. In the United States, an average of 29 cases of tetanus were reported annually from 2001 to 2008 with a mortality of 13.2%, and almost all occurred in unimmunized or inadequately immunized persons.[14] In the U.S., patients 65 years of age and older constituted 31% of patients and had the highest mortality at 31%.

PATHOBIOLOGY

Tetanospasmin, also known as tetanus neurotoxin or TeNT, ranks with botulinum toxin as one of the most potent known microbial toxins; 2.5 ng/kg is a lethal human dose. Clinical tetanus usually results from entry of the organism into a wound and low oxygen conditions that allow spore germination and survival of the vegetative organism to produce toxin. Entry is usually through a traumatic or surgical wound, drug injection site, burn, skin ulcer, or infected umbilical cord. Tetanospasmin binds the peripheral nerve terminals and is then carried intra-axonally within membrane-bound vesicles to spinal neurons at a transport rate of approximately 75 to 250 mm/day. The light chain passes to the presynaptic terminals, where it blocks the release of neurotransmitters in inhibitory afferent motor neurons. Loss of the inhibitory influence results in sustained muscle contraction. Binding of the toxin is irreversible, so recovery requires the generation of new axon terminals.

CLINICAL MANIFESTATIONS

Forms of tetanus include generalized, local, cephalic, and neonatal. Generalized tetanus, which is the most common form, accounts for 80 to 90% of reported cases in the United States. The usual incubation period is 3 to 21 days (mean, 8 days), depending largely on the distance between the site of injury and the central nervous system. A short incubation period is associated with more severe symptoms. Generalized tetanus is characterized by a persistent tonic spasm with brief exacerbations. The neck and jaw are almost always involved. Trismus (lockjaw) is the initial complaint in 75% of cases, so the patient is often initially seen by a dentist or oral surgeon. Other early features include irritability, restlessness, diaphoresis, and dysphagia with hydrophobia and drooling. Persistent spasm of the back musculature may cause opisthotonos. These early manifestations reflect involvement of the paraspinous muscles. With progression, all muscles contract, with stronger muscles overtaking weaker muscles. Noise or tactile stimuli may precipitate spasms and generalized convulsions. Involvement of the autonomic nervous system may result in severe arrhythmias, blood pressure oscillation, profound diaphoresis, hyperthermia, rhabdomyolysis, laryngeal spasm, and urinary retention. In most cases, the patient remains lucid and afebrile. The condition may continue for 3 to 4 weeks, despite antitoxin therapy, because of the time required for intra-axonal toxin transport. Complications include fractures from sustained contractions, pulmonary emboli, bacterial infections, and dehydration.

Local tetanus, in which the patient has persistent muscle contractions in the extremity involving a contaminated wound, is rare and shows considerable variation in severity. In mild cases, a patient may simply have spasms of the involved extremity; in more severe cases, local painful spasms progress to generalized tetanus. This relatively unusual form of tetanus has an excellent prognosis, with only about 1% mortality.

Cephalic tetanus is also rare and generally follows a head injury or occurs with *C. tetani* infection of the middle ear. Clinical symptoms consist of isolated or combined dysfunction of the cranial motor nerves, most frequently cranial nerve VII. This dysfunction may remain localized or progress to generalized tetanus. The incubation period is only 1 or 2 days, and the prognosis for survival is usually poor.

Neonatal tetanus is generalized tetanus resulting from *C. tetani* infection in neonates. It occurs primarily in underdeveloped countries, where it accounts for up to half of all neonatal deaths.

DIAGNOSIS

The diagnosis of tetanus is usually based on clinical observations. The putative agent, *C. tetani*, is recovered from wound culture only about 30% of the time. Results of cerebrospinal fluid analysis are entirely normal. Diagnostic testing is usually not necessary except in cases lacking an identified portal of entry. The differential diagnosis depends on the dominant clinical features and includes dystonic reactions as a result of neuroleptic toxicity, seizure disorders, hypocalcemic or alkalotic tetany, alcohol withdrawal, and strychnine poisoning. Strychnine also antagonizes glycine, and strychnine poisoning is the only condition that truly mimics tetanus. Strychnine levels in blood and urine establish the diagnosis. Dystonic reactions may resemble tetanus and are distinguished by rapid response to anticholinergic agents.

PREVENTION

Immunization with tetanus toxoid is virtually 100% effective, so nearly all cases of tetanus occur in unimmunized or inadequately immunized individuals. The Advisory Committee on Immunization Practices has recommended diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) for active immunization of infants and children at 2 months, 4 months, 6 months, 15 to 18 months, and 4 to 6 years of age. Protective levels of serum antitoxin in persons who complete the primary series persist for at least 10 years. Td (tetanus and diphtheria toxoids adsorbed for adult use) is recommended every 10 years, but this recommendation has been modified because of concerns about waning adult pertussis antibody protection; as a result, the Advisory Committee on Immunization Practices recommends that all adults aged 19 years and older who have not yet received a dose of Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis) should receive a single dose regardless of the interval since last Td.[15] The recommended primary immunization series for unimmunized persons older than 7 years is Td at time 0, 4 to 8 weeks, and 6 to 12 months after the second dose, and then every 10 years. Nearly all states now require DTaP immunization for school enrollment. Immunization of childbearing women with Tdap confers protection to their infants through transplacental maternal antibody and is recommended during the third trimester of each pregnancy for optimal fetal passive antibody protection.[16]

Prevention of tetanus after injury (Table 296-1) requires appropriate wound management, assurance of adequate immunity, and consideration of antibiotic prophylaxis. The aim of surgery is to eliminate necrotic tissue, purulent collections, and foreign bodies that promote the environmental conditions necessary for spore germination. Passive immunization with tetanus immune globulin (TIG) is recommended only for "tetanus-prone"

TABLE 296-1 GUIDE TO TETANUS PROPHYLAXIS IN ROUTINE WOUND MANAGEMENT

HISTORY OF ADSORBED TETANUS TOXOID (NO. OF DOSES)	CLEAN MINOR WOUNDS		ALL OTHER WOUNDS*	
	Tdap or Td†	*TIG*‡	*Tdap or Td*†	*TIG*‡
<3 or unknown	Yes	No	Yes	Yes
≥3	No§	No	No¶	No

*Such as (but not limited to) wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
†For children younger than 7 years, DTaP (pediatric diphtheria–tetanus toxoid plus acellular pertussis vaccine) is recommended; if pertussis vaccine is contraindicated, DT (pediatric diphtheria–tetanus toxoid) is given. For persons aged 7 to 9 years or 65 years or older, Td (adult tetanus–diphtheria toxoid) is recommended. For persons 10 to 64 years, Tdap (adult tetanus–diphtheria toxoid plus acellular pertussis vaccine) is preferred to Td if the patient has never received Tdap and has no contraindication to pertussis vaccine. For persons 7 years and older, if Tdap is not available or not indicated because of age, Td is preferred to TT (tetanus toxoid alone). Note that pediatric formulations (DT and DTaP) contain an amount of tetanus toxoid similar to that of adult Td, but they contain three to four times as much diphtheria toxoid. DTaP and Tdap vaccines do not contain thimerosal as a preservative.
‡TIG is human tetanus immune globulin. Equine tetanus antitoxin should be used when TIG is not available.
§Yes, if more than 10 years since the last dose.
¶Yes, if more than 5 years since the last dose.

wounds in patients with an inadequate or unknown primary immunization status. The determination of whether a wound is tetanus prone depends on the interval between injury and treatment, the degree of contamination, the extent of devitalized tissue or foreign bodies at the site of injury, and the depth of injury. Antimicrobial agents, such as penicillin and metronidazole, may be given to inhibit replication of the vegetative forms of *C. tetani*, but immunization and wound cleansing are considered more important.

TREATMENT

Patients with tetanus require intensive care with particular attention to respiratory support, treatment with benzodiazepines, autonomic nervous system support, passive and active immunization, surgical débridement, and antibiotics directed against *C. tetani*.[17] There may be clinical progression for 2 to 4 weeks, despite antitoxin treatment, because of the time required to complete the transport of toxin. The severity of disease may be reduced by partial immunity; as a result, some patients have mild disease with minimal mortality, whereas others have mortality rates as high as 60% despite expert care.

Supportive Care

It is most important to assess airway function. Many patients require endotracheal intubation with benzodiazepine sedation and neuromuscular blockade; a tracheostomy should be placed if the endotracheal tube causes spasms. A feeding tube is usually required for nutritional support.

Control of Muscle Spasms

Benzodiazepines have become the mainstay of therapy to control spasms and to provide sedation. The most extensively studied is diazepam given in 5-mg increments; lorazepam and midazolam are equally effective. Patients with tetanus may have high tolerance for the sedative effects of these drugs and may require exceptionally high doses. When tetanus symptoms resolve, the drugs must be tapered during at least 2 weeks to prevent withdrawal reactions. If control of spasms cannot be achieved by benzodiazepines, long-term neuromuscular blockade is performed with vecuronium (6 to 8 mg/hour).

Passive Immunization

Human TIG should be given as soon as possible to neutralize toxin that has not entered neurons. The usual dose is 500 IU intramuscularly. Higher doses or intrathecal administration does not appear to be more effective. An alternative to TIG is pooled intravenous immune globulin. Equine TIG is equally effective, but the rate of allergic reactions is high because of the equine source; this preparation should not be used if human TIG is available.

Active Immunization

The standard three-dose schedule of immunization with tetanus toxoid should be given at an injection site separate from that used for immune globulin.

Antibiotic Therapy

C. tetani is susceptible in vitro to penicillins, cephalosporins, imipenem, macrolides, metronidazole, and tetracyclines. Clinical studies favor the use of metronidazole, which should be given in an intravenous dose of 2 g/day for 7 to 10 days.

Autonomic Nervous System Dysfunction

This complication generally reflects excessive catecholamine release and is usually treated with labetalol (0.25 to 1.0 mg/minute) for blood pressure control. Hypotension may require norepinephrine infusion. Bradycardia may require a pacemaker.

Surgery

Any wounds should be appropriately débrided.

PROGNOSIS

The overall mortality rate for generalized tetanus is 20 to 25%, even in modern medical facilities with extensive resources. Patients with moderate or severe generalized tetanus generally require treatment for 3 to 6 weeks. The highest mortality rates are at the extremes of age. The most frequent cause of death is pneumonia, but many patients have no obvious findings at autopsy, suggesting that death was directly due to the neurotoxin. Patients who recover usually recover completely.

OTHER CLOSTRIDIAL INFECTIONS

Clostridium perfringens Type C Enteritis

C. perfringens type C enteritis, also called enteritis necroticans, is a necrotizing disease involving the proximal small intestine caused by β-toxin–producing strains of *C. perfringens*. Enteritis necroticans occurs as sporadic cases or in outbreaks, most often in underdeveloped countries, most notably in Papua New Guinea in the 1960s and 1970s, where it was called pigbel because of its association with pork feasts by aboriginal people in the highlands. Outbreaks have also been reported among Khmer refugees in Thailand in the 1980s and in Sri Lanka in 2007. Enteritis necroticans also occurs rarely in isolated cases in the developed world, particularly among patients with diabetes mellitus.

PATHOBIOLOGY

Experimental and clinical evidence supports infection with *C. perfringens* type C and β-toxin as the causative agent of and key virulence factor in enteritis necroticans. The organism has been identified at the site of necrotic lesions, the disease can be reproduced in guinea pigs, isogenic β-toxin gene null mutants are avirulent, and vaccination with a toxoid preparation of β-toxin is protective. β-Toxin production is rapidly upregulated in the presence of Caco-2 enterocytes, and the toxin localizes to the endothelium in humans and piglets infected with *C. perfringens* type C.[18] These findings may explain key histopathologic hallmarks of this disease, that is, deep small intestinal necrosis with vascular necrosis and hemorrhage in the lamina propria.

CLINICAL MANIFESTATIONS

In Papua New Guinea, affected patients usually develop severe abdominal pain 12 hours to several days after a ritual pork feast (or, presumably, other infected food). Vomiting and bloody diarrhea are frequently associated findings. The abdomen becomes distended, and thickened bowel loops are sometimes appreciated on palpation. Disease severity and whether the patient experiences spontaneous recovery or bowel perforation and death depend on the extent of intestinal involvement.

DIAGNOSIS

Recognition of the clinical syndrome is critical to making the diagnosis. Culture to identify specific β-toxin–producing strains of *C. perfringens* remains a research tool and is not helpful in the management of patients. Plain radiographs of the abdomen may show dilated small bowel loops and ileus.

PREVENTION

An effective toxoid vaccine was available and used in Papua New Guinea (where the disease is endemic) as well as in the Khmer refugee camp outbreak in 1986. Vaccination was discontinued in the mid-1990s, and the vaccine is no longer available. A 2002 survey of Papua New Guinea children in the highlands suggested that pigbel was responsible for 9 to 16% of acute abdominal cases and clustered in three close geographic regions.

TREATMENT

Treatment is primarily supportive, including nasogastric suction and intravenous hydration. Surgical resection of the infected bowel is often required for those who do not initially respond to supportive measures. Antibiotics (penicillin, chloramphenicol, metronidazole) are almost always given empirically, but their role has not been defined. Prognosis depends on the extent of disease and the availability of surgery for those with more extensive intestinal involvement.

Clostridium perfringens Type A Diarrhea

C. perfringens type A is a well-recognized cause of food poisoning due to the ingestion of food, usually meat, heavily contaminated with enterotoxin-producing *C. perfringens* after storage at inappropriate temperatures. Enterotoxin production is associated with sporulation of ingested vegetative bacteria in the small intestine. The incubation period is 7 to 15 hours after ingestion, and the most prominent symptoms are diarrhea and abdominal pain. The syndrome is usually mild and self-limited.

In contrast to food poisoning due to *C. perfringens* type A, a more severe and protracted infectious diarrhea syndrome due to this organism has been recognized among hospitalized or institutionalized patients. These patients often have a history of prior or concomitant antibiotic use, and an enzyme immunoassay for *C. perfringens* enterotoxin is commercially available for investigative use. Metronidazole treatment is recommended for those with protracted diarrhea. As with CDI, diarrhea may recur after successful treatment.

Despite the self-limited nature of most food-associated diarrheal syndromes, *C. perfringens* type A has also been responsible for outbreaks of fatal illness in institutionalized mentally ill patients. A recent outbreak in a state psychiatric hospital linked to improperly prepared chicken was notable for three deaths (7% case-fatality rate) in patients taking antimotility agents and in whom necrotizing colitis was found at autopsy.[19]

REVIEW QUESTIONS

1. What is the preferred treatment for a patient with a first episode of mild to moderate *C. difficile* infection (CDI)?

A. Metronidazole 500 mg orally three times a day for 10 days
B. Vancomycin 125 mg orally four times a day for 10 days
C. Fidaxomicin 200 mg orally twice a day for 10 days
D. Fecal microbiota transplant
E. A or B

Answer: E This is an evolving area of treatment recommendation that will likely change with update of the CDI guidelines, so E is the current best answer. Both metronidazole and vancomycin orally are effective for mild to moderate CDI treatment, but the publication of the largest randomized controlled trial of metronidazole versus vancomycin demonstrated that metronidazole was significantly inferior to vancomycin ($P = .02$) for all patients with CDI, which is likely to change future recommendations to vancomycin. Fidaxomicin is also effective but is much more expensive than metronidazole or vancomycin. Fecal transplants are also effective, but experience with them has been limited to treatment of patients with multiple recurrences of CDI, for which it is effective in preventing additional recurrences.

2. What is the preferred treatment for patients with severe first-episode CDI?

A. Metronidazole 500 mg orally three times a day for 10 days
B. Vancomycin 125 mg orally four times a day for 10 days
C. Fidaxomicin 200 mg orally twice a day for 10 days
D. Both A and B used together
E. Metronidazole 500 mg IV three times a day plus vancomycin 500 mg orally four times a day for 10 days

Answer: B CDI guidelines recommend vancomycin for severe CDI.[3] Metronidazole was inferior to vancomycin for severe CDI in one randomized controlled trial and was inferior to vancomycin for all CDI in another larger randomized controlled trial. Fidaxomicin is also effective in treating severe CDI, but it is no better than vancomycin in eliciting cure; however, it is superior in reducing recurrence of CDI. Because of much higher pricing than for vancomycin, it is not the preferred treatment of first-episode CDI. Combined use of metronidazole and vancomycin has not been demonstrated to be superior to vancomycin alone for severe disease; however, use of IV metronidazole and higher dose oral vancomycin is recommended for severe complicated or fulminant CDI where there is significant risk of ileus that might prevent oral vancomycin from reaching the colon.

3. A California injection heroin user is "skin popping" because of exhausting all intravenous sites of injection. He has noted increased swelling and pain at an arm injection site during the past week and now also notes that his vision is blurred and his speech is slurred, and he has chills and feels weak and feverish. The most likely cause of his symptoms is

A. *Clostridium novyi* injection site abscess
B. *Clostridium tetani* injection site infection
C. *Clostridium botulinum* infection at the injection site
D. *Clostridium perfringens* injection site abscess
E. *Clostridium sordelli* injection site infection

Answer: C Most drug injection site infections are polymicrobial, and any of the listed clostridia could be present in addition to other anaerobes and aerobic bacteria, such as staphylococci and streptococci. However, of the clostridia listed, only *C. botulinum*, the cause of botulism, is associated with the symptoms of blurred vision, slurred speech, and weakness, a hallmark of early cranial nerve involvement and descending paralysis.

4. Which of the following statements about tetanus is *not* true?

A. It is the cause of hundreds of thousands of neonatal deaths globally because of inadequate maternal tetanus vaccination.
B. Although it is rare in the United States, most cases occur in patients inadequately vaccinated.
C. A short incubation period from injury to tetanus symptoms is indicative of a rapid resolution of symptoms and increased survival.
D. Immunization of childbearing women with Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis) is recommended during the third trimester of each pregnancy for optimal fetal passive antibody protection, which is largely directed at preventing pertussis.
E. The mortality rate for generalized tetanus is 20 to 25%, even in modern medical facilities with extensive resources.

Answer: C This statement is incorrect. The shorter the period from injury to tetanus symptoms, the worse the prognosis is and the longer symptoms are likely to last. The other statements are all true.

5. Which clostridial organism is most likely responsible for the following syndrome? A 12-year-old boy with poorly controlled type 1 diabetes mellitus was admitted to the hospital with ketoacidosis and altered mental status 2 to 3 days after eating several large meals that included chitterlings. His white blood cell count was 11,300 mm^3, and his abdominal radiograph showed dilated loops of small bowel with gas in the bowel wall. His hospital course was notable for persistent hematemesis and increasing abdominal distention. Bloody ascites and necrotic jejunum and ileum were found at laparotomy.

A. *C. difficile*
B. *C. perfringens* type A
C. *C. perfringens* type C
D. *C. sordellii*
E. *C. botulinum*

Answer: C Although it is rare in developed countries, enteritis necroticans due to *C. perfringens* type C is responsible for this unique syndrome of small intestinal necrosis. Diabetes mellitus is a common risk factor noted in cases outside endemic areas, as in this case, which was reported in the southern United States in 2000. (Petrillo TM, Beck-Sagué CM, Songer JG, et al. Enteritis necroticans [pigbel] in a diabetic child. *N Engl J Med.* 2000;342:1250-1253.) *C. difficile* may cause severe intestinal disease, but disease is limited to the colon. *C. perfringens* type A rarely causes necrotizing intestinal syndromes, but again, disease is typically limited to the colon. *C. sordellii* and *C. botulinum* are usually not associated with acute abdominal syndromes.

297 DISEASES CAUSED BY NON–SPORE-FORMING ANAEROBIC BACTERIA

ITZHAK BROOK

DEFINITION

Anaerobic bacteria are the predominant members of the indigenous, normal human flora, including the skin and the oral, gastrointestinal, and vaginal mucosa (Fig. 297-1; Table 297-1). However, the types of predominant anaerobes are different at each location.

The Pathogens

Advances in taxonomics have led to reclassification of many anaerobic species (E-Table 297-1). The genus *Bacteroides* is used only for species of the *Bacteroides fragilis* group. The "oral" *Bacteroides* and "pigmented" *Bacteroides* species have been reclassified as *Prevotella* (saccharolytic, pigmented species), *Porphyromonas* (asaccharolytic species), and other genera. Capnophilic organisms (which require an elevated concentration of carbon dioxide for growth), sometimes referred to as microaerophiles, are not true anaerobes and are often more related to *Campylobacter*, *Capnocytophaga*, and other genera. In addition, many new genera and several new species have been created to accommodate pathogens such as *Bilophila wadsworthia*, *Sutterella wadsworthensis*, *Centipeda periodontii*, and *Anaerobiospirillum thomasii*. *Fusobacterium nucleatum* is the predominant *Fusobacterium* species isolated from clinical specimens.

EPIDEMIOLOGY

Anaerobes are opportunistic pathogens that can cause serious infections, generally in synergistic infections in combination with aerobic bacteria. Because the microbiology of these infections is often complex and culture results may be delayed, awareness of the normal bacterial flora at the site of infection is an indispensable guide for selection and institution of empirical antimicrobial therapy.

TABLE 297-1 LOCATION OF VARIOUS GROUPS OF ANAEROBES AS NORMAL MICROFLORA IN HUMANS

LOCATION	NO. OF ORGANISMS PER GRAM		PREDOMINANT ANAEROBIC BACTERIA
	Aerobes	*Anaerobes*	
Skin	—	—	*Propionibacterium acnes* *Peptostreptococcus* spp
Mouth/upper respiratory tract (in saliva)	10^8-10^9	10^9-10^{11}	Pigmented *Prevotella* and *Porphyromonas* spp *Fusobacterium* spp *Peptostreptococcus* spp *Actinomyces* spp
Gastrointestinal tract (in fecal material)			
Upper	10^2-10^5	10^3-10^7	*Bacteroides fragilis* group *Clostridium* spp
Lower	10^5-10^9	10^{10}-10^{12}	*Peptostreptococcus* spp *Bifidobacterium* spp *Eubacterium* spp
Female genital tract (in vaginal secretions)	10^8	10^9	*Peptostreptococcus* spp *Prevotella bivia* *Prevotella disiens*

Modified from Duerden BI. Virulence factors in anaerobes. *Clin Infect Dis.* 1994;18(Suppl 4):253.

PATHOBIOLOGY

Anaerobic bacteria range from those that cannot survive even a brief exposure to oxygen to those that can survive even in the presence of atmospheric oxygen (e.g., *B. fragilis*). Most anaerobes require an environment with a low oxidation-reduction potential (E_h gradient), which can be achieved in association with low pH, tissue destruction, byproducts from aerobic bacterial metabolism, or low oxygen content. Although they are not true anaerobes, some organisms, such as microaerophilic streptococci and other capnophilic or difficult-to-cultivate bacteria, are sometimes lumped together with anaerobes because of their fastidious nature. Some genera, such as *Lactobacillus* and *Actinomyces*, include both aerobic and anaerobic species.

Anaerobic bacteria possess a variety of virulence factors that are species specific (Table 297-2).

CLINICAL MANIFESTATIONS

Bacteremia

Transient anaerobic bacteremia occurs in about 85% of patients immediately after dental cleaning or manipulation. It is estimated that more than 200 cases of endocarditis from anaerobes are reported annually in the United States, usually in association with anatomic abnormalities or damaged cardiac valves (Chapter 76). Most anaerobic bacteremias are intermittent and associated with serious intra-abdominal or female genital tract, skin, and soft tissue infections, often proximal to the gastrointestinal tract. Which organisms are involved depends on their portal of entry and the underlying disease. The most common isolates are the *B. fragilis* group (60 to 75% of isolates). About 5 to 15% of bacteremias are caused by anaerobes, and they are the sole isolates in two thirds of these. Mortality associated with *B. fragilis* group bacteremia is 15 to 30%. Bacteremia with the *B. fragilis* group generally originates from a gastrointestinal source; with pigmented *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp, from oropharyngeal and pulmonary sources; with *Fusobacterium* spp, from the female genital tract; and with *Propionibacterium acnes*, from foreign body sources. Bacteremia with peptostreptococci is associated with all sources but especially with the oropharyngeal, pulmonary, and female genital tracts.

Central Nervous System Infections

Anaerobes can cause brain abscess, subdural empyema, epidural abscess, and meningitis. The main source of brain abscess is an adjacent, generally chronic infection in the ears, mastoids, sinuses, oropharynx, teeth, or lungs. Rarely, bacteremia of another origin or endocarditis can cause such infection.

Meningitis caused by anaerobes is uncommon and can follow respiratory or dental infection or develop as a complication of a cerebrospinal fluid shunt. The isolates usually isolated from brain abscesses that complicate respiratory and dental infections include *Prevotella*, *Porphyromonas*, *Bacteroides*, *Fusobacterium*, and *Peptostreptococcus* spp. Microaerophilic and other streptococci are also often isolated. *Propionibacterium acnes* is common in shunt infections.

Head and Neck

Dental infections (Chapter 425) associated with a variety of oral anaerobes include periodontal disease, gingivitis, pulpitis, acute necrotizing ulcerative gingivitis, localized juvenile periodontitis, adult periodontitis, pericoronitis, endodontitis, periapical and dental abscesses, and postextraction infection.[1] Peritonsillar, retropharyngeal, and parapharyngeal abscesses (Chapter 429) are deep-seated, potentially life-threatening infections that may spread into the various potential spaces of the neck or mediastinum and cause jugular vein thrombosis. Oral anaerobes can be recovered in more than 50% of such cases, usually mixed with aerobes. Other regional infections include cervicofacial actinomycosis (Chapter 329), Ludwig's angina, *Fusobacterium necrophorum* sepsis with metastatic infection (Lemierre's syndrome), suppurative sialoadenitis (including parotitis), neck space infections, thyroiditis and chronic sinusitis (Chapter 426), otitis media (Chapter 426), and mastoiditis. Management involves surgical drainage and appropriate antimicrobial therapy.

Pleuropulmonary

Anaerobes predominate in oral and upper respiratory tract normal flora, and most aspiration pneumonias are due to this flora (Chapter 97).[2] Aspiration can result from altered consciousness, dysphagia, or mechanical devices such as intubation equipment. Poor oral hygiene is associated with an increased anaerobic bacterial burden, and the presence of aerobes or necrotic tissue lowers the pH, which facilitates the growth of anaerobes. Anaerobes are involved in 90% of community-acquired aspiration pneumonia and in about a third of nosocomial aspiration pneumonia, empyema, lung abscess, and pneumonia associated with tracheostomy. If the anaerobic component of aspiration pneumonia is not treated, the anaerobes can cause a lung abscess. Management requires good pulmonary toilet and antimicrobial therapy.

Intra-abdominal

Because anaerobes outnumber aerobes by 1000 to 1 in the large intestine, they play a major role in almost all intra-abdominal infections. Most visceral abscesses (e.g., hepatic; Chapter 151), chronic cholecystitis (Chapter 155), perforated and gangrenous appendicitis (Chapter 142), postoperative wound infections and abscesses, diverticulitis (Chapter 142), and any infection associated with fecal contamination of the abdominal cavity involve both aerobes and anaerobes. *B. fragilis* group members predominate because they are encapsulated, resist phagocytosis, are often resistant to many antimicrobials, and promote abscess formation. They may also be associated with concomitant bacteremia and sepsis. Randomized controlled trials have found that prophylactic antibiotics covering both anaerobic and aerobic bacteria administered orally and/or intravenously prior to elective colorectal surgery reduce the risk of surgical wound infection by as much as 75%.

Obstetric-Gynecologic

A variety of obstetric-gynecologic infections involve anaerobes. These are polymicrobial and include bacterial vaginosis; soft tissue perineal, vulvar, and Bartholin gland abscesses; endometritis; pyometra; salpingitis; tubo-ovarian abscesses; adnexal abscess; pelvic inflammatory disease, which may include pelvic cellulitis and abscess; chorioamnionitis; vaginal cuff cellulitis; septic pelvic thrombophlebitis; intrauterine contraceptive device–associated infection; septic abortion; and postsurgical obstetric and gynecologic infections. Bacterial vaginosis has been associated with preterm labor or delivery, chorioamnionitis, low birthweight, postpartum endometritis, and postabortal pelvic inflammatory disease. Bacterial vaginosis can increase the risk for infection with human immunodeficiency virus type 1 and the development of other sexually transmitted diseases (Chapter 285).

Skin and Soft Tissue

Cutaneous infections include infected ulcers, cellulitis (including synergistic necrotizing cellulitis), pyoderma, paronychia, hidradenitis suppurativa, and a variety of secondarily infected sites. Such sites include secondarily infected gastrostomy or tracheostomy site wounds, subcutaneous sebaceous or inclu-

sion cysts, eczema, psoriasis, poison ivy, atopic dermatitis, eczema herpeticum, scabies or kerion, and postsurgical wounds.

Subcutaneous infections include abscesses, decubitus ulcers, infected diabetic (vascular or trophic) ulcers, human and animal bite wounds, anaerobic cellulitis and gas gangrene, bacterial synergistic gangrene, Fournier's gangrene, infected pilonidal cyst or sinus, and burn wounds. Anaerobic soft tissue infections that occur deeper are necrotizing fasciitis, necrotizing synergistic cellulitis, and gas gangrene. These infections can involve the fascia and can induce myositis and myonecrosis.

Cultures frequently yield isolates that are members of the normal flora of the region of the infection. In addition to oral and skin flora, human bite infections often contain *Eikenella* species, and animal bites harbor *Pasteurella multocida*.

The infections are generally polymicrobial, and some (e.g., decubitus ulcers, diabetic foot ulcers) are often complicated by osteomyelitis or bacteremia. Deep tissue infections, such as necrotizing cellulitis, fasciitis, and myositis, often involve *Clostridium* species, *Streptococcus pyogenes*, or a polymicrobic aerobic and anaerobic flora. They are often associated with gas in the tissues and putrid-like pus with a gray, thin quality and have a high rate of bacteremia and mortality. Management of deep-seated soft tissue infection includes surgical débridement, drainage, and vigorous surgical management.

Osteomyelitis and Septic Arthritis

Anaerobes can be involved in osteomyelitis of the long bones after trauma and fracture, osteomyelitis related to peripheral vascular disease, decubitus ulcers, and osteomyelitis of the cranial and facial bones. Most of these infections are polymicrobial.

Cranial and facial bone osteomyelitis is generally caused by spread from a contiguous soft tissue source or from sinus, ear, or dental infection. Intestinal anaerobes originating from decubitus ulcers are involved in pelvic osteomyelitis. Osteomyelitis of long bones and septic arthritis are generally caused by hematogenous spread, trauma, or the presence of a prosthetic device.

The most commonly recovered anaerobes are peptostreptococci and *P. acnes* (often in prosthetic joint infection), *B. fragilis* group and fusobacteria (often of hematogenous origin), and clostridia (associated with trauma).

DIAGNOSIS

Anaerobic infections should be suspected in a number of specific clinical scenarios (Table 297-3). An appropriately collected microbiologic specimen (Table 297-4) is critical for accurate diagnosis.

TREATMENT

Rx

General principles of treatment (Table 297-5) include appropriate antimicrobial therapy coupled with prompt drainage, decompression of closed space infections, relief of obstructions, and surgical débridement.[3,4] The various clinically important anaerobes can be characterized by reasonably predictable antimicrobial susceptibility patterns (Table 297-6). However, some anaerobes have become resistant to antimicrobials, and many can develop resistance during therapy.[5] Reliable culture and sensitivity results should ultimately guide therapy. The efficacy of hyperbaric oxygen is unproved, but its use in conjunction with other therapeutic measures is not contraindicated.

In choosing antimicrobials for the treatment of mixed infections, their aerobic and anaerobic antibacterial spectra and their availability in oral or parenteral form should be considered. Some antimicrobials have a limited range of activity.[6] For example, metronidazole is active only against anaerobes and therefore cannot be administered as a single agent for the treatment of mixed infections. Others (i.e., carbapenems, a penicillin plus a β-lactamase inhibitor) have wide spectra of activity against aerobes and anaerobes.

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on normal flora, and their bactericidal activity. Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may suggest the types of anaerobes present in the infection and the nature of the infectious process.

Even though the length of therapy for anaerobic infections is generally longer than that for aerobic and facultative infections, the length of treatment must be individualized, depending on the response. In some cases, treatment may require 6 to 8 weeks, but therapy may be shortened with proper surgical drainage. An anti–gram-negative enteric agent is generally added to treat Enterobacteriaceae in managing intra-abdominal infections.

The available parenteral antimicrobials for most infections are metronidazole, chloramphenicol, clindamycin, cefoxitin, a penicillin (i.e., ticarcillin, ampicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanic acid, sulbactam, tazobactam), a carbapenem (i.e., imipenem, meropenem, doripenem, ertapenem), and tigecycline.

An agent effective against gram-negative enteric bacilli (e.g., an aminoglycoside, fluoroquinolone) or an antipseudomonal cephalosporin (e.g., cefepime) is generally added to metronidazole and, occasionally, cefoxitin in treatment of intra-abdominal infections. Penicillin can be added to metronidazole for the treatment of intracranial, pulmonary, or dental infections to cover microaerophilic streptococci and *Actinomyces* species. Penicillin is added to clindamycin to supplement its coverage against *Peptostreptococcus* species and other gram-positive anaerobic organisms. For *Chlamydia* and

TABLE 297-3 CLINICAL INDICATORS OF ANAEROBIC INFECTION

Infection adjacent to a mucosal surface
Foul-smelling discharge
Necrotic gangrenous tissue and abscess formation
Free gas or crepitus in tissue
Bacteremia or endocarditis with no growth on aerobic blood cultures
Infection related to the use of antibiotics effective against aerobes only (e.g., trimethoprim-sulfamethoxazole, aminoglycosides, older quinolones)
Infection related to tumors or other destructive processes
Infected thrombophlebitis
Infection after bites
Black discoloration of exudates containing *Prevotella melaninogenica*, which may fluoresce under ultraviolet light
"Sulfur granules" in discharges caused by actinomycosis
Clinical finding of gas gangrene or necrotizing fasciitis
Clinical condition predisposing to anaerobic infection (e.g., after maternal amnionitis, fistulous tracks, bites, dental infection, bowel perforation)

TABLE 297-4 SPECIMEN ACCEPTABILITY FOR ANAEROBIC CULTURE

SPECIMENS THAT SHOULD NOT BE CULTURED FOR ANAEROBES
Feces or rectal swabs
Throat or nasopharyngeal swabs
Sputum or bronchoscopic specimens
Routine or catheterized urine
Vaginal or cervical swabs
Material from superficial wounds or abscesses not collected properly to exclude surface contamination
Material from abdominal wounds obviously contaminated with feces, such as an open fistula
SPECIMENS APPROPRIATE FOR ANAEROBIC CULTURE
All normally sterile body fluids other than urine, such as blood, pleural fluid, and joint fluid
Urine obtained by suprapubic bladder aspiration
Percutaneous transtracheal aspiration, direct lung puncture, or double-lumen catheter bronchial brushing and bronchoalveolar lavage (both cultured quantitatively)
Culdocentesis fluid obtained after decontamination of the vagina
Material obtained from closed abscesses
Material obtained from sinus tracks or draining wounds

TABLE 297-5 GENERAL PRINCIPLES OF THERAPY FOR ANAEROBIC INFECTIONS

Decompression of closed spaces
Débridement
Drainage
Relief of obstructions
Irrigation
Provision of adequate circulation when possible
Removal of foreign bodies
Antimicrobials
Activity against most likely pathogen or pathogens: location dependent, minimal effect on normal flora
Absorption, appropriate route of administration (intravenous, oral)
Penetration into site of infection
Dosage appropriate for local tissue levels, body mass of patient, renal and liver function
Duration appropriate for condition
Susceptibility testing of isolate to guide specific therapy

TABLE 297-6 ANTIMICROBIAL SUSCEPTIBILITY PATTERNS FOR ANAEROBIC BACTERIA*

BACTERIA	PENICILLIN	β-LACTAMASE†	CEFOXITIN	CEFOTETAN	CARBAPENEMS, TIGECYCLINE	MOXIFLOXACIN	CLINDAMYCIN	METRONIDAZOLE

REVIEW QUESTIONS

1. What culture is appropriate for isolation of anaerobic bacteria?

A. Vaginal or cervical swabs
B. Routine or catheterized urine
C. Throat or nasopharyngeal swabs
D. Aspirate of abscess
E. Feces or rectal swabs

Answer: D Obtaining an aspirate after sterilizing the skin or bypassing the normal flora avoids contamination of the specimen by normal skin or mucous membrane bacterial flora.

2. *Bacteroides fragilis* bacteremia is usually associated with

A. Trauma
B. Aspiration
C. Rupture of abdominal viscus
D. Malignant disease
E. Osteomyelitis

Answer: C Although *B. fragilis* group is the most common species found in clinical specimens, it is the least common *Bacteroides* present in fecal flora, representing only 0.5% of the bacteria present in stool. The pathogenicity of this group of organisms probably results from its ability to produce capsular material, which is protective against phagocytosis. Because of its presence in normal flora of the gastrointestinal tract, this organism is predominant in bacteremia associated with intra-abdominal infections, peritonitis, and abscesses following rupture of a viscus.

3. Which of the following antimicrobials is not effective against anaerobic bacteria?

A. Amoxicillin
B. Metronidazole
C. Gentamicin
D. Moxifloxacin
E. Cefoxitin

Answer: C Aminoglycosides, including gentamicin, are not effective against anaerobic bacteria because of their inability to reach the ribosome. Gentamicin is effective only in aerobic microorganisms because it enters cells through an electron transport–linked system that requires oxygen.

4. Which anaerobic organism cannot produce β-lactamase?

A. *Fusobacterium nucleatum*
B. *Bacteroides fragilis*
C. *Prevotella melaninogenica*
D. *Peptostreptococcus* spp
E. *Bacteroides thetaiotaomicron*

Answer: D Most *B. fragilis* group, up to 20 to 50% of *Prevotella* spp, and *Fusobacterium nucleatum* isolates can produce β-lactamase.

5. *Propionibacterium acnes* is associated with

A. Chronic sinusitis
B. Splenic abscess
C. Cellulitis
D. Abdominal trauma
E. Central nervous system shunt infection

Answer: E *Propionibacterium* species are part of the normal bacterial flora that colonizes the skin, conjunctiva, oropharynx, and gastrointestinal tract. These non–spore-forming, anaerobic, gram-positive bacilli are frequent contaminants of specimens of blood and other sterile body fluids and have been generally considered to play little or no pathogenic role in humans. *Propionibacterium acnes* has, however, been recovered in specimens obtained from patients with infections associated with a foreign body (such as an artificial valve), endocarditis, and central nervous system shunt infections.

298

NEISSERIA MENINGITIDIS INFECTIONS

DAVID S. STEPHENS

DEFINITION

Neisseria meningitidis (the meningococcus) is the cause of epidemic bacterial meningitis, fulminant sepsis (meningococcemia), milder bacteremia, and, less commonly, focal infections (such as pneumonia, septic arthritis, purulent pericarditis, and conjunctivitis).[1-3]

The Pathogen

N. meningitidis is an aerobic, diplococcal gram-negative β-proteobacterium and a member of the family Neisseriaceae, which also includes *Neisseria gonorrhoeae* (Chapter 299), another important human pathogen. The meningococcus is a commensal of the human upper respiratory tract, but it can also cause local and devastating invasive human disease. Human mucosal surfaces, most commonly the nasopharynx, are the only known reservoir. There are 12 confirmed serogroups of *N. meningitidis*, based on different capsular polysaccharide structures, but only 6 serogroups (A, B, C, W, X, and Y) cause almost all invasive meningococcal disease (Fig. 298-1). Highly pathogenic meningococci are also distinguished by genetically defined clonal complexes that can emerge and spread worldwide.[4] Dissecting the basis of meningococcal disease has provided important scientific lessons for bacterial emergence and pathogenesis, antibiotic resistance mechanisms, innate and adaptive human immune responses, and vaccine development.

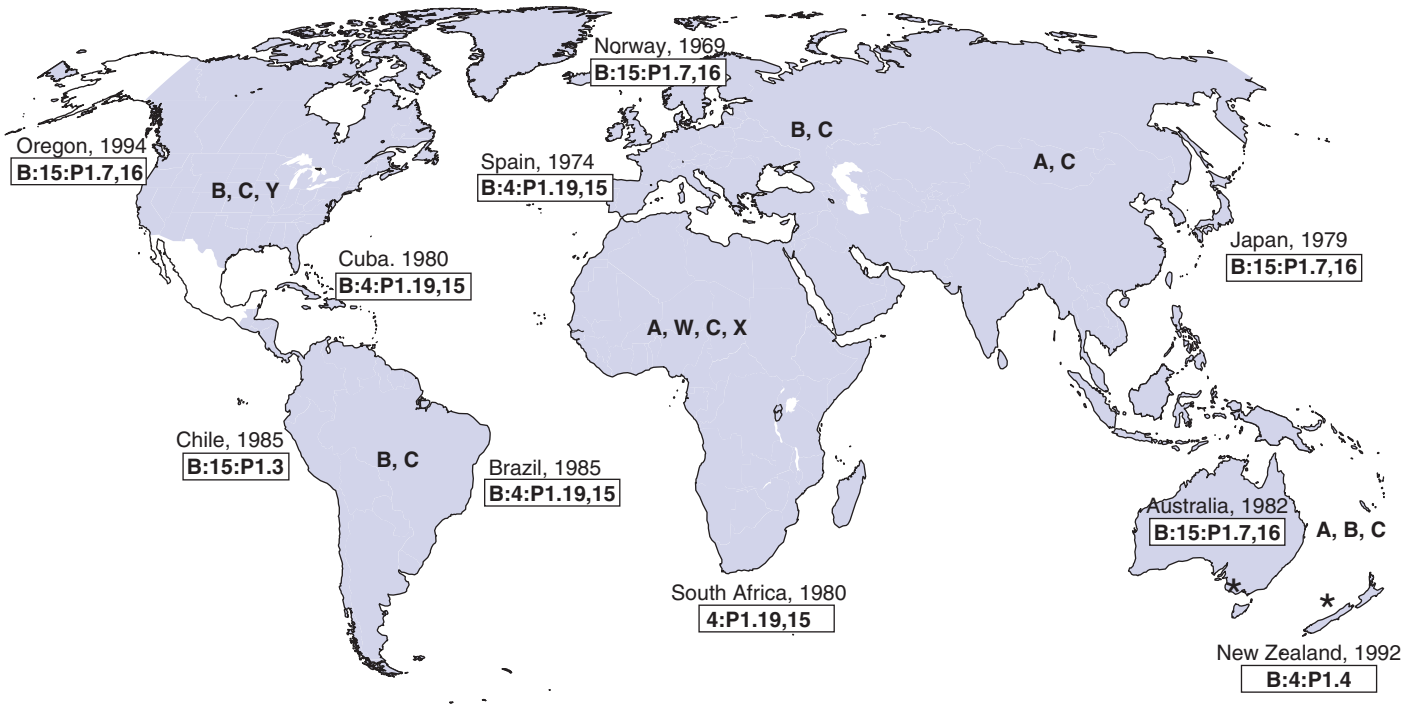
EPIDEMIOLOGY

For at least 200 years, *N. meningitidis* has inflicted rapid death, disability, and fear on disparate human populations. Beginning with the initial descriptions of outbreaks in Geneva in 1805 and New Bedford, Massachusetts, in 1806, the meningococcus has caused endemic disease, case clusters, epidemics and pandemics of meningitis and septicemia, and less commonly pneumonia. An estimated 500,000 cases occur worldwide each year. The greatest burden of disease occurs in Africa and in parts of Asia, where endemic rates of disease have been 3 to 10 per 100,000 population. In sub-Saharan Africa, seasonal increases in disease and cyclic pandemics occurred every 8 to 10 years since 1905. During epidemics and cyclic pandemics, the incidence can climb to 1 per 1000 population for weeks before the frequency of disease declines in the immediate outbreak area. For example, until the introduction in 2010 of a new meningococcal conjugate vaccine for serogroup A, the dry seasons in Burkina Faso, located in the sub-Saharan meningitis belt, were accompanied by more than 5000 cases of meningitis per week (>680/100,000 population), an almost yearly occurrence in the country. Meningococcal epidemics in developing countries have been catastrophic and contribute to a cycle of poverty and hence the disorganization of social structures.

Meningococcal disease remains endemic, with focal outbreaks/clusters, in the United States, Canada, Europe, Japan, Australia, and other industrialized countries, with a lower overall incidence now at 0.1 to 2 per 100,000 population. The introduction and widespread use of new meningococcal conjugate vaccines in North America, Australia, and Europe have helped to lower the incidence,[5,6] but slow declines in industrialized countries began before new vaccine introductions. Endemic disease and outbreaks also occur in China, eastern Europe, Russia, South America, India, and Southeast Asia. Before and during World War II, large epidemic outbreaks (mainly due to serogroup A) affected the United States, Europe, Japan, and Australia; after the war, these outbreaks disappeared, for reasons that are not understood. Meningococcal disease has the highest incidence in children younger than 4 years and in adolescents, but in endemic settings, half of all cases occur in adults.

PATHOBIOLOGY

N. meningitidis is transmitted among humans through close contact by large respiratory droplets. Colonization of the upper respiratory mucosal surfaces (e.g., nasopharynx) by *N. meningitidis* is the first step in establishment of a human carrier state and invasive meningococcal disease. Acquisition of meningococci through contact with respiratory secretions or saliva can be transient, lead to colonization (carriage), or result in invasive disease. The inoculum size needed for transmission is unknown. Meningococcal disease usually occurs within 1 to 14 days of acquisition. Meningococci can be found in the urogenital tract and rectum and may be transmitted sexually.



*Group B by serotype, modified from Caugant, APMIS 1998; 106:505-525

FIGURE 298-1. Epidemiology of meningococcal disease (major serogroups causing disease by region and serogroup B epidemics). (Modified from Stephens DS, Greenwood B, Brandtzaeg P. Epidemic meningitis, meningococcemia and *Neisseria meningitidis*. *Lancet*. 2007;369:2196-2210.)

Initial contact of meningococci with mucosal epithelial cells is mediated by type IV pili. These structures provide mobility ("twitching motility") to penetrate mucus and are the initial adhesins for human epithelial cells. Meningococci proceed to proliferate on the surface of human nonciliated epithelial cells, forming small microcolonies at the site of attachment; they can disseminate from colonies by post-translational glycan modifications of pili and migrate to adjacent cells by the pili-mediated motility.[7,8] Meningococci can also spread from the nasopharynx to adjacent epithelial surfaces and can infrequently cause local infections, including pneumonia, sinusitis, and otitis media. Other less common local infections include conjunctivitis, urethritis, and proctitis. Close adherence of meningococci to the host epithelial cells results in the formation of epithelial cell cortical plaques and leads to the recruitment of factors ultimately responsible for the formation and extension of host epithelial cell pseudopodia that can surround the meningococcus. Intimate meningococcal association with the epithelial cell is mediated by the bacterial opacity proteins Opa and Opc with CD66/carcinoembryonic antigen–related cell adhesion molecules and integrins, respectively, on the surface of the cell. However, other meningococcal epithelial cell mediators include the meningococcal adhesin NadA and meningococcal lipo-oligosaccharide. The formation of epithelial cell membrane protrusions and pseudopodia stems from the organization of specific molecular complexes involving the linkers ezrin and moesin along with the clustering of several membrane-integral proteins, including CD44, intracellular adhesion molecule 1, and cortical actin polymerization.[9] These events can lead to internalization of *N. meningitidis* in epithelial cells (Fig. 298-2). Intracellular meningococci reside within a membranous vacuole and are capable of translocating through the epithelial layers within 18 to 40 hours. Meningococci are capable of intracellular replication (in part because of the protective capsule), can survive under microaerophilic conditions, use lactate as a carbon source, and have the capacity to acquire iron through specialized transport systems.

Meningococci cross mucosal surfaces, enter the blood stream, and, in some individuals, produce systemic infections. Damage to the mucosal surface by coinfection, drying (e.g., very low humidity), or smoke exposure may increase this risk of meningococcal invasion. Similar molecular interactions noted for meningococci and epithelial cells also occur with endothelial cells, and meningococci can translocate across the blood-meninges barrier, possibly at the choroid plexus or by opening of intercellular junctions, and proliferate in the subarachnoid space, resulting in meningitis. In the vasculature and cerebrospinal fluid (CSF), high levels of multiplying bacteria lead to an intense inflammatory response, with pronounced increases in concentrations of tumor necrosis factor-α, interleukins (1β, 6, 8, and 10), different chemokines, and other inflammatory mediators.[10]

Resistance to complement-mediated lysis or phagocytosis is due to the expression of the capsule, lipo-oligosaccharide, and several surface-exposed proteins (factor H–binding protein, NspA, Opc, NalP). Meningococcal endotoxin released in blebs plays a major role in the inflammatory events of meningococcemia and meningococcal meningitis. Meningococcal lipid A is responsible for much of the biologic activity and toxicity of meningococcal endotoxin. The toll-like receptor 4 (TLR4) is critical to the innate immune response to bacterial endotoxins, and meningococcal endotoxin is no exception. Activation of TLR4 by endotoxin requires association with the accessory protein MD-2, an *N*-glycosylated 19- to 27-kD protein expressed in both a soluble and a membrane-bound form. Binding of endotoxin to MD-2 in association with TLR4 leads to dimerization or oligomerization of two or more TLR4s, subsequent cellular activation, and cytokine and chemokine release.

In contrast to invasive disease, an asymptomatic *N. meningitidis* carrier state is found in up to 8 to 25% of healthy individuals. Meningococcal carriage is affected by age, intimate personal contact, crowding (e.g., bars, dormitories), and vaccination or chemoprophylaxis interventions in the community. Variable carriage rates have been reported, even during epidemics. Meningococcal carriage is a dynamic process, is less common in young children (<3% and *Neisseria lactamica* predominates) than in older children, is highest in adolescents (7 to 37%), and increases in closed populations (e.g., military recruits, hajj pilgrims). Rates as high as 36 to 71% have been reported in military recruits. Damage to the upper respiratory tract by coinfections (e.g., mycoplasma, influenza, other respiratory viral infections), smoking, very low humidity, drying of mucosal surfaces, and trauma induced by dust predisposes to both meningococcal carriage and meningococcal disease. Meningococcal carriage has also been linked to status as a secretor of glycoprotein ABO blood group antigens, which are water soluble, and to ethnic background. In a large U.K. study, social behavior (e.g., attendance at pubs or clubs, intimate kissing, cigarette smoking or exposure to passive smoke) was highly associated with the risk of meningococcal carriage. Carriage can be transient or last for days, weeks, or months and is an immunizing event leading to protective immunity (e.g., serum bactericidal activity against the meningococcus).

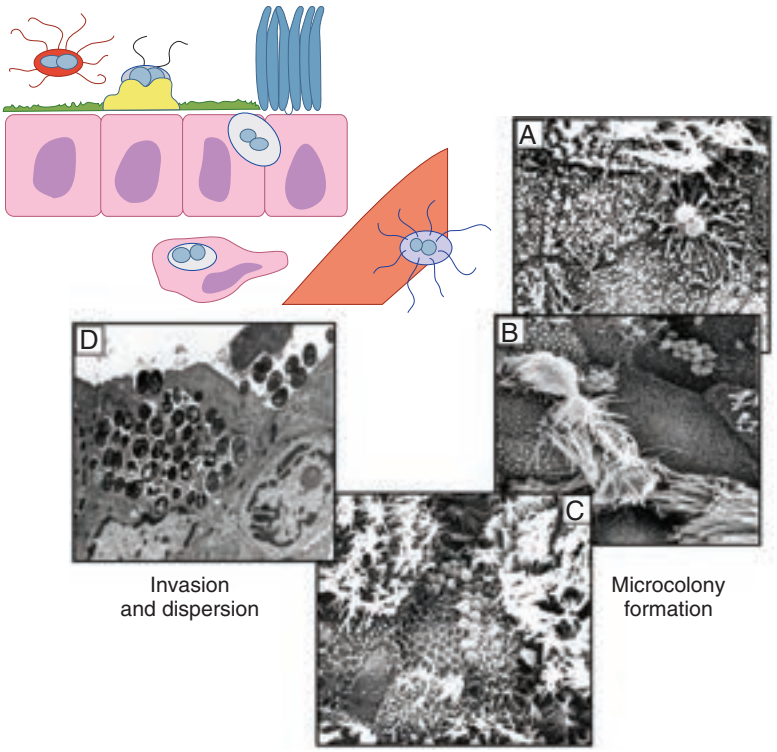


FIGURE 298-2. Steps in initiation of meningococcal colonization and invasion at the human nasopharynx. Biology and pathogenesis of the evolutionarily successful, obligate human bacterium *Neisseria meningitidis. Vaccine.* 2009;27S:B71-B77.)

The absence of protective bactericidal antibodies is the most important predisposing factor for systemic meningococcal disease, but complement deficiencies, genetic polymorphisms, and other host cofactors can contribute to meningococcal disease and disease severity. Disappearance of protective maternal antibodies increases the risk in older infants and young children. Congenital and acquired antibody deficiencies also increase risk. Opsonization and phagocytic function do contribute to meningococcal host defense mechanisms, as shown by disease reduction after polysaccharide vaccination in individuals with complement deficiencies. Rapidly progressive, fatal meningococcemia can arise in patients without properdin, and there is a marked risk of recurrent meningococcal infections in those with defects in the terminal complement pathway (C5-C9) and C3 deficiency.[11]

Polymorphisms in genes coding for the Fcγ-receptor II (CD32), Fcγ-receptor III (CD16), mannose-binding lectin, TLR4, and β_2-adrenoceptor gene have been associated with increased risk. Mannose-binding lectin is a plasma opsonin that initiates complement activation; specific polymorphisms in the gene are identified more frequently in children with meningococcal disease than in controls in some studies. Plasminogen activator inhibitor 1 concentrations appear to affect the severity and mortality of meningococcal sepsis, suggesting that impaired fibrinolysis is an important factor in its pathophysiology. Meningococcal disease is occasionally linked to immunosuppressive disorders, such as nephrotic syndrome, congenital or acquired hypogammaglobulinemia, splenectomy, and human immunodeficiency virus (HIV) infection/AIDS (about a 10-fold increased risk for sporadic disease). However, there has been no documented increase in epidemic outbreaks of meningococcal disease in countries with very high rates of HIV infection.

Meningococci can multiply rapidly in the vascular compartment, with an estimated doubling time of 30 to 45 minutes in some patients, or in the CSF.[12] The release of high levels of inflammatory mediators such as meningococcal endotoxin in the circulation or CSF triggers an exaggerated release of chemokines, cytokines, bradykinin, and nitric oxide. Vascular dilation, hypovolemia, capillary leak, and pronounced reduction in myocardial function are the result. At a later stage, substantial complement activation contributes to the altered endothelial barrier function and relaxation of the smooth muscles in the vessel wall through the generation of high levels of anaphylatoxins (C3a and C5a). The capillary leak syndrome results in an increased flux of albumin and water across the altered capillary wall to the extravascular space. A patient with fulminant meningococcemia accumulates a large amount of fluid in the extravascular tissue. Circulatory collapse and multiorgan dysfunction are the primary causes of death due to meningococcemia. In meningitis, morbidity and death are due predominantly to cerebral edema.

Unraveling the pathogenic mechanisms of this devastating, evolutionarily successful obligate human pathogen has significance for the understanding of human sepsis as well as for prevention through vaccines directed at mucosal pathogens.

CLINICAL MANIFESTATIONS

The meningococcus causes meningitis (37 to 50% of cases), septicemia (meningococcemia, 10 to 18% of cases), or both in 7 to 12% of cases. The presentations are less commonly a mild bacteremia or pneumonia (10% of cases) and much less commonly (<5% of cases) septic arthritis, pericarditis, chronic bacteremia, or conjunctivitis . Very rarely, meningococci can cause urethritis or proctitis. In endemic and epidemic disease outbreaks, hemorrhagic skin lesions (petechiae, purpura; Fig. 298-3) are present in 28 to 77% of patients with invasive meningococcal disease on admission, but these lesions may be absent or difficult to see in patients with dark skin. Hemorrhagic lesions sometimes occur on mucous membranes and sclera, but they are especially prevalent on the limbs. Petechiae of meningococcemia are usually larger and bluer than the pinpoint petechiae caused by thrombocytopenia, leukocytoclastic vasculitis induced by other infections or drugs, or vomiting or coughing. A nonblanching macular rash can also be a manifestation of meningococcal bacteremia. Evolving ecchymoses and purpura (diameter >10 mm) are noted mainly in patients with meningococcemia and disseminated intravascular coagulation (Chapter 175), but they may not appear until 12 hours into the illness. In addition to vasculitis, other conditions in the differential diagnosis of meningococcemia include Rocky Mountain spotted fever and enteroviral infections.

Meningitis is the most common clinical presentation of invasive meningococcal disease.[13] Headache, fever, and rash with meningismus and altered mental status are the characteristic features; however, the rash may be absent, and the presentation can resemble pneumococcal or bacterial meningitis of other causes, viral meningitis, or early-stage encephalitis. Bacteremic meningococcal pneumonia has been linked most often to serogroup Y and is more common in adolescents and adults, especially older adults (approximately one third of cases occur in those older than 65 years). Isolated septic pericarditis or septic arthritis can also be a presentation, and an autoimmune- or antibody-mediated polyarthritis can be seen in the recovery phase following invasive meningococcal disease. Chronic meningococcemia can be

FIGURE 298-3. Clinical manifestations of meningococcal disease. A and B, Macular and petechial rashes of meningococcal bacteremia. C, Fulminant meningococcal sepsis with ecchymoses. D, Digital necrosis of meningococcemia sepsis. E, Hemorrhagic adrenals in fulminant meningococcal sepsis. (Modified from Stephens DS, Greenwood B, Brandtzaeg P. Epidemic meningitis, meningococcemia and *Neisseria meningitidis*. *Lancet.* 2007;369:2196-2210.)

manifested with low-grade fever and a polyarticular arthritis that can be confused with rheumatoid arthritis.

DIAGNOSIS

The clinical diagnosis of meningococcal meningitis relies on the recognition of fever, rash, meningeal signs, and altered mental status. The early clinical diagnosis of meningococcemia is a challenge because a rash, meningeal signs, and high fever may not be present. The course can be fulminant (<24 hours), and the early stages of disease can mimic viral infections such as those caused by enterovirus or influenza. Thus, it can be difficult to identify and to treat the disease quickly. General symptoms of sepsis (nausea and vomiting, drowsiness, irritability, leg pains, cold hands and feet, abnormal skin color) are present. However, these symptoms (in contrast to fever and rash) are not likely to be specific markers. Parents and relatives should be instructed to undress and inspect a febrile child, adolescent, or adult for a rash, and physicians and other health care providers should be alert to the concerns of parents or relatives about the abrupt or rapid deterioration of a patient.

The definitive diagnosis of invasive meningococcal disease is based on bacteriologic isolation or antigen or DNA identification of *N. meningitidis* in a usually sterile body fluid, such as blood, CSF, synovial fluid, pleural fluid, urine, or pericardial fluid. Blood and CSF are the most fruitful sources of positive cultures and for DNA identification by the polymerase chain reaction (PCR), but urine and skin lesions can also yield results in systemic meningococcal disease. The diagnosis of meningococcal meningitis is confirmed by CSF pleocytosis and Gram stain showing gram-negative diplococci (often inside neutrophils) and CSF culture, latex agglutination detecting meningococcal capsular polysaccharide in CSF, or PCR identifying *N. meningitidis* in CSF.

PCR is increasingly used for the diagnosis of meningococcal disease, including serogrouping and multilocus sequence typing, and has the potential to detect antibiotic resistance determinants. PCR techniques include real-time PCR of CSF, blood, and other sterile sites. Urine is a less sensitive fluid for PCR. An increasing number of patients are now diagnosed by PCR without culture, especially if they have received empiric prehospital antibiotic treatment.[14] The sensitivity of PCR for the diagnosis of meningococcal meningitis is more than 90 to 95%; in contrast, the sensitivity of CSF or blood culture is less than 65%.

TREATMENT

Rx

Early recognition and antibiotic administration (Table 298-1) are critical for effective treatment because effective antibiotics immediately stop the growth of *N. meningitidis*. Ceftriaxone, cefotaxime, and penicillin are effective antibiotics, as are meropenem and chloramphenicol.[15] Meningococci in CSF are killed within 3 to 4 hours after intravenous treatment with an adequate dose of a third-generation cephalosporin or penicillin, and concentrations of endotoxin in plasma fall by 50% within 2 hours. The concentrations of key cytokines and chemokines fall in parallel. Antibiotic treatment does not induce a large release of meningococcal endotoxin or lead to an increased inflammatory response.

Prehospital antibiotic treatment is advocated if the disease is suspected. One goal is to reduce the case-fatality rate for patients with fulminant meningococcal sepsis or meningitis with rapidly increasing concentrations of meningococci and inflammatory mediators in the circulation or CSF. If antibiotic treatment is initiated before admission, ceftriaxone or another effective antibiotic can be injected intravenously or intramuscularly. During epidemics in developing countries, a single injection of ceftriaxone or long-acting chloramphenicol may be sufficient for patients with meningitis,[■] and this simple treatment has saved many thousands of lives. The sensitivity of meningococci to penicillin is decreasing worldwide because of a reduced affinity for penicillin-binding protein 2, although high-level penicillin resistance remains rare in most countries. Fluoroquinolone resistance of meningococcal isolates, although rare, has also emerged. Ceftriaxone and cefotaxime can achieve CSF concentrations 45- to 8750-fold higher than the minimal inhibitory concentrations for meningococci. First-generation cephalosporins should not be used.

Patients with suspected bacterial meningitis of unknown cause are often given ceftriaxone or cefotaxime, often combined with vancomycin, until the causative agent has been identified. When *N. meningitidis* is identified, antibiotic treatment can be continued with a third-generation cephalosporin

TABLE 298-1 ANTIBIOTIC TREATMENT OF MENINGOCOCCAL MENINGITIS AND MENINGOCOCCEMIA

DRUG	AGE GROUP	DOSAGE
Ceftriaxone*	Children > 3 months Adults	50 mg/kg IV q12h 1-2 g IV q12h
Cefotaxime	Adults	50-75 mg/kg q6-8h; maximum dose, 12 g/day
Penicillin G	Adults	50,000 U/kg IV q4h; up to 4 million U q4h
Meropenem	Adults	2 g IV q8h, 6 g/day
If penicillin and cephalosporin allergic, chloramphenicol	Adults	25 mg/kg IV q6h, up to 1 g q6h

*Because of concerns in neonates from calcium/ceftriaxone precipitates and displacement of bilirubin from albumin by ceftriaxone, babies younger than 3 months should be started on cefotaxime 50 mg/kg q6-8h.

or possibly benzylpenicillin alone. Meropenem is also active clinically in the treatment of meningococcal meningitis, or chloramphenicol is a choice in penicillin- and cephalosporin-allergic patients. Traditionally, patients with meningococcal meningitis were treated for 7 days or longer, but 3 or 4 days of intravenous treatment can provide a cure without relapse.

Recognition of the different pathophysiologic processes associated with meningococcal meningitis (which causes death and morbidity predominantly by cerebral edema) and meningococcal septic shock (which causes death and morbidity predominantly through hypovolemia, capillary leak, myocardial dysfunction, and multiorgan failure) has led to improved management strategies for these two different forms of disease. Early and aggressive management of shock through the use of volume expansion, intensive care monitoring, and inotropic support can reduce fatality rates of meningococcal sepsis from higher than 30% to 5 to 10%. In meningococcemia with hypotension, the primary goal is to increase the circulating blood volume by aggressive fluid treatment. Both colloids and crystalloids (saline 0.9%) can be used without a demonstrated difference in effectiveness. Adults are given saline starting with 1 L infused intravenously during 15 to 20 minutes, followed by several liters at a reduced rate. Some patients require two to three times their own blood volume during the first 24 hours. The total fluid volume needed per 24 hours is determined by response to treatment—tissue perfusion, blood pressure, urine output, and evidence of intravascular volume overload. The volume treatment may be combined with a vasopressor such as dopamine, norepinephrine, epinephrine, or dobutamine. Fluid treatment may be complicated in patients with reduced renal function. They may need dialysis or hemofiltration to compensate for renal failure and to reduce the substantial edema that accumulates.

Patients with meningitis or mild meningococcemia should be given the normal daily fluid requirement, supplemented with the volume lost before admission unless there is evidence of the syndrome of inappropriate antidiuretic hormone. Excessive volume treatment in patients with meningitis can induce fatal brain edema and herniation. Management of raised intracranial pressure (hyperosmolar solutions, diuretics, mechanical ventilation), seizures, and hyponatremia is indicated.

Anticoagulant treatment of patients with meningococcemia and disseminated intravascular coagulation has not been documented to improve outcome. A phase III study of recombinant activated protein C in children with sepsis of all causes, including meningococcemia, was stopped because no benefit was noted, and recombinant activated protein C has been withdrawn from the market. Administration of activated protein C is associated with an increased risk of cerebral hemorrhage. The use of recombinant human tissue plasminogen activator does not appear to be beneficial. Randomized controlled clinical trials using hyperimmune serum, antibodies, or recombinant bactericidal or permeability-increasing protein (designed to inactivate *N. meningitidis* endotoxin) have not demonstrated a beneficial effect on survival. Blockade of other specific inflammatory mediators has not been adequately tested in meningococcal septic shock.

Patients with fulminant meningococcal septicemia can develop adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The corticotropin concentration is higher, the cortisol concentration is lower, and the corticotropin-to-cortisol ratio is higher in patients with fatal meningococcal shock than in survivors. Adults with septic shock and indications of inadequate adrenal function are given low doses of steroids. Although the benefit has not been documented, many intensive care specialists use stress replacement doses of hydrocortisone in children with shock caused by *N. meningitidis*.

Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have been used in patients with meningococcemia; however, no controlled trials to assess the results have been done. Plasmapheresis and blood exchange appear to have little additive effect on the endogenous clearance of endotoxin and cytokines from the circulation. Extracorporeal membrane oxygenation has been used in several centers, with better results in children with acute pulmonary failure than in those with refractory septic shock. The use of insulin to control mild hyperglycemia in critically ill adults has not shown benefits (Chapter 108).

Pharmacologic doses of dexamethasone have been shown to reduce morbidity in pneumococcal and *Haemophilus influenzae* type b meningitis. The use of dexamethasone to reduce death caused by brain edema or to prevent sequelae such as deafness in patients with meningococcal meningitis remains unproved on the basis of large randomized controlled trials, but trends toward reductions in hearing loss, mortality, and arthritis after meningococcal disease are reported. Many now recommend that dexamethasone (10 mg every 6 hours for the first 4 days and in children at a dose of 0.15 mg/kg every 6 hours for 4 days beginning before or with the first dose of antibiotics) be given early in suspected or confirmed bacterial meningitis.■ Glycerol has been used to reduce intracranial pressure in bacterial meningitis, but its value is not proven. Other major life-threatening complications necessitating therapy include adult respiratory distress syndrome, neurologic sequelae ranging from coma to diabetes insipidus, pneumonia that is not necessarily meningococcal but may be secondary to aspiration during the obtunded state, and pericarditis.

Immune complex–mediated complications, such as arthritis, cutaneous vasculitis, iritis, episcleritis, pleuritis, and pericarditis, can first appear several days to 2 to 3 weeks after onset of illness, when the patient is otherwise improving. These complications, which can be multiple, are due to the deposition of antigen-antibody complexes composed of meningococcal capsular polysaccharide or other antigens, meningococcal-specific immunoglobulins, and C3 and complicate 6 to 15% of meningococcal meningitis or septicemia. Treatment is with aspirin or nonsteroidal anti-inflammatory drugs, and resolution is complete, usually within 14 days from the onset and usually without residual sequelae.

PREVENTION

Chemoprophylaxis to eliminate meningococcal carriage is recommended for close contacts of patients to prevent further transmission and disease (Table 298-2). The occurrence of meningococcal disease in household contacts is approximately 100-fold higher than in the general population. Secondary cases usually occur within 1 to 14 days of the primary case. Chemoprophylaxis can be helpful to control localized outbreaks, but it is generally not recommended for the control of large epidemics (see the later discussion of vaccines). Rifampin, ceftriaxone, azithromycin, and quinolones (but not penicillin) have the ability to eradicate meningococci in the nasopharynx. A majority of meningococcal isolates are now resistant to sulfonamides; resistance to rifampin can develop rapidly, and quinolone resistance in meningococci is reported.

Prevention through vaccination is the best option for the long-term control of meningococcal disease.[16] Capsular polysaccharide vaccines to decrease serogroup A, C, Y, and W-135 meningococcal disease were introduced in the 1970s and 1980s. These vaccines were safe, with mild local adverse events, and effective (>85%) in children older than 2 years and adults but less immunogenic in younger children; immunity to the polysaccharide vaccines was limited to 3 to 5 years of protection, and immunologic hyporesponsiveness was induced by repeated doses of the polysaccharide. Also, meningococcal polysaccharide vaccines do not induce immunologic memory and have little or no effect on nasopharyngeal carriage. Although these vaccines were used extensively to control disease in military populations and in epidemics in the African meningitis belt, in the latter they were often deployed too late in the course of an outbreak. There was no evidence that widespread use of polysaccharide vaccines reduced the frequency of epidemics in Africa.

A major advance in the past 15 years has been the development and now widespread use of meningococcal polysaccharide-protein conjugate vaccines and their introduction first into the United Kingdom and then other parts of Europe, Canada, Australia, the United States, and, more recently, the African meningitis belt. These vaccines are safe and immunogenic in young children, induce immunologic memory, and can decrease nasopharyngeal carriage of meningococci.■ In the United Kingdom, the introduction of the serogroup C conjugate meningococcal vaccine in 2000 to all children and young adults greatly reduced the rate of serogroup C disease (90% vaccine effectiveness at 3 years for patients aged 11 to 18 years). A major protective effect of the C conjugate vaccine is mediated through herd immunity.[17] Rates of serogroup C carriage and disease in nonvaccinated individuals were reduced by more than 50% through herd immunity. Polysaccharide-protein conjugate meningococcal vaccines containing serogroups A, C, Y, and W-135 were introduced for adolescents in the United States in 2005 and subsequently extended to children aged 2 months to 10 years at increased risk for meningococcal disease. In addition to routine use in older children and adolescents (first dose at the age of 11 or 12 years with booster at 16 years), populations that should benefit from the new conjugate vaccines are college freshmen, military recruits, patients with immunoglobulin or complement deficiencies (inherited or chronic deficiencies such as C3, properdin, factor D, or late complement components), patients with anatomic or functional asplenia, microbiologists who are routinely exposed to isolates of *N. meningitidis*, adults with HIV type 1 infections, and people who travel to or reside in countries where *N. meningitidis* is epidemic. An important example of a new approach to meningococcal conjugate vaccine development is the Meningitis Vaccine Program, a partnership between PATH, the World Health Organization, and the Global Alliance for Vaccines and Immunization for the development of a group A meningococcal conjugate vaccine for Africa, designated MenAfriVac, at less than $0.50 a dose.[18] Because of the huge impact of herd immunity of the serogroup C conjugate vaccines in the United Kingdom, MenAfriVac was introduced as a mass vaccination strategy for those 1 to 29 years old. The MenAfriVac vaccination campaign began in Burkina Faso in December 2010 and has been extended to Mali, Chad, Niger, Nigeria, Benin, Ghana, Senegal, Cameroon, Sudan, and other regions of the African meningitis belt. More than 100 million doses have been administered. Initial results

TABLE 298-2 CHEMOPROPHYLAXIS AGAINST MENINGOCOCCAL INFECTION

DRUG	AGE GROUP	DOSAGE	DURATION AND ROUTE OF ADMINISTRATION*	CONSIDERATIONS
Rifampin	Children <1 month	5 mg/kg q12h	2 days	
	Children >1 month	10 mg/kg q12h (maximum, 600 mg)	2 days	
	Adults	600 mg q12h	2 days	Rifampin can interfere with efficacy of oral contraceptives and some seizure prevention and anticoagulant medications; may stain soft contact lenses Not recommended for pregnant women
Ceftriaxone	Children <15 years	125 mg	Single IM dose	
	Children >15 years and adults	250 mg	Single IM dose	Ceftriaxone is recommended for prophylaxis in pregnant women.
Ciprofloxacin	Adults	500 mg	Single dose	Not recommended routinely for persons <18 years of age, but use in infants and children (20 mg/kg) may be justified after careful assessment of the risks and benefits Not recommended for pregnant or lactating women Cases of ciprofloxacin resistance have been reported, and use for prophylaxis should be based on local sensitivity of the meningococcus to the drug.
Azithromycin		10 mg/kg (maximum, 500 mg)	Single dose	Equivalent to rifampin for eradication of meningococci from nasopharynx, but data are limited

ANTIBIOTIC CHEMOPROPHYLAXIS FOR HOUSEHOLD OR INTIMATE CONTACTS:

- Household contacts and persons sharing the same living quarters, particularly young children
- Daycare center, nursery school, or child care contacts; frequent playmates of young children
- Close social contacts that were exposed to oral secretions in the week before onset, such as by kissing and sharing of eating and drinking utensils or toothbrushes
- For airline travel lasting more than 8 hours, passengers who are seated directly next to an infected person should receive prophylaxis.
- Routine prophylaxis is not recommended for health care professionals unless they have had intimate exposure to respiratory secretions.
- As the risk of secondary cases is highest during the first few days after exposure, chemoprophylaxis should be initiated as soon as possible, ideally <24 hours after identification of the index patient.
- If more than 14 days have passed since the last contact with the index patient, chemoprophylaxis is not likely to be of benefit.
- Pharyngeal cultures are not helpful in determining the need for chemoprophylaxis and may unnecessarily delay the use of effective chemoprophylaxis.
- Chemoprophylaxis has also been recommended for patients given penicillin or chloramphenicol for treatment because pharyngeal carriage may not be eliminated with these antibiotics and the patient could remain colonized with a virulent strain.
- Ceftriaxone is recommended for pregnant women.
- May want to avoid ciprofloxacin or azithromycin in individuals at risk of QT-prolongation.

Recommended groups for chemoprophylaxis based on exposure to the case in the week before onset of illness.
*Administered orally unless otherwise stated.

show the virtual elimination of serogroup A meningococcal disease in the countries vaccinated in the first 2 years after the mass campaigns.

The development of vaccines for serogroup B *N. meningitidis* has also shown progress. Serogroup B can cause prolonged outbreaks during many years, such as those seen in the past two decades in the Pacific Northwest (Oregon, parts of Washington), Brazil, Norway, and New Zealand. The serogroup B capsule has an identical structure to polysialic structures expressed in fetal neural tissue and does not induce a protective bactericidal immunoglobulin G response. Thus, strategies have been focused on noncapsular antigens, such as outer membrane proteins containing vesicles (OMV) or conserved protein antigens. The diversity of major outer membrane structures in meningococci has limited OMV approaches, but this approach has been successful in controlling serogroup B epidemics that are strain specific (e.g., in New Zealand). New serogroup B vaccines based on semiconserved surface protein antigens identified by "reverse vaccinology" are the most advanced candidates and are obtaining licensure. One of these, 4CMenB or Bexosero,■ recently approved in Europe, contains three semiconserved surface protein antigens—a member of the factor H–binding protein family, neisserial adhesin A (NadA), and neisserial heparin-binding antigen—and a meningococcal serogroup B PorA-containing OMV preparation previously used to control the serogroup B clonal outbreak in New Zealand. Alum is the adjuvant. A second serogroup B vaccine is based on two members of the factor H–binding protein family and was recently licensed in the United States.[19] Initial evaluation of the immunogenicity and safety of these vaccines appears promising. The prevention of serogroup B disease appears to be a significant step closer with these new vaccines.

PROGNOSIS

Historically, the mortality of untreated systemic meningococcal disease was 70 to 90%. Despite highly effective antibiotics and aggressive supportive care, the mortality of invasive meningococcal disease remains at about 10%. The failure to recognize disease early, the very rapid development of disease (especially meningococcemia), and the time to administration of antibiotics remain the most significant challenges. The chance of surviving shock is directly correlated to plasma concentrations of endotoxin, and half the nonsurviving patients with shock die within the first 12 hours of hospital admission.

Long-term sequelae and morbidity after invasive meningococcal disease are significant.[20] Neurologic impairment occurs in 7 to 10% with meningococcal meningitis, with palsies of the sixth, seventh, and eighth cranial nerves and hemiparesis and quadriparesis. Unilateral or bilateral sensorineural hearing loss occurs in 2 to 9% of cases, which is profound in 2% of affected individuals and necessitates cochlear implantation in 0.4%. Neurodevelopmental impairment, including behavioral and psychological problems, learning difficulties, memory deficits, executive function problems, decreased academic performance, spasticity, seizures, and focal neurologic signs, is seen in approximately 10%. Visual difficulties, seizures, and motor deficits are reported in 2 to 3%, with multiple neurologic disabilities occurring in 1 to 2% of affected individuals. Survivors of meningococcal sepsis in childhood have, in 5 to 20% as young adults, long-term behavioral and emotional problems, decreased intellectual functioning, and illness-related physical or social consequences.

Scarring of the skin, secondary to necrotic purpura, may vary from unnoticeable to requiring skin grafting. Multiple areas may be involved; the lower limbs are most frequently affected, followed by the arms, chest, and face. Amputations, of the digits or limbs, are frequently multiple; these result from necrosis of the skin, muscle, and bone of the affected parts (Fig. 298-3D) and, depending on the site and extent, may require prostheses to improve function or appearance. Bone growth disturbances, stump overgrowth, scar contractures, and soft tissue and bone infections may complicate amputations. Limb length discrepancies, which may result from the growth plate infarction, often necessitate further surgical intervention. Following acute renal failure at presentation, renal function recovers in the majority of individuals; however, evidence of renal dysfunction may persist for more than 4 years in both children and adults, with the risk being higher in those who required renal replacement therapy.

Meningococcal disease and its complications, often occurring rapidly in otherwise healthy individuals, also produce significant family, community, health care, and public health impact. The emotional toll on individuals who

survive and on the families of those with meningococcal disease in intensive care units, of those who survive with complications, and of those who die is considerable and a global phenomenon. In communities, meningococcal disease may also create considerable fear and anxiety. Post-traumatic stress disorder occurs at a higher frequency in both patients and families, often months after the illness. In one study, post-traumatic stress disorder occurred in 15% of children, in half of the mothers, and in 19% of fathers at 3 months. Meningococcal disease and its complications also result in substantial hospital and long-term health care costs. Furthermore, delay in the diagnosis of meningococcal sepsis and meningitis and septicemia is a common reason for litigation.

If parents and health care professionals recognize the importance of fever and headache with a nonblanching rash and seek treatment early, morbidity and mortality can be reduced with prehospital antibiotic treatment, rapid transportation to medical facilities, and stabilization in an intensive care unit. Prevention of meningococcal disease with new vaccines and vaccine strategies remains the major worldwide goal.

REVIEW QUESTIONS

1. *Neisseria meningitidis* is a

A. Gram-negative rod causing pneumonia and bacteremia
B. Gram-positive diplococcus causing primarily pneumonia
C. Gram-negative diplococcus causing epidemic meningitis and septicemia
D. Gram-positive rod causing meningitis in immunocompetent patients
E. Gram-variable coccobacillus causing meningitis and otitis media

Answer: C *N. meningitidis* is an aerobic, diplococcal gram-negative β-proteobacterium and a member of the family Neisseriaceae, which also includes *Neisseria gonorrhoeae* (Chapter 299), another important human pathogen. *N. meningitidis* is the cause of epidemic bacterial meningitis, fulminant sepsis (meningococcemia), milder bacteremia, and, less commonly, focal infections (such as pneumonia, septic arthritis, purulent pericarditis, and conjunctivitis).

2. Serogroup A *N. meningitidis*

A. Causes significant disease in the United States and Japan
B. Has been a major cause of epidemic meningococcal outbreaks in sub-Saharan Africa
C. Expresses a sialic acid capsule
D. Has no effective vaccine
E. Is usually treated with sulfonamides

Answer: B In sub-Saharan Africa, seasonal increases in disease and cyclic pandemics, which have occurred every 8 to 10 years since 1905, have been predominantly caused by serogroup A *N. meningitidis*. A new serogroup A conjugate vaccine introduced in 2010 has rapidly lowered the incidence of meningococcal disease in this region.

3. Which one is not true? The rash of invasive meningococcal disease

A. Can be a blanching macular rash
B. Is typically petechial or purpuric
C. Can be confused with leukocytoclastic vasculitis, Rocky Mountain spotted fever, and enteroviral infections
D. Is almost always present and easily detected
E. Is usually a single "bull's-eye" lesion

Answer: D Hemorrhagic skin lesions (petechiae, purpura; Fig. 298-3) are present in 28 to 77% of patients with invasive meningococcal disease on admission, but these lesions may be absent or difficult to see in patients with dark skin. A nonblanching macular rash can also be a manifestation of meningococcal bacteremia.

4. Which one is not true regarding antibiotic treatment of meningococcal meningitis?

A. It should be administered as soon as the diagnosis is considered.
B. It takes 10 to 14 days to be effective.
C. Options include ceftriaxone or cefotaxime, penicillin, or meropenem.
D. Quinolone resistance has been reported.
E. Sulfonamide resistance is now common.

Answer: B Meningococci in cerebrospinal fluid are killed within 3 to 4 hours after intravenous treatment with an adequate dose of a third-generation cephalosporin or penicillin. Traditionally, patients with meningococcal meningitis were treated for 7 days or longer, but 3 or 4 days of intravenous treatment can provide a cure without relapse.

5. Which one is not true regarding prevention of meningococcal disease?

A. Chemoprophylaxis is given to prevent secondary cases that occur usually 10 to 14 days after the primary case.
B. Meningococcal polysaccharide- protein conjugate vaccines are a long-term control measure of meningococcal disease.
C. Meningococcal vaccines have effectiveness in complement-deficient patients.
D. Rifampin, ceftriaxone, ciprofloxacin, and azithromycin are used for chemoprophylaxis.
E. Meningococcal polysaccharide vaccines are now preferred for prevention strategies.

Answer: E Meningococcal conjugate vaccines are safe and immunogenic in young children, induce immunologic memory, and can decrease nasopharyngeal carriage of meningococci. Meningococcal conjugate vaccines have largely replaced the older polysaccharide vaccines and are now preferred for prevention strategies.

299 *NEISSERIA GONORRHOEAE* INFECTIONS

MATTHEW R. GOLDEN AND H. HUNTER HANDSFIELD

DEFINITION

Neisseria gonorrhoeae is a sexually transmitted organism that infects primarily the columnar epithelia of mucosal surfaces and causes urethritis in men and endocervicitis and urethritis in women. Other sites of primary infection include the rectum, pharynx, and conjunctiva, and vulvovaginitis can occur in prepubertal girls. The most common complication of gonococcal infection is pelvic inflammatory disease, which can lead to infertility, ectopic pregnancy, and chronic pelvic pain. Other much less common complications include epididymitis, posterior urethritis, urethral stricture, Bartholin's gland abscess, and perihepatitis. Bacteremia may occur, with the production of characteristic cutaneous lesions, arthritis, and, rarely, endocarditis or meningitis. Neonatal conjunctivitis (ophthalmia neonatorum) was formerly a common cause of blindness. Gonococcal infections are also thought to increase the risk of human immunodeficiency virus (HIV) transmission from persons dually infected with HIV and *N. gonorrhoeae* and to increase the risk of HIV acquisition among persons with gonorrhea who are exposed to HIV.

The Pathogen

The gonococcal envelope is similar in its basic structure to that of other gram-negative bacteria and is composed of an inner cytoplasmic membrane, a middle peptidoglycan cell wall, and an outer membrane. The outer membrane contains several surface components that play a central role in the organism's interaction with the host and its pathogenicity. Pili, hairlike projections also referred to as fimbriae, are composed of several different protein subunits and, along with other outer membrane adhesins (i.e., opacity-related proteins), facilitate attachment and invasion of host cells. Gonococci vary the composition of these proteins and surface lipo-oligosaccharides over time, allowing the organism to elude host defenses. This phase variation has also been a barrier to successful vaccine development.

EPIDEMIOLOGY

Gonorrhea is the second most commonly reported infectious disease in the United States, with 334,826 cases reported to the Centers for Disease Control and Prevention (CDC) in 2012.[1] The incidence of gonorrhea in the United States in 2012 was 107.5 per 100,000 population, although this number, which is based on cases reported to U.S. health departments, is undoubtedly an underestimate. The overall incidence of gonorrhea in the United States has been relatively stable for more than a decade, and current rates are more than 70% lower than the incidence observed in the mid-1970s. The prevalence of gonorrhea varies widely, depending on the population tested. The National Longitudinal Study of Adolescent Health (Add Health) tested a representative sample of U.S. 18- to 26-year-olds in 2001 and 2002 and found that 0.43% were infected, with wide variations geographically and among population groups. This prevalence estimate is almost identical to one derived from the National Health and Nutrition Examination Survey of 1998 to 2008, another population-based survey.[2] Among women aged 15 to 24 years tested for gonorrhea in family planning clinics in 48 U.S. states and territories in 2011, the median prevalence of gonorrhea was 0.7%, but it varied from 0 to 3.5%. By comparison, the prevalence of chlamydial infection in the Add Health study was 4.19%, and among 15- to 24-year-old females tested in U.S. family planning clinics in 2011, it was 8.3% (range, 3.8 to 15.9%).

Like virtually all other sexually transmitted infections (STIs; Chapter 285), gonorrhea rates vary widely with age, geographic location, sexual orientation, and race or ethnicity. In the United States, the rate of reported infection is highest among 15- to 24-year-olds, and rates in the South are more than twice those observed in the West and Northeast. However, the most glaring disparities are observed in comparing rates of infection among different racial and ethnic groups and in comparing heterosexuals to men who have sex with men (MSM).

Rates of reported gonorrhea among U.S. African Americans are almost 15 times higher than those among non-Hispanic whites, and rates among American Indians/Alaska Natives and Hispanics are 4 and 1.9 times higher, respectively, than those among non-Hispanic whites. Variations in reporting probably account for some of these observed differences because low socioeconomic status is associated with receiving care in public health clinics and other venues where there is more complete reporting than in the private health care sector. However, the marked disparity in reported rates is also apparent in population-based studies, clearly establishing that the different rates of infection in different racial and ethnic groups are not simply a result of reporting bias. The reasons for this profound disparity are certainly multifactorial and are not entirely clear. Different racial groups in the United States vary little in terms of their number of sex partners, so this cannot explain the different rates of STIs. Although inadequate access to medical care is likely to play a role in the racial disparities in STI rates, profound racial and ethnic disparities are also observed in the United Kingdom and the Netherlands, nations with nationalized health care systems in which access to care should be more uniform than it is in the United States. Research has highlighted the importance of concurrency (i.e., partnerships that overlap in time) and patterns of sexual mixing based on age, race, and level of sexual activity as critical determinants of a population's risk of STI. These factors are thought to be shaped by social factors (e.g., poverty, incarceration, joblessness, racism) that play a central role in defining the epidemiology of all STIs worldwide.

Gonorrhea also disproportionately affects gay and bisexual men and other MSM. Numerous cities in the United States, western Europe, and Australia have reported increases in the rate and number of gonorrhea cases among MSM since the mid-1990s. For example, in King County, Washington State, in 2012 the estimated incidence of reported gonorrhea in MSM was more than 2114 cases per 100,000, compared with 40 and 41 per 100,000 heterosexual men and women, respectively.

Gonorrhea is highly transmissible. Although it is not precisely defined, the risk of transmission from a man to a woman during a single episode of unprotected vaginal intercourse is thought to be 50 to 70%, and the risk of transmission from a woman to a man is 20%. The transmission risks associated with anal sex, fellatio, or cunnilingus are not well defined, but anal intercourse is probably a relatively efficient mode of transmission, and receipt of fellatio is likely to be an important source of gonococcal infections in at

least some populations (e.g., MSM). Gonococci die rapidly on drying, and with the exception of occasional acquisition by laboratory personnel working with the organism, nonsexual transmission does not occur in adults. Perinatal transmission causing neonatal ophthalmitis or pharyngeal infection is now rare.

PATHOBIOLOGY

After attachment to host epithelial cells, gonococci are endocytosed into the cell in a process thought to be facilitated by Por (or protein 1). Gonococci then replicate within the host cell and are released into the subepithelial space.

Typical urethral infections result in prominent inflammation, probably as a result of the release of toxic lipo-oligosaccharide and peptidoglycan fragments as well as the release of chemotactic factors that attract neutrophilic leukocytes. The reasons that some gonococcal strains selectively cause asymptomatic genital infection are poorly understood, but this propensity may be related to differences in the organism's ability to bind complement-regulatory proteins that downregulate the production of chemotactic peptides. In particular, gonococcal strains that express PorB1A appear to bind factor H and complement-binding protein and have an increased propensity for causing disseminated gonococcal infections.

Although the gonococcus is not highly mutable, many gonococci possess conjugative plasmids and are consequently able to efficiently transfer other, nontransferable plasmids, such as those conferring resistance to penicillin and tetracycline. Gonococci are also capable of efficiently transferring naked DNA (transformation). These characteristics are important in the organism's ability to develop resistance to antimicrobials. For example, recent evidence suggests that the gonococci with diminished susceptibility to oral cephalosporins possess genetic resistance mutations acquired from commensal *Neisseria* species commonly found in the oropharynx.[3,4]

CLINICAL MANIFESTATIONS

Gonococcal infections can result in a number of specific clinical syndromes, each of which has its own manifestations, differential diagnosis, and recommended evaluation. The major clinical manifestations of gonococcal infection are discussed separately later. Gonococcal ophthalmia, now a rare complication, can result from direct contact or by autoinoculation in individuals with anogenital gonorrhea and is manifested as an acute, purulent conjunctivitis that can result in corneal ulceration if it is not treated promptly.

DIAGNOSIS

Microscopy

Microscopy of a Gram-stained smear is positive when polymorphonuclear neutrophils are observed to contain intracellular gram-negative diplococci of typical morphology (Fig. 299-1). Gram-stained urethral smears are 90 to 98% sensitive in the diagnosis of symptomatic gonococcal urethritis in men and have a specificity greater than 95%. However, Gram stain is only approximately 50% sensitive for cervical or rectal infection and for asymptomatic urethral gonorrhea. Although Gram stain is often considered highly specific for such infections, the actual performance varies with the skill and experience of the examiner, and rectal and cervical smears are unreliable in many clinical settings. Smears are both insensitive and nonspecific for pharyngeal gonococcal infection and are not recommended.

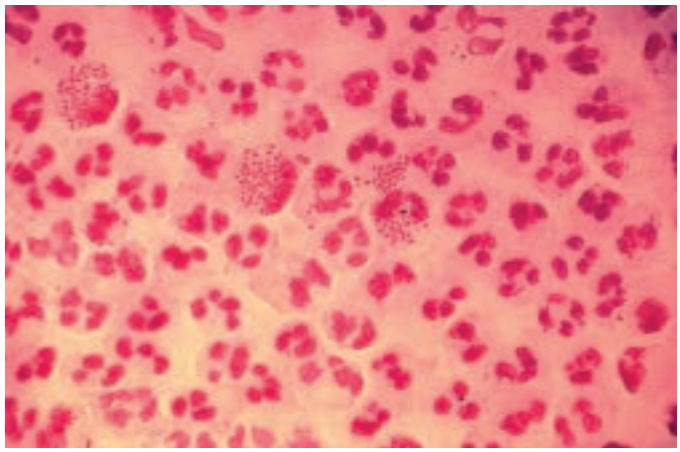

FIGURE 299-1. Gram stain in an acute case of gonococcal urethritis. This slide is used to demonstrate the nonrandom distribution of gonococci among polymorphonuclear neutrophils. Note that there are both intracellular and extracellular bacteria in the field of view.

Culture

Isolation of *N. gonorrhoeae* by culture, generally with antibiotic-containing selective media, is the historic mainstay of the diagnosis of gonorrhea. Despite the proliferation of molecular diagnostic methods, culture retains important roles in surveillance for antimicrobial resistance and selected clinical settings. Ideally, growth media should be inoculated directly and placed promptly into a humid atmosphere with increased carbon dioxide, such as a candle extinction jar. However, standard transport systems (e.g., Culturette) are acceptable if specimens are kept moist, are not refrigerated, and are processed within 6 hours. In testing of specimens not likely to be colonized by competing flora (e.g., synovial fluid), nonselective chocolate agar should be used.

Nucleic Acid Amplification Tests

In most settings in the United States, nucleic acid amplification tests (NAATs) have now supplanted culture as the dominant laboratory test used to diagnose gonorrhea.[5] NAATs approved by the Food and Drug Administration include polymerase chain reaction, transcription-mediated amplification (TMA), and DNA strand displacement (SDA). The advantages of NAATs include a slight increase in sensitivity over culture, the ability to test urine specimens and self-obtained vaginal swabs, and the fact that most NAATs are now marketed as combination assays that allow simultaneous testing for *N. gonorrhoeae* and *Chlamydia trachomatis*. The disadvantages of NAATs include the inability to perform antimicrobial susceptibility testing and the poor or inadequately defined positive predictive value of some NAATs when they are used to test low-prevalence populations. Because the prevalence of *N. gonorrhoeae* in family planning clinics in many parts of the United States and other nations is now well below 1%, the risk of false-positive screening results may be high, and reliable results depend on the use of assays with exquisite specificity. Existing evidence suggests that TMA has a high positive predictive value even in very low-prevalence settings; the positive predictive value of SDA and the current-generation Roche polymerase chain reaction is not well defined.

Although NAATs have been approved by the Food and Drug Administration only for the testing of genital tract and urine specimens, increasing evidence suggests that at least some NAATs (e.g., TMA, SDA) are substantially more sensitive than culture in detecting *N. gonorrhoeae* in pharyngeal and rectal specimens and that these NAATs are sufficiently specific to screen high-risk populations for rectal and pharyngeal gonorrhea. Given the decreasing availability of gonococcal culture, the poor sensitivity of culture on non–genital tract specimens, and the high prevalence of asymptomatic rectal and pharyngeal infections in some populations (particularly MSM), clinicians caring for patients at high risk for nongenital gonococcal infections should be able to use NAATs. Recent studies suggest that self-obtained rectal and pharyngeal specimens yield accurate results and are acceptable to MSM.

CLINICAL SYNDROMES

Urogenital Gonorrhea in Males

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Gonococcal urethritis in men is typically characterized by a purulent urethral discharge and dysuria. The usual incubation period is 2 to 6 days. A small minority of men who acquire urethral infection—generally estimated at 1 to 10%, and varying between specific strains of *N. gonorrhoeae*—remain asymptomatic.

Physical examination typically reveals purulent urethral exudate (Fig. 299-2); this is usually readily apparent, but compression of the urethra is sometimes required to express the exudate. Erythema of the meatus is sometimes present. Nongonococcal urethritis (Chapter 285) is typically characterized by less copious and less purulent discharge.

The diagnosis of gonococcal urethritis is usually suspected clinically, confirmed preliminarily by a Gram-stained smear showing leukocytes with intracellular gram-negative diplococci (see Fig. 299-1), and made definitively when *N. gonorrhoeae* is identified by culture or NAAT. Despite the usual clinical differences between gonococcal urethritis and nongonococcal urethritis, substantial overlap exists, and microbiologic diagnosis should be routine even in clinically typical cases.

FIGURE 299-2. Male patient with a purulent penile discharge from gonorrhea and an overlying penile pyodermal lesion. Pyoderma involves the formation of a purulent skin lesion, which in this case is located on the glans penis.

PROGNOSIS

With prompt treatment, urethral gonorrhea seldom results in significant long-term morbidity. Acute epididymitis complicates gonococcal urethritis in less than 1% of cases. Patients with epididymitis usually present with unilateral testicular pain and swelling, sometimes with fever. Posterior urethritis or prostatitis, typically manifested as pelvic or perineal pain and urinary retention, was once fairly common but is now rare. Urethral stricture, another formerly common complication, is now very rare. Gonorrhea is associated with an elevated risk of HIV infection, both directly and as an epidemiologic risk factor. Diagnosis of gonorrhea should alert clinicians to counsel such patients about sexual risks, test them for HIV infection, and encourage patients to seek frequent follow-up testing for HIV infection and other STIs.

Lower Genital Tract Gonorrhea in Females

CLINICAL MANIFESTATIONS, DIAGNOSIS, AND PROGNOSIS

The primary site of infection in women is the endocervical canal. The proportion of infected women who develop symptoms is not precisely known, but probably about 50% of incident infections are symptomatic. In any case, asymptomatic infections accumulate in populations, whereas many or most symptomatically infected women present for diagnosis and treatment. Therefore, most prevalent infections among women are asymptomatic or are associated with mild symptoms not perceived by patients as abnormal or important. Gonorrhea is sometimes associated with an abnormal vaginal discharge, but other lower genital tract infections, such as bacterial vaginosis, trichomonas vaginitis, and candidal vaginitis, are much more common causes of this symptom. Lower genital tract gonorrhea in women can be associated with abnormal vaginal bleeding, which typically is manifested as metrorrhagia, scant intermenstrual bleeding, or postcoital spotting. *N. gonorrhoeae* sometimes causes dysuria and can be isolated from the urethra in up to 80% of women with gonorrhea. However, the urethra is rarely the only infected site, except in women who have had hysterectomies. In a minority of women, physical examination is notable for a purulent or mucopurulent cervical discharge, cervical edema, or easily induced cervical bleeding, signs of mucopurulent cervicitis. In uncomplicated infections, purulent exudate can sometimes be expressed from a Bartholin's gland duct, near the vaginal introitus laterally, or from Skene's glands, adjacent to the urethral meatus.

Microbiologic diagnosis usually rests on identifying *N. gonorrhoeae* in cervical secretions by NAAT or culture. Gram-stained smears are insensitive and seldom used.

The most important common complication of lower genital tract gonorrhea in women is pelvic inflammatory disease (see later). Rarer complications include Bartholin's gland abscess, which is manifested as a tender introital mass and may involve superinfection with facultative and anaerobic bacteria.

Pelvic Inflammatory Disease

CLINICAL MANIFESTATIONS

Pelvic inflammatory disease (PID) refers to an infection of the lower female genital tract and can involve the uterus (endometritis), fallopian tubes (salpingitis), and ovaries (oophoritis) as well as neighboring pelvic structures.[6] An estimated 10 to 40% of women with endocervical gonococcal infections develop PID, and gonorrhea is thought to be the cause of approximately 5 to 30% of all diagnosed cases of PID in the United States. However, this proportion varies with overall rates of gonorrhea and other causes of PID in the population, such as chlamydial infection.

Low abdominal pain is the dominant symptom of PID. Pain is variable in intensity and is often mild; it is usually bilateral, typically present for days to weeks before clinical presentation, and can be exacerbated by coitus. Symptoms often coincide with the onset or cessation of menses. Approximately one third of women have abnormal vaginal bleeding. Fever, chills, anorexia, vaginal discharge, urethritis, and proctitis occur, but they are neither sensitive nor specific in identifying women with PID. There is little if any difference in the severity of symptoms and signs of PID associated with *N. gonorrhoeae*, *C. trachomatis*, or neither of these pathogens.

The physical examination is typically notable for diffuse abdominal tenderness that is greatest in the lower quadrants and for tenderness of the pelvic organs on bimanual examination, with or without manipulation of the cervix. Most women have signs of cervicitis or bacterial vaginosis. Fever is present in a minority of cases. Abdominal or adnexal signs are occasionally unilateral, and this finding can cause confusion with appendicitis (Chapter 142), ectopic pregnancy, and other conditions. Right upper quadrant abdominal tenderness due to perihepatitis (Fitz-Hugh–Curtis syndrome) is sometimes present, which can mimic acute cholecystitis or viral hepatitis. Perihepatitis sometimes occurs in the absence of other abdominal or pelvic findings typical of PID, especially when it is caused by *C. trachomatis*. Severe PID may be accompanied by signs of generalized peritonitis.

DIAGNOSIS

The clinical diagnosis of PID is imprecise. Published studies, which have used somewhat variable criteria in populations with different prevalences of the syndrome, have reported positive predictive values of 65 to 90% compared with the "gold standard" of laparoscopically defined PID. Although nonspecific, the presence of neutrophils on a saline wet mount of vaginal secretions was 91% sensitive for endometritis in one study. The absence of white blood cells on a wet mount of vaginal secretions, particularly if mucopurulent cervicitis is also absent, should prompt the consideration of alternative diagnoses. The differential diagnosis of PID includes ectopic pregnancy; appendicitis; rupture, bleeding, or torsion of an ovarian cyst; endometriosis; urinary tract infection or pyelonephritis; renal or ureteral stones; inflammatory bowel disease; and, rarely, viral hepatitis or cholecystitis.

Because of the potential seriousness of the infection and the relative simplicity, low cost, and low toxicity of treatment, clinical diagnostic criteria emphasize sensitivity at the cost of specificity. Clinicians therefore should maintain a low threshold for tentative diagnosis and presumptive treatment of PID. The CDC recommends that all sexually active women with pelvic or lower abdominal pain and uterine, adnexal, or cervical motion tenderness be treated for possible PID if no other cause of their symptoms and signs is readily apparent. Furthermore, screening of asymptomatic sexually active young women with NAATs is recommended by the U.S. Preventive Services Task Force.[7] Factors such as fever, an elevated erythrocyte sedimentation rate or C-reactive protein level, and concurrent bacterial vaginosis or mucopurulent cervicitis further support the clinical diagnosis, but these are frequently absent. Definitive diagnosis requires histologic evidence of endometritis on endometrial biopsy; transvaginal ultrasound or other diagnostic imaging showing thickened or fluid-filled fallopian tubes or tubo-ovarian abscess; or laparoscopy demonstrating purulent tubal exudate, erythema, or edema.

PROGNOSIS

Fallopian tube scarring secondary to PID often results in tubal factor infertility (TFI), ectopic pregnancy, and chronic pelvic pain. Previous gonococcal and chlamydial infections are among the most common antecedents of these complications. Each episode of PID, whether due to *N. gonorrhoeae*, *C. trachomatis*, or neither of these organisms, significantly increases the risk for recurrent salpingitis.

The natural history of clinically apparent PID is well defined. In what is probably the best single study on the subject, TFI occurred in 8% of women after a single episode of laparoscopically proved PID, in 20% after two such episodes, and in 40% after three or more episodes. The first pregnancy after an episode of PID was ectopic in almost 8% of women, and like TFI, the risk of ectopic pregnancy increased with each successive episode of the syndrome. Chronic pelvic pain, sometimes disabling in its severity, occurs in almost 20% of women after one or more episodes of PID. Importantly, these outcomes were best studied in women with clinically apparent PID, and the pertinent studies were undertaken at a time when clinical recognition and treatment were likely delayed. Many women suffer clinically mild or silent

PID. The risk of sequelae associated with silent PID is not well defined, but more clinically severe PID is associated with a higher risk of sequelae. Most women with TFI deny a history of PID, and it seems likely that silent PID, particularly silent PID associated with *C. trachomatis*, is responsible for most cases of STI-related reproductive tract sequelae. For example, *C. trachomatis* seropositivity is strongly associated with TFI, independent of clinical or historical evidence of PID.

Rectal Infection

CLINICAL MANIFESTATIONS

Gonococcal infection of the rectum is common in women and in MSM. In women, infection is acquired either through perineal contamination with cervicovaginal secretions or by anal intercourse; the latter is the exclusive route of infection in MSM. In women with cervical gonorrhea and in MSM with gonorrhea at any anatomic site, about 40% have rectal infection. More than 80% of rectal infections are subclinical, but symptomatic proctitis sometimes is manifested as varying combinations of anal pruritus, mucopurulent discharge (often characterized by the patient as mucus-coated feces), pain, tenesmus, and bleeding. Symptomatic proctitis seems to be more common in MSM than in women with rectal gonorrhea, which suggests that the size of the infecting inoculum or trauma from anal intercourse may influence the clinical manifestations. Among MSM, rectal gonorrhea is a potent epidemiologic risk marker for the acquisition of HIV and may be a direct risk factor because anorectal inflammation enhances susceptibility to HIV infection.

DIAGNOSIS

Diagnosis of rectal gonorrhea depends on the identification of *N. gonorrhoeae*, usually by NAAT. The Gram-stained smear is insensitive and nonspecific. The differential diagnosis of symptomatic proctitis includes other traditional STIs (herpes, syphilis, and chlamydial infection, including lymphogranuloma venereum; Chapter 318) as well as ulcerative colitis, Crohn's colitis, anal fissure, rectal lacerations, and proctocolitis caused by *Shigella*, *Campylobacter*, *Yersinia enterocolitica*, and other enteric pathogens. Recent studies using NAAT among STI clinic patients suggest that approximately 5% of tested MSM and 1% of tested women have rectal infections without concurrent genital tract infections. Although less than 20% of women with gonorrhea have extragenital infections, more than half of MSM with gonorrhea have only extragenital infections, highlighting the importance of routine screening of MSM, but not women, for rectal gonorrhea.

Pharyngeal Infection

CLINICAL MANIFESTATIONS

Pharyngeal gonococcal infection results from orogenital exposure. It is more efficiently acquired by fellatio than by cunnilingus and is typically found in 3 to 7% of heterosexual men, 10 to 30% of women, and 10 to 30% of MSM with genital tract gonorrhea. Asymptomatic infection is the rule, although rare cases may exhibit exudative pharyngitis and cervical lymphadenopathy. Isolated pharyngeal infection is common is MSM and may also be common in at least some populations of heterosexuals. Complications are infrequent, and most infections eventually resolve spontaneously or in response to therapy for genital or rectal infection. Although the modest morbidity associated with pharyngeal infections probably does not justify extensive screening efforts, the oropharynx may be an important reservoir for infection in some populations, particularly MSM. The oropharynx is also a site of gene exchange between *N. gonorrhoeae* and commensal Neisseriaceae, and pharyngeal infections are thought to play a critical role in fostering the emergence of antimicrobial-resistant gonococci. Failure to identify and to eradicate pharyngeal infections probably helps sustain high levels of gonococcal transmission and may foster the spread of antibiotic-resistant gonococci. Accordingly, current guidelines suggest that MSM at risk for STIs be tested periodically for pharyngeal gonorrhea.

Gonorrhea in Children

Gonococcal conjunctivitis may develop in infants born to mothers with gonorrhea, a condition termed ophthalmia neonatorum. Formerly a common cause of blindness, gonococcal ophthalmia is now rare in industrialized countries because of both improved control of gonorrhea and routine use of neonatal ocular prophylaxis with topical antibiotics or 1% silver nitrate. Neonates may also acquire pharyngeal or rectal infection and, rarely, gonococcal pneumonia or sepsis. Beyond the neonatal period, purulent vaginitis is the most common manifestation of gonorrhea or chlamydial infection in girls, and rectal or pharyngeal infection is the most common manifestation in prepubertal boys. Most cases are acquired through sexual abuse, but occasional cases in young children may be acquired from fomites or by nonsexual personal exposure in crowded conditions, especially in tropical climates.

Disseminated Gonococcal Infection

CLINICAL MANIFESTATIONS

Disseminated gonococcal infection (DGI) usually is manifested with various combinations of polyarticular tenosynovitis, dermatitis secondary to focal septic embolization, and septic arthritis. Studies undertaken in the 1960s and 1970s estimated that DGI occurred in 1 to 3% of adults with gonorrhea, but the risk depends on characteristics of the particular strains of *N. gonorrhoeae* circulating in the population. Today, DGI probably occurs in well under 1% of gonococcal infections in most geographic areas. Women may be somewhat more susceptible to DGI than men, and the onset often coincides with menstruation. Severity varies from a mild illness with slight joint discomfort, a few skin lesions, and little or no fever to a fulminant illness with overt polyarthritis, innumerable skin lesions, high fever, and prostration. Most persons with DGI have no symptoms of genital gonorrhea, probably because some strains of *N. gonorrhoeae* that are prone to disseminate are also associated with subclinical mucosal infections. The absence of clinical symptoms and signs of mucosal infection in these strains is probably due to their ability to bind complement downregulatory molecules, thereby diminishing the local inflammatory response.

The presentation of DGI can be divided into the clinical syndromes of tenosynovitis-dermatitis and monarticular or oligoarticular arthritis, although these presentations sometimes overlap. Tenosynovitis-dermatitis is thought to predominate early in the course of dissemination, and approximately 70% of DGI cases in published series present with this syndrome. These patients usually suffer migratory polyarthralgias without purulent arthritis. There is often tendon inflammation affecting the wrists, fingers, ankles, or toes. Skin lesions are typically painless, are few in number (5 to 30), affect predominantly the extremities, and are pustular or vesiculopustular (Fig. 299-3), although petechiae, hemorrhagic macules, papules, bullae, and nodules rarely occur (see Fig. 441-5). Axial skeletal involvement is uncommon, a feature that can help differentiate DGI from reactive arthritis (Chapter 265). The tenosynovitis-dermatitis syndrome often subsides spontaneously, or it may evolve during a period of several days into an overt septic arthritis with purulent synovial fluid, usually involving only one or two joints. Approximately 25 to 50% of persons with DGI present initially with purulent monarticular or oligoarticular arthritis, often without apparent sequential evolution from arthritis-dermatitis syndrome. This form of DGI typically affects the knee, ankle, elbow, or wrist, but any joint may be involved.

DIAGNOSIS

Sexually active young persons with arthritis, tenosynovitis, or papulopustular skin lesions should be tested for *N. gonorrhoeae* at all potentially exposed anatomic sites. The diagnosis of DGI is secure when gonococci are identified by culture or NAAT in the blood, a skin lesion, or synovial fluid, but it is often made presumptively when genital, rectal, or pharyngeal gonorrhea is present in a patient with a compatible clinical syndrome that responds promptly to antibiotics.

Blood, synovial fluid, and mucosal tract cultures are positive in approximately 4 to 35%, 10 to 34%, and 80% of patients, respectively. However, the yield from culture varies with the clinical presentation. The performance of NAAT versus culture of blood, synovial fluid, or skin lesions has not been studied in patients with DGI. Patients with tenosynovitis-dermatitis more frequently have bacteremia, whereas patients with septic gonococcal arthritis are seldom bacteremic, and close to 50% have positive synovial fluid cultures; it is reasonable to suspect that the yield might be higher with NAAT. Because bacteremia is intermittent, clinicians should obtain more than one set of blood cultures to maximize the likelihood of isolating the organism. Similarly, NAAT or culture specimens should be obtained from all potentially exposed anatomic sites (genital tract, pharynx, rectum). Cultures of skin lesions are generally negative despite demonstrable gonococci by fluorescent antibody, but NAAT results may be positive in persons with negative blood and mucosal site cultures. The peripheral blood leukocyte count is generally elevated but may be normal. The synovial fluid leukocyte count is usually 20,000 to 60,000/mm^3, with higher numbers of white blood cells seen in persons with clinically apparent arthritis than in those with tenosynovitis-dermatitis. Liver function tests often show elevations in aminotransferase levels, suggestive of mild hepatitis.

The differential diagnosis of DGI includes reactive arthritis (Chapter 265), meningococcemia (Chapter 298), other kinds of septic arthritis (Chapter 272), rheumatoid arthritis (Chapter 264), systemic lupus erythematosus

FIGURE 299-3. Cutaneous gonococcal lesion secondary to disseminated *Neisseria gonorrhoeae* infection. Although gonorrhea is a sexually transmitted disease, if it remains untreated, the *N. gonorrhoeae* bacteria responsible for the infection can disseminate throughout the body and form lesions in extragenital locations (also see Fig. 441-5). (From Handsfield HH. *Color Atlas and Synopsis of Sexually Transmitted Diseases*. 3rd ed. New York: McGraw-Hill; 2011.)

(Chapter 266), acute HIV infection (Chapter 385), syphilis (Chapter 319), and other rheumatologic conditions and infectious diseases. Reactive arthritis, often triggered by sexually acquired chlamydial infection, is the principal consideration in young adults. The skin lesions of the two conditions, when present, are generally distinct and often pathognomonic for one syndrome or the other. In addition, conjunctivitis and involvement of the axial skeleton (e.g., sacroiliitis) are common in reactive arthritis and infrequent in DGI.

PROGNOSIS

Many cases of arthritis-dermatitis syndrome resolve spontaneously; with prompt treatment, few patients suffer sequelae of DGI, but untreated septic arthritis can lead to contiguous osteomyelitis or joint destruction. Endocarditis, meningitis, and myocarditis are occasionally seen, with or without a typical DGI syndrome. Gonococcal endocarditis usually involves the aortic valve and often progresses rapidly, leading to valve destruction and heart failure.

PREVENTION

Control of gonorrhea depends on prompt diagnosis and effective treatment of infected persons, screening of sexually active women and MSM in settings where gonorrhea is prevalent, treatment of patients' partners, rescreening of persons with a recent history of gonorrhea, and efforts to promote safer sexual behaviors (e.g., condom use, abstinence, fewer partners). Sexually active MSM outside of mutually monogamous relationships, including HIV-infected men, are at high risk for gonorrhea and should be tested at least annually for rectal and pharyngeal gonococcal infection as well as for chlamydial infection, syphilis, and HIV infection. The value of screening of asymptomatic men for urethral infection (by NAAT of urine) is uncertain; the yield is low in most settings. Gonococcal screening criteria for woman are not well defined. However, because most NAATs for *C. trachomatis* also test for *N. gonorrhoeae*, most chlamydia screening includes gonorrhea testing.

Public education and personal counseling of persons with gonorrhea or at risk of contracting it should emphasize the effectiveness of mutual monogamy and condoms for vaginal or anal sex for new or casual partnerships. Every patient with gonorrhea should be counseled about the risks for HIV infection and should be tested for HIV, *C. trachomatis*, and syphilis. Because accurate epidemiologic data are essential to generate and to maintain resources for the prevention and control of STIs, all cases of gonorrhea, chlamydial infection, syphilis, and HIV infection should be promptly reported to the health department in accordance with local laws. Ultimate control of gonorrhea may require immunization, but no effective vaccine is on the horizon, despite intensive research for more than four decades.

TREATMENT Rx

Antimicrobial Susceptibility

Gonococci with chromosomal or plasmid-borne mutations that confer relative or absolute resistance to the penicillins, tetracyclines, and sulfonamides are prevalent worldwide, and none of these drugs is acceptable as empirical therapy anywhere in the world. The prevalence of β-lactamase (penicillinase) plasmids, which confer absolute resistance to penicillin, ampicillin, and amoxicillin, varies from about 10% of gonococci in the United States and western Europe to almost 50% in some developing countries. Approximately 27% of gonococcal infections in MSM and 9% of infections in heterosexuals are caused by organisms that are resistant to ciprofloxacin and other fluoroquinolones. Resistant gonococci are still more prevalent in Europe (up to 50% in some countries). Fluoroquinolone-resistant gonococci are prevalent worldwide, and fluoroquinolones are no longer suitable for routine use unless recent local data demonstrate low levels of resistance. Approximately 5% of gonococcal isolates in the United Kingdom are no longer susceptible to azithromycin, and azithromycin-resistant *N. gonorrhoeae* has been identified in the western United States, although such strains were rare as recently as 2012.

Gonococcal resistance to cephalosporins is now a major public health concern. Strains with relative resistance to oral cephalosporins (e.g., cefixime, heretofore a mainstay of gonorrhea treatment) are common in Japan, and in 2011 almost 8% of gonococcal isolates in Europe and 1.4% of isolates in the United States had reduced susceptibility to cefixime. In the United States, organisms with diminished susceptibility to oral cephalosporins are more common on the West Coast than in other parts of the country and more common among MSM than among heterosexuals.[8] Diminished susceptibility to ceftriaxone remains very rare, although isolated cases of multidrug-resistant gonorrhea—organisms that are resistant to ceftriaxone therapy—have been identified in Japan and Europe. Although recent data suggest that the proportion of gonococcal infections caused by organisms with diminished susceptibility to oral third-generation cephalosporins is now declining, ongoing surveillance for cephalosporin resistance remains a high priority, and decisions on how to treat gonorrhea need to incorporate strategies for diminishing the development of population-level antimicrobial resistance. Clinicians who treat patients for gonorrhea and other STIs should keep abreast of regional trends in resistance and be alert to modified therapeutic recommendations.[9]

Principles of Treatment

Because of the need to curtail transmission, therapy is usually based on clinical or epidemiologic suspicion before the diagnosis is confirmed microbiologically.[10] Clinicians should presumptively treat all patients evaluated as contacts to persons with known gonococcal infections, all women with PID or mucopurulent cervicitis, and, if Gram staining cannot be performed, all men presenting with a clinical syndrome of urethritis. (Men with urethritis and no evidence of gonorrhea on Gram stain should be treated for nongonococcal urethritis.) Diagnosis by NAAT precludes antimicrobial resistance testing, and even when *N. gonorrhoeae* is isolated by culture, susceptibility testing is rarely performed routinely. Accordingly, treatment of uncomplicated gonorrhea is dictated by national or local patterns of antimicrobial susceptibility, without knowledge of susceptibility in individual patients. However, susceptibility testing should be used to guide the treatment of gonococcal septic arthritis, endocarditis, or other serious complications and may increasingly become routine even in genitourinary infections.[11]

Dual treatment of uncomplicated gonorrhea, typically with both a cephalosporin and either azithromycin or doxycycline, has long been recommended to cover the possibility of simultaneous chlamydial infection, typically present in 5 to 10% of MSM, 15 to 25% of heterosexual men, and 35 to 50% of women with gonorrhea in North America. In addition, dual therapy using antibiotics with differing mechanisms of action may reduce selection pressure for antimicrobial resistance in *N. gonorrhoeae*, so that dual therapy is now recommended routinely even when chlamydial infection is unlikely or has been excluded by negative testing.

Treatment Regimens

Ceftriaxone 250 mg intramuscularly plus azithromycin 1 g orally is the preferred treatment regimen for uncomplicated gonorrhea (Table 299-1).[12] This regimen is highly effective against pharyngeal gonorrhea, which may be relatively resistant to oral therapies, and is designed to diminish the spread of cephalosporin-resistant *N. gonorrhoeae* as well as to cover simultaneous chlamydial infection. Cefixime 400 mg orally (with azithromycin 1.0 g orally)

TABLE 299-1 ANTIBIOTIC REGIMENS FOR THE TREATMENT OF GONORRHEA IN THE UNITED STATES*

UNCOMPLICATED GONORRHEA OF THE URETHRA, CERVIX, OR RECTUM
Preferred
Ceftriaxone 250 mg IM single dose *plus* azithromycin 1 g PO
Alternatives
Cefixime 400 mg PO single dose *plus* azithromycin 1 g PO *or* Azithromycin 2 g PO single dose *plus* gentamicin 240 mg IM single dose *or* gemifloxacin 320 mg PO as a single dose
INFECTION OF THE PHARYNX
Ceftriaxone 250 mg IM single dose *plus* azithromycin 1 g PO as a single dose
CONJUNCTIVITIS (NOT OPHTHALMIA NEONATORUM)
Ceftriaxone 1 g IM single dose *plus* azithromycin 1 g PO as a single dose
DISSEMINATED GONOCOCCAL INFECTION
Preferred
Ceftriaxone 1 g IM or IV q24h† *or* Ceftizoxime 1 g IV q8h *plus* Azithromycin 1 g PO as a single dose
Alternative
Cefotaxime 1 g IV q8h

*Treatment of gonorrhea in adults should always include treatment of sex partners and advice to abstain from sex for 7 days.
†Treat with intravenous therapy until the patient has been clinically improved for 24 to 48 hours. Then switch to cefixime 400 mg orally twice a day to complete a 7-day course.

remains appropriate when ceftriaxone therapy is not feasible (e.g., if a patient declines injection) or in expedited (unobserved) treatment of patients' sex partners. Clinicians should be mindful that ensuring that all patients and partners are treated is more important than always using intramuscular ceftriaxone. Persons with severe β-lactam allergies should receive azithromycin 2 g orally once, *plus* either a single dose of gentamicin 240 mg IM *or* a single dose of gemifloxacin 320 mg orally.

Women with acute PID should be treated with antibiotics active against *N. gonorrhoeae* and *C. trachomatis*.[13] The role of anaerobic bacteria in PID is uncertain, although it is not known whether anaerobic treatment is required for PID. Most women can be treated as outpatients, but the following factors should prompt hospital admission: possible surgical cause of symptoms (e.g., appendicitis), pregnancy, failure to respond to oral therapy within 72 hours of initiation, inability to tolerate or to adhere to oral therapy, severe symptoms, and tubo-ovarian abscess. The suggested outpatient regimen is ceftriaxone 250 mg IM plus doxycycline 100 mg PO twice daily for 14 days or cefoxitin 2 g IM plus probenecid 1 g PO as a single dose and doxycycline 100 mg twice daily for 14 days. Either regimen can be given with or without metronidazole (500 mg twice daily) for 14 days. For hospitalized patients or others who require parenteral therapy, the CDC recommends intravenous cefotetan or cefoxitin plus oral doxycycline or parenteral therapy with clindamycin plus gentamicin. Intravenous ampicillin-sulbactam plus oral doxycycline can also be used. Parenteral therapy is continued until improvement is observed, after which oral therapy is prescribed to complete 14 days' total treatment.

Most persons with DGI should be hospitalized and treated with a parenteral third-generation cephalosporin such as ceftriaxone, cefotaxime, or ceftizoxime. Joint irrigation or drainage appears to be unnecessary for septic arthritis, although repeated aspiration of synovial fluid may speed clinical improvement. Oral treatment (e.g., cefixime, cefpodoxime, or a fluoroquinolone) can usually be substituted after improvement begins and then continued to complete 7 days' therapy. More prolonged parenteral treatment and higher doses are indicated for the treatment of gonococcal meningitis or endocarditis, although modern data are lacking. Gonococcal epididymitis, bartholinitis, and other localized complications should generally be treated for 7 to 14 days with drugs active against both *N. gonorrhoeae* and *C. trachomatis*. Gonococcal conjunctivitis in adults can be managed with a single dose of ceftriaxone, 1 g IM, with optional saline lavage. The diagnosis of all forms of complicated gonococcal infection should be confirmed by culture with determination of antimicrobial susceptibility, which can guide completion of treatment after initial empirical therapy.

Management of Sex Partners

Failure to ensure treatment of patients' sex partners contributes to the continued transmission of gonorrhea and other bacterial STIs and often results in reinfection of the index case. For gonorrhea and chlamydial infection, all partners in the preceding 2 months should be treated; if the patient has not had sex in the preceding 2 months, the most recent partner should be treated. Very few U.S. health departments routinely make an effort to ensure that sex partners receive treatment, and the responsibility to ensure partner treatment lies jointly with the patient and the diagnosing clinician. Optimally, the partners of persons with gonorrhea should undergo diagnostic testing for gonorrhea, chlamydial infection, syphilis, and HIV infection. However, clinicians should not wait to obtain the results of diagnostic testing before treating a potentially exposed sex partner; all partners of infected persons should be treated when they initially present for evaluation.

In most settings, approximately 50% of potentially exposed sex partners go untreated, risking ongoing transmission and reinfection of the original patient. In an effort to address this problem, the CDC and several state health departments recommend that clinicians offer heterosexual patients with gonorrhea or chlamydial infection medication to give to their sex partners. This practice, termed patient-delivered partner therapy (PDPT)—sometimes termed expedited partner therapy—is supported by three randomized controlled trials showing that treating sex partners without requiring attendance for care in person decreases the risk of reinfection and increases the proportion of partners treated. PDPT requires single-dose treatment, typically with cefixime plus azithromycin for gonorrhea or azithromycin alone for the partners of patients with chlamydial infection. PDPT currently is legal in most states of the United States and is likely to become permissible in other states, and clinicians should offer PDPT as an option for most heterosexual patients with gonorrhea or chlamydial infection. The CDC website maintains up-to-date information on the legality of PDPT in U.S. states and territories (http://www.cdc.gov/STD/ept/legal/default.htm). In addition to direct delivery of drugs to the patient for PDPT, it is often feasible to write or to telephone a prescription to a cooperating pharmacy. However PDPT is implemented, when practical, clinicians should provide written information about the medication and STI prevention as well as advice to seek clinical care in addition to taking the drugs provided. Examples of forms that can be dispensed with PDPT can be found at the following websites: http://www.doh.wa.gov/YouandYourFamily/IllnessandDisease/SexuallyTransmittedDisease/ExpeditedPartnerTherapy; http://www.cdph.ca.gov/HealthInfo/discond/Pages/SexuallyTransmittedDiseases.aspx. PDPT is not recommended for MSM with gonorrhea or chlamydial infection owing to potentially high rates of syphilis and HIV infection; the partners of such patients should be evaluated and treated in person.

Follow-up

The recommended treatment regimens cure 96 to 100% of uncomplicated cases of genital or rectal gonorrhea caused by susceptible strains and at least 90% of pharyngeal infections. Retesting of infected patients to document eradication of *N. gonorrhoeae* ("test of cure") is not recommended except in pregnant women, when adherence to therapy is in doubt, or when atypical treatment regimens are employed. When test of cure is indicated, culture can be performed a week after treatment is completed, but retesting by NAAT should be delayed at least 3 weeks after treatment to reduce the possibility of detecting persistent gonococcal DNA despite the eradication of viable organisms.

Although test of cure is generally not advised, all persons diagnosed with gonorrhea should be rescreened 3 to 4 months after treatment. In prospective studies, 10 to 20% of both men and women with gonorrhea or chlamydial infection are infected when they are retested 3 to 4 months later. The likelihood of recurrent or persistent gonococcal infection appears to be reduced by up to 70% when partners are managed with PDPT. Rescreening can be done with urine or self-obtained vaginal swab testing by NAAT and does not require a second visit with a clinician.

REVIEW QUESTIONS

1. A 26-year-old man comes to your office complaining of pain with urination and a discharge from his penis. He reports having both insertive and receptive anal sex with two men in the last 2 months but says that he always uses condoms when having anal sex. He also reports both giving and receiving oral sex. The patient reports testing negative for HIV infection approximately 6 months ago. He thinks he had chlamydia several years ago but otherwise denies any prior history of sexually transmitted infection. Physical examination is notable for purulent urethral discharge. Your office does not have a microscope to allow you to perform a Gram stain. Which of the following would be part of the recommended management of this patient?

A. Ceftriaxone 250 mg IM plus azithromycin 1 g PO as a single dose
B. Test for HIV infection and syphilis.
C. Test for gonorrhea (rectal, pharyngeal, and urethral gonorrhea) and chlamydial infection (urethral, rectal).
D. Notify the health department of the patient's infection if he has laboratory confirmation of infection.
E. All of the above

Answer: E This patient presents with typical signs and symptoms of urethritis. Although a urethral Gram stain would be useful in determining whether this patient has gonorrhea, most clinicians in the United States cannot perform Gram stains in their office, and the patient should be empirically treated for both gonorrhea and chlamydial infection. Ceftriaxone is more active against *Neisseria gonorrhoeae* than are third-generation oral cephalosporins like cefixime and should be used in this patient. The addition of azithromycin is designed both to treat a possible concurrent chlamydial infection and as a strategy to diminish the risk of selecting for antimicrobial resistance. Of note, this patient denies having unprotected anal sex, and his only clear urethral exposure is through oral sex. Although his history may be inaccurate, an ill-defined but probably sizable proportion of all urethral gonorrhea in men who have sex with men (MSM) is likely to be acquired through oral sex, highlighting the importance of screening for pharyngeal gonorrhea among MSM. In contrast, *Chlamydia trachomatis* infrequently infects the pharynx and probably is rarely transmitted by fellatio, and no readily available tests are approved for pharyngeal chlamydial infection.

2. A 19-year-old woman comes to your office requesting contraception. She recently started a new relationship with a man and sometimes uses condoms. Before her current sex partner, she reports not having sex for about 6 months. As part of her care, you perform a routine screening test for gonorrhea and chlamydial infection on a self-obtained vaginal swab using Aptima Combo 2, a nucleic acid amplification test. The test result comes back positive for both gonorrhea and chlamydial infection. You call the patient to give her the results and arrange her follow-up. She continues to be asymptomatic. Which of the following would be part of your initial management of this patient?

A. Have the patient return to your office for treatment with ceftriaxone 250 mg IM plus azithromycin 1 g PO as a single dose.
B. Arrange for the patient to return to your office for follow-up testing in 3 months.
C. Ask the patient to bring her partner to your office with her so that he can be treated.
D. Talk to the patient and her partner about condoms and risk reduction when she returns to see you, and advise them to abstain from sex for 1 week after the completion of both of their treatment.
E. All of the above

Answer: E A regimen of ceftriaxone and azithromycin is effective for both gonorrhea and chlamydial infection. Although a test of cure is not indicated among nonpregnant women with gonorrhea or chlamydial infection, repeated testing 3 months after treatment is recommended because of the high prevalence (approximately 12%) of persistent or recurrent gonorrhea or chlamydial infection. Failure to ensure treatment of sex partners is thought to be one major cause of recurrent infection, and the management of sexually transmitted infections should include ensuring the treatment of patients' sex partners. Although gonorrhea and chlamydia are both reportable infections in all U.S. states, most U.S. health departments do not make any routine effort to contact people diagnosed with gonorrhea or chlamydial infection, and clinicians should regard partner treatment as part of their responsibility when treating patients. The best course of action here is to ask the patient to bring her partner to your office for treatment when she comes for her ceftriaxone injection. If she does not bring the partner when she returns, you should offer her patient-delivered partner therapy (PDPT) with cefixime 400 mg and azithromycin 1 g at that time. PDPT is now legal in most parts of the United States and is recommended as a routine option in the Centers for Disease Control and Prevention (CDC) treatment guidelines for sexually transmitted diseases. PDPT should be dispensed with written information about sexually transmitted infections and the drugs being provided. Helpful links for additional resources related to PDPT are available:

CDC website on expedited partner therapy, including information about the legal status of PDPT in different states: http://www.cdc.gov/STD/ept/legal/default.htm

Washington State Department of Health EPT website: http://www.doh.wa.gov/YouandYourFamily/IllnessandDisease/SexuallyTransmittedDisease/ExpeditedPartnerTherapy.aspx. Includes information sheets for patients.

3. A 30-year-old man who you have seen several times during the last few years comes to your office complaining of a urethral discharge and dysuria for 3 days. The patient only has sex with other men and reports two sex partners in the last 2 months; he uses condoms inconsistently. He has a purulent discharge on physical examination. You treat him with ceftriaxone and azithromycin, both of which he receives while in your office. He has positive nucleic acid amplification test (NAAT) results demonstrating both urethral and pharyngeal gonorrhea. His test results for *Chlamydia trachomatis*, syphilis, and HIV infection are all negative. He returns to see you 10 days later because he still has discomfort when he urinates. He reports that the discharge from his penis has improved but not resolved. On examination, his discharge is scant and cloudy, not overtly purulent. He denies having sex, including oral sex, since his treatment. A sample of the initial 30 mL of voided urine is leukocyte esterase positive. How do you manage this patient?

A. Treat him again with ceftriaxone 250 mg IM and azithromycin 1 g.
B. Perform a urethral culture and NAAT for gonorrhea.
C. Treat him with moxifloxacin 400 mg PO for 7 to 14 days.
D. Treat him with metronidazole 2 g PO once.
E. B and C

Answer: E Patients presenting with persistent symptoms of urethritis should have a Gram stain or, if that is not available, leukocyte esterase testing of their urine to identify objective evidence of inflammation. This patient has a positive leukocyte esterase test result and a visible discharge, establishing a diagnosis of persistent or recurrent urethritis. The differential diagnosis here includes reinfection, treatment failure related to gonorrhea, and persistent urethritis due to a cause other than gonorrhea. Although reinfection is always a possibility in patients whose symptoms do not completely resolve, this patient denies having sex since his treatment. Treatment failure is also possible. Treatment failure related to gonococcal resistance is now an important concern, and treatment failures have been observed, particularly among persons treated with an oral cephalosporin (i.e., cefixime) without concurrent azithromycin therapy. However, treatment failure with ceftriaxone, although conceivable, remains unlikely, given the current epidemiology of gonococcal resistance in the United States, and testing for persistent gonorrhea with both culture and a NAAT is a reasonable course of management for this patient. A positive culture for *Neisseria gonorrhoeae* would establish the diagnosis of gonorrhea, whereas a negative NAAT result would rule that diagnosis out. A positive NAAT result could reflect either persistent infection or simply the continued presence of RNA or DNA, which can persist in the absence of active infection for 7 to 21 days. Thus, a positive NAAT result with a negative culture would not establish a definitive diagnosis. Persons with possible gonorrhea treatment failures should have antimicrobial susceptibility testing performed on a cultured specimen and receive a second course of ceftriaxone 250 mg IM and azithromycin 1 g while awaiting antimicrobial susceptibility test results. The most likely diagnosis in this patient is persistent urethritis due to a pathogen that was not treated with the initial antimicrobial regimen. The most common identifiable cause of persistent urethritis in MSM is *Mycoplasma genitalium*. No Food and Drug Administration–approved commercial test is widely available for *M. genitalium*. Neither azithromycin nor doxycycline is consistently effective against this pathogen, and β-lactam antibiotics do not have activity against the organism. The best therapy for persistent urethritis in MSM is moxifloxacin 400 mg PO qd for 7 to 14 days. The CDC recommends 7 days, but treatment failures have been reported with that regimen, and longer courses may be superior. Clinicians should consider adding metronidazole 2 g PO in a single dose to the therapy for persistent urethritis in heterosexuals to treat *Trichomonas vaginalis*; *Trichomonas* is very uncommon in MSM, like the patient described here.

4. A 21-year-old women comes to your office complaining of mild low abdominal pain and vaginal discharge for 2 weeks. She denies fever, chills, nausea, vomiting, or diarrhea and has no significant past medical history. She has had an intrauterine device (IUD) in place for 2 years. She has been monogamous with a new male partner for 2 months; they used condoms for vaginal sex for 1 to 2 weeks but not since then. Her most recent sexual contact before starting her current relationship was 7 to 8 months ago. On physical examination, the patient is afebrile and well appearing. She has mild bilateral lower abdominal tenderness without rebound tenderness; her bowel sounds are normal. Her pelvic examination is notable for a yellow discharge coming out of the cervical os, cervical motion tenderness, and mild bilateral adnexal tenderness without palpable masses. How do you manage this patient?

A. Test her for gonorrhea and chlamydial infection and treat her with ceftriaxone 250 mg IM once, doxycycline 100 mg PO bid for 14 days, and metronidazole 500 mg PO bid for 14 days.
B. Arrange to see the patient again or speak to her by telephone in 48 to 72 hours to ensure that her symptoms are improving.
C. Admit her to the hospital for parenteral therapy with IV cefoxitin and oral or IV doxycycline.
D. Arrange to have her IUD removed.
E. A and B

Answer: E This patient has signs and symptoms consistent with mucopurulent cervicitis and mild pelvic inflammatory disease (PID). *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the main sexually transmitted pathogens, but neither can be identified in half or more of women with PID. PID is often considered to be a polymicrobial infection, but the role of anaerobic bacteria and the importance of treating patients with mild or moderate PID (e.g., without overt pyosalpinx or pelvic abscess) for anaerobes is controversial. Therefore, the addition of metronidazole to the patient's treatment regimen is optional. This patient does not require hospital admission but should have follow-up in the 48 to 72 hours after treatment to ensure that she is improving. An IUD called the Dalkon Shield was associated with PID many years ago, and IUD insertion is a risk factor for PID in women with gonorrhea or chlamydia at the time of device insertion. However, the diagnosis of PID does not mandate IUD removal in women with an IUD in place. At the same time, few data are available on the risk of recurrent PID in women using IUDs, and the presence of an IUD in this patient is an additional reason for close medical follow-up.

5. A 29-year-old man comes to your clinic with pain and swelling affecting his right knee. He returned from a 3-week trip to Thailand, Vietnam, and Cambodia 4 days ago. He was well throughout most of his trip and took malaria prophylaxis while traveling. He did visit some rural areas. He does not inject drugs and denies having a rash. He did have unprotected vaginal sex with two sex workers during his trip. About 1 week ago, he developed pain in his wrists, fingers, and ankles. He does not recall fever with this. This pain resolved, but he subsequently noted pain and swelling of his knee, which has affected his ability to walk. On physical examination, he is afebrile. His right knee is swollen with an effusion. His other joints are unremarkable. He has no rash. You perform an arthrocentesis, which reveals 30,000 white blood cells (90% polymorphonuclear neutrophils) with no crystals and no organism seen on Gram stain. Synovial fluid culture is pending. Which of the following is *not* indicated?

A. Call orthopedics to perform open drainage of the knee.
B. Obtain culture specimens and nucleic acid amplification test (NAAT) specimens for gonorrhea from all anatomic sites of potential sexual exposure to gonorrhea and a synovial fluid sample for NAAT.
C. Obtain blood culture samples.
D. Initiate therapy with ceftriaxone and vancomycin while awaiting additional laboratory information.
E. Test the patient for HIV infection and syphilis.

Answer: A This patient presents with a syndrome consistent with disseminated gonococcal infection (DGI). DGI is a rare complication of gonorrhea, sometimes occurring in persons with late complement component deficiencies or as a result of infections caused by gonococci that have the ability to cleave complement. DGI can be manifested as a tenosynovitis-dermatitis syndrome, a monarticular or oligoarticular arthritis, or a combination of both; 25 to 50% of patients will have a purulent arthritis, and synovial fluid cultures for gonorrhea are positive in approximately half of persons with frank arthritis. Most patients with DGI lack genital discharge or other typical symptoms of sexually transmitted infection because the strains of *N. gonorrhoeae* prone to disseminate tend to cause asymptomatic localized infections. Nevertheless, approximately 80% have gonorrhea identifiable in the genital tract, rectum, or pharynx, and all patients with suspected DGI should be tested by NAAT at all recently exposed anatomic sites. This patient's history of a migratory tenosynovitis, recent high-risk sexual exposure, and arthritis with a relatively low synovial fluid white blood cell count are all consistent with the septic joint stage of DGI, apparently preceded by the tenosynovitis-dermatitis syndrome. The most prudent course of action in this patient is to initiate therapy for both DGI and other common causes of septic arthritis, especially possible methicillin-resistant *Staphylococcus aureus*. The vancomycin can be discontinued if gonorrhea is identified in any culture or NAAT assay. Arthritis associated with DGI usually responds rapidly to antimicrobial therapy, and patients who enjoy rapid clinical improvement often receive only 2 days of intravenous ceftriaxone followed by oral cefixime 400 mg twice daily to complete a week of therapy. Septic gonococcal arthritis usually responds completely to antibiotics and does not require surgical drainage.

300 *HAEMOPHILUS* AND *MORAXELLA* INFECTIONS

MICHAEL S. SIMBERKOFF

HAEMOPHILUS INFECTIONS

DEFINITION

The name *Haemophilus* is derived from the Greek nouns *haima*, meaning "blood," and *philos*, meaning "lover." *Haemophilus* species colonize the respiratory tract; cause infections of the respiratory tract, skin, or mucous membranes of humans; and from these sites can invade and cause bacteremia, meningitis, epiglottitis, endocarditis, septic arthritis, or cellulitis (Table 300-1).

The Pathogen

Haemophilus species are small, nonmotile, aerobic or facultative anaerobic, pleomorphic, gram-negative bacilli. The prototype of this genus, *Haemophilus influenzae*, was originally recovered from patients with influenza by Pfeiffer in 1893, and it was considered the cause of that disease for many years. Primary isolation of *Haemophilus* species is best accomplished on chocolate agar medium in a carbon dioxide–enriched atmosphere.

EPIDEMIOLOGY

The precise prevalence and incidence of *H. influenzae* infections are unknown.[1] This organism can be detected in the nasopharynx of both children and adults. Before the introduction of an effective vaccine, between 3 and 5% of infants harbored *H. influenzae* type b in their nasopharynx. Children who have been immunized against *H. influenzae* type b are far less likely to be colonized and infected with this organism. However, the risk for infection in nonimmune household contacts of a patient with invasive *H. influenzae* disease is approximately 600-fold greater than the risk in the age-adjusted general population. Nontypeable *H. influenzae* can be detected in the nasopharyngeal cultures of more than 70% of young children, but infection occurs in only a small proportion of colonized individuals.

H. influenzae type b was the most common cause of meningitis in young children before effective vaccines were introduced in the 1980s. Vaccination has had a dramatic impact on the incidence of infection in this group. In a population-based study in Atlanta during the 18-month period from December 1, 1988, through May 31, 1990, invasive *H. influenzae* disease occurred in only 5.6 per 100,000 children and 1.7 per 100,000 adults. Forty of the 47 strains associated with invasive disease from adult patients in this study were serotyped. Twenty of these isolates (50%) were *H. influenzae* type b, 19 (47.5%) were nontypeable, and 1 (2.5%) was type f. A more recent study covering the period from 1989 to 2008 from the Centers for Disease Control and Prevention's Active Bacterial Core surveillance system showed that the overall incidence of invasive *H. influenzae* infections fell from 4.39 cases per 100,000 population in 1989 (shortly after introduction of the *H. influenzae* type b conjugate vaccine in the United States) to 1.55 cases per 100,000 in 2008, and the percentage of invasive infections caused by *H. influenzae* type b fell from 87 to 3%, whereas the percentage caused by nontypeable *H. influenzae* strains increased from 16.8 to 68.4%.[2]

Patients with human immunodeficiency virus (HIV) infection are at increased risk for *H. influenzae* infection. Rates of invasive *H. influenzae* infection in men aged 20 to 49 years with HIV infection and acquired immunodeficiency syndrome (AIDS) were 14.6 and 79.2 per 100,000, respectively. The majority of these infections were caused by nontypeable *H. influenzae* strains, although in a second study, 10 of 15 bacteremic *H. influenzae* type b infections observed in adults occurred in patients at risk for HIV infection, and AIDS was documented in seven of these patients.

Other factors also increase the risk for *H. influenzae* infection, including immunoglobulin deficiencies, sickle cell disease, splenectomy, malignant disease, pregnancy, cerebrospinal fluid (CSF) leaks, head trauma, alcoholism, chronic obstructive pulmonary disease (COPD), and race. Eskimo, Navajo, and Apache children have *H. influenzae* type b infection rates that are significantly greater than those in comparable non-native populations. In addition, daycare attendance, crowding, the presence of siblings, prior hospitalizations, and previous otitis media have been shown to increase the risk for *H. influenzae* type b disease in young children, whereas breast-feeding decreases this risk.

PATHOBIOLOGY

H. influenzae consists of encapsulated (typeable) and nonencapsulated (nontypeable) forms. The encapsulated forms are responsible for most of the invasive infections in children and acute epiglottitis in both children and adults, whereas the nonencapsulated forms cause respiratory mucosal infections, conjunctivitis, female genital tract infections, and invasive disease in adults. The capsules of *H. influenzae* consist of polysaccharide antigens. Six capsular serotypes (a through f) exist and are important virulence factors that inhibit opsonization, clearance, and intracellular killing of the organisms. *H. influenzae* type b, formerly the most common cause of meningitis in infancy and childhood worldwide, contains a pentose capsular polysaccharide consisting of polyribosyl ribitol phosphate (PRP). Other serotypes contain hexose polysaccharides. *H. influenzae* type b is more virulent than the other serotypes, probably because it is highly resistant to clearance once bacteremia has been initiated. Since the introduction of *H. influenzae* serotype b conjugate vaccines in the 1990s, most infections are now caused by non-b serotypes, and *H. influenzae* serotype a has emerged as a cause of serious morbidity and mortality.[3] Recent findings suggest that *H. influenzae* strains have the capacity to induce variations in their surface oligosaccharides when serially passed in the presence of human antibody and complement. It has been hypothesized that this may contribute to the organism's capacity to colonize and to survive in nares of patients before causing respiratory tract infections including otitis, sinusitis, epiglottitis, bronchitis, and pneumonia.

Fimbriae are important virulence factors that enhance the adherence of *H. influenzae* to mucosal surfaces. Both typeable and nontypeable *H. influenzae* isolates contain fimbriae. The lipo-oligosaccharides of *H. influenzae* also contribute to their virulence. Lipo-oligosaccharides appear to play a crucial role in facilitating the survival of *H. influenzae* on mucosal surfaces within the nasopharynx and in initiating invasive disease (blood stream invasion) from these sites.[4]

Outer membrane proteins also serve as virulence factors in *H. influenzae* disease. At least 15 different *H. influenzae* outer membrane proteins have been identified. One of these (P2, 39 to 40 kD) functions as a porin, and others are associated with iron binding. Successful scavenging of iron within the human host is crucial for multiplication of *H. influenzae*.

Antibodies have been recognized for decades as an important part of host defenses against *H. influenzae* diseases. The classic studies of Fothergill and Wright in 1933 demonstrated that most cases of *H. influenzae* meningitis occur in young children after they lose passively acquired maternal antibodies and before active humoral immunity to the organism develops. These protective antibodies function primarily to opsonize and to facilitate the clearance of *H. influenzae* rather than to kill virulent organisms directly.

Complement is also an essential component of host defenses against some *H. influenzae* diseases. Children with congenital deficiencies of C2, C3, and factor I have an increased incidence of *H. influenzae* infections. Patients who lack a functional spleen (e.g., those with sickle cell disease) or who have undergone splenectomy also are at risk for the development of overwhelming infection with *H. influenzae* type b.

TABLE 300-1 SITES OF COLONIZATION AND INFECTIONS BY *HAEMOPHILUS INFLUENZAE*

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES

H. influenzae, biogroup *aegyptius*		Purulent conjunctivitis Brazilian purpuric fever

CLINICAL MANIFESTATIONS

Meningitis

H. influenzae meningitis commonly occurs in children younger than 5 years and in adults with a history of skull trauma or CSF leaks. *H. influenzae* type b strains cause most of these cases. A review of 493 episodes of acute bacterial meningitis in adults at the Massachusetts General Hospital during the 27-year period from 1962 through 1988 showed that 19 cases (4%) were due to *H. influenzae*.

H. influenzae meningitis is clinically indistinguishable from other forms of acute bacterial meningitis. Most patients with *H. influenzae* meningitis have CSF white blood cell counts greater than 1000/mm^3 and hypoglycorrhachia. CSF Gram stain shows pleomorphic gram-negative bacilli in 60 to 70% of untreated cases. In some patients, however, the bipolar staining may result in a mistaken diagnosis of pneumococcal meningitis. Thus, Gram stain is neither sensitive nor specific for diagnosis of *H. influenzae* meningitis.

A diagnosis of *H. influenzae* type b meningitis can be rapidly and reliably established by detecting PRP capsular antigens in CSF. The diagnosis can be established in most cases even when antibiotics have been given before CSF is obtained. Other serotypes (most commonly type f) can also cause meningitis in adults. Therefore, serologic tests for type b antigen in CSF cannot be relied on to rule out *H. influenzae* meningitis in all cases.

Epiglottitis

H. influenzae type b is the most common cause of acute epiglottitis in both children and adults. Epiglottitis is a life-threatening infection in children that usually occurs in those younger than 5 years. The symptoms are fever, drooling, dysphagia, and respiratory distress or stridor, which appear during the course of hours. In adults, fever, sore throat, dysphagia, and odynophagia occur. Cervical tenderness and lymphadenopathy can be found at all ages. Laryngoscopy demonstrates a swollen, cherry-red epiglottis. However, this procedure should be avoided or undertaken only by experts because it may precipitate acute airway obstruction and thus make emergency tracheotomy necessary. A lateral radiograph of the neck more safely confirms the diagnosis of acute epiglottitis. The patient must be maintained in an upright position during this procedure, however, to avoid additional compromise of the airway. The cause is usually established by blood culture. Cultures of the pharynx and other mucosal surfaces are less useful because *H. influenzae* may be part of the normal flora. One review suggests that although vaccination has effectively reduced the incidence of this disease in children, it may be increasing in adults.

Pneumonia

H. influenzae is a common cause of pneumonia in both children and adults. These organisms can also cause nosocomial infections, including ventilator-associated pneumonia. The clinical features of *H. influenzae* pneumonia include fever, cough, and signs and radiographic findings of lobar consolidation.[5] Parapneumonic effusions or empyema occur commonly in patients with *H. influenzae* pneumonia. Gram-negative bacilli in sputum suggest the diagnosis, but isolation of *H. influenzae* from sputum culture alone is inadequate to prove a cause because of the high frequency with which this organism colonizes the respiratory tract. A diagnosis can be established by isolating *H. influenzae* from either blood or pleural fluid. Most isolates are nontypeable.

Tracheobronchitis

Tracheobronchitis is a condition characterized by fever, cough, and purulent sputum that occurs in the absence of radiographic infiltrates suggestive of pneumonia.[6] It frequently develops in patients with known chronic lung disease. Blood cultures are rarely positive. A combination of pleomorphic gram-negative bacilli predominating in purulent sputum, antibody titers to *H. influenzae* that rise after infection, and a response, at least transiently, to treatment of *H. influenzae* infection strongly suggests this diagnosis.

Sinusitis

H. influenzae and *Streptococcus pneumoniae* are the most frequent bacterial isolates from antral punctures or surgical specimens of patients with acute purulent sinusitis. Most *H. influenzae* isolates are nontypeable. Although patients may respond initially to treatment directed against *H. influenzae*, the response is transient if the sinus obstruction is not relieved. *H. influenzae* is not an important pathogen in patients with chronic sinusitis.

Otitis Media

H. influenzae is the most frequent cause of otitis media in young children. Approximately 90% of the *H. influenzae* isolates obtained by tympanocentesis are nontypeable; *H. influenzae* type b causes most of the remaining 10% of infections. Patients with otitis media may have ear pain or exhibit irritability. Drainage can be present. An inflamed, opaque, bulging, or perforated tympanic membrane is usually demonstrated. The cause can be proved by Gram stain and culture of purulent fluid obtained by tympanocentesis. Otitis caused by *H. influenzae* type b may occur in association with bacteremia and meningitis.

Cellulitis

H. influenzae type b is the cause of 5 to 15% of cases of cellulitis in young children. Most of the infections occur on the face or neck. *H. influenzae* cellulitis is often described as causing a distinctive blue or violaceous discoloration of the skin. However, the fever, erythema, and tenderness observed may not be distinguishable from those attributable to other causes. The diagnosis is established by culture of blood or tissue aspirates from the involved area, or both.

Bacteremia without a Primary Focus of Infection

H. influenzae causes primary bacteremia in both children and adults. In infants or children, occult meningitis or epiglottitis can be present. Rigorous clinical and laboratory evaluation is essential to avoid missing a diagnosis of life-threatening focal infection in these patients. In adults, primary *H. influenzae* bacteremia often occurs in those with underlying diseases, such as lymphoma, leukemia, or alcoholism.

Obstetric and Gynecologic Infection

Pregnancy is associated with a significant risk for *H. influenzae* infection. In the Atlanta study, 7 of 47 adult *H. influenzae* invasive infections occurred in pregnant women. Nontypeable *H. influenzae* is also an important cause of tubo-ovarian abscess and salpingitis in women. A recent study of women in England and Wales showed that pregnancy was associated with an increased risk of invasive, mostly unencapsulated *H. influenzae* infection and that these infections were associated with poor pregnancy outcomes, including fetal loss and extremely premature births or stillbirths.[7]

Pericarditis

H. influenzae type b is an important cause of primary bacterial pericarditis in children. It rarely causes this infection in adults; however, pericarditis can occur in association with pneumonia, probably as a result of contiguous spread of the infection.

Endocarditis

H. influenzae is an unusual cause of endocarditis in view of the frequency with which invasive disease occurs. Most infections occur in patients with preexisting valvular heart disease. Because of its slow initial growth in blood culture media, diagnosis of this infection may be delayed or missed. Patients with *H. influenzae* endocarditis are at high risk for arterial embolic phenomena.

Septic Arthritis

H. influenzae type b is a common cause of septic arthritis in young children; it is rare in adults. *H. influenzae* type b arthritis is clinically indistinguishable from other causes of pyogenic arthritis.

Purulent Conjunctivitis and Brazilian Purpuric Fever

H. influenzae, biogroup *aegyptius* (Koch-Weeks bacillus), causes epidemic purulent conjunctivitis in children. This disease commonly occurs in hot climates or in the summer season.

The infection is characterized by conjunctival erythema, edema, mucopurulent exudate, and varying discomfort in the eyes. An unusually virulent clone of *H. influenzae*, biogroup *aegyptius*, causes an invasive infection called Brazilian purpuric fever, which is characterized by petechial or purpuric skin lesions and vascular collapse; it occurs days to weeks after an initial episode of conjunctivitis in infants and children younger than 10 years.

TREATMENT Rx

Third-generation cephalosporins are considered the treatment of choice for serious *H. influenzae* infections, such as meningitis or epiglottitis. Treatment

with ceftriaxone (adult dose, 1 to 2 g intravenously every 12 hours) or cefotaxime (adult dose, 2 g intravenously every 6 hours) should be started in patients with proven or suspected *H. influenzae* infection, and it should be continued at least until full susceptibility data are available.

Ampicillin was effective treatment of all *H. influenzae* infections until the mid-1970s. Since the first reports of ampicillin-resistant *H. influenzae* isolates in 1972, however, the prevalence of resistance has increased dramatically. Most resistance is due to a plasmid-mediated, R-factor enzyme (tumor endothelial marker 1) β-lactamase, which can be detected rapidly in the laboratory. A small number of isolates, however, have altered penicillin-binding proteins that have decreased binding affinity to penicillin and other β-lactam antibiotics. As a consequence, the isolates may be resistant to some cephalosporins, such as cefaclor, cefamandole, and cefuroxime, in addition to ampicillin. Therefore, patients with proven or suspected *H. influenzae* infections should not be treated with ampicillin or second-generation cephalosporins until susceptibility to these antibiotics has been proved. Chloramphenicol resistance also occurs in *H. influenzae*; an inactivating enzyme, chloramphenicol acetyltransferase, causes resistance. A small number of *H. influenzae* isolates are resistant to both ampicillin and chloramphenicol.

Oral antibiotics are commonly used to treat tracheobronchitis in patients with COPD and otitis media in children, in whom *H. influenzae* isolates are common. Because of resistance, ampicillin and amoxicillin cannot be recommended for the more serious of these infections unless the susceptibility of isolates is known. Most *H. influenzae* isolates are susceptible to amoxicillin-clavulanate. They are also susceptible to azithromycin and clarithromycin, the newer macrolide antibiotics. Fluoroquinolones, such as ciprofloxacin, ofloxacin, levofloxacin, and gatifloxacin, are active against these organisms. Trimethoprim-sulfamethoxazole is also effective for most isolates.

PREVENTION

The first *H. influenzae* type b vaccines were licensed for use in the United States in 1985. They contained purified PRP antigens. However, postlicensing studies of PRP vaccines in the United States showed variable efficacy. The PRP vaccines elicit a type 2, thymus-independent B-cell response, generate few (if any) memory B cells, and fail to stimulate a response in neonates and infants.

Protein-conjugated PRP vaccines were developed to overcome the problem of lack of immune response in the most susceptible infants and some young children. Several are now licensed for use in infants.[8] At present, protein-conjugated PRP vaccines are recommended for use in all infants older than 2 months but not earlier than 6 weeks of age. Studies have shown that protein-conjugated vaccines are effective in diverse populations, including adults with COPD.

Antibiotic prophylaxis should be used for the nonimmunized household or daycare contacts of patients with invasive *H. influenzae* type b disease. Rifampin is the treatment of choice. It should be given in a dosage of 10 mg/kg once daily for 4 days to neonates younger than 1 month, 20 mg/kg (up to a maximum of 600 mg) once daily for 4 days to older children, and 600 mg/day for 4 days to adults.

Other *Haemophilus* Species

Haemophilus parainfluenzae can be found as part of the normal flora of the mouth and pharynx (Table 300-1). It is a rare cause of meningitis in children and an even rarer cause of meningitis in adults. It may cause dental infections or dental abscesses. Cases of brain abscess, epidural abscess, liver abscess, osteomyelitis, pneumonia, empyema, epiglottitis, peritonitis, septic arthritis, and bacteremia have been reported to be caused by this organism. *H. parainfluenzae* also causes subacute endocarditis, often in young adults. *Haemophilus* species are responsible for approximately 1% of cases of infective endocarditis in non–drug-abusing patients. *H. parainfluenzae*, *Haemophilus aphrophilus*, and *Haemophilus paraphrophilus* are the species most frequently recovered from these patients. *H. parainfluenzae* forms bulky vegetations on heart valves. Arterial embolization is common in patients with *H. parainfluenzae* endocarditis. Most isolates are sensitive to ampicillin, but some produce β-lactamases.

MORAXELLA INFECTIONS

DEFINITION

Moraxella species are associated with a variety of infections, the most common of which is exacerbation of chronic bronchitis by *Moraxella catarrhalis*.[9]

The Pathogen

Moraxella organisms are small, gram-negative bacteria that grow well on blood or chocolate agar. They are catalase and oxidase positive. These small diplococci are morphologically difficult to distinguish from *Neisseria*. Some *Moraxella* species are gram-negative bacilli. *M. catarrhalis* is the most important pathogen of this genus (Table 300-2).

PATHOBIOLOGY

The organism is isolated exclusively from humans and is found predominantly in the respiratory tract. *M. catarrhalis* adheres to mucosal cells with the aid of pili. Infection is believed to result from contiguous spread of the organism from sites of colonization, possibly as a result of the introduction of new, more virulent strains to which the host lacks immunity. *M. catarrhalis* possesses multiple virulence factors that can be carried through biologically active outer membrane vesicles to contribute to the pathobiology of otitis media.[10]

M. catarrhalis can often be found in respiratory secretions together with *H. influenzae*. Although the mechanism for coexistence of these pathogens is not known, evidence suggests that the outer membrane vesicles of *M. catarrhalis* inactivate complement, thus enhancing survival of *H. influenzae*.

CLINICAL MANIFESTATIONS

M. catarrhalis is associated with exacerbations of chronic bronchitis. Studies indicate that this organism can be isolated from 0.2 to 8.1% of the sputum aspirates of patients with this disease. It is the third most common pathogen isolated from these patients behind *S. pneumoniae* and *H. influenzae*.

M. catarrhalis can cause pneumonia, particularly in elderly patients with COPD and other underlying conditions such as diabetes mellitus. Sir William Osler is believed to have died as a result of *M. catarrhalis* pneumonia. Cases of bacteremic pneumonia have been reported. In addition, *M. catarrhalis* can cause nosocomial pneumonia with evidence of patient-to-patient spread of the organism.

M. catarrhalis is a common cause of otitis media in young children. Microbiologic studies indicate that this organism is present in approximately 15% of the aspirates from such patients. The organism also causes sinusitis and is a rare cause of bacteremia in children and adults.

Serious infections with other *Moraxella* species are uncommon. However, these organisms are associated with chronic conjunctivitis. Furthermore, case reports have documented the rare occurrence of invasive infections, including bacteremia, endocarditis, arthritis, pericarditis, and meningitis. Meningitis may occur in patients with complement deficiency.

TREATMENT Rx

Oral antibiotics are sufficient for the treatment of most *M. catarrhalis* infections. Inducible β-lactamases are present in many isolates. Therefore, treatment with a β-lactamase–stable antibiotic such as amoxicillin-clavulanate (usual adult dose, 500 mg every 12 hours), a cephalosporin (e.g., cefaclor, usual adult dose, 500 mg every 8 hours), or a non–β-lactam antibiotic such as trimethoprim-sulfamethoxazole (usual adult dose, 1 double-strength tablet every 12 hours) should be initiated pending susceptibility test results.

TABLE 300-2 SITES OF COLONIZATION AND INFECTION BY *MORAXELLA* SPECIES

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES
M. catarrhalis	Oral cavity and upper respiratory tract	Chronic bronchitis exacerbation Otitis media Pneumonia Sinusitis Bacteremia, endocarditis Arthritis, osteomyelitis, epiglottitis (all extremely rare)
M. lacunata	Upper respiratory tract	Chronic conjunctivitis
Other *Moraxella*	Upper respiratory tract	Rare cases of bacteremia, endocarditis, arthritis, meningitis

REVIEW QUESTIONS

1. Which of the following statements about *Haemophilus influenzae* is true?

A. It is a gram-positive bacterium that commonly causes skin infections in infants, children, and older adults.
B. It is a gram-negative bacterium that commonly causes respiratory tract infections in infants, children, and older adults.
C. It is a gram-negative bacterium that can be isolated on and grows easily on MacConkey's agar plates without blood or other supplements.
D. It is a virus that causes epidemic influenza infections.

Answer: B *H. influenzae* is a gram-negative bacterium that causes respiratory and invasive infections in infants, children, and older adults. It is fastidious and grows best on chocolate agar in a carbon dioxide–enriched environment. It was originally recovered from patients with influenza and was considered the cause of that disease, hence its name. (See section on the pathogen.)

2. Which of the following statements about human host defenses against *Haemophilus influenzae* is true?

A. Cell-mediated immunity is the most important host defense against infection.
B. Antibody directed against the cell wall and complement are the most important host defenses against infection.
C. Antibody against the cell capsule and complement are the most important host defenses against infection.
D. Complement plays no role in host defense against infection.

Answer: C Antibody directed against the cell capsule and complement provide bactericidal immunity to *H. influenzae*. Subjects lacking either are at risk of invasive infection. Complement is an essential component of host defenses against some *H. influenzae* diseases, and complement deficiency states predispose to infection with the organism. (See section on pathobiology.)

3. Which of the following statements about treatment of *Haemophilus influenzae* infections is true?

A. Ampicillin is the initial treatment of choice for infection pending results of susceptibility tests in the laboratory.
B. Chloramphenicol is the initial treatment of choice for infection pending results of susceptibility tests in the laboratory.
C. Rifampin is the treatment of choice pending results of susceptibility tests in the laboratory.
D. A third-generation cephalosporin (e.g., ceftriaxone) is the treatment of choice pending results of susceptibility tests in the laboratory.

Answer: D Many strains of *H. influenzae* produce β-lactamases that inactivate ampicillin, and the prevalence of ampicillin resistance has increased dramatically. An inactivating enzyme, chloramphenicol acetyltransferase, causes resistance to that antibiotic. Rifampin is the treatment of choice for prophylaxis of nonimmunized contacts but not for established infection. (See sections on treatment and prevention.)

4. Which of the following statements about prevention of *Haemophilus influenzae* infections is true?

A. The unconjugated Hib polysaccharide vaccine has been effective in preventing otitis, meningitis, and bacteremic *H. influenzae* type b infections in infants, toddlers, children, and adults.
B. The conjugated Hib polysaccharide vaccine has been effective in preventing otitis, meningitis, and bacteremic *H. influenzae* type b infections in infants, toddlers, children, and adults.
C. The conjugated Hib polysaccharide vaccine has been effective in preventing otitis, meningitis, and bacteremic all serotypes of *H. influenzae* infections in infants, toddlers, children, and adults.
D. Vaccines are generally ineffective in preventing *H. influenzae* type b infection, and rifampin is the only effective prophylactic treatment.

Answer: B The conjugated vaccine protects infants, children, and, by reducing the carrier state, older adults against invasive *H. influenzae* infections. (See section on prevention.)

5. Which of the following statements about *Moraxella catarrhalis* infections is true?

A. *M. catarrhalis* is a commensal of the respiratory tract and rarely causes infection.
B. *M. catarrhalis* is commonly associated with bacteremia and meningitis.
C. *M. catarrhalis* is commonly associated with exacerbations of chronic bronchitis.
D. *M. catarrhalis* is commonly found in the respiratory tract of pet animals including dogs and cats and is transmitted from them to humans, in whom it can cause disease.

Answer: C New strains of *M. catarrhalis* are commonly associated with exacerbations of chronic bronchitis, and treatment of these speeds recovery. (See section on *Moraxella* infections).

301

CHANCROID

STANLEY M. SPINOLA

DEFINITION

Chancroid is a sexually transmitted disease characterized by painful genital ulcers and inguinal lymphadenitis. Chancroid is caused by *Haemophilus ducreyi*, a gram-negative coccobacillus that is not a true *Haemophilus* species. Within the Pasteurellaceae, *H. ducreyi* is grouped in a distinct lineage with *Mannheimia haemolytica* and *Actinobacillus pleuropneumoniae*. *H. ducreyi* is likely to have diverged from these animal respiratory pathogens to occupy its niche in the human genital epithelium.

EPIDEMIOLOGY

Chancroid is endemic in resource-poor regions of Africa and Asia and facilitates the transmission of human immunodeficiency virus (HIV-1). In the 1990s, the World Health Organization estimated the annual global prevalence of chancroid to be 4 million to 6 million cases. Because of the widespread use of syndromic management, which consists of treatment for syphilis and chancroid without diagnostic testing, the prevalence of chancroid has dramatically declined in endemic areas. Chancroid can be maintained only in networks with high sex partner change rates; female sex workers play an important role in its epidemiology. Targeted treatment of infected sex workers leads to eradication of the disease in endemic areas. Despite these successes, reports of chancroid persist from many countries. Such reports imply a reservoir of untreated sex workers. Urban outbreaks of chancroid associated with sex work occurred in the United States in the 1980s and 1990s. Owing to contact tracing and treatment efforts, the number of domestic cases of chancroid has decreased steadily, with a 65-year low of eight cases in 2013; such sporadic cases are likely to be imported after contact with infected persons in endemic areas.

The male-to-female ratio of chancroid is 3 : 1. The excess number of male cases is usually attributed to the infection of multiple partners by sex workers. However, human inoculation experiments indicate that men are twice as susceptible as women for development of pustules, suggesting that male gender is a risk factor for disease progression.[1]

PATHOBIOLOGY

Much of what is known about the pathogenesis of *H. ducreyi* is derived from experiments in which bacteria are inoculated into the skin of the upper arm of human volunteers. Puncture wounds are required to initiate infection, and the estimated infectious dose is as low as one bacterium. Papules develop within 24 hours and either spontaneously resolve or evolve into pustules in 2 to 5 days. Neutrophils and macrophages surround the organism and form an abscess that erodes the epidermis. Below the abscess, there is a collar of macrophages and regulatory T cells and a dermal infiltrate of macrophages, CD4 and CD8 T cells, natural killer (NK) cells, and dendritic cells. This histopathology resembles a suppurative granuloma and is identical to that of natural ulcers. In both experimental and natural infection, *H. ducreyi* associates with neutrophils and macrophages, which fail to ingest the organism. Mutant versus parent trials have revealed bacterial components that are required for infection; several are involved with adherence and resistance to serum killing and phagocytosis. In addition to gender, the human model has shown that there are host effects on disease progression. Differential host susceptibility is associated with distinct dendritic cell responses to the organism, which may shape T-cell and NK-cell responses that influence the ability of phagocytes to ingest the organism.

CLINICAL MANIFESTATIONS

H. ducreyi enters the skin through breaks in the epithelium that occur during intercourse.[2] Papules form within hours to days and evolve into pustules in 2 to 3 days. After a few days to 2 weeks, the pustules ulcerate. Patients typically develop one to four painful ulcers (Fig. 301-1) but do not seek treatment until they have had ulcerative symptoms for 1 to 3 weeks. By this time, 10 to 40% have suppurative inguinal lymphadenopathy or buboes (see Fig. 301-1).

FIGURE 301-1. Typical chancroidal ulcer and lymphadenitis in a man. (From Herpes-Coldsores.com. http://www.herpes-coldsores.com/std/chancroid_pictures.htm.)

Natural ulcers are classically very painful and nonindurated, with ragged edges. The ulcer may be covered by a yellow or gray necrotic exudate and bleeds when scraped. However, this presentation occurs in a minority of patients; chancroid is frequently indistinguishable from syphilis and genital herpes. Lesions in men are usually on the foreskin, coronal sulcus, or penile shaft. Lesions in women are usually on the labia; but women may have internal vaginal and cervical ulcers that are painless. Lesions also occur on the thighs and buttocks or at distant sites; extragenital lesions are thought to be due to autoinoculation. Untreated, chancroid persists for months and causes giant ulcers, erosion of the infected area, or fibrosis, leading to phimosis in men.

In the western Pacific, *H. ducreyi* causes a chronic limb ulceration syndrome that is not sexually transmitted and occurs primarily in children.[3] Close contact with family members with ulcers is implicated in these cases. In a cohort study done in yaws-endemic villages in Papua New Guinea, the prevalence of this syndrome is 3.2 cases per 100 persons. *H. ducreyi*, *Treponema pallidum* subspecies *pertenue*, and dual infections accounted for 58%, 26%, and 16% of the ulcers, respectively. The overall prevalence of *H. ducreyi* infection in children aged 5 to 15 years is an astoundingly high 7%. Similar data are emerging from other yaws-endemic areas.[4]

DIAGNOSIS

Diagnosis requires either a positive culture or a polymerase chain reaction (PCR) test. In research settings, PCR has a resolved sensitivity of 95 to 98% and a specificity of 99% for *H. ducreyi*. In comparison, the sensitivity for culture is approximately 75%, but clinical diagnosis is neither sensitive (range, 50 to 75%) nor specific (range, 50 to 75%). Unfortunately, PCR-based tests are not commercially available.[5] Most sexually transmitted disease clinics do not routinely test patients for chancroid, and the diagnosis is typically made by the exclusion of genital herpes and syphilis. If patients with genital ulcers and lymphadenitis or treatment failure for primary syphilis appear in a community, public health authorities should be notified so that specific diagnostic testing can be initiated.

The differential diagnosis includes syphilis, genital herpes, lymphogranuloma venereum, and granuloma inguinale. Mixed infections with herpes simplex virus or syphilis are common, occurring in approximately 17% of chancroid cases diagnosed by PCR. Patients with suspected chancroid

should be tested for genital herpes and have serologic tests for syphilis and HIV-1 and a dark-field examination.

TREATMENT

Rx

Because of syndromic management, little is known about the current prevalence of antibiotic resistance in *H. ducreyi*, but most clinical isolates have had plasmid-mediated resistance to ampicillin, tetracyclines, and sulfonamides. The only reliable treatment regimens are macrolides, quinolones, and third-generation cephalosporins; there have been isolated reports of erythromycin and ciprofloxacin resistance. Owing to the propensity of *H. ducreyi* to acquire plasmids, the fact that some Enterobacteriaceae harbor plasmids that encode extended-spectrum β-lactamases and quinolone resistance is a concern. Current treatment recommendations include single-dose azithromycin 1 g orally or ceftriaxone 250 mg intramuscularly, ciprofloxacin 500 mg orally twice a day for 3 days, and erythromycin base 500 mg orally three times a day for 7 days.[6]

Repeated aspiration of buboes may be required to effect a cure. In a randomized study comparing repeated aspiration versus incision and drainage, incision and drainage was considered preferable. However, incision and drainage may cause excessive scarring, especially in persons of African descent, and should be avoided according to some experts.

Initial reports of coinfection with HIV infection and chancroid suggest that such individuals have a greater number of ulcers that do not heal as readily after antibiotic treatment compared with patients infected with *H. ducreyi* alone and that single-dose regimens may not be effective in this setting. Antibiotic treatment failure is also associated with lack of circumcision. If close follow-up cannot be ensured, most experts recommend multidose regimens in HIV seropositives.

PROGNOSIS

Clinical cure correlates with a reduction in pain and purulence and re-epithelialization of the ulcer within 7 days. Patients who do not show improvement within 7 days should be regarded as treatment failures and given an alternative agent. Even if *H. ducreyi* is eradicated, ulcers may persist if genital herpes or syphilis is present and not treated. Most ulcers heal in 2 weeks; large ulcers may take 4 weeks to heal.

PREVENTION

Circumcision protects against chancroid in men. Condoms are likely to be protective. Although several antigens that may afford protection in animal models have been identified, there is no vaccine. Contacts of patients with chancroid should be treated with an approved regimen.

REVIEW QUESTIONS

1. Which of the following drugs would not be used to empirically treat a patient with suspected chancroid?

A. Ampicillin
B. Erythromycin
C. Ciprofloxacin
D. Ceftriaxone
E. Azithromycin

Answer: A Most strains of *Haemophilus ducreyi* harbor plasmids that encode β-lactamase. Although there are few data on the current state of antibiotic resistance in *H. ducreyi*, there have been few reports of resistance to quinolones, macrolides, or third-generation cephalosporins.

The following scenario applies to questions 2, 3, and 4.

A 28-year-old man who recently traveled to Africa presents with two painful, large genital ulcers and inguinal lymphadenopathy. He states that he had sex with a bar worker during the trip and subsequently had sex with his usual partner when he returned home before he noted symptoms. The lesions evolved during a period of 3 weeks. A dark-field examination for *Treponema pallidum* and a polymerase chain reaction (PCR) analysis for herpes simplex virus of the ulcer exudate are negative.

2. Serologic tests that should be ordered in this situation include those for

A. HIV-1
B. Syphilis
C. *H. ducreyi*
D. Both A and B
E. A, B, and C

Answer: D All patients with genital ulcer disease should be tested for HIV-1 and syphilis. There are no serologic tests for *H. ducreyi.*

3. Presumptive therapy should be given with

A. Doxycycline for suspected lymphogranuloma venereum
B. Acyclovir for suspected herpes simplex
C. Benzathine penicillin for suspected syphilis
D. A 3-week course of azithromycin for suspected granuloma inguinale
E. A single dose of azithromycin for suspected chancroid

Answer: E Provided his syphilis serologic test result is also negative, the patient has met clinical criteria for a presumptive diagnosis of chancroid; a single 1-g dose of oral azithromycin has cure rates of more than 90%.

4. His regular partner should be

A. Notified and be told to seek care if she develops symptoms
B. Notified and be examined but not treated if there are no lesions
C. Notified, be examined, and be treated regardless of the presence or absence of lesions or laboratory findings
D. Notified only if the patient consents
E. Notified, be examined, and be treated only if she has laboratory confirmation of infection

Answer: C The estimated transmission rate of *H. ducreyi* from infected men to women is 70%. As is true for all bacterial agents of sexually transmitted infections, all contacts should be notified, be examined, have a laboratory evaluation, and be treated regardless of clinical or laboratory findings.

5. The most sensitive and specific method for diagnosis of *H. ducreyi* infection is

A. Gram stain of the ulcer exudate
B. PCR-based test of a swab of the exudate
C. The typical clinical findings of large, nonindurated ulcers with inguinal lymphadenitis
D. Culture of the exudate
E. Direct fluorescence microscopy with specific antibodies

Answer: B PCR has a high sensitivity and specificity for *H. ducreyi*; culture is 100% specific but at most 75% sensitive. The other modalities hover in the 50% sensitivity and specificity range.

CHOLERA AND OTHER *VIBRIO* INFECTIONS

EDUARDO GOTUZZO AND CARLOS SEAS

CHOLERA

DEFINITION

Cholera is a feared epidemic diarrheal disease caused by *Vibrio cholerae* serogroup O1 and, since 1992, by the new serogroup O139. The disease is characterized by acute watery diarrhea. In its more severe form, a person may be severely dehydrated and in hypovolemic shock; the patient may die in a matter of a few hours after contracting the infection if treatment is not provided. Cholera is endemic today in Africa and Asia, and cases are also reported from Latin America, North America, and Europe. Seven pandemics have been registered in history since 1816; the most recent has lasted more than five decades since its recognition in Indonesia in 1961.

The Pathogen

V. cholerae is a curved gram-negative bacillus that belongs to the family Vibrionaceae and shares common characteristics with the family Enterobacteriaceae. *V. cholerae* O1 can be classified into three serotypes according to the presence of somatic antigens and into two biotypes, classic and El Tor, according to specific phenotypic characteristics. There is no evidence of different clinical spectra among the three serotypes of *V. cholerae*. The classic biotype, responsible for the first six pandemics of cholera, causes an approximately equal number of symptomatic and asymptomatic cases, whereas the El Tor biotype causes more asymptomatic infections. The classic biotype is confined to the south of Bangladesh, and the El Tor biotype is responsible for the current pandemic. The O139 serogroup is composed of a variety of genetically diverse strains, both toxigenic and nontoxigenic; it is genetically closer to El Tor *V. cholerae*.

EPIDEMIOLOGY

Cholera has both a predisposition to cause epidemics with pandemic potential and an ability to remain endemic in all affected areas. People of all ages are at risk to contract the infection in epidemic settings, whereas children older than 2 years are mainly affected in endemic areas. *V. cholerae* lives in riverine, brackish, and estuarine ecosystems, where both O1 and non-O1 strains coexist, with non-O1 and nontoxigenic O1 strains predominating over toxigenic O1 strains. In its natural environment, *V. cholerae* lives attached to algae or to crustacean shells and copepods, with which it coexists in a symbiotic manner. Several conditions, such as temperature, salinity, and availability of nutrients, determine the survival of *V. cholerae*; when these conditions are adverse, vibrios survive in a viable but nonculturable state. More recent data suggest that cholera phages modulate the abundance of *V. cholerae* in the environment and determine the beginning and end of epidemics. Phages may also play a role in the emergence of new *V. cholerae* serogroups by transferring genetic material to nontoxigenic strains.

From its aquatic environment, *V. cholerae* is introduced to humans through contamination of water sources and food. Once humans are infected, very high attack rates may take place, particularly in previously naïve populations.[1] Acquisition of the disease by drinking contaminated water from rivers, ponds, lakes, and even tube well sources has been documented. Drinking unboiled water, introducing hands into containers used to store drinking water, drinking beverages from street vendors, drinking beverages to which contaminated ice has been added, and drinking water outside the home are risk factors; these factors contributed to the acquisition of cholera during the large Peruvian epidemic of 1991. Drinking boiled water, acidic beverages, and carbonated water and using narrow-necked vessels for storing water are protective measures. Epidemics of cholera associated with the ingestion of leftover rice, raw fish, cooked crabs, seafood, raw oysters, and fresh vegetables and fruits have been documented. Person-to-person transmission is less likely to occur because a large inoculum is necessary to transmit disease. High transmission rates (approximately 50%) are reported among household contacts of patients with cholera in endemic areas.[1]

Epidemics of cholera tend to occur during the hot season. Factors affecting climate change and climate variability have an impact on the incidence of cholera. The El Niño–southern oscillation (ENSO), a periodic phenomenon representative of global climate variability, affects the transmission of cholera and vector-borne diseases. ENSO causes the warming of normally cool waters in the Pacific coastline of Peru, thereby promoting phytoplankton bloom, zooplankton bloom, and *V. cholerae* proliferation.

Some host factors are important in the transmission of cholera. The chronic gastritis associated with *Helicobacter pylori* predisposes to cholera by inducing hypochlorhydria, which reduces the ability of the stomach to contain the infection. An unexplained predisposition to severe disease in persons with the O blood group has been observed in Asia and more recently in Latin America. Thus, complex associations among climatic, seasonal, bacterial, and human factors affect cholera transmission. Although for the most part developing countries are affected by cholera, several developed countries, such as the United States, Canada, and Australia, have reported indigenous and imported cases.[2] The most recent epidemic occurred in Haiti in 2010. During the first 2 years of the epidemic, 604,634 cases were reported; the cumulative case-fatality rate was 1.2%.[3] Figure 302-1 shows the distribution of cholera in the world from 1990 to 2011.[4]

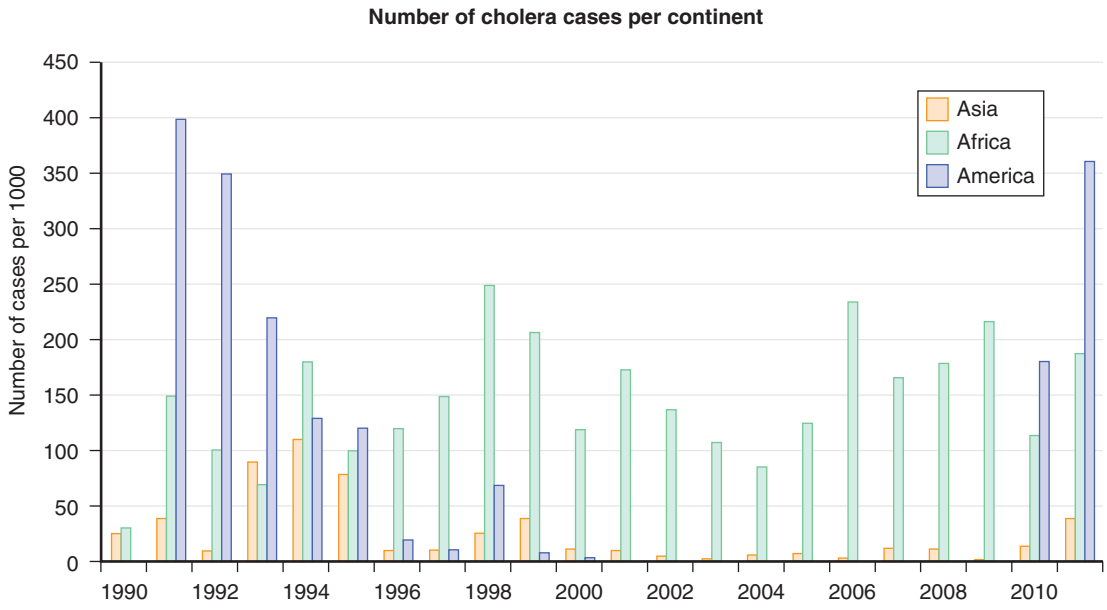

FIGURE 302-1. World distribution of cholera from 1990 to 2011 based on reports to the World Health Organization. (Reprinted with permission from the World Health Organization. Cholera, 2011. *Wkly Epidemiol Rec*. 2012;87:289-304.)

TABLE 302-1 ELECTROLYTE COMPOSITION OF CHOLERA STOOLS AND SOLUTIONS RECOMMENDED FOR TREATMENT

	Na^+	Cl^-	K^+	HCO_3^-	GLUCOSE	OSMOLARITY
Stools of adults with severe cholera	130	100	20	44		
Intravenous lactated Ringer solution	130	109	4	28*	0	271
Intravenous normal saline	154	154	0	0	0	308
Standard oral rehydration solution promoted by the WHO	90	80	20	10†	111	311
Reduced-osmolarity oral rehydration solution promoted by the WHO	75	65	20	10†	75	245
Rice-based oral rehydration solution	90	80	20	10†		270

*Lactated Ringer solution contains citrate instead of bicarbonate.
†Bicarbonate is replaced by trisodium citrate.
Glucose concentration is in mg/dL, electrolyte concentrations are in mEq/L, and osmolarity is in mOsm/L. WHO = Word Health Organization.

PATHOBIOLOGY

V. cholerae O1 and O139 cause clinical disease by secreting an enterotoxin that promotes the secretion of fluids and electrolytes by the small intestine. The infectious dose of bacteria varies with the vehicle. When water is the vehicle, more bacteria are needed to cause disease (10^3 to 10^6), but when the vehicle is food, lower amounts are needed (10^2 to 10^4). The incubation period varies from 12 to 72 hours; the median is 1.4 days.[5] Cholera toxin (CTX) has two subunits, a pentamer B subunit and a monomer A subunit. The B subunit allows binding of the toxin to a specific receptor, a ganglioside (GM_1) located on the surface of cells lining the mucosa along the intestine of humans and certain suckling mammals. The active, or A, subunit has two components, A1 and A2, linked by a disulfide bond. Activation of adenylate cyclase by the A1 component results in an increase in cyclic adenosine monophosphate in intestinal epithelial cells, which blocks the absorption of sodium and chloride by microvilli and promotes the secretion of chloride and water by crypt cells. These events lead to the production of watery diarrhea with electrolyte concentrations similar to those of plasma, as shown in Table 302-1. A few other toxins have been isolated from pathogenic *V. cholerae*, but their roles in genesis of the disease are less clear.

The genetic material of El Tor *V. cholerae* O1 is included in two circular chromosomes, the larger containing 3 megabases and the smaller containing 1.07 megabases. The main virulence genes are *ctxA* and *ctxB*, which encode CTX subunits A and B, respectively, and *tcpA*, which codes for toxin coregulated pilus. Regulation of expression of these genes is complex. Recent data suggest that vibrios are able to upregulate the expression of CTX in response to intestinal fluid components as well as in the presence of certain environmental factors. Genes unique to El Niño–southern oscillation (ENSO) *V. cholerae* may encode specific features that allow this biotype to better survive in the environment as well as to be more infectious to humans.

CLINICAL MANIFESTATIONS

Cholera is characterized by watery diarrhea and dehydration, which ranges from mild to severe and life-threatening. Patients with mild dehydration cannot be differentiated from those infected by other enteric pathogens causing watery diarrhea. In contrast, patients with severe dehydration secondary to cholera are easy to identify in that their stools have the appearance of rice water and no other clinical illness produces such severe dehydration as quickly (in a matter of a few hours) as cholera. Onset of the disease is abrupt and characterized by watery diarrhea, vomiting, generalized cramps, and oliguria. Physical examination shows a feeble pulse, fever is rarely present, patients look anxious and restless, the eyes are very sunken, mucous membranes are dry, the skin has lost its elasticity and when pinched retracts very slowly, the voice is almost nonaudible, and intestinal sounds are prominent. Although watery diarrhea is the hallmark of cholera, some patients do not have diarrhea but instead have abdominal distention and ileus, a relatively rare type of cholera called cholera sicca.

Laboratory findings in patients with severe dehydration consist of an increase in hematocrit, urine specific gravity, and total serum protein; azotemia; metabolic acidosis with a high anion gap; normal or low serum potassium levels; and normal or slightly low sodium and chloride levels. The calcium and magnesium content in plasma is high as a result of hemoconcentration. Leukocytosis is observed in patients with severe cholera. Hyperglycemia, caused by high concentrations of epinephrine, glucagon, and cortisol stimulated by hypovolemia, is more commonly seen than hypoglycemia. Acute renal failure is the most severe complication of cholera. Incidence rates of 10.6 cases per 1000 were reported in Peru during the first months of the

1991 epidemic. Patients with acute renal failure almost always have a history of improper rehydration. Cholera in pregnant women carries a poor prognosis. Pregnant women have more severe clinical illness, especially when the disease is acquired at the end of the pregnancy. Fetal loss occurs in as many as 50% of these pregnancies. Cholera in the elderly also carries a poor prognosis because of an increase in complications, particularly acute renal failure, severe metabolic acidosis, and pulmonary edema.

DIAGNOSIS

Chaotic movement under dark-field microscopy and a high number of bacteria in a stool sample from patients with diarrhea are characteristic of *V. cholerae* infection. Specific antisera against the serotype block the movement of vibrios and allow confirmation of the diagnosis. Under epidemic conditions, observing bacteria with a darting movement in a stool sample from a patient with suspected infection under dark-field microscopy is adequate to make the diagnosis. Definitive confirmation requires isolation of the bacterium in culture. Specific medium is needed to isolate *V. cholerae* from stool. Higher sensitivity and specificity have been reported with DNA amplification by polymerase chain reaction for detection of vibrios in stool and environmental samples.

TREATMENT

Rx

The objectives of therapy are to restore the fluid losses caused by diarrhea and vomiting, to correct the metabolic acidosis, to restore potassium deficits, and to replace continuous fluid losses.[6] Treatment of patients with milder forms of dehydration is easy, but treatment of patients with severe dehydration requires experience and proper training. The intravenous route should be restricted to patients with some dehydration who do not tolerate the oral route, those who purge more than 10 to 20 mL/kg/hour, and all patients with severe dehydration. Rehydration should be accomplished in two phases: the rehydration phase and the maintenance phase. The purpose of the rehydration phase is to restore normal intravascular volume, and it should last no longer than 4 hours. Intravenous fluids should be infused at a total volume of 100 mL/kg during the rehydration phase in severely dehydrated patients. Lactated Ringer solution is preferred, but other solutions may be used as well (see Table 302-1). All signs of dehydration should have disappeared and the patient should pass urine at a rate of 0.5 mL/kg/hour or greater after the rehydration phase is finished. The maintenance phase follows immediately. During this phase, the objective is to maintain normal hydration status by replacement of ongoing losses. The oral route is preferred during this phase, and the use of oral rehydration solutions is highly recommended. Oral rehydration therapy uses the principle of common transportation of solutes, electrolytes, and water by the intestine not affected by cholera toxin. People with diarrhea can undergo successful rehydration with simple solutions containing glucose and electrolytes. The World Health Organization recommends an oral rehydration solution with reduced osmolarity (245 mOsm/L) to treat all diarrheal diseases. This solution contains lower sodium than the standard oral rehydration solution promoted since 1975 (75 vs. 90 mEq/L). No more symptomatic hyponatremia is observed with the reduced-osmolarity solution than with the standard solution. The addition of L-histidine to rice-based oral rehydration solutions has been shown to reduce the volume and duration of diarrhea and the unscheduled use of intravenous therapy in adult cholera patients.[■] Patients without severe dehydration who tolerate the oral route can be rehydrated with oral rehydration solutions exclusively and discharged promptly from the health center. Recommendations for treatment of cholera patients are shown in Table 302-2. Treatment of cholera caused by *V. cholerae* O139 is the same as described earlier.

Antimicrobial agents are not life-saving and always need to be accompanied by fluid therapy.[7] Effective antibiotics in patients with severe dehydration decrease the duration of diarrhea and the volume of stool by nearly half.[■] Oral tetracycline and doxycycline are the agents of choice in areas of the globe where sensitive strains predominate. A single dose of doxycycline (300 mg) is the preferred regimen. Pregnant women can be treated with erythromycin or furazolidone. Because of the emergence of resistance to tetracyclines and other antimicrobials in many endemic areas, the quinolones and, more recently, azithromycin have been tested in clinical trials. A single-dose regimen of azithromycin (20 mg/kg) showed clinical and bacteriologic results that were comparable to a 3-day regimen with erythromycin in children and comparable to a single-dose regimen of ciprofloxacin (1 g) in adults.[■] The addition of oral zinc (30 mg/day) to an erythromycin regimen in children reduced the duration of diarrhea by 12%, with an additional 11% reduction in the volume of diarrhea in comparison to placebo.[■] Antimotility agents such as loperamide or diphenoxylate, adsorbents, analgesics, and antiemetics are not recommended. Antisecretory drugs, including racecadotril, an enkephalinase inhibitor, are not useful in patients with severe cholera. Chemoprophylaxis of household contacts of cholera cases is not routinely recommended.

TABLE 302-2 RECOMMENDATIONS FOR TREATMENT OF CHOLERA PATIENTS

Determine the degree of dehydration on arrival.
Rehydrate the patient in two phases:
- Rehydration phase—lasts 2 to 4 hours
- Maintenance phase—lasts until the end of the diarrheal episode

Register and periodically review input and output in predesigned charts.
Use the intravenous route in the following situations:
- In all severely dehydrated patients, in whom the total volume to be infused during the rehydration phase is 100 mL/kg. For patients older than 1 year, 30 mL/kg should be infused in the first 30 minutes, the remaining 70 mL/kg should be infused in 2.5 hours. For children younger than 1 year, the first 30 mL/kg should be infused in 1 hour.
- Patients with some dehydration who are unable to tolerate the oral route
- Patients with high stool output (>10 mL/kg/hour) during the maintenance phase

Use oral rehydration solutions, glucose or rice based, during the maintenance phase to match ongoing losses. Volumes of 800 to 1000 mL/hour are usually required. Low-osmolarity solutions are not recommended.
Start an oral antimicrobial agent in patients with severe cholera when full rehydration has been achieved and oral tolerance is confirmed. Single-dose doxycycline, 300 mg, is the preferred regimen. Erythromycin or a quinolone is a suitable alternative.
Discharge patients only if oral tolerance is adequate (≥1000 mL/hour), urine output is satisfactory (≥40 mL/hour), and stool volume is low (≤400 mL/hour).

Modified with permission from Seas C, DuPont HL, Valdez LM, et al. Practical guidelines for the treatment of cholera. *Drugs.* 1996;51:966-973.

PREVENTION

Access to potable water and ensuring proper management of excreta to avoid contamination of other water sources are important measures to reduce transmission of cholera. Alternative ways to prevent cholera transmission are necessary in developing countries. Water can be made safer to drink by boiling, adding chlorine, or filtering it with cloth made of cotton. An inability to implement these measures to curtail cholera transmission has prompted a search for vaccines. An ideal vaccine against cholera should elicit a fast and long-lasting immune response with minimal side effects. Parenteral vaccines are no longer recommended. Two oral vaccines, the two-dose regimen of the inactivated vaccine WC-BS (whole cell plus B subunit) and a single dose of the live attenuated CVD 103-HgR vaccine, have been tested extensively in epidemic settings and in field trials in endemic areas. Although the WC-BS vaccine showed good short-term protective efficacy (85% at 6 months), the results at 3 and 5 years were less impressive (60%), particularly in children. A large effectiveness study in Mozambique confirmed the high short-term protection against cholera (80%) by this vaccine, especially against severe dehydration (90%). In Guinea, oral vaccine was 87% protective.[8] In addition, reanalysis of data on this vaccine in field trials and in Zanzibar has shown that it may also confer herd protection in the unvaccinated population.[9] Cost-effectiveness of interventions like this require prices of the oral vaccine below 1.3 USD.[10] A large field trial of the live attenuated vaccine showed no protective efficacy. Indications for use of the currently available cholera vaccines include travel to endemic areas and situations in which high attack rates of cholera are expected, such as after environmental disasters, in refugee camps, and in urban slums in highly endemic areas. Preemptive and reactive vaccination approaches should be thoroughly evaluated in epidemic settings.[11] New oral vaccines, including both killed and live *Vibrio*, are being evaluated in endemic areas, with promising preliminary reports.

PROGNOSIS

Patients with severe cholera left untreated or improperly treated carry a poor prognosis, with mortality rates higher than 50%. However, case-fatality rates during epidemics may be reduced to values below 1% even in disaster situations, provided adequate access to health care centers and proper management of patients can be ensured. In contrast, figures higher than 10% have been reported in epidemic settings when patients had no access to health care or received improper treatment.

OTHER *VIBRIO* INFECTIONS

Noncholera vibrios have worldwide distribution and coexist in environments in which *V. cholerae* lives. They cause a spectrum of clinical syndromes, including acute diarrhea, soft tissue infections, and sepsis, especially in immunocompromised hosts. In the United States, 7700 cases of *Vibrio* infections

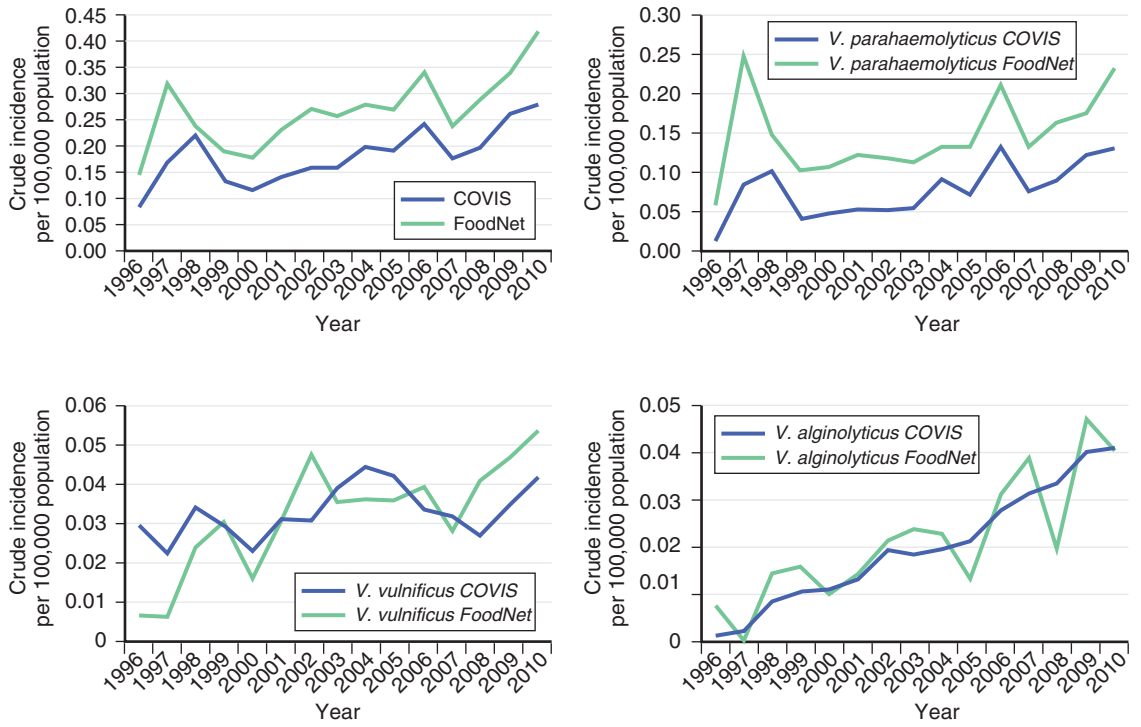

FIGURE 302-2, Crude incidence rates per 100,000 population of noncholera *Vibrio* infections based on two U.S. surveillance reports from 1996 to 2010. COVIS = Cholera and Other *Vibrio* Illness Surveillance; FoodNet = Foodborne Diseases Active Surveillance Network. (Redrawn from Newton A, Kendall M, Vugia DJ, et al. Increasing rates of vibrosis in the United States, 1996-2010: review of surveillance data from 2 systems. *Clin Infect Dis*. 2012;54[Suppl 5]:S391-S395.)

were reported by two surveillance networks covering the period from 1996 to 2010.[12] The incidence of *Vibrio* infection increased during the study period; *Vibrio parahaemolyticus* predominated (44.9% of isolates) but was associated with a low case-fatality rate of 0.7%. In contrast, *Vibrio vulnificus* accounted for 18.8% of the isolates but was associated with a case-fatality rate of 31.9%. *Vibrio* illnesses in the United States are seasonal and peak during the summer (Fig. 302-2). The incubation period for noncholeragenic *Vibrio* infection is usually 12 to 72 hours but can be as long as 1 week.

Nontoxigenic *V. cholerae* causes gastroenteritis, but unlike toxigenic *V. cholerae* O1 or O139, nontoxigenic *V. cholerae* does not cause epidemics. Illness ranges in severity from mild diarrhea to severe watery diarrhea. Fever and bloody diarrhea are unusual, but immunocompromised persons and those with liver disease can experience more severe illness, including fever, chills, and septic shock.

V. parahaemolyticus lives in marine environments and is a source of intestinal illness associated with the ingestion of contaminated shellfish. Certain serovars have shown pandemic spread (O3:K6 and O4:K68). It is not well known how this *Vibrio* causes infection in humans, but the clinical illness may mimic cholera, although most cases are milder and self-limited forms of acute watery diarrhea. Acute dysentery is reported rarely.

In the United States, *V. parahaemolyticus* and *V. vulnificus* as well as other noncholeragenic vibrios caused skin and soft tissue infections in victims and responders affected by the Gulf Coast hurricane disasters in fall 2005. *V. parahaemolyticus* wound infections are generally less severe than those caused by *V. vulnificus*.[13] However, in persons with liver disease or those who are immunocompromised, fatal infections can occur.

V. vulnificus is associated with wound infections in persons in contact with contaminated water as well as with primary sepsis in immunocompromised hosts. Wound infections follow trauma and are characterized by rapid progression of skin and soft tissue involvement, with necrosis and bulla formation occurring in more severe cases. Fever, chills, and sepsis syndrome may ensue rapidly. Primary sepsis with bacteremia and metastatic lesions on the skin, characterized by disseminated erythematous lesions that may evolve to necrotic lesions, is a distinctive clinical manifestation in patients with chronic liver illnesses, alcoholics, and patients with blood disorders such as thalassemia. A history of seafood ingestion, usually oysters, is typical. Patients are acutely ill with high fever and need to be managed aggressively with fluid resuscitation, surgical débridement, general supportive care, and antibiotic coverage. An intravenous combination of cefotaxime, 2 g four times a day, plus doxycycline, 100 mg two times a day, is recommended. This combination is synergistic in vitro. Alternative antimicrobials are ceftazidime and ciprofloxacin.

REVIEW QUESTIONS

1. Cholera is an acute diarrheal disease caused by

A. *Vibrio cholerae* O1 and *Vibrio cholerae* O139
B. *Vibrio cholerae* O1 only
C. *Vibrio cholerae* O139 only
D. Non-O1 *Vibrio cholerae*
E. *Vibrio vulnificus*

Answer: A Cholera is the disease caused by both O1 *V. cholerae* and, since 1992, O139 *V. cholerae*. These two pathogens have the potential to cause local epidemics with pandemic potential.

2. The typical solute concentration of cholera stools, compared with plasma, is

A. Hypertonic
B. Hypotonic
C. Isotonic
D. Hyperosmolar
E. Hypo-osmolar

Answer: C Typical diarrhea of cholera is isotonic compared with plasma, having almost the same concentration of sodium.

3. The benefit of using effective antimicrobials in patients with severe cholera is

A. To reduce the excretion of vibrio
B. To reduce the duration of diarrhea and volume of stool by half
C. To reduce the duration of hospitalization by half
D. To reduce the need for intravenous treatment
E. To reduce the need for oral rehydration solutions

Answer: B Effective antimicrobials reduce the duration of diarrhea and the volume of stools by almost half compared with controls.

4. Intravenous fluids are indicated in patients with cholera under the following conditions:

A. In every patient with cholera irrespective of the degree of dehydration
B. In patients with some degree of dehydration
C. In patients with severe dehydration, in those who cannot tolerate the oral route, and in those with high stool output
D. In patients who do not respond to antimicrobials
E. In those thought to be infected by resistant pathogens

Answer: C Intravenous fluids should be restricted to those with severe dehydration, to those with lesser degrees of dehydration who cannot tolerate the oral route, and to those with high stool output.

5. A patient with chronic liver disease presents to the emergency department with the acute onset of fever after ingestion of oysters. The physical examination reveals a patient in shock with multiple erythematous lesions on the extremities. The most likely pathogen involved is

A. *Vibrio cholerae* O1
B. *Vibrio cholerae* O139
C. *Vibrio vulnificus*
D. *Salmonella enterica*
E. *Shigella dysenteriae* type 1

Answer: C *Vibrio vulnificus* is the most likely pathogen. It causes severe sepsis with soft tissue involvement in patients with chronic liver disease.

303

CAMPYLOBACTER INFECTIONS

BAN MISHU ALLOS

DEFINITION

Campylobacter jejuni is one of the most commonly recognized bacterial causes of diarrhea in developed and developing nations. More than 95% of campylobacters isolated in developed countries are *C. jejuni* or *Campylobacter coli.* However, other *Campylobacter* species are also associated with human disease.

The Pathogen

Campylobacters are motile, curved, gram-negative rods that are found in domestic and wild animals—especially poultry—all over the world. *C. jejuni*

is microaerophilic, requires 3 to 15% oxygen for growth, and is oxidase and catalase positive. It grows best at 42° C; however, other *Campylobacter* species that may also be pathogenic grow best at 37° C. The whole genome sequences for multiple *Campylobacter* species have been determined.

EPIDEMIOLOGY

C. jejuni infections are endemic in young children in developing nations,[1] where they may be isolated in up to 20% of children younger than 5 years with diarrhea. In developed nations, *Campylobacter* infections are among the most common bacterial causes of diarrhea in children and adults. The incidence of *C. jejuni* infection in the United States fell by more than 30% from 21.7 per 100,000 population in 1998 to 12.7 in 2008, but by 2012 the incidence had increased again to its highest level since 2000. The actual burden of disease caused by *Campylobacter* is probably much higher because even active surveillance systems substantially underreport the true incidence of infection. Epidemiologic studies have estimated that more than 2 million people in the United States are infected with *C. jejuni* each year. For reasons that are not clear, the incidence is highest in western states, such as California and Hawaii. Similarly high rates of infection are observed in Europe. In the United States, Europe, and Australia, *C. jejuni* infections show a substantial peak in warmer months. Such seasonality is not observed in tropical developing countries, perhaps because of the absence of extreme temperature variations.

The incidence of *Campylobacter* infections is highest in early childhood, an epidemiologic feature common to many food-borne bacterial pathogens. However, in the United States and other industrialized countries, the incidence of *Campylobacter* infections peaks again in early adulthood. The incidence of infection is also higher in men, a gender difference most pronounced in young adults.

Most human *C. jejuni* infections occur sporadically, with only a tiny fraction occurring as part of outbreaks. The dominant source of sporadic infections in both developed and developing countries is consumption or handling of poultry. Other sources of transmission in developed nations include foreign travel, contact with pets and other animals, contaminated drinking water, and consumption of unpasteurized milk.[2] Cross-contamination within a kitchen (e.g., use of the same utensils or cutting boards to prepare uncooked chicken and to chop fruit) has led to a variety of foods being implicated as sources of human *C. jejuni* infection. In contrast to sporadic infections, the most common source of *C. jejuni* outbreaks is unpasteurized milk; large waterborne outbreaks occasionally occur. Transmission of *C. jejuni* infection from ill food handlers is uncommon. Even in households in which an individual has culture-proven *C. jejuni* gastroenteritis, secondary transmission to other family members is unusual.

PATHOBIOLOGY

Persons become infected with *C. jejuni* as a result of orally ingesting the organism, usually in food or water. Factors that affect whether *Campylobacter* infection leads to illness include the dose of bacteria ingested, the virulence of the organism, and the specific immunity of the host to the ingested organism.[3] The minimum number of bacteria needed to cause illness varies between people, but it may be quite low; because *C. jejuni* is susceptible to gastric acidity, ingestion of very few organisms may cause illness if gastric pH is elevated as a result of illness or medication. The median incubation period is 2 to 4 days, although it may range from 1 to 7 days.

In early infection, *C. jejuni* multiplies in the bile-rich upper intestines; subsequently, tissue injury is seen in the jejunum, ileum, and colon. Gross inspection of the bowel shows a diffuse, bloody, edematous enteritis. Microscopic examination shows an inflammatory infiltrate consisting of neutrophils, mononuclear cells, and eosinophils in the lamina propria. The mucosal epithelium is ulcerated, and crypt abscesses may be seen. The pathologic appearance is nonspecific and may mimic ulcerative colitis or Crohn's disease.

Invasion of the epithelium by *C. jejuni* appears to be central to its pathogenesis, and many factors influence how *C. jejuni* adheres to and invades intestinal tissues. A superficial conserved antigen, PEB1, appears to be a major adhesin and is a target of the immune response to *C. jejuni* infection. Other factors contributing to the invasiveness and pathogenicity of *C. jejuni* that may be encoded by a virulence plasmid include type IV secretion systems and mechanisms that disrupt microtubules in host cells. The presence of the plasmid pVir in clinical isolates is significantly associated with bloody stools. *C. jejuni* also may invade in an actin- and microtubule-independent manner. Glycolipids and glycoproteins on the surface of *C. jejuni* are important in the organism's survival in the intestinal lumen and in pathogenesis because they have an impact on cell-to-cell interactions as well as on the host's immune response to infection. The bacteria's flagella facilitate its ability to colonize the gastrointestinal tract by promoting the organism's motility and chemotaxis. *C. jejuni* may produce extracellular toxins, but their role in pathogenesis has not been confirmed, with the possible exception of the cytoskeletal distending toxin (cdt), which may facilitate intracellular activities that lead to apoptosis.

Regardless of the organism's virulence, host factors are pivotal in affecting the clinical outcome of infection. In healthy volunteers fed a fixed dose of a single *C. jejuni* strain, a spectrum of illnesses develops. Patients infected with *C. jejuni* excrete the organism in feces for 2 to 3 weeks. In developing nations, where the level of immunity to *C. jejuni* is higher because of recurrent exposure, the period of convalescent excretion of *C. jejuni* is shorter.

After recovery from *Campylobacter* infection, at least short-term immunity develops. The decreasing illness-to-infection ratio with age seen in developing nations also suggests that individuals are acquiring immunity. Specific immunoglobulin A, G, and M antibodies in serum and immunoglobulin A antibodies in intestinal secretions develop in patients infected with *C. jejuni.* Patients with congenital or acquired hypogammaglobulinemia are at risk for severe or recurrent *C. jejuni* infections. Because the incidence of *C. jejuni* infection is markedly higher in persons infected with human immunodeficiency virus (HIV), cell-mediated immunity might also play a role in preventing and terminating infection.

CLINICAL MANIFESTATIONS

The clinical consequences of *Campylobacter* infection range from complete absence of symptoms to fulminant sepsis and death. In most cases, however, illnesses are brief and do not require hospitalization. In developed nations, detection of *C. jejuni* in the stool of asymptomatic persons is rare. However, in developing nations, where infections are endemic and recurrent infections occur frequently, asymptomatic infections are more common. In both developing and developed nations, persons infected with *C. jejuni* typically contract a diarrheal illness that resolves within a week. The case-fatality rate associated with this infection is low, about 0.05 death per 1000 infections, and is not surprisingly highest among the elderly and persons with comorbid conditions.

The gastroenteritis that is caused by infection with *C. jejuni* is clinically indistinguishable from that caused by other bacterial enteric pathogens, such as *Salmonella* (Chapter 308), *Shigella* (Chapter 309), or *Escherichia coli* O157:H7 (Chapter 304). The most common symptoms are diarrhea, malaise, fever, and abdominal pain (Table 303-1). Most patients with *C. jejuni* gastroenteritis experience at least 1 day with 10 or more stools; the diarrhea may be loose, watery, or bloody. Nausea is reported by some patients, but vomiting is less common. More than half the patients describe subjective fever. The abdominal cramping may be severe and is sometimes the predominant symptom. Although in most patients the symptoms resolve within 7 days, symptoms may persist in 10 to 20% of patients, and another 5 to 10% may experience a relapse.

Almost regardless of the nature of the symptoms, fecal leukocytes are found in 75% of infected patients; gross or occult blood is seen in 50%. Peripheral white blood cell counts may be elevated, but liver function test results, the hematocrit, and serum electrolyte values are usually normal.

TABLE 303-1 CLINICAL FEATURES OF *CAMPYLOBACTER* ENTERITIS DERIVED FROM OUTBREAKS IN WHICH MORE THAN 50 PATIENTS WERE INFECTED

SYMPTOM	MEDIAN FREQUENCY (%)	RANGE (%)
Fever	50	6-75
Diarrhea	84	52-100
Headache	41	6-69
Abdominal pain	79	56-99
Myalgia	42	28-59
Vomiting	15	1-42
Blood in feces	15	0.5-32

Modified from Blaser MJ, Engberg J. Clinical aspects of *Campylobacter jejuni* and *Campylobacter coli* infections. In: Nachamkin I, Szymanski CM, Blaser MJ, eds. *Campylobacter.* 3rd ed. Washington, DC: ASM Press; 2008:99-121.

Sigmoidoscopic examination reveals diffuse colonic inflammation, which is nonspecific.

Local complications of *C. jejuni* gastroenteritis are rare. In its most severe form, infection may lead to massive gastrointestinal hemorrhage or toxic megacolon. Infection of the biliary tract may result in obstructive hepatitis, cholecystitis (Chapter 155), or pancreatitis (Chapter 144). Other reported local complications include peritonitis (Chapter 142), splenic rupture, and exacerbations of inflammatory colitis. Bacteremia is detected in 1.5 per 1000 intestinal infections, with higher rates in persons who are immunocompromised or elderly, but transient bacteremia may be more common because blood cultures are infrequently obtained in patients with diarrhea and the bacteria are killed rapidly by normal human serum. Other extraintestinal complications, such as meningitis, endocarditis, osteomyelitis, and purulent arthritis, are rare.

Guillain-Barré syndrome (Chapter 420), which is a postinfectious complication of *C. jejuni* infection, occurs about once in every 2000 infections; between 30 and 50% of all cases may be triggered by a preceding *C. jejuni* infection.[4] Because the onset of neurologic symptoms occurs about 1 to 3 weeks after the onset of gastrointestinal symptoms, cross-reactivity between antibodies formed against the lipopolysaccharide and capsule of *C. jejuni* and proteins in peripheral nerve myelin or other glycolipids in peripheral nerves is probably the cause. Certain *C. jejuni* serotypes (O type 19, O type 41) are overrepresented in patients in whom Guillain-Barré syndrome develops after culture-documented *C. jejuni* infection. Other postinfectious complications of *C. jejuni* infection include reactive arthritis (seen mostly in persons with HLA-B27 histocompatibility antigens), uveitis, hemolytic-uremic syndrome, erythema nodosum, encephalitis, carditis, hemolytic anemia, and chronic gastrointestinal consequences such as irritable bowel syndrome, inflammatory bowel disease, and celiac disease.[5]

DIAGNOSIS

The diagnosis of *C. jejuni* infection should be considered in any patient with an acute febrile diarrheal illness. The diagnosis is established by culturing the organism from stool or tissue. Primary isolation of *Campylobacter* species from blood may take up to 14 days.

The presence of curved gram-negative rods on a Gram stain of stool is specific but only 50 to 75% sensitive for detecting *C. jejuni.* Examination of fecal specimens by dark-field microscopy is useful if it is done within 2 hours of passage; the characteristic darting motility of *Campylobacter* provides a presumptive diagnosis. Serum serologic studies of stool are currently available only as research tools. Use of polymerase chain reaction techniques for direct detection of organisms has been successful in research studies but has not yet been applied to the general clinical setting.

Differential Diagnosis

In patients with acute colitis and bloody diarrhea, especially those whose symptoms last longer than 1 week, *Campylobacter* enteritis may be mistaken for ulcerative colitis or Crohn's disease (Chapter 141). In such cases, it is critical to exclude infectious colitis before starting immunosuppressive therapy. In patients with severe abdominal pain, appendicitis may be suspected and unnecessary appendectomy may result (Chapter 142).

PREVENTION

Because the most common source of transmission of *C. jejuni* infection to humans in developed countries is by consumption and handling of poultry, interrupting this route of infection will probably have the greatest effect on reducing the burden of disease caused by *Campylobacter.* The nearly universal colonization of poultry flocks with *C. jejuni* makes eradication of the organism in chickens unlikely, but improvements in slaughtering plants appear to be reducing the level of contamination of products reaching humans. For the consumer, careful food preparation methods are critical; chicken must be cooked thoroughly. To avoid cross-contamination in the kitchen, cutting boards, knives, and other utensils used to prepare raw chicken should be washed with hot soapy water before being used to prepare foods eaten uncooked, such as fruits and vegetables. Person-to-person transmission of *Campylobacter* is not common; nevertheless, all persons with diarrhea, especially those who handle food, should wash their hands after using the bathroom. Travelers and campers should be cautioned against drinking untreated water. Many outbreaks of *C. jejuni* infection might also be avoided if persons abstain from drinking unpasteurized milk. Antibiotic prophylaxis for travelers is not advised. An effective anti-*Campylobacter* vaccine has not yet been developed.

TREATMENT

Rx

As is true for most patients with infectious or noninfectious diarrhea, the most important principle of treatment of *Campylobacter* gastroenteritis is restoration of proper hydration and electrolyte balance, typically with oral fluids. On occasion, intravenous fluids are needed, especially in elderly patients or young children. Most *C. jejuni* infections are self-limited and resolve without specific antibiotic treatment. Furthermore, treatment with antibiotics shortens the duration of illness by less than 48 hours.■ Prompt antimicrobial therapy is indicated for patients with high fever (>38.5° C), prolonged illness (>1 week), bloody stools, or worsening symptoms and for those who have relapsed. Antimicrobial treatment is also warranted in the elderly, infants, pregnant women, and persons who are immunocompromised, including those infected with HIV.

For many decades, the antibiotic of choice for the treatment of *C. jejuni* gastroenteritis has been erythromycin (500 mg twice daily for 5 days). A single 1-g dose of azithromycin is at least as effective,■ but it and clarithromycin are considerably more expensive. One concern with erythromycin, which is primarily metabolized by CYP3A4, is the risk of sudden cardiac death. The risk is increased five-fold when erythromycin is given with medications that inhibit CYP3A4. In patients taking one or more of these medications, azithromycin may be substituted for erythromycin.

Fluoroquinolones, carbapenems, aminoglycosides, and clindamycin may also be effective, but resistance to quinolones is now common in many parts of the world.[6] In general, rates of resistance to ampicillin, amoxicillin, and cephalosporins are too high for them to be useful in the treatment of *C. jejuni* infections.

Critically ill or septic persons with *Campylobacter* infection may benefit from carbapenems or aminoglycosides, agents to which campylobacters are exquisitely susceptible, with resistance rates consistently less than 1%. In contrast, persons with persistent or relapsing infection, especially those who are immunocompromised, may require prolonged use (sometimes months) of antibiotics. In the absence of continuing sepsis, oral agents may be used.

OTHER *CAMPYLOBACTER* SPECIES

Campylobacter fetus may cause systemic and diarrheal illnesses in compromised hosts and diarrheal illnesses in normal hosts.[7] Most *C. fetus* strains, unlike *C. jejuni*, are not susceptible to the lethal effect of normal human serum because they possess a protein capsule (S layer). In immunocompromised persons, *C. fetus* can cause extraintestinal illnesses such as bacteremia, vascular infections, and meningitis. *C. fetus* infection may also cause perinatal infection and fetal loss. Prolonged treatment with erythromycin plus either imipenem, meropenem, an aminoglycoside, or a third-generation cephalosporin is indicated for serious *C. fetus* infections.

Campylobacter upsaliensis may cause acute or chronic diarrhea in healthy or immunocompromised persons. The organism is frequently isolated from dogs with diarrhea, which could be a source for transmission to humans. Some *C. upsaliensis* strains are resistant to erythromycin, but most are susceptible to fluoroquinolones, doxycycline, third-generation cephalosporins, and amoxicillin-clavulanate.

Campylobacter hyointestinalis was first recognized as a cause of proliferative enteritis in swine; *Campylobacter lari* is most often cultured from gulls and other birds. Both organisms have now been identified as rare causes of watery diarrhea and abdominal cramping in immunocompetent children and adults. Most infected patients do not require antimicrobial therapy; all isolates studied in vitro have been susceptible to erythromycin.

Campylobacter concisus, long believed to be part of the microbiota of healthy persons, is now considered a possible cause of human gastrointestinal illness. An increasing body of evidence also has linked *C. concisus* infection with childhood Crohn's disease.

Helicobacter cinaedi and *Helicobacter fennelliae*, once called *Campylobacter*-like organisms, are causes of proctocolitis or enterocolitis and have also been reported to cause bacteremia in immunocompromised patients. The organisms are frequently resistant to erythromycin; fluoroquinolones are considered the treatment of choice in patients who require antimicrobial therapy. The organisms are also susceptible to third-generation cephalosporins, aminoglycosides, and carbapenems.

Other *Campylobacter* or related species that have been associated with human illness include *Campylobacter mucosalis, Campylobacter doylei, Campylobacter curvus, Campylobacter insulaenigrae, Campylobacter rectus, Campylobacter helveticus, Arcobacter butzleri*, and *Arcobacter cryaerophila*. Illnesses include diarrhea and localized infections, presumably as a result of transient bacteremia from intestinal sources. Recently identified *Campylobacter* species

that may be clinically relevant include *Campylobacter ureolyticus, Campylobacter troglodytis, Campylobacter lari* subspecies *concheus,* and *Campylobacter peloridis*. New pathogenic species of *Campylobacter* are being identified with some regularity.

PROGNOSIS

Even in critically ill patients, 1 week of therapy is generally sufficient to eradicate infection. *Campylobacter* infections in HIV-positive patients may be more severe, persist, recur, and be antibiotic resistant. More severe and extraintestinal illness is also more likely to occur in patients with acquired or congenital hypogammaglobulinemia. Most *C. jejuni* gastrointestinal infections in pregnant women are mild and self-limited, with no severe consequences for the mother or baby. However, if bacteremia develops in the mother, placental infection and fetal death may ensue. Infection during the third trimester can also cause neonatal sepsis and death if the woman is excreting *Campylobacter* in her stool at the time of delivery.

REVIEW QUESTIONS

1. Which one of the following statements best characterizes the epidemiology of *Campylobacter jejuni*?

A. *C. jejuni* gastroenteritis is common in developed countries such as the United States but uncommonly causes illness in developing nations.
B. In developing nations, the incidence of *C. jejuni* infection peaks during winter and spring.
C. In developed nations, the incidence of *C. jejuni* is higher in men than in women.
D. Most *C. jejuni* infections occur as a result of person-to-person transmission.
E. Most *C. jejuni* infections occur as part of outbreaks rather than as sporadic infections.

Answer: C *C. jejuni* infections are common in both developed and developing nations. In developed nations, infections peak in late summer and fall; in developing nations, no seasonality is observed. The incidence of infection in developed nations is higher in young men than in young women. Person-to-person transmission of infection is possible but not common. Most infections are sporadic. (See section on epidemiology.)

2. Which one of the following statements about the pathogenesis of *C. jejuni* is true?

A. Microscopic examination of the bowel will show an inflammatory infiltrate consisting of neutrophils, mononuclear cells, and eosinophils in the lamina propria.
B. The incubation period is short, sometimes less than 4 hours from exposure to symptom onset.
C. Extracellular toxins are important in the pathogenesis of colitis associated with *C. jejuni* infections.
D. Development of long-term immunity after a single infection makes recurrent infections unlikely.
E. *C. jejuni* exerts it pathogenic effects on superficial intestinal mucosa only; invasion to deeper tissues does not occur.

Answer: A The incubation period is usually 2 to 4 days. Extracellular toxins are elaborated but are not important in pathogenesis. Immunity to infection is short-lived; one infection does not protect against future infections. (In developing nations where recurrent infections are common, asymptomatic infections may occur in adults.) *C. jejuni* infection is capable of invasion; that is why bacteremia occasionally occurs. (See section on pathobiology.)

3. The most common clinical manifestation of *C. jejuni* infection in developed nations is

A. Asymptomatic infection
B. Chronic, watery diarrhea
C. Acute, self-limited diarrhea
D. Guillain-Barré syndrome
E. Sepsis

Answer: C Asymptomatic infections are unusual in developed nations, although they are more common in developing nations. Diarrheal illness is usually self-limited; chronic illness is not a typical feature of infection with this pathogen. Guillain-Barré syndrome is a rare complication of infection. Sepsis, although possible, also is rare. (See section on clinical manifestations.)

4. Which of the following preventive measures would be most likely to reduce the incidence of *C. jejuni* infections in developed nations?

A. More consistent use of currently available vaccines
B. Proper treatment of water from rivers or streams before being consumed by hikers and campers
C. Exclusion of persons with diarrhea from work as food handlers
D. Requirement that all eggs served in hospitals or other health care facilities be pasteurized
E. Avoidance of eating undercooked chicken in both homes and restaurants

Answer: E There is not currently a commercially available vaccine. Consumption of untreated water from rivers and streams is a risk factor but is not as important a contributor to infection as is eating undercooked chicken. Although all persons with an acute diarrheal illness should be excluded from work as food handlers, transmission from infected food handlers is not a big contributor to the incidence of *C. jejuni* infections. For example, transmission within households of infected persons is uncommon. Eggs served in hospitals should be pasteurized because of the risk of *Salmonella* infections; however, this is not likely to have a big impact on rates of *C. jejuni* infections. Consumption of undercooked chicken is the single most common risk factor for development of *C. jejuni* infections. (See section on prevention.)

5. Which one of the following antibiotics is the best choice for treatment of gastroenteritis caused by *C. jejuni* infection?

A. Amoxicillin
B. Azithromycin
C. Cephalexin
D. Gentamicin
E. Chloramphenicol

Answer: B Penicillins and cephalosporins are not effective in the treatment of *C. jejuni*. Gentamicin is effective but not an appropriate choice for an uncomplicated gastrointestinal infection. Chloramphenicol also is effective, but the side effects associated with this drug make it a less accepted choice than azithromycin. (See section on treatment.)

304 *ESCHERICHIA COLI* ENTERIC INFECTIONS

THEODORE S. STEINER

DEFINITION

Bacteria belonging to the species *Escherichia coli* are a normal component of the intestinal microbiota (Chapter 279). The majority of *E. coli* are harmless commensals, but specific isolates have acquired pathogenicity genes that enable them to cause diseases, including urinary tract infections, bacteremia, meningitis, and diarrheal illness. One particular challenge to the clinician and microbiology laboratory is how to distinguish these pathogenic *E. coli* from harmless commensal strains to better guide diagnosis and treatment.

Enteric infections caused by *E. coli* may involve the small intestine, colon, or both, depending on the organism's genetic codes for virulence traits. These virulence traits include a variety of toxins, adherence factors, and secreted mediators that work together to perturb host intestinal physiology. Specific combinations of these factors produce six major pathotypes of diarrheogenic *E. coli*: enterotoxigenic (ETEC), enteroinvasive (EIEC), enterohemorrhagic (EHEC), enteropathogenic (EPEC), enteroaggregative (EAEC), and diffusely adherent (DAEC). In addition, these pathotypes can overlap; for example, some strains can express Shiga-like toxins that are characteristic of EHEC without the usual associated adherence factors; these are collectively known as shigatoxigenic *E. coli* (STEC). Taken together, diarrheogenic *E. coli* not only constitute the major category of bacterial enteric pathogens but also provide important scientific models for the many ways in which enteric pathogens can cause disease.

The Pathogen

E. coli is a small catalase-positive, oxidase-negative, gram-negative bacillus in the family Enterobacteriaceae. It characteristically reduces nitrates, ferments glucose and usually lactose, and is either motile (with peritrichate flagella) or nonmotile. It exhibits a positive methyl red reaction and negative reactions with Voges-Proskauer, urease, phenylalanine deaminase, and citrate agents. *E. coli* is the predominant member of the Gammaproteobacteria in the intestinal tract of humans and other mammals, although it is greatly outnumbered by members of other bacterial phyla, which largely consist of strict anaerobes.

As with other gram-negative organisms, the lipopolysaccharide cell wall of *E. coli* contains immunostimulatory lipid A attached to a core oligosaccharide chain. Most *E. coli* have immunogenic carbohydrate chains known as O antigens attached to this core glycolipid to produce 173 O serogroups. There are also at least 56 distinct flagellar (H) antigens based on variable domains of the flagellin gene. Some 80 variably heat-labile capsular (K) antigens have also been described. These O, H, and K antigen combinations have allowed serotyping of thousands of different strains, which historically was the simplest way to distinguish them. Whereas serotypes are sometimes useful in identifying specific pathotypes of *E. coli*, there are numerous adherence, enterotoxic, cytotoxic, and invasiveness factors that may be gained or lost by a particular serotype because they are characteristically encoded on transmissible genetic elements such as plasmids or bacteriophages. It is these factors that convey disease pathotype because they allow colonization and perturbation of host intestinal physiology. Indeed, molecular analysis available during the past decade has shown that commensal and pathogenic *E. coli* cluster into phylogenetic groups that are often independent of O:H serotype. Nevertheless, relatively few O serogroups tend to predominate in the normal human colon (O groups 1, 2, 4, 6, 7, 8, 18, 25, 45, 75, and 81), whereas others (Table 304-1) tend to be associated with specific virulence traits and thus different types of pathogenesis in the intestine.

Well-established mechanisms of *E. coli* pathogenesis include secretion of enterotoxins (ETEC), *Shigella*-like tissue invasion (EIEC), and epithelial necrosis as a result of Shiga-like toxins (SLTs SLT-1/2 or Stx1/Stx2) causing food-borne hemorrhagic colitis (EHEC and STEC) (see Table 304-1). By comparison, the classically recognized EPEC serotypes are neither enterotoxigenic nor invasive but rather attach and efface the epithelium. Still other types of "enteroadherent" *E. coli* exhibit aggregating (EAEC) or diffuse adherence (DAEC) traits, and EAEC in particular is associated with prolonged diarrhea in children in tropical developing areas, in patients infected with human immunodeficiency virus (HIV), and in acute diarrhea in outbreak settings and travelers from developed areas.

EPIDEMIOLOGY

Part of the challenge in studying the epidemiology of enteric *E. coli* infections is that, with the exception of EHEC/STEC strains, they are not identified in routine microbiology procedures in most clinical laboratories. In addition, the diagnostic methodologies have evolved, making it difficult to compare older and more recent studies. Nevertheless, several clear epidemiologic patterns have been revealed. In addition, specific single-nucleotide polymorphisms in the lactoferrin, osteoprotegerin, CD14, and interleukin-8 genes are associated with traveler's diarrhea caused by ETEC, EAEC, or both.[1]

Enteric *E. coli* infections are acquired by the fecal-oral route, although the fecal sources and infectivity differ among the pathotypes. It is believed that a human reservoir is required for most recognized types of EPEC and ETEC, although domestic dogs and cats can also harbor human pathogenic strains.[2] Different ETEC strains can also be important veterinary pathogens, especially in calves and piglets, but the attachment and virulence traits of animal strains are different from those of strains that infect humans. The infectious dose of ETEC in volunteers is 10^6 to 10^{10} organisms, meaning that it usually requires multiplication in contaminated food or water vehicles for its transmission, rather than spreading directly from person to person. Heavy contamination with ETEC has been documented in foods prepared in homes and restaurants and by street vendors as well as in drinking water in many tropical areas. Contaminated water and food probably represent the major sources of their acquisition, primarily in warm or wet seasons.

As with most diarrheal illnesses, the highest age-specific attack rates of ETEC are found in young children, especially at the time of weaning, when ETEC accounts for anywhere from 3% to 39% (average, 13%) of acute diarrheal illnesses, depending on the population studied. Like immunologically inexperienced young children, a traveler visiting tropical areas has a 30 to 50% chance of acquiring traveler's diarrhea (Chapters 283 and 286) during a 2- to 3-week stay unless untreated water or ice and uncooked foods such as salads are strictly avoided. The most commonly recognized pathogen associated with traveler's diarrhea in most tropical areas of the world is ETEC that produces the heat-stable toxin STa, the heat-labile toxin LT, or both. A close second to ETEC as a cause of traveler's diarrhea is EAEC, now reported in 19 to 33% of affected travelers to India or Mexico.

Typical EPEC strains have been recognized primarily in poor urban areas, especially among hospitalized infants in their first year of life, with apparent

TABLE 304-1 DIFFERENT TYPES OF ENTERIC *ESCHERICHIA COLI* INFECTIONS

TYPE	MECHANISM	PREDOMINANT O SEROGROUPS	GENETIC CODE	DETECTION	CLINICAL SYNDROMES
ENTEROTOXIGENIC *E. COLI* (ETEC)					
Heat-labile toxin (LT)	Activates intestinal adenylate cyclase	6, 8, 11, 15, 20, 25, 27, 63, 80, 85, 139	Plasmid	Gene probe, PCR for LT	Watery diarrhea, traveler's diarrhea
Heat-stable toxin (STa: STh or STp)	Activates intestinal guanylate cyclase	12, 78, 115, 148, 149, 153, 155, 166, 167	Plasmid (transposon)	EIA, suckling mice, 6-hour ileal loop assay, gene probes, PCR	Watery diarrhea, traveler's diarrhea
ENTEROINVASIVE *E. COLI* (EIEC)					
	Cell invasion and spread	11, 28ac, 29, 124, 136, 144, 147, 152, 164, 167	Plasmid (140 MIa, pWR110)	Sereny test, gene probe, PCR for *ipaH*	Inflammatory dysentery
SHIGATOXIGENIC *E. COLI* (STEC)					
Enterohemorrhagic (EHEC)	Shiga-like toxins (SLTs/Stxs) and attaching/effacing ability	26, 39, 113, 121, 128, 139, 145, 157, occ 55, 111	SLT phages and adhesin plasmids; type III secretion system	EIA or PCR for SLT, serotype, cell adhesion with pedestal formation; Vero cell cytotoxicity; sorbitol agar; PCR for *eae*	Afebrile, bloody diarrhea; HUS in some cases
Non-EHEC STEC	SLTs only without attaching/effacing	26, 111, 103, 121, 45, 104, 145	SLT phage; may possess other virulence traits (e.g., O104:H4 EAEC)	SLT EIA or PCR; negative for *eae*	Hemorrhagic colitis, HUS, or benign watery diarrhea
ENTEROADHERENT *E. COLI*					
Typical enteropathogenic (EPEC)	Attach, then efface the mucosa	55, 86, 111, 114, 119, 127, 142	Bundle-forming pili on plasmid and chromosomal LEE	Serotype, focal HEp2/HeLa cell adhesion, pedestal formation, gene probe or PCR *eae*	Infantile diarrhea in developing areas
Atypical enteropathogenic (EPEC)	Attaching and effacing but different microcolony formation	26, 55, 86, 111, 119, 125, 128	Possess the LEE but not bundle-forming pili	Gene probe or PCR for LEE; cell adherence (variable)	Infantile and animal diarrhea in developed areas
Enteroaggregative (EAEC)	Colonize in aggregates; toxins (EAST, Pet), biofilm formation	3, 15, 44, 51, 77, 78, 91	Plasmid (AA); chromosome (Pic/ShET and type VI secretion)	HEp2 cell adherence; AA probe; PCR for *aggR* or other virulence genes; biofilm formation	Endemic persistent diarrhea, acute traveler's diarrhea, sporadic acute diarrhea
Diffusely adherent (DAEC)	Colonize (F 1845 afimbriate adhesin)	86, 75, 15	Chromosomal/plasmid	HEp2 cell adherence; DA gene probe/PCR	Persistent diarrhea in children >18 months old

AA = aggregative adherence; DA = diffuse adherence; EIA = enzyme immunoassay; HUS = hemolytic-uremic syndrome; LEE = locus of enterocyte effacement; PCR = polymerase chain reaction.

cross-infection in hospital nurseries. Although sporadic cases still occur, nosocomial outbreaks of EPEC diarrhea during the summer appear to have become less common and less severe in industrialized countries in the past few decades. "Atypical" EPEC strains lacking certain virulence factors have tended to predominate in developed areas but can be found in developing areas as well.[3]

EHEC frequently colonizes commercial livestock but does not infect them. EHEC (O157:H7 and others) infections were first attributed to eating undercooked hamburgers, but subsequent large outbreaks have been associated with contamination of unpasteurized apple juice, spinach, seed sprouts, and other vegetable items. Approximately 600 people were infected in a large outbreak caused by contamination of the domestic water supply in Walkerton, Ontario, in 2000. More recently, a 2011 outbreak of shigatoxigenic EAEC strain O104:H4 (ST/EAEC) associated with fenugreek sprouts sickened almost 4000 people in Europe.[4] In addition, the low infectious dose of EHEC O157:H7 means that person-to-person spread can occur, leading to secondary cases. Secondary cases of ST/EAEC O104:H4 may also have occurred but appear to be very rare. EHEC and STEC infections are especially alarming because of the risk of hemolytic-uremic syndrome (HUS) (Chapter 172). HUS can be fatal despite antimicrobial therapy, which in some instances may actually induce SLT production from bacteriophage carried within the organism and hence is generally not recommended. Patients who recover from HUS may also suffer chronic kidney injury as a result.

The natural reservoir of EAEC is not known, but outbreaks have been traced to contaminated food, and live organisms can be found in drinking water, table salsa, and other consumable items in endemic tropical areas. Volunteer studies demonstrated that a high infectious dose is required for acquisition of EAEC, suggesting that direct person-to-person spread may be difficult. In addition to its role in traveler's diarrhea, EAEC is an important cause of both acute diarrhea and persistent diarrhea and malnutrition, especially in children in tropical areas and in patients with HIV/AIDS. It was also shown in several studies to be a major cause of sporadic diarrhea in the United States and the United Kingdom.

Limited data on EIEC suggest that infectious doses are relatively high, but as with ETEC infections, adequate numbers of organisms have readily been spread in food with high attack rates in outbreak situations. This distinguishes EIEC epidemiologically from *Shigella*, which is easily spread person to person as well as in contaminated food and water.

DAEC remains the least well understood pathotype and has not consistently been found more often in diarrheal cases than in controls. Nevertheless, some studies have shown a clear association with acute diarrhea in developing areas, particularly in children 1 to 4 years of age. Part of the difficulty is the heterogeneity of strains, some of which express different types of adhesins and different groups of virulence traits, leading to inconsistent pathogenicity.

PATHOBIOLOGY

The pathogenesis of enteric *E. coli* infection begins with ingestion of the organism in contaminated food or water or rarely direct person-to person spread, in the case of EHEC. It then faces the normal gastric acid barrier. Both ETEC and EIEC appear to be sensitive to gastric acid; neutralization of gastric acid reduces the infectious dose by 100- to 1000-fold. Hypochlorhydria increased the risk of EPEC diarrhea in a volunteer study. Whereas EHEC expresses acid tolerance factors that may facilitate its survival in the stomach, hypochlorhydria was shown to be a risk factor for HUS in one study.

After ingestion and passage through the stomach, enteric *E. coli* colonize the involved part of the intestinal tract using specialized adhesins and the coordinated expression of virulence traits. This can lead to toxin production, intracellular invasion, or other disruptions of host cell physiology. These virulence traits may be shared among different enteric *E. coli* as well as related enteric pathogens, and it is their combination that leads to the characteristic pathogenic and clinical features of infection. The incubation period between ingestion and symptom development varies from pathogen to pathogen. For example, it averaged 14 hours for EAEC and 2 days for ETEC in volunteer studies; epidemiologic studies found an average incubation period of 3 to 4 days for EHEC O157:H7 but 8 days for ST/EAEC O104:H4.

ETEC colonizes the upper portion of the small bowel using fimbriate or fibrillar surface proteins known as colonization factor antigens. The colonization factor antigens bind the organism to cell surface receptors on enterocytes. Whereas this colonization itself can lead to mild inflammatory changes in the epithelium, the majority of ETEC illness is due to its enterotoxins. LT, with a molecular weight of about 86,000, has a binding and active subunit and, like the closely related choleratoxin, binds to a monosialoganglioside (GM_1) receptor. Also like choleratoxin (Chapter 302), the active subunit is an enzyme that ADP-ribosylates the regulatory subunit of adenylate cyclase, leading to constitutive production of cyclic adenosine monophosphate. The consequently increased chloride secretion and reduced sodium absorption combine to cause net isotonic electrolyte loss that can be as great as 1 liter/hour. Other human ETEC strains produce heat-stable toxin (STa), which is a much smaller molecule than LT (18 to 19 amino acids) and activates intestinal particulate guanylate cyclase. Like cyclic adenosine monophosphate, the cyclic guanosine monophosphate thus formed also causes net secretion. The roles of other enterotoxins, such as LTII, EAST, EIET, and others seen in ETEC, EAEC, and EIEC, respectively, are unclear at present. Both the colonization traits and production of enterotoxin are encoded on transmissible plasmids. Besides the complications of dehydration, the only significant pathologic change with ETEC is depletion of mucus from intestinal goblet cells.

EIEC, like the closely related *Shigella*, can invade and multiply in epithelial cells, cause experimental conjunctivitis in guinea pigs (known as the Sereny test), and produce inflammatory colitis and dysenteric or bloody diarrhea. As seen with shigellosis, a striking inflammatory response occurs, with numerous polymorphonuclear leukocytes in stool. The colon shows patchy, acute inflammation in the mucosa and submucosa with focal denuding of the surface epithelium, usually without deeper invasion or systemic spread. Although epithelial cell invasiveness in both EIEC and *Shigella* appears to be encoded on a large 120- to 140-Md plasmid, several chromosomal determinants, including the O antigen, are crucial for full invasive virulence.

Typical EPEC strains are well-established causes of infantile diarrhea. They express both plasmid-encoded localized adherence to epithelial cells (through specialized bundle-forming pili) and chromosomally mediated attachment and effacement of microvilli. The latter is characterized by the formation of cellular pedestals that hold the bacteria intimately to the cell surface. These changes in the host epithelia are mediated through protein effectors injected directly into host cells by a specialized type III secretion system encoded on the chromosomal locus of enterocyte effacement. These secreted effectors cause cellular changes that lead to villous atrophy, mucosal thinning, inflammation in the lamina propria, and variable crypt cell hyperplasia. These morphologic changes are associated with a reduction in mucosal brush border enzymes and may contribute to the impaired absorptive function and diarrhea.[5] Atypical EPEC strains are generally defined as those expressing the locus of enterocyte effacement but not the bundle-forming pili; they maintain the ability to attach/efface and cause disease.

EHEC, most notably serotype O157:H7 but also serogroups O26, O39, and others, cause type III secretion-dependent intimate adherence and microvillous effacement like EPEC, but they also produce SLTs that are responsible for the characteristic colonic mucosal disruption and hemorrhage as well as the complication of HUS. These toxins bind to the Gb3 surface ganglioside, leading to internalization and enzymatic inactivation of ribosomes, halting protein synthesis. Gb3 is highly expressed on vascular endothelial cells in the colon, kidney, and brain, which may explain the predilection for HUS to affect these organs. Organisms that produce SLTs without intimate adherence and pedestal formation are known as STEC or VTEC (Shiga-toxigenic or verotoxigenic *E. coli*), and often they lack the other virulence traits necessary for colonization and disease production. A notable exception was the ST/EAEC O104:H4 that caused the 2011 European outbreak; this strain was essentially an EAEC that also expressed SLT. The terms EHEC, STEC, and VTEC were often used interchangeably in the older literature, until the important role of the attaching/effacing ability of true EHEC strains like O157:H7 was understood.

EAEC is defined by a characteristic aggregative adherence pattern to cells and the substrata associated with biofilm formation. This adherence requires a large plasmid known as the AA plasmid, which encodes specialized aggregative adherence fimbriae and other virulence genes, including a serine protease autotransporter toxin known as Pet and an antiaggregative protein called dispersin. Chromosomal virulence traits include a mucinase, Pic, and a second enterotoxin, ShET, as well as type VI secretion systems. Limited studies on human infections with EAEC suggest that the organisms do not intimately adhere or invade but reside within a biofilm at the epithelial surface, where secreted factors contribute to a damaging host inflammatory response.

The fundamental pathogenesis of DAEC is still an area of active investigation but appears to depend on direct interactions between specialized adhesins (Afa/Dr) and host membrane proteins such as CD55 (decay-accelerating factor) or carcinoembryonic antigen. Many DAEC strains are closely related to uropathogenic *E. coli* with similar virulence traits. Some also express other virulence factors, including the serine protease autotransporter toxin SAT and a type III secretion system.

Host risk factors for diarrheogenic *E. coli* infection differ among the various bacterial pathotypes but in general include age, recent antibiotic use, and loss of gastric acid.

CLINICAL MANIFESTATIONS

The clinical manifestations of enteric *E. coli* infections differ among the pathotypes. ETEC infections generally produce watery diarrhea, particularly in young children and travelers to tropical or developing areas. Diarrhea may range from mild to severe and cholera-like; it may be life-threatening, especially in small children and elderly individuals, who are particularly prone to dehydration, undernutrition, and electrolyte imbalance (especially hypokalemia and acidosis). Other characteristic symptoms include malaise, abdominal cramping, anorexia, and occasionally nausea, vomiting, or low-grade fever. The illness is generally self-limited to 1 to 5 days and rarely extends beyond 10 to 14 days. Infections with ETEC that produce both ST and LT or ST alone may be more severe than those caused by ETEC that produce only LT. The persistence of impaired mucosal absorptive capacity for 1 to 3 weeks may further compound the cycle of malnutrition that complicates diarrheal illnesses in children in developing, tropical areas.

Infection with EIEC is characterized by inflammatory colitis, often with abdominal pain, high fever, tenesmus, and bloody or dysenteric diarrhea, essentially like that seen with *Shigella*. The incubation period is usually 1 to 3 days, with the duration generally self-limited to 7 to 10 days.

Outbreaks of EPEC infection in newborn nurseries have ranged from mild transient diarrhea to severe and rapidly fatal diarrheal illnesses, especially in premature or otherwise compromised infants. The more severe illnesses appear to have been more common in industrialized countries before 1950. However, more recent outbreaks and sporadic cases are well documented.

Hemorrhagic colitis associated with EHEC classically begins with watery diarrhea that quickly turns grossly bloody, with a conspicuous absence of fever or inflammatory exudate in stool but with significant abdominal pain. Although this diarrheal illness is self-limited, potentially fatal HUS or thrombotic thrombocytopenic purpura subsequently develops in a significant number of children and older adults (Chapter 172). Outbreaks of hemorrhagic colitis secondary to EHEC in nursing homes or other institutions may be common and severe. The incubation period in two outbreaks has been 3 to 4 days (range, 1 to 7 days), and the illness is characteristically self-limited to 5 to 12 days (mean, 7.8 days). The clinical manifestations in the ST/EAEC O104:H4 outbreak were similar, although rates of HUS were significantly higher (more than 20%) and women were disproportionately affected.[6]

EAEC has been associated with persistent diarrhea and malnutrition in children in developing areas, in HIV/AIDS patients, and in travelers who experience diarrhea (especially those genetically predisposed to greater inflammatory responses). No characteristic clinical features of EAEC have been consistently identified, although some outbreaks were associated with bloody diarrhea and several studies suggest that elevated inflammatory markers in stool are fairly common. DAEC has also been associated with diarrhea with no particular identifying features in children older than 18 months.

DIAGNOSIS

With the exception of EHEC, definitive etiologic diagnosis of *E. coli* diarrhea requires documentation of a specific virulence trait or serotype, which requires specialized immunologic tests, tissue culture, animal bioassay, and molecular testing[7] that are usually available only in research and reference laboratories. Other than for EHEC, such tests are rarely cost-effective or clinically indicated, except in outbreak or research situations. Fortunately, a probable diagnosis can often be suspected by the clinical and epidemiologic setting.

EHEC O157:H7 can be identified with reasonable accuracy by culture on sorbitol-MacConkey agar to identify nonfermenting colonies. However, it has long been recommended that any stool sample with visible blood should also be tested specifically for SLTs by enzyme-linked immunosorbent assay,

polymerase chain reaction, or other molecular methods, which can identify non-O157 serotypes and rare sorbitol-fermenting O157 strains.[8] Many experts recommend that all stools submitted for culture be tested in this way. In hemorrhagic colitis due to EHEC, sigmoidoscopy, which is rarely indicated, generally reveals only moderately hyperemic mucosa, and barium enema or CT scan may show a thumbprint pattern of segmental or diffuse colonic wall thickening. Some patients have superficial ulceration with mild neutrophil infiltration in the edematous submucosa. These changes are not pathognomonic.

Differential Diagnosis

Numerous other causes of diarrhea must be considered, depending on the clinical circumstances (Chapters 140 and 283). For example, self-limited, noninflammatory diarrhea in tropical, developing areas is most likely due to ETEC, EAEC, rotaviruses (young children), or noroviruses (older children and adults) (Chapter 380). Noninflammatory diarrhea in older children or adults in temperate areas is more likely to be due to noroviruses (Chapter 380). *Vibrio* infections (Chapter 302) are common in areas endemic for cholera or in any coastal area where inadequately cooked seafood may be eaten. If noninflammatory diarrhea persists beyond a week, especially with weight loss, other possibilities include *Giardia lamblia* (Chapter 351), *Cryptosporidium* (Chapter 350), *Cyclospora* (Chapter 353), and microsporidial infection (Chapter 353). In outbreaks of food poisoning, *Staphylococcus aureus* (Chapter 288), *Clostridium perfringens* (Chapter 296), and *Bacillus cereus* should be considered.

Inflammatory colitis with high fever and tenesmus as well as leukocytes, mucus, and blood in the stool may well be due to EIEC but should prompt a stool culture for more common invasive pathogens, such as *Campylobacter jejuni* (Chapter 303), *Shigella* (Chapter 309), *Salmonella* (Chapter 308), *Yersinia enterocolitica* (Chapter 312), or noncholera *Vibrio* (Chapter 302). Any patient with diarrhea and a history of recent antibiotic use, gastrointestinal surgery, or parturition should be screened for toxigenic *Clostridium difficile* (Chapter 296). EHEC should be strongly considered in any case of bloody diarrhea, particularly in the absence of fever; it is recommended that laboratories now routinely screen for this pathogen in all stool cultures, and they should automatically screen any grossly bloody samples. Ischemic colitis and cytomegalovirus colitis can mimic EHEC but should occur only in people at risk (vascular disease and immune compromise or inflammatory bowel disease, respectively)

TREATMENT

Rx

As with all diarrheal illnesses, the primary treatment for most *E. coli* diarrhea is replacement and maintenance of water and electrolytes, usually with a simple oral rehydration solution that uses the intact, sodium-coupled glucose or amino acid absorption (or both) to replace the fluid losses.[9] Oral rehydration solution should be given ad libitum with free water, and in breast-fed infants, continued breast-feeding and early refeeding can compensate for the nutritional losses without an adverse effect on diarrhea output. Zinc supplementation is also recommended for diarrhea in children older than 6 months in developing areas where zinc deficiency is common as it significantly reduces diarrhea volume. The enkephalinase inhibitor racecadotril, which is available in Europe but not currently in North America, also reduces diarrheal volume in children with acute gastroenteritis and is as effective as loperamide in adults but less likely to cause constipation. Certain probiotic preparations have been shown in small studies to improve symptoms when they are added to oral rehydration solution in children with infectious diarrhea but are not yet universally recommended. Antimotility agents reduce the frequency of diarrheal stools but should not be used when fever or bloody diarrhea is present as they can increase the risk of mortality due to toxic megacolon or HUS. Bismuth subsalicylate may reduce symptoms in traveler's diarrhea but should be used with caution to avoid toxic doses of salicylate.[10]

Because most *E. coli* diarrhea is self-limited, the role of antimicrobial agents is debated and remains of secondary importance to rehydration. One situation in which treatment is generally favored is traveler's diarrhea (Chapter 286) because strong clinical studies have shown a benefit of antibiotics in reducing the duration of symptoms. Unfortunately, rising antimicrobial resistance has narrowed the options for empirical therapy; currently, azithromycin, a fluoroquinolone, or rifaximin is recommended, with trimethoprim-sulfamethoxazole a somewhat less reliable alternative.[11] Antimicrobials are not recommended in EHEC infection because of the possibility of increasing the risk of HUS and a lack of evidence of efficacy.

PREVENTION

Prevention of most *E. coli* enteric infections is ultimately related to basic economic development, adequate sanitary facilities, and sufficient availability of safe water. In the interim, especially in areas where adequate water supplies and sanitary facilities are not available, measures such as exclusive breast-feeding for at least 6 to 12 months and hand hygiene reduce the likelihood of acquiring *E. coli* enteric infections. Simple, portable water filters to reduce bacterial contamination are also in development.

Travelers to developing or tropical areas should avoid drinking untreated or unboiled water or ice and eating uncooked fruits or vegetables that may have been washed with highly contaminated water. Although a number of antimicrobial agents are effective during short periods when taken prophylactically, their effectiveness is ultimately limited by rapidly emerging resistance to antimicrobial drugs as well as by the potential side effects of their indiscriminate, widespread use. For example, tetracycline resistance among ETEC is now common, and resistance to trimethoprim-sulfamethoxazole and fluoroquinolones is quickly emerging around the world. This, combined with the rapid effect of empirical antibiotics at the onset of diarrhea symptoms, has diminished enthusiasm for prophylactic antibiotics. Bismuth subsalicylate is modestly effective at preventing traveler's diarrhea, although with side effects. Another option is the killed *Vibrio cholerae*/cholera toxin B subunit vaccine (Dukoral), which provides transient, partial protection against ETEC in travelers and hence may somewhat reduce the incidence of traveler's diarrhea, although strong evidence is lacking.

Sporadic EHEC infections may be reduced by adequately cooking beef, especially hamburger, and by careful handwashing and other hygienic measures in daycare centers and nursing homes. Unfortunately, large outbreaks due to contaminated produce continue to occur and are frequently associated with items meant to be eaten raw (such as sprouts). A vaccine composed from type III secreted effectors of EHEC to reduce colonization of livestock (Econiche) is on the market but has not yet entered widespread use.

PROGNOSIS

The greatest concern with enteric *E. coli* infections in developed areas is EHEC/STEC-associated HUS, which develops in 3 to 7% of sporadic cases up to as high as 20% in outbreaks. Whereas most patients with HUS recover, they frequently require intensive medical care (including temporary hemodialysis), and as many as 30% of survivors have renal sequelae such as proteinuria, hypertension, reduced glomerular filtration rate, or, more rarely, dialysis dependence.[12]

On a global scale, the greatest impact of diarrheogenic *E. coli* is in children in poor, developing areas, who are prone to death from dehydration from these otherwise self-limited infections. Moreover, children who survive repeated episodes of infectious diarrhea (due to *E. coli* and other pathogens) may experience permanent deficits in growth and even cognitive development, the full impact of which remains unknown.[13]

REVIEW QUESTIONS

1. A previously healthy 22-year-old student returned home to Connecticut 2 days ago from a 2-week trip to southern India. She drank only bottled water but did eat food from street vendors. On her last day, she developed nausea followed by loose stools, which have persisted. On examination, she is afebrile with normal orthostatic vital signs and appears tired but otherwise well. Her abdomen is soft and nontender with increased bowel sounds. She has had four watery stools so far today. Which of the following is appropriate for her?

A. Oral rehydration solution and azithromycin 500 mg PO daily for 3 days for presumed ETEC or EAEC traveler's diarrhea
B. Stool ova and parasite examination and empirical metronidazole 500 mg three times a day for 7 days
C. Stool culture; alert clinical laboratory to look for ETEC and EAEC
D. Intravenous saline
E. Blood cultures and stool cultures for typhoid fever

Answer: A Traveler's diarrhea is the most common treatable illness encountered by North American visitors to developing areas. The majority of cases are caused by diarrheogenic *E. coli*, particularly ETEC and EAEC. Empirical treatment with azithromycin is appropriate, and oral rehydration should be administered. This acute presentation is unlikely to be due to a protozoan, and examination by ova and parasite and empirical antiprotozoal therapy are inappropriate. A stool culture would be appropriate if she had a fever or bloody diarrhea to look for *Campylobacter*, *Shigella*, or *Salmonella*, but clinical laboratories cannot identify ETEC or EAEC. Intravenous rehydration would be appropriate only in the setting of significant volume depletion and inability to consume oral rehydration fluid. Whereas India is endemic for typhoid fever, this illness rarely is manifested with acute diarrhea in the absence of fever.

2. How is infection with diarrheogenic *E. coli* most commonly acquired?

A. Ingestion of food or water that was contaminated with virulent *E. coli* and maintained at a temperature favorable for replication of organisms to an infectious dose
B. Exposure to fecal material from an infected person (e.g., changing diapers)
C. Transfer of genetic material encoding toxins or adherence factors from pathogenic species to commensal *E. coli* within the gut
D. Ingestion of food containing preformed heat-stable or heat-labile toxins from *E. coli*
E. Spread of virulent *E. coli* from other body sites (urinary tract or skin) through hematogenous or direct extension of infectious foci

Answer: A With the exception of EHEC, diarrheogenic *E. coli* have a high infectious dose, meaning that they must be present in large concentrations to establish disease. This is usually achievable only through environmental replication within contaminated food or water, in contrast to EHEC, which can be spread person to person. Whereas virulence genes are readily transferred between bacteria, diarrheogenic strains are distinct from commensal *E. coli* and generally exist in a relatively limited number of related phylogenetic groups. Unlike *Staphylococcus aureus* and *Clostridium perfringens* enterotoxins, the ETEC enterotoxins are produced by live organisms after they reach and adhere to the small bowel epithelium. Most diarrheogenic *E. coli* are distinct from the strains adapted to cause invasive infections, such as bacteremia, meningitis, or pyelonephritis (although many DAEC and some EAEC are phylogenetically related to uropathogenic *E. coli*).

3. An *E. coli* clone is isolated in high concentrations in stool from several patients with nonbloody diarrhea. The organism is able to adhere to HeLa cells in tissue culture but does not produce actin pedestals. Genetic analysis of the organism reveals it to be negative for AA, Afa/Dr, ST, LT, and LEE genes but positive for the SLT-1 (Stx1) and SLT-2 (Stx2) genes. To which pathotype does this organism likely belong?

A. Enterotoxigenic *E. coli* (ETEC)
B. Enteroaggregative *E. coli* (EAEC)
C. Enterohemorrhagic *E. coli* (EHEC)
D. Shigatoxigenic *E. coli* (STEC)
E. Enteropathogenic *E. coli* (EPEC)

Answer: D The ability to adhere to HeLa cells suggests the possibility of pathogenicity, but the lack of actin pedestals and LEE genes rules out EPEC and EHEC. The organism does not express the AA plasmid of EAEC, the Afa/Dr adhesin of DAEC, or the ETEC toxins. However, it does express the Shiga-like toxins, making it a non-EHEC STEC strain. These strains can cause bloody or nonbloody diarrhea or can be nonpathogenic.

4. A 6-year-old previously healthy boy is admitted with 1 day of watery and then bloody diarrhea and abdominal cramps. His temperature is 37.3° C, and he has mild tachycardia. Results of laboratory tests on admission show an elevated white blood cell count of 14.4 with 85% neutrophils. Stool culture results are pending. What is the appropriate empirical antimicrobial while awaiting stool culture results?

A. Ciprofloxacin PO
B. Trimethoprim-sulfamethoxazole PO
C. Ceftriaxone IV
D. Azithromycin PO
E. No antibiotics should be given

Answer: E This is a typical presentation of hemorrhagic colitis due to EHEC or STEC. Antibiotics are not recommended in this disease because there is inadequate proof that they are beneficial, and in fact a number of studies have shown an association with increased risk of hemolytic-uremic syndrome. Fluoroquinolones and trimethoprim-sulfamethoxazole, in particular, have been shown to increase SLT production. Whereas azithromycin was shown to reduce shedding of O104:H4 ST/EAEC, its use was not shown to reduce hemolytic-uremic syndrome risk. Although this child could have *Shigella* or *Campylobacter* infection, the lack of fever makes these less likely, and a 1-day delay in antibiotic administration until culture results return would not be harmful, given that antibiotics have a relatively small effect on those self-limited infections.

5. Which of the following would have the greatest global impact on reducing *E. coli* diarrhea infections?

A. Universal vaccination with the killed cholera/*E. coli* LT-B vaccine
B. Universal vaccination of commercial livestock with the EHEC veterinary vaccine
C. Universal antibiotic prophylaxis of travelers to developing areas
D. Universal ban on antibiotic use in animal feed
E. Universal provision of treated potable water to developing areas

Answer: E The greatest burden of all diarrheal illness, and of *E. coli* in particular, is in children in developing areas who lack regular access to treated water. The ETEC vaccine and antibiotic prophylaxis, although somewhat effective in reducing the risk of traveler's diarrhea, offer only short-term protection. The EHEC veterinary vaccine might reduce human cases of EHEC associated with contamination of food and water, but EHEC, fortunately, remains largely a rare concern and occurs mostly in developed countries. Because most *E. coli* enteric infections do not require antibiotic treatment, the emergence of antibiotic resistance due to overuse of antibiotics in people and commercial livestock is less of a concern for diarrheogenic *E. coli* than for invasive *E. coli* and other important infections.

305 INFECTIONS DUE TO OTHER MEMBERS OF THE ENTEROBACTERIACEAE, INCLUDING MANAGEMENT OF MULTIDRUG-RESISTANT STRAINS

DAVID L. PATERSON

DEFINITION

The Enterobacteriaceae are a family of gram-negative bacilli that are responsible for a broad range of infections in humans and in animals. They may be motile or nonmotile, depending on the species. They are aerobic or facultatively anaerobic in growth and have a predilection for inhabiting the gastrointestinal tract. Only extra-gastrointestinal manifestations of disease are discussed in this chapter. Enteric infections caused by *Escherichia coli* are discussed in Chapter 304.

From a microbiologic perspective, the members of the Enterobacteriaceae ferment sugars. They grow on a variety of solid media and are usually readily identified by clinical microbiology laboratories. A number of subtleties arise in detection of antibiotic resistance mechanisms by laboratories, however, sometimes leading to issues in reporting of antibiotic susceptibilities. A worldwide trend is the development of multidrug resistance in all gram-negative bacilli, including the Enterobacteriaceae. Particular emphasis is placed in this chapter on treatment and prevention of these multidrug-resistant strains.

Medically important members of the Enterobacteriaceae are listed in Table 305-1. Infections due to *Salmonella*, *Shigella*, and *Yersinia* are discussed in Chapters 308, 309, and 312, respectively.

EPIDEMIOLOGY

The Enterobacteriaceae are among the most common pathogens to infect humans worldwide. They are responsible for community-acquired, hospital-acquired, and health care–associated infections. Examples of the last category include infections acquired in nursing homes and those associated with outpatient management of cancers or hematologic malignant disease. As resident components of the flora of the gastrointestinal tract, isolates of Enterobacteriaceae may represent examples of colonization rather than true infection. This may apply to isolates from rectal swabs, urine, or respiratory secretions. In many hospitals, multidrug-resistant Enterobacteriaceae have become endemic, leading to substantial problems in the management of serious infections.[1]

E. coli is the most common cause of urinary tract infections (UTIs), accounting for more than 80% of isolates from urine in most clinical situations. Any of the remaining members of the Enterobacteriaceae can cause this infection; *Klebsiella* spp and *Proteus mirabilis* are among other common causes of UTI. *Providencia stuartii* is notable as a cause of UTI among chronically catheterized patients. The Enterobacteriaceae can cause uncomplicated UTI in healthy women as well as acute pyelonephritis and UTI complicating renal tract abnormalities or catheterization. The Enterobacteriaceae may colonize the urine or be found in contaminated, improperly collected samples.

Antibiotic-resistant, uropathogenic *E. coli* may spread clonally. In other words, *E. coli* isolates from multiple different people with UTI may be identical or closely related at a genetic level. Trimethoprim-sulfamethoxazole–resistant *E. coli* is notable for its spread in a clonal fashion in the United States (e.g., "clonal group A" and *E. coli* O15:K52:H1). A widely spread *E. coli* clone, defined by multilocus sequence typing as sequence type 131 (ST131), has been found to be associated with ciprofloxacin resistance and production of extended-spectrum β-lactamases (ESBLs).[2,3] This clone is typically associated with community-acquired UTI. It has been detected in every inhabited continent.

Given the niche of most Enterobacteriaceae in the gastrointestinal tract, it is not surprising that these bacteria are prominent as causes of peritonitis. *E. coli* ranks most common as a cause of both spontaneous bacterial peritonitis (occurring in cirrhotic patients) and bacterial peritonitis arising from visceral perforation. Pyogenic liver abscess and intra-abdominal abscess may also be due to *E. coli*. Other members of the Enterobacteriaceae may also cause these intra-abdominal infections, especially in patients with "tertiary" peritonitis occurring after prior surgery for intra-abdominal disease.

The Enterobacteriaceae may also be the causative pathogens of pneumonia. They are more frequently the cause of hospital- and health care–associated pneumonia than community-acquired pneumonia. *Klebsiella pneumoniae* was once renowned as a cause of community-acquired pneumonia in alcoholics but has declined in significance during the last few decades. One exception is the finding of community-acquired pneumonia, liver abscess, or meningitis in Asia due to highly mucoid strains of *K. pneumoniae*.[4] Hospital-acquired pneumonia due to the Enterobacteriaceae may be ventilator associated. The Enterobacteriaceae rank most common as causes of ventilator-associated pneumonia after *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*. The Enterobacteriaceae may also cause hospital-acquired pneumonia in non–mechanically ventilated patients, such as those with neurologic impairment from head injury or cerebrovascular accident.

Outbreaks of antibiotic-resistant *K. pneumoniae* infection in hospitals have been prominent for more than three decades. In the hospital setting, *K. pneumoniae* is usually the cause of peritonitis, pneumonia, or complicated UTI. Blood stream infection arising from these sites of infection, from vascular catheters, or in association with neutropenia may also occur. In the 1970s, outbreaks due to gentamicin-resistant strains occurred. In the 1980s and 1990s, hospital outbreaks of ESBL-producing *K. pneumoniae* became commonplace. Finally, in the last decade, *K. pneumoniae* carbapenemase (KPC)–producing *K. pneumoniae* became a substantial infection control issue. The KPC-producing organisms are discussed in detail in a subsequent section of this chapter.

TABLE 305-1 SELECTED MEDICALLY IMPORTANT MEMBERS OF THE FAMILY ENTEROBACTERIACEAE

GENUS	SOME IMPORTANT SPECIES
Enterobacter	*E. cloacae*
Escherichia	*E. coli*
Klebsiella	*K. pneumoniae, K. oxytoca*
Morganella	*M. morganii*
Plesiomonas	*P. shigelloides*
Proteus	*P. mirabilis, P. vulgaris*
Providencia	*P. stuartii*
Salmonella	*S. enterica*
Serratia	*S. marcescens*
Shigella	*S. sonnei*
Yersinia	*Y. pestis, Y. enterocolitica*

PATHOBIOLOGY

The virulence factors associated with *E. coli* causing enteric infections are discussed in detail in Chapter 304. At least 40 different virulence genes have been described in *E. coli* causing extraintestinal infections. Among the virulence properties of these strains is the renowned ability of *E. coli* to adhere to uroepithelial cells. The ST131 *E. coli* clone is typically highly virulent. It belongs to "phylogenetic group" B2, which is known for extraintestinal pathogenic infections. In an evaluation of the ST131 clone, numerous extraintestinal virulence genes were found. Enterobacteriaceae other than *E. coli* also possess a number of virulence mechanisms, but it is beyond the scope of this chapter to describe these in detail.

Many Enterobacteriaceae are now multidrug resistant. Resistance of the Enterobacteriaceae to aminoglycosides is usually mediated by production of aminoglycoside-modifying enzymes. However, 16S ribosomal RNA methylation is a more recently described mechanism that results in resistance to gentamicin, tobramycin, and amikacin. Resistance of the Enterobacteriaceae to fluoroquinolones is a growing problem. In most areas, more than 20% of *E. coli* strains are resistant to fluoroquinolones. Resistance is usually mediated by mutations at target sites and is associated with the ST131 strain. Mechanisms such as efflux pump overexpression and expression of the plasmid-mediated *qnr* genes may also play a role in quinolone resistance. The mechanisms of resistance of the Enterobacteriaceae to β-lactam antibiotics are worthy of detailed description (Table 305-2).

TABLE 305-2 ANTIBIOTIC RESISTANCE ISSUES IN THE ENTEROBACTERIACEAE

ORGANISM	β-LACTAMASE	COMMENTS
NARROW-SPECTRUM β-LACTAMASES		
Escherichia coli	TEM-1	Present in at least 40% of strains globally
Klebsiella pneumoniae	SHV-1	Universally found
EXTENDED-SPECTRUM β-LACTAMASES		
E. coli	CTX-M-15	International clone ST131
K. pneumoniae	SHV, TEM, CTX-M	Hospital outbreaks
AmpC β-LACTAMASES		
Enterobacter cloacae	AmpC	Universally found
E. coli	AmpC	Occasional plasmid-mediated strains
CARBAPENEMASES		
K. pneumoniae	KPC	Endemic in many parts of the United States
K. pneumoniae	NDM	Hospital outbreaks in India

Narrow-Spectrum β-Lactamases

Ampicillin was introduced into clinical practice in the early 1960s. Enterobacteriaceae, with genes encoding β-lactamases inherent to their chromosome, were found to be intrinsically resistant to this antibiotic. Examples of these include the production of the SHV-1 β-lactamase by *K. pneumoniae* and the AmpC β-lactamase by *Enterobacter cloacae*. Other Enterobacteriaceae (e.g., *E. coli*, *Proteus mirabilis*, or *Salmonella*) lacked substantial production of chromosomally encoded β-lactamase. However, within months of the release of ampicillin, a plasmid-mediated β-lactamase leading to resistance of *E. coli* to the antibiotic was discovered. This β-lactamase was coined the TEM β-lactamase, in honor of the patient (Temoneira) from whom the TEM β-lactamase–producing *E. coli* was first isolated. Plasmids encoding resistance to ampicillin have now become widespread, with at least 40% of *E. coli* in most parts of the world now being TEM β-lactamase producers.

Extended-Spectrum β-Lactamases

Third-generation cephalosporins (such as ceftriaxone) were active against Enterobacteriaceae producing narrow-spectrum β-lactamases. However, mutant genes encoding β-lactamases capable of inactivating third-generation cephalosporins were discovered in the 1980s. The genes encoding these β-lactamases were identical to TEM or SHV, except for point mutations that led to an altered amino acid sequence. The subsequent structural change led to an ability to hydrolyze and thus to inactivate third-generation cephalosporins. In view of the extended spectrum of antibiotic-hydrolyzing abilities compared with the parent TEM and SHV enzymes, these β-lactamases were coined extended-spectrum β-lactamases (ESBLs). In addition to the TEM and SHV types of ESBLs, many new types of ESBLs have now been described, most notably the CTX-M type.

Frequently, the ST131 *E. coli* clone produces a CTX-M type of ESBL (especially CTX-M-15). Although ESBLs are typically susceptible to β-lactamase inhibitors (e.g., clavulanic acid), many ST131 *E. coli* isolates produce an additional β-lactamase (OXA-1) that confers resistance to β-lactamase inhibitors. The antibiotic resistance phenotype of the ST131-positive *E. coli* is that the organisms are typically resistant to ceftriaxone, cefotaxime, fluoroquinolones, trimethoprim, trimethoprim-sulfamethoxazole, penicillin–β-lactamase inhibitor combinations, and tetracyclines. Resistance to aminoglycosides is variable. The clone confers multidrug resistance by the presence of multiple antibiotic resistance genes. These are usually encoded on plasmids.

AmpC β-Lactamases

A number of genera within the Enterobacteriaceae have a chromosomally encoded β-lactamase capable of producing resistance to all penicillins and all cephalosporins except cefepime. In addition, these β-lactamases are not inhibited by β-lactamase inhibitors, such as clavulanic acid or tazobactam. These β-lactamases are known as AmpC β-lactamases. They are not derived from narrower-spectrum parent β-lactamases, so it is not correct to call these extended-spectrum β-lactamases. These AmpC β-lactamases may be overproduced in the presence of certain antibiotics (i.e., the genes encoding the AmpC β-lactamases are "inducible"). *Enterobacter* spp, *Citrobacter freundii*, *Serratia marcescens*, and *Morganella morganii* have inducible, chromosomally encoded AmpC β-lactamases. The genes encoding these β-lactamases have now been found on plasmids in *E. coli*, *Salmonella*, and other gram-negative bacteria.

KPC, NDM, and Other Carbapenemases

In 2001, a novel carbapenem-hydrolyzing β-lactamase from a carbapenem-resistant strain of *K. pneumoniae* was first described. This enzyme was described as the *K. pneumoniae* carbapenemase (KPC). KPC-producing organisms are typically resistant to penicillins, cephalosporins, and carbapenems and are not inhibited by clavulanic acid or other commonly used β-lactamase inhibitors, such as sulbactam and tazobactam. KPC production has been documented in *E. coli* and in many genera of the Enterobacteriaceae, such as *Enterobacter*, *Citrobacter*, *Proteus*, and *Salmonella*.

The epicenter of KPC-producing *K. pneumoniae* has been New York City. By 2004, approximately one quarter of *K. pneumoniae* isolates in a surveillance study in Brooklyn, New York, were KPC producing. The Centers for Disease Control and Prevention now reports KPC-producing organisms in numerous cities across the United States. International spread of KPC-producing organisms has been well described, with outbreaks in Israel, Italy, and Greece being particularly problematic. Parts of China and South America have also reported endemic KPC-producing organisms.[5]

Another carbapenem-hydrolyzing β-lactamase, the New Delhi metallo-β-lactamase (NDM), has emerged in the last decade as a major cause of carbapenem resistance. As its name suggests, its epicenter is the Indian subcontinent. However, it has also been found to be endemic in some hospitals in the Balkan states as well as causing outbreaks in North America and Europe. Many outbreaks of NDM-producing organisms have been associated with interhospital transfers from hospitals in the Indian subcontinent.[6] Worryingly, NDM-producing organisms have been found in drinking water in India[7] and in food-producing animals in China.[8]

Other carbapenem-hydrolyzing β-lactamases include the OXA-48 type, which is found in North Africa, the Middle East, and India and has since spread to other parts of the world, as well as a variety of metallo-β-lactamases (such as of the IMP and VIM types). These enzymes have in common the ability to render Enterobacteriaceae resistant to carbapenems and other β-lactam antibiotics.

CLINICAL MANIFESTATIONS

The clinical manifestations of UTI, peritonitis, pneumonia, and blood stream infection due to the Enterobacteriaceae are described in other chapters.

DIAGNOSIS

Infection with the Enterobacteriaceae is readily diagnosed in clinical microbiology laboratories after collection of appropriate specimens. Examination of the Gram stain enables a rapid differentiation of gram-negative bacilli from other pathogens. However, it is frequently difficult on clinical grounds and by Gram stain results to differentiate infection with the Enterobacteriaceae from other gram-negative bacilli, such as *Pseudomonas aeruginosa*.

Once a member of the Enterobacteriaceae has been identified, it is important to ensure that appropriate antibiotic susceptibility testing has been performed. In some instances, specialized tests need to be performed by the clinical microbiology laboratory to detect ESBL or carbapenemase production. Molecular epidemiologic assessment may need to be undertaken to determine if an isolate belongs to an outbreak strain.

TREATMENT

Rx

Treatment depends on the site of infection and the extent of antibiotic resistance. Empirical antibiotic choices for orally administered therapy for UTI due to *E. coli* and the other Enterobacteriaceae may include fluoroquinolones, trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, and nitrofurantoin. *P. mirabilis* is resistant to nitrofurantoin. Empirical parenteral choices may include third-generation cephalosporins, penicillin–β-lactamase inhibitor combinations, aminoglycosides, fluoroquinolones, and carbapenems.

The advent of antibiotic resistance in the Enterobacteriaceae has the potential to have a huge impact on treatment of common infections. UTI is a pertinent example. Orally administered choices such as fluoroquinolones, trimethoprim-sulfamethoxazole, and amoxicillin-clavulanate are typically inactive in the ST131 *E. coli* strain. There may be a need to now admit some patients for parenteral antibiotics because of this antibiotic resistance. Worse still, some patients with hospital-acquired infection may need "last-line" antibiotics like colistin or polymyxin B. Specific details of treatment choices for antibiotic-resistant Enterobacteriaceae are given in Table 305-3.

TABLE 305-3 TREATMENT OPTIONS FOR MULTIPLY RESISTANT ENTEROBACTERIACEAE

ESBL PRODUCERS
Carbapenems (first choice, serious infections)
Piperacillin-tazobactam, cefepime (second choice, serious infections)
Nitrofurantoin, fosfomycin (first choice, UTI)
Ciprofloxacin, amoxicillin-clavulanate (second choice, UTI)
KPC OR NDM PRODUCERS
Colistin, polymyxin B, tigecycline, meropenem (as part of a combination)

ESBL = extended-spectrum β-lactamases; KPC = *K. pneumoniae* carbapenemase; NDM = New Delhi metallo-β-lactamase; UTI = urinary tract infection.

Treatment of ESBL-Producing Organisms

In vitro, the carbapenems (including imipenem, meropenem, doripenem, and ertapenem) have the most potent activity against ESBL-producing organisms. This is not surprising because these antibiotics are not inactivated by ESBLs. Carbapenems should be regarded as the drugs of choice for serious infections with ESBL-producing organisms on the basis of extensive positive clinical experience. No randomized trials have been completed comparing carbapenems with other antibiotic classes against ESBL producers. Although a substantial proportion of ESBL-producing organisms will be resistant to piperacillin-tazobactam, observational studies have shown a similar mortality from carbapenem-treated blood stream infections due to ESBL-producing compared with β-lactam/β-lactamase inhibitor–treated infections.[9] There is no evidence that combination therapy involving a carbapenem is superior to use of a carbapenem alone for ESBL producers.

Thus, meropenem or piperacillin-tazobactam is the treatment of choice for serious infections due to ESBL producers. The ability to use ertapenem once daily makes it potentially useful in serious infections with ESBL producers in nursing home residents or patients continuing parenteral therapy out of the hospital. UTIs may be treated with orally administered fosfomycin, nitrofurantoin, or amoxicillin-clavulanate if susceptible.

Treatment of Carbapenem-Resistant Organisms

Treatment of carbapenem-resistant organisms (e.g., due to KPC or NDM production) is difficult because they may lack susceptibility to all β-lactam antibiotics (including penicillins, cephalosporins, aztreonam, and carbapenems), fluoroquinolones, and aminoglycosides. Carbapenemase-producing organisms may sometimes appear susceptible to carbapenems such as meropenem and imipenem (although they are almost always recognized as resistant to ertapenem), but these antibiotics should not be relied on as monotherapy.

No randomized controlled trials have yet been performed evaluating different antibiotic options for carbapenemase producers. On the basis of observational studies, combination therapy appears to be superior to single-drug therapy. Combinations of a polymyxin, tigecycline, and meropenem have met with the greatest success.[10-12] Meropenem has been used in these combinations despite a lack of in vitro susceptibility.

A variety of new antibiotics with activity against ESBL producers and some carbapenemase producers are undergoing evaluation. These include the combination of ceftazidime and a novel β-lactamase inhibitor called avibactam and a new aminoglycoside, plazomicin. These appear to have significant activity against KPC producers. Unfortunately, avibactam does not inhibit NDM or other metallo-β-lactamases. Furthermore, plazomicin is not active against NDM producers because most exhibit aminoglycoside resistance by way of 16S ribosomal RNA methylation.

PREVENTION

Prevention of hospital-acquired outbreaks of ESBL, KPC, or NDM producers rests on a number of basic infection control principles. First, if a focus of infection exists in the hospital environment, it should be removed. Examples have included contamination of ultrasonography coupling gel and bronchoscopes. Outbreaks have been dramatically curtailed when these sources of contamination have been properly cleaned or removed from the hospital environment.

Present evidence suggests that transient carriage on the hands of health care workers is the most important means of transfer of ESBL-, KPC-, or NDM-producing Enterobacteriaceae from patient to patient. The hands of health care workers are presumably colonized by contact with the skin of patients with skin colonization of the organism or by contact with a contaminated environment around the patient. Many patients may have asymptomatic colonization with ESBL-, KPC-, or NDM-producing organisms without signs of overt infection. These patients represent an important reservoir of organisms. In some hospital wards with ongoing issues with ESBL, KPC, or NDM producers, more than 30% of patients have gastrointestinal tract colonization with these organisms at any one time. These patients should be nursed with use of contact precautions. Hand carriage by health care workers is usually eliminated by hand hygiene with alcohol-based agents. Compliance with contact isolation precautions and hand hygiene needs to be high to maximize the effectiveness of these interventions.

Changes in antibiotic policy may play a role in controlling outbreaks of ESBL, KPC, or NDM producers, but this concept remains controversial. In one reported outbreak of ESBL producers, no effort was made to change infection control procedures. Instead, at this hospital, ceftazidime use decreased and piperacillin-tazobactam was introduced into the formulary. This coincided with curtailment of the outbreak. In another institution, cephalosporins as an entire class were removed to exact control over endemic ESBL producers. The difficulty with this approach is that replacement of one antibiotic class with another may result in replacement of one antibiotic resistance issue with another. No study has demonstrated that removal of carbapenems from a hospital formulary leads to elimination of KPC or NDM producers. Because these organisms are resistant to multiple antibiotic classes, classes as diverse as β-lactam/β-lactamase inhibitor combinations and fluoroquinolones have been more commonly received than carbapenems before colonization or infection with KPC producers. Prudent use of all antibiotic classes with an emphasis on reducing duration of antibiotic use may be more useful than individual antibiotic class restriction.

PROGNOSIS

The prognosis of infection with the Enterobacteriaceae depends on multiple factors, such as site of infection, presence of underlying diseases, and adequacy of empirical antibiotic therapy. At one extreme, inadequate orally administered antibiotic therapy for uncomplicated UTI due to an ESBL producer may have no impact on mortality, although it may have an impact on duration of symptoms and need for parenteral therapy for treatment failure. At the other extreme, patients in an intensive care unit with serious infections due to KPC or NDM producers may have an in-hospital mortality rate exceeding 70%. This may compare with in-hospital mortality rates of 20 to 30% in comparable patients without infection due to a KPC or NDM producer.

REVIEW QUESTIONS

1. A 78-year-old man was admitted to a surgical intensive care unit in New York City for management of severe, necrotizing pancreatitis. He was empirically treated with meropenem. On the 18th day of surgical intensive care unit admission, while still receiving meropenem, he developed a fever (temperature of 39.5° C) and hypotension requiring inotropic support. Blood culture samples were collected, and nonmotile gram-negative bacilli were seen after incubation for 12 hours. Which of the following statements about management of the bacteremia is true?

A. He should receive ampicillin for a likely *Enterobacter cloacae* blood stream infection.
B. He should receive ampicillin-sulbactam for a likely *Escherichia coli* blood stream infection.
C. He should be maintained on meropenem for a likely ESBL-producing *Klebsiella pneumoniae* blood stream infection.
D. He should receive a polymyxin in combination with other antibiotics for blood stream infection because of a probable carbapenem-resistant organism.
E. His antibiotics should be discontinued and the blood stream infection should be managed by changing all intravascular lines.

Answer: D Carbapenem-resistant gram-negative organisms are now endemic in many parts of the world. Carbapenem resistance, mediated by the KPC carbapenemase, is widespread in many parts of the United States, Greece, Italy, and Israel. This creates significant management issues for severe sepsis due to gram-negative bacilli. At present, a polymyxin in combination with meropenem or tigecycline is the treatment of choice for KPC producers. Source control should also be used, when appropriate.

2. A 27-year-old woman has a history of recurrent urinary tract infections. She presents with symptoms of dysuria and urinary frequency. *Escherichia coli* is isolated from her urine and is found to be resistant to ampicillin, trimethoprim-sulfamethoxazole, and ciprofloxacin. The organism is susceptible to piperacillin-tazobactam and ertapenem. Which of the following scenarios is most likely?

A. TEM-1 accounts for the resistance to ciprofloxacin.
B. NDM-1 accounts for the resistance to trimethoprim-sulfamethoxazole.
C. She is most likely infected with the ST171 strain of *E. coli*.
D. She is most likely infected with the ST131 strain of *E. coli*.
E. She most likely works in a New York City nursing home and has infection with KPC-producing *E. coli*.

Answer: D ST131 *E. coli* is an international pandemic clone that is typically resistant to ciprofloxacin. It may also be ESBL producing due to production of the CTX-M-15 β-lactamase. Although there are reports of ST131 producing carbapenemases, this is not commonplace.

3. A 24-year-old medical student undertakes an elective in Nepal. While there, he goes mountain climbing but falls and breaks his leg. After undergoing surgery in Kathmandu, he is transferred back to the United States after 2 weeks of hospitalization in Nepal. A rectal swab is taken on admission to the hospital in the United States. Which of the following are most likely to be found?

A. NDM-producing *Klebsiella pneumoniae*
B. KPC-producing *Klebsiella pneumoniae*
C. AIM-1–producing *Klebsiella pneumoniae*
D. VIM-1–producing *Klebsiella pneumoniae*
E. IMP-4–producing *Klebsiella pneumoniae*

Answer: A NDM-producing organisms are endemic in many hospitals in the Indian subcontinent. Patients hospitalized in this area may become colonized with NDM producers. They may then serve as reservoirs for these organisms when transferred to hospitals in countries without endemic NDM producers. Outbreaks may result unless adequate infection control interventions are used.

4. A 66-year-old man has been ventilated for 3 weeks after a severe head injury. He develops radiologic changes in his chest consistent with right middle and lower lobe consolidation. His endotracheal aspirates have become purulent, and he has developed a new fever. The laboratory identifies a motile gram-negative bacillus. It is able to ferment sugars. It is oxidase negative. On susceptibility testing, it is resistant to ampicillin and ceftazidime but susceptible to ciprofloxacin, gentamicin, and meropenem. The most likely organism is

A. *Pseudomonas aeruginosa*
B. *Staphylococcus aureus*
C. *Streptococcus pneumoniae*
D. *Acinetobacter baumannii*
E. *Enterobacter cloacae*

Answer: E The Enterobacteriaceae are able to ferment sugars, whereas "nonfermenters" like *P. aeruginosa* (an oxidase-positive organism) and *A. baumannii* (an immotile organism) are not. Staphylococci and streptococci are gram-positive organisms. Only *E. cloacae* fits the description.

PSEUDOMONAS AND RELATED GRAM-NEGATIVE BACILLARY INFECTIONS

MATTHEW E. FALAGAS AND PETROS I. RAFAILIDIS

DEFINITION

Infections due to *Pseudomonas* spp are caused by members of the family Pseudomonadaceae. The Pseudomonadaceae is a group of gram-negative rods, including *Pseudomonas aeruginosa*, the most frequently recovered human pathogen in the family. Other *Pseudomonas* spp include *Pseudomonas putida, Pseudomonas alcaligenes, Pseudomonas fluorescens, Pseudomonas luteola, Pseudomonas mendocina, Pseudomonas oryzihabitans, Pseudomonas pseudoalcaligenes, Pseudomonas stutzeri, Pseudomonas chlororaphis, Pseudomonas delafieldii, Pseudomonas kingii, Pseudomonas pertucinogena,* and *Pseudomonas* CDC group 1.

Related gram-negative bacillary infections include infections due to *Stenotrophomonas maltophilia* (formerly known as *Pseudomonas maltophilia* and *Xanthomonas maltophilia*) and members of the genus *Burkholderia* (*Burkholderia pseudomallei*, *Burkholderia mallei*, and *Burkholderia cepacia* complex).

The Pathogens

Pseudomonas aeruginosa is a gram-negative, lactose nonfermenting, straight or slightly curved rod with a length ranging from 1.5 to 7 µm and a width of 0.5 to 1.0 µm. It is catalase positive, oxidase positive, and motile with one or more polar flagella. Most species oxidize glucose and reduce nitrate to nitrite or nitrogen gas. It has the ability to grow at 42° C. This pathogen is admirably armed on its exterior: a polysaccharide capsule along with lipopolysaccharides, pili, and flagella. Furthermore, the interior arsenal includes toxins such as exotoxin A, pyocyanin (blue or blue-green pigment), pyorubin (red or red-brown pigment), pyomelanin (black pigment), and pyoverdin (yellow-green pigment). *P. aeruginosa* is notorious for its ability to acquire resistance genes and to spread by horizontal transfer.

Stenotrophomonas maltophilia is a gram-negative nonfermenting bacillus motile by polar flagella. It is also catalase positive; the majority of strains are oxidase negative, but some strains are oxidase positive. *Burkholderia cepacia* and *Burkholderia pseudomallei* are also motile gram-negative lactose nonfermenting bacteria. In contrast, *Burkholderia mallei* is nonmotile.

EPIDEMIOLOGY

P. aeruginosa is one of the most common pathogens in health care–associated infections. Ventilator-associated pneumonia, bacteremia associated with central venous catheters or secondary to infections present elsewhere in the body, urinary tract infections, and surgical site infections are the main types of infections associated with *P. aeruginosa* in the hospital setting. Data from the National Healthcare Safety Network at the Centers for Disease Control and Prevention indicate that during 2009 to 2010, *P. aeruginosa* was responsible for 8% of a total of 69,475 health care–associated infections and was the sixth most frequent culprit among 81,139 pathogens.[1] Approximately 2% of these strains are resistant to carbapenems, a powerful antibiotic against them. This organism is able to survive in environments that have only minimal nutritional components. *P. aeruginosa* can colonize moist surfaces of the axilla, ear, and perineum. It is also isolated from other moist, inanimate environments within the hospital, including water in sinks and drains, mechanical ventilation equipment, dialysis equipment, toilets, showers, hydrotherapy pools, mops, water for flowers, and even cleaning solutions.

Strains of *P. aeruginosa* resistant to multiple classes of antibiotics, including quinolones and β-lactams, are a major cause of morbidity and mortality worldwide. During a relatively short time, a multidrug-resistant *P. aeruginosa* strain spread through neighboring countries.[2] The use of broad-spectrum antibiotics is certainly a risk factor for the development of multidrug-resistant *P. aeruginosa*, as are deficiencies in infection control implementation.

A range of hosts are particularly prone to infections by this pathogen: patients with neutropenia, patients with burns, cystic fibrosis (CF) patients, cancer patients, transplant recipients, diabetics, and patients with AIDS. Patients with compromised immunity due to treatment or by the disease, either humoral (hypogammaglobulinemia) or cellular (steroid treatment), as well as patients with foreign bodies (e.g., vascular grafts, orthopedic implants) are also more vulnerable to *P. aeruginosa* infections.

Community-acquired *P. aeruginosa* infection is related to exposure to water by the use of hot tubs, whirlpools, swimming pools, spas, and other types of baths as well as to the use of contact lenses, particularly the extended-wear variety. Puncture wounds including those through tennis shoes can give rise to *P. aeruginosa* infection. *P. aeruginosa* endophthalmitis after eye trauma can result in visual compromise, and *P. aeruginosa* endocarditis is frequently found in intravenous injection drug users. In addition, there is the possibility for drug-resistant *P. aeruginosa* in the community, and this risk has to be taken into account in prescribing antibiotic therapy.

S. maltophilia, once thought to be of limited virulence, is a significant emerging pathogen.[3] It is an environmental gram-negative, multidrug-resistant organism that mainly causes pneumonia and acute exacerbation of chronic obstructive pulmonary disease. Bacteremia, urinary tract infection, skin and soft tissue infections including cellulitis, osteomyelitis, endocarditis, and meningitis are among the infections caused by *S. maltophilia*.

Once isolated in the geographic setting of Southeast Asia and Australia with an incidence of approximately 50/100,000 in the general population, infections due to *B. pseudomallei* are of special interest because they are reported now more frequently also from the Indian subcontinent.[4] Fortunately, infection due to *B. mallei* is rare in humans.

Burkholderia cepacia belongs to the *Burkholderia cepacia* complex, which includes also *Burkholderia ambifaria, Burkholderia anthina, Burkholderia arboris, Burkholderia cenocepacia, Burkholderia contaminans, Burkholderia diffusa, Burkholderia dolosa, Burkholderia latens, Burkholderia lata, Burkholderia metallica, Burkholderia multivorans, Burkholderia pyrrocinia, Burkholderia seminalis, Burkholderia. stabilis, Burkholderia ubonensis,* and *Burkholderia vietnamiensis*. *B. cepacia* was previously reported under the name of *Pseudomonas cepacia*. *B. cepacia* infects mainly patients with CF and chronic granulomatous disease. However, there are many reports of *B. cepacia* infections in hospitalized patients without CF. Patients with central venous catheters, manipulation of the urogenital tract (catheterization, instrument insertion, and biopsy), burns, and wounds (surgical and other) may develop infection due to *B. cepacia*.

PATHOBIOLOGY

Pathogenesis and Pathophysiology

Innate immunity, primarily through inflammatory cytokine production and phagocytic clearance by neutrophils and macrophages, is the key to endogenous control of *P. aeruginosa* infection.[5] Patients with neutropenia and also patients in whom there are defects of recruitment and activation of polymorphonuclear neutrophils, such as those with CF, are susceptible to *P. aeruginosa* infections. This happens because the lipopolysaccharide of *P. aeruginosa* binds to the CF transmembrane conductance regulator (CFTR), which is a channel involved in chloride movement across the cell. When there is normal CFTR, release of interleukin-1 and signaling through the interleukin-1 receptor and adaptor molecule MyD88 occur. Furthermore, CFTR lipid rafts are formed and NF-κB is translocated, followed by transcription of NF-κB–dependent genes and the production of interleukin-6, interleukin-8, and intercellular adhesion molecule 1. After that follows the recruitment of polymorphonuclear neutrophils to infected tissue and the induction of apoptosis and resolution of infection. In the absence of MyD88, however, lethal pneumonia and sepsis can be induced by fewer than 60 bacterial cells applied to the noses of mice. Patients with CF have a defective CFTR and thus cannot mount a normal defensive response to *P. aeruginosa*. The major challenge has been to correlate the genetic defect leading to the synthesis of either no CFTR protein or dysfunctional CFTR to the pathogenesis of *P. aeruginosa* infection.

Other host factors that predispose to *Pseudomonas* infections are burns and wounds, especially necrotic tissue, and AIDS/HIV infection. In addition, loss of mucosal function of the tracheobronchial tree of mechanically ventilated patients and patients with cancer and disruption of the normal bacterial flora in the gastrointestinal tract are ideal settings for the growth of *P. aeruginosa*.

Bacterial Factors in Pathogenesis

P. aeruginosa is one of the ESKAPE (*Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa,* and *Enterobacter* species) group of bacteria that the Infectious Diseases Society of America has specifically addressed as a cause of concern. It survives in aquatic as well as in soil environments. Its armamentarium is vast and adaptable to the challenges faced, and its intraspecies but also interspecies communication in the microbial kingdom is noteworthy. Several factors including flagella, pili, exopolysaccharides, phospholipases, proteases, endotoxins, secreted toxins (types I, II, II, IV, and VI), exotoxins, and iron-binding proteins are involved in pathogenesis (E-Table 306-1). Defensive weapons of *Pseudomonas* are the production of high levels of an extracellular mucoid polysaccharide called alginate, which is the main constituent of the glycocalyx allowing growth in a biofilm. Furthermore, the expression of O side chains on the bacterium's lipopolysaccharide prevents lysis by complement. Aggressive mediators to kill immune cells and to invade and degrade tissues are the toxins and enzymes produced by the bacterium. Exotoxin A, an adenosine diphosphate–ribosylating toxin, has activity similar to that of diphtheria. The production of this cellular toxin is affected by iron levels. *P. aeruginosa* uses pyoverdin and pyochelin, typical siderophore systems, to acquire iron.

P. aeruginosa can induce hemolysis by PlcHR, a hemolytic phospholipase C. A nonhemolytic phospholipase C, PlcN, is also made by *P. aeruginosa* strains. *P. aeruginosa* type III secretion systems allow direct injection of bacterial toxins into eukaryotic cells and disrupt cellular trafficking by inhibiting the actin cytoskeleton and by affecting protein synthesis. For *P. aeruginosa*, clinical isolates expressing type III toxins are isolated significantly more frequently from patients who have poor clinical outcomes. Four major effector proteins are known: ExoS, ExoT, ExoU, and ExoY. More than these factors, the ability of *Pseudomonas* to communicate with other members of its microbial community through quorum sensing leads to the formation of biofilms, a daunting obstacle in attempting to eradicate the pathogen. Quorum sensing systems of *Pseudomonas* are lasR1, rhlR1, and *Pseudomonas* quinolone system. These systems have a complex interaction with other factors in

E-TABLE 306-1 VIRULENCE FACTORS FOR *PSEUDOMONAS AERUGINOSA*

LOCATION OR CLASS	EXAMPLES	ACTIVITY/EFFECTS ON HOST
Cell surface	Alginate	Antiphagocytic, resists opsonic killing
	Lipopolysaccharide	Endotoxic, antiphagocytic, avoids preformed antibody to previously encountered O antigens
	Pili (produced by type IV secretion)	Twitching motility, biofilm formation, adherence to host tissues
	Flagella	Motility, biofilm formation, adherence to host tissues and mucin components
	Injection of type III secretion factors	PcrG, PcrV, PcrH, PopB, and PopD proteins form injection bridge for type III effectors
Outer membrane	Siderophore receptors	Provides iron for microbial growth and survival
	Efflux pumps	Remove antibiotics
Secretion systems		
Type II	Elastase, lipase, phospholipases, chitin-binding protein, exotoxin A and others	Variety of proteolytic, lipolytic, and toxic factors; degrade host immune effectors
Type III	ExoS, ExoT, ExoU, ExoY	Intoxicates cells (ExoS, ExoT); cytotoxic (ExoU), disrupts actin cytoskeleton
Type VI	Cytoplasmic and membrane-associated proteins, ATPases, lipoproteins, Hcp1 protein	Poorly characterized but found in animal studies to be needed for optimal virulence, particularly in chronic infection
Iron acquisition	Pyoverdin, pyochelin	Scavenge iron from the host for bacterial use
Secreted toxins	Hemolysins, rhamnolipid phospholipases	Kill leukocytes, hemolysis of red cells, degrade host cell surface glycolipids
Secreted oxidative factors	Pyocyanin, ferripyochelin	Produce reactive oxygen species: H_2O_2, O_2^- Inflammatory, disrupts epithelial cell function
Quorum sensing	LasR/LasI, RhlR/RhlI, PQS	Biofilm formation, regulation of virulence factor secretion

ATPases = adenosine triphosphatases; PQS = *Pseudomonas* quinolone signal.

the context of regulation of gene transcription and production of virulence factors.

Both intrinsic (mutation-driven) and transferable (such as β-lactamase production) mechanisms confer *Pseudomonas* resistance to antibiotics, including carbapenems. Transferable resistance to aminoglycosides entails modification of aminoglycosides through phosphoryltransferases, acetyltransferases, nucleotidyltransferases, or ribosomal methyltransferases (RmtA, RmtB, RmtC, RmtD, and ArmA). Chromosomally encoded resistance involves the following:

- AmpC cephalosporinase overproduction or derepression;
- porin OprD, which facilitates diffusion of basic amino acids and carbapenems;
- class D oxacillinase (OXA-50); and
- efflux-mediated resistance through efflux pumps of the RND (resistance-nodulation-division) family, such as the MexXY, which among others affects fluoroquinolones, β-lactams, and aminoglycosides; MexAB-OprM and MexCD-OprJ, which among others affect fluoroquinolones and β-lactams; and MexEF-OprN (F), MexGHI-opmD (F), MexVW (F), and MexPQ-OpmE, which among others affect fluoroquinolones.

Chromosomally mediated resistance also is related to mutations in the quinolone resistance-determining region of gyrase A and the topoisomerase IV gene parC, which hamper the attack of fluoroquinolones on the bacterium. Aminoglycoside-inactivating enzymes are related to the *P. aeruginosa* chromosome and involve 3-*N*-aminoglycoside acetyltransferases [AAC(6)-I, AAC(6)-II, AAC(3)-I, AAC(3)-II, AAC(3)-III, AAC(3)-IV] or nucleotidyltransferases ANT(2)-I and ANT(4)-II and phosphotransferase APH(3)-VI. Impermeability resistance to aminoglycosides is also chromosomally mediated.

The production of such powerful enzymes as the metallo-β-lactamase (such as VIM-1, VIM-2, VIM-4, and IMP-29) is capable of destroying the carbapenem antibiotics, which are important for the treatment of patients with multidrug-resistant gram-negative bacteria. Furthermore, as reported in a study from French intensive care units,[6] additional intrinsic mechanisms may be present concurrently, such as the complete loss of porin OprD as a consequence of mutations or gene disruption by insertion sequences. Downregulation of OprD may be coupled with overexpression of efflux pumps (MexXY, MexEF-PprN, CzcCBA).

Pathology

The pathologic spectrum of *P. aeruginosa* infections depends on the site afflicted. Hemorrhage and necrosis may be present in severe *Pseudomonas* infections, such as in pneumonia and endocarditis. Notably, as regards the skin in the case of ecthyma gangrenosum, bacteria invade the arteries and veins of the skin, but there is little accompanying inflammation. This is reflected in the small quantity, if any, of pus present in these skin lesions. The pathology of *B. pseudomallei* infection is in sharp contrast, with intense inflammation leading to abscess formation and necrosis in the affected organs, as in the skin, liver, spleen, or lungs.

CLINICAL MANIFESTATIONS

A constellation of manifestations are included in the clinical spectrum of *P. aeruginosa* infections. There are no symptoms or signs to effectively discriminate *P. aeruginosa* infection from infections by other pathogens. Even ecthyma gangrenosum, which was once thought to represent a unique effect of *P. aeruginosa* infection, can be caused by other bacteria, such as *S. aureus* or *Citrobacter freundii*.

Febrile Neutropenia

P. aeruginosa infections during febrile neutropenia (Chapters 167 and 281) have a cardinal role. It is the organism against which empirical coverage must always be included. This principle remains unaltered in the span of time. The importance of *P. aeruginosa* infection in neutropenic patients has not diminished, and the antimicrobial resistance of the bacterium has evolved to a painstaking therapeutic challenge. Mortality is high if infection is not appropriately treated by empirical therapy. The classic clinical syndromes in febrile neutropenic patients are bacteremia, pneumonia, and soft tissue infection, mainly manifested as ecthyma gangrenosum.

Bacteremia

Bacteremia due to *P. aeruginosa* remains one of the most difficult challenges a physician may face. It is usually caused by primary infection at different sites, such as pneumonia, urinary tract infection, complicated intra-abdominal tract infection (peritonitis, abscess), and endocarditis. Manifestations can include those of sepsis and septic shock, that is, fever, tachycardia, tachypnea, hypotension, and mental status changes ranging from confusion to coma (Chapter 108). Multiorgan failure with adult respiratory distress syndrome and acute renal failure along with coagulation defects (disseminated intravascular coagulation) may occur. In the ventilated patient, an increased index of suspicion for *P. aeruginosa* must be present in case of clinical deterioration.

Eye Infections

Keratitis is among the most frequent type of disease seen, and it is associated with contact lens wear, especially extended-wear lenses. However, any form of trauma may predispose to keratitis by direct inoculation into tissue, including surgery and burns. *P. aeruginosa* keratitis is a medical emergency because of the speed with which it can progress and lead to loss of vision. Pain and redness of the eye are cardinal manifestations of keratitis. The entire cornea is opacified, and sometimes perforation occurs.

Endophthalmitis is another fulminant *P. aeruginosa* eye infection that may result from penetrating injuries, surgery, perforation of a corneal ulcer, or seeding from bacteremia. Severe pain, chemosis, decreased visual acuity or even loss of vision, anterior uveitis, vitreous involvement, and panophthalmitis are manifestations of endophthalmitis.

Other rarer eye infections include orbital cellulitis in neutropenic patients and gangrene necrosis of the eyelids, both of which are metastatic foci of bacteremia.

Ear Infections

Acute otitis externa presenting with otalgia (ear pain) is commonly seen in children and results from infection of moist, macerated skin of the external ear canal. The source of the organism is likely to be hot tubs or swimming pools (swimmer's ear), particularly if they are not sufficiently chlorinated. The natural history is usually resolution without sequelae, but chronic drainage occurs in some patients. Chronic suppurative otitis media has been associated with *P. aeruginosa*. The main clinical manifestation is drainage of fluid. Cultures are usually polymicrobial, including *P. aeruginosa*. In a third of patients, it is found in isolation.

One of the most dramatic clinical manifestations of *Pseudomonas* infections is malignant otitis externa. The diagnosis is made easily as long as there is a high index of suspicion, which should be the case in diabetics and patients with AIDS. Although literally a misnomer (as this is not a cancerous process), the fulminant evolution to death if it is not diagnosed and treated appropriately justifies this nomenclature. It usually afflicts the diabetic patient and is manifested with pain in the ear accompanied by fever (not always), drainage, and nerve palsies that may even be bilateral. Traction of the pinna will elicit pain in the majority of patients. Most commonly, cranial nerves VI to XII (in various combinations) may be involved, and thus hoarseness and dysphagia accompanying facial paralysis may be evident. Mental status may be affected (obtundation, coma) and signifies intracranial spread of the infection. A characteristic of the disease is the presence of granulation tissue at the junction of bone and cartilage in the meatus, in contrast with the generally intact tympanic membrane. Culture specimens should be taken from the external auditory canal. Computed tomography or magnetic resonance imaging findings include temporomandibular joint destruction, infratemporal fossa or nasopharyngeal soft tissue involvement, and evidence of meningitis or empyema.

Ventilator-Associated Pneumonia and Health Care–Associated Pneumonia

The respiratory tract is among the most frequent sites of infection due to *P. aeruginosa.* This organism is a well-established and frequent cause of ventilator-associated pneumonia (VAP) and health care–associated pneumonia.[7] Identification of the bacterium as a culprit can be based on culture of endotracheal tube aspirates as well as bronchoalveolar lavage fluid in the corresponding clinical setting. Ventilator-associated tracheobronchitis is usually far from innocuous, and treatment is needed to avoid progression to the more severe VAP. Obviously, for the ventilated patient, the liberation of the patient from the mechanical ventilation when feasible is a key management issue. Even when only colonization of the tracheobronchial tree is thought to be present, a watchful and vigilant eye by the clinician has to be in place as the pathogen is notorious.

Pseudomonas necrotizing pneumonia is not uncommon, and its significance is reflected by the fact that the currently suggested 8 days of antimicrobial treatment for most microbial causes of VAP does not apply to VAP related to *P. aeruginosa*. The duration of treatment of VAP due to nonfermen-

tative, gram-negative bacteria (such as *P. aeruginosa* and *A. baumannii*) has been proposed by the American Thoracic Society to be 14 days. Pneumonia due to *P. aeruginosa* can also be community acquired.

Chronic Respiratory Tract Infections

P. aeruginosa is responsible for chronic infections of the airways associated mainly with CF and chronic obstructive pulmonary disease. A description and management of *P. aeruginosa* infection in patients with CF can be found in Chapter 89. Patients with advanced chronic obstructive pulmonary disease may become infected by *P. aeruginosa* and present with an exacerbation.

Another chronic infection of the respiratory tract associated with *P. aeruginosa* is diffuse panbronchiolitis. Diffuse panbronchiolitis affects mainly Asian populations. Nevertheless, forms of this disease have also been reported in white, Hispanic, and African American patients. Criteria have been established for diagnosis of this disease[8]:

1. persistent cough, sputum and exertional dyspnea;
2. history of chronic paranasal sinusitis;
3. bilateral diffuse small nodular shadows on a plain chest radiograph or centrilobular micronodules on chest computed tomography images;
4. coarse crackles;
5. FEV_1/FVC <70% and Pao_2 <80 mm Hg; and
6. titer of cold hemagglutinin >64.

Criteria for definite diagnosis are a compilation of criteria 1 to 3 plus two criteria from criteria 4 to 6. *P. aeruginosa* is isolated in advanced stages of the disease. It shows similarities to CF in terms of respiratory tract involvement, but it is characterized by the lack of affliction of other systems (pancreas, genital tract). Furthermore, the amount of sputum produced is usually at least 50 to 100 mL/day, and the genetic background is different, with associations to HLA-Bw52 and HLA-A11 reported.

Bone and Joint Infections

P. aeruginosa is not a frequent cause of bone or joint infections (Chapter 272) in patients without foreign bodies. Such infections result from bacteremia, direct inoculation into bone, or spread from contiguous infection. Bacteremia secondary to either injection of contaminated illicit drugs or infective endocarditis in the population of intravenous drug users has been well documented to cause vertebral osteomyelitis and septic arthritis of the sternoclavicular joint. The clinical manifestations of vertebral *P. aeruginosa* osteomyelitis are more indolent than those of staphylococcal osteomyelitis. The duration of symptoms in the addict population with vertebral osteomyelitis is generally prolonged, ranging from weeks to months. Tenderness of the affected region has to be elicited, and there may be a decreased range of motion. Low-grade fever is more likely to be encountered than the high fever associated more classically with staphylococcal osteomyelitis. Sternoclavicular and sacroiliac septic arthritis from *P. aeruginosa* is seen almost exclusively in intravenous drug users. It may occur with or without endocarditis, but a primary site of infection is often not found. Its causative role seems to lag behind *S. aureus* in the affliction of the sternoclavicular joint. *P. aeruginosa* is also a cause of bone infections when medical material is present, such as that used in orthopedic surgery or neurosurgery.

Pseudomonas osteomyelitis of the foot most frequently follows puncture wounds through sneakers. The bacterium has been found between the rubber sole layers of sneakers in many cases. Most of these cases are reported in children, but it is also seen in adults. The main manifestation is pain in the foot, and there may be superficial cellulitis around the puncture wound and tenderness on deep palpation of the wound. Also, a group of patients that seems prone to *Pseudomonas* infections are those with Charcot's arthropathy. Prolonged hospital stay and more surgical operations are associated with *P. aeruginosa* secondary bone infection in patients with Charcot's arthropathy. *P. aeruginosa* also has the potential to affect the diabetic foot, especially when there is high local prevalence of the bacterium, warm climate, and frequent exposure to water.

Central Nervous System Infections

Involvement of the central nervous system is almost always secondary to a surgical procedure or penetrating head trauma and is rare after bacteremia. The entities seen most often are postoperative or post-traumatic meningitis, subdural empyema, and epidural infections resulting from initial contamination of access areas. Brain abscess secondary to embolic disease from endocarditis may be seen. Extension of the infection in necrotizing malignant otitis to the brain heralds an ominous clinical course. The cerebrospinal fluid profile of *P. aeruginosa* meningitis is that of pyogenic meningitis. Brain abscess and epidural and subdural empyema generally require surgical drainage in addition to antibiotics.

Urinary Tract Infections

P. aeruginosa urinary tract infections usually occur as a complication of the presence of a foreign body, such as a catheter or stent in the urinary tract or an obstruction (mainly stone or malignant neoplasm) of the urinary system, or after instrumentation or surgery in the urinary tract. Notwithstanding the relationship between obstructive lesions and *P. aeruginosa* urinary tract infections, there have been descriptions of *P. aeruginosa* urinary tract infections in outpatient children and adults without relevant foreign bodies, stones, or other causes of evident obstruction. *P. aeruginosa* urinary tract infection frequently is associated with bacteremia.

Skin and Soft Tissue Infections, Including Burns

P. aeruginosa causes ecthyma gangrenosum in neutropenic patients. These are small, round lesions that occur either isolated or as aggregates. There is no skin site immune to their presence. More commonly, the limbs and the perineum are affected. The mouth may be involved as well. There is an evolution from vesicles to nodules that become hemorrhagic and necrotic and eventually ulcerate. Thus they best fit in the vesiculonodular type of skin lesion description. Secondary infection of chronic skin ulcers or burns can also occur. Maceration of normal skin, such as from soaking in a hot tub, can lead to superficial infection. Folliculitis and other papular or vesicular lesions have also been attributed to *P. aeruginosa*. Other types of skin and soft tissue involvement are cellulitis, abscesses, and myositis.

Burn wound infections by *P. aeruginosa* constitute one of the most significant problems caused by this organism. A distinct clinical picture of sepsis, in which high colony counts of *P. aeruginosa* exceed 10^5 organisms per gram of tissue, is the defining feature. Patients generally exhibit the progressive formation of a black necrotic eschar, with or without bacteremia. *P. aeruginosa* remains a major pathogen in settings in which burn patients have high rates of infection. The diagnosis may be made by culture of blood or by the pathognomonic clinical picture of an expanding burn lesion caused by infection with *P. aeruginosa*.

Endovascular Infections

P. aeruginosa may cause endovascular infections, including infective endocarditis, mainly of native valves but also of prosthetic ones. In intravenous drug users, the source is generally contaminated material, needles, or other paraphernalia; in this population, *P. aeruginosa* may even lead to outbreaks of endocarditis. The manifestations of *P. aeruginosa* endocarditis resemble those of other forms of acute endocarditis in addicts except that it appears to be more indolent than *S. aureus* endocarditis. *P. aeruginosa* endocarditis occurs also in non–intravenous injection drug users.

Gastrointestinal Infections

P. aeruginosa is a pathogen involved in complicated intra-abdominal infections,[9] usually as part of a polymicrobial infection. It is recovered in cases of secondary peritonitis, tertiary peritonitis, peritonitis associated with continuous ambulatory peritoneal dialysis, and intra-abdominal abscesses. Gastrointestinal infections due to *P. aeruginosa* include necrotizing enterocolitis in children and typhlitis in neutropenic patients (neutropenic enterocolitis).

Uncommon *P. aeruginosa* Infections

P. aeruginosa can cause a number of infrequently seen syndromes: noma neonatorum, a necrotizing mucosal and perianal infection of newborns; toe web infections; the "green nail syndrome" caused by *P. aeruginosa* paronychia as a result of diffusion of pyocyanin into the nail bed; and *Pseudomonas* hot-foot syndrome, which is manifested with tender plantar nodules. Shanghai fever is a sporadic community-acquired disease of previously healthy infants that is manifested as a necrotizing enteritis with fever and diarrhea and may lead to bowel perforation, seizures, and ecthyma gangrenosum. Laboratory parameters include leukopenia, thrombocytopenia, high C-reactive protein levels, coagulopathy, and hypoalbuminemia. The mortality is approximately 15%.

Infection due to *Pseudomonas* spp Other than *P. aeruginosa*

Infection due to other *Pseudomonas* spp may occur. *P. fluorescens* may lead to bacteremia associated with central venous catheters or transfusion-related bacteremia. Notably, a multistate outbreak due to contaminated heparinized

saline flush occurred in the United States. Reports of *P. stutzeri* infections include peritonitis, meningitis, endocarditis, pneumonia, bacteremia, and endophthalmitis. *P. putida* has been reported as a causative pathogen in bacteremia, pneumonia, cholecystitis, cholangitis, and skin and soft tissue infections.

DIAGNOSIS

Diagnosis rests on the culture of the pathogen from various human biologic samples or fluids pertinent to the clinical presentation. Newer methods, including multiplex polymerase chain reaction tests, which are based on the detection of the bacterial DNA, have received clearance from the Food and Drug Administration (FDA) for use in clinical practice. They are especially of value in the setting of the intensive care unit, where speed is important in decreasing the mortality associated with delay in treatment of sepsis. Serology is not helpful in the diagnosis of *P. aeruginosa* infections. Pulsed-field gel electrophoresis, restriction fragment length polymorphism, multilocus sequence typing, and random amplified polymorphic DNA polymerase chain reaction are used mainly for epidemiologic purposes.

The differential diagnosis lies between *P. aeruginosa* and pathogens that can lead to the same spectrum of diseases, especially in the hospital environment. External otitis, infection after a nail injury, or infection after immersion in water can provide some important clues that narrow the differential diagnosis spectrum in their respective settings. Nevertheless, diagnostic considerations have to include other pathogens as well. For example, fungal otitis has to be included in the differential diagnosis of external otitis as well as of other causes of earache.

In addition, the specific population of patients (e.g., neutropenic patients, patients with burns and wounds, CF patients, patients who have medically inserted equipment or foreign bodies) should be considered to have a high pretest probability of having a *P. aeruginosa* infection. Other types of infection in the hospital environment necessitate coverage for *Pseudomonas* until microbiologic data are available either from cultures or from molecular tests detecting the bacterium's DNA. A de-escalation protocol can then be performed to narrow the antibiotic spectrum.

At times, clinical acumen has to differentiate frank infection due to *P. aeruginosa* from colonization mainly on the basis of local symptoms and signs (pain, erythema, necrosis, exudate, edema, loss of function, dysuric symptoms, productive cough) or systemic symptoms and signs (fever, hypotension, tachycardia, dyspnea, hypoxia, rash, organ failure, radiologic change of previous imaging) of infection.

TREATMENT

Rx

Treatment of *P. aeruginosa* Bacteremia

Guidelines from the Surviving Sepsis Campaign for patients with severe infections associated with respiratory failure and septic shock suggest combination therapy with an extended-spectrum β-lactam and either an aminoglycoside or a fluoroquinolone for *P. aeruginosa* bacteremia. Empirical combination therapy should not be administered for more than 3 to 5 days. De-escalation to the most appropriate single-agent therapy should be performed as soon as the susceptibility profile is known.[10] This recommendation is based on the higher possibility that at least one of the antibiotics used will have activity against the potentially multidrug-resistant pathogen. This recommendation is not based on better synergistic effect between the two antibiotics. Indeed, evidence-based data from meta-analyses suggest that a combination may not provide an advantage in terms of clinical outcomes, such as cure of the infection, or less emergence of resistance. Furthermore, a combination of a β-lactam and an aminoglycoside carries a higher rate of nephrotoxicity. There is therefore currently a trend that a β-lactam/β-lactamase inhibitor (piperacillin-tazobactam) or an antipseudomonal carbapenem (meropenem or imipenem-cilastatin) may be used alone as monotherapy without compromising patient outcomes. Nevertheless, monotherapy with an aminoglycoside is not suggested as it is associated with poor clinical outcomes. Local in vitro antimicrobial susceptibility data regarding the level of resistance of local clinical isolates of *P. aeruginosa* to various antibiotics have to be taken into consideration.[11]

Removal of an infected vascular catheter or another infected foreign device (urinary catheter, implant) may be needed to control device-related infection due to *P. aeruginosa*. Source control of an infection nidus (drainage of an abscess or empyema, excision of necrotic tissue) is also of paramount significance.

Depending on the antibiotic susceptibility of *P. aeruginosa* isolates routinely found in a specific setting, one of the following regimens would be appropriate for *P. aeruginosa* bacteremia, provided renal function as assessed by creatinine clearance is relatively normal (>50 to 60 mL/minute): intravenous piperacillin-tazobactam, 3.375 to 4.5 g every 6 to 8 hours; ceftazidime, 2 g every 8 hours; cefepime, 2 g every 8 to 12 hours; meropenem, 1 to 2 g every 8 hours; imipenem, 0.5 to 1 g every 6 hours; doripenem, 0.5 g (1-hour infusion) every 8 hours; or aztreonam, 1.5 to 2 g every 6 to 8 hours (aztreonam has been used mainly for patients with β-lactam allergy). The addition of an aminoglycoside to the other regimens depends on the level of resistance to β-lactam antibiotics seen at any given institution. If administration of a second drug is indicated, amikacin 15 mg/kg every 24 hours may be added to the β-lactam antibiotic therapy. Addition of ciprofloxacin 400 mg every 8 to 12 hours IV (instead of an aminoglycoside) has been suggested to fare equally well.

Antibiotics that have to be considered on a compassionate basis if resistance to carbapenems with antipseudomonal spectrum is encountered include colistimethate sodium (polymyxin E or colistin parenteral form)[12] and polymyxin B. Two forms of colistin are commercially available: colistin sulfate and colistimethate sodium (also called colistin methanesulfonate, pentasodium colistimethanesulfate, and colistin sulfonyl methate). Colistimethate sodium is less potent than colistin sulfate. Specifically, activity as assessed biologically is 20,500 IU/mg for colistin sulfate and approximately 12,500 IU/mg for colistimethate sodium. Colistimethate sodium is produced by the reaction of colistin with formaldehyde and sodium bisulfite. Colistin sulfate is administered orally (tablets or syrup) in bowel decontamination regimens and topically as a powder for the treatment of bacterial skin infections. Colistimethate sodium is available in parenteral formulations. The term *colistin* throughout this chapter refers to the formulation of colistimethate sodium, except if otherwise specified.

The suggested dosage of intravenous colistin for adult patients with normal renal function is different for manufacturers in the United States and the United Kingdom. Specifically, recommended dosage in the United States is 2.5 to 5 mg/kg/day of colistin base activity (75,000 to 150,000 IU/kg), divided into two to four equal doses (1 mg of colistin base activity, ≈30,000 IU; 1 mg of colistimethate sodium activity, ≈12,500 IU). In the United Kingdom, the suggested dosage is 4 to 6 mg/kg/day of colistimethate sodium activity (50,000 to 75,000 IU/kg) in three divided doses for adults and children with body weight of 60 kg or less and 80 to 160 mg of colistimethate sodium activity (1 to 2 million IU) every 8 hours for body weight of more than 60 kg. However, we and others have treated patients with higher daily doses of intravenous colistin, up to 720 mg/day (9 million IU) in three divided doses. For serum creatinine level of 1.3 to 1.5 mg/dL, 1.6 to 2.5 mg/dL, or 2.6 mg/dL and higher, the dosage of intravenous colistin recommended by the manufacturers is 160 mg (2 million IU) every 12 hours, 24 hours, or 36 hours, respectively. During hemodialysis, the recommended dose is 80 mg (1 million IU) after each hemodialysis session. However, further studies are needed to better clarify the appropriate dosing regimens of colistin, especially for patients with renal dysfunction or failure. In a small study, on the basis of pharmacokinetic and pharmacodynamic data, a loading dose of intravenous 9 million IU of colistimethate sodium followed by 4.5 million IU every 12 hours was used successfuly.[13] When dosing colistin, clinicians should be aware of the existing differences in dosage recommendations based on the specific formulation of colistin used. Lately, the parenteral formulation of fosfomycin sodium has been used in various European countries in combination with other antibiotics with an antipseudomonal spectrum.[14]

Another important consideration is the prolonged intravenous infusion of the antibiotics to exploit the pharmacodynamic properties of β-lactams in the treatment of *P. aeruginosa* and other infections. β-Lactam antibiotics have time-dependent antimicrobial activity, and thus their concentration in blood achieved by their prolonged intravenous administration is above the minimum inhibitory concentration for longer periods (proportion of the time between doses above minimum inhibitory concentration). There are data, mainly from nonrandomized studies and a relevant meta-analysis, that support the fact that a prolonged infusion of piperacillin-tazobactam during 4 hours may provide a survival benefit.[15] Meropenem is usually infused in a relatively short infusion of 30 minutes; an extended meropenem infusion is one that extends to 3 hours. Doripenem should not be used in pneumonia according to an FDA warning based on a study comparing it with imipenem-cilastatin.

Despite the introduction of new broad-spectrum antibiotics in the antibiotic arsenal, one should remember that ertapenem, ceftaroline, and tigecycline do not possess antipseudomonal activity.

Treatment of Pneumonia

The principles of treatment that apply to bacteremia are also the basis for treatment of pneumonia. Patients with nosocomial pneumonia may have *P. aeruginosa* isolates resistant to many antibiotics, a problem that appears to be becoming progressively worse. Provided renal and liver function is normal, the following recommendations have been made by the American Thoracic Society and the Infectious Diseases Society of America: IV ceftazidime, 2 g every 8 hours; cefepime, 1 to 2 g every 8 to 12 hours; imipenem, 500 mg every 6 hours or 1 g every 8 hours; meropenem, 1 g every 8 hours; or piperacillin-tazobactam, 4.5 g every 6 hours plus an aminoglycoside (amikacin 15 to 20 mg/kg once daily, with a trough level of less than 4 to 5 μg/mL for amikacin).

Aminoglycosides are not optimally active in the lungs at concentrations used for intravenous administration. The administration of aerosolized aminoglycoside may provide adequate drug levels in the tracheobronchial tree.

Tobramycin (300 mg inhaled daily) and inhaled aztreonam lysine (75 mg three times daily for 28 days) have shown safety and efficacy for CF patients and have FDA approval only in patients with CF. Another antibiotic that has been used in different parts of the world on a compassionate basis is the inhaled form of colistin. The effectiveness and safety of inhaled colistin in patients with CF have led to a revival of the use of the medication also in patients with *P. aeruginosa* infection in the critical care setting. Inhaled colistin does not have FDA approval.

Treatment of Other Infections

Standard therapy to treat meningitis due to *P. aeruginosa* includes ceftazidime or cefepime. Alternative therapies are aztreonam, ciprofloxacin, and meropenem; the addition of aminoglycosides to these alternatives should be considered as well. The duration of treatment extends to 3 weeks or 2 weeks after the first sterile cerebrospinal fluid culture. No antimicrobial agent has been approved by the FDA for intraventricular use, and the specific recommendations are not well defined. The daily intraventricular dose is 1 to 8 mg for gentamicin, 5 to 20 mg for tobramycin, 5 to 50 mg (usually 30 mg) for amikacin, 5 mg for polymyxin B, and 10 mg for colistin. The removal of all components of the infected shunt, in combination with appropriate antimicrobial therapy, appears to be the most effective treatment for cerebrospinal fluid shunt infections. The ventriculitis of the shunt infection appears to clear more rapidly with the drainage catheter still in place, and the presence of the catheter allows continued treatment of the hydrocephalus until the infection has cleared. Reshunting (placement of a new shunt) necessitates 10 to 14 days of sterile cerebrospinal fluid culture.

Formulations of aminoglycosides or fluoroquinolones for topical use are recommended for the treatment of keratitis. In cases in which involvement is extensive, ceftazidime or gentamicin may be given by subconjunctival injection. Therapy for endophthalmitis includes both systemic antibiotics at high doses to achieve better concentrations in the eye and intravitreal antibiotics. Ceftazidime has been the most frequently used antibiotic for this entity. Aminoglycosides are also injected subconjunctivally and by intraocular routes and sometimes given intravenously. Adjunctive surgery is generally performed to remove infected vitreous.

Management of otitis externa involves also the use of topical antibiotic agents (otic solutions). Protection of the ear from additional moisture and avoidance of further mechanical injury by scratching are also important. Aminoglycoside-containing otic solutions (neomycin plus polymyxin B and hydrocortisone) and quinolone-containing otic solutions (ciprofloxacin 0.2% or ofloxacin 0.3%) are the most frequently used. Gentle removal of debris and cleaning with a mixture of acetic acid, alcohol, and distilled water may also help. Chronically draining ears may require more intensive topical therapy.

Treatment of malignant external otitis involves débridement of the ear canal, including any necrotic tissue cartilage and adjacent bone, rather than extensive bone débridement or facial nerve decompression. Furthermore, treatment with ciprofloxacin or an antipseudomonal β-lactam (cephalosporin such as ceftazidime or cefepime, carbapenem, or monobactam) is necessary for a period of 6 to 8 weeks.

The majority of *P. aeruginosa* urinary tract infections are complicated. Urinary catheters, stents, or stones should be removed if possible to prevent relapse. In general, 7 to 10 days of antibiotic treatment will suffice, with up to 2 weeks for severe pyelonephritis. Quinolones (ciprofloxacin, levofloxacin) have the pharmacodynamic advantage of excellent concentrations in the urinary tract. Antipseudomonal β-lactam/β-lactamase inhibitors and carbapenems (doripenem is approved for the treatment of complicated and uncomplicated urinary tract infections and intra-abdominal infections) are equally acceptable, given their normally high levels of urinary excretion.

Management of *P. aeruginosa*–infected burn wounds is both surgical and medical. Extensive débridement of colonized eschar or necrotic tissue is required in addition to antibiotic treatment. Medical treatment follows the principles detailed in the bacteremia treatment section.

For treatment of chronic osteomyelitis due to *Pseudomonas*, ciprofloxacin has been used extensively. Experts infer that oral treatment is acceptable as an alternative to parenteral treatment.[16] Of note, an increased dosage of orally administered ciprofloxacin (750 mg twice a day) is used in the majority of the relevant studies. There are relatively few data regarding the appropriate duration of treatment. A duration of 6 to 12 weeks is most commonly reported.

Infections Caused by Organisms at One Time Classified as Pseudomonads

Most of these infections are due to members of the genus *Burkholderia*, including *B. cenocepacia*, a complex of about 10 related species previously referred to as genomovars that are phenotypically similar but distinguished primarily by nucleic acid sequences, as well as *B. mallei* and *B. pseudomallei*, causes of glanders and melioidosis, respectively.

S. maltophilia causes a variety of organ afflictions. It is manifested as pneumonia, acute exacerbation of chronic obstructive pulmonary disease, bacteremia, soft tissue and skin infection, cellulitis, myositis, osteomyelitis, catheter-related bacteremia or septicemia, meningitis, endophthalmitis, keratitis, scleritis, dacryocystitis, endocarditis, urinary tract infection, and biliary sepsis. One notices the commonalities with the clinical manifestations of *P. aeruginosa* as well as the commonalities regarding the sources of infection. Whereas it has been regarded as a rare pathogen in the past, this is far from the truth. Indeed, it is the 11th most frequently cultured microorganism in a U.S. multiple hospital study covering 1993 to 2004 (4.3% of 74,934 gram-negative bacilli). Furthermore, the prevalence of *S. maltophilia* in patients with CF has increased in a relevant study from 6% to 12.7% from 1995 to 2008. Selective media (vancomycin–imipenem–amphotericin B, gram-negative selective agar, BTB, and SM2i) have been developed to ease detection of *S. maltophilia*, especially because the pathogen is frequently co-cultured in samples of polymicrobial infections. Polymerase chain reaction amplification of 16 rRNA in blood has also been used. The bacterium is usually susceptible to trimethoprim-sulfamethoxazole, which is regarded as the first-choice antibiotic.[17] However, resistant strains are emerging. Other antibiotics that have been effective against *S. maltophilia* isolates include ciprofloxacin, ceftazidime, and ticarcillin-clavulanate; sometimes these are used in combination with trimethoprim-sulfamethoxazole. Inherent resistance to carbapenems is a notable characteristic of this bacterium.

Melioidosis is an infection due to *B. pseudomallei* and occurs mainly in Southeast Asia and Australia. A notable current addition to these geographic regions is the Indian subcontinent and Sri Lanka. One should also be aware of potential niduses in the Americas (Mexico and the northern part of South America) and Africa (Madagascar). Risk factors for acquisition of melioidosis include renal failure, diabetes mellitus, heavy alcohol consumption, chronic respiratory disease, thalassemia, glucocorticoid therapy, and cancer. It can also afflict immunocompetent travelers to the regions mentioned. Interestingly, there is a seasonal association with the rainy season in more than three quarter of cases. Clinical manifestations vary from asymptomatic infection to localized skin infection, pneumonia, and fulminant sepsis due to bacteremia. The formation of abscesses is a usual feature of the disease. Other manifestations include septic arthritis, osteomyelitis, prostatitis, neurologic manifestations such as brain stem encephalitis associated with cranial nerve palsies or myelitis with peripheral motor weakness, and kidney and spleen involvement. Suppurative parotitis, even bilateral in 10%, is a feature present in patients with melioidosis in Thailand and Cambodia. Parotitis afflicts mainly children. The bacterium may remain dormant and then reactivate. The portal of entry includes the respiratory system, the skin, and the gastrointestinal system. Indeed, recurrence of melioidosis is due to reactivation in approximately three quarters of cases. There is a need for prolonged treatment of the bacterium that entails a 2- to 4-week regimen of intravenous antibiotic administration: ceftazidime, 2 g every 8 hours; meropenem, 1 g every 8 hours; or imipenem, 1 g every 8 hours.[18] An extended course of oral eradication with trimethoprim-sulfamethoxazole for 3 to 6 months is necessary after initial intravenous antibiotics. In the case of allergy or adverse events, amoxicillin-clavulanate and doxycycline have been proposed as alternatives to trimethoprim-sulfamethoxazole. Of note, *B. pseudomallei* is a bioterrorism factor B, and thus appropriate infection control and notification of authorities are mandatory.

Glanders is an equine infection due to *B. mallei*. Humans acquire the disease from contact with horses or more rarely donkeys or mules in an occupational setting. It mainly is manifested with tracheobronchitis, pneumonia, skin lesions, or lymphadenopathy. The disease has been eradicated in many countries. Nevertheless, cases can occur especially in association with an occupational risk in veterinarians, veterinary students, farriers (hoof care workers), flayers (hide workers), transport workers, soldiers, slaughterhouse personnel, farmers, and horse fanciers. *B. mallei* remains a significant cause of zoonosis, and therefore appropriate veterinary surveillance is necessary, especially because *B. mallei* is also a significant bioterrorism agent (class B). Treatment of glanders in humans is based on limited data. The approach to treatment is similar to that used for melioidosis, with intravenous meropenem, imipenem, or ceftazidime initially and then oral trimethoprim-sulfamethoxazole for 3 to 12 months.

B. cepacia is a bacterial pathogen that is a plant and human pathogen. Its classification has evolved, as has its name. It was previously known as *Pseudomonas cepacia* and then *Xanthomonas cepacia*. *B. cepacia* belongs to the *B. cepacia* complex and is a pathogen mainly of patients with CF and chronic granulomatous disease. Relatively recent reports have implicated *B. cepacia* in infections of the lung, blood, and other sites in immunocompromised patients and even in immunocompetent patients and children in the hospital environment due to outbreaks. Aerosolized medications, chlorhexidine solutions, napkins, and prefabricated clothes along with horizontal transmission have led to significant morbidity and mortality. Patients with CF typically present initially with asymptomatic carriage. Nevertheless, progressive decline of lung function is associated with *B. cepacia*. The most dramatic presentation of the lung ailment is the cepacia syndrome, a fulminant lung infection often accompanied by bacteremia. Other types of infection include meningitis, pericarditis, endocarditis, cholangitis, peritonitis, and abscesses in the abdomen, perineum, or scrotum.

PREVENTION

Primary prevention of *Pseudomonas* infections applies to preventing pollution of water by *Pseudomonas*. This applies to both the public environment and the hospital environment. Outbreaks have been linked to aquatic

environments such as whirlpools, swimming pools, and spas. Thus, control of growth of this organism in the recreational environment by proper antibacterial treatment of water is essential, comparable to the control practiced in hospitals. Contamination of various equipment and devices (i.e., breast implants, ocular implants, and sinus irrigation devices) must be avoided. Handwashing cannot be emphasized enough in the prevention of infections due to *P. aeruginosa*, *S. maltophilia*, and *B. cepacia*. Hospital point-of-use water filtration has also been employed in the battle against *P. aeruginosa* and *S. maltophilia* infections. Barrier nursing practices may decrease horizontal transmission, especially in the critical care environment. Isolation of patients infected with extensively drug-resistant and pandrug-resistant *P. aeruginosa* and strict infection control measures (dedicated personnel and equipment, use of gowns and gloves) may be needed to avoid intrahospital spread. The most important measure is the washing of hands. Nevertheless, even antiseptic solutions may be contaminated by *P. aeruginosa*, *S. maltophilia*, and *B. cepacia*. Factors that shorten hospital length of stay and decrease the use of antibiotics are likely to decrease the incidence of these infections.

PROGNOSIS

P. aeruginosa infections carry a high mortality, even with treatment. Mortality rates of 26 to 36% have been reported. Differences also exist between appropriately and inappropriately treated *P. aeruginosa* infections, with mortality rates even double when inappropriate antibiotics are used. Furthermore, *P. aeruginosa* infections are associated with increased length of hospitalization and medical costs. Loss of vision is the grave outcome of ophthalmic infection. Antibiotic resistance associated with *P. aeruginosa* will most likely continue to pose an enormous burden on human lives and financial resources in years to come.

S. maltophilia infections are associated with attributable mortality of up to about 37% if they are not appropriately treated. Melioidosis is associated with a 14% mortality rate in Australia and up to 40% in countries in Southeast Asia when it is treated. Fortunately, reports of glanders are rare in humans. Mortality of glanders with treatment is about 40 to 50%. *B. cepacia* has a predilection for CF patients and often signals impaired overall prognosis in these patients. Furthermore, *B. cepacia* seems to adversely affect transplantation. Indeed, in patients presenting with the cepacia syndrome, survival is unusual. Furthermore, many transplant centers do not support transplantation when *B. cepacia* is present because of the grave prognosis associated with the infection in the post-transplantation period.

REVIEW QUESTIONS

1. Which of the following bacteria is most commonly associated with hospital-acquired infections in the United States?

A. *Stenotrophomonas maltophilia*
B. *Burkholderia cepacia*
C. *Pseudomonas aeruginosa*
D. *Burkholderia mallei*
E. *Burkholderia pseudomallei*

Answer: C Data from the National Healthcare Safety Network at the Centers for Disease Control and Prevention indicate that during 2009 to 2010, *P. aeruginosa* was responsible for 8% of a total of 69,475 hospital-acquired infections and was the sixth most frequent culprit among 81,139 pathogens. *S. maltophilia* is a pathogen responsible for hospital-acquired infections but ranks lower in frequency than *P. aeruginosa*. *B. pseudomallei* and *B. mallei* are not causes of hospital-acquired infections in the United States. However, these pathogens are bioterrorism factors B. *B. cepacia* is an important emerging pathogen that is associated with hospital-acquired infections in immunocompromised patients beyond its established role as a pathogen in cystic fibrosis patients. *B. cepacia* hospital-acquired infections rank much lower in frequency than hospital-acquired infections due to *P. aeruginosa*.

2. Which of the following statements regarding *Pseudomonas aeruginosa* is true?

A. It is a nonmotile gram-negative bacterium.
B. It is not the only cause of ecthyma gangrenosum.
C. Endocarditis due to the *P. aeruginosa* is always associated with high fever.
D. Ertapenem is effective as treatment against *P. aeruginosa*.
E. Tigecycline is effective as treatment against *P. aeruginosa*.

Answer: B Other causes of ecthyma gangrenosum include *Staphylococcus aureus, Aeromonas hydrophila, Klebsiella pneumoniae, Morganella morganii, Stenotrophomonas maltophilia, Citrobacter freundii*, and fungi (*Candida albicans, Aspergillus fumigatus*). *P. aeruginosa* is a motile bacterium. Ertapenem and tigecycline are not effective treatment against *P. aeruginosa*. Endocarditis due to *P. aeruginosa* is usually more indolent than endocarditis due to *S. aureus*. It is not always associated with high fever.

3. Which of the following patient groups is at increased risk for the development of *P. aeruginosa* infections?

A. Neutropenic patients
B. Patients with cystic fibrosis
C. Patients with Charcot's arthropathy
D. Patients requiring mechanical ventilation
E. All the above

Answer: E Neutropenia, Charcot's arthropathy, mechanical ventilation, and also burns, cystic fibrosis, cancer, transplantation, diabetes, steroid treatment, foreign bodies, hypogammaglobulinemia, and AIDS are associated with an increased risk for *P. aeruginosa* infection.

4. Which of the following is considered the drug of first choice for *Stenotrophomonas maltophilia*?

A. Doxycycline
B. Meropenem
C. Trimethoprim-sulfamethoxazole
D. Ciprofloxacin
E. Ceftazidime

Answer: C *S. maltophilia* has inherent resistance to carbapenems. Trimethoprim-sulfamethoxazole is the choice for first-line treatment. Ciprofloxacin and ceftazidime have been used in the treatment of *S. maltophilia* infections either alone or in combination but are not first-choice treatment. Tetracyclines have some activity against *S. maltophilia* but are not first-choice options for treatment.

5. The following are true regarding infection due to *Burkholderia pseudomallei* except which one?

A. Southeast Asia, Australia, the Indian subcontinent, and Sri Lanka are locations with an increased risk for this infection.
B. Risk factors for infection include renal failure, diabetes mellitus, and heavy alcohol consumption.
C. The infection is called melioidosis.
D. An extended eradication regimen with oral trimethoprim-sulfamethoxazole for 1 month is necessary to follow initial intravenous treatment.
E. Recurrence of melioidosis is due to reactivation.

Answer: D An extended oral eradication regimen with oral trimethoprim-sulfamethoxazole for 3 to 6 months (not only 1 month) is recommended to follow initial intravenous treatment for the treatment of melioidosis.

DISEASES CAUSED BY *ACINETOBACTER* AND *STENOTROPHOMONAS* SPECIES

KEITH S. KAYE AND ROBERT A. BONOMO

ACINETOBACTER SPECIES

DEFINITION

The Pathogen

Acinetobacter species are gram-negative aerobic bacteria that are coccobacillary in shape and are generally described as aerobic, non–lactose-fermenting, nonfastidious, nonmotile, catalase positive, and oxidase negative. Unique among microbial pathogens, the appearance of *Acinetobacter* species visualized with a Gram stain is highly dependent on the life cycle. In the early growth phases, *Acinetobacter* species appear rod shaped. In the stationary phase, they acquire a coccobacillary *Acinetobacter* spp. morphology.

In the context of this chapter, *Acinetobacter* species refers specifically to *Acinetobacter baumannii* and *Acinetobacter baumannii-calcoaceticus* complex. A full list of *Acinetobacter* species is provided in E-Table 307-1. Molecular methods used to identify and to classify *Acinetobacter* are listed in E-Table 307-2.

EPIDEMIOLOGY

Acinetobacter species can colonize all body surfaces and cause infection in almost any organ system. Consequently, there are a number of common clinical syndromes associated with infection by *Acinetobacter.* The most common infections are respiratory (pneumonia), blood stream (bacteremia), urinary tract, wound, skin and soft tissue, and burn infections; osteomyelitis secondary to trauma; and meningitis.[1,2] In general, infection is observed only in critically ill, immunocompromised, or injured hosts. Recently, infections by *Acinetobacter* spp. are being described in patients without significant medical problems from the community setting.

During the past several years, *Acinetobacter* spp emerged in the United States from a pathogen that was primarily found in intensive care units (ICUs) to one that can affect patients in non-ICU wards, patients in long-term care settings, and military personnel with combat injuries acquired in the Middle East.[3] Overall, there are few distinguishing features of *Acinetobacter* infection except for skin manifestations. The frequency of *Acinetobacter* infections is often greater in the summer than in other seasons.

CLINICAL MANIFESTATIONS

Pneumonia

Because of colonization of the oropharynx and tracheostomy tubes in patients on ventilators, the upper respiratory tract is the most common site for infection by *Acinetobacter* species. The two distinct syndromes associated with respiratory tract infection due to *Acinetobacter* are community-acquired pneumonia (CAP) and healthcare-associated pneumonia (HCAP). In tropical regions of China, Asia, Australia, and the South Pacific, CAP due to *Acinetobacter* species is increasingly recognized. In some locations, the incidence can exceed 15%. Reports have highlighted the emergence of *Acinetobacter* as a common cause of CAP in western China.[4] In Saudi Arabia, *Acinetobacter* is the most common pathogen associated with late-onset and recurrent ventilator-associated pneumonia (VAP) in one adult ICU.[5]

The common comorbid conditions predisposing to CAP due to *Acinetobacter* species are mainly chronic obstructive pulmonary disease (emphysema), renal disease, diabetes mellitus, and alcoholism. CAP due to *Acinetobacter* species appears to be associated with a high incidence of bacteremia, acute respiratory distress syndrome, sepsis, and death (mortality rates ≥50%). The reasons for these fulminant presentations are still unknown. Rarely, CAP due to *Acinetobacter* species can be manifested with consolidation and multiple lung abscesses.

More frequently, *Acinetobacter* species are a cause of HCAP, often manifested as VAP. In the United States, *Acinetobacter* species are the third leading cause of VAP. HCAP due to *Acinetobacter* largely resembles the clinical spectrum of gram-negative pneumonias (bilateral infiltrates, pleural effusion, cavitations, hypoxemia, and bacteremia). Most cases are described in patients on ventilators. The main factors associated with HCAP due to *Acinetobacter* species are mechanical ventilation, previous antibiotic exposure, ICU stay, surgery, and underlying pulmonary disease. The major challenge complicating nosocomial pneumonia due to *Acinetobacter* species is the frequent recovery of MDR and sometimes XDR strains. When isolates are MDR or XDR, the options for treatment are limited, and complications quickly arise. HCAP due to MDR *Acinetobacter* has been associated with excess lengths of stay and mortality, although some studies have reported similar outcomes compared with control patients matched by severity of illness and duration of ICU stay.

Bacteremia

Blood stream infection due to *Acinetobacter* species is often a consequence of infection of intravenous catheters (i.e., central line–associated blood stream infection or CLABSI) or is secondary to HCAP due to *Acinetobacter*. *Acinetobacter* is the ninth most common cause of CLABSI among U.S. hospitals reporting to the Centers for Disease Control and Prevention. Less commonly, wound infections can cause bacteremia. In most series,

E-TABLE 307-2 IDENTIFICATION AND TYPING METHODS USED TO CHARACTERIZE *ACINETOBACTER* SPECIES

16S rRNA gene restriction analysis
Amplified fragment length polymorphism
$bla_{\text{OXA-51}}$ gene amplification
Polymerase chain reaction coupled with electrospray ionization mass spectrometry
Multilocus sequence typing
Ribotyping
Restriction enzyme digestion of the 16S-23S rRNA intergenic spacer sequences
Sequence analysis of the 16S-23S rRNA gene spacer region
rpoB gene sequencing and its flanking spacers
Matrix-assisted laser desorption/ionization time-of-flight
Polymerase chain reaction–electrospray ionization/mass spectrometry

mortality associated with blood stream infection ranges from approximately 15 to 50%.

Urinary Tract Infection

Urinary tract infections are most commonly caused by enteric gram-negative bacilli; only rarely are these infections caused by *Acinetobacter* species. The indwelling bladder catheter has been implicated as the major risk factor for urinary tract infection (cystitis and pyelonephritis) due to *Acinetobacter* species.

Wound, Burn, and Skin and Soft Tissue Infections

In many clinical series to date, traumatic or postoperative wounds, burns, and skin and soft tissue infections (SSTIs) are the most common causes of *Acinetobacter* infections. Most likely, the combination of antibiotic use, colonization, and compromised or devitalized tissues is responsible. The spectrum of infection can extend from cellulitis to necrotizing fasciitis.

As a result of the outbreak of *A. baumannii* among military personnel in Iraq and Afghanistan, reports of severe wound infections and SSTIs caused by this pathogen are increasing in frequency. Necrotizing SSTI associated with *A. baumannii* occurs in hosts with underlying comorbidities (e.g., trauma, cirrhosis) and is often accompanied by bacteremia. *Acinetobacter* infection has become increasingly common among patients residing in burn units, sometimes resulting in unit-wide outbreaks. Multiple drug resistance and the presence of copathogens frequently complicate treatment. Most cases require surgical débridement and lead to substantial mortality. In addition, the use of central venous catheters and total parenteral nutrition is more common among patients with SSTIs. *Acinetobacter* species–associated SSTIs can be manifested with a peau d'orange appearance, with overlying tiny vesicles (Fig. 307-1), and, when untreated, can progress to necrotizing infection with bullae (hemorrhagic and nonhemorrhagic).

FIGURE 307-1 Cellulitis caused by *Acinetobacter baumannii*. There is characteristic edematous peau d'orange erythema, with associated vesicles that may coalesce to form nonhemorrhagic bullae. (From Guerrero DM, Perez F, Conger NG, et al. *Acinetobacter baumannii*–associated skin and soft tissue infections: recognizing a broadening spectrum of disease. *Surg Infect [Larchmt]*. 2010;11:49-57.)

Osteomyelitis

The conflicts in Iraq and Afghanistan highlighted the first cases of osteomyelitis due to *Acinetobacter* species. Before this time, rare cases of osteomyelitis occurring in soldiers were reported during the Korean and Vietnam wars. Most of the initial reports from the Middle East described "contiguous focus" osteomyelitis. These patients had open fractures or exposed bone, with gross findings of infection: purulence, necrotic tissue, or environmental contamination with exposed bone; temperature higher than 38° C; leukocyte count greater than 12,000/μL; and *Acinetobacter* species identified from culture of deep wound tissue obtained intraoperatively. Frequently, these infections require multiple surgical débridements of necrotic bone.

Meningitis

Acinetobacter meningitis is occasionally found in the post-neurosurgical setting, with mortality exceeding 15 to 30%. Infection often involves intraventricular catheters. Although *Acinetobacter* is an uncommon cause of meningitis from the community, the frequency is almost 4% in cases of hospital-acquired meningitis and almost 11% among patients with meningitis involving an indwelling intraventricular catheter. Treatment is problematic because some cephalosporins do not achieve high enough levels in cerebrospinal fluid to be effective and because of the increasing incidence of MDR and XDR *Acinetobacter* (see later).

DIAGNOSIS

There are now more than 30 different species in the genus *Acinetobacter*, and their classification and identification remain problematic for clinicians (to date, 38 species are known; 27 are named and 11 are unnamed genospecies).[6] Automated and biochemical systems are sometimes inaccurate for the identification of *Acinetobacter* species. The introduction of matrix-assisted laser desorption/ionization time-of-flight into the clinical laboratory may facilitate better diagnosis.[7]

TREATMENT Rx

An increasing number of strains of *Acinetobacter* species are resistant to all antibiotics, and these strains are often responsible for outbreaks in large hospitals. These multidrug-resistant (MDR) or extremely drug-resistant (XDR) strains are often resistant to three or more classes of antibiotics. Among the resistance genes found in *Acinetobacter* species are a large collection of genes encoding β-lactamases, aminoglycoside-modifying enzymes, and many efflux pumps. Even more concerning is the emergence of XDR strains of Acinetobacter that are resistant to carbapenems and ampicillin-sulbactam, leaving few treatment options.[8] Unfortunately, resistance to "last-line" agents, such as the cationic antimicrobial peptides colistin (polymyxin E) and its close relative polymyxin B, also occurs. Regrettably, colistin resistance is becoming more common as clinicians are forced to use this agent more frequently. In hospital environments, *Acinetobacter* species can withstand drying (desiccation) and may even be transmitted by aerosol/respiratory droplet. Combined with drug resistance, these characteristics create a formidable infection control challenge.

Increasing resistance to a variety of antimicrobial agents complicates the treatment of *Acinetobacter* species infections. In general, infections due to more resistant strains of *Acinetobacter* are associated with less favorable outcomes than are infections due to more susceptible strains. These worse outcomes are likely due in part to limited treatment options as well as delays in the time to implementation of effective antimicrobial therapy for patients with infections due to MDR and XDR *Acinetobacter* strains.

The treatment doses that follow all assume normal renal function; doses need to be adjusted on the basis of the degree of renal insufficiency. When it is susceptible, *Acinetobacter* is typically treated with sulbactam (in the formulation of ampicillin-sulbactam in the United States, 3 g IV every 6 hours); the carbapenems imipenem (500 to 1000 mg IV every 6 hours) or meropenem (500 to 1000 mg IV every 8 hours); or broad-spectrum cephalosporins.[9] Based on ampicillin component, aminoglycosides are an option for treatment of urinary tract infection. One must be cautious: susceptibility to imipenem does not always translate to susceptibility to meropenem, and susceptibility to ceftazidime does not always indicate that cefepime can be used. In addition, there are data suggesting that doripenem may be the carbapenem with the most in vitro activity.

Treatment of infection with XDR *Acinetobacter* is challenging.[10] Tigecycline (100 mg loading dose, then 50 mg IV every 12 hours) and minocycline (200 mg IV or PO initially, followed by 100 mg IV or PO every 12 hours) have good in vitro activity against many strains of XDR *Acinetobacter*. Some experts recommend higher maintenance dosages of tigecycline (100 mg IV every 12 hours) and minocycline (200 mg IV or PO every 12 hours). These agents are appropriate for treatment of SSTI, but because of poor serum concentrations and lack of clinical experience in the treatment of MDR and XDR *Acinetobacter*, monotherapy with these should be avoided for invasive infections such as bacteremia and pneumonia. Sometimes, there is no choice but to use tigecycline as it might be the only available agent with in vitro activity against infecting *Acinetobacter* strains.

Invasive infections, such as bacteremia, pneumonia, and deep wound infections, are often treated with a polymyxin antimicrobial, either colistimethate sodium (CMS, often referred to as colistin) or polymyxin B. If CMS is used, a loading dose of 5 mg/kg colistin base activity, with a maximum dose of

300 mg, should be administered, followed by daily administration of 5 mg/kg colistin base activity per day in divided doses every 8 hours. If polymyxin B is used, a loading dose of 2.5 mg/kg × 1 should be administered intravenously, followed by a dose of 1.5 to 2.5 mg/kg/day by continuous IV infusion or in divided doses every 12 hours infused during a period of 60 minutes.[11]

Clinicians often treat invasive infections due to XDR *Acinetobacter* with combination therapy, although there is a lack of prospective controlled data demonstrating the superiority of combination therapy. Agents often combined with the polymyxins include rifampin (10 mg/kg/day, not to exceed 600 mg), imipenem or meropenem, sulbactam (ampicillin-sulbactam), tigecycline or minocycline, and aminoglycosides. At the time of this writing, data obtained from clinical trials conducted in Italy suggest that rifampin may not add measurable benefit to the treatment of MDR or XDR *Acinetobacter* despite the in vitro efficacy of the combination. In addition, the benefit of aerosolized colistin has not yet been established. Interest is rising in the use of the combination of colistin and tigecycline or fosfomycin, but further studies are needed.

The major adverse effect of polymyxin therapy is nephrotoxicity.[12] Current advances have improved our understanding of the pharmacokinetics, pharmacodynamics, and dosing of the polymyxins, but this is still an emerging and changing field. There is promising interest in the use of antioxidants (e.g., ascorbic acid) to prevent nephrotoxicity, but these studies are still preliminary.

In cases of meningitis due to *Acinetobacter* species, treatment should be intravenous meropenem (2000 mg every 8 hours) plus the intraventricular administration of an aminoglycoside (gentamicin or amikacin, depending on susceptibilities). Intraventricular gentamicin is administered at a dose of 4 mg once daily every 1 to 3 days until clinical and microbiologic improvement occurs. Amikacin can be used in place of gentamicin at the dose of 30 mg once a day, if required. For cases of meningitis due to XDR *Acinetobacter*, intravenous CMS or polymyxin B should be supplemented with intraventricular or intrathecal administration of CMS 10 mg/day, colistin base activity, or polymyxin B 5 to 10 mg/day for the initial 3 days of therapy and then every other day.

PREVENTION

Infection prevention practices, including hand hygiene, use of contact precautions, maintenance of environmental cleanliness, and implementation of antimicrobial stewardship, can help prevent spread of *Acinetobacter* in the hospital. During outbreaks, cohorting of patients and use of dedicated staff to care for cohorted patients might be necessary to control spread. Removal of indwelling devices from patients, including vascular catheters and endotracheal tubes, can help prevent colonization and infection with *Acinetobacter*.

PROGNOSIS

Invasive infection due to *Acinetobacter* has been associated with crude mortality rates in excess of 50% and increases in duration of ICU stay of 6 days and duration of total hospital stay of more than 14 days. With appropriate early empiric therapy, however, the mortality rate for community-acquired infection can be as low as 11%.[13] By comparison, infections due to strains of MDR and XDR *Acinetobacter* are associated with increases in mortality and durations of hospitalization compared with more susceptible *Acinetobacter* strains.[14]

STENOTROPHOMONAS MALTOPHILIA

DEFINITION

Stenotrophomonas maltophilia has attracted significant attention because it is often MDR due to intrinsic and acquired factors. *S. maltophilia* contributes significantly to morbidity, but usually not mortality, in immunocompromised patients.

The Pathogen

S. maltophilia are gram-negative bacteria that need methionine for growth and, like *Pseudomonas aeruginosa* and *Acinetobacter* species, are non–lactose fermenters. *S. maltophilia* possess flagella that are multitrichous (more than one flagellum arising from the pole) and are distinguished from *P. aeruginosa* as oxidase negative. Colonies of *S. maltophilia* may appear pale yellow or lavender-green on blood agar plates. The organism emits a mild ammonia-like odor that is used for preliminary identification.[15]

S. maltophilia can colonize inanimate surfaces in the hospital, including catheters, intravenous fluid, water supplies, and hospital equipment. This pathogen may also survive in hospital-grade disinfectant. Other health care–associated sources of *S. maltophilia* include contaminated intravenous fluids, hospital water and ice supplies, nebulizers, dialysis machines, ventilator circuits, thermometers, blood gas analyzers, intra-abdominal balloon pumps, and central venous or arterial pressure monitors.

TABLE 307-1 RISK FACTORS FOR INFECTION BY *STENOTROPHOMONAS MALTOPHILIA*

Prolonged hospitalization or intensive care unit stay
Intravascular catheters
Indwelling devices
Mechanical ventilation or tracheostomy
Neutropenia or cytotoxic chemotherapy
Solid organ transplantation
Immunocompromised state
Mucositis
Malignant disease
Chronic lung disease (especially cystic fibrosis and chronic obstructive pulmonary disease)
HIV infection
Hemodialysis
Antibiotic exposure (especially to carbapenems, extended-spectrum cephalosporins, and fluoroquinolones)
Exposure to other patients with *S. maltophilia*

EPIDEMIOLOGY

Despite its harboring many resistance genes, little is known about the virulence of *S. maltophilia*. Nevertheless, a number of risk factors are associated with infection by *S. maltophilia* (Table 307-1).[16] Although *S. maltophilia* is regarded as primarily a nosocomial pathogen (it is the third most common nonfermenting gram-negative bacillus health care–associated pathogen), community-acquired infection can occur. *S. maltophilia* infection primarily affects patients who are immunocompromised (including patients with hematologic malignant neoplasms[17] and patients who underwent solid organ transplantation), patients cared for in ICUs who are mechanically ventilated, hemodialysis patients with intravascular catheters, neonates, and patients with cystic fibrosis. Colonization or infection with *S. maltophilia* among patients with cystic fibrosis (Chapter 89) has been associated with reduction in lung function.[18]

CLINICAL MANIFESTATIONS

Respiratory Tract

The respiratory tract is the most common site of isolation of *S. maltophilia* in the hospital. Surveillance programs reveal a rate of recovery of *S. maltophilia* from hospitalized patients with pneumonia of more than 3% in the United States. Nosocomial pneumonia due to *S. maltophilia* is often associated with significant pulmonary disease such as emphysema, bronchiectasis, lung transplantation, or endobronchial obstruction. In addition, many of these patients are on mechanical ventilators, have tracheostomy tubes in place, or are receiving broad-spectrum antibiotics. Among mechanically ventilated patients, it can be challenging to differentiate colonization due to *S. maltophilia* from infection. CAP due to *S. maltophilia* has been reported but is very rare.

The incidence of respiratory tract infection due to *S. maltophilia* in patients with cystic fibrosis (Chapter 89) is increasingly being reported. There may be clear links with resistance to antipseudomonal antibiotics (tobramycin, imipenem, ceftazidime) used to treat these patients. The presence of chronic *S. maltophilia* infection has been associated with increases in cystic fibrosis exacerbations, hospitalizations, need for lung transplantation, and mortality. It remains unclear whether *S. maltophilia* has a causative association with poor outcomes or is merely a marker for severe underlying disease.

Blood Stream Infection and Endocarditis

Bacteremia may be secondary to a respiratory, urinary, or gastrointestinal source but is most commonly due to infection of an indwelling intravascular device. In many cases, except for those involving intravenous catheters, the portal of entry is not apparent. Immunocompromised patients with indwelling intravascular catheters, including those with hematologic malignant disease, are at particularly high risk for CLABSI due to *S. maltophilia*. In cases of CLABSI due to *S. maltophilia*, removal of the infected catheter is an important component of management. On occasion, an environmental reservoir or contaminated vascular access device is linked to the presence of bacteremia. Intravenous drug users are at especially high risk for

TABLE 307-2 MECHANISMS OF RESISTANCE IN *STENOTROPHOMONAS MALTOPHILIA*

DRUG	MECHANISM OF RESISTANCE
β-Lactams, including imipenem	L1 and L2 β-lactamases Outer membrane permeability/efflux
Aminoglycosides	Aminoglycoside-modifying enzymes, transport

contaminating prosthetic valves with S. *maltophilia*. In the case of endocarditis, favorable outcomes are reported with antimicrobial therapy, but surgery may also be required.

Urinary Tract Infection

Although *S. maltophilia* is frequently recovered from urine specimens in patients with indwelling urinary catheters, the role of this organism as a pathogen in this setting is unclear.

Meningitis

Cases of central nervous system infection due to *S. maltophilia* are reported rarely. These are often associated with central nervous system devices or antecedent neurosurgery.

Skin and Soft Tissue Infection

S. maltophilia can be isolated from postoperative wounds, but its role as a pathogen in this setting is unclear. In contrast, *S. maltophilia* can cause burn wound sepsis, manifested as a syndrome very similar to ecthyma gangrenosum (Chapter 441) in immunocompromised oncology patients.

TREATMENT

Rx

As a pathogen that is an increasingly important cause of nosocomial infections, *S. maltophilia* exhibits intrinsic resistance to many antibiotics. The complexity of resistance genes and mechanisms is summarized in Table 307-2. Resistance to imipenem, piperacillin-tazobactam, ceftazidime, and aminoglycosides is common. Despite significant resistance to many agents, trimethoprim-sulfamethoxazole remains the drug of choice (10 to 15 mg/kg/day IV, based on the trimethoprim component).[19] Treatment duration is uncertain, but it is usually 14 days or longer. In addition, in vitro studies indicate that ticarcillin-clavulanate (3.1 g every 6 hours), minocycline (200 mg followed by 100 mg every 12 hours, not to exceed 400 mg in 24 hours), some of the fluoroquinolones, and tigecycline may be useful agents. Polymyxin-based regimens may serve as alternatives in the face of resistance to trimethoprim-sulfamethoxazole (see earlier for details regarding polymyxin treatment). New regimens attempting to combine tigecycline and colistin for invasive *S. maltophilia* infections appear promising. Aztreonam is effective against strains exhibiting resistance to β-lactams by metallo-β-lactamases.

PROGNOSIS

Among patients with VAP or bacteremia due to *S. maltophilia*, crude mortality rates in the range of 60% have been reported. The attributable mortality of invasive *S. maltophilia* infection has been reported to be between 12 and 37.5%,[20] but patients who receive early appropriate antibiotic therapy appear to do better.[21]

PREVENTION

Standard infection control practices including hand hygiene and thorough environmental cleaning can help prevent spread of *Stenotrophomonas* in the hospital. In outbreak settings, contact precautions and possibly cohorting of patients have been used to control spread.

REVIEW QUESTIONS

1. Your patient has a blood culture turn positive. The preliminary result from the laboratory indicates possible *Acinetobacter baumannii*. Which of the following agents is most likely to have in vitro activity against *A. baumannii*?

A. Ertapenem
B. Ampicillin-sulbactam
C. Piperacillin-tazobactam
D. Trimethoprim-sulfamethoxazole
E. Doxycycline

Answer: B Increasing resistance to a variety of antimicrobial agents complicates the treatment of *Acinetobacter* species infections today. When it is susceptible, *Acinetobacter* is typically treated with sulbactam (in the formulation of ampicillin-sulbactam in the United States at a dose of 3 g intravenously every 6 hours). Other options are the carbapenems imipenem and meropenem and the broad-spectrum cephalosporins. See treatment section under *Acinetobacter* species.

2. Your patient has a blood culture turn positive. The preliminary result from the laboratory indicates possible *Stenotrophomonas maltophilia*. Which of the following agents is most likely to have in vitro activity against *S. maltophilia*?

A. Ertapenem
B. Ampicillin-sulbactam
C. Piperacillin-tazobactam
D. Trimethoprim-sulfamethoxazole
E. Meropenem

Answer: D *S. maltophilia* is an increasingly important cause of the nosocomial infections, and it exhibits intrinsic resistance to many antibiotics. Nevertheless, trimethoprim-sulfamethoxazole remains the drug of choice, at a dose of 10 to 15 mg/kg/day intravenously, based on the trimethoprim component, and it is given for 14 days or longer with positive blood cultures. See treatment section under *Stenotrophomonas maltophilia*.

3. Your patient has been admitted to the intensive care unit because of respiratory failure. He is intubated and mechanically ventilated. The intensive care unit is in the midst of an *Acinetobacter* outbreak. What would be the most effective intervention to decrease risk for development of an infection due to *Acinetobacter* in your patient?

A. Extubate the patient and remove him from mechanical ventilation as soon as possible.
B. Institute contact precautions (i.e., gowns and glove precautions).
C. Prescribe prophylaxis for the patient with intravenous imipenem.
D. Clean frequently touched objects in the patient's room with bleach.
E. Prescribe prophylaxis for the patient with *Saccharomyces* through a nasogastric tube.

Answer: A During outbreaks in the hospital, cohorting of patients and use of dedicated staff to care for the cohorted patients might be necessary to control spread. Removal of indwelling devices from the patients, including vascular catheters and endotracheal tubes, can help prevent colonization and infection with *Acinetobacter*. See prevention section under *Acinetobacter* species.

4. You are managing a patient with a deep wound infection resulting from a combat injury that occurred in Iraq. After incision and drainage, preliminary results from operative cultures indicate growth of possible *A. baumannii*. The patient has an anaphylactic reaction to β-lactam antibiotics. Which agent would be most likely to be an effective therapeutic agent for the patient?

A. Aztreonam
B. Ciprofloxacin
C. Tigecycline
D. Chloramphenicol
E. Rifampin

Answer: C Since initial reports of the outbreak of *A. baumannii* among military personnel in Iraq and Afghanistan, reports of severe wound infections and skin and soft tissue infections by this pathogen have increased in frequency. Multiple drug resistance and the presence of copathogens frequently complicate treatment. Most cases require surgical débridement and are associated with substantial mortality. Tigecycline might be the only available agent with in vitro activity against this pathogen in this setting. See the section on wound, burn, and skin and soft tissues infections under clinical manifestations of *Acinetobacter* species.

5. Your patient with cystic fibrosis has colonization of the respiratory tract with *Stenotrophomonas maltophilia*. The patient asks you what the significance of this colonization is and what can be done. Which of the following is the most accurate answer?

A. Because *Stenotrophomonas* is only a colonizer, there is no association with poor outcomes.
B. Treatment of colonization with an active antimicrobial improves the outcomes of cystic fibrosis patients.
C. *Stenotrophomonas* increases mortality risk among cystic fibrosis patients primarily by causing necrotizing pneumonia.
D. Pneumonia due to *S. maltophilia* in a patient with cystic fibrosis is an indication for lung transplantation.
E. Colonization with *S. maltophilia* among patients with cystic fibrosis has been associated with reduction in lung function.

Answer: E Colonization or infection with *S. maltophilia* among patients with cystic fibrosis has been associated with reduction in lung function. See reference 15 and the epidemiology section under *Stenotrophomonas maltophilia*.

SALMONELLA INFECTIONS (INCLUDING ENTERIC FEVER)

JOHN A. CRUMP

DEFINITION

A member of the family Enterobacteriaceae, *Salmonella enterica* subspecies *enterica* includes more than 2500 serovars (also called serotypes) found in humans and other warm-blooded animals. These serovars may be associated with human asymptomatic intestinal carriage, intestinal infection, and invasive disease with extraintestinal infection. Each serovar designation follows the species name (e.g., *Salmonella enterica* subspecies *enterica* serovar Typhimurium) and is frequently abbreviated as simply *Salmonella* followed by the serovar name (e.g., *Salmonella* Typhimurium).

The Pathogen

Salmonellae are gram-negative, non–spore-forming bacilli. They are differentiated from other Enterobacteriaceae by biochemical tests. They ferment glucose, maltose, and mannitol but typically not lactose or sucrose. They reduce nitrates and do not produce cytochrome oxidase. Almost all salmonellae produce acid and gas with fermentation. Most *Salmonella* serovars cannot be distinguished by biochemical reactions. However, *Salmonella* Typhi may be preliminarily identified by its production of only trace amounts of hydrogen sulfide and diminished biochemical activity compared with other serovars.

Salmonellae can be differentiated into more than 2500 serovars by their somatic (O) antigens, which are composed of lipopolysaccharides and are part of the cell wall, and by their flagellar (H) and capsular (Vi) antigens. *Salmonella* serogroups were traditionally designated by letters based on O antigens (e.g., A, B, C1, C2). More recently, the growing number of serogroups has made it necessary to move to a numeric designation. During the transition, the traditional letter-based serogroup may be retained in brackets after the numeric designation (e.g., O:2 [A], O:4 [B], O:6,7 [C1], O:8 [C2]). Some of the important serovars and their serogroups are Typhi (group O:9 [D1]), Choleraesuis (group O:7 [C1]), Typhimurium (group O:4 [B]), and Enteritidis (group O:9 [D1]). *Salmonella* Enteritidis and Typhimurium are the most common nontyphoidal serovars causing human disease.

EPIDEMIOLOGY

Salmonella Typhi, *Salmonella* Paratyphi A, *Salmonella* Paratyphi B, *Salmonella* Paratyphi C, and *Salmonella* Sendai are either solely or almost exclusively pathogens of humans; they cause primarily enteric fever rather than diarrhea, and transmission between humans is usually through water or food. As a result of modern sewage and water treatment facilities and improved food safety practices, typhoid fever and paratyphoid fever have become rare in developed countries but remain a problem in countries that lack adequate sanitation and a safe water supply. There are usually fewer than 500 cases of typhoid fever each year in the United States, mainly acquired abroad[1]; in contrast, an estimated 26.9 million cases occurred globally in 2010.[2]

Other serovars of *Salmonella* (described here as nontyphoidal *Salmonella*) have reservoirs in warm-blooded animals and cause human foodborne illness after the consumption of contaminated meat or animal products, contamination of produce or water by animal feces or animal products, or contact with animals and their environments. Some nontyphoidal *Salmonella* serovars appear frequently in particular animal species, and human illness is often associated with exposure to these animals and their products. For example, *Salmonella* Enteritidis has a reservoir in chickens, and infection is often linked to the consumption of undercooked eggs and poultry products or exposure to live chicks. Such a relationship is less clear for some other nontyphoidal serovars (e.g., *Salmonella* Typhimurium). Foodborne nontyphoidal *Salmonella* was estimated to be associated with approximately 1.0 million domestically acquired illnesses and 378 deaths in the United States in 2006.[3] A disproportionate number of infections occur in July through October, probably related to warm weather. *Salmonella* infections are most common among infants and children younger than 5 years. Worldwide, nontyphoidal

Salmonella was estimated to cause 93.8 million diarrheal illnesses, 80.3 million food-borne illnesses, and 155,000 deaths in 2005.[4]

Antimicrobial Resistance

Salmonellae have become increasingly resistant to antimicrobial agents, usually by acquiring resistance transfer factors (e.g., plasmid mediated). It is thought that antimicrobial resistance in the human-restricted salmonellae (e.g., *Salmonella* Typhi) is driven primarily by antimicrobial use in humans, whereas antimicrobial resistance among the nontyphoidal salmonellae (e.g., *Salmonella* Typhimurium) is associated with the use of antimicrobial agents in farm animals. Among *Salmonella* Typhi isolated in the United States during 1999 to 2006, 13% were resistant to the traditional first-line antimicrobials ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole, and 38% showed decreased fluoroquinolone susceptibility. Resistance to extended-spectrum cephalosporins is rare in *Salmonella* Typhi and *Salmonella* Paratyphi. Among nontyphoidal *Salmonella* isolated from humans in the United States, resistance to three or more antimicrobial classes is common but declining, whereas resistance to ceftriaxone and nonsusceptibility to ciprofloxacin are uncommon but increasing.[5] Susceptibility breakpoints and interpretive criteria were established for azithromycin in 2015 in response to reports of *Salmonella* with elevated azithromycin minimum inhibitory concentrations.

PATHOBIOLOGY

Etiology

Salmonellae are transmitted by the ingestion of fecally contaminated food or water; contact with animals, their environments, and other fomites; and, rarely, close contact with infected persons (e.g., oral-anal intercourse). The ultimate sources of contamination are humans or animals that are acutely ill or are asymptomatic carriers.

Contaminated Animal Products

Salmonella infection in humans usually occurs from ingestion of contaminated animal food products, most often eggs, poultry, and meat. *Salmonella* Choleraesuis is associated with pig products, *Salmonella* Dublin with cattle and unpasteurized milk from cattle, and *Salmonella* Enteritidis with poultry and poultry products, including eggs. Fecal material on poultry and other animal carcasses can spread at slaughterhouses, such as when many poultry carcasses are placed in the same hot-water tank to remove feathers. *Salmonella* contaminating carcasses can multiply to high levels if meat or other animal products are not refrigerated. Human illness may result if such animal products are inadequately cooked or if utensils or other uncooked foods are cross-contaminated during preparation. A wide range of foods can be contaminated with animal or human feces, from production on the farm through consumption in the home. Reports of produce-associated *Salmonella* outbreaks, due to contamination by animal or human feces during production, are increasing.[6] *Salmonella* outbreaks have occurred from contaminated cheese, ice cream, vegetables, fruit, juice, and alfalfa sprouts.

Contaminated Food and Water

Contamination by Pets

Salmonella infections may be acquired after contamination of food or water with the feces of pet turtles, chicks, ducks, birds, dogs, cats, and many other species.

Contamination by Humans

Salmonella infection can also be acquired by eating food or by drinking water contaminated by human carriers who have not adequately washed their hands. Infection has been spread by the fecal-oral route among children, by contaminated enema and fiberoptic instruments, by diagnostic and therapeutic preparations made from animal or insect products (e.g., pancreatic extract, carmine dye), and from intentional or unintentional contamination of restaurant salad bars. Outbreaks of salmonellosis may occur in institutionalized patients, who are probably more prone to the development of *Salmonella* infections for three reasons. First, within institutionalized populations, there is an increased prevalence of underlying diseases that decrease host defense mechanisms against salmonellae, such as disorders of gastric acidity and intestinal motility; second, the use of antimicrobial agents modifies the normal, protective intestinal flora; and third, institutional food prepared in bulk may be more likely to be contaminated than are individually prepared meals. Outbreaks in nurseries and among the elderly in nursing homes are associated with the highest case-fatality ratios (>5%).

Contact with Animals and Their Environments

Both healthy and sick animals may harbor and shed *Salmonella*. Transmission of *Salmonella* from animals and their environment to humans occurs primarily by the fecal-oral route. Animal hides and saliva often harbor fecal organisms, and transmission can occur when persons pet, touch, feed, or are licked by animals. Transmission has also been associated with contaminated animal bedding, flooring, barriers, other environmental surfaces, and clothing and shoes. Contact with calves, turtles and other reptiles, rodents, and young poultry and their environments has been associated with *Salmonella* outbreaks. Humans may also become infected when animals come into contact with their food or water. Infections can be prevented by education, supervision of animal contact, provision and promotion of handwashing facilities, and separation of food handling and consumption from animal areas.[7]

Contact with Infected Persons

Close contact with persons shedding *Salmonella* is an occasional source of infection. Transmission has been documented among persons handling feces (e.g., parents changing the diapers of an infected infant) and is associated with certain sexual practices (e.g., oral-anal intercourse).

Pathophysiology

After the ingestion of organisms, the likelihood for development of infection, as well as the severity of infection, is related to the dose, the virulence of the *Salmonella* strain, and the status of host defense mechanisms. Usually at least 10^2 to 10^3 bacteria are required to produce clinical infection in a normal host. Higher inocula are associated with increased disease severity, whereas smaller inocula are more likely to result in transient intestinal carriage. Gastric acid serves as a host defense mechanism by killing many of the ingested organisms, and intestinal motility is probably another host defense mechanism. In the absence of or with a decrease in gastric acidity (e.g., in infants and the elderly; after gastrectomy, vagotomy, or gastroenterostomy; or with the use of drugs that reduce gastric acidity) and with decreased intestinal motility (e.g., the use of antimotility drugs), much smaller inocula can produce infection, and the infection tends to be more severe.

Administration of antimicrobial agents before the ingestion of salmonellae can markedly reduce the size of the inoculum needed to produce infection, presumably by reducing the concentration of protective bowel flora.

Although any *Salmonella* serovar can produce any of the *Salmonella* syndromes (transient asymptomatic carrier state, enterocolitis, enteric fever, bacteremia, and chronic carrier state), each serovar tends to be associated with certain syndromes much more frequently than with others. For example, *Salmonella* Anatum usually causes asymptomatic intestinal infection, whereas *Salmonella* Typhimurium generally causes enterocolitis. *Salmonella* Choleraesuis is more likely to produce bacteremia (often with metastatic infection) than asymptomatic infection or enterocolitis, and some serovars such as *Salmonella* Typhi and *Salmonella* Paratyphi are most likely to cause enteric fever as well as the chronic carrier state. Fortunately, most *Salmonella* serovars are of relatively low pathogenicity for humans. Therefore, although food products are commonly contaminated, large outbreaks tend to involve the more virulent serovars.

To produce infection, invasion must occur across the mucosa of the intestine. When the organisms reach the lamina propria, an influx of polymorphonuclear leukocytes serves as a host defense mechanism to prevent invasion of the lymphatics. Certain serovars seem to have a greater ability than others to invade the lymphatics and subsequently to produce bacteremia (e.g., *Salmonella* Choleraesuis and *Salmonella* Dublin, which commonly produce bacteremia after intestinal infection). Both the small intestine and the colon are involved in the inflammatory process.

In the case of *Salmonella* Typhi and other causes of enteric fever, salmonellae invade the mononuclear phagocytes in Peyer's patches in the ileum and mesenteric lymph nodes. Some intracellular salmonellae form a nonreplicating population of "persisters" that could provide a reservoir for relapsing infection; intracellular persistence is determined by conditions in the vacuolar environment of the infected cells.[8] Others multiply intracellularly and are carried through the lymphatic system and blood stream to the liver, spleen, bone marrow, and other parts of the reticuloendothelial system. Once in the reticuloendothelial system, they multiply intracellularly in mononuclear phagocytes and produce the systemic manifestations of enteric fever. The onset of fever is associated with bacteremia and the release of cytokines (e.g., tumor necrosis factor and interleukins) from mononuclear phagocytes.

Ulcerations over Peyer patches are responsible for the intestinal manifestations of enteric fever, such as pain, perforation, and bleeding.

In *Salmonella* enterocolitis, the organisms remain localized in the intestinal mucosa, and diarrhea results from the inflammation produced by polymorphonuclear leukocytes. In addition, watery diarrhea may occur, apparently the result of the secretion of water and electrolytes by small intestinal epithelial cells in response to an enterotoxin secreted by some of the *Salmonella* strains or in response to tissue mediators of inflammation.

Patients with diseases that impair host defense mechanisms seem to have an increased frequency of severe *Salmonella* infection. A striking association has been recognized between diseases producing hemolysis and *Salmonella* bacteremia. Specifically, *Salmonella* bacteremia is common in patients with sickle cell disorders, malaria, and bartonellosis. In fact, because of the frequency of *Salmonella* bacteremia in sickle cell diseases and the underlying bone disease in these patients to which salmonellae localize, these organisms are the most common cause of osteomyelitis in patients with sickle cell disorders (Chapter 163). Prolonged *Salmonella* bacteremia may occur in patients with hepatosplenic schistosomiasis, possibly related to localization on and in the intravascular schistosomes. Patients with lymphoma and leukemia are also more prone to the development of *Salmonella* bacteremia. A markedly increased frequency and severity of *Salmonella* infections in general have been observed in patients with human immunodeficiency virus (HIV) infection, particularly those with $CD4^+$ T-lymphocyte counts less than 200 cells/mm^3. Prolonged and recurrent, refractory *Salmonella* bacteremia is common among these patients. Other risk factors that increase the frequency and severity of *Salmonella* infection are extremes of age, immunocompromised states (e.g., from immunosuppressive agents), malnutrition, and probably diabetes. Nontyphoidal *Salmonella* serovars are a leading cause of community-acquired blood stream infection in sub-Saharan Africa, where children younger than 3 years and HIV-infected adults carry most of the burden of invasive disease.[9]

CLINICAL MANIFESTATIONS

Asymptomatic Intestinal Carrier State

The asymptomatic intestinal carrier state may result from inapparent infection (which is the most common form of *Salmonella* infection), or it may follow clinical disease (in which case the patient becomes a convalescent carrier). The carrier state is usually self-limited to several weeks to months, with the prevalence of positive stool cultures rapidly decreasing over time. By 1 year, far less than 1% of carriers still have positive stools. The main exception is *Salmonella* Typhi; about 3% of those infected excrete the organism for life. Women and older men are most likely to become chronic carriers of *Salmonella* Typhi, related to the presence of biliary tract disease, especially calculi. A patient who has had salmonellae in stool for 1 year (chronic carrier) is likely to become a lifelong carrier; the reservoir is in the biliary tree, usually in calculi in the gallbladder. Patients with *Schistosoma haematobium* infection are predisposed to become chronic urinary carriers of salmonellae.

Enterocolitis

After an incubation period of usually 12 to 48 hours, the illness starts suddenly with crampy abdominal pain and diarrhea. Nausea and vomiting may occur but are usually not prominent or persistent. The diarrhea may be watery and of large or small volume. Stools may contain mucus and are occasionally bloody. Polymorphonuclear leukocytes are present in the stool. Diarrhea may be mild or severe, with up to 20 to 30 stools a day. Fever is present in most patients, and the temperature may reach 40°C (104°F) or higher. The abdomen is tender to palpation. Transient bacteremia may occur and is most commonly seen in infants, the elderly, and patients with impaired host defense mechanisms.

Symptoms generally improve during a period of days, with fever lasting no more than 2 to 3 days and diarrhea lasting no more than 5 to 7 days. However, these symptoms occasionally persist for up to 14 days. More severe disease is seen with malnutrition, inflammatory bowel disease, and HIV infection. Reactive arthritis may follow enterocolitis in up to 7% of cases, especially among those with the HLA-B27 phenotype.

Enteric Fever

Enteric fever is produced by *Salmonella* Typhi (typhoid fever), *Salmonella* Paratyphi A, B, and C (paratyphoid fever), and occasionally other serovars. Sometimes it immediately follows classic enterocolitis caused by the same organism. The syndrome is characterized by prolonged, sustained fever and may be associated with relative bradycardia, splenomegaly, rose spots, and leukopenia. In Africa, the common symptoms of invasive nontyphoidal *Salmonella* disease, which is seen predominantly in patients with HIV infection, malaria, and malnutrition, are fever, hepatosplenomegaly, and respiratory symptoms; features of enterocolitis are often absent.[10]

Therapy aborts the course of the disease. The following is a description of untreated illness. After an incubation period of 5 to 21 days (generally 7 to 14 days), fever and malaise develop, often associated with cough. A small proportion of patients may have diarrhea during the incubation period. The fever tends to rise in a stepwise fashion during the first few days to a week and then becomes sustained, usually at 39.4° to 40.0°C (103° to 104°F) or higher. Relative bradycardia is seen in up to half of patients. Apathy, confusion, delirium, and even psychosis may occur. Abdominal distention, pain, and tenderness may occur in the first week and may be associated with diarrhea or constipation; these symptoms are generally more pronounced during the second week of fever. Most patients have abdominal tenderness during the course of the illness.

In about 30% of patients, rose spots develop on the abdomen or chest (or both) toward the end of the first week or during the second week of fever. These faint, salmon-colored maculopapular lesions are subtle and may be difficult to see, particularly in dark-skinned patients. Salmonellae can be cultured from punch biopsies of these lesions. Hepatosplenomegaly occurs in about half of patients. Leukopenia and neutropenia are seen in about 20%. Abnormal liver function test results are common.

After 2 weeks of illness, the severe complications of intestinal hemorrhage and perforation related to necrosis of Peyer patches may be observed in about 5% of patients. These perforations may require surgical as well as medical therapy and can occur even in a patient treated with antimicrobials. Intestinal perforation is the leading cause of death from enteric fever.

The illness usually resolves by the end of the fourth week in an untreated patient. Relapse may occur in untreated as well as in treated patients, but the illness is milder than the original episode.

Rarely, some of the following complications may occur: pancreatitis, cholecystitis, infective endocarditis, meningitis, pneumonia, hepatic or splenic abscess, orchitis, or focal infection at virtually any site.

Bacteremia

Patients with *Salmonella* bacteremia usually complain of fever and chills lasting days to weeks. Gastrointestinal symptoms are unusual, but in some patients *Salmonella* bacteremia follows classic enterocolitis. Other symptoms are nonspecific, such as malaise, anorexia, and weight loss. Metastatic infection of bones, joints, aneurysms (particularly of the abdominal aorta), meninges (mainly in infants), pericardium, pleural space, lungs, heart valves, cysts, uterine myomas, malignant neoplasms, and other sites is common, and symptoms may be related to the site of metastatic infection. Stool cultures are often negative for salmonellae, but blood cultures are positive.

Although any *Salmonella* serovar can produce bacteremia, *Salmonella* Dublin, *Salmonella* Choleraesuis, *Salmonella* Heidelberg, *Salmonella* Oranienburg, *Salmonella* Panama, and *Salmonella* Sandiego are associated with increased likelihood of bacteremia.

Salmonella bacteremia occurs with increased frequency in infants, the elderly, and patients with diseases associated with hemolysis (e.g., sickle cell diseases, malaria, bartonellosis), HIV infection, lymphoma, leukemia, disseminated histoplasmosis, and perhaps systemic lupus erythematosus. Localization to bone is common in patients with sickle cell diseases (Chapter 163).

Prolonged *Salmonella* bacteremia lasting for months may occur in patients with hepatosplenic schistosomiasis. In patients with HIV infection, recurrent, relapsing *Salmonella* bacteremia may develop, which may be difficult to cure with antimicrobial agents.

DIAGNOSIS

Although *Salmonella* enterocolitis is an invasive disease, the differential diagnosis includes all causes of acute diarrhea, including invasive bacteria such as *Campylobacter jejuni, Shigella* species, invasive *Escherichia coli, Yersinia enterocolitica,* and *Vibrio parahaemolyticus;* toxigenic bacteria such as *Vibrio cholerae,* enterotoxigenic *E. coli,* enterohemorrhagic *E. coli* (e.g., *E. coli* O157:H7), *Staphylococcus aureus, Bacillus cereus, Clostridium perfringens,* and *Clostridium difficile;* viruses; and protozoa such as *Entamoeba histolytica, Giardia intestinalis,* and *Cryptosporidium* species. The invasive bacterial causes of diarrhea, enterohemorrhagic *E. coli* and *C. difficile* infection, are also associated with polymorphonuclear leukocytes in stool, whereas bacterial toxigenic causes (other than *C. difficile* and enterohemorrhagic *E. coli*), viruses, and protozoa

generally are not. The bacterial toxigenic causes of diarrhea other than *C. difficile* and enterohemorrhagic *E. coli* do not produce fever.

Stool culture is definitive for the diagnosis of *Salmonella* enterocolitis, but by the time the results of stool culture are available, most patients are recovering. A stained smear of the stool usually demonstrates polymorphonuclear leukocytes. Serologic studies are of little clinical value in *Salmonella* enterocolitis, but they may be of use in epidemiologic studies.

The differential diagnosis of *Salmonella* bacteremia includes virtually all acute infectious and noninfectious causes of fever, including bacteremia caused by other organisms. The diagnosis is proved by isolation of the microorganism from blood or from another normally sterile site.

The differential diagnosis of enteric fever is broad and depends in part on the area of the world where the infection was acquired. All causes of sustained fever are in the differential diagnosis, including infective endocarditis, disseminated tuberculosis, brucellosis, tularemia, *Mycoplasma pneumoniae* infection, rickettsial infections, Q fever, and viral infections such as infectious mononucleosis. Depending on the site of acquisition, diseases such as malaria, amebic abscesses of the liver, and visceral leishmaniasis also enter into the differential diagnosis.

The diagnosis of enteric fever is best proved by isolation of the microorganism from blood, stool, or bone marrow.[11] During the first week of illness, blood cultures are positive in about 90% of patients, but culture positivity decreases in the next 2 weeks to less than 50% during the third week of illness. Stool cultures are usually negative during the first week but are generally positive by the third week. Bone marrow cultures give the highest yield, with up to 95% being positive; they should be considered in suspected cases with negative blood cultures. Bone marrow cultures may be positive even after several days of antimicrobial treatment, when blood cultures have become negative. Urine cultures and cultures of punch biopsies of rose spots may also be positive. The string test to obtain samples of bile from the duodenum has also yielded positive cultures.

The peripheral leukocyte count is usually normal, but leukopenia, which occurs in about 20% of cases, may be suggestive of enteric fever. Fecal leukocytes are generally present.

The Widal and other serologic tests that detect serum antibodies against *Salmonella* Typhi are limited by shortcomings of both sensitivity and specificity and rarely provide useful information to guide management of the patient. Polymerase chain reaction and other molecular techniques lack sensitivity for diagnosis from blood and other specimens, but they have been used to determine the *Salmonella* serovar of bacterial isolates.

TREATMENT Rx

Enterocolitis

The primary approach to the treatment of *Salmonella* enterocolitis is fluid and electrolyte replacement. Drugs with antiperistaltic effects, such as loperamide or diphenoxylate with atropine, can relieve cramps, but they should be used sparingly because they can prolong the diarrhea.

Salmonella enterocolitis is self-limited, and antimicrobial therapy is usually not indicated, except perhaps in groups of patients at high risk for invasive disease. Antimicrobial therapy reportedly has little effect on the clinical course, and in some studies, it has prolonged the duration of *Salmonella* excretion in stool. In addition, most patients are improving by the time salmonellae or other bacterial pathogens are isolated from stool.

The fluoroquinolones are active against virtually all bacterial pathogens that cause diarrhea (including salmonellae), except for *C. difficile* and many *Campylobacter* organisms. Thus, it is reasonable to use fluoroquinolones for patients with suspected or known *Salmonella* enterocolitis who are severely ill and suspected of being bacteremic. The threshold for antimicrobial treatment is also decreased in those at increased risk for severe illness (e.g., infants, the elderly, patients with sickle cell disease, immunosuppressed individuals). As an example, in adults, ciprofloxacin, 500 mg every 12 hours orally or 400 mg every 12 hours intravenously for 3 to 5 days, or until defervescence, has been widely used. An extended-spectrum cephalosporin such as ceftriaxone is an alternative. In the presence of gross bloody diarrhea, antimicrobial therapy should be withheld until the possibility of *E. coli* O157:H7 infection has been eliminated because antimicrobial therapy may increase the frequency of hemolytic-uremic syndrome.

Other agents, such as amoxicillin and trimethoprim-sulfamethoxazole, have also been widely used in severely ill adults. However, many strains of *Salmonella* are now resistant to these agents.

Enteric Fever

Resistance to the traditional first-line antimicrobial agents (ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole) has emerged worldwide among the salmonellae causing enteric fever. Consequently, alternative antimicrobial agents are now preferred.

The fluoroquinolones have become the agents of choice for the treatment of enteric fever, for several reasons. They can be administered orally and have high bioavailability, they concentrate in bile and the bowel, and they often retain activity against multidrug-resistant strains of *Salmonella* Typhi and other causes of enteric fever. Most important, the fluoroquinolones have proved to be effective in the treatment of enteric fever, even with short courses (e.g., 3 to 7 days). The proportion of patients cured exceeds 95%, and relapse and chronic fecal carriage after therapy are uncommon. Ciprofloxacin (500 mg orally twice a day) for 7 to 14 days has been the fluoroquinolone of choice for enteric fever. If a patient cannot tolerate oral therapy, the fluoroquinolones can be administered intravenously. Reduced susceptibility and resistance to fluoroquinolones are increasingly reported in *Salmonella* Typhi and *Salmonella* Paratyphi strains both in the United States and elsewhere and are associated with treatment failure. If decreased fluoroquinolone susceptibility or resistance is suspected or demonstrated, alternative agents include extended-spectrum cephalosporins (e.g., intravenous ceftriaxone) and azithromycin.

Extended-spectrum cephalosporins such as ceftriaxone are reliable agents for the treatment of enteric fever. Ceftriaxone dosed at 1 to 2 g every 12 to 24 hours for adults and 75 mg/kg/day for children, given intravenously or intramuscularly for 10 to 14 days, results in cure of 95% of patients. Resistance to ceftriaxone has been described in clinical strains of *Salmonella* Typhi, but this occurs rarely.

If the *Salmonella* isolate is shown to be susceptible by antimicrobial susceptibility testing, ampicillin, chloramphenicol, or trimethoprim-sulfamethoxazole may be considered. The ampicillin dose is 25 mg/kg intravenously every 6 hours. The use of chloramphenicol should be weighed against the risk of bone marrow toxicity. The chloramphenicol dose is 50 mg/kg/day orally, divided into four doses. Chloramphenicol can be given intravenously at the same dose if oral therapy is not possible. Trimethoprim-sulfamethoxazole (4/20 mg/kg intravenously or orally every 12 hours) is given for 10 to 14 days.

Azithromycin (10 mg/kg/day orally for 7 days) is effective in the treatment of patients with uncomplicated typhoid fever caused by multidrug-resistant strains. The oral route of administration makes it a particularly attractive choice in settings where multidrug resistance is common and intravenous extended-spectrum cephalosporins are impractical, unavailable, or too expensive.

Patients often require supportive care with intravenous saline, correction of electrolyte and acid-base disturbances, and, in the setting of intestinal bleeding, blood transfusion. If perforation is suspected, abdominal imaging should be performed to evaluate for free air. If perforation seems likely, laparotomy should be performed as soon as possible to repair the perforation. In the setting of perforation, antimicrobial therapy should be broadened to cover bowel flora.

Steroid therapy is beneficial in some patients with severe enteric fever and coma, delirium, or shock. Dexamethasone is administered at doses of 3 mg/kg initially, followed by 1 mg/kg every 6 hours for 48 hours. Steroids can mask the signs and symptoms of abdominal perforation and should not be continued for more than 48 hours. Salicylates should be avoided.

Relapses of typhoid fever may be treated with the same antimicrobial regimen as the initial attack.

Bacteremia

The agents of choice to treat *Salmonella* bacteremia are the fluoroquinolones, such as ciprofloxacin, and the extended-spectrum cephalosporins, such as ceftriaxone. Typical doses are ciprofloxacin 400 mg every 12 hours intravenously and ceftriaxone 1 to 2 g every 12 to 24 hours intravenously. When the salmonellae are known to be susceptible, ampicillin 1 to 2 g intravenously every 4 to 6 hours or trimethoprim-sulfamethoxazole 8 mg/kg/day (of the trimethoprim component) intravenously can be used. Chloramphenicol is another option. Antimicrobial susceptibility testing is necessary because of the emergence of infections resistant to the fluoroquinolones or extended-spectrum cephalosporins.

In cases of sustained bacteremia, the possibility of endovascular infection should be investigated. For transient bacteremia or bacteremia without localization, therapy is continued for 7 to 14 days. With localization to bone, aneurysms, heart valves, and various other sites, antimicrobial therapy should be given for much longer periods (e.g., 6 weeks). Surgical drainage, removal of foreign bodies, or resection of an aneurysm is often necessary to cure localized infection. The possibility of schistosomiasis should be considered and treated, when present, in patients with sustained *Salmonella* bacteremia (Chapter 355). Patients with HIV infection tend to experience repeated relapses after treatment courses for *Salmonella* bacteremia. In this group, initial treatment with ciprofloxacin for 2 weeks or longer is recommended. Long-term suppressive therapy has been suggested for those experiencing frequent relapses.[12]

Carriers

Chronic carriers (i.e., >1 year) of salmonellae other than *Salmonella* Typhi are rare. Stools of convalescent carriers spontaneously become negative

during a period of weeks to months, and no therapy should be given. The rare chronic carrier of *Salmonella* serovars other than Typhi (usually infected with *Salmonella* Paratyphi A, B, or C) may be treated with a fluoroquinolone, amoxicillin, or trimethoprim-sulfamethoxazole in the doses listed later for 4 to 6 weeks. Patients who experience relapse usually have gallbladder disease (most often calculi) and will not be cured with antimicrobial therapy alone. Cholecystectomy plus antimicrobial therapy may cure these patients, but it is doubtful that the carrier state is a sufficient indication for cholecystectomy.

Chronic fecal carriers of *Salmonella* Typhi can be treated with ciprofloxacin (500 to 750 mg twice daily) for 6 weeks or with amoxicillin at doses of 6 g/day in three or four divided doses plus probenecid 2 g/day in divided doses for 6 weeks. Trimethoprim-sulfamethoxazole (160/800 mg twice daily) plus rifampicin (300 mg twice daily) for 6 weeks may be considered as an alternative regimen. Patients with persistent urinary carriage and *S. haematobium* infection should be treated with praziquantel before eradication of *Salmonella* Typhi is attempted. For patients with persistent carriage and anatomic abnormalities (e.g., gallstones), cholecystectomy combined with antimicrobial therapy is often necessary. For patients with persistent carriage despite adequate antimicrobial therapy and without an identifiable anatomic abnormality, chronic suppressive therapy may be considered. Chronic carriers who do not prepare food and who practice adequate personal hygiene usually do not constitute a public health hazard. Therefore, after the institution of appropriate personal hygienic precautions, and in the absence of evidence of a chronic carrier infecting others, cholecystectomy is probably not indicated to eradicate the carrier state.

PREVENTION

Salmonella infection is best prevented by protecting the water supply, preventing fecal contamination during food production, cooking and refrigerating foods, pasteurizing milk and milk products, and handwashing before preparing foods. Travelers should judiciously avoid consuming untreated water (including ice), raw vegetables, and fruits. Food should be cooked or peeled, and drinks should be boiled, carbonated, or commercially bottled. The widespread presence of salmonellae in the animal kingdom means that reducing the risk for *Salmonella* infections requires a multifaceted approach.

There is no vaccine for *Salmonella* infection other than that for *Salmonella* Typhi. Travelers should be vaccinated before going to areas that are endemic for typhoid fever.[13] Two vaccines are available in the United States. One is the typhoid Vi capsular polysaccharide vaccine, which is administered as a single intramuscular injection, with booster doses given every 2 years if needed. This vaccine provides a degree of herd protection against typhoid fever when it is used at the population level. The other licensed typhoid fever vaccine is the oral live attenuated Ty21a vaccine. Revaccination is necessary every 5 years, if indicated. Ty21a vaccine should not be used in immunocompromised persons or those receiving antimicrobials. Both these vaccines confer greater than 75% protective efficacy. Efforts are under way to develop typhoid vaccines that are effective in young children.

Vaccines afford only partial immunity to typhoid fever. Persons who have been vaccinated should still restrict their diets to avoid potentially contaminated food and fluids. When cases of imported typhoid are identified in the United States, the local health department should be informed and will monitor stool cultures. Typhoid fever acquired in the United States is typically investigated by the public health department to identify potential sources and chronic carriers.

PROGNOSIS

Mortality in patients with *Salmonella* enterocolitis is rare; infants and the elderly are at greatest risk, with death occurring as a result of dehydration and electrolyte imbalance. Mortality from *Salmonella* bacteremia is not uncommon and is most likely to occur in the very young, the very old, the malnourished, and the immunocompromised.

Before the advent of antimicrobial therapy, typhoid fever had a case-fatality ratio of 15 to 20%. This has been reduced to less than 1% in industrialized countries. However, the case-fatality ratio remains high in some developing countries. The case-fatality ratio of invasive nontyphoidal *Salmonella* in Africa is approximately 20%. In treated patients, the temperature usually returns to normal after 3 to 5 days of therapy, but this may take longer in patients treated with extended-spectrum cephalosporins than in those treated with fluoroquinolones and in those infected with isolates with decreased fluoroquinolone susceptibility who are treated with ciprofloxacin.

In the era before antimicrobial therapy, 5 to 10% of patients who recovered from typhoid fever had relapses. Relapses continued to occur in 10 to 15% of patients treated with chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole, but this seemed to be much less frequent (<5%) among those treated with ceftriaxone and fluoroquinolones. Intestinal bleeding or perforation occurs in about 5% of patients. With perforation, case-fatality ratios of 10 to 30% have been reported. Up to 3% of patients recovering from *Salmonella* Typhi infection become chronic fecal carriers.

REVIEW QUESTIONS

1. Regarding antimicrobial resistance among *Salmonella* Typhi isolated in the United States, which of the following is *true*?

A. Ceftriaxone resistance occurs in the majority of strains.
B. Decreased fluoroquinolone susceptibility is seen in more than a third of isolates.
C. Multiple drug resistance is not observed.
D. Gentamicin is an appropriate choice for treatment of enteric fever.
E. The clinical microbiology laboratory will be unable to provide susceptibility results for azithromycin.

Answer: B Among U.S. *Salmonella* Typhi isolated during 1999 to 2006, less than 1% were resistant to ceftriaxone, 38% showed decreased fluoroquinolone susceptibility, and 13% were multdrug resistant (resistant to the traditional first-line antimicrobials ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole). For *Salmonella*, aminoglycosides may appear active *in vitro* but are not effective clinically. The Clinical Laboratory and Standards Institute (CLSI) published breakpoints and interpretive criteria for azithromycin and *Salmonella* for the first time in 2015.

2. Which of the following statements about nontyphoidal *Salmonella* is *false*?

A. Typhimurium and Enteritidis are the most common nontyphoidal *Salmonella* serovars isolated in most high-income countries.
B. Chickens are common reservoirs of *Salmonella* Enteritidis.
C. *Salmonella* Dublin has a great propensity to cause blood stream infection.
D. *Salmonella* Typhimurium is a human host–restricted serovar.
E. Produce is an increasingly important source of nontyphoidal *Salmonella* infection.

Answer: D *Salmonella* Typhimurium and *Salmonella* Enteritidis are the most commonly isolated nontyphoidal *Salmonella* from the stool of humans with diarrhea. Chickens are major reservoirs of *Salmonella* Enteritidis. *Salmonella* Dublin is commonly isolated from blood. *Salmonella* Typhi and *Salmonella* Paratyphi, but not *Salmonella* Typhimurium, are human host–restricted serovars. Uncooked produce eaten fresh is an increasingly important source of nontyphoidal *Salmonella*. This may be related to fecal contamination of produce by animals.

3. A previously healthy 23-year-old male chef develops diarrhea. Stool culture grows *Salmonella* Typhimurium but the diarrhea persists. Which of the following is the most appropriate recommendation?

A. Treat with ciprofloxacin.
B. Prescribe loperamide.
C. Encourage fluid and electrolyte replacement.
D. Suggest that he continue work if he has no fever.
E. Administer vaccine for typhoid fever.

Answer: C Nontyphoidal *Salmonella* diarrhea is usually self-limited in healthy, immunocompetent persons who are not at the extremes of age. Antimicrobials prolong *Salmonella* shedding. Drugs with antiperistaltic effects can prolong diarrhea and should be used sparingly. Individuals with diarrhea should be excluded from food handling. Typhoid vaccine does not protect against *Salmonella* Typhimurium infection.

4. A 36-year-old woman develops fever and abdominal pain after a trip to a typhoid-endemic country. Which of the following recommendations is most appropriate?

A. Order a Widal test.
B. Prescribe ampicillin for empirical treatment of typhoid fever.
C. Collect blood culture specimens.
D. Arrange for bone marrow culture.
E. Administer dexamethasone.

Answer: C Blood culture represents the conventional standard diagnostic test for typhoid fever. Bone marrow culture is more sensitive than blood culture, but it is not often used as the first test. The Widal test and other serologic approaches to typhoid fever perform poorly. The high prevalence of ampicillin resistance in *Salmonella* Typhi and *Salmonella* Paratyphi make it a poor choice for empirical treatment. Any role for dexamethasone for treatment of typhoid fever is restricted to carefully selected patients with severe disease.

5. A 45-year-old woman with a history of blood culture–confirmed typhoid fever continues to have stool cultures that grow *Salmonella* Typhi 18 months after her initial illness despite remaining well. Which of the following recommendations is *not* appropriate?

A. Do nothing because the patient feels well.
B. Treat her with antimicrobials for *Salmonella* Typhi chronic carriage.
C. Encourage handwashing.
D. Exclude the patient from food handling.
E. Determine whether she has gallbladder disease.

Answer: A This patient is a *Salmonella* Typhi chronic carrier because her stool culture is positive more than 12 months after the initial infection. Although she remains well, she continues to shed *Salmonella* Typhi in her stool, posing a risk for transmission to others. It is appropriate to treat her with antimicrobials suitable for the elimination of *Salmonella* Typhi carriage and to promote handwashing. She should be excluded from food preparation until she is demonstrated to no longer be a carrier. Gallbladder disease is a risk factor for the development of the chronic carrier state, although it is doubtful that the carrier state is a sufficient indication for cholecystectomy.

309

SHIGELLOSIS

GERALD T. KEUSCH

DEFINITION

Shigellosis is an acute infection of the large bowel due to bacteria of the genus *Shigella*, characterized by mucosal inflammation and fever. Clinical disease ranges from watery diarrhea to bloody diarrhea or dysentery, a syndrome consisting of multiple small-volume bloody stools per day, abdominal cramping, and tenesmus, a painful straining with the urge to defecate.

The Pathogen

The etiologic agents of shigellosis are gram-negative bacilli of the family Enterobacteriaceae, tribe Escherichieae, and genus *Shigella.* The organism is so closely related to *Escherichia coli* (Chapter 304) that if it were discovered today, *Shigella* would be classified as distinct serotypes of *E. coli*. Indeed, a number of *E. coli* serotypes causing *Shigella*-like illness and possessing conserved virulence factors are now well described.

EPIDEMIOLOGY

In the United States, the incidence of microbiologically confirmed cases has been steadily trending down during the past four decades on the basis of data compiled from voluntary reporting by state health departments to the Centers for Disease Control and Prevention (CDC) (Fig. 309-1). In 2011, the latest year for which data are available, 7062 cases were identified, corresponding to an all-time low incidence rate of 2.3 per 100,000.[1] However, this is not uniform across the country. For example, the incidence rate of *Shigella sonnei* infection, which accounts for more than 75% of all isolates reported to the CDC, was considerably higher in the seven southern states from Alabama across to Arizona. In addition, the incidence rate was nearly 11 per 100,000 in children 0 to 4 years old and more than 8 per 100,000 in children 5 to 9 years old, reflecting the fact that about one third of cases occur in these age groups.[2] Pediatric shigellosis in the United States is commonly associated with daycare centers, where hygiene is difficult to maintain. However, most cases of acute shigellosis are never reported because they are mild or not part of an outbreak and therefore never microbiologically investigated. For this reason, the CDC estimates that around 450,000 cases of *Shigella* infection occur each year in the United States, primarily self-limited watery diarrheas. The small inoculum, from just 10 to 10,000 organisms, documented to cause infection and illness in experimental human infections explains why shigellosis is so readily transmitted from person to person from the stool of an infected person to a susceptible individual, often by the hands and direct skin contact or indirectly through objects (fomites) previously handled by the infected person. It also explains why one case in a family is associated with transmission to 20 to 40% of household members, although children are much more likely to develop clinical illness than are adults, who may be immune as a

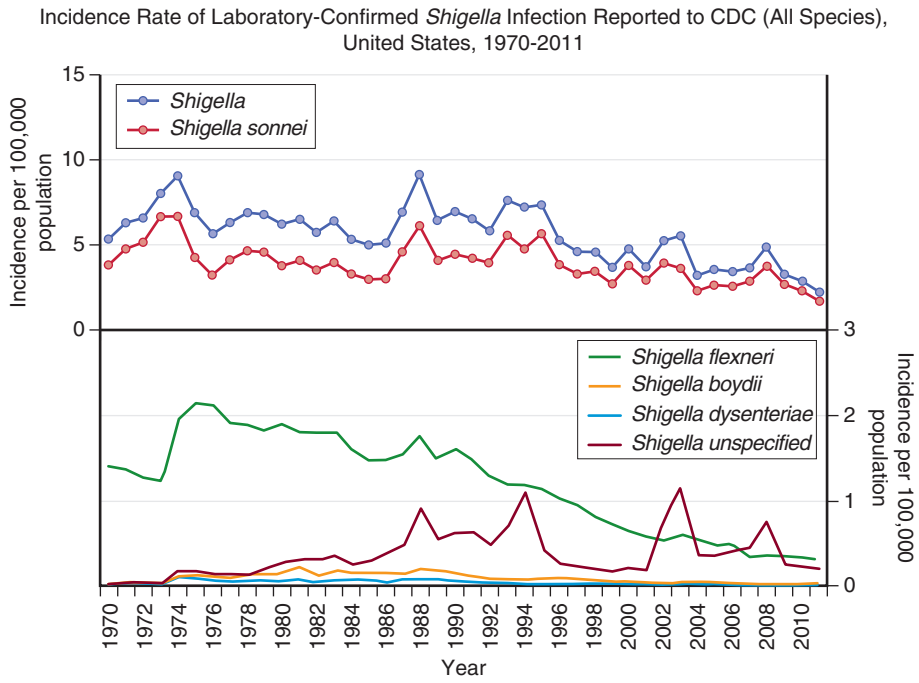

FIGURE 309-1. Incidence rate of laboratory-confirmed *Shigella* infection reported to the Centers for Disease Control and Prevention (all species), United States, 1970-2011. ***Top panel,*** **The incidence rates of infection with *Shigella* (all species) and *Shigella sonnei*. Since 1970, the incidence rate of infection with *Shigella* (all species) has been driven by the incidence of infection with *Shigella sonnei*. *Bottom panel,* The incidence rate of infection with all *Shigella* species other than *Shigella sonnei,* including infections with an unspecified species. The incidence rate of infection with *Shigella flexneri* has been decreasing since the 1980s. Since the mid-1980s, the incidence rate of *Shigella* infection in which the species is not indentified has fluctuated, likely representing, at least to some extent, outbreak situations in which public health laboratories did not characterize all outbreak-associated *Shigella* isolates to the species level. *Shigella boydii* and *Shigella dysenteriae* infections are rare in the United States.**

result of prior contact with the organism.[3] Asymptomatic carriage of *Shigella* is typically limited to a few weeks; but because an etiologic diagnosis of *S. sonnei* is rarely made, except in common-source outbreaks most likely to be investigated by public health officials, convalescent carriers often return to their normal activities while still able to transmit infection. This may account, in part, for the predilection for outbreaks in daycare centers.

Fecal contamination of food or water is another route for transmission. In settings where there are no facilities for sanitary disposal of feces, flies can serve to transfer the organism to food or water. In the United States, foodborne shigellosis results in multiperson or multistate outbreaks.[4] In 2012, the CDC Foodborne Diseases Active Surveillance Network (FoodNet) identified *Shigella* in 2128 individuals, the third leading cause, of whom 23% were hospitalized and two died. The overall incidence rate was 4.5 per 100,000 at risk in the sentinel populations, but it was four times higher in children 0 to 9 years old. These events are generally related to an infected food handler and continually seem to involve new vehicles, such as recent outbreaks traced to fresh salsa or guacamole prepared in restaurants. Multicountry outbreaks of *S. sonnei* due to contaminated fresh foods shipped from Africa or Southeast Asia demonstrate how globalization of the food supply can also globalize infection with particular strains of *Shigella*. This has important implications for the importation of antibiotic-resistant strains from areas of the world where the prevalence is particularly high. In the United States, contamination of swimming pools or bathing areas, usually by young children harboring the organism who defecate in the water, can result in common-source outbreaks. Because of the small infectious inoculum, outbreaks readily occur during complex humanitarian emergencies such as floods, landslides, earthquakes, or the gathering of refugees of conflict into crowded camps with limited sanitary facilities.

Shigella dysenteriae type 1 and *Shigella flexneri* generally cause more severe illness, resulting in bloody diarrhea or dysentery, whereas *S. sonnei* and *Shigella boydii* are typically mild infections causing self-limited watery diarrhea.[5] For still unknown reasons, *S. sonnei* is most common in high-income countries; most *Shigella* infections in developing countries are due to *S. flexneri* strains,[6] with *S. dysenteriae* type 1 periodically causing outbreaks that may last several years. *S. boydii* is present primarily in the Indian subcontinent and clinically resembles *S. sonnei*. Wherever there is severe underlying childhood malnutrition, however, any *Shigella* infection can be lethal.

In the United States, the incidence peaks in summer and fall. Females are more often infected than are males in the age range of 5 to 29 years, whereas males predominate in the 30- to 49-year age group, possibly related to anal-oral sex among men who have sex with men. Among the latter, *S. flexneri* is more common than *S. sonnei*, the reverse ratio observed in the general population. Thus, the median age of individuals with *S. sonnei* infection is 6 years, in contrast to a median age of 26 years in those harboring *S. flexneri*. In developing countries, seasonal peaks occur in the rainy season, when organisms from open defecation can be washed into the water used for drinking, or in the dry season, when water for personal hygiene is scarce. In contrast to the low case-fatality rate for *Shigella* in the United States (approximately 50/100,000 infected in the FoodNet survey), the rate in developing countries may be as high as 100-fold greater, despite the continuing decline in global diarrhea mortality during the past three decades. However, it is difficult to determine how many of the currently estimated 700,000 annual global diarrheal disease deaths are due to *Shigella* because bloody diarrhea or dysentery is not separately reported and cultures are not routinely performed, but it is likely to be a substantial proportion.[7] A careful microbiologic study of moderate to severe diarrhea in nearly 10,000 patients 0 to 5 years of age in seven sites in Africa and South Asia revealed *Shigella* as the fourth leading cause in the age group younger than 1 year, the second leading cause in the age group 1 to 2 years, and the leading cause in the age group 3 to 5 years.[8]

PATHOBIOLOGY

When *Shigella* exit an infected host in feces, they are resistant to acid pH. This facilitates their ability to survive gastric acid when ingested and accounts in large part for the small inoculum required. Once past the stomach, the organisms turn off genes governing acid resistance and turn on genes that allow them to invade the host's colon. *Shigella* initially gain entry into M cells overlying lymphoid Peyer's patches; they are then transcytosed to the lamina propria, where they are ingested by macrophages and induce inflammatory cytokines, leading to macrophage death and the recruitment and migration of polymorphonuclear leukocytes through the mucosa.[9] This forces open the tight junctions between epithelial cells and allows many more organisms from the lumen to gain access to the basolateral membrane of colonic epithelial cells, where they induce the host cells to ingest them by a mechanism resembling phagocytosis. *Shigella* then lyse the phagocytic vesicle to enter the cytoplasm and multiply; although they are nonmotile, they use their capacity to cross-link actin in the cytoplasm to propel themselves to the host cell membrane. There, by the induced phagocytosis-like mechanism, they pass laterally from one epithelial cell to another. The inflammation and death

of contiguously invaded host epithelial cells result in mucosal ulcerations and further exudation of blood and leukocytes into the colonic lumen and ultimately in stool. At the same time, regulatory pathways are engaged to transmit alarm signals that activate the innate immune system in bystander cells to confine the invading organisms to the localized area of involvement. Mucosal inflammation and ulceration are the characteristic pathologic changes caused by *Shigella*. The difference between infection by one species and that by another is the severity of the process, which is proportional to the severity of the illness they cause.

The attributes of virulence are present in a large virulence plasmid present in all *Shigella* and in enteroinvasive *E. coli* serotypes capable of causing a similar clinical illness. The virulence plasmid encodes the proteins for a type III secretion system that is capable of transferring microbial effector proteins into the host cell; these proteins regulate the cytoskeleton of the host cell to ingest the organism. Once inside the epithelial cell, shigellae are sequestered from host immune responses. Whereas the short-term gain for the organism is microbial multiplication and excretion in feces, the same mechanisms subsequently act to eliminate the organisms. For example, at later stages of infection, neutrophils play a major role in disease resolution by killing the bacteria and degrading some *Shigella* virulence proteins. *S. dysenteriae* type 1 also produces a chromosomally encoded toxin, Shiga toxin, that inhibits protein synthesis and directly causes cell death. It is one important reason that infection due to this species is so severe.

Structurally and antigenically similar toxins are produced by certain *E. coli*, notably serotype O157:H7, responsible for cases of hemorrhagic colitis (Chapter 304). All Shiga toxin–producing organisms are known causes of hemolytic-uremic syndrome (HUS; Chapter 172), a potentially lethal complication due to the toxin's effects on vascular endothelium within the kidneys.

CLINICAL MANIFESTATIONS

Infections due to *S. sonnei* or *S. boydii* typically are manifested after an incubation period of 1 to 3 days with fever and mild to moderate watery diarrhea (Table 309-1). They do not cause serious dehydration and generally resolve without treatment in 3 to 5 days. However, if the stool is examined under the microscope, white and red blood cells are found, indicative of the underlying inflammation of the mucosa. When the inflammation is more severe, as with *S. flexneri*, the watery diarrhea turns bloody and may progress to dysentery, with its characteristic small-volume bloody mucoid stool passed many (10 to >40) times per day, abdominal cramps, and tenesmus. The most severe infections are due to *S. dysenteriae* type 1 and progress rapidly from watery to bloody diarrhea and frequently to frank dysentery.

The variety of consequences and complications of *S. flexneri* and *S. dysenteriae* type 1 contributes to their importance as causes of death in children in developing countries. Bacteremia with the infecting strain or other enteric flora occurs in up to 10% of cases of severe dysentery due to *S. dysenteriae* type 1 and in some patients with *S. flexneri* infection. Intense mucosal inflammation can result in toxic megacolon, associated in many patients with leukemoid reactions and HUS. Colonic perforation and pancolitis are rare complications that may require surgical intervention. In resource-limited settings, where colostomy management may be difficult to ensure, conservative management with fluids and antibiotics or limited surgery to oversew perforations is the prudent choice; however, mortality may still be as high as 50%. In young children, in whom mesenteric support for the rectosigmoid colon is not fully developed, the intense proctitis that results in straining to pass stool may cause rectal prolapse. A rapid rise in temperature can lead to a seizure in this age group and is distinguishable from typical febrile seizures by the older age of the child and the rarity of multiple seizures. However, patients may become obtunded or even comatose, usually with *S. dysenteriae* type 1 or *S. flexneri* infections. This is often associated with hypoglycemia, due to poor food intake and inadequate gluconeogenesis, or hyponatremia, secondary to inappropriate secretion of antidiuretic hormone. Anorexia may be intense and prolonged. Combined with ongoing catabolism of host muscle protein associated with excessive pro-inflammatory cytokine production and protein-losing enteropathy due to colitis, this always results in some degree of protein-energy malnutrition (Chapter 215). Even with adequate protein-containing and energy-dense diets after infection, replacement of nutrient stores may take as long as four times the duration of the clinical illness. This is more of a problem in developing countries where the diet is poor and full nutritional recovery may not be possible before the next infection occurs, causing further nutritional deterioration. Because of its prolonged metabolic effects, shigellosis is often the precipitating cause of severe and often fatal protein-energy malnutrition or kwashiorkor. *S. flexneri* infection is also associated with reactive arthritis and other autoimmune inflammatory manifestations, such as tendinitis, conjunctivitis, uveitis, urethritis, or erythema nodosum, a constellation of findings commonly termed Reiter's syndrome (Chapter 265). This occurs primarily in individuals positive for HLA-B27 antigen and may be a consequence of molecular mimicry.

Routine laboratory studies document leukocytosis with many immature "band" forms, especially in patients with bloody diarrhea or dysentery. In as many as 20% of hospitalized patients with *S. dysenteriae* type 1 infection and 1 to 2% with *S. flexneri* infection, this may progress to a leukemoid reaction with thrombocytopenia and microangiopathic hemolytic anemia. HUS (Chapter 172) occurs in approximately 8% of patients with *S. dysenteriae* type 1 infection, usually preceded by a leukemoid reaction, and results in some degree of acute renal failure that might progress and require dialysis.

DIAGNOSIS

Shigellosis presenting with watery diarrhea is clinically indistinguishable from the many other causes of watery diarrhea, except for the frequency of fever in *Shigella*, unless the stool is examined microscopically to demonstrate the presence of red and white blood cells or infection is confirmed microbiologically. Bloody diarrhea or dysentery in patients in the developed world is most commonly due to a Shiga toxin–producing *E. coli* (STEC), such as serotype O157:H7, or *S. flexneri* and less often *Campylobacter jejuni*, nontyphoidal *Salmonella* species, or rarely *Yersinia enterocolitica* or *Entamoeba histolytica*. In patients who have recently received antibiotics, bloody diarrhea is often the consequence of *Clostridium difficile* (Chapter 296). In developing countries, *Shigella* (*S. flexneri* or *S. dysenteriae* type 1) is the most common cause of bloody diarrhea or frank dysentery. Although more sophisticated and more sensitive methods of diagnosis are available, such as quantitative

TABLE 309-1 CLINICAL SYNDROMES AND COMPLICATIONS OF SHIGELLOSIS

STAGE	TIME OF APPEARANCE AFTER ONSET OF ILLNESS	SYMPTOMS AND SIGNS	PATHOLOGY AND PATHOGENESIS
Prodrome	Earliest findings	Fever, chills, myalgias, anorexia	None or early colitis
Watery diarrhea	0-3 days	Fever, abdominal cramps, loose stools	Colitis with fecal leukocytes and erythrocytes
Bloody diarrhea	1-3 days	Frequent stools containing blood and mucus, abdominal cramps and tenderness, fever, anorexia	Colitis with fecal leukocytes and erythrocytes
Dysentery	1-5 days	Frequent small-volume stools consisting of blood, mucus, and pus; severe abdominal cramps; tenesmus	More extensive colitis with crypt abscesses and mucosal ulcerations
Acute complications	3-7 days	Seizures, obtundation, bacteremia, colonic obstruction, mucosal perforation, peritonitis	Severe colitis, terminal ileitis
Additional acute complications due to infection with *Shigella dysenteriae* type 1	3-7 days	Toxic megacolon, leukemoid reaction, hemolytic-uremic syndrome	Severe colitis, expression of Stx toxin
Postinfectious syndromes	1-3 weeks	Reactive arthritis, with or without urethritis and conjunctivitis	Autoimmune inflammatory response, most common in individuals expressing HLA-B27 antigen

polymerase chain reaction (which may double the positivity rate), the standard method remains microbiologic culture. For a genus capable of causing such severe illness, *Shigella* species are remarkably fragile outside the intestine and will rapidly die unless samples (preferentially stool and not rectal swabs) are processed rapidly, ideally at the bedside. Using more than one selective culture medium (e.g., MacConkey and xylose-lysine-deoxycholate or *Salmonella-Shigella* agar) and obtaining multiple culture specimens will increase the yield. Initially, laboratory screening is based on the failure of *Shigella* species to ferment lactose. Subculture of lactose-negative colonies to differential media such as triple sugar–iron confirms this property and reveals the ability to ferment glucose anaerobically, whereas the lack of motility or production of hydrogen sulfide distinguishes *Shigella* from *Salmonella* species. Specific diagnosis can then be made by standard serologic methods for *Shigella* O antigens. In the case of mild watery diarrhea due to *S. sonnei*, the patient is often recovered by the time the laboratory results are available, so they are of little use in guiding treatment. Culture yields are maximized when patients with bloody diarrhea or dysentery are studied. Typically in the United States, it is only these patients who are likely to be cultured, and the results are valuable for selection of empirical treatment and for epidemiologic purposes when antibiotic sensitivity is also determined to track the emergence of antibiotic resistance.

TREATMENT

Because of the typically mild nature of *S. sonnei* infection in well-nourished children, cultures are not performed, the diagnosis remains unproven, and no specific treatment is given or required. Although it might be sensible from a public health perspective to eliminate convalescent carriers with antibiotics to prevent subsequent transmission (e.g., in the setting of daycare centers), it cannot be justified because of the predilection for *Shigella* to acquire antibiotic resistance, resulting in the loss of valuable therapeutics to treat more severe illness. Hence, antibiotics should be reserved for such episodes, even in outbreak settings. Some authorities have suggested that culture-positive patients—particularly food handlers, caretakers in daycare or clinical care settings, teachers or other school employees, and the immunocompromised—should be kept at home until three consecutive stool cultures are negative; however, the question of who pays means this recommendation is unlikely to be followed in most instances.

In the case of bloody diarrhea or dysentery, antibiotics are the mainstay of treatment. This is particularly problematic in developing countries, where many of the inexpensive, safe, and useful oral drugs, such as ampicillin and trimethoprim-sulfamethoxazole, have become ineffective because of drug resistance. Presently, a fluoroquinolone, such as ciprofloxacin, or azithromycin is reliable in most patients, but these drugs are expensive (particularly azithromycin), and resistance in some isolates has been documented, especially in clusters of men who have sex with men with *S. sonnei* infection. Parenteral ceftriaxone has been useful in severe or drug-resistant illness. However, intravenous treatment requires hospitalization and monitoring and seriously increases the cost of treatment in both developed and developing countries. Isolates of *S. sonnei* expressing the CTX-M type of β-lactamase that confers resistance to all β-lactam antibiotics except cephamycins and carbapenems are increasingly being identified in Asia and elsewhere.

In severe shigellosis, the prompt initiation of effective antibiotic treatment shortens the duration of illness and achieves a more rapid improvement in symptoms such as fever, cramps, and tenesmus. Evidence from Bangladesh in patients with *S. dysenteriae* type 1 infection also demonstrates that prompt treatment reduces the frequency of HUS and presumably other complications due to colonic inflammation, such as megacolon, perforation, and rectal prolapse. In the United States and other developed countries where *S. dysenteriae* type 1 is not present, HUS is almost exclusively associated with STEC. The toxin genes in these *E. coli* are present on plasmids, in contrast to the chromosomal location of the *stx* gene in *S. dysenteriae* type 1, and are actually upregulated by commonly used antibiotics. Hence, most experts recommend that antibiotic treatment be withheld in patients with STEC infections; but if it is necessary, a drug should be selected that does not have this effect, such as azithromycin, rifaximin, or intravenous meropenem.

Given the known epidemiology of antibiotic resistance among *Shigella* species, empirical therapy for adults with bloody diarrhea or dysentery can be initiated with ciprofloxacin 500 mg orally twice daily for 3 to 5 days.[10] There is increasing evidence that shorter courses are sufficient, even for known or suspected *S. dysenteriae* type 1 infections, but given its severity, many experts would still recommend a full 5-day course. A still reliable oral alternative is azithromycin, with an initial dose of 500 mg followed by 250 mg/day for an additional 4 days, although the identification of *S. sonnei* with reduced susceptibility to azithromycin during an outbreak in Los Angeles in 2012 is of concern. Depending on the epidemiology of resistance in specific geographic areas, ampicillin (500 mg orally four times daily for 3 days) or trimethoprim-sulfamethoxazole (160/800 mg combination twice daily for 3 days) may still be effective. Doses for young children are ciprofloxacin 10 mg/kg twice daily for 3 days; azithromycin 10 mg/kg on day 1, followed by 5 mg/kg for 4 days more; ampicillin 25 mg/kg four times daily for 5 days; and a pediatric syrup of trimethoprim-sulfamethoxazole containing 4/20 mg, respectively, twice daily for 5 days. β-Lactam antibiotics, such as amoxicillin and oral cephalosporins, are not recommended because initial studies have shown that they are less effective in vivo than predicted by in vitro drug sensitivity studies. This may be due to efficient absorption, leaving insufficient amounts in the intestinal lumen. Pivamdinocillin (mecillinam; marketed as Coactin) is effective but is not available in the United States. Nonabsorbable antimicrobial agents are not recommended because optimal treatment requires therapeutic levels of the drugs in both the lumen and the mucosal compartments.

In more severe infections, complications such as hypoglycemia or hyponatremia can be managed with appropriate glucose or saline given intravenously, but patients must be monitored by trained clinical staff. Colitis with toxic megacolon and intestinal perforation represent difficult problems, especially in resource-poor settings where these complications are most likely to occur. In such settings, conservative medical or surgical management is best, even if it is not optimal. Renal failure due to HUS can generally be managed conservatively or with peritoneal dialysis, if it is available. Seizures are usually self-limited, and other neurologic complications respond to fluid and electrolyte management and correction of hypoglycemia and hyponatremia. Reactive arthritis is a greater problem as it is an autoimmune response that occurs primarily in genetically susceptible individuals positive for HLA-B27 antigen. In addition to effective antibiotic treatment to eliminate the causative organism, chronic arthritis may ensue, requiring nonsteroidal anti-inflammatory agents, steroids, or inflammatory cytokine inhibitors. In the susceptible host, infection-induced reactive arthritis can result in troublesome destructive joint disease that requires ongoing medical management. Some evidence suggests that antimotility agents are contraindicated in shigellosis, particularly in cases of bloody diarrhea or dysentery in young children, because these drugs may slow peristalsis and prolong contact between the organisms and the mucosa, thereby increasing microbial invasion, pathologic changes, and severity, including toxic megacolon.

Because of the prolonged anorexia and catabolic responses in shigellosis, attention to nutritional rehabilitation, especially in malnourished children in developing countries, is an important component of early and continuing management.

PREVENTION

Personal hygiene (in particular handwashing after handling the diapers of infected children and before food preparation), the sanitary disposal of feces, and protection of food and water sources from microbial contamination are essential to limit the spread of shigellosis. Preventing spread in daycare settings is a particular problem because it is so difficult to stop young children from constantly exploring their world, picking up bacteria on their hands, and bringing their potentially contaminated fingers or fomites to their mouths. In such settings, it is particularly important for the adult caretakers to observe good personal hygiene and to supervise children in handwashing. Soap and water are sufficient, but hand sanitizers do work and may be more convenient. In environments where soap is unavailable, water used with sand or ash for scrubbing is helpful. Keeping infected children away from daycare until their stool is negative, if indeed it was cultured, or separating recently ill children from the susceptible has been recommended but is not easy to accomplish. Household hygiene in the setting of an index case, including frequent handwashing, caution in the disposal of soiled diapers or underwear, regularly wiping down the area where these are collected with a disinfectant such as Lysol, and precautions in food preparation, can help limit intrahousehold spread.

Vaccines, particularly for the more virulent species, would be useful. However, despite much effort, a safe and effective vaccine has not been developed or approved for general use. It is doubtful whether a vaccine for *S. sonnei* infection would be recommended for children in a developed country such as the United States, even if it is safe and effective, because the illness is so mild and self-limited and because other vaccines are more important to administer in the context of an increasingly antivaccine public. Once it is available, it could be useful for travelers or among military who are deployed to high-risk locations. In contrast, effective and safe vaccines for *S. flexneri* or *S. dysenteriae* type 1 would be extremely useful in developing countries, where shigellosis accounts for a significant portion of the annual mortality due to diarrheal diseases.[11,12] Our current understanding of immunity in shigellosis indicates that serotype-specific immunity is most important; however,

whether this is best conveyed by antibody (and, if so, immunoglobulin G or A) or by cell-mediated mechanisms remains uncertain. Vaccine development has focused on attenuated live oral vaccines; unfortunately, vaccines most effective in inducing immunity have also been the most reactogenic, causing fever and often diarrhea in recipients. Recent efforts employ killed whole cells, O antigen–protein conjugates, and subunit candidates. Unless common protective antigens are identified, the most likely vaccine strategy will be based on a combination of serotype-specific antigens from the most common *S. flexneri* strains and *S. dysenteriae* type 1. We are a long way from having an approved vaccine for shigellosis.

PROGNOSIS

S. sonnei infection and most cases of *S. boydii* infection are mild and self-limited, with no sequelae. Infection with *S. flexneri* or *S. dysenteriae* responds to proper treatment with antibiotics. When treatment is not effective, either a drug-resistant strain or another etiologic agent should be suspected. In some instances, severe shigellosis with pancolitis has been misdiagnosed as inflammatory bowel disease. This can be a disaster if the patient is treated with steroids. Whereas early and effective treatment of *S. dysenteriae* type 1 reduces the risk of complications such as HUS and probably megacolon and bowel perforation, about 25% of those with HUS will have some permanent renal impairment, and a small percentage may progress to end-stage renal failure. Because of the autoimmune nature of reactive arthritis, usually associated with *S. flexneri*, early treatment might not prevent its occurrence but could mitigate its severity. Infection with one serotype of *Shigella* generally provides durable immunity to reinfection with the same strain but leaves the individual susceptible to other antigenically distinct strains and serotypes.

REVIEW QUESTIONS

1. Spread of shigellosis can be difficult to control because the major route of transmission of infection is

A. Food
B. Water
C. Person to person
D. Aerosol
E. Dirty toilet seats

Answer: C Because *Shigella* resist the antibacterial effects of gastric acid and invade intestinal epithelial cells, which protect them from immune mechanisms, the infectious inoculum can be very small, which eliminates the need to multiply before ingestion and facilitates direct (skin-to-skin) or indirect (by contaminated fomites) person-to-person spread. It is true that the organism can be transferred to food or water and subsequently cause outbreaks; however, transmission by these routes can be prevented by commonsense care around food preparation and chlorination of the water supply. *Shigella* are not respiratory pathogens and so aerosol transmission does not occur. Whereas transmission by dirty toilet seats is possible, acquisition of infection by this route has not been described.

2. The most common presentation of shigellosis in the United States is

A. Watery diarrhea associated with fever
B. Dysentery
C. Hemolytic-uremic syndrome
D. Leukemoid reaction
E. Reactive arthritis

Answer: A The most common cause of shigellosis in the United States is *Shigella sonnei*, which only rarely proceeds beyond the watery diarrhea stage to bloody diarrhea or the dysentery syndrome. However, even *S. sonnei* induces an inflammatory enteritis with the production of pyrogenic cytokines such as interleukins 1, 6, and 8, and therefore elevated temperature is present in the majority of infected individuals. Some observations from experimentally infected adults suggest that the peak fever correlates with the severity of other clinical manifestations of shigellosis. The other options are all potential consequences of *Shigella* infection but largely found in cases due to either *Shigella flexneri* or *Shigella dysenteriae* type 1. *S. flexneri* in the United States is primarily found in cases involving men who have sex with men, who therefore often present with more severe presentations of shigellosis. *S. dysenteriae* type 1 is rarely found in the United States, and when such cases are identified, the infection has typically been acquired abroad.

3. The pathobiology of *Shigella* infection is a consequence of

A. Activation of intestinal secretion pathways
B. Lactose malabsorption
C. Hyperperistalsis
D. Mucosal edema
E. Mucosal invasion and inflammation

Answer: E A hallmark of pathogenic shigellae is their ability to invade cells, including phagocytic leukocytes and nonphagocytic intestinal epithelial cells, by inducing a process analogous to phagocytosis. The release of proinflammatory cytokines during this process results in fever, recruitment of leukocytes to the intestinal mucosa, epithelial cell death and mucosal ulceration, and the characteristic finding of white and red blood cells in the stool. When the genes mediating these processes are deleted or experimental infections are treated with cytokine inhibitors, the severity of the typical clinical manifestations is attenuated.

Copious watery diarrhea, typically associated with the activation of specific ion secretion pathways in intestinal mucosa and characteristic of *Vibrio cholerae* infection, is not characteristic of shigellosis. The watery diarrhea induced by *S. sonnei*, for example, is not sufficient to cause serious dehydration, except in unusual cases. Lactose malabsorption is a consequence of damage to intestinal epithelial brush border membranes, where this disaccharidase is localized, and therefore may develop during and after clinical shigellosis, but it is not a cause of altered physiology underlying the infection. Inflammation of the colonic mucosa is common in shigellosis, manifested as cramps or, in severe cases, with bloody diarrhea or dysentery and tenesmus, but again, this is a consequence of the underlying inflammatory reaction. Rather than mucosal edema resulting from the myriad inflammatory pathways being activated, the histology of the affected intestine reveals leukocytic infiltration, blood, organisms in the submucosa and within epithelial cells, and mucosal ulcerations where dead epithelial cells have been sloughed off the mucosal surface.

4. The primary treatment of bloody diarrhea due to *Shigella* species is

A. Oral rehydration fluids
B. Intravenous rehydration fluids
C. H_2 blockers
D. Antibiotics such as ciprofloxacin (Cipro)
E. Loperamide (Lomotil)

Answer: D Mild to moderate shigellosis presenting as watery diarrhea, and typically due to *S. sonnei*, is a self-limited illness, usually lasting only a couple of days and uncommonly the cause of significant dehydration requiring supervised rehydration by either the oral or the intravenous route. More severe clinical shigellosis, associated with bloody diarrhea, is uncomfortable because of the high frequency of bowel movements and associated cramps, and there is the potential for subsequent complications, depending on the etiologic agent involved. Antibiotic treatment with an agent to which the infecting organism is susceptible is well documented to resolve clinical symptoms and, if it is administered early, to prevent late complications of shigellosis. The problem has been to administer a proven effective antibiotic to which the causative organism is susceptible because of the acquisition of multidrug resistance genes over time. At present, a quinolone such as ciprofloxacin (Cipro) or a macrolide such as azithromycin (Zithromax) is the most reliable choice as the prevalence of resistance is still low in most parts of the world, although it is not unknown and is slowly increasing.

Rehydration, by either oral rehydration solutions or intravenously administered fluids, is usually not necessary as the degree of dehydration in shigellosis is mild or is readily corrected if it is more significant. However, rehydration will not reverse the clinical manifestations due to inflammation and in this sense is a secondary consideration at best. H_2 blockers are known to increase the susceptibility to acid-sensitive enteric pathogens such as *V. cholerae* but not acid-resistant organisms like *Shigella* and have no effect on already established infections. Lomotil or other gut motility–inhibiting drugs such as Imodium that reduce peristalsis are, in fact, potentially dangerous in that they can prolong the contact between invasive *Shigella* and the mucosa and worsen the clinical severity of the infection. Where *S. flexneri* or *S. dysenteriae* type 1 is common, these drugs are in fact considered to be contraindicated, especially in children. In some studies, the combined use of ciprofloxacin and loperamide reduces the duration of symptoms or the number of stools passed compared with treatment with ciprofloxacin alone.

5. The best available way to prevent shigellosis is

A. Immunization with *Shigella* vaccine
B. High standards of personal and household hygiene
C. Provision of prophylactic antibiotics to contacts of patients
D. Quarantine
E. Anti-inflammatory drugs

Answer: B Shigellosis is primarily contracted directly through fecal-oral transmission by the hands of an infected individual or indirectly by contaminated fomites to a susceptible individual. The way to break the cycle of transmission is to wash hands, especially when taking care of a patient with shigellosis (e.g., after handling soiled diapers or other clothes) or before preparing and serving food in the household. Additional measures, such as disinfecting the areas where soiled clothes are gathered with a simple disinfectant such as Lysol or diluted bleach, are also useful. Application of these measures within a household with an infected individual will reduce the transmission of infection to others in proximity to the index case. In other settings, such as developing countries with higher incidence and limited supplies of safe drinking water or facilities for the sanitary disposal of feces, use of hand sanitizers is useful and care in the consumption of nonbottled water or drinking of boiled water will be effective.

There is no available vaccine for shigellosis, although considerable effort has been expended to develop one that is both effective and safe. Prophylactic administration of antibiotics is a bad idea as hygiene is an effective way to prevent infection, and antibiotic exposure only increases the selective pressure for drug resistance to emerge. Quarantine is no longer a primary strategy for control of most infectious diseases because diagnosis and more specific measures can usually be implemented. Quarantine usually fails to prevent the spread of contagious diseases in the community as it is difficult to isolate all of the potential spreaders of infection. Whereas certain anti-inflammatory drugs (e.g., cytokine antagonists) have been shown to be effective in experimental models of shigellosis, none are currently available for clinical use.

310 BRUCELLOSIS

EDSEL MAURICE T. SALVANA AND ROBERT A. SALATA

DEFINITION

Brucellosis is a zoonotic disease with protean manifestations caused by bacteria of the genus *Brucella*. Human infection is acquired via ingestion or inhalation of bacteria in contaminated material. Although occupational exposure is a common risk factor for infection, the vast majority of disease occurs through ingestion of unpasteurized dairy products. Despite continuing efforts to control its spread, brucellosis remains a significant health and economic burden in many countries.

The Pathogen

Brucellae are slow-growing, small, aerobic, nonmotile, nonencapsulated, non–spore-forming, gram-negative coccobacilli. *Brucella abortus* (from cattle), *Brucella suis* (from pigs), *Brucella melitensis* (from sheep, goats and camels), and *Brucella canis* (from dogs) are the species that most commonly infect humans. Genome sequencing shows a high degree of homology among strains despite disparate preferred hosts.[1]

EPIDEMIOLOGY

Etiology

Virulence traditionally varies among the four major species of *Brucella*, although this concept has been recently challenged. Because of its pathogenicity and ability to remain viable in storage for long periods, *Brucella* spp. are potential agents for bioterrorism. *B. abortus* is usually associated with mild to moderate sporadic disease. *B. suis* and *B. melitensis* infections are associated with suppurative or disabling complications and can have a prolonged course. Infection with *B. canis* has an insidious onset, relapses frequently, and has a chronic but relatively mild course. Two marine species, *Brucella pinnipediae* and *Brucella cetaceae,* related to seals and cetaceans, respectively, can cause mild infection in humans. *Brucella microti,* with a high potential for pathogenicity, has been isolated from the common vole, red fox, and soil, but no instances of human infection have been reported. Other newly described *Brucella* species with known or potential human pathogenicity include *Brucella inopinata* (one human case of breast implant infection), *Brucella ovis* (sheep infection; no human cases reported), and *Brucella neotomae* (rodent infection; no human cases reported). BO2, a proposed future species closely related to *B. ovis*, has caused one human case of chronic destructive pneumonia.[1,2]

Incidence and Prevalence

More than 500,000 cases of brucellosis are reported yearly to the World Health Organization (WHO) from 100 countries. *B. melitensis* infection accounts for the majority of cases, distributed primarily in the Mediterranean region (particularly Spain and Greece), Latin America, the Arabian Gulf, and the Indian subcontinent. *B. abortus* infection occurs worldwide but has been effectively eradicated in several European countries, Japan, and Israel. Whereas *B. suis* occurs mainly in the Midwestern United States, South America, and Southeast Asia, *B. canis* infection is most common in North America, South America, Japan, and central Europe. Identification of the infecting *Brucella* species helps determine the likely source of infection.[3]

In animals, brucellosis is a chronic infection that can persist throughout life. Because of effective control programs in animals, the incidence of human brucellosis has decreased dramatically in the United States, from more than 6000 cases in 1947 to fewer than 200 cases each year since 1980. States reporting the greatest number of cases include Texas, California, Virginia, and Florida. In North America, brucellosis occurs mainly in the spring and summer, is more common in men, and is usually related to occupational exposure.

Brucella infection in the United States occurs mostly through direct contact with animals or animal secretions in high-risk groups, including slaughterhouse workers, farmers, dairy workers, veterinarians, and travelers returning from endemic areas. Laboratory workers handling infected animals or *Brucella* cultures are also at risk. More than half of the reported cases are associated with the meat-processing industry, particularly the "kill areas," where infection is spread through abraded or lacerated skin; the conjunctiva, possibly by aerosolization; and, rarely, by ingestion of infected tissue. Many cases of *B. abortus* infection in veterinarians have resulted accidentally from exposure to the strain 19 vaccine used to immunize cattle. In the southern United States, 20% of feral swine are positive for *B. suis,* and human infections in hunters have been reported. *B. melitensis* infection, transmitted through the ingestion of goat's milk cheese, has been seen in U.S. travelers to and immigrants from Mexico. Brucellosis contracted abroad may not become symptomatic until the patient returns to the United States. Although persons with human immunodeficiency virus (HIV) infection are generally at higher risk for intracellular pathogens, the clinical manifestations of brucellosis in HIV-infected and noninfected individuals are similar in the few cases of coinfection that have been reported. Human-to-human transmission is rare, but there have been increasing reports of sexually transmitted brucellosis.[4]

Brucellosis in pregnancy has been associated with spontaneous abortions, congenital abnormalities, and neonatal infections. Childhood brucellosis also occurs, mostly in school-aged children, but accounts for only 3% to 10% of all reported cases worldwide. It is more common in endemic areas, where it may account for 20% to 25% of cases, and is often a mild, self-limited process.[5]

PATHOBIOLOGY

Pathogenesis

After penetrating the epithelial cells of human skin, conjunctiva, pharynx, intestine, or lung, *Brucella* organisms in naive individuals induce a delayed inflammatory response (up to 48 hours) with polymorphonuclear leukocyte infiltration at the infection site. *Brucella* organisms are then ingested by dendritic cells, neutrophils and tissue macrophages, and these subsequently spread to regional lymph nodes. If host defenses within the lymph nodes are overwhelmed, bacteremia follows. The usual incubation period from

infection to bacteremia is 2 to 4 weeks. Bacteremia is accompanied by phagocytosis of free *Brucella* organisms by macrophages, and localization of the disease primarily to the spleen, liver, and bone marrow, with the formation of small, noncaseating granulomas, which can serve as persistent sources of infection.

As an intracellular organism, *Brucella* spp. have to avoid detection by the immune system on entry and must be able to survive a hostile intracellular environment. *Brucella* organisms avoid initial detection by the host through multiple mechanisms. Its cell wall lipopolysaccharide (smooth LPS) differs significantly from regular bacterial LPS in two important ways: it has very little effect on Toll-like receptor type 4 (TLR4) activation, and it is resistant to complement activation. In addition, *Brucella* organisms deploy a protein that interferes with TLR signaling. Upon successful entry into the host, *Brucella* organisms in phagosomes are able to survive acidification and lysosome fusion through the induction of specific virulence factors such as the VirB type IV secretion system (T4SS). To replicate, *Brucella* organisms intercept traffic between the endoplasmic reticulum and the Golgi apparatus. They also seem to inhibit apoptosis of the infected cell, thereby maintaining a persistent presence protected from the immune system.[2]

Immunity

Humoral factors play an important role in host defense against *Brucella* spp. Even in the absence of specific agglutinating antibody, normal human serum is bactericidal for *Brucella* organisms; *B. abortus* is more susceptible to serum lysis than is *B. melitensis.* The intracellular location of *Brucella* spp. within macrophages enables it to escape the lethal effects of serum to a certain extent. Specific serum agglutinating antibody has opsonic activity but does not correlate with the development of protective immunity.

A role for mononuclear phagocytes and cell-mediated immunity in brucellosis has been demonstrated. Prior infection with *Listeria monocytogenes* or *Mycobacterium tuberculosis,* both of which stimulate cell-mediated immune mechanisms, is protective against *Brucella* infection in animals. Skin testing with *Brucella* proteins elicits a typical delayed hypersensitivity response in infected individuals. Macrophages, activated with T helper 1 (T_H1)–type cytokines (including interferon-γ, tumor necrosis factor-α, interleukin-1, interleukin-12), kill *Brucella.* Studies have shown that despite high levels of T_H1 cytokine production, deficient effector phagocytic activity persists. Later in the course of infection, there is evidence of an unexpected inhibitory effect from neutrophils. Animal models have demonstrated more efficient killing of *Brucella* organisms in the absence of polymorphonuclear cells, which somehow dampen the immune response to this pathogen.[6]

CLINICAL MANIFESTATIONS

Clinically, human brucellosis can be divided into subclinical illness, acute or subacute disease, localized disease, relapsing infection, and chronic disease (Table 310-1).[7]

Subclinical Illness

Asymptomatic or clinically unrecognized human brucellosis often occurs in high-risk groups, including slaughterhouse workers, farmers, and veterinarians. The diagnosis is usually made through serologic means. More than 50% of abattoir workers and up to 33% of veterinarians have high anti-*Brucella* antibody titers but no history of recognized clinical infection. Children in endemic areas frequently have subclinical illness.

Acute and Subacute Disease

After an incubation period of several weeks or months, acute brucellosis may occur as a mild, transient illness (*B. abortus* or *B. canis*) or as an explosive, toxic illness with the potential for multiple complications (*B. melitensis*). Approximately 50% of patients have an abrupt onset over days, but the remainder have an insidious onset over weeks. Symptoms in brucellosis are protean and nonspecific. More than 90% of patients experience malaise, chills, sweats, fatigue, and weakness. More than 50% of patients have myalgias, anorexia, and weight loss. Fewer patients complain of arthralgias, cough, testicular pain, dysuria, ocular pain, or blurring of vision. Few localizing physical signs are apparent. Fever, with temperatures often greater than 39.4° C (103° F), occurs in 95% of patients. An undulating or intermittent fever pattern is not unusual. A pulse–temperature deficit (i.e., relative bradycardia) may occur. Splenomegaly is present in 10% to 15% of cases, and lymphadenopathy occurs in about 14% of patients. Axillary, cervical, and supraclavicular lymphadenopathy are most frequent and may be related to hand wounds or oropharyngeal routes of infection. Hepatomegaly is less frequent. Other laboratory findings in acute or subacute disease may include mild anemia; lymphopenia; or neutropenia (especially with bacteremia); lymphocytosis; thrombocytopenia; or, in rare cases, pancytopenia. The majority of infected individuals recover completely without sequelae if diagnosed early with prompt initiation of therapy.[8]

Localized Disease and Complications

Brucella organisms can localize to almost any organ but usually target the bones, joints, central nervous system, heart, lung, spleen, testis, liver, gallbladder, kidney, prostate, pancreas, and skin. Disease may occur at multiple sites. Complications with local manifestations most often appear in association with chronic illness, although complications may also occur with acute disease caused by *B. melitensis* or *B. suis.* In the United States, localized disease is most frequently related to *B. suis.* Osteoarticular complications account for 10% to 80% of localized disease in most reported series. Whereas sacroiliitis is the most common manifestation in young persons, spondylitis is more frequently encountered in elderly adults. Vertebral osteomyelitis, particularly in the lumbar area, is also a well-recognized complication and can be associated with paravertebral, epidural, and psoas abscesses.

Relapsing Infection

Up to 10% of patients with brucellosis relapse after antimicrobial therapy. The intracellular location of *Brucella* organisms predisposes to recurrence because the organisms are relatively protected from host defense mechanisms, and antimicrobial agents may be unable to penetrate efficiently enough to kill all the bacteria. Acquired resistance to antibiotics is another factor that can lead to treatment failure. Relapses usually occur 3 to 6 months after completion of therapy but may be seen up to 2 years after initial treatment. Relapsing

TABLE 310-1 CLINICAL CLASSIFICATION OF HUMAN BRUCELLOSIS

CLASSIFICATION	DURATION OF SYMPTOMS BEFORE DIAGNOSIS	MAJOR SYMPTOMS AND SIGNS	DIAGNOSIS	COMMENTS
Subclinical	—	Asymptomatic	Positive (low-titer) serology, negative cultures	Occurs in abattoir workers, farmers, and veterinarians
Acute and subacute	Up to 2-3 mo and 3 mo-1 yr, respectively	Malaise, chills, sweats, fatigue, headache, anorexia, arthralgias, fever, splenomegaly, lymphadenopathy, hepatomegaly	Positive serology, positive blood or bone marrow cultures	Presentation can be mild, self-limited *(B. abortus)* or fulminant with severe complications *(B. melitensis)*
Localized	Occurs with acute or chronic untreated disease	Related to involved organs	Positive serology, positive cultures in specific tissues	Bone or joint, genitourinary, hepatosplenic involvement most common
Relapsing	2-3 mo after initial episode	Same as acute illness but may have higher fever and more fatigue, weakness, chills, and sweats	Positive serology, positive cultures	May be extremely difficult to distinguish relapse from reinfection
Chronic	>1 yr	Nonspecific presentation, but neuropsychiatric symptoms and low-grade fever most common	Low titer or negative serology, negative cultures	Most controversial classification; localized disease may be associated

infection is difficult to distinguish from reinfection in high-risk groups with continued exposure. Relapses are associated with inappropriate or insufficient antimicrobial therapy, growth on blood cultures during the initial presentation, and an acute onset of disease.

Chronic Disease

Disease with a duration of more than 1 year is referred to as *chronic brucellosis.* A majority of patients classified as having chronic brucellosis really have persistent disease caused by inadequate treatment of the initial episode, or they have focal disease in bone, liver, or spleen. About 20% of patients diagnosed with chronic brucellosis complain of persistent fatigue, malaise, and depression; in many respects, this condition resembles chronic fatigue syndrome. These symptoms are frequently not associated with clinical, microbiologic, or serologic evidence of active infection and may represent a preexisting psychoneurosis.

DIAGNOSIS

Culture

Many common illnesses mimic the clinical presentation of brucellosis, and a thorough history is essential, including occupation, travel to endemic areas, avocations, and ingestion of at-risk food and beverages. The most conclusive means of establishing the diagnosis of brucellosis is the recovery of the organism from a culture from normally sterile body fluid or tissue. Sensitivity of cultures have ranged from 15% to 90%, depending on the methods used and the specimen type. In cases of suspected brucellosis, the microbiology laboratory should be asked to extend the length of incubation because it may take more than 5 days for *Brucella* organisms to grow. Handling of *Brucella* cultures is potentially hazardous to laboratory personnel.

In acute brucellosis, blood cultures are positive in 10% to 30% of cases, but this may be as high as 85% with *B. melitensis*. The sensitivity of blood cultures decreases with increasing duration of illness. With *B. melitensis* infection, bone marrow cultures are more sensitive than blood cultures. With localized brucellosis (e.g., lymph nodes, spleen, liver, skeletal system), cultures of purulent material or tissues usually yield *Brucella* organisms. Culture of cerebrospinal fluid turns positive in 45% of patients with meningitis. Antibodies against *Brucella* may be demonstrated in cerebrospinal fluid by enzyme-linked immunosorbent assay (ELISA).

Standard Tube Agglutination

In the absence of microbiologic confirmation, a presumptive diagnosis can be made by history and serology. The most frequently used test is the standard tube agglutination (STA) test, measuring antibody titers against *B. abortus* antigen. A fourfold or greater rise in titer over 2 weeks is considered significant. A presumptive case is one in which the agglutination titer is positive (1 : 160 in endemic areas; 1 : 80 in nonendemic areas) in single or serial specimens, with symptoms consistent with brucellosis. By 3 weeks of illness, more than 97% of patients demonstrate serologic evidence of infection. This test detects antibodies to *B. abortus, B. suis,* and *B. melitensis* but not to *B. canis.* Serologic confirmation of *B. canis* infection requires *B. canis* or *B. ovis* antigen. After adequate antibiotic treatment, significant STA titers can persist for up to 2 years in 5% to 7% of cases. Because of this, STA titers are not useful in differentiating relapsing infection from other febrile illnesses in patients with a history of past *Brucella* infections. Individuals with subclinical infection may demonstrate significant STA titers. In chronic localized brucellosis, STA titers may appear absent or low owing to a prozone phenomenon. This prozone effect appears to be related to the presence of immunoglobulin G or immunoglobulin A blocking antibodies; it can be eliminated if dilutions are carried out to at least 1 : 1280. False-positive STA titers related to immunologic cross-reactivity have been associated with *Brucella* skin testing, cholera vaccination, or infection with *Vibrio cholerae, Francisella tularensis,* or *Yersinia enterocolitica.*

Other Tests

Newer generation antibody tests, including ELISA, are more sensitive and specific than STA and are being used more widely. Preliminary studies using polymerase chain reaction of blood and other fluids or tissues offers rapid and highly accurate diagnosis of brucellosis.[9] Sequencing of specific gene products can identify the organism up to the species level. However, protocols still need to be standardized on a wider scale, and access to expertise and adequate laboratory facilities remains a significant limiting factor.

TREATMENT

Rx

Effective treatment of *Brucella* infection requires antibiotics that can penetrate the intracellular compartment, have little or no toxicity even with prolonged use for preventing relapse, and are bactericidal for adequate treatment of central nervous system infection and endocarditis. There remains considerable debate over which antibiotic regimen is best. In adults, the combination of oral doxycycline at 100 mg orally twice a day for 6 weeks plus intramuscular gentamicin at 5 mg/kg for 5 to 7 days is equally effective as traditional therapy using doxycycline for 6 weeks plus streptomycin 1 g intramuscularly for 14 days.■ The WHO recommends doxycycline plus rifampin 15 mg/kg orally for 6 weeks. This regimen is less effective for cases of spondylitis, which may require up to 3 months of treatment with any of the above regimens. Monotherapy with fluoroquinolones has been disappointing, and if these agents are used, they should always be combined with another active agent. Recent in vitro studies have demonstrated significant activity and synergy of tigecycline with gentamicin and rifampin; these observations must be supported in clinical trials. A prospective, non-randomized trial of triple combination doxycycline, streptomycin, and rifampicin versus the standard double combination doxycycline plus streptomycin showed a significantly higher rate of undetectable Brucella DNA on follow-up.[10] Recommendations are summarized in Table 310-2.

PREVENTION

The control of human brucellosis is directly related to prevention programs in domestic animals and the avoidance of unpasteurized milk and milk products. In slaughterhouses, important means of prevention include careful wound dressing, the use of protective glasses and clothing, the prohibition of raw meat ingestion, and the use of previously infected (immune) individuals in high-risk areas. Work is ongoing to find an effective vaccine for humans. Postexposure antimicrobial prophylaxis is controversial.

TABLE 310-2 TREATMENT FOR BRUCELLOSIS

	TREATMENT	COMMENTS
Acute, with no endocarditis or CNS involvement	Doxycycline (200 mg/day) plus rifampin (15 mg/kg/day) for 6 wk *Or* Tetracycline (2 g/day) for 6 wk plus streptomycin (1 g/day) or gentamicin (5 mg/kg/day) for 1 wk	Treatment of choice by WHO; widely used; low rate of relapse; IMG administration of streptomycin may be difficult
Alternative agents: chloramphenicol, fluoroquinolones, TMP-SMX, imipenem	Combination therapy still preferred; fluoroquinolones plus rifampin is an alternative	
In children	TMP-SMX plus rifampin	
CNS	Doxycycline plus rifampin and TMP-SMX	Third-generation cephalosporin can be substituted if susceptible in vitro
Localized	Surgically drain abscesses plus antimicrobial therapy for ≥6 wk	
Brucella endocarditis	Bactericidal drugs; early valve replacement may be necessary	Possible aortic valve destruction and/or major arterial emboli

CNS, Central nervous system; *IM,* intramuscular; *TMP-SMX,* trimethoprim–sulfamethoxazole; *WHO,* World Health Organization.

PROGNOSIS

Brucellosis treated appropriately within the first month of symptom onset is curable. Acute brucellosis often produces severe weakness and fatigue, and patients are frequently unable to work for up to 2 months. Immunity to reinfection follows initial *Brucella* infection in the majority of individuals. With early antimicrobial therapy, cases of chronic brucellosis or localized disease and complications are rare. Of the patients who die of brucellosis, 84% have endocarditis involving a previously abnormal aortic valve, often associated with severe congestive heart failure. A recent retrospective review showed a much higher risk of death with medical treatment alone compared with a combined medical and surgical approach for *Brucella* endocarditis, although this needs to be confirmed in prospective trials.[11]

REVIEW QUESTIONS

1. A 44 year-old abattoir worker of Middle Eastern origin working in Ashtabula, Ohio develops fever and back pain over the past 2 weeks. He has three pet dogs at home. A standard tube agglutination (STA) shows a *Brucella* titer of 1 : 80. Which of the following is true regarding the diagnosis of *Brucella* in this patient?

A. A single titer of 1 : 80 is sufficient to make the diagnosis of *Brucella* infection in this patient.
B. This patient may have *Brucella canis* infection based on the positive STA titer result.
C. The sensitivity of a blood culture at this time is about 30% and will likely increase with increasing length of illness.
D. A bone marrow culture will be less sensitive than blood culture.
E. The microbiology laboratory should be alerted regarding the suspected diagnosis.

Answer: E The microbiology laboratory should always be alerted in cases of suspected brucellosis. Aside from a potential biohazard, cultures may need to be kept longer than the usual incubation periods to increase yield. A single titer of 1 : 80 on STA is sufficient for a presumptive diagnosis in a nonendemic country. However, this person is from the Middle East, where Brucella is endemic, and this titer may represent previous exposure or infection. *B. canis* is not detected by the STA, and although the patient does have possible exposure from his three dogs, the STA would not be positive from this *Brucella* species. Blood culture sensitivity is about 30% and decreases with increasing duration of illness. Bone marrow culture is invasive but may be more sensitive than blood culture, especially in *B. melitensis* infection.

2. A 54-year old female veterinarian is admitted with a 1-week history of dyspnea and fever. Chest radiography shows cephalization and congestive changes with small bilateral pleural effusions. On examination, she has neck vein engorgement, fine bibasilar crackles, and a grade 4/6 systolic murmur. A transthoracic echocardiogram shows an 8-mm vegetation on the aortic valve. She is started on vancomycin 1 g intravenously every 12 hours, ceftriaxone 2 g intravenously every 24 hours, and diuretics with some improvement. Blood cultures grow *Brucella melitensis*. Which exposure is the most likely cause of this patient's brucellosis?

A. Ingestion of unpasteurized goat cheese smuggled from Europe
B. Assisting in the delivery of a stillborn calf
C. A recent encounter with seals and sea lions at the local aquarium
D. A visit to a pig farm to give vaccines
E. A bite from a dog

Answer: A *B. melitensis* is acquired from goats, sheep, and camels, including unpasteurized dairy products from these animals. Bovine hosts transmit *B. abortus,* especially from spontaneously aborted fetuses. Seals and sea lions are possible sources of *B. pinnipedia,* pigs transmit *B. suis,* and dogs harbor *B. canis*.

3. The patient in question 2 continues to have shortness of breath and signs of congestion despite adequate diuresis. Then correct management for this patient is

A. continue vancomycin but shift the ceftriaxone to ciprofloxacin and repeat transthoracic echocardiography in 6 weeks.
B. continue vancomycin and ceftriaxone and refer to a cardiothoracic surgeon for early valve replacement.
C. continue vancomycin but shift the ceftriaxone to ciprofloxacin and refer to a cardiothoracic surgeon for early valve replacement.
D. stop vancomycin and ceftriaxone and start doxycycline and intramuscular streptomycin and refer to a cardiothoracic surgeon for early valve replacement.
E. stop vancomycin and ceftriaxone and start doxycycline and intramuscular streptomycin and repeat echocardiogram in 6 weeks.

Answer: D The regimens of choice for *Brucella* infection include doxycycline in addition to either streptomycin or gentamicin. Early valve replacement has been shown to decrease mortality in *Brucella* endocarditis, so prompt referral to a cardiothoracic surgeon should be made. Vancomycin and ceftriaxone are not reliable alternative agents, and even though third-generation cephalosporins are used in alternative regimens, monotherapy is not recommended. Fluoroquinolones likewise have some activity against *Brucella* spp. but should not be used as monotherapy.

4. The intracellular nature of *Brucella* means that it must be able to avoid detection before entry into the cell and survive the defense mechanisms that the cell deploys to destroy pathogens. Which of the following statements is consistent with the strategy *Brucella* uses in its pathogenesis?

A. *Brucella* has a modified lipopolysaccharide (LPS) that has substantially decreased activity against TLR9 but is still activated by complement.
B. Pathogenic *Brucella* organisms are able to prevent acidification of the phagosome.
C. Specific virulence factors such as the VirB type IV secretion system (T4SS) are induced with phagosome acidification, which enables the bacteria to survive both acidification and lysosome fusion.
D. *Brucella* intercepts traffic between the nucleus and the ribosomes in order to replicate.
E. Neutrophils are an integral part of the response against *Brucella*, and their absence leads to substantially depressed immune activation.

Answer: C Specific virulence factors such as T4SS are activated by phagosome acidification and enable *Brucella* to survive both acidification and lysosome fusion. Modified Brucella LPS has little activity against TLR4 and is resistant to complement activation. Acidification is an integral part of inducing T4SS, and *Brucella* does not inhibit this process. *Brucella* intercepts traffic between the endoplasmic reticulum and the Golgi apparatus, not between the nucleus and ribosomes. Neutrophils have been found to be inhibitory to the immune response toward *Brucella,* and absence of these cells leads to an enhanced response.

5. A 28-year-old farmer develops fever and severe hip pain over the past 3 weeks. Magnetic resonance imaging shows sacroiliitis, and his blood cultures grow gram-negative coccobacilli. The following measures could have been taken to decrease the risk of this disease EXCEPT

A. wearing protective glasses and clothes when handling cattle and cattle products.
B. pasteurization of cheese and dairy.
C. eating only fully cooked meat.
D. vaccination against the pathogen.
E. vaccination of farm animals against the pathogen.

Answer: D There is currently no approved human vaccine against *Brucella* spp. All of the other choices are correct.

311 TULAREMIA AND OTHER *FRANCISELLA* INFECTIONS

WILLIAM SCHAFFNER

DEFINITION

Tularemia is an infectious zoonosis caused by *Francisella tularensis,* a small aerobic, pleomorphic, gram-negative bacillus. Many animal species harbor the organism, most prominently rabbits, squirrels, and muskrats. Humans acquire the infection through various means, including direct contact with infected animal tissues, ingestion of contaminated water or meat, the bite of an infected tick or deer fly, or breathing an aerosol of bacteria.[1,2] Although *F. tularensis* is highly infectious and is a well-recognized risk to laboratory personnel manipulating culture plates of the organism, it is a paradox that the illness is not communicable from person to person. Edward Francis established that deer flies can transmit the infection from animals to humans and provided detailed descriptions of its clinical manifestations. Colloquially, the disease is often referred to as *rabbit fever* or *deer fly fever.*

The Pathogen

The organism occurs in two major subspecies (biovars). *F. tularensis* biovar *tularensis* (type A) is more virulent in animals and humans, has distinctive biochemical reactions (it produces acid from glycerol and has citrulline ureidase activity), and is the common North American biovar. In contrast, *F. tularensis* biovar *holarctica* (type B) is less virulent and occurs commonly in Europe and Asia. Type B is most frequently isolated from rodent species, including muskrats *(Ondatra zibethicus),* mice *(Mus musculus),* beavers *(Castor canadensis),* voles (*Microtus* spp.), and water voles *(Arvicola terrestris),* and has been associated with an outbreak of infection in wild-caught prairie dogs. Specific virulence factors for *F. tularensis* have not been identified.

EPIDEMIOLOGY

Tularemia has been reported in the United States, Canada, Mexico, Japan, and Europe (particularly Scandinavia). It has not been reported in the United Kingdom or the Southern Hemisphere. In the United States, reported cases diminished during the second half of the 20th century from a high of 2291 cases in 1939 to the approximately 125 cases reported annually at present. Tularemia has occurred in all the continental states, but four states account for 56% of reported cases: Arkansas, Missouri, Oklahoma, and South Dakota. The island of Martha's Vineyard off the coast of Massachusetts is also a focus of tularemia.

In the United States, tularemia is usually acquired from tick bites or from contact with infected animals, especially rabbits. Tick-associated cases now constitute the majority and occur during the summer. The most common vectors in the United States are the wood tick *(Dermacentor andersoni),* the dog tick *(Dermacentor variabilis),* and the Lone Star tick *(Amblyomma americanum).* A smaller peak of autumn and winter cases is a consequence of rabbit hunters skinning and eviscerating their game. Public health education materials aimed at decreasing the hazards of handling wild animals have contributed to the reduction of tularemia in hunters. Mosquitoes are the common vectors in northern Europe. Occasional individuals acquire infection from the bite of an infected animal or, more likely, from the bite of an animal whose mouth was contaminated from recently eating a diseased animal. The latter likely explains most instances of cat-bite tularemia.

Males experience a higher incidence of disease than females in all age groups, probably as a consequence of their greater exposure to the outdoors and animal-related activities and less use of protective measures against tick bites. Persons in all age groups are affected, with children 5 to 14 years of age and older adults most prominently represented. In the United States, American Indians and Alaska natives experience the highest annual incidence (0.5 per 100,000); whites have a lower risk (0.04 per 100,000), and African Americans and Asians/Pacific Islanders have the lowest occurrence of tularemia (≤0.01 per 100,000).

Although tularemia is usually a sporadic infection, outbreaks of disease have been traced to laboratory exposure, contaminated groundwater, muskrat handling, lawn mowing, and brush cutting. In the latter two cases, primary pneumonic tularemia apparently occurred when the affected individuals created an environmental aerosol by mowing grass and cutting brush that had been contaminated with *F. tularensis* excreted in the urine and feces of infected rodents. The organism can survive in water, mud, and straw for weeks to months.

Interest in tularemia has been enhanced because of its potential use as a bioterrorism agent.[3] Its high infectivity (as few as 10 organisms have induced pneumonic disease), its ease of dissemination, and the difficulty of rapidly diagnosing acute illness are characteristics that merit its inclusion among threat agents. Thus, tularemia must be reported immediately to local public health authorities. Unusual patterns of disease will be investigated for both conventional and bioterrorist sources.

PATHOBIOLOGY

F. tularensis can infect humans through several portals of entry, including the skin, mucous membranes, and gastrointestinal and respiratory tracts. It requires intracellular residence and can multiply within macrophages and other cells. After inoculation into the skin and subcutaneous tissue, local bacterial multiplication occurs and evokes a suppurative necrotic reaction characterized by an initial polymorphonuclear response followed by an influx of macrophages and lymphocytes. These suppurative lesions evolve into granulomas. Bacteremia can occur both early and late during this process. The infection can disseminate to the lymph nodes, liver, spleen, lungs, and pleura. Viable *F. tularensis* can persist in tissues for long periods, contributing to the tendency to relapse after treatment.

CLINICAL MANIFESTATIONS

Classically, the clinical manifestations of tularemia have been separated into six categories: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic. Although this classification has historic roots, it should not be used rigidly because many patients have features of several types. The course of illness is determined by the portal of entry, the degree of systemic involvement, and the dose and virulence of the infecting strain of *F. tularensis.*[4]

The general features of tularemia are similar regardless of the portal of entry. After exposure, the usual incubation period is 3 to 5 days (range, 1-21 days). The disease begins abruptly with the onset of fever (≥101° F), chills, malaise, and headache. Myalgia, vomiting, sore throat, and abdominal pain can also occur. Almost half the patients have a pulse rate that is substantially slower than would be anticipated based on the degree of fever (pulse–temperature dissociation). The fever may abate somewhat after 1 to 3 days, only to recur and continue along with other symptoms for 2 to 3 weeks. Untreated, weight loss, easy fatigue, and lymphadenopathy may persist for weeks longer.

Ulceroglandular Disease

Ulceroglandular disease is the form of infection most readily recognized by physicians. Along with fever and other constitutional symptoms, the patient calls attention to tender, swollen lymph nodes that drain an inoculation site. The nodes are usually axillary or inguinal, and a local lesion appears concurrently or 1 or 2 days before or after the lymphadenopathy. The lesions at the site of inoculation begin as small, red, tender, or painful papules that progress to pustules and then undergo necrosis to produce an ulcer with sharp, somewhat elevated edges and a flat base that becomes black. Untreated, the ulcers heal over a period of weeks and leave scars. Tick-induced infections produce lesions on the trunk, about the waist, and in the perineum, along with the expected local adenopathy. Children typically have occipital and cervical adenopathy from tick bites on the neck and in the hair. Animal exposure often produces lesions on the hands and forearms. Lesions may be multiple. Because the organisms evoke a localized granulomatous response, frank lymphangitis does not occur in uncomplicated tularemia, but an occasional patient manifests a chain of nodules in "sporotrichoid" fashion along the lymphatic drainage.

Patients with such apparently "localized" disease often have symptoms and findings indicating a more widespread infection. Sore throat with or without an erythematous pharynx occurs, as well as chest radiographic findings of patchy infiltrates in the lower lobes, pleural effusions, and hilar adenopathy.

Glandular and Typhoidal Disease

Glandular disease is essentially the same clinical syndrome as ulceroglandular disease but without the local lesion. Thus, the patient has fever, constitutional symptoms, and lymphadenopathy. The local lesion may have been on a part of the body where it was not seen, or it may have been small and already healed by the time the patient sought medical care. Glandular disease accounts for only 3% to 20% of cases. Typhoidal disease does not show evidence of lymphadenopathy and is essentially characterized by fever of unknown cause. These illnesses evade diagnosis unless the physician specifically considers the possibility of tularemia and inquires about tick or animal exposure. Occasionally, the diagnosis is made fortuitously when a positive blood culture is reported.

Oculoglandular Disease

Oculoglandular disease is rare (<5% of cases) and occurs when the conjunctival sac is the portal of entry via an aerosol, splash, or contaminated fingers. It is almost always unilateral and can have a dramatic manifestation with inflamed, swollen eyelids, chemosis, and painful conjunctivitis. The palpebral conjunctiva often shows small yellow nodules and ulcers, counterparts to the skin lesions of ulceroglandular disease. The affected regional lymph nodes are those of the head and neck.

Oropharyngeal Disease

Oropharyngeal disease is also uncommon in the United States and occurs when the mucous membranes of the mouth and pharynx are the portal of entry. Contaminated water or food (inadequately cooked game meat) is the source. Painful exudative pharyngitis and tonsillitis, pharyngeal ulcers, and swollen retropharyngeal and cervical lymph nodes are seen.[5]

Pneumonic Disease

Although pneumonia may be one aspect of the other tularemic syndromes, *pneumonic tularemia* refers to an illness that manifests as a distinctive pneumonia.[6] It accounts for about 10% of reported cases and occurs from inhalational exposure. This is the form of the disease that would result from bioterrorism. In addition to fever and malaise, patients may have a dry cough, substernal discomfort, pleural pain, dyspnea, and sore throat. These pulmonary symptoms may not be very prominent in the context of the systemic illness. Hemoptysis is unlikely. The results of physical examination reflect the extent and distribution of the pneumonic process, which may range from barely evident to frank consolidation with pleural effusion. Radiographic findings range from modest peribronchial infiltrates early in the illness to distinctive bronchopneumonia with effusion. Hilar adenopathy is present in more than one third of cases. Sputum examination is not helpful. Pleural effusions generally contain more than 1000 lymphocytes/mm^3. Gram stain results are negative, and pleural biopsies occasionally contain granuloma, thus inviting confusion with tuberculosis. Without a suggestive history of tick or animal exposure, patients with tularemic pneumonia may be thought to have poorly responding community-acquired pneumonia. Fluoroquinolone antibiotics are commonly used as empirical therapy in this circumstance to treat some patients with undiagnosed tularemia pneumonia.

DIAGNOSIS

The diagnosis of tularemia usually involves serologic testing with tube agglutination or microagglutination techniques. Antibody concentrations do not reach diagnostic levels until after the 11th day of illness. A single acute titer of 1 : 160 is considered presumptive; a confirmed diagnosis requires a fourfold rise in titer between acute and convalescent specimens. Titers of both immunoglobulin M and immunoglobulin G antibodies may remain elevated for many years after the illness.

Differential Diagnosis

The differential diagnosis of patients with tularemia is substantial. The local lesions can be confused with cat-scratch disease, brown recluse spider bites, *Mycobacterium marinum* infection, herpes simplex infection (Chapter 374), and even syphilis (Chapter 319) and chancroid (Chapter 301) when the lesions are in the perineum or on the penis. Pneumonic tularemia resembles common community-acquired pneumonia (Chapter 97), as well as less common infections such as psittacosis, legionellosis, and Q fever. The glandular and typhoidal forms can resemble typhoid fever (Chapter 308), brucellosis (Chapter 310), ehrlichiosis, and other illnesses accompanied by nonspecific fevers.

Routine laboratory studies do not provide specific results. Leukocyte counts may be within normal limits or elevated; thrombocytopenia, elevated liver enzymes, and sterile pyuria occur with some frequency. *F. tularensis* may be isolated from blood cultures and tissue specimens when media containing cysteine are used. Laboratory personnel should be notified when tularemia is suspected so that appropriate media can be used and to ensure that safeguards are in place to protect against the production of hazardous aerosols.

TREATMENT

Rx

Because tularemia is a relatively uncommon disease, therapeutic recommendations are based on a combination of in vitro studies and accumulated clinical experience. The preferred antimicrobials are streptomycin and gentamicin; either one is given for 10 days. Streptomycin is given at a dose of 1 g intramuscularly twice daily. Gentamicin may be more readily available and is administered at a dose of 5 mg/kg intramuscularly or intravenously once daily. Both chloramphenicol and the tetracyclines have been used in the past to treat tularemia; however, use of both these bacteriostatic agents has resulted in higher rates of relapse than treatment with streptomycin or gentamicin. Because chloramphenicol may produce bone marrow toxicity, it is rarely used today. Doxycycline is administered at a dose of 100 mg intravenously twice daily for 14 days. In recent years, ciprofloxacin has been used successfully in a growing number of patients; the dosage is 750 mg intravenously twice daily for 10 days. Both of these drugs can be switched to oral administration of the same doses as soon as tolerated by the patient. There is a need to develop new therapeutic strategies to improve the management of patients with tularemia.[7,8]

PREVENTION

Prevention of tularemia entails minimizing exposure to ticks and avoiding direct exposure to wild animals. Tick protection includes clothing that extends to the wrists and ankles, regular inspection for attached ticks, and the use of insect repellents containing diethyltoluamide (DEET). Gloves should be worn when skinning and dressing game animals, especially rabbits, and all wild rabbit and other game meats should be cooked thoroughly.

A live, attenuated vaccine has been used in the past to provide some protection to researchers working with *F. tularensis*. The vaccine is not available commercially.

PROGNOSIS

Before treatment became available, acute tularemia often lasted as long as 1 month followed by several months of debility. The mortality rate approached 10%. When appropriately diagnosed and treated, the mortality rate from tularemia is now 1% or less.

REVIEW QUESTIONS

1. In the United States, persons most commonly acquire *F. tularensis* infection from

A. mosquitoes.
B. tick bites.
C. skinning infected rabbits.
D. person-to-person contact.
E. both B and C.

Answer: E Mosquito bites are a common mode of acquisition of infection in Europe. Although highly infectious, tularemia is not spread from person to person.

2. Tularemia is considered a potential bioterrorism agent. Among characteristic(s) of the disease that merit its inclusion among threat agents, which one of the following is not true?

A. *F. tularensis* produces an easily diagnosed illness.
B. It is highly infectious.
C. It can survive in the environment for long periods.
D. It can be disseminated readily (e.g., by aerosol).
E. A vaccine is not available.

Answer: A Indeed, because aerosol inoculation produces a nonspecific pneumonia that often defies quick diagnosis, many cases may occur before a bioterrorism event might be detected. This would have the advantage of disabling a large proportion of the target population rather quickly; the fear initiated by the recognition of the terrorism event would follow when the diagnosis became apparent.

3. It is thought that tularemic pneumonia may occur more commonly than is reported. Reasons for this include

A. underreporting of diagnosed cases to public health authorities.
B. physicians not eliciting exposure histories.
C. omission of specific serologic diagnostic testing.
D. empiric therapy of community-acquired pneumonia with fluoroquinolone antibiotics.
E. all of the above.

Answer: E Because fluoroquinolones are active against *F. tularensis,* empiric treatment may cure some patients even though a specific diagnosis was not established.

PLAGUE AND OTHER *YERSINIA* INFECTIONS

KENNETH L. GAGE AND PAUL S. MEAD

The genus *Yersinia* currently contains at least 18 species, only three of which are known to be significant human pathogens (*Yersinia pestis, Yersinia enterocolitica,* and *Yersinia pseudotuberculosis*). The remaining species are normally considered nonpathogenic and are most frequently isolated from environmental specimens, including fish, water, and fecal samples. Although these minor yersiniae have been identified primarily from environmental samples, they are occasionally recovered from patient samples, suggesting a possible role as human pathogens.

YERSINIA PESTIS

DEFINITION

Plague is a highly fatal flea-borne disease that is best known as the cause of the Black Death of the Middle Ages.[1] Its etiologic agent, *Y. pestis,* is a gram-negative coccobacillus belonging to the family Enterobacteriaceae.

The Pathogen

Y. pestis is microaerophilic, gram negative, nonmotile, and nonsporulating; it can exist as a facultative intracellular pathogen and exhibits bipolar staining with Wayson, Giemsa, and Wright stains (Fig. 312-1). It is fragile outside its hosts or vectors but can be grown within 24 to 48 hours on a variety of bacteriologic media at temperatures ranging from 4° to 40° C. *Y. pestis* lacks a true capsule but has a carbohydrate-protein envelope comprised of the *capsular* or *fraction 1 antigen.* Production of this antigen occurs only at temperatures above 33° C. Wild-type strains typically bear three plasmids with sizes of approximately 100 to 110 kilobases (kb), 70 to 75 kb, and 9.5 kb (19 kb if present as a dimer), respectively. Although only one serotype is thought to exist, strains can be classified into biotypes. The three classic biotypes (*antiqua, mediaevalis,* and *orientalis*) differ in their ability to ferment glycerol and reduce nitrates. All three biotypes occur in Asia, which is generally accepted as the continent where plague originated. Two biotypes exist in Africa (*antiqua* and *orientalis*), but only the *orientalis* biotype occurs in the Americas. Although these three biotypes have historical and biogeographic significance, all are highly virulent and appear to cause virtually identical signs and symptoms in humans. Recently, a fourth biotype (*microtus* or *pestoides*), which is purportedly nonpathogenic for humans, was reported from east-central Asia.[2] More modern typing methods, including ribotyping, multiple-locus variable-number tandem repeat assays, and single-nucleotide polymorphism analysis, are proving useful for molecular epidemiology studies, identification of probable environmental sources of human infection, and phylogenetic analyses.

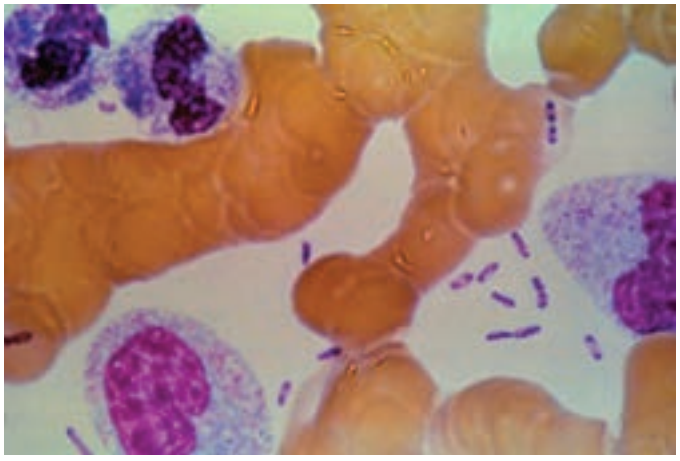

FIGURE 312-1. Wayson-stained blood smear from a fatal case of human septicemic plague (Centers for Disease Control and Prevention).

EPIDEMIOLOGY

Y. pestis is maintained in nature through transmission cycles involving certain rodent species and their fleas, which act as vectors. Although other mammals often become infected with *Y. pestis* and occasionally succumb to plague, the only nonrodent species reported to be important hosts for infecting vector fleas and perhaps contributing to the maintenance of plague in some natural foci are certain species of rabbits and hares, the steppe pika of central Asia, and the house shrew of southeastern Asia and Madagascar. Rodent-consuming carnivores and raptors might play indirect roles in spreading plague by transporting infected rodent fleas from one area to another.

Foci of *Y. pestis* infection occur in rodent populations in many regions of Africa, Asia, and the Americas, although only about 2000 to 5000 human cases were reported each year to the World Health Organization (WHO) in the period 1987 to 2009. In the 1960s and 1970s, the majority of human cases occurred in Southeast Asia, which was the site of civil wars and political unrest. However, beginning in the 1980s, this situation began to change, and most cases now occur in Africa, especially the Congo,[3] and nearby Madagascar.[4] According to the most recently released WHO statistics for 2004 to 2009, 96.6% of the world's cases occurred in the Democratic Republic of Congo, Madagascar, Uganda, and other countries in Africa (Fig. 312-2). Asian countries reported only 1.6% of the total cases, and another 1.8% were reported from five countries in the Americas, including the Brazil, Bolivia, Ecuador, Peru, and the United States. Since 1970, evidence of *Y. pestis* infection has been identified in animals or their fleas in 17 western states, and human cases have been identified in 13 of these states (Fig. 312-3). Most of these cases have occurred in three southwestern states (New Mexico, Arizona and Colorado) and California.

Humans most frequently acquire plague as a result of being bitten by infectious fleas (Fig. 312-4). On a worldwide basis, the risk of flea bite exposure is highest in poverty-stricken areas that are situated near natural plague foci and have large infestations of commensal rats (*Rattus* spp.) heavily infested with fleas, particularly the oriental rat flea (*Xenopsylla cheopis*). *X. cheopis* readily feeds on humans and is an efficient vector of *Y. pestis* to people as well as to rats. Persons are most likely to be bitten by infectious *X. cheopis* when plague epizootics cause massive mortality among susceptible rats, forcing these fleas to seek new hosts. Currently, certain regions of central and southern Africa (including Madagascar), southeastern Asia and India, and a few areas in South America remain at relatively high risk for rat-associated plague outbreaks. The spread of rat-associated plague from one region to another, perhaps by the natural movement of rats or their transport along with trade goods, poses a threat of epidemics in large rat-infested cities, as demonstrated by the repeated spread of plague from the central highlands of Madagascar to the port city of Majunga, where the disease has caused multiple outbreaks in the past 2 decades. The appearance of bubonic cases acquired via flea bite in large cities also greatly increases the possibility that secondary pneumonic plague with hemoptysis will develop in untreated bubonic cases and that the infection will spread to others through inhalation of infectious respiratory droplets expelled by coughing pneumonic plague patients. Such spread will result in cases of primary pneumonic plague, a form of the disease that is often fatal and can spread rapidly from person to person under appropriate circumstances. The persons most at risk for acquiring plague through respiratory droplet spread are those who fail to take appropriate respiratory precautions and come into close contact (≤2 m) with coughing pneumonic plague patients experiencing hemoptysis. Human-to-human spread of primary pneumonic plague has not been reported in the United States since 1924, when an outbreak occurred in Los Angeles, California. The few cases of naturally acquired primary pneumonic plague that have occurred in this country since that time, and for which likely sources of exposure were identified, have involved pet owners or veterinary staff handling cats with signs of plague pneumonia, pharyngitis, or oral abscesses. Although rare in the United States, primary pneumonic plague still poses a threat in developing countries, with outbreaks occurring in the past 20 years in India, Ecuador, Madagascar, the Democratic Republic of Congo, and Uganda. It should be noted, however, that the spread of pneumonic plague depends on many factors, and relatively simple control measures can quickly and effectively stop the respiratory droplet spread of pneumonic plague.[5]

At present, rat-associated plague poses little risk to persons in the United States, with most cases resulting from exposure to the bites of infectious wild rodent fleas (79% in one case series), although a significant number (19%)

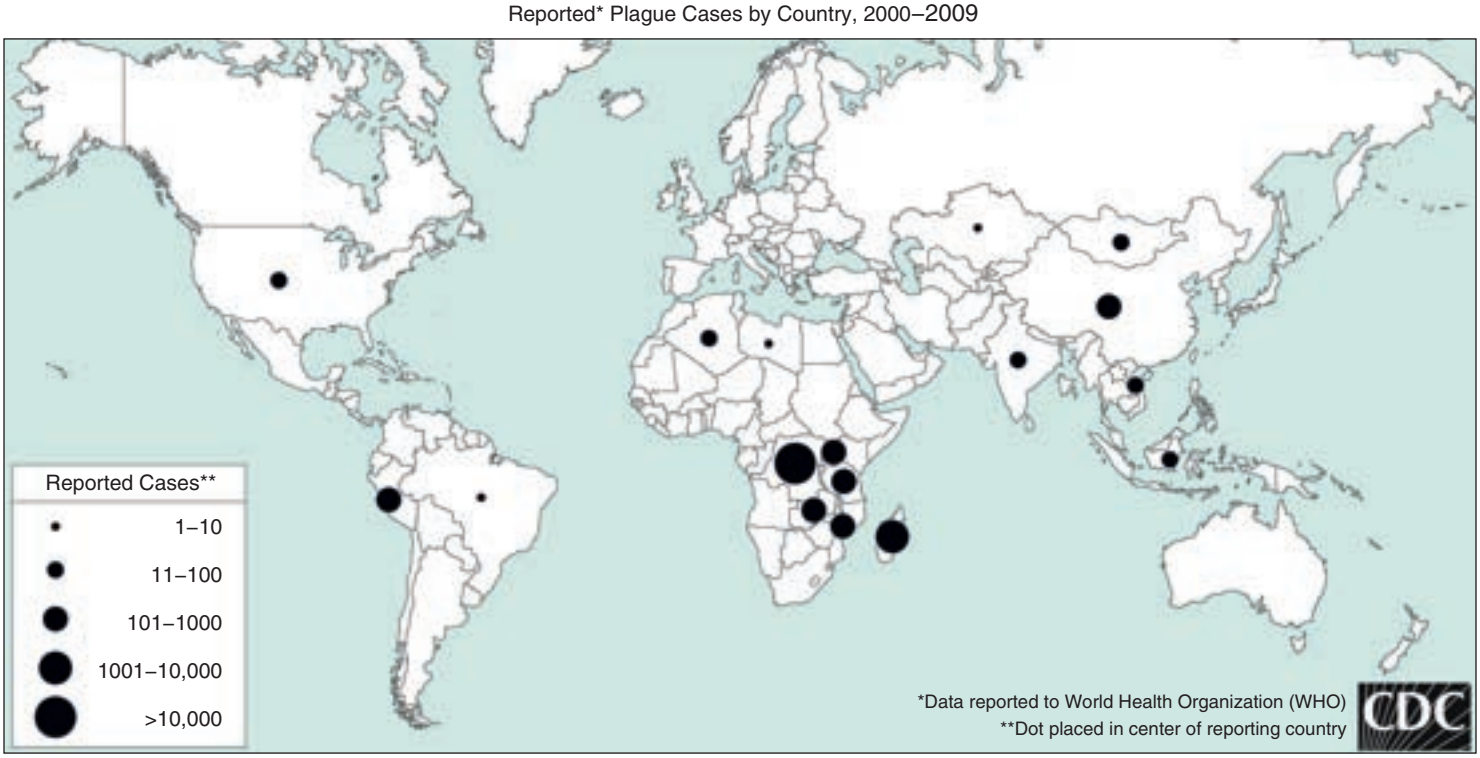

FIGURE 312-2. Worldwide distribution of plague in humans, 2000 to 2009. (Data compiled from the World Health Organization, Centers for Disease Control and Prevention, and other sources.)

were exposed while handling *Y. pestis*–infected animals, including rabbits, domestic cats, wild rodents, and wild carnivores. These direct-contact exposures occurred primarily in persons who had been bitten or scratched by infected cats or had skinned infectious rabbits or rodents for meat or certain wild carnivores for their fur. The risk of exposure to infectious wild rodent fleas or animals is typically greatest when epizootics cause high mortality rates in certain rodent species in the western United States, particularly ground squirrels, prairie dogs, wood rats, and chipmunks. Epizootics appear to progress most rapidly during late spring to early fall, when human cases also peak, probably because this is the period of greatest flea vector activity. Most cases arising from flea bite occur when persons are exposed to fleas as a result of close contact with dead hosts that are flea infested or with the nests or burrows of infected hosts. Evidence also exists that allowing dogs from plague-endemic areas to sleep in their owners' beds increases plague risk for these persons, presumably because these animals carry infectious fleas into beds. The few human cases reported during the winter months are typically acquired through direct contact with infected animals, and affected individuals have a history of hunting or trapping wild animals or handling domestic cats. The exposure sites for most U.S. cases are peridomestic environments, with smaller numbers of exposures occurring during recreational activities such as hunting or camping.[6] Occupational exposure has also rarely occurred among veterinary staff, biologists, and trappers. Rarely, primary pneumonic plague has been acquired in the United States through the inhalation of infectious materials (2% of cases) by means of close face-to-face contact with *Y. pestis*–infected cats that had oral lesions or signs of plague pneumonia, including cough.

Recently, concern has been raised that plague could be used as an agent of bioterrorism (Chapter 21). In most projected scenarios, bioterrorists would spread plague in an aerosol form, potentially resulting in numerous primary pneumonic cases, a high mortality rate, and widespread panic, especially if the *Y. pestis* strains released had been engineered to be resistant to antimicrobial agents commonly used to treat plague.

PATHOBIOLOGY

Y. pestis possesses a variety of virulence factors that promote its initial invasion of the host, evasion of the host's immune system, survival in lymph nodes, and the development of a fulminant bacteremia that can lead to fatal gram-negative sepsis and the spread of the pathogen to other organs.[7] Few bacteria rival the pathogenicity of *Y. pestis* for humans. *Y. pestis* usually enters the body at the site of a flea bite or perhaps as a result of contact between abraded or cut skin and blood or other body fluids from a *Y. pestis*–infected animal. On entering the body, plague bacteria come under attack by host phagocytes and other host defenses. Although many of the invading *Y. pestis* are killed by arriving polymorphonuclear leukocytes, some enter into and survive in mononuclear cells, where they are carried via the lymphatics to regional lymph nodes. The ability to escape from the host's innate immune defenses and disseminate to regional lymph nodes depends in part on a protease (Pla) encoded on the 9.5 kb plasmid that helps degrade fibrin clots and promote the production of excess plasmin, which can affect inflammatory exudates, break down extracellular proteins and basement membranes, and reduce levels of chemoattractants, possibly because of the inhibition of interleukin-8 production at the site of initial infection. Another virulence factor, YopM, is one of many *Yersinia* outer proteins (Yops), encoded by genes on the midsized (70-75 kb) plasmid of *Y. pestis*. Although most other Yops are degraded by the Pla protease, YopM is resistant to its activity and probably aids in the dissemination of *Y. pestis* by competing with platelets for thrombin, a factor that not only reduces clotting but also inhibits the activation of platelets, thereby lowering local inflammatory responses and promoting the dissemination of *Y. pestis* to regional lymph nodes. Initial invasion and dispersal to regional lymph nodes also depend on the ability of *Y. pestis* to survive for at least brief periods in host phagocytes. Survival in such environments is promoted by other Yops that work in concert with a type III secretory apparatus to deliver into host phagocytes those Yops that act as intracellular effectors. These effector Yops disturb the cytoskeletal dynamics of phagocytic cells and block their production of proinflammatory cytokines. Affected phagocytes are rendered incapable of killing the invading *Y. pestis,* thereby allowing this bacterium to survive extracellularly in lymphoid tissues. Survival of *Y. pestis* in mammalian hosts also depends on its ability to acquire sufficient quantities of iron for growth. The most important means of iron uptake in *Y. pestis* is a siderophore (yersiniabactin) system that can effectively compete with host iron-binding molecules for this essential nutrient. Although the ability of *Y. pestis* to resist host phagocytic killing and survive intracellularly in phagocytes is thought to be particularly important during the early stages of infection, plague bacteria also express a glycoprotein capsular antigen (caf1 or fraction 1 antigen) that confers resistance to phagocytosis. Expression of caf1 is temperature dependent, being repressed at the

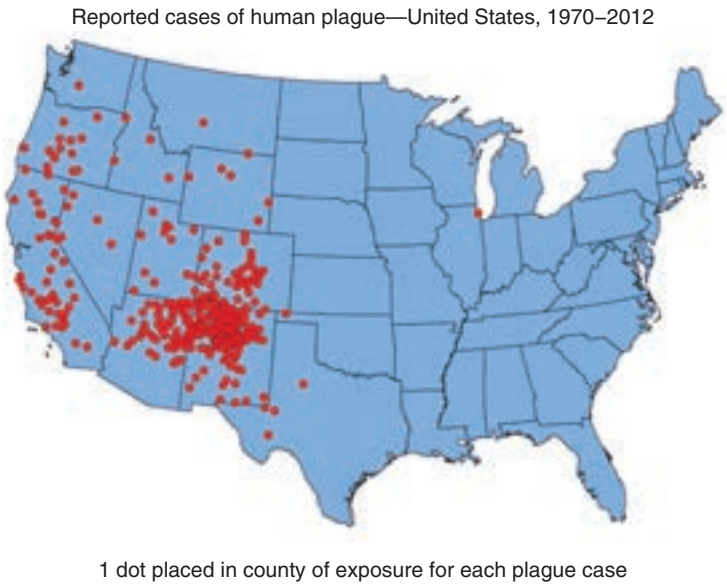

FIGURE 312-3. Distribution of human plague cases in the United States, 1970 to 2012. Case points were randomly placed within counties where exposures occurred to indicate the general distribution and clustering of cases by region. One dot placed in county of exposure for each plague case (Centers for Disease Control and Prevention).

cooler temperatures found in the flea vector and upregulated at mammalian host body temperatures.

Infected lymph nodes, termed *buboes,* can appear edematous and congested early in the course of illness but exhibit little evidence of inflammatory infiltrates or vascular injury. These buboes represent the most obvious manifestation of the lymphatic system's efforts to arrest the spread of *Y. pestis,* and within a few days after infection, they contain massive numbers of *Y. pestis* and heavy neutrophil infiltrates, which cause them to swell to the size of a hen's egg and become surrounded by serous fluid. As the illness progresses, hemorrhagic necrosis and vascular damage in the node become apparent; some nodes spontaneously rupture, and abscesses appear. Although *Y. pestis* can be present in small quantities in blood samples taken relatively early in the course of infection, large quantities of plague bacteria usually appear in the blood of patients with bubonic plague only after the lymph node defenses are overwhelmed.

As the bacteria escape from the node and proliferate in blood, patients with bubonic plague begin to exhibit evidence of plague septicemia (secondary septicemic plague). Patients with inadequately treated septicemic plague can experience widespread and overwhelming destruction of tissues as *Y. pestis* spreads to various organs, eventually resulting in their failure. Patients who die of plague often experience diffuse interstitial myocarditis, cardiac dilation, diffuse hemorrhagic splenic necrosis, renal glomeruli containing fibrin thrombi, and multifocal necrosis in the liver. Disseminated intravascular coagulation can lead to thrombosis within capillaries, vascular necrosis, ecchymoses, acral gangrene, and cutaneous, mucosal, and serosal petechiae

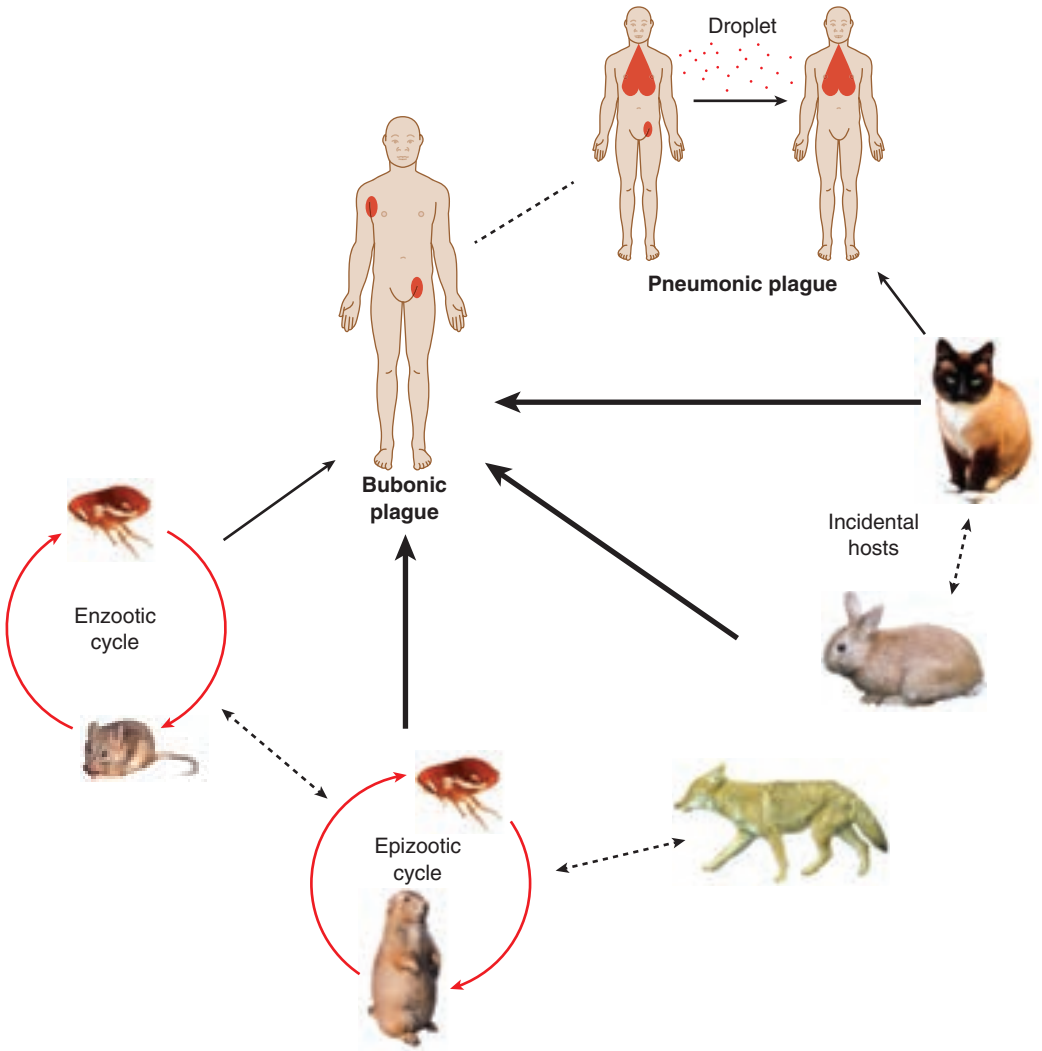

FIGURE 312-4. Ecology and transmission of plague. *Red circles* indicate zoonotic cycles. Common routes of transmission to humans indicated by *wide solid arrows* and uncommon routes by thin *arrows* (Centers for Disease Control and Prevention).

FIGURE 312-5. Hand of a patient with plague displaying acral gangrene, a manifestation that may have given rise to the term "black death" (Centers for Disease Control and Prevention).

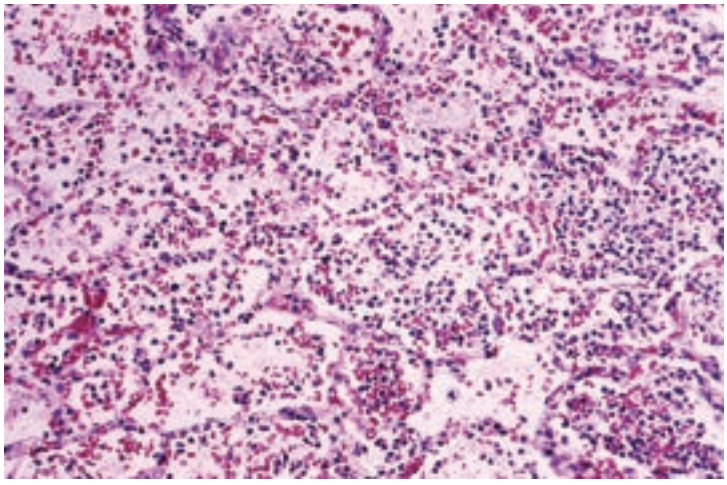

FIGURE 312-6. Photomicrograph of lung tissue from fatal case of primary pneumonic plague and septicemic plague. Note filling of alveolar spaces with inflammatory cells and debris (Centers for Disease Control and Prevention).

(Fig. 312-5). In a small proportion of cases, septicemia occurs in the absence of buboes or other signs of localized infection, a condition referred to as *primary septicemic plague.* Septicemic plague can also occur secondary to primary pneumonic plague.

Rarely, plague can be acquired through the inhalation of infectious respiratory droplets or other materials. Patients with primary pneumonic plague typically experience a rapidly progressing lung infection that is initially lobular, then lobar, and finally multilobar, with large numbers of *Y. pestis* being present in the alveoli and pulmonary secretions of affected sites (Fig. 312-6). Pneumonic plague can also occur secondary to bubonic or primary septicemic plague. In these instances, *Y. pestis* invades the lungs in a diffuse manner, with most bacilli appearing in interstitial spaces. The most common pathologic findings are edema, diffuse pulmonary congestion, limited neutrophilic infiltration, and hemorrhagic necrosis. Cavitation and liquefaction necrosis can also occur and result in scarring of the lungs, particularly at sites of consolidation.

CLINICAL MANIFESTATIONS

The three most commonly observed forms of plague (in order of decreasing occurrence) are bubonic, septicemic, and pneumonic. Unusual manifestations of plague include meningitis and pharyngitis. In rare instances, *Y. pestis* has been inoculated through the conjunctiva, resulting in oculoglandular plague. The incubation periods are 2 to 6 days for bubonic plague and 1 to 3 days for primary pneumonic plague.

FIGURE 312-7. Young Malagasy boy with a bubo. (Courtesy Brook Yockey, Centers for Disease Control and Prevention.)

The characteristic swollen and tender lymph nodes (buboes) of bubonic plague usually appear in the node or nodes located closest to the site of initial infection (Fig. 312-7). Most cases of bubonic plague in the United States are thought to be acquired from flea bites on the legs, as indicated by the appearance of inguinal or femoral lymph node involvement on the side where the flea bite occurred. Axillary buboes are also common, often indicating the handling of an infected animal or other flea-infested object. Cervical buboes are much less common in the United States than in many developing countries, perhaps because persons in the latter are more likely to sleep on dirt floors in flea-infested huts, thus increasing their chances of being bitten about the head and neck by infectious fleas. Rarely, a skin lesion appears at the site of an infectious flea bite or other source of inoculation.

Symptoms of bubonic plague include fever, chills, myalgia, arthralgia, headache, malaise, and prostration. Untreated patients with bubonic plague become increasingly toxic, remain febrile, and experience tachycardia, agitation, confusion, delirium, and convulsions.

Septicemic plague manifests as a rapidly progressive, overwhelming endotoxemia. Patients often complain of gastrointestinal (GI) symptoms, including nausea, vomiting, diarrhea, and abdominal plain. Disseminated intravascular coagulation can also occur with the appearance of petechiae, ecchymoses, bleeding, and ischemia in the tips of the extremities. Later-stage septicemic patients are likely to experience refractory hypotension, renal shutdown, obtundation, and other signs of shock. Patients with late-stage septicemic plague can also exhibit acute respiratory distress syndrome (Chapter 104), which has occasionally been confused with hantaviral pulmonary syndrome (Chapter 381) in the American Southwest. Because septicemic plague is likely to be fulminant and fatal, favorable outcomes depend on rapid diagnosis and prompt treatment with appropriate antimicrobials.

Pneumonic plague can be accompanied by fever, cough, chest discomfort that becomes increasingly painful, tachycardia, dyspnea, bacteria-laden sputum, chills, headache, achiness, weakness, and dizziness. As the illness progresses, patients may experience increasing respiratory distress, hemoptysis, cardiopulmonary insufficiency, and circulatory collapse. In the early stages of illness, patients with primary pneumonic plague may have signs of localized pulmonary involvement, beginning in a single lung and rapidly progressing to segmental consolidation and later bronchopneumonia, with death ensuing in as little as 1 to 3 days after the onset of symptoms. Localized infection is unlikely to be observed in the lungs of patients with secondary pneumonic plague because the lung tissues are infected initially through circulatory spread, which results in a diffuse interstitial pneumonitis. The appearance of sputum also differs in primary versus secondary pneumonic plague, being watery or mucoid, frothy, and perhaps tinged with blood in primary pneumonic cases but scanter, thicker, and more tenacious in secondary pneumonic cases.

DIAGNOSIS

Plague fatalities are typically related to delay in seeking treatment or misdiagnosis. The differential diagnosis of plague in its various clinical forms

includes staphylococcal (Chapter 288) or streptococcal adenitis (Chapter 290) or pneumonia (Chapter 97); cat-scratch disease (Chapter 315); tularemia (Chapter 311); chancroid (Chapter 301); acute filarial lymphadenitis (Chapter 358); mycobacterial infection (Chapter 325); septicemia caused by other bacteria; meningococcemia; bacterial endocarditis; mycoplasmal pneumonia and other community-acquired pneumonias; legionnaires' disease (Chapter 314); Q fever; influenza pneumonitis (Chapter 364); hantaviral pulmonary syndrome (Chapter 381); viral pneumonia caused by respiratory syncytial virus (Chapter 362), cytomegalovirus (Chapter 376) or other viruses; and strangulated inguinal hernia.

Laboratory confirmation relies on bacterial culture accompanied by specific bacteriophage lysis tests or detection of a fourfold rise in antibody titer to the *Y. pestis* F1 capsular antigen over a period of 2 to 4 weeks. Although the procedures for confirming the laboratory diagnosis of *Y. pestis* infection are relatively simple, delays can occur because the relevant expertise and reagents are often limited to a few public health or reference laboratories. Because cases of plague can rapidly progress to a life-threatening illness and because culture of *Y. pestis* on bacteriologic media may require 48 hours or longer before colonies become visible, it is essential that patients suspected of having plague receive appropriate antimicrobial therapy immediately after samples have been taken. Direct fluorescent antibody assays can be used to identify *Y. pestis* bacteria in bubo aspirates, sputum samples, and tracheal washes; this procedure requires about 1 hour and provides strong presumptive evidence of infection. A presumptive diagnosis can also be obtained rapidly by detecting *Y. pestis* DNA in polymerase chain reaction (PCR) assays or *Y. pestis*–specific antigens in immunologic assays, but these tests are not widely available. Recently, rapid immunochromatographic tests have been developed that can detect plague antigen or antibodies. The potential advantages of these tests are that they require few laboratory resources, can be done in field settings, and yield results in less than 1 hour. One such test designed to detect *Y. pestis* antigens in patient samples has been used in some developing countries to diagnose plague, but these assays are still being evaluated and are not widely available. Preferred laboratory samples include blood, serum, bubo aspirates, tracheal washes, and swabs of skin lesions or pharyngeal mucosa. Cerebrospinal fluid can also be collected from patients in whom plague meningitis is suspected.

PREVENTION

No commercially available plague vaccine exists in the United States. Newer recombinant vaccines designed to stimulate immune responses to the F1 and V antigens of *Y. pestis* are undergoing clinical trials and have yielded promising results, but they are unlikely to be available in the near future.

Human plague risk can be reduced through the implementation of effective surveillance programs to rapidly identify human cases and threatening epizootics and allow effective intervention measures to be implemented. When appropriate, affected areas can be treated with insecticides to reduce the risk for flea bite exposure. Measures also should be taken to reduce the amount of food and shelter available to rodents. In rare instances, rodenticides can be used to reduce host numbers, but their use is not recommended before the implementation of effective flea control measures. Persons living in or visiting areas endemic for plague should avoid sick and dead animals and use insect repellents to reduce the risk for infectious flea bites. Dogs and cats should be prevented from roaming freely in rodent-infested areas, and these animals should be treated with flea control agents that safely and effectively kill fleas. Although most dogs appear to be somewhat resistant to plague, cats are highly susceptible, often experience severe illness, and can serve as sources of infection for their owners or veterinary staff. Cats that roam outside in endemic areas and suddenly become seriously ill should be taken to a veterinarian for evaluation.

Persons with pneumonic plague should be held in respiratory isolation for at least 48 hours after the initiation of appropriate antimicrobial therapy, and persons caring for such patients should follow respiratory droplet precautions (masks, gloves, gowns, and eye protection). Although human-to-human transmission has not been reported in the United States for many decades, rare cases of primary pneumonic plague have occurred after face-to-face contact with infected cats that had oral lesions or symptoms of pneumonic plague. Veterinary staff from plague-enzootic areas should take appropriate precautions (masks, gloves, gowns, eye protection) when handling sick cats with illnesses suggestive of plague.

Prophylactic antimicrobial therapy is generally recommended for persons with possible plague exposure only in relatively high-risk situations, such as after close contact with patients with pneumonic plague, handling of *Y. pestis*–infected animals, or being bitten by rodent fleas in an area with a recent history of epizootic activity. The most recently recommended prophylactic antimicrobials are doxycycline and ciprofloxacin (Table 312-1).

TREATMENT

Rx

The most commonly recommended agent for treating plague is streptomycin (see Table 312-1), but a randomized trial in Tanzania concluded that gentamicin and doxycycline are effective for treating plague in adults and children and cause few adverse responses.[■] A review of human cases treated in New Mexico also strongly suggests that gentamicin is effective and can be substituted for streptomycin. Tetracyclines are effective for treating uncomplicated cases of bubonic plague, and chloramphenicol is believed to be effective, particularly for plague meningitis. Although antimicrobial resistance is not believed to be a problem in the United States, strains resistant to tetracyclines and other agents have been described occasionally, and resistance to streptomycin and chloramphenicol may also occur. Recently, the Food and Drug Administration approved levofloxacin (Levaquin) to treat patients with plague under the agency's Animal Efficacy Rule, which allows evidence from animal studies, in this case those involving nonhuman primates, to be used to demonstrate the efficacy of a proposed treatment when it is not possible to conduct adequate trials in humans.

PROGNOSIS

Patients with uncomplicated bubonic plague respond quickly to appropriate antimicrobial therapy and typically defervesce, with relief from most other systemic manifestations within 2 to 5 days. Large buboes can remain swollen, however, for more than 1 week and may require incision and drainage if necrotic. In rare instances, ischemic necrosis in septicemic cases has resulted in the amputation of digits.

ENTEROPATHOGENIC YERSINIAE

DEFINITION

Y. enterocolitica and *Y. pseudotuberculosis* differ significantly from *Y. pestis* in that they are enteropathogenic, rarely cause death, and are spread via the fecal–oral route. Similar to *Y. pestis,* both of these bacteria are gram-negative members of the family Enterobacteriaceae.

The Pathogens

Y. enterocolitica is genetically quite distinct from *Y. pseudotuberculosis* and *Y. pestis;* the plague bacterium is thought to have arisen as a recent clone of *Y. pseudotuberculosis,* and the chromosomal DNA of these two species is extremely similar but markedly different from that of *Y. eneterocolitica.*[8] All three species, however, share an approximately 70-kb plasmid that encodes for various proteins (Yops) that are key virulence factors. Unlike *Y. pestis,* the enteropathogenic yersiniae are urease positive and motile at temperatures lower than 30° C. *Y. pseudotuberculosis* is rhamnose positive, thereby distinguishing it from the closely related *Y. pestis* and the more distantly related *Y. enterocolitica.* The enteropathogenic yersiniae are genetically more diverse than the more recently evolved plague bacterium. *Y. enterocolitica* contains six biogroups, five of which are known to be pathogenic for humans, and nearly 60 serogroups; *Y. pseudotuberculosis* has been classified into six distinct serogroups (O groups 1-6).

EPIDEMIOLOGY

Enteropathogenic yersiniae are transmitted via the fecal–oral route, and successful infection of the host requires large doses of bacteria (median infective dose of 10^8 to 10^9 bacteria). Typical sources of infection include the consumption of contaminated foods such as dairy products, inadequately cooked pork, and certain vegetables. Both *Y. enterocolitica* and *Y. pseudotuberculosis* can survive and proliferate slowly at refrigerator temperatures. Although far less common, person-to-person transmission has been reported, as has transmission via blood transfusion. Pigs, rodents, rabbits, sheep, goats, cattle, horses, dogs, cats, and sometimes birds serve as reservoirs for these yersiniae. Most hosts act as asymptomatic carriers, but a few human cases have been associated with handling sick animals. Symptomatic patients shed large amounts of yersiniae for as long as 2 to 3 weeks. Untreated, infected persons can become carriers and shed for 2 to 3 months.

Yersiniosis is a reportable disease in many countries. Most cases result from *Y. enterocolitica* infection, and this agent reportedly accounts for 1% to

TABLE 312-1 RECOMMENDATIONS FOR THE TREATMENT OF PATIENTS WITH PNEUMONIC PLAGUE IN CONTAINED AND MASS CASUALTY SETTINGS AND FOR POSTEXPOSURE PROPHYLAXIS*

PATIENT CATEGORY	RECOMMENDED THERAPY
CONTAINED CASUALTY SETTING	
Adults	Preferred choices: Streptomycin 1 g IM twice daily Gentamicin 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily Alternative choices: Doxycycline 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin 400 mg IV twice daily† Chloramphenicol 25 mg/kg IV 4 times daily‡
Children§	Preferred choices: Streptomycin 15 mg/kg IM twice daily (maximum daily dose, 2 g) Gentamicin 2.5 mg/kg IM or IV 3 times daily‖ Alternative choices: Doxycycline: if ≥45 kg, give adult dosage; if <45 kg, give 2.2 mg/kg IV twice daily (maximum, 200 mg/day) Ciprofloxacin 15 mg/kg IV twice daily† Chloramphenicol 25 mg/kg IV 4 times daily‡
Pregnant women¶	Preferred choice: Gentamicin 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily‖ Alternative choices: Doxycycline 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin 400 mg IV twice daily†
MASS CASUALTY SETTING AND POSTEXPOSURE PROPHYLAXIS**	
Adults	Preferred choices: Doxycycline 100 mg PO twice daily†† Ciprofloxacin 500 mg PO twice daily† Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡
Children§	Preferred choices: Doxycycline††: if ≥45 kg, give adult dosage; if <45 kg, give 2.2 mg/kg PO twice daily Ciprofloxacin 20 mg/kg PO twice daily Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡
Pregnant women¶	Preferred choices: Doxycycline 100 mg PO twice daily†† Ciprofloxacin 500 mg PO twice daily Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡

*These are consensus recommendations of the Working Group on Civilian Biodefense and are not necessarily approved by the U.S. Food and Drug Administration. In general, one antimicrobial agent should be selected, and therapy should be continued for 10 days. Oral therapy should be substituted when the patient's condition improves. Although animal and limited human studies support their use, gentamicin and ciprofloxacin are not currently approved by the U.S. Food and Drug Administration (FDA) for treatment of plague in humans. The related drugs, streptomycin and levofloxacin, are FDA approved for treatment of plague.
†Other fluoroquinolones can be substituted at doses appropriate for age. The ciprofloxacin dosage should not exceed 1 g/day in children.
‡The concentration should be maintained between 5 and 20 μg/mL. Concentrations >25 μg/mL can cause reversible bone marrow suppression.
§In children, the ciprofloxacin dose should not exceed 1 g/day, and the chloramphenicol dose should not exceed 4 g/day. Children younger than 2 years should not receive chloramphenicol.
‖Aminoglycoside dosages must be adjusted based on renal function. Evidence suggests that gentamicin 5 mg/kg intravenously or intramuscularly once daily would be efficacious in children, although this is not yet widely accepted in clinical practice. Neonates up to 1 week of age and premature infants should receive gentamicin 2.5 mg/kg intravenously twice daily.
¶In neonates, a gentamicin loading dose of 4 mg/kg should be given initially.
**The duration of treatment of plague in a mass casualty setting is 10 days. The duration of postexposure prophylaxis to prevent plague infection is 7 days.
††Tetracycline can be substituted for doxycycline.
‡‡Children younger than 2 years should not receive chloramphenicol. An oral formulation is available only outside the United States.
IM, Intramuscular; *IV,* intravenous; *PO,* oral.

3% of all cases of acute enteritis in some areas. From 1996 to 2009, the overall annual incidence in the United States was about 0.5 cases per 100,000 persons, with higher rates among children and African Americans.[9] The incidence has decreased over the past decade, especially among African American children younger than 5 years of age. Nevertheless, rates remain markedly higher among African American and Asian American children, at 3.5 and 5.1 cases per 100,000, respectively. In the past, high rates among African American populations were associated with the home preparation of chitterlings made from contaminated pork intestines. Exposure of contaminated pork products was also considered a likely source of infection for Asian Americans.

Y. enterocolitica serotypes O:3, O:8, O:9, and O:5,27 have been associated with human disease. Serotype O:3 (biotype 4) predominates in most countries and is found most commonly in swine. Serotype O:9 (biotype 2) has been isolated from sheep, cows, and goats. These last two serotypes are the most common causes of human infection worldwide but are considered less pathogenic than strains of the O:8 (biotype 1B) serotype, which are associated with the most severe outbreaks. Although serotype O:8 infections appear to be decreasing in incidence in the United States, they are becoming increasingly important in Japan, Italy, and France. In Europe, most cases involve serotype O:3 infections, although a few are associated with serotypes O:9 and O:5,27. Biotype 1A appears to be nonpathogenic, and biotype 5 has been isolated only from hares. Strains pathogenic in humans are esculin, salicin, and pyrazinamidase negative.

Y. pseudotuberculosis has been isolated from rodents, cattle, sheep, cats, dogs, and birds.[10] It occurs worldwide but human infections are most commonly reported in northern Europe and in Asia, including Japan. O group 1, 2, and 3 strains are associated with human disease, with most cases being attributed to O:1 or O:2 strains. Infected animals serve as chronic carriers and sources for the infection of water and foods such as meat, dairy products, and stored vegetables. Some cases have been associated with the handling of kittens and puppies. Recent outbreaks of *Y. pseudotuberculosis* in Finland were traced to eating iceberg lettuce and carrots (serotypes O:3 and O:1, respectively). A large Canadian outbreak was associated with milk that had been pasteurized but nevertheless became contaminated. Outbreaks in the former Soviet Union have been associated with the consumption of root vegetables that were stored underground for winter consumption and presumably became contaminated with rodent excreta containing *Y. pseudotuberculosis.*

PATHOBIOLOGY

Y. enterocolitica possesses numerous virulence factors responsible for its persistence in the GI tract and ability to cause disease in susceptible hosts. Upon reaching the ileum, *Y. enterocolitica* adheres to the mucosa, where intracellular infections in Peyer's patches, mucosal cells, and macrophages can occur. Invasion of the ileal mucosa is favored by the presence of invasin, an outer membrane protein, and a 17-kD surface factor (Ail). An inflammatory response causes abdominal pain and diarrhea, as well as ulcerative ileitis, mesenteric adenitis, and necrosis within Peyer's patches. If the regional defenses are breached, the bacteria can disseminate and cause sepsis and hepatic and splenic abscesses. Polyarthritis can also occur later in the course of illness, particularly in human leukocyte antigen (HLA)-B27–positive individuals.

Similar to *Y. pestis,* the enteropathogenic yersiniae attack host lymphoid tissues. Invasion of these tissues and resistance against host defenses depend on the possession of the approximately 70-kb plasmid that is shared by each of the three pathogenic yersiniae and bears genes encoding for various Yops and the so-called V antigen. The products of this plasmid work in concert to inhibit phagocytosis and reduce inflammation, thereby suppressing the host immune response and favoring persistence of these microbes.

When *Y. enterocolitica* and *Y. pseudotuberculosis* become established in the lymph nodes, they can resist phagocytosis, which allows them to replicate extracellularly and form aggregates in the nodes. The ability to acquire host iron can be a significant factor contributing to the virulence of *Y. enterocolitica* strains. O:8 serotypes, which are virulent for mice, have the *irp2* (iron repressible 2) gene that encodes for a pair of high-molecular-weight outer membrane proteins, but the mouse avirulent O:3 and O:9 serotypes lack *irp2.* O:3 and O:9 serotypes typically remain confined to the guts of their hosts, except when iron overload is present or patients are being treated with an iron chelator.

Patients with reactive arthritis (Chapter 265) are more likely to have fewer GI symptoms, lower T-cell proliferative responses to *Yersinia* antigens, lower initial immunoglobulin (Ig) M responses, higher and more persistent IgG and IgA responses, and increased levels of IgA with a secretory

component. *Yersinia*-specific antibody responses are also more likely to persist in patients with reactive arthritis than in those with uncomplicated GI disease. *Yersinia* antigens thought to contribute to reactive arthritis include Yops and released proteins, which stimulate host CD4 cells, and heat shock protein 60, which has been hypothesized to work in conjunction with other antigens to modulate the host immune response. Evidence exists that hosts can maintain chronic *Y. enterocolitica* infections for years after the initial infection, a factor that may induce the inflammation associated with reactive arthritis (Chapter 265).

CLINICAL MANIFESTATIONS

After an incubation period of about 3 to 7 days, a gastroenteritis typically develops that can be difficult to distinguish from *Salmonella* (Chapter 308) or *Campylobacter* (Chapter 303) gastroenteritis. The most common clinical syndromes associated with *Y. enterocolitica* infection are acute enteritis with fever, diarrhea, vomiting, right lower quadrant pain suggestive of appendicitis (Chapter 142), erythema nodosum, and reactive arthritis. Other common symptoms include associated pharyngitis, rash, joint pain, and headache. Stool examination reveals leukocytes or erythrocytes, and one fourth of patients experience bloody diarrhea.

Y. pseudotuberculosis infections most commonly manifest as enterocolitis, pharyngitis, and pseudoappendicitis.

Whereas enterocolitis is most likely to occur in young children, older children more frequently experience acute terminal ileitis, mesenteric adenitis, and systemic disease. Pseudoappendicitis has been reported in patients with mesenteric lymphadenitis. Sepsis is uncommon and is most likely to occur in persons with underlying conditions such as diabetes mellitus, cirrhosis, immunosuppression, older age, and hemochromatosis. Splenic abscesses, meningitis, or endocarditis can develop in septic patients, and the mortality rate can approach 50%. Erythema nodosum is identified in about one third of all patients and in 10% of adults.

DIAGNOSIS

Yersiniosis should be suspected in patients with abdominal pain and fever, especially if they live in high-incidence areas. The diagnosis is best accomplished by isolation of the bacterium from stool, blood, or other appropriate samples.[11] Recovery of *Y. enterocolitica* and *Y. pseudotuberculosis* from clinical and environmental samples can be greatly complicated by the presence of other bacteria that are likely to predominate. The preferred selective agar for isolation from stool specimens is CIN (cefsulodin–irgasan–novobiocin) agar prepared with relatively low cefsulodin concentrations. Isolation of yersiniae is also helped by culture at 25° to 30° C, which results in better growth than when cultures are kept at 35° C and favors growth of the more cold-tolerant yersiniae over other bacteria that require higher temperatures. After being obtained, isolates can be confirmed as enteropathogenic *Yersinia* by biochemical tests. Biotyping and serotyping, which are often available only in research or reference laboratories, can provide useful epidemiologic information. Isolation difficulties and the reported low sensitivity (about 10^3 to 10^6 colony-forming units per gram of sample) of current isolation techniques have led some to suggest that PCR or other DNA-based methods are likely to result in the more rapid and sensitive detection of these bacteria.[12]

Tube or microagglutination tests can identify antibodies to the pathogenic *Y. enterocolitica* serogroups O:3, O:9, O:5,27, and O:8, but cross-reactivity can be a problem, particularly between *Y. enterocolitica* O:9 and *Brucella* spp. PCR for O genotyping of *Y. pseudotuberculosis* could eventually replace traditional serotyping methods. Immunologically mediated *Yersinia* illnesses, including reactive arthritis, are associated with the production of IgA antibodies that can be detected by enzyme-linked immunosorbent assay (ELISA) or immunoblotting. IgG antibodies can persist for many years, but persistence of IgA antibodies for more than a few months could indicate a chronic *Yersinia* infection.

PREVENTION

Prevention depends on measures intended to protect persons from contact with contaminated environments, foods, and wastes. These include using proper sewage disposal methods, protecting water supplies from contamination with human or animal wastes, following appropriate procedures for animal husbandry and slaughtering, thoroughly cooking meats (especially pork), avoiding long-term storage of meats at temperatures higher than 39° F, and consuming only pasteurized milk. Individuals should thoroughly wash their hands after handling potentially contaminated pork or other foods. Persons with diarrhea should not work in food-handling areas, care for young children, or work with patients, and hospital staff should follow enteric precautions. Vaccines are not available.

TREATMENT

Rx

Antibiotics do not improve the course of uncomplicated enterocolitis or mesenteric adenitis, and the use of antimicrobial therapy is not generally recommended for intestinal forms of the disease. Such therapy is, however, recommended for immunocompromised patients, patients with septicemia, and those with systemic disease or extraintestinal foci of infection. It should be noted that in vitro susceptibility does not necessarily indicate efficacy in vivo.

Broad-spectrum cephalosporins, sometimes accompanied by aminoglycosides, have resulted in successful outcomes in patients with extraintestinal forms of yersiniosis, including septicemia. Ciprofloxacin, cefotaxime, and ceftriaxone are considered the most effective agents for treating *Y. enterocolitica* serogroup O:3 infection. In addition, *Y. enterocolitica* serogroup O:3 and O:9 isolates possess chromosomally determined β-lactamases that can confer resistance to ampicillin, carbenicillin, and cephalothin. Although serogroup O:8 strains, which produce type A β-lactamase, show resistance to the latter two agents, they are susceptible to ampicillin. It has yet to be determined whether antimicrobial therapy is useful for treating immunologically mediated forms of yersinial illness, including reactive arthritis.

PROGNOSIS

Cases of *Y. enterocolitica* enteritis are generally mild and self-limited after a 2- to 3-week course of illness. Sequelae most commonly include reactive arthritis and erythema nodosum.[13] Glomerulonephritis and myocarditis have also been reported, particularly with serogroup O:3, biotype 4, phage type 8 infections. Other sequelae can include endocarditis, pericarditis, and osteitis. *Y. enterocolitica*–induced reactive arthritis, which can appear 1 to 3 weeks after infection, is oligoarticular, asymmetrical, and peripheral; it occurs most frequently in the lower limbs and eventually resolves over a period of a few weeks to months. HLA-B27–positive patients are more likely to experience severe and prolonged arthritis.

Y. pseudotuberculosis infections are also generally mild and self-limited. Reported complications include erythema nodosum, iritis, reactive arthritis, and nephritis. Although infection of the bloodstream by *Y. pseudotuberculosis* is rare, one review of 72 such cases reported that 26 (36%) were fatal.

REVIEW QUESTIONS

1. A 45 year-old New York City police officer is brought to the emergency department (ED) with a 2-day history of fever to 104° F (40° C) and worsening cough, dyspnea, confusion, nausea, and vomiting. The patient is intubated emergently in the ED because of respiratory distress. Chest radiographs demonstrate dense lower lobe infiltrates bilaterally. Sputum is blood tinged; Gram staining reveals numerous gram-negative bacilli with faint bipolar staining.

Appropriate actions at this time include all of following except

A. begin treatment with intravenous gentamicin and ciprofloxacin.
B. obtain blood for culture and sensitivity testing.
C. isolate the patient under airborne precautions.
D. alert infection control, public health, and law enforcement officials.
E. offer prophylaxis to ED personnel who intubated the patient.

Answer: C This scenario should raise serious concern for bioterrorism. Although naturally acquired infections can be treated with gentamicin alone, intentionally released strains may be engineered for resistance; therefore, use of multiple antimicrobials is advisable until sensitivities are known. Pneumonic plague is spread through droplets and can be prevented with droplet precautions; airborne precautions are unnecessary and likely to hinder patient care and management, especially if additional cases are identified. Although person-to-person transmission of plague has not been reported in the United States since 1925, unprotected close contact (<6 ft) is a risk factor, and prophylaxis with oral doxycycline is generally recommend.

2. A 34 year-old Los Angeles woman is hospitalized for fever and septic shock. On hospital day 2, admission blood cultures grow *Y. pestis*. On more careful reexamination, a large painful bubo is discovered in the patient's right axilla. The diagnosis of bubonic plague had not been suspected because the patient did not report traveling outside her urban Los Angeles neighborhood. Further interviews reveal that 3 days before illness onset, the patient had butchered a wild rabbit hunted by her husband and transported it to her home. In addition to handing tissues of infected wild animals, all of the following have been identified as risk factors for plague in the United States except

A. living west of the 100th meridian.
B. allowing dogs to sleep on the bed.
C. contact with an ill cat.
D. rodent die off in the area around the home.
E. failure to use insect repellent.

Answer: E Plague is endemic in the western United States. For reasons not fully known, it has not been able to establish itself east of approximately the 100th meridian. Epidemiologic studies have identified allowing dogs to sleep on the bed as a risk factor, likely by increasing opportunities for exposure to infected fleas. Unlike dogs, which are relatively unaffected by plague, cats are highly susceptible and prone to infection through capture of rodents. Plague epizootics among rodents can lead to mass mortality and an abundance of infectious fleas seeking blood meals from other sources, including humans. Although it may be helpful, insect repellent has not been demonstrated to prevent human infection.

3. A previously healthy 55 year-old wildlife biologist presents to the emergency department in Santa Fe, New Mexico, with a 4-day history of fever, severe abdominal pain, and bloody stools. While being evaluated, the patient begins vomiting blood and develops acute respiratory distress. He is admitted but dies within a few hours. Two days later, blood cultures obtained at admission reveal an unidentified gram-negative rod. The isolate is sent to three different laboratories that use automated systems to identify the organism as *Acinetobacter lwoffi*, *Pseudomonas luteola,* and *Yersinia pseudotuberculosis*. The most likely explanation for this situation is

A. laboratory contamination.
B. the correct identification is *Y. pseudotuberculosis.*
C. the correct identification is *P. luteola.*
D. The correct identification is *A. lwoffi*.
E. none of the above.

Answer: E Epidemiologic and clinical features are strongly suggestive of septicemic plague and not consistent with any of these other agents. Because of a lack robust biochemical profiles for *Y. pestis*, some automated microbiologic identification systems can misidentify the organism, usually as *Y. pseudotuberculosis*.

4. Which of the following regarding primary pneumonic plague is *false*?

A. Can be acquired from infected cats
B. Has not resulted in person-to-person transmission in North America since 1925
C. Requires isolation of patients using droplet precautions
D. Occurs in about 3% of patients with bubonic plague
E. Is a likely presentation of an intentional release

Answer: D In North America, most cases of primary pneumonic plague are acquired from ill, infected cats. The last case of person-to-person transmission occurred in Los Angeles in 1925; however, cases acquired from cats continue to occur. Person-to-person transmission can be prevented with droplet precautions; airborne precautions are not necessary. Secondary, not primary, pneumonic plague occurs after bubonic plague. Although plague may be dispersed and acquired through various routes, an aerosol release resulting in primary pneumonic plague is considered the most likely and deadly.

5. Two previously healthy sibling boys, age 6 and 16 years, are brought to the clinic by their father. Both boys are complaining of fever (102° F) and abdominal pain. The 6-year-old boy reports diarrhea with bloody stools, verified by the father. The older boy denies diarrhea but has marked right lower quadrant abdominal pain with some rebound tenderness. When asked about dietary exposures, the father mentions that both boys had eaten poorly cooked pork at a winter solstice pig roast a few days earlier. Which of the following selective media is best for isolating the most likely cause of illness?

A. Sorbitol MacConkey agar (SMAC)
B. Xylose lysine deoxycholate agar (XLD)
C. Cefsulodin–irgasan–novobiocin(CIN)
D. Campylobacter blood agar plates (Campy-BAP)

Answer: C Although several pathogens can produce bloody diarrhea and abdominal pain, features of the scenario suggest infection with *Yersinia enterocolitica*. These include the association with undercooked pork, the mixed clinical features of bloody diarrhea in a younger child and pseudoappendicitis in an older child, and onset in winter. SMAC is the preferred media for isolating Shiga toxin *Escherichia coli* O157:H7, which classically cause bloody diarrhea with little or no fever. Both *Salmonella* and *Campylobacter* infections occur more often in the summer and fall, and both are generally associated with exposures to nonpork products, especially beef, eggs, produce, and poultry.

313

WHOOPING COUGH AND OTHER *BORDETELLA* INFECTIONS

ERIK L. HEWLETT

DEFINITION

Pertussis (whooping cough), an acute respiratory illness with a potentially protracted clinical course, is caused by infection with *Bordetella pertussis* or related members of the genus, especially *Bordetella parapertussis*. The infection is highly contagious and can have both endemic and epidemic features in a population, but there are no known chronic carriers of the organism. Pertussis is currently a serious public health problem worldwide, with

reported U.S. cases in 2012 the highest in more than 50 years.[1,2] The greatest risks of morbidity and mortality are in infants, but increases in incidence in recent years include adolescents and adults and are highest in the cohort of children who have only ever received acellular pertussis vaccines.[3,4]

The Pathogens

There are now eight species in the genus *Bordetella,* but *B. pertussis, B. parapertussis,* and *B. bronchiseptica* (primarily a veterinary pathogen) are most likely to cause respiratory infections in humans. Recently identified species such as *B. holmesii* and *B. trematum* have been associated with bacteremia, meningitis, and wound infections, and *B. holmesii* has been isolated concurrently with *B. pertussis* in an outbreak of respiratory illnesses.[5] The *Bordetellae* are gram-negative, coccobacilli, and particularly fastidious and small relative to other gram-negative organisms. *B. pertussis* was first isolated by Bordet and Gengou in 1906, and a medium used for culture (Bordet-Gengou agar) still bears their names.

EPIDEMIOLOGY

In the prevaccine era (before the mid-1950s), pertussis was primarily a childhood illness; as a result, the disease received little attention in adult medicine. The extensive use of whole-cell pertussis vaccines in the United States and other parts of the world resulted in a marked reduction of pertussis. In addition, however, the vaccine elicited a change in the age-specific incidence of disease, with the majority of cases subsequently occurring in infants too young to be vaccinated and in adolescents and adults, who become susceptible because of waning immunity after childhood vaccination.[6,7] In recent years, this shift has been particularly notable, with 48,277 cases of pertussis reported in the United States in 2012, approximately 50% of those occurring in patients 7 to 19 years old. In fact, seroepidemiologic data suggest that 25% of adolescents and adults with a cough lasting more than 1 week have pertussis. The disease is endemic in the United States, but epidemics also occur every 3 to 4 years.

B. pertussis is highly contagious and the presumption that transmission can occur by aerosol droplet has recently been documented for the first time in nonhuman primate studies. There is no classic "carrier" state such as that recognized for other infectious organisms. In recent studies, however, nonhuman primates (baboons) immunized with acellular pertussis vaccine and challenged directly with *B. pertussis* were without clinical signs of disease but were able to transmit *B pertussis* to susceptible cage mates.[8] Dissemination in a community is often caused by symptomatic (or now perhaps asymptomatic) adolescents, who spread the organism during school attendance and social events. Health care personnel are also important sources of transmission, and health care–associated outbreaks can affect both vulnerable patients and their care providers.

PATHOBIOLOGY

Although *B. pertussis* and related organisms produce a number of interesting toxins, and pertussis has been described as a "toxin-mediated" disease, there is no clear pathophysiologic link between the known virulence factors and clinical manifestations of disease.[9] The infection is localized to the respiratory tract, where organisms adhere to the ciliated surface of epithelial cells. Mucous secretion is prominent, especially during later stages of the illness. Intracellular *B. pertussis* organisms have been demonstrated both *in vitro* and in samples collected from patients, but it is not an obligate intracellular organism, and the significance of these observations remains unknown.

Toxins and adhesins are important both for their potential role in the pathogenesis of disease and for their use as antigens in acellular pertussis vaccines. Filamentous hemagglutinin (FHA), pertactin (PRN), and fimbriae are adhesins that are components of some acellular vaccines, and all currently available vaccines include chemically inactivated pertussis toxin (PT). In addition to their adhesin function, FHA, PRN, and fimbriae have been shown to modulate the functions of host immune-effector cells. PT is a member of the family of adenosine diphosphate–ribosylating toxins that includes cholera toxin and diphtheria toxin, and its intracellular targets consists of several guanosine triphosphate–binding proteins such as $G_{i\alpha}$. Although PT causes lymphocytosis and enhances insulin secretion, its target cell or cells and its contribution to the clinical manifestations of pertussis are still a mystery. *Bordetellae* also possess adenylate cyclase (AC) toxin, a bacterial AC that enters host cells to produce supraphysiologic levels of cyclic adenosine monophosphate (cAMP). AC toxin acts against phagocytic cells, such as polymorphonuclear leukocytes and alveolar macrophages, whose antibacterial functions are inhibited by the increased cAMP. Additional "toxins," including the tracheal cytotoxin, tracheal colonization factor, and heat-labile or dermonecrotic toxin, have been identified by virtue of their activities in vitro or in animals. The relationship of these toxins to disease also remains ill defined.

CLINICAL MANIFESTATIONS

Although the classic paroxysmal cough of pertussis is striking and unforgettable, not all patients experience this characteristic symptom. Infants may have apnea as their only manifestation of pertussis; in others, the characteristic cough develops subsequently. Existing clinical case definitions of pertussis are decades old and based largely on presentations in infants and children. Because of the increasing incidence in adolescents and adults, who may manifest distinct symptoms and signs, the Global Pertussis Initiative has developed an algorithm based on different age groups in order to encourage expanded use of laboratory testing in suspected cases.[10]

Incubation Period

After exposure of an individual to active pertussis (typically by way of aerosol from an infected patient who is coughing), the onset of symptoms is not experienced until 1 to almost 3 weeks later. This relatively long incubation period makes it difficult to track transmission and increases the time necessary for intervention and implementation of control measures.

Catarrhal Phase

Importantly, the symptoms that reflect onset of the catarrhal phase (rhinorrhea, increased lacrimation, conjunctival injection, and sometimes low-grade fever) are nonspecific and are not suggestive of pertussis, except in the setting of an ongoing hospital or community outbreak. This phase, which can last from a few days to as long as 1 week, is often associated with a nonproductive cough.

Paroxysmal Phase

A patient's transition to the paroxysmal phase and initiation of the typical cough can suggest the diagnosis of pertussis. This striking cough consists of a series of uncontrollable expirations followed by gasping inhalation, which, depending on the airway anatomy, can result in the characteristic "whooping" sound. The whoop is more frequent in children than in adults. It is common for each episode of coughing to be associated with cyanosis and end with gagging and vomiting, which in infants can result in dehydration and malnutrition. The paroxysmal stage can last up to 4 weeks, and the development of fever or worsening pulmonary function during this time suggests the possibility of secondary pneumonia. Eighty percent or more of adolescents and adults with pertussis have paroxysmal cough, but the frequency of whoop and posttussive vomiting in this population is quite variable. In addition, during the paroxysmal stage, adults experience symptoms, such as a scratchy throat, other pharyngeal symptoms, and episodes of sweating, which are not described in children.

Convalescent Phase

A reduction in the frequency and severity of coughing attacks marks the transition to the convalescent phase, which can last weeks to months. It is often during this time that adults present to the health care system with "chronic cough" and may be evaluated for conditions such as asthma, tuberculosis, other chronic lung diseases, malignancies, and gastroesophageal reflux. After the coughing spells have ended, patients may experience a return of the paroxysmal cough in conjunction with unrelated upper respiratory illnesses or stimuli or irritants; this phenomenon is often incorrectly interpreted as a recurrence of pertussis. Eighty percent of adults with pertussis have an illness of at least 3 weeks' duration, and 27% are still coughing after 90 days.

Complications

In infants and children younger than 5 years, hospitalization is common; 5% to 10% have pneumonia, nearly 1% of infants experience seizures, and encephalopathy is seen in 0.1%. Pertussis in infants and small children can be associated with pulmonary hypertension, now known to result from the elevated white blood cell (WBC) count, which can exceed 100,000/mm^3 in a naïve host. In one study, this phenomenon occurred in fewer than 15% of cases but was present in 75% of patients who died.[11] Adolescents and adults have these same complications with a lower frequency, but adults can experience other problems associated with underlying medical conditions. For example, there are anecdotal reports of cough syncope, herniated

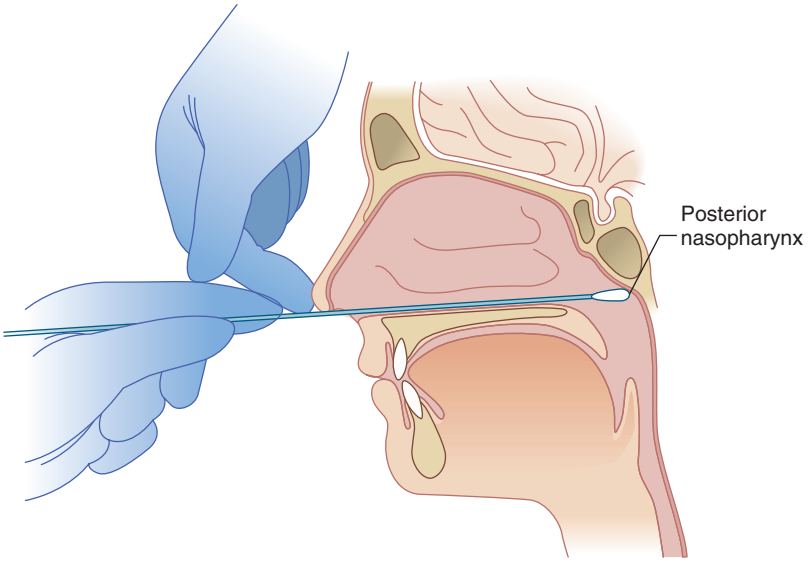

FIGURE 313-1. Technique for obtaining a nasopharyngeal specimen for the isolation of *Bordetella pertussis*. Dacron or calcium alginate swabs are recommended to obtain culture specimens. Dacron swabs are appropriate if polymerase chain reaction testing will be performed. (Redrawn from Cornia PB, Lipsky BA, Saint S, Gonzales R. Clinical problem solving: nothing to cough at. *N Engl J Med*. 2007;357:1432-1437.)

intervertebral disc, sudden-onset hearing loss, angina episodes, and carotid artery dissection.

DIAGNOSIS

Several methods can be used to detect *B. pertussis,* its products, and the host response to them, but each has its limitations. Culture of a nasopharyngeal swab or aspirate (Fig. 313-1) is the "gold standard" (specificity approaching 100% in symptomatic patients), but even with the use of specialized transport medium and processing in a careful, interested laboratory, recovery rates are often less than 50% and are completely dependent on the duration of illness and whether antimicrobial treatment was initiated before specimen collection. Polymerase chain reaction (PCR)–based diagnostic tests of nasopharyngeal swabs or aspirates are much more sensitive than culture, and results can remain positive for several days after the initiation of antimicrobial treatment. In addition, appropriately designed PCR assays can identify and distinguish among *B. pertussis, B. parapertussis,* and *B. bronchiseptica* and detect insertion sequence elements suggestive of other *Bordetella* species.[12] However, several apparent "outbreaks" of pertussis have later been found to represent false-positive PCR results. Detection of serum antibodies to products of *B. pertussis* can be used to identify patients during infection, but care must be taken to distinguish an acute response from residual antibodies elicited by prior immunization.

In view of the limited resources and equipment available for the diagnosis of pertussis, the World Health Organization has established a clinical case definition, which is 21 or more days of paroxysmal coughing with laboratory confirmation or epidemiologic linkage. Although this definition is often used for clinical trials, it is now clear that its application can result in cases of lesser severity or shorter duration being missed.

TREATMENT

Rx

Supportive Therapy

Because infants and young children have the highest risk for complications and death, supportive therapy is often the most important component of their medical care. Close observation (preferably in the hospital) is essential to ensure adequate feeding, oxygenation, and hydration to minimize complications in this age group. None of the pharmacologic interventions tested for the amelioration of cough and other symptoms is effective in pertussis. Leukophoresis has been used to reduce the WBC count and thus ameliorate pulmonary hypertension in infants and young children, but there is no agreement as to whether this approach affects mortality rates.

Antimicrobial Agents

There are two reasons to use antimicrobials in a patient with pertussis: (1) to eliminate the causative organism and reduce transmission and (2) to limit the course of illness in the treated patient. Because individuals can remain culture positive and can potentially transmit *B. pertussis* for several weeks after onset of symptoms, it is appropriate to treat patients who are seen within that time frame. Antimicrobials do not provide symptomatic relief or affect the course of the illness in the later stages of the infection, but they can do so when treatment is started within the first few days of symptoms. Although macrolide resistance is not a significant problem, it has been reported.

The recommendation of the Centers for Disease Control and Prevention for the treatment of pertussis in adults is azithromycin (500 mg on day 1 followed by 250 mg/day on days 2-5), clarithromycin (1 g/day in two divided doses for 7 days), erythromycin (2 g/day in four divided doses for 14 days), or trimethoprim–sulfamethoxazole (trimethoprim 320 mg/day, sulfamethoxazole 1600 mg/day, in two divided doses for 14 days). It has now been shown that treatment with erythromycin for 7 days is as effective as treatment for 14 days. The newer macrolides (azithromycin and clarithromycin) are better tolerated but more expensive.

PREVENTION

Chemoprophylaxis

Chemoprophylaxis with the aforementioned antimicrobial agents is an important mechanism for controlling outbreaks in hospitals or in the community. This approach is effective when initiated before the onset of symptoms and is recommended for individuals exposed within the preceding 3 weeks; high-risk persons with underlying health problems, particularly infants; or those who might have occupational or other contact with susceptible hosts.

Immunization

A killed, whole-cell vaccine was introduced in the late 1940s. Use of that product had a dramatic effect on the incidence of pertussis, with the number of reported cases in the United States falling from more than 200,000 annually to less than 2000 in 1980. In the 1970s and 1980s, recognition of the adverse events associated with the whole-cell product and public concern about the extent of those reactions led to the development of the purified acellular pertussis vaccines that are in use today.[13]

Current pediatric acellular pertussis vaccines (DTaP), which contain one or more purified protein antigens (all contain PT and other combinations of FHA, pertactin, and fimbriae types 2 and 3), are administered to infants and children up to the age of 6 years and cause significantly fewer adverse reactions than the whole-cell vaccines. In recognition of the significant incidence of pertussis in adolescents and adults and their role in transmitting the disease to infants and small children, Tdap (tetanus, diphtheria and pertussis) vaccines, which contain reduced quantities of the pertussis components, are now licensed for administration to these age groups. Their use is recommended to boost immunity in adolescents and adults who completed the recommended childhood vaccination series. Importantly, this adult booster immunization is now recommended for women during each pregnancy to prevent acquisition of *B. pertussis* and transmission to their neonates.

The increasing incidence of pertussis, including in immunized populations, appears to be attributable to a markedly reduced duration of protection relative to that anticipated from experience with whole-cell vaccines and prior infection. There is, however, an increasing number of *B. pertussis* isolates that do not express pertactin.[14] In addition, there is increasing prevalence of strains harboring the *ptxP3* allele, which is associated with increased production of PT and with alterations in expression of other virulence factors.[15,16]

In consideration of the adverse events and negative publicity associated with the whole-cell vaccines and the poor efficacy of the current acellular vaccines, there is active development of a live, attenuated pertussis vaccine, which would be administered intranasally.[17]

PROGNOSIS

Most patients will eventually clear *B. pertussis* even without antimicrobial treatment, but in most cases, the illness lasts weeks to months. Antimicrobials are of limited effectiveness in altering the course of the illness unless they are started before the paroxysmal phase. The introduction of booster doses of vaccines for adolescents and adults has not, however, resulted in the control of pertussis in well-immunized populations as had been anticipated. The next steps to address this serious public health problem are still being debated. Of major concern is the recent demonstration that baboons immunized with acellular pertussis vaccine can become infected and transmit *B. pertussis* in the absence of symptoms.

REVIEW QUESTIONS

1. The leading or most logical explanation for the current resurgence of pertussis in the United States is

A. limited efficacy and duration of protection elicited by current acellular pertussis vaccines.
B. prolonged, asymptomatic carriage of *B. pertussis* after infection.
C. enhanced detection of *B. pertussis* with the use of polymerase chain reaction (PCR) technologies.
D. development of antibiotic resistance among circulating strains of *B. pertussis*.
E. adaptation of *B. pertussis* to selective pressure imposed by acellular vaccines containing only four or five protein antigens.

Answer: A The limited protection induced by acellular pertussis vaccines and the rapid decrease in that protection with time have been documented in numerous studies. Although animal recipients of acellular vaccine can become infected and transmit to other animals without developing signs, such as cough, there is no evidence for a prolonged carrier state such as that documented for other infectious diseases. The sensitivity of PCR for identification of *B. pertussis* is greater than that of classical methods such as culture. PCR has, however, been used for a number of years and cannot explain the striking increases observed from 2010 to 2012 and the current incidence in the United States, which is the highest in more than 50 years. Antibiotic resistance among *B. pertussis* strains has been reported but is rare and not clinically relevant at present. Finally, there is an increasing number of clinical isolates of *B. pertussis* that do not express pertactin, one of the antigens in the cellular vaccine, but these existed before use of acellular vaccines, and there is no evidence that they are appearing as a result of acellular vaccine use.

2. The characteristic paroxysmal cough associated with *B. pertussis* infection is caused by

A. tracheal cytotoxin (TCT).
B. pertussis toxin (PT).
C. filamentous hemagglutinin (FHA).
D. pertactin (PRN).
E. none of the above.

Answer: E Although is has been speculated that several of the listed virulence factors could be responsible for the cough of whooping cough, none of these molecules alone can cause the cough in experimental animals (or, in some cases, in humans). It is unknown how infection with *B. pertussis* results in paroxysmal cough associated with whooping.

LEGIONELLA INFECTIONS

THOMAS J. MARRIE

DEFINITION

Legionellosis is the term for infection due to bacteria in the *Legionella* genus, of which there are two main manifestations—pneumonia (legionnaires' disease) and Pontiac fever (named after Pontiac, Michigan, where it was first recognized). Pontiac fever is usually a mild febrile illness presumed to be a reaction to lipopolysaccharide of *Legionella* species.

The 58th annual convention of the American Legion was held at a hotel in Philadelphia from July 21 to July 24, 1976. Subsequently, 182 of the delegates became ill (hence the name legionnaires' disease), and 146 were hospitalized at 87 institutions across the United States. Most had radiographic evidence of pneumonia, and 29 (16%) died. Within about 6 months of the outbreak, a new microorganism, *Legionella pneumophila*, was isolated from the pulmonary tissue of some of those who had died in the Philadelphia outbreak. In retrospect, the organism had first been isolated in 1943.

The Pathogen

Legionellae are small, gram-negative, aerobic, non–spore-forming bacilli that measure 0.3 to 0.9 µm wide by 2 to 20 µm long (Fig. 314-1A to D). These organisms require special media for growth, and many laboratories are unable to isolate legionellae; thus, when laboratory expertise is uncertain, a negative culture is meaningless. They usually do not stain with Gram stain. In tissue specimens, Dieterle or Warthin-Starry stain is used to visualize these organisms. *Legionella micdadei* retains the modified acid-fast stain and can appear as acid-fast bacilli in clinical specimens. Legionellae are aquatic organisms that thrive in both natural and man-made waterways and distribution systems, especially hot-water pipes, water heaters (electrical more so than gas heaters), cooling towers, and water fountains. In these systems, they are found in biofilms that help confer resistance to biocides and chlorine. They are also found in moist soil and mud. They can survive in these environments for long periods and can tolerate temperatures of 0° to 68° C and a pH range of 5 to 8.5. In their natural environments, they are intracellular parasites of protozoa, such as the freshwater amebae *Acanthamoeba* and *Hartmannella* species (Fig. 314-1E). Indeed, legionellae can live in at least 20 species of ameba, two species of ciliated protozoa, and one species of slime mold. Free-living legionellae in biofilms are inactivated within a few weeks, whereas those residing in amebae survive for 6 months or more. Humans are accidental hosts who become infected by inhaling *Legionella* bacteria or amebae laden with these bacteria. Genomes of four different strains of *L. pneumophila* have been sequenced, and they range in size from 3.3 to 3.5 Mb. Legionellae have many eukaryotic-like proteins, which may help the intracellular growth of these organisms in human macrophages by mimicking host proteins. *Legionella* species have type I, II, IV, and V secretion systems, which allow the efficient and rapid delivery of molecules into the phagocytic host cell.

The number of new *Legionella* species continues to grow; there are now at least 56 *Legionella* species and 73 serogroups or more, including 15 serogroups of *L. pneumophila*. A variety of typing systems can be used to further refine the isolates so that individual strains can be identified, a factor that is important for determining the source of an outbreak or understanding the difference between environmental and clinical isolates. It is noteworthy that *L. pneumophila* and all its serotypes cause disease in humans (with serotype 1 predominant), whereas only about 50% of the remaining species of *Legionella* cause such disease.[1]

Legionella longbeachae was first isolated in 1980 from a patient with pneumonia in Long Beach, California. In Australia, New Zealand, and Japan, reported cases of *L. longbeachae* infection occur as often as cases of *L. pneumophila* infection. This organism is rarely isolated from aquatic environments. The primary environmental reservoir remains unknown, but the major source of human infection is considered to be commercial potting mixes and other decomposing material, such as bark and sawdust. The *L. longbeachae* genome encodes for a range of proteins that might assist in the degradation of plant material. These enzyme systems are not present in *L. pneumophila*.

EPIDEMIOLOGY

The incubation period for legionnaires' disease (LD) is most commonly cited as 2 to 10 days, with extremes of 1 to 28 days. Person-to-person transmission

TABLE 314-1 RISK FACTORS FOR LEGIONNAIRES' DISEASE

RISK FACTOR	APPROXIMATE INCREASED RISK (-FOLD) OVER PERSONS WITHOUT THIS RISK FACTOR
HOST FACTORS	
Renal failure requiring dialysis	20
Corticosteroid therapy	5-10
Hairy cell leukemia	20
Lung or hematologic malignant neoplasm	7-20
Cytotoxic chemotherapy	5
>3 Alcoholic drinks/day	3-4
Cigarette smoking	2-10
Age older than 50 years	2
Diabetes mellitus	2
Solid organ transplantation (immunosuppression)	2
Anti–tumor necrosis factor treatment	16-21
Chronic heart or lung disease	>1
Splenectomy (non-*pneumophila* strains only)	—
ENVIRONMENTAL FACTORS	
Travel	2
Recent plumbing work in home or at work	2
Hospitalization	—
Exposure to contaminated water sources—cooling towers, hot tubs, decorative fountains	—
Exposure to potting soil (Australia) for *Legionella longbeachae*	—

does not occur. Legionellosis is found worldwide, predominantly in developed countries owing to the frequent use of cooling towers and complex plumbing systems. Underdiagnosis may be a feature in developing countries because of the laboratory facilities required. In recent years, there has been an increase in *Legionella* cases in Japan from 56 cases in 1999 to 804 cases in 2011, reaching a rate of 1.15 per 100,000 population; in Europe, the rate in 2010 was 1.25 cases per 100,000, and in the United States, the rate increased from 0.39 to 1.15 per 100,000. From 1990 to 2005, 23,076 cases of LD were reported in the United States. Only 1.7% of these cases occurred in children, whereas 63% occurred in those aged 45 to 64 years. Males accounted for 61% of cases, and rates were highest in the eastern United States, where most cases occur in the summer or fall. More recent U.S. data show an annual increase of 217% in the number of cases from 2000 to 2009, with the highest rates in the Mid-Atlantic states at 2.60 per 100,000. Twenty-four percent were travel related, and 81% of these cases involved domestic travel; noteworthy is that 5% involved cruise ship travel. The overall case-fatality rate was 8%. Eastern Canada also has higher rates of LD than the rest of that country. The epidemiology of LD in Europe is not dissimilar to that of the United States. The countries with rates of more than 2 per 100,000 were France, Denmark, Spain, Netherlands, and Italy. Twenty percent were travel associated, and the overall case-fatality rate was 11%.

There is an association between increased rainfall and cases of LD. The connection may be aerosolization of *Legionella* from rain puddles on roads. In one study, 33 (47.8%) of puddle water samples were positive for *Legionella*, yielding 325 isolates. Among the 14 sequence types of the clinical isolates, 4 were present in puddle water isolates.

The most common risk factors for the acquisition of LD are listed in Table 314-1. *Legionella* species account for 1 to 5% of community-acquired pneumonia requiring admission to a hospital. In some areas, *Legionella* accounts for about the same percentage of pneumonia treated on an ambulatory basis. *Legionella* infections can be sporadic or occur in outbreaks.[2] Outbreaks have been associated with exposure to a variety of aerosol-producing devices, including showers, a grocery store mist machine, cooling towers, whirlpool spas, decorative fountains, and evaporative condensers. Other water sources implicated in transmission of LD include water on trains, birthing pools, dental units, asphalt paving machines, and windscreen wiper fluid without added screen wash. LD can be acquired up to 10 to 11 km away from contaminated cooling towers. Aspiration of contaminated potable water by immunosuppressed patients is another mechanism by which *Legionella* is acquired. From 1985 to 2007, 14 of 2946 (0.5%) solid organ transplant recipients developed LD at one center in Barcelona; 5 (36%) were nosocomially acquired.

Exposure to contaminated potting soil is a risk factor for *L. longbeachae* infection in Australia and New Zealand.

Pontiac fever occurs predominantly in outbreaks with very high attack rates. *L. pneumophila, L. micdadei,* and *L. anisa* have been implicated in outbreaks of Pontiac fever. Among residents of nursing homes, Pontiac fever has been associated with *L. pneumophila* concentrations of greater than 10^4 colony-forming units/L in shower water. Those receiving corticosteroid therapy have a six-fold higher risk for development of Pontiac fever.

PATHOBIOLOGY

After being inhaled, legionellae are phagocytosed in the lungs by alveolar macrophages.[3] Only virulent strains of *Legionella* are capable of initiating organism-directed endocytosis when attachment to the alveolar macrophage through E-cadherin and β1 integrin receptors occurs. Legionellae abrogate phagosome-lysosome fusion and replicate in an endosome surrounded by the endoplasmic reticulum. Once it is intracellular, the bacteria-laden endosome recruits small vesicles, mitochondria, and ribosomes, and within 4 to 6 hours it becomes enveloped by the endoplasmic reticulum, thereby establishing the replicative endosome. After a latent period of about 12 hours, the bacteria start dividing. During this latent period, there is synthesis of up to 35 proteins and repression of 32 proteins. Iron must be available in the phagosome for growth. Growth continues in the macrophages for approximately 24 hours, at which time the macrophage disintegrates by apoptosis and the bacteria are released. The released bacteria are often phagocytosed by other macrophages, dendritic cells, and epithelial cells, perpetuating the infection. Cell-mediated immunity is necessary for recovery from *Legionella* infection. Production of type 1 interferons has a protective effect by promoting the activation of macrophages. Activated macrophages limit the intracellular replication of legionellae by downregulating the expression of their transferrin receptors and limiting the availability of iron to the bacteria. Toll-like receptors 2, 4, 5, and 9 are activated during infection with *L. pneumophila*. Interleukins 1α, 1β, 4, 6, 12, and 18 are detected during *Legionella* infection. Vaccination of guinea pigs with the purified major outer membrane protein OmpS protects against an LD_{100} lethal challenge, whereas immunization with purified heat shock protein 60 provides little protection. Polymorphonuclear leukocytes are present in abundance in the infected lung, but their role in clearing the infection is unclear. Bacteria can spread beyond the lung and cause metastatic infection. However, many extrapulmonary effects of LD, such as cerebellar ataxia and confusion, are not due to metastatic infection; they are presumably due to as yet unidentified toxins. The infected lung is consolidated, and there is usually no parenchymal damage once recovery occurs. Abscess formation and bronchiolitis obliterans or fibrosing alveolitis are occasionally seen.

The pathogenesis of Pontiac fever is unclear. The onset of illness occurs within 12 to 36 hours after the inhalation of, presumably, endotoxin. This period is too short for bacterial multiplication to cause the symptoms.

CLINICAL MANIFESTATIONS

Most of our knowledge of the clinical features of LD comes from studying patients who have been hospitalized with this illness, that is, those with the most severe manifestations. Fever (often high), malaise, and cough are present in most patients. Chills occur in about 75%, and dyspnea in just more than half the patients. Other features include myalgias, headache, chest pain, and diarrhea. The cough is nonproductive in 50% of patients; others have scant sputum production that is usually mucoid, rarely purulent, and very rarely bloody. There are no clinical features that distinguish individual patients with LD from those with pneumonia caused by other pathogens.[4-6] However, when patients with LD are compared with those with community-acquired pneumonia due to other agents, the patients with LD are more likely to have myalgias, headache, diarrhea, and a higher mean oral temperature at the time of presentation. They also present to the hospital sooner after the onset of symptoms, 4.7 days versus 7.7 days. When patients with LD were compared with patients with bacteremic pneumococcal pneumonia, the following features were associated with *Legionella* pneumonia: male sex (odds ratio [OR], 4.6), heavy drinking of alcohol (OR, 4.8), previous β-lactam therapy (OR, 19.9), axillary temperature higher than 39° C (OR, 10.3), myalgias (OR, 8.5), and gastrointestinal symptoms (OR, 3.5). Pleuritic chest pain and purulent sputum were less likely to be present. In a young, otherwise healthy person with rapidly progressive pneumonia (especially if the progression occurs in the setting of β-lactam therapy), LD should be strongly

suspected. Mental confusion is common, and on occasion, the presentation is dominated by extrapulmonary manifestations such as reactive arthritis, cerebellar ataxia, seizures, myoclonus, or encephalitis. Rarely, extrapulmonary infection, such as prosthetic valve endocarditis, sinusitis, dialysis shunt infection, or abscess formation, occurs.

Physical findings include fever, tachypnea, relative bradycardia, and initially only a few crackles on chest examination. Later, the findings of pulmonary consolidation are not uncommon. Abdominal examination is usually unremarkable. Rash as a manifestation of LD is very rare. Progression of the illness is not uncommon, even after the institution of antibiotic therapy. This is more likely in immunocompromised patients, who may require up to a week to respond to therapy. About half the patients with LD who require hospitalization have a complicated course.

Pontiac fever has an incubation period of about 36 hours. Fever, severe myalgia, headache, and extreme fatigue are the dominant manifestations. The illness is of short duration, lasting, on average, 3 days.

DIAGNOSIS

It is most important to have a high index of clinical suspicion that a patient might have LD. Routine laboratory test results are nonspecifically abnormal. Leukocytosis is common; leukopenia, thrombocytopenia, and disseminated intravascular coagulation also occur. Other laboratory abnormalities may include hyponatremia (in about half the patients, sometimes severe), hypophosphatemia (also common, occurring early and resolving within a few days of the initiation of treatment), mild liver function test abnormalities (except for alkaline phosphatase, which is occasionally very elevated), elevated creatine kinase (occasionally with rhabdomyolysis), microscopic hematuria, and mild proteinuria. High procalcitonin levels exceeding 1.5 are associated with a higher rate of admission to intensive care units and death. Combinations of findings may be suggestive of LD. These include high temperature, absence of sputum production, high lactate levels, increased C-reactive protein level, and low platelet counts.

There are a number of specific tests for the diagnosis of LD. Tests to detect *L. pneumophila* SG 1 antigen in urine are available commercially.[7] These are easy to use, but there is a false-negative rate of up to 26%. The sensitivity of the urinary antigen test in a review of published data was 0.74 (0.68 to 0.81), and the specificity was 0.991 (0.984 to 0.997). Rarely, the urinary antigen test result can remain positive for up to 1 year. Use of this test has allowed early diagnosis of LD because of the very short time required to do the test. This may be a factor in the lower mortality rates from LD compared with historic rates. Sputum culture has a low sensitivity but is 100% specific. It should be performed on all patients suspected of having LD. Serologic tests are not useful in the immediate management of a patient because of the long time (6 to 12 weeks) required to seroconvert; however, they do have a role in the work-up of outbreaks of LD. False-negative and false-positive serologic results do occur. A four-fold or greater increase in antibody titer between the acute and convalescent phase serum samples is diagnostic. A former criterion of a high stable antibody titer of 1 : 256 or higher is no longer considered diagnostic. Polymerase chain reaction can be used to amplify *Legionella* DNA in sputum, bronchoalveolar lavage fluid, pleural fluid, pulmonary tissue, or serum. Polymerase chain reaction can detect 1 fg of *Legionella* DNA, equivalent to one microorganism. These tests have not yet gained widespread use clinically. *Legionella* can be isolated from the blood with special media or by subculturing onto BCYE (buffered charcoal–yeast extract) agar plates, but this is not used in practice.

A chest radiograph is necessary to establish a diagnosis of pneumonia. About half the patients with LD have unilateral pulmonary involvement. The lower lobes are involved most commonly. About one third of patients have a pleural effusion. Dense opacification is common, but interstitial and nodular opacities also occur. Cavitation is uncommon; 70% of the 79 patients reported to date with lung abscess due to *Legionella* were receiving corticosteroids. Figures 314-2 to 314-5 illustrate some of the radiographic findings in LD.

The diagnosis of Pontiac fever is based on demonstration of *Legionella* in water to which the patient was exposed, seroconversion to *Legionella*, and a compatible clinical course.

Differential Diagnosis

LD should be considered in any patient with pneumonia who is admitted to the hospital, especially those who require treatment in an intensive care unit. If *Legionella* is present in a hospital's water supply, LD should be considered in all patients with nosocomial pneumonia.

FIGURE 314-2. Posteroanterior chest radiograph of a patient with community-acquired pneumonia due to *Legionella pneumophila*. Note the dense consolidation of the right upper lobe, with bulging of the fissure. Such dense consolidation is a common radiographic appearance of legionnaires' disease.

FIGURE 314-3. Posteroanterior chest radiograph of a patient with community-acquired legionnaires' disease (*L. pneumophila*) manifesting as a right lower lobe nodular opacity.

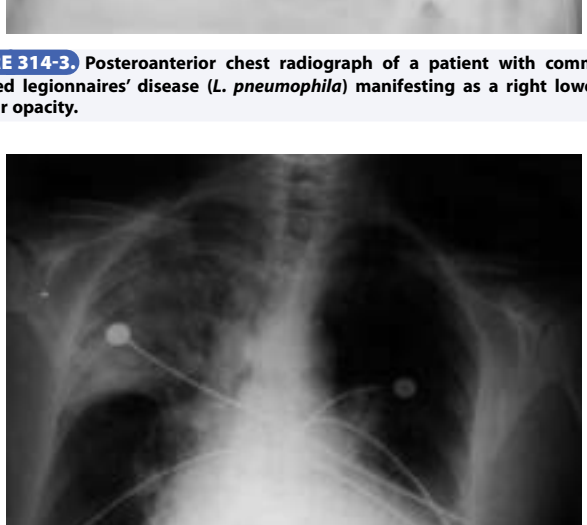

FIGURE 314-4. Posteroanterior chest radiograph of a patient with community-acquired *Legionella feeleii* pneumonia. There is patchy consolidation of the right upper lobe.

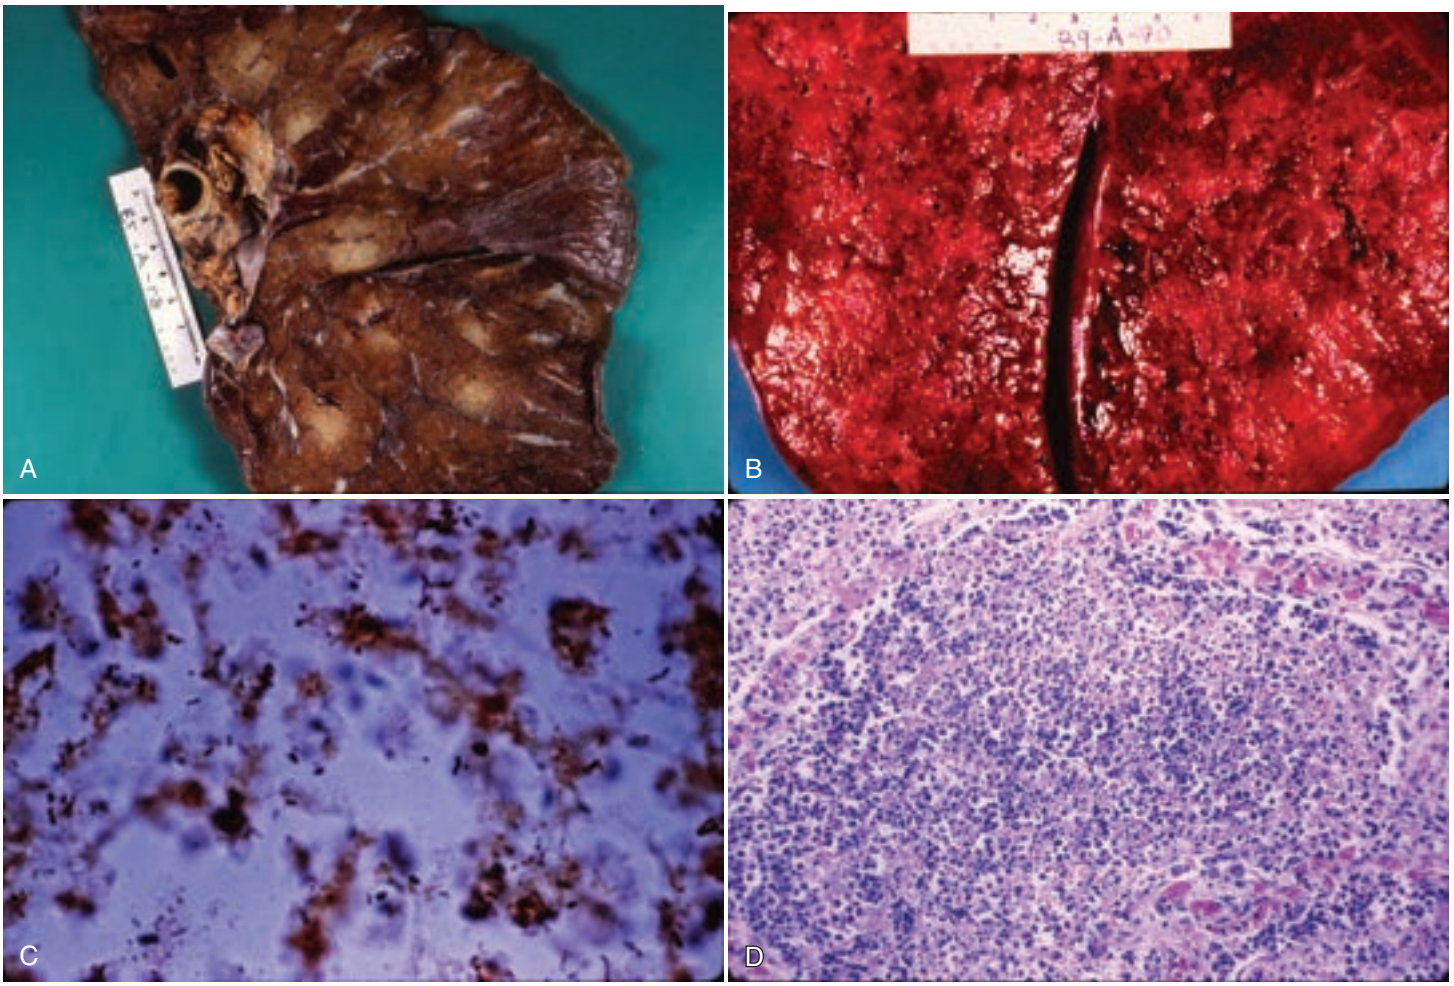
In patients who have died of legionnaires' disease, the gross pathology examination shows focal or patchy lesions in about one third of cases, lobar pneumonia in about half, and focal hemorrhages in about one quarter. On microscopic examination, there is bronchopneumonia with diffuse alveolar damage and heavy infiltration of neutrophils, macrophages, desquamation of alveolar epithelial cells, and fibrin proteinaceous debris. On occasion, there is inflammation of blood vessels mimicking a vasculitis. Organisms can be visualized with Dieterle's silver impregnation stain or by direct immunofluorescent staining (E-Fig. 314-1).



E-FIGURE 314-1. **A,** Gross pathology specimen of formalin-fixed lung from a patient with nosocomial legionnaires' disease (LD). Note the multiple nodular consolidated areas. **B,** Gross appearance of fresh lung tissue from a patient with LD. Note the "hepatization of the lung" representing consolidation. **C,** Dieterle stain on lung tissue from a patient with LD showing many microorganisms (magnification ×1000). **D,** Histologic appearance of pulmonary tissue from a patient with LD. Note the dense inflammatory infiltrate with evolving microabscess (magnification ×200).

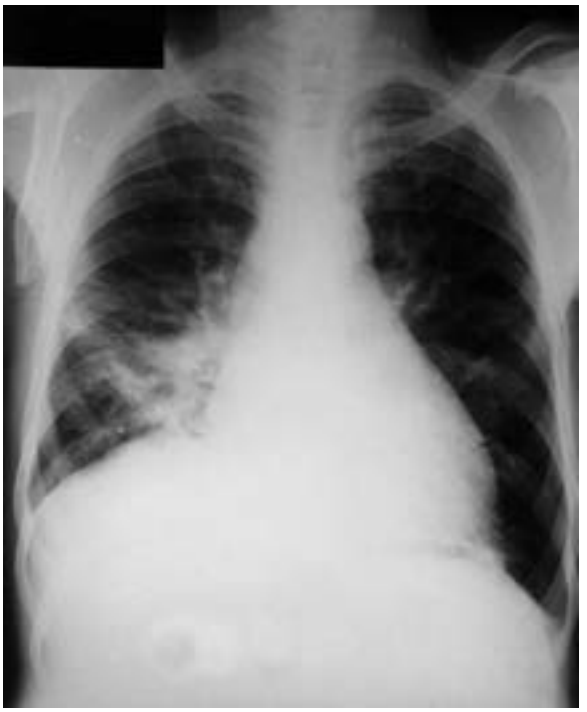


FIGURE 314-5. Posteroanterior chest radiograph of a patient with community-acquired pneumonia due to *Legionella pneumophila*. There is patchy consolidation at the right base, with subsegmental atelectasis and elevation of the right hemidiaphragm.

TABLE 314-2 TREATMENT FOR LEGIONNAIRES' DISEASE

SEVERITY OF *LEGIONELLA* PNEUMONIA	DRUG	DOSAGE
Mild pneumonia in a nonimmunocompromised person treated at home	Azithromycin	500 mg once daily for 5 days
	Clarithromycin	500 mg bid for 10 days
	Doxycycline	200 mg loading dose, then 100 mg bid for 10 days
	Levofloxacin	500 mg once daily for 10 days
	Moxifloxacin	400 mg once daily for 10 days
Pneumonia requiring hospitalization or pneumonia in an immunocompromised person	Levofloxacin	750 mg once daily (IV initially) for 10-14 days*
	Azithromycin	500 mg once daily for 10 days*
	Moxifloxacin	400 mg once daily for 10 days*
	Ciprofloxacin	400 mg q8h IV for 14 days*
	Erythromycin *plus* Rifampin	1000 mg IV qid for 3 days; then 500 mg qid for a total of 21 days 600 mg bid for 5 days

*Increase duration of treatment to 21 days for immunocompromised persons.

TREATMENT

If the diagnosis of LD is known, levofloxacin and moxifloxacin are first-choice agents (Table 314-2). Unfortunately, no randomized controlled trials have studied the therapy for LD. Data from a prospective, nonrandomized study indicate that levofloxacin is superior to macrolides for the treatment of severe LD. In this study carried out in Murcia, Spain, 3.4% of the patients receiving levofloxacin had complications, compared with 27.2% of those receiving macrolides; the levofloxacin patients had a shorter length of stay, 5.5 versus 11.3 days. The addition of rifampin to levofloxacin produced no additional benefit. In one clinical trial, 20 of 21 patients with LD were cured when treated with azithromycin. In another study, the authors selected 139 cases of *L. pneumophila* pneumonia in a prospective series of 1934 consecutive cases of community-acquired pneumonia. The overall mortality rate was 5%. Eighty patients received initial therapy with a macrolide, and 40 received levofloxacin. Those who received levofloxacin had a faster time to defervescence (2 vs. 4.5 days) and to clinical stability (3 vs. 5 days) and a shorter median length of stay (8 vs. 10 days); there were no significant differences in complications or mortality. In a review of data from six clinical trials, 75 patients with *Legionella* infection were treated with levofloxacin, and 90% of these infections had resolved clinically at the post-therapy visit 2 to 14 days after the termination of treatment. The authors concluded that treatment with levofloxacin 500 mg/day for 7 to 14 days or 750 mg/day for 5 days was effective. In a study of 33 patients admitted to an intensive care unit with LD, fluoroquinolone administration within 8 hours of arrival was associated with decreased mortality. There are no good data on the duration of treatment of LD. The consensus is that 7 to 10 days of treatment with azithromycin or a quinolone is sufficient. However, longer treatment is required if there is lung abscess, empyema, or endocarditis. In immunosuppressed patients, therapy should last for 21 days.

A meta-analysis of 24 trials involving 5015 patients with pneumonia showed that for patients with LD, there was a significant benefit when empirical therapy for pneumonia included agents active against *Legionella*. All patients who are severely ill with pneumonia should receive empirical therapy that treats *Legionella* as well as other pathogens. This is in line with the pneumonia guidelines issued by the American Thoracic Society and the Infectious Diseases Society of America.

Rifampin is frequently added to the treatment regimen of patients who are seriously ill with LD. There are no data suggesting synergy when this antibiotic is used in combination with antibiotics other than a macrolide. When it is used in this context, patients have a longer length of stay and higher bilirubin levels.

PROGNOSIS

In one study, the case-fatality rate from LD fell from 35% in 1993 to 5.6% in 2004. Such a decline in mortality was substantiated in a 15-year study of 217 cases of LD requiring admission to the hospital from Barcelona, Spain. The mortality decreased over time from 9% in 1995 to 2007 to 4% in 2007 to 2010.

In general, the fatality rate is higher in sporadic cases than in outbreak cases, and it is higher in nosocomial cases compared with community-acquired cases. The highest fatality rate is seen in nosocomial LD, for which it is still about 30%. Earlier diagnosis by the urinary antigen test and more effective antibiotic therapy account for much of the reduction in mortality. Factors associated with mortality are older age, immunosuppression, and severity of pneumonia.

Cases of LD should be reported to local health officials. An investigation is often required to determine the source of the *Legionella*.

REVIEW QUESTIONS

1. All of the following are risk factors for legionnaires' disease, except

A. Cigarette smoking
B. Travel to Europe
C. Treatment with anti–tumor necrosis factor
D. Using potting soil for your garden in Australia
E. Being a member of the American Legion

Answer: E The disease was first recognized during a convention by the American Legion and was caused by water contamination with the organism at the hotel in Philadelphia that served as the meeting headquarters, not by any host factors. All of the other factors have been shown in one or more studies to increase one's risk of acquiring legionnaires' disease.

2. You have just seen a 55-year-old man with right lower lobe pneumonia. He has been receiving dialysis three times per week at an outpatient facility. He is quite ill, and you are concerned that he might have legionnaires' disease. The result of the *Legionella* urinary antigen test that you ordered is negative. Which of the following is correct?

A. Your patient does not have legionnaires' disease.
B. Your patient may still have legionnaires' disease.
C. Serologic testing will confirm the diagnosis.
D. Blood cultures will be positive for *Legionella*.
E. Sputum culture is a good test for *Legionella*.

Answer: B The urine antigen test detects only infection due to *L. pneumophila* serogroup 1, and even then it is only 74% sensitive. So your patient could still have legionnaires' disease, either serogroup 1 or another *Legionella* species. Sputum culture, if positive, is 100% specific. Unfortunately, most patients with legionnaires' disease do not produce sputum, and even more problematic is the fact that many laboratories are unable to grow this microorganism. Serologic diagnosis takes 4 to 6 weeks, so it is not of any use in therapeutic decision making. Also, the sensitivity can be low, especially in patients with an impaired immune response.

3. A patient has developed legionnaires' disease while hospitalized for treatment of acute pancreatitis. He spent 3 weeks in intensive care and had a nasogastric tube in place for most of that time. What was the most likely source of the patient's *Legionella*?

A. He acquired it before admission.
B. His daughter, who lives in Athens, came to visit him. She was coughing frequently during her many visits.
C. The air conditioning system
D. The potable water

Answer: D In all likelihood, the potable water is the source. You should check the protocol for nasogastric tubes in your hospital. Not uncommonly, potable water is used to initiate feeding. If the potable water is contaminated with *Legionella*, it is readily aspirated into the lungs in patients who are in a recumbent position in an intensive care unit. Person-to-person transmission of *Legionella* has not been documented. If the air conditioning system was contaminated, it would likely be through a cooling tower, and there would have likely been an outbreak of many cases of *Legionella*. Whereas it is always possible that *Legionella* was acquired before admission, the incubation period for legionnaires' disease is 2 to 10 days. It is possible to have a much longer incubation period. In the event of other cases in the hospital, molecular biology typing techniques can be used to identify the organism as coming from the potable water.

4. The following are extrapulmonary manifestations of legionnaires' disease.

A. Prosthetic valve endocarditis
B. Cerebellar ataxia
C. Reactive arthritis
D. Oral ulcers
E. A, B, and C

Answer: E Prosthetic valve endocarditis is due to direct infection of the valve by circulating *Legionella* bacteria. Cerebellar ataxia and reactive arthritis represent immunologic reactions in these tissues and are not due to direct infection.

5. The treatment of choice for moderate to severe legionnaires' disease is

A. Erythromycin
B. Amoxicillin
C. Levofloxacin
D. Vancomycin
E. Ceftriaxone

Answer: C A respiratory fluoroquinolone is probably the best antibiotic class for treatment of moderate to severe legionnaires' disease. There are not data from randomized clinical trials to provide guidance in this regard. Our recommendations are from observational studies. We do know that β-lactams are ineffective and erythromycin, although initially used to treat legionnaires' disease, takes 4 to 5 days to show improvement. Indeed, most patients get worse before they get better after treatment with erythromycin. Vancomycin would not be expected to work on a microorganism with a gram-negative cell wall.

BARTONELLA INFECTIONS

JEAN-MARC ROLAIN AND DIDIER RAOULT

DEFINITION

Bartonella species belong to the alpha-2 subgroup of Proteobacteria and are closely related to the genera *Brucella*, *Agrobacterium*, and *Rhizobium*. Since 1993, the genus *Bartonella* has been reorganized by addition of the genera *Rochalimaea* and *Grahamella* to the family Bartonellaceae. More than 30 known *Bartonella* species have been isolated from both animals and humans.[1] These bacteria are considered emerging pathogens that are associated with zoonosis and human infections. Among them, 14 validated species have been implicated in human diseases: *B. henselae, B. quintana, B. bacilliformis, B. elizabethae, B. clarridgeiae, B. vinsonii* subsp. *arupensis, B. vinsonii* subsp. *berkhoffii, B. alsatica, B. tamiae, B. grahamii, B. washoensis, B. rochalimae, B.*

TABLE 315-1 *BARTONELLA* SPECIES CAUSING HUMAN DISEASE

BARTONELLA SPECIES	FIRST CULTIVATION		YEAR OF DESCRIPTION	RESERVOIR HOST/VECTOR	HUMAN DISEASE
	Mammal	*Country*			
B. alsatica	Wild rabbit (*Oryctolagus cuniculus*)	France	1999	Rabbit	Endocarditis, lymphadenopathy
"*Candidatus* B. ancashi"		Peru	2013		Verruga peruana
B. bacilliformis	Human		1909	Human/sandfly	Carrión's disease, Oroya fever, verruga peruana
B. clarridgeiae	Cat		1996	Cat/cat flea	Cat-scratch disease
B. elizabethae	Endocarditis patient	United States	1993	Rat	Endocarditis, neuroretinitis
B. grahamii	Woodland mammal (*Clethrionomys glareolus*)	United Kingdom	1995	Rat, insectivore	Neuroretinitis
B. henselae	Cat		1990	Cat/cat flea	Cat-scratch disease, endocarditis, bacillary angiomatosis, bacillary peliosis, Parinaud oculoglandular syndrome, neuroretinitis, osteomyelitis, arthropathy, bacteremia with fever
B. koehlerae	Domestic cat	United States	1999	Cat	Endocarditis
B. mayotimonensis	Endocarditis patient	United States	2009	Unknown	Endocarditis
B. quintana	Human		1920	Human/body louse	Trench fever, endocarditis, bacillary angiomatosis
B. rochalimae	Human	United States	2007		Bacteremia, fever, splenomegaly
B. tamiae	Human	Thailand	2008		Febrile illness
B. vinsonii arupensis	Cattle rancher	United States	1999	Dog, rodent/ticks	Bacteremia with fever
B. washoensis			2000	Ground squirrel	Myocarditis

koehlerae, and "*Candidatus* B. ancashi" (Table 315-1). The other *Bartonella* species have been isolated only from the blood of animals, including rodents, felids, canids, dolphins, and ruminants. The route of transmission of *Bartonella* species in mammals and humans is by fleas, ticks, mites, and lice (see Table 315-1).

Bartonella infections are emerging infectious diseases that lead to a wide spectrum of either acute or chronic diseases. The status of the host immune response plays an important role in the development of the different manifestations. Four different clinical syndromes may occur with *Bartonella* infections: (1) infection of red blood cells and erythrophagocytosis, (2) granulomatous disease controlled by the immune response, (3) blood culture–negative endocarditis and bacteremia, and (4) vasculoproliferative diseases. A single *Bartonella* species can cause either acute or chronic infections and either vasculoproliferative or suppurative manifestations, but with different pathogenetic mechanisms that mainly depend on the patient's immune status. For example, *B. quintana* is responsible for trench fever as well as for endocarditis, bacteremia in the homeless population, and vasculoproliferative diseases, whereas *B. bacilliformis* is the agent of Carrión's disease, which corresponds to either an acute intraerythrocytic bacteremic disease (Oroya fever) or a chronic vasculoproliferative disease (verruga peruana). Infection of red blood cells has been well established for *B. bacilliformis* (Oroya fever) and *B. quintana* (trench fever and bacteremia in the homeless), whereas *B. henselae* and *B. koehlerae* have been seen in erythrocytes of infected cats. *B. henselae* can cause granulomatous disease, that is, cat-scratch disease (CSD), which affects lymph nodes, but can also be responsible for other clinical manifestations or complications, such as endocarditis. Vasculoproliferative diseases include bacillary angiomatosis caused by *B. henselae* and *B. quintana,* peliosis hepatis caused by *B. henselae,* and verruga peruana caused by *B. bacilliformis*. The immune status of the host plays a critical role in the development of these different forms of the disease. *B. henselae* usually causes CSD (a self-limited disease) in immunocompetent hosts, whereas it is responsible for bacillary angiomatosis in immunocompromised patients. In patients with a previous valvulopathy, any *Bartonella* infection may lead to endocarditis.

The Pathogen

Bartonella species are small, gram-negative, fastidious, pleomorphic coccobacilli or slightly curved rods (0.5 by 1 to 2 µm). Because of the slow growth of these bacteria and the lack of reproducible biochemical methods for their identification, they are usually identified by molecular methods. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry has emerged as a new technique for species identification and is an accurate and reproducible method for the rapid and inexpensive identification of *Bartonella* species. The bacteria can grow on enriched blood-containing media with a 5% carbon dioxide atmosphere after 5 to 15 days to up to 45 days on primary culture. The optimal growth temperature ranges from 28° C for *B. bacilliformis* to 35° to 37° C for the other species. *Bartonella* species can also be cocultured with endothelial cells. *Bartonella* species are either flagellated or nonflagellated cells. *B. bacilliformis* uses flagella for binding and deforming into the surface of erythrocytes. Bacteria can either persist in the blood stream of the host as intraerythrocytic parasites or colonize human endothelial cells.

EPIDEMIOLOGY

Almost all *Bartonella* species are vector-borne bacteria (see Table 315-1). Some are limited geographically, such as *B. bacilliformis,* which is found only in the Andes Mountains in South America at high altitudes, where its principal vector, *Lutzomyia verrucarum,* is distributed; others have a worldwide distribution, such as *B. henselae* and *B. quintana*. Each *Bartonella* species is highly adapted to its mammalian reservoir, in which bacteria usually cause a long-lasting intraerythrocytic bacteremia that may be asymptomatic. Humans are the hosts and reservoirs for *B. bacilliformis* and *B. quintana*. *B. quintana* is transmitted by the human body louse by inoculation of arthropod feces through broken skin (Chapter 359). Cats represent the main reservoir hosts for *B. henselae* infection; this pathogen is the agent of CSD in humans, caused by cat bites or scratches. *B. henselae* infection is transmitted from cat to cat by the cat flea. Cat fleas may also be infected by *B. quintana*. The role of dogs as reservoir hosts has been documented for several species, including *B. vinsonii* subsp. *arupensis*, *B. vinsonii* subsp. *berkhoffii*, and *B. henselae*. Wild rabbits are the reservoir hosts for *B. alsatica,* which is an agent of endocarditis and lymphadenopathy[2] in humans in close contact with rabbits. For other *Bartonella* species known to cause diseases in humans (see Table 315-1), their pathogenic role and mode of transmission are not fully understood.

INFECTION OF RED BLOOD CELLS: OROYA FEVER AND TRENCH FEVER

PATHOBIOLOGY

In Oroya fever, *B. bacilliformis* invades up to 80% of erythrocytes and produces their massive lysis, which results in severe hemolytic anemia, the major symptom of the disease.[3] Similarly, trench fever is characterized by an intracellular erythrocyte parasitism by *B. quintana*, with the percentage of infected red blood cells ranging from 0.001 to 0.005% (Fig. 315-1). Bacteria can also be seen extracellularly and in erythroblasts. This intracellular erythrocyte parasitism can presumably preserve the pathogens for efficient transmission by body lice, protect *B. quintana* from the host immune response, and

contribute to decreased antimicrobial efficacy.[4] During bacteremia in the homeless, *B. quintana* can also be seen in red blood cells.

CLINICAL MANIFESTATIONS

The main clinical manifestations of infection by *Bartonella* species are summarized in Table 315-2.[5]

Oroya fever is the acute or hemolytic phase of Carrión's disease, caused by *B. bacilliformis*; it usually develops 3 to 12 weeks after inoculation. Oroya fever results from the massive invasion of erythrocytes by *B. bacilliformis*, and without antibiotic treatment, it causes death in up to 85% of infected humans by hemolysis or when complicated by opportunistic infections such as salmonellosis. The onset is usually abrupt, with high fever, chills, headache, and anorexia. Patients have intense myalgias and arthralgias, abdominal pain, and jaundice. Complications are frequent, including meningoencephalitis, dyspnea, delirium, and superinfection leading to death. Asymptomatic persistent bacteremia may serve as the reservoir of the organism.

Trench fever is transmitted by lice (Chapter 359) and is the clinical manifestation of *B. quintana*. Trench fever affected more than 1 million people during World War I; more recently, *B. quintana* has been recognized in immunocompromised hosts, homeless people, and chronic alcoholics.[6] Clinical manifestations of trench fever may range from asymptomatic infection to severe, life-threatening illness. After an incubation period of 2 to 3 weeks, there is a sudden onset of fever that lasts 1 to 3 days associated with headache, shin pain, and dizziness. Although fatal cases have not been reported, the disease may persist for 4 to 6 weeks and result in prolonged disability. Relapses may occur years later, and in some cases there may be bacteremia with no clinical signs.

CAT-SCRATCH DISEASE

PATHOBIOLOGY

Little is known about the pathogenesis of the long-lasting lymphadenopathy in CSD. Immunopathogenesis is assumed to play an important role in CSD because bacteria have only rarely been isolated from affected lymph nodes. Thus, the disease is usually controlled by the host immune response, and there are few or no viable bacteria when lymph node biopsy specimens are analyzed; they are necrotic by pathologic examination.

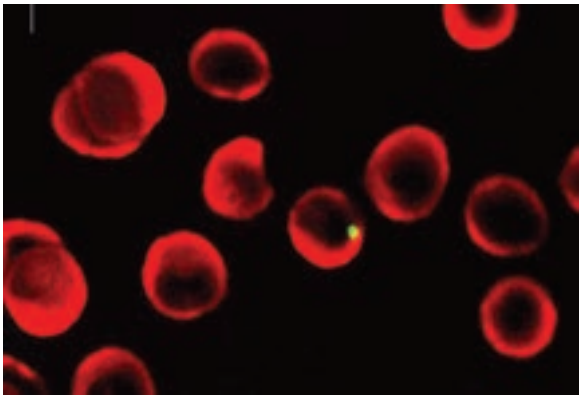

FIGURE 315-1. Section of human red blood cell infected with *Bartonella quintana* as viewed by confocal microscopy.

CLINICAL MANIFESTATIONS

Typical CSD is the most common manifestation of infection with *B. henselae* and usually is manifested as a self-limited regional lymphadenitis.[7] Transmission from cat to human occurs directly by a cat scratch or cat bite or possibly by a cat flea or tick bite. A typical papule or pustule may be seen 3 to 10 days after the scratch or bite at the site of inoculation and may last for 1 to 3 weeks. The subsequent lymphadenopathy is localized mainly to the axillary, cervical, or submaxillary nodes that drain the area where the cat scratch occurred. The enlarged lymph node is often painful and tender. Lymphadenopathy sometimes lasts for months, and in a few cases it can persist for as long as 1 to 2 years. In some cases, the lymph node may suppurate if it is not drained. Most patients are not febrile during the course of typical CSD. Systemic or severe disease may occur in about 5 to 14% of patients, with most of them suffering severe systemic symptoms due to disseminated infection. *B. alsatica* has been reported as a cause of lymphadenitis in a woman scratched on the finger while butchering a wild rabbit. After exposure to *B. henselae*, patients may develop bacteremia with or without clinical signs of typical CSD, and in patients with valvular lesions, this may result in infective endocarditis. Thus, CSD represents the primary infection of *B. henselae*, and endocarditis may follow in patients with heart valve lesions.

Approximately 10% of patients with CSD have atypical clinical manifestations, including prolonged fever (>2 weeks), malaise, neuroretinitis, encephalitis, erythema nodosum, hepatitis, fatigue, weight loss, and splenomegaly. A recent clinical study showed that musculoskeletal manifestations (myalgia, arthritis, arthralgia, tendinitis, osteomyelitis, neuralgia) were present in more than 10% of patients with CSD, demonstrating that these clinical manifestations are not as rare as might be expected from the cases reported in the past. In this series of 913 patients, myalgia and arthropathy were the most common manifestations, with an incidence of 5.8% and 5.5%, respectively. Moreover, these manifestations occurred primarily in adults whose ages ranged from 20 to 59 years. Myalgia had a mean duration of 4 weeks and was often severe. Arthropathy had a mean duration of 5.5 weeks, was more common in female patients older than 20 years, affected large and medium joints (half of those involved being weight-bearing joints), and was associated with symmetrical erythema nodosum early in the course of CSD. These musculoskeletal manifestations are often severe and may evolve into chronic forms that persist for more than a year. Tendinitis, neuralgia, and osteomyelitis are less common, with incidences lower than 1%.

Ocular and Neurologic Manifestations

Parinaud oculoglandular syndrome is a self-limited conjunctivitis associated with preauricular lymphadenopathy. Other atypical manifestations include neurologic syndromes (meningoencephalitis, meningitis, neuroretinitis). Encephalopathy may occur in 2 to 4% of CSD patients, mainly adolescents and adults. Patients usually have persistent headaches with or without fever and may develop seizures. Acute neurologic disorders range from self-limited nuchal rigidity to pupillary dilation or aphasia and hemiplegia; they may last

TABLE 315-2 CLINICAL MANIFESTATIONS ASSOCIATED WITH *BARTONELLA* SPECIES

CLINICAL MANIFESTATION	*B. BACILLIFORMIS*	*B. QUINTANA*	*B. HENSELAE*	*B. ALSATICA*	OTHERS
Intraerythrocytic bacteremia	+	+			
Chronic bacteremia	+	+	+		+

Lymphadenopathy		+	+ (CSD)	+	+
SENLAT with skin lesion			+		
Meningoencephalitis			+		
Uveitis-retinitis		+	+		+

CSD = cat-scratch disease; SENLAT = scalp eschar and neck lymphadenopathy.

for several weeks to months. Neuroretinitis has been associated with CSD in patients experiencing a sudden unilateral loss of visual acuity.[8] The most common picture remains papilledema associated with macular exudates causing stellar retinitis. A few reports have now established that *B. henselae* can be responsible for uveitis, along with *B. grahamii* and *B. quintana*. Patients present with either nongranulomatous or granulomatous uveitis.

Finally, tick-borne *B. henselae* infection has been described, including scalp eschar and neck lymphadenopathy after tick bites in three patients during the colder months in France. *B. henselae* was detected by molecular tools both in skin biopsy specimens (cervical and occipital) and in a *Dermacentor marginatus* tick removed from the scalp of one patient. All three patients had asthenia, but none had alopecia.

ENDOCARDITIS

PATHOBIOLOGY

B. quintana, B. henselae, B. alsatica, B. vinsonii subsp. *berkhoffii, B. elizabethae,* and "*Candidatus* Bartonella mayotimonensis" have been associated with blood culture–negative endocarditis, whereas *B. vinsonii* subsp. *arupensis* has been detected in a patient with fever and bacteremia; *B. washoensis* has been identified in one patient with myocarditis; *B. rochalimae* was reported in a patient with fever, bacteremia, and splenomegaly; and *B. tamiae* has been isolated in a patient with a febrile illness. Patients with endocarditis usually have preexisting heart valve disease that promotes the development of infective endocarditis and, in some cases, a definite risk factor for infection specifically with *Bartonella*. Endocarditis caused by *Bartonella* species exhibits slight inflammation, with a few inflammatory mononuclear cells and small vegetations; the bacteria are seen extracellularly in dense immunopositive clusters that are mainly included in vegetations and in neutrophil and macrophage cytoplasm.

CLINICAL MANIFESTATIONS

The most commonly identified agents of *Bartonella* endocarditis are *B. quintana*, followed by *B. henselae* and other *Bartonella* species.[9] Patients appear to have chronic, blood culture–negative endocarditis, usually with fever (90%). Echocardiography reveals vegetations (in 90%) that should be removed by surgery in the majority of patients. Infections with *B. henselae* are epidemiologically linked to close contact with cats or cat fleas and previous valvular heart disease, whereas *B. quintana* endocarditis is frequently described in homeless and alcoholic patients with body lice infection and can be observed in patients without previous valve lesions. The onset is usually subacute, with some patients being afebrile at the time of admission. About half the patients have embolic phenomena. Interestingly, there is a north (Europe) to south (North Africa) gradient for the proportion of *Bartonella* endocarditis in humans; thus *Bartonella* is apparently a common cause of endocarditis in North Africa. Sporadic cases of endocarditis have also been associated with *B. koehlerae, B. vinsonii* subsp. *berkhoffii, B. vinsonii* subsp. *arupensis, B. elizabethae, B. alsatica,* and "*Candidatus* Bartonella mayotimonensis."

VASCULOPROLIFERATIVE DISEASE: VERRUGA PERUANA, BACILLARY ANGIOMATOSIS, AND PELIOSIS HEPATIS

PATHOBIOLOGY

Bartonella species have the ability to cause vasculoproliferative lesions through a process of pathologic angiogenesis resulting in the formation of new capillaries from preexisting ones. These typical vasoproliferations can be expressed as skin lesions called bacillary angiomatosis, which are caused by *B. quintana* and *B. henselae*[10]; there is also a cystic form in the liver and spleen called peliosis hepatis, which is caused only by *B. henselae.*[11] Skin lesions are similar to those reported for verruga peruana, the chronic form of Carrión's disease. Bacillary angiomatosis is a neovascular proliferation that has been reported most commonly in AIDS patients and involves the skin (Fig. 315-2) and lymph nodes; it occurs less frequently in patients with other causes of immunosuppression and only exceptionally in immunocompetent patients. In bacillary angiomatosis, lesions comprise proliferating endothelial cells, bacteria, and mixed infiltrates of macrophages/monocytes and polymorphonuclear neutrophils, leading to chronic inflammation. Bacteria are clustered as aggregates both surrounding and within endothelial cells, indicating that the vascular endothelium represents a target tissue for intracellular and extracellular colonization in vivo. On histologic evaluation, bacillary angiomatosis

FIGURE 315-2. Skin lesion of bacillary angiomatosis.

is a lobular proliferation of small blood vessels containing endothelial cells and bacteria, usually seen in clusters when stained with Warthin-Starry. As in bacillary angiomatosis, lesions of verruga peruana are characterized by lobular proliferations and atypical endothelial cells forming both relatively solid sheets and small, well-formed vessels with patent lumens. Lesions are typically infiltrated, indicating a chronic inflammatory process.

CLINICAL MANIFESTATIONS

As already noted, bacillary angiomatosis is seen most often in AIDS patients. Cutaneous lesions often arise in crops and can be subcutaneous or dermal nodules with red or purple papules millimeters to centimeters in diameter. When cutaneous lesions are absent, the diagnosis is often difficult and delayed because signs of visceral involvement are usually nonspecific. The potentially systemic nature of bacillary angiomatosis is reflected by the involvement of brain, bone, lymph node, bone marrow, skeletal muscle, conjunctiva, and mucosal surfaces of the gastrointestinal and respiratory tracts. Peliosis hepatis affects solid internal organs, primarily the liver, with reticuloendothelial elements; in the liver, it is defined as a vascular proliferation of sinusoidal hepatic capillaries resulting in blood-filled spaces. The spleen, abdominal lymph nodes, and bone marrow may also be involved.

Following acute Oroya fever, patients usually develop angioproliferative cutaneous tumors called verruga peruana after a latent period ranging from weeks to months. The infection is characterized by benign cutaneous vascular lesions typically consisting of round papules that are frequently pruritic and bleeding. The infection is accompanied by malaise and arthralgias. Skin lesions may change over time from miliary to nodular subcutaneous lesions to large mulaire lesions. These large lesions are often engorged with blood and prone to ulceration and bleeding. This eruptive phase clinically resembles Kaposi's sarcoma or bacillary angiomatosis. However, it has a low morbidity, and there are no reports of mortality.

DIAGNOSIS OF *BARTONELLA* INFECTION

Methods used for the diagnosis of *Bartonella* infection include serology, microscopy, culture, molecular amplification of *Bartonella* species genes, direct immunofluorescence, and immunohistochemistry. The usefulness of these techniques may vary according to the disease involved (Table 315-3).

Serologic Tests

Serology remains the most widely used method for the diagnosis of CSD and *Bartonella* endocarditis because culture and isolation are difficult and time-consuming, and molecular methods are not available in all laboratories. There are currently two classic serologic methods for the diagnosis of *Bartonella* infections: enzyme-linked immunosorbent assay and immunofluorescence assay. By immunofluorescence assay, an immunoglobulin G titer of 1 : 64 or greater should be considered positive for CSD, whereas patients with endocarditis usually have higher antibody titers (≥1 : 800). In homeless patients, bacteremia has been associated with serologic tests that were positive for *B. quintana*. However, reported sensitivities of immunofluorescence assay vary considerably, from nearly 100% to less than 30%, depending on the nature of the antigens used and the selected patients. Moreover, owing to cross-reactive antibodies between *Bartonella* species, the diagnosis of *Bartonella* infection at the species level is usually not possible. More sophisticated methods should be used, especially Western blot with cross-adsorption analysis. Western blot is also useful for the differential diagnosis of endocarditis

TABLE 315-3 LABORATORY METHODS FOR THE DIAGNOSIS OF *BARTONELLA* INFECTIONS

CLINICAL MANIFESTATION	SEROLOGY	CULTURE	MOLECULAR METHODS	IMMUNOHISTOCHEMISTRY (WARTHIN-STARRY STAIN)	MICROSCOPY FOR INTRAERYTHROCYTIC ORGANISM (GIEMSA OR IF)

IF = immunofluorescence; SENLAT = scalp eschar and neck lymphadenopathy.

because the profile obtained for endocarditis is specific compared with that for CSD or chronic bacteremia.

Microscopy, Immunofluorescence, and Immunohistochemistry

The diagnosis of Oroya fever is based on examination of a peripheral blood smear stained by Giemsa; the percentage of infected red blood cells is sufficiently high so that bacteria are visible. Similarly, *B. quintana* can be seen within red blood cells with use of specific monoclonal antibody by immunofluorescence and confocal microscopy (see Fig. 315-1). Microscopic examination after Warthin-Starry silver staining or immunohistochemistry of a cardiac valve or skin biopsy specimen is also useful for the detection of *Bartonella* organisms in patients with endocarditis and bacillary angiomatosis.

Culture

Bartonella species can be recovered from the blood of bacteremic patients as well as from cardiac valves, skin and liver biopsy specimens, and, rarely, lymph nodes. Bacteria can be isolated directly from these specimens after plating onto blood agar solid media, blood culture in broth, and cocultivation in endothelial cells. Cultures are usually positive after 2 weeks of incubation, but up to 45 days may be necessary for primary isolation.

Molecular Detection Methods

Direct detection and final identification of *Bartonella* species from blood and tissue specimens, including lymph node, cardiac valve, skin, and liver, can be achieved by polymerase chain reaction amplification and sequencing of various housekeeping genes. Real-time polymerase chain reaction with TaqMan probes has been added to the panel of molecular techniques for the specific detection of *Bartonella* at the species level from lymph nodes in CSD, directly from cardiac valves in patients with endocarditis, and in patients with bacillary angiomatosis or peliosis hepatis.

Differential Diagnosis

The differential diagnosis of bacillary angiomatosis is Kaposi's sarcoma, but visualization of bacteria in the tissue specimen can help distinguish between these two entities. Trench fever may be confused mainly with typhus group rickettsiosis, relapsing fever, and malaria. CSD may be confused with tularemia, pyogenic lymphadenitis, mycobacterial infection, and neoplasia.

TREATMENT

Trench Fever

Before the advent of antibiotics, acetylsalicylic acid was the most effective drug for the pain caused by trench fever. However, a randomized clinical trial in homeless persons with episodes of bacteremia demonstrated that the combination of gentamicin and doxycycline is more effective in stopping bacteremia compared with no treatment or the use of β-lactams or doxycycline alone. Because the intraerythrocytic presence of *B. quintana* decreases antimicrobial efficacy, the duration of treatment is critical in trench fever. Patients with *B. quintana* bacteremia should be treated with gentamicin (3 mg/kg body weight/day IV for 14 days), in combination with doxycycline (200 mg/day PO) for 28 days.

Oroya Fever and Verruga Peruana

In Oroya fever, treatment with penicillin, streptomycin, fluoroquinolones, tetracycline, or erythromycin produces rapid defervescence and disappearance of the organisms from the blood, usually within 24 hours. As an alternative treatment, chloramphenicol can be used alone or in combination with a β-lactam. Treatment with chloramphenicol may also have the advantage of covering commonly associated *Salmonella* species. Patients with Oroya fever should be treated with chloramphenicol (500 mg PO four times a day) for 14 days in combination with another antibiotic (especially a β-lactam compound). Streptomycin (15 to 20 mg/kg/day for 10 days) was the traditional treatment for verruga peruana. However, its use is problematic, especially in children, and rifampin has become the drug of choice for the treatment of eruptive-phase bartonellosis. Failures of rifampin treatment have been reported in verruga peruana. Finally, ciprofloxacin (500 mg PO twice daily for 7 to 10 days) has been used successfully for the treatment of multiple eruptive-phase lesions in adults and has been proposed as an appropriate alternative. Doxycycline in association with gentamicin may be used to treat the eruptive phase of Carrión's disease.

Cat-Scratch Disease

Typical CSD is a self-limited illness that resolves within 2 to 6 months and usually does not respond to therapy because the bacteria within necrotic lymph nodes are not alive. In cases of long-lasting lymphadenopathy, patients should be reassured that it is benign and will probably subside spontaneously within 2 to 4 months. Management consists of analgesics for pain and prudent follow-up.[12] However, azithromycin (500 mg PO on day 1 and 250 mg PO on days 2 to 5 as single daily doses) is an alternative for patients with large, bulky lymphadenopathy.[13] If lymphadenopathy does not resolve, lymph nodes can be removed surgically. For atypical presentations of CSD, there are no data regarding the benefit of specific antimicrobial therapy for immunocompetent patients. For neuroretinitis, the combination of doxycycline (100 mg PO or IV twice daily) with rifampin (300 mg PO twice daily) seems to promote disease resolution, to improve visual acuity, to reduce optic disc edema, and to decrease disease duration.

Endocarditis

Patients with *Bartonella* endocarditis have a higher death rate and undergo valvular surgery more frequently than patients with endocarditis caused by other pathogens. Patients with suspected (but culture-negative) *Bartonella* endocarditis or proved *B. quintana* endocarditis should be treated with oral doxycycline 100 mg twice a day for 6 weeks in combination with gentamicin 3 mg/kg/day in one intravenous daily dose for 14 days.[14] The American Heart Association consensus on treating infective endocarditis is ceftriaxone plus gentamicin, with or without doxycycline, when *Bartonella* is suspected, and doxycycline plus gentamicin when *Bartonella* endocarditis is confirmed. However, there is direct evidence that patients receiving an aminoglycoside are more likely to fully recover, and those treated with aminoglycosides for at least 14 days are more likely to survive than those receiving a shorter duration

of therapy. In the absence of any prospective study for the treatment of *Bartonella* endocarditis, the same regimen as for *B. henselae* and *B. quintana* should be used for endocarditis when another *Bartonella* species has been identified as the causative agent.

Bacillary Angiomatosis and Peliosis Hepatis

Without appropriate therapy, infection spreads systemically and can involve virtually any organ, and the outcome is sometimes fatal. Thus, antibiotic treatment is warranted in all cases of *Bartonella*-associated vasculoproliferative disease. On the basis of empirical clinical reports, erythromycin remains the treatment of choice and has been used successfully to treat many patients with bacillary angiomatosis. The response to treatment in bacillary angiomatosis can be dramatic in immunocompromised patients, with resolution of palpable subcutaneous lesions within hours. Erythromycin also has an antiangiogenic effect on microvascular endothelial cells that could explain this quick disappearance of lesions. Erythromycin (500 mg four times daily) for 3 months is first-line therapy. Doxycycline (100 mg PO or IV twice daily) is currently proposed as an appropriate alternative. In patients with serious infections, erythromycin or doxycycline can be used in combination with rifampin (300 mg PO twice daily). The duration of therapy is critical. We recommend that treatment be given for at least 3 months for bacillary angiomatosis and 4 months for peliosis hepatis. Peliosis hepatis responds slowly, and hepatic lesions continue to improve after several months of treatment, whereas cutaneous bacillary angiomatosis demonstrates improvement after 4 to 7 days of treatment and resolves after about 1 month of treatment. Relapses of peliosis hepatis and bacillary angiomatosis lesions after antibiotic treatment have been reported frequently, especially in immunocompromised patients with a shorter duration of therapy. Patients who relapse after the recommended treatment should probably be re-treated for 4 to 6 months with erythromycin (500 mg PO four times daily) or doxycycline (100 mg PO twice daily), and those with repeated relapses should receive antibiotic therapy as long as they are immunocompromised.

PREVENTION

Because arthropods play an important role in the transmission of feline *Bartonella* species to humans, rigorous arthropod control (Chapter 359) should be recommended by health care workers, particularly when advising immunocompromised individuals on the risks related to pet ownership. Cat fleas live on both cats and dogs and are best controlled by fumigating areas where these animals live.

PROGNOSIS

Mortality in those with Oroya fever was as high as 50% before the antibiotic era but is now limited by the use of antibiotics. Trench fever should be treated with antibiotics to avoid more severe disease, especially in patients with valvulopathy who are at risk for development of endocarditis. CSD usually resolves spontaneously without any treatment in immunocompetent patients. In the case of complications or in immunocompromised patients, antibiotic therapy should be given, and patients usually respond well to treatment. Finally, for vasculoproliferative diseases, antibiotics are usually effective if they are given for a long time, but cutaneous lesions in verruga peruana may benefit from surgery.

REVIEW QUESTIONS

1. Which of the following is the main vector of *Bartonella quintana* infections in humans?

A. Mites
B. Lice
C. Ticks
D. Bed bugs
E. Fleas

Answer: B The human body louse is the main vector (see Table 315-1), but *B. quintana* could be detected in fleas and ticks.

2. Which treatment is the most appropriate recommendation for *Bartonella* endocarditis?

A. Erythromycin
B. Doxycycline plus rifampin
C. Doxycycline
D. Doxycycline plus gentamicin
E. Streptomycin

Answer: D *Bartonella* endocarditis should be treated with doxycycline for 6 weeks plus gentamicin for 14 days. (See Treatment section.)

3. Which laboratory method is the most appropriate for the diagnosis of cat-scratch disease (CSD)?

A. Real-time polymerase chain reaction
B. Serology
C. Gram staining
D. Cell culture
E. Immunohistochemistry

Answer: A Serology remains a widely used method where molecular methods are not available for the diagnosis of CSD and *Bartonella* endocarditis because culture and isolation are difficult and time-consuming. However, the reported sensitivities of immunofluorescence assays vary considerably, depending on the nature of the antigen used and the selected patients. Furthermore, because of cross-reactivity of antibodies between *Bartonella* species, serologic methods usually cannot make the diagnosis of *Bartonella* infection at the species level. Direct detection and definitive *Bartonella* species identification are possible from blood and tissue (e.g., lymph node) specimens. See Table 315-3.

4. Which *Bartonella* species is the causative agent of peliosis hepatis?

A. *B. quintana*
B. *B. henselae*
C. *B. bacilliformis*
D. *B. grahamii*
E. *B. alsatica*

Answer: B Peliosis hepatis is characterized by the development of cystic, blood-filled cavities throughout the liver parenchyma and can be caused by a variety of drugs, malignant neoplasms, post–renal transplantation, and different infections including human immunodeficiency virus infection, tuberculosis, and *Bartonella henselae*.

5. Which treatment is the most appropriate recommendation for bacillary angiomatosis?

A. Erythromycin
B. Doxycycline plus rifampin
C. Doxycycline
D. Doxycycline plus gentamicin
E. Streptomycin

Answer: A Erythromycin (500 mg four times daily) for 3 months is first-line therapy. (See Treatment section.)

316

GRANULOMA INGUINALE (DONOVANOSIS)

EDWARD W. HOOK III

DEFINITION

Granuloma inguinale, also known as donovanosis, is a slowly progressive ulcerative disease that involves principally the skin and subcutaneous tissues of the genital, inguinal, and anal regions.

The Pathogen

The causative organism is *Klebsiella granulomatis* (formerly *Calymmatobacterium granulomatis*), a facultative intracellular parasite. The organism is challenging to cultivate but can sometimes be grown in yolk sacs, and successful cell culture has been reported from South Africa and Australia. Successful culture, in turn, has permitted the development of polymerase chain reaction assays, currently for research purposes.

EPIDEMIOLOGY

The organism is primarily transmitted sexually, but it can probably be transmitted by nonsexual contact as well. Transmission efficiency is relatively low, and multiple sexual contacts with an infected partner seem to be necessary for the transmission of infection. The disease is rarely encountered in the United States. Although still relatively rare, it is more common in other areas of the world, including India, Papua New Guinea, the Caribbean, southern Africa, and parts of Australia, and it may be becoming less common even in these areas.

CLINICAL MANIFESTATIONS

After an incubation period of up to 50 days, the initial lesion usually appears as a subcutaneous nodule that erodes through the surface and develops into a beefy, elevated granulomatous lesion (Fig. 316-1).[1,2] The lesion is painless but tends to bleed easily, and it is not associated with systemic symptoms. Lesion exudate is often described as foul smelling. Secondary bacterial infection may cause a necrotic, painful, ulcerative lesion that may be rapidly destructive. A cicatricial form may also occur, with a depigmented elevated area of keloid-like scar containing scattered islands of granulomatous tissue. About 90% of lesions occur on the genitals and are commonly associated with pseudobuboes; these swellings usually are not due to involvement of the inguinal lymph nodes but rather are due to granulomatous involvement of subcutaneous tissue. Metastatic infection of bones or viscera is occasionally seen. Clinical experience suggests that secondary carcinomas may be a rare complication of granuloma inguinale.

DIAGNOSIS

The diagnosis is made by demonstrating intracellular Donovan's bodies in histiocytes or other mononuclear cells from lesion scrapings or biopsy samples. Wright stain and Giemsa stain of fresh impression smears or unfixed biopsy specimens usually demonstrate the bacilli relatively easily, although multiple biopsies may be necessary in chronic cases. Histologic examination of biopsy specimens shows plasma cells with some infiltration by polymorphonuclear leukocytes but no giant cells. In infected lesions, *K. granulomatis* is found primarily in histiocytes or other mononuclear cells. Cell culture and polymerase chain reaction methods are currently primarily research tools. No serologic test is clinically available.

Differential Diagnosis

The differential diagnosis includes squamous cell carcinoma, chancroid (Chapter 301), lymphogranuloma venereum (Chapter 318), syphilis

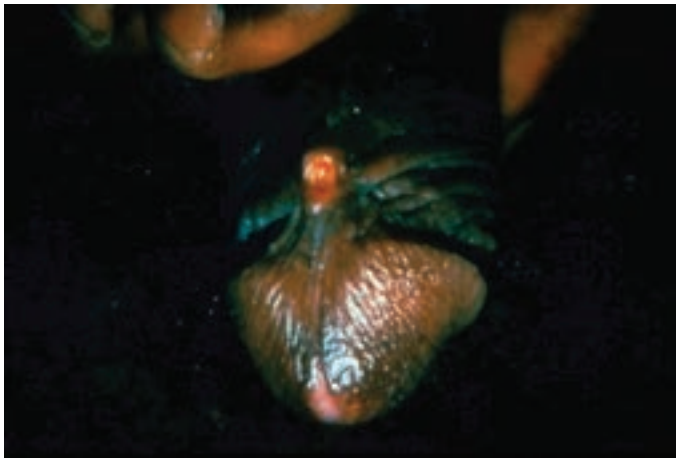

FIGURE 316-1. Typical primary lesion of granuloma inguinale. (Reproduced with permission from Herpes-Coldsores.com. http://www.herpes-coldsores.com/std/lymphogranuloma-pictures.htm.)

(Chapter 319), and other ulcerative granulomatous diseases.[3] In the absence of therapy, patients may not present until lesions have been present for months, long after the lesions of syphilis and other ulcerative sexually transmitted diseases have resolved. Chancroid is usually differentiated by its irregular undermined borders, which are not seen in typical cases of granuloma inguinale. Dark-field examination and serologic tests should help distinguish syphilis. Biopsy of lesions may be necessary to distinguish granuloma inguinale from certain tumors.

TREATMENT

Rx

There are no recent clinical trials of therapy for granuloma inguinale. Recommended treatment consists of azithromycin administered either as 1.0 g weekly or 500 mg daily or doxycycline 100 mg twice daily.[4] One double-strength trimethoprim-sulfamethoxazole tablet twice daily or erythromycin base 500 mg four times daily is recommended as alternative therapy. An aminoglycoside (e.g., gentamicin 1 mg/kg intravenously every 8 hours) may be added if these regimens do not result in clinical improvement within a few days. Treatment should be administered for at least 3 weeks and until lesions are completely healed. Patients should be monitored for at least several weeks after treatment is discontinued because of the possibility of relapse. Although the risk of communicability appears to be low, sexual contacts should also be examined; at present, treatment of contacts is not indicated in the absence of clinically evident disease.

REVIEW QUESTION

1. Which of the following statements regarding granuloma inguinale is correct?

A. It is transmitted efficiently and only by sexual contact.
B. The initial lesion is typically painful and associated with fever.
C. Lesions are associated with buboes.
D. Diagnosis requires demonstration of intracellular Donovan's bodies.
E. Diagnosis requires serologic confirmation.

Answer: D No serologic test is clinically available for granuloma inguinale, and definitive diagnosis depends on demonstration of Donovan's bodies in mononuclear cells from lesion scrapings or biopsy samples. Although it is primarily transmitted through sexual contact, the organism can probably be transmitted by nonsexual contact as well; transmission efficiency is low. The lesion is painless, and it is not accompanied by systemic symptoms. It is associated with a so-called pseudobubo, a swelling in the inguinal area caused by granulomatous infiltration of subcutaneous tissue—not actual inguinal lymph node involvement that would constitute a bubo.

317

MYCOPLASMA INFECTIONS

STEPHEN G. BAUM

DEFINITION

Mycoplasma organisms of the class Mollicutes are ubiquitous as pathogens and colonizing agents in the plant, animal, and insect kingdoms. They represent the smallest known free-living forms, but because they have fastidious growth requirements, they are difficult to culture. However, the presence of several species of *Mycoplasma* as commensals in animals and on human oral and genital mucosa frequently resulted in contamination of cell cultures. Such contamination led to the false implication of mycoplasmas as causative agents in many human diseases, both trivial and life-threatening. Of the human diseases proved to be due to mycoplasmas, pneumonia caused by *Mycoplasma pneumoniae* is by far the most clinically important. This infection constitutes a significant proportion of cases previously classified as atypical pneumonia, a nonspecific term for patchy pneumonias that generally do not respond to β-lactam antibiotics and have etiologic agents that are not easily cultured or visible on Gram stain. The term *atypical pneumonia* persists despite our increasing ability to identify specific etiologic agents, such as viruses, *Legionella*, and *Chlamydophila*. Other proven *Mycoplasma* infections include those in the urogenital tract caused by *Ureaplasma* species, *Mycoplasma hominis*, and *Mycoplasma genitalium*; wound infections caused by *M. hominis*; and overwhelming systemic infection in immunocompromised patients caused by *Mycoplasma fermentans* (*incognitus* strain).

The Pathogen

Mycoplasmas are short rods (10 × 200 nm) that have no cell wall and are bounded by a sterol-containing membrane; thus, they are unaffected by cell wall–inhibiting antimicrobials such as β-lactams. In tissue culture, mycoplasmas are intracellular; but in vivo, infection is primarily extracellular and affects epithelial cells and their organelles, such as cilia. Attachment to respiratory epithelium is by way of terminal adhesin proteins in specialized tip organelles.

EPIDEMIOLOGY

M. pneumoniae infection is spread person to person by respiratory droplets produced by coughing. Relatively close association with the index case appears to be required. The disease is usually introduced into families by a young child; in some studies, most of the infected adults were the parents of young children. As opposed to most viral respiratory infections, which are manifested 1 to 3 days after infection, *Mycoplasma* has an incubation period of 2 to 3 weeks. Therefore, a careful history showing several weeks between cases within a family may be an important clue to the mycoplasmal etiology. Organisms can be cultured from the sputum of infected individuals for weeks to months after clinically efficacious treatment.

Most cases of *Mycoplasma* respiratory infection occur singly or as family outbreaks. However, in closed populations, such as military recruit camps and boarding schools, *Mycoplasma* can cause mini-epidemics and may be responsible for 25 to 75% of cases of pneumonia in such settings. Serologically based epidemiologic studies have documented the high incidence of *Mycoplasma* respiratory infection throughout the world. In the United States, it is estimated that each year at least one case of *Mycoplasma* pneumonia occurs for every 1000 persons, or more than 2 million cases annually. The incidence of *Mycoplasma* nonpneumonic respiratory infection may be 10 to 20 times greater. The highest attack rates are in individuals 5 to 20 years old, but *M. pneumoniae* infection can occur at any age and may cause particularly severe disease in neonates.

As opposed to viral respiratory infections that peak in winter in temperate climates, a few studies have reported a peak incidence of *M. pneumoniae* outbreaks in the fall. Most surveys, however, show little or no seasonal predominance in sporadic cases. There is an age-related relationship of upper versus lower respiratory tract infection caused by *M. pneumoniae.* In children younger than 3 years, primarily upper respiratory tract infection develops, whereas in those 5 to 20 years old, bronchitis and pneumonia tend to occur. In older adults, pneumonia predominates.

The prevalence and incidence of clinical urogenital disease caused by *Ureaplasma urealyticum*, *Ureaplasma parvum*, *M. hominis*, and *M. genitalium* are much less well documented (Table 317-1). These organisms are rarely cultured outside the realm of clinical studies, and they exist as clinically inapparent commensals of the genitourinary tract. Diseases attributed to *Ureaplasma* species include urinary tract infection with and without calculus formation. The organism has been implicated as a cause of low birthweight in neonates. *M. hominis* is a common genitourinary and oral commensal as well and has been documented as a cause of endometritis and postpartum fever.

M. hominis has also caused sternal wound infection after cardiothoracic surgery and has been implicated in arthritis in immunocompromised patients. *Mycoplasma salivarium* may be involved in periodontal disease, and *M. genitalium* is implicated in some cases of nongonococcal urethritis and vaginitis.

TABLE 317-1 SITES AND INFECTIONS RELATED TO HUMAN MYCOPLASMAS

SUBGROUP	SITES OF ISOLATION	DISEASES	OCCURRENCE
M. hominis	GU tract (F > M)	Cervicitis, vaginitis, ?prostatitis	Common
	Conjunctivae (neonate)	Conjunctivitis	
	Blood (peripartum)	Peripartum sepsis	
	Surgical wounds, joints	Sternotomy infection, arthritis	
M. orale	Oropharynx	?	Common
M. pneumoniae	Respiratory tract	URI, pneumonia	Common
M. salivarium	Oropharynx, gingiva	?Periodontal disease	Common
M. fermentans	GU tract, blood, tissues	Multisystem disease in AIDS	Uncommon
M. genitalium	GU tract	Urethritis, cervicitis, PID	Uncommon
Ureaplasma spp	GU tract	Urethritis, upper GU infection	Common

AIDS = acquired immunodeficiency syndrome; F = female; GU = genitourinary; M = male; PID = pelvic inflammatory disease; URI = upper respiratory tract infection.

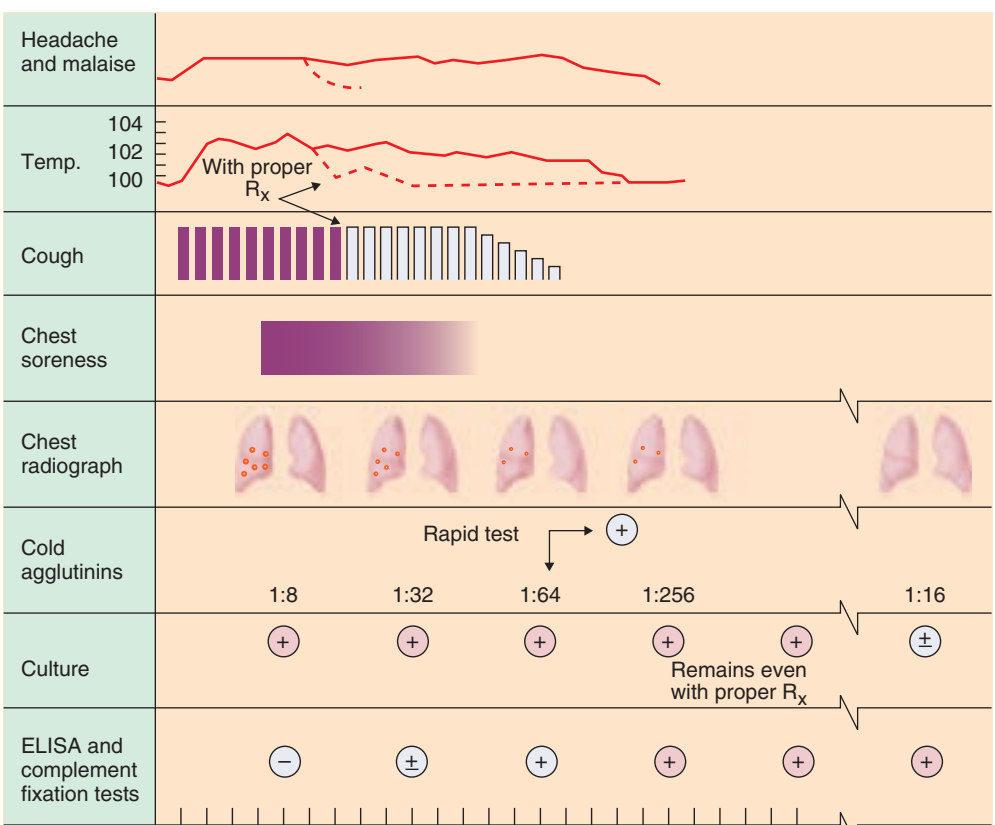

FIGURE 317-1. Major clinical and laboratory manifestations of mycoplasmal pneumonia. ELISA = enzyme-linked immunosorbent assay. (Modified from Baum SG. Mycoplasmal infections. In: Wyngaarden JB, Smith LH Jr, eds. *Cecil Textbook of Medicine*.17th ed. Philadelphia: Saunders; 1985:1506.)

M. fermentans, incognitus strain, was identified about four decades ago as an infectious agent in immunocompromised patients, in whom it causes overwhelming multisystem involvement.

PATHOBIOLOGY

Because of the low fatality of most *Mycoplasma* infections, there is little human pathologic material. Inoculation onto animal tracheal organ cultures is followed by ciliary damage and desquamation of surface epithelium. This latter effect is probably responsible for the hacking cough in *Mycoplasma* respiratory infection.

Several characteristics of *M. pneumoniae* probably play a direct role in the respiratory pathogenicity of this organism. The first is the affinity of *M. pneumoniae* for respiratory epithelial cells. Attachment appears to be between a terminal organelle at one end of the filamentous organism and a sialated glycoprotein (I-FI) on the surface of both respiratory epithelium and erythrocytes that acts as a receptor. *M. pneumoniae* attaches to ciliated epithelial cells at the base of cilia and appears to produce most of its physiologic and cytolytic changes while remaining extracellular. Hydrogen peroxide produced by *M. pneumoniae* (the only human mycoplasma to do so) may be responsible for some in vivo cell damage, as it is for the hemolysis seen when the organisms are grown on blood agar plates. *Mycoplasma* infection activates T and B cells and induces many pro-inflammatory and anti-inflammatory cytokines and chemokines that may play a role in inflammation-related cell destruction. Strain-specific elaboration of biofilms probably plays a role in protecting the organism from host immune cells and may decrease antimicrobial penetration.

In the course of *M. pneumoniae* infection, some patients produce cold agglutinins. These oligoclonal M-type immunoglobulins (IgM) cross-react with I antigens, one of the blood group antigens common to almost all mature human erythrocytes, and high titers may cause hemolysis (presumably as a result of complement-activated, Coombs-positive erythrocyte destruction) and lead to some of the complications described in the Clinical Manifestations section. Like other IgM antibodies, the *Mycoplasma*-induced cold agglutinins (Chapter 160) develop early in the disease (7 to 10 days) and are often present by the time the patient seeks medical attention. The titer of these agglutinins peaks at 2 to 3 weeks, and they persist for 2 to 3 months (Fig. 317-1).

Several theories about the factors triggering the formation of cold agglutinins in *Mycoplasma* pneumonia have been proposed. One is that the organism alters the I antigen such that it becomes antigenic to the patient. The hydrogen peroxide elaborated by *M. pneumoniae* could be responsible for this alteration. One study indicated that the I antigen in a sialated state may serve as a receptor for *M. pneumoniae* and that the cold agglutinins are directed at the modified receptor. Other studies indicate that the cold agglutinins are directed at mycoplasmal substructures themselves and merely cross-react with the I antigen (altered or native) on red cells. Given their apparent target, these antibodies could either contribute to cytolysis and exacerbate infection or interfere with cell-to-cell spread by blocking or disrupting the cell receptor for the mycoplasma. High titers of cold agglutinins have also been associated with hemolysis, presumably as a result of the activation of complement-mediated erythrocyte destruction (Chapter 160). Although clinically significant hemolysis is uncommon, subclinical levels of red cell destruction are common.

Sickle cell disease, sickle-related hemoglobinopathies, and hypogammaglobulinemia predispose to increased severity and mortality. Therefore, some of the available pathologic data may be influenced by the pathophysiologic mechanisms of these underlying conditions. Deaths have occurred in patients with diffuse pneumonia, acute respiratory distress syndrome, thromboembolism, and disseminated intravascular coagulation.

In nonfatal cases in which lung biopsy was performed, the inflammatory process involved primarily the trachea, bronchioles, and peribronchial tissue. The lumen of the respiratory tree was filled with a purulent exudate rich in polymorphonuclear leukocytes. The lining of the bronchial and bronchiolar walls showed metaplastic cells, and the walls themselves were infiltrated with monocytic elements, especially plasma cells. There was widening of the peribronchial septa and hyperplasia of type II pneumocytes.

CLINICAL MANIFESTATIONS

In view of the very high incidence of *Mycoplasma* respiratory infection when it is studied epidemiologically in large populations, versus the rarity of individual sporadic diagnoses, it appears that a specific, laboratory-confirmed diagnosis of this entity is seldom accomplished in routine clinical practice. There are probably four reasons for this. The first is that *Mycoplasma* pneumonia is usually self-limited and rarely fatal. This fact dampens the zeal to establish the cause of infection. Second, mycoplasmas are relatively fastidious and slow growing; therefore, culture results, if obtained at all, often return after the patient has recovered. Third, *M. pneumoniae* responds to the empirical antimicrobial therapy suggested for community-acquired pneumonia. Finally, knowledge of the epidemiology and clinical manifestations of infection is deficient, so the diagnosis is often not considered outside the classic age group.

Respiratory Infection

The majority of *M. pneumoniae* infections involve only the upper respiratory tract. After a 2- to 3-week incubation period, the disease has an insidious onset consisting of fever, malaise, headache, and cough (see Fig. 317-1). Cough is the clinical hallmark of *M. pneumoniae* infection. The frequency and severity of the cough increase during the next 1 to 2 days, and it may become debilitating. The gradual onset of symptoms is in contradistinction to the often fulminant manifestation of respiratory infection caused by influenza virus or adenovirus. Unfortunately, no clinical signs or symptoms reliably differentiate *M. pneumoniae* infections from other community-acquired pneumonias.[1]

In 5 to 10% of patients, depending somewhat on age, the infection progresses to tracheobronchitis or pneumonia. In these cases, the original manifestations persist, and the cough becomes more severe. It is usually relatively nonproductive but may yield white or occasionally blood-flecked sputum. Gram staining of this sputum reveals inflammatory cells but no predominant bacterial species (part of the definition of atypical pneumonia). With continued cough, parasternal chest soreness may develop as a result of muscle strain, but true pleuritic pain is unusual. Fever is usually at the level of 101° to 102° F and may be associated with chilly sensations. As opposed to pneumonia caused by *Streptococcus pneumoniae* (Chapter 289), that caused by *M. pneumoniae* rarely produces true shaking chills. In comparison to influenza, which can also be manifested as an atypical pneumonia syndrome, myalgias and gastrointestinal complaints of nausea and vomiting are unusual. Diarrhea, sometimes a concomitant of adenoviral or *Legionella* pneumonia, is uncommon in *Mycoplasma* infection.

On physical examination, the patient does not appear to be terribly ill. In fact, this disease is the paradigm of the term *walking pneumonia*. The pharynx may be injected and erythematous, usually without the marked cervical adenopathy seen with group A streptococcal pharyngitis. *M. pneumoniae* is not a common cause of isolated pharyngitis in the pediatric or adult population. Much has been made of the finding of bullous myringitis in this disease. Although this abnormality was present in about 20% of volunteers with experimentally induced *M. pneumoniae* infection, true bullous myringitis in naturally occurring *Mycoplasma* disease is rare. In a study involving children, otitis was rarely associated with isolation of *Mycoplasma* and, on the contrary, was often associated with bacterial and viral upper respiratory tract pathogens. Thus, the absence of myringitis, bullous or otherwise, should not dissuade one from a diagnosis of *Mycoplasma* pneumonia.

Examination of the chest in patients with *Mycoplasma* pneumonia is often unrevealing, even in those with severe, productive cough. There may be no auscultative or percussive findings, or only minimal rales (crackles) may be present. The disparity between physical findings and radiographic evidence of pneumonia in this condition may be the greatest of any of the atypical pneumonia syndromes (Fig. 317-2). Although wheezing can occur in this disease, in one study of asthmatic patients, the presence of wheezing had a negative correlation with isolation of *M. pneumoniae* compared with isolation of viral respiratory pathogens such as respiratory syncytial virus (Chapter 362). *M. pneumoniae* does not seem to be a common pathogen in patients with preexisting chronic obstructive lung disease, either. Bacterial superinfection after *M. pneumoniae* respiratory infection is rare. The radiographic finding of interstitial or patchy alveolar pneumonia does not allow differentiation from any of the other causes of the atypical pneumonia syndrome.

Pleural effusion (usually small) occurs in 5 to 20% of patients with *M. pneumoniae* pneumonia. This low incidence of pleural inflammation is consistent with the rarity of pleuritic pain. If effusion is present, thoracentesis reveals serous fluid that is exudative, with minimal inflammatory reaction.

FIGURE 317-2. Chest radiograph showing moderate interstitial pneumonia due to *Mycoplasma pneumoniae* infection in a patient with a paucity of findings on chest auscultation.

FIGURE 317-3. Stevens-Johnson syndrome in a child with *Mycoplasma* pneumonia. (From Baum SG. *Mycoplasma pneumoniae* and atypical pneumonia. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 6th ed. Philadelphia: Churchill Livingstone; 2005:2274.)

The cell differential count in the fluid is variable, and bloody effusions are rare. It is unusual to isolate *M. pneumoniae* from effusions when they do occur, but several reports of such isolation exist. Although the pneumonia is generally mild and self-limited, fulminant, severe, and lethal cases have been reported in normal young adults and may be underdiagnosed.

Extrapulmonary Involvement

Abnormalities in almost every organ system have been described as examples of the extrapulmonary manifestations of *M. pneumoniae* infection. The frequency of these extrapulmonary manifestations varies greatly from one report to another, and they are much less common when viewed as part of a prospective epidemiologic study rather than as the sum of isolated case reports. The conclusion appears to be that the high prevalence of *Mycoplasma* infection predisposes to the reporting of many concurrent but perhaps unrelated events as though they were part of the mycoplasmal disease. Several clinical syndromes have been reported with sufficient frequency to provide some support for a causal relationship.

Dermatologic Involvement

A wide variety of transient dermatologic conditions have been reported in conjunction with *Mycoplasma* pneumonia, including macular, morbilliform, and papulovesicular eruptions as well as erythema nodosum and urticaria. Again, the variety and high incidence of these rashes in the absence of *Mycoplasma* infection make it difficult to define the relationships, if any, among these occurrences. Furthermore, the role of concurrent antibiotic therapy in the development of exanthems during *M. pneumoniae* infection is unknown. One skin condition that occurs often enough in concert with *M. pneumoniae* infection to provide some basis for relatedness is erythema multiforme majus, or Stevens-Johnson syndrome (Fig. 317-3). This rash has been reported in up to 7% of patients with *Mycoplasma* pneumonia and consists of erythematous vesicles, plaques, and bullae involving the skin, with particular localization at mucocutaneous junctions. The conjunctivae as well as

organs of the gastrointestinal and genitourinary tracts and the joints may also be involved. Stevens-Johnson syndrome has been associated with isolated cases of many other infections, including some that can be manifested as atypical pneumonia syndrome, such as legionnaires' pneumonia, adenovirus respiratory-conjunctivitis syndrome, and influenza B infection. However, the association with *M. pneumoniae* infection is by far the most common. Stevens-Johnson syndrome tends to occur in younger patients with *Mycoplasma* pneumonia and has a definite male preponderance (2 : 1 to 4 : 1).

The pathogenesis of Stevens-Johnson syndrome is unclear. It has long been supposed that immunity plays a major role, but several reports have noted the culture of *M. pneumoniae* from the lesions. The relationship to the level of cold agglutinins in this disease is variable. It has been suggested that the development of Stevens-Johnson syndrome may be the result of augmented sensitivity to antibiotics in the presence of *M. pneumoniae* infection, but erythema multiforme majus develops in some patients in the absence of previous or concurrent antibiotic therapy. Most patients clear the lesions in 1 to 2 weeks without scarring unless impetiginization supervenes.

A debilitating form of *M. pneumoniae*–associated mucositis without skin involvement has been described as an atypical Stevens-Johnson syndrome, but it is now increasingly recognized as a separate entity, termed *M. pneumoniae*–associated mucositis.[2]

Raynaud's syndrome (Chapter 80), a transient, reversible vasospasm of the digits that develops on exposure to cold, is not technically a dermatologic syndrome; however, it is manifested in the skin. This phenomenon occurs in many people, usually women, without any association with infection. It has been reported in patients with acute *Mycoplasma* pneumonia, regardless of whether they exhibited the syndrome before infection. Although the pathophysiologic mechanism of this condition in *M. pneumoniae* infection is unclear, it may be related to the in vivo action of cold agglutinins (see Diagnosis, later). Other vascular complications reported in *M. pneumoniae* infection include internal carotid artery occlusion and cerebral infarction.

Cardiac Complications

Cardiac abnormalities are among the most commonly reported extrapulmonary manifestations of *M. pneumoniae* infection. Signs and symptoms suggesting involvement of the heart are arrhythmia, congestive failure, chest pain, and electrocardiographic abnormalities, particularly conduction defects. Although cardiac abnormalities have been reported in as many as 10% of cases of *M. pneumoniae* infection, other reports indicate a much lower prevalence. Cardiac complications are more common with increasing age. They prolong the illness but rarely lead to death. The mechanism of heart damage is unknown, but *M. pneumoniae* has been isolated from the pericardial fluid of at least one patient.

Neurologic Complications

Neurologic complications are said to occur in about 0.1% of *Mycoplasma* infections, but proof of the cause of central nervous system involvement is somewhat tenuous. Central nervous system involvement is most common in children, with encephalitis the most common and perhaps the most devastating.[3] Aseptic meningitis and meningoencephalitis, transverse myelitis, brain stem dysfunction, Guillain-Barré syndrome, cerebral ataxia, and peripheral neuropathy have all been reported. Cerebrospinal fluid findings in these cases are variable, but the cellular response is usually minimal, with slightly elevated protein level and normal to slightly depressed glucose concentration. Most often, the diagnosis of *Mycoplasma*-related central nervous system involvement is based on the exclusion of other causes, the presence of an antecedent or intercurrent respiratory illness, and a rise in antibody titer to *M. pneumoniae* in serum. On occasion, *Mycoplasma*-specific antibodies have been demonstrated in cerebrospinal fluid, but these titers have paralleled serum antibody titers. Neurologic complications are usually reversible; however, mortality in patients with central nervous system involvement is higher than in those without such involvement. Although *M. pneumoniae* has been isolated from a few of these patients, polymerase chain reaction (PCR) failed to detect *M. pneumoniae* DNA in the cerebrospinal fluid of 11 patients deemed to have *M. pneumoniae*–related central nervous system disease on serologic grounds. Therefore, immune mechanisms of neural damage have been suggested. Some mycoplasmas elaborate a neurotoxin, but this has not been described for *M. pneumoniae.*

Musculoskeletal, Renal, and Hematopoietic Complications

Polyarthralgias are common in *Mycoplasma* pneumonia, but monarticular or migratory arthritis is rare. Immune mechanisms have been postulated, but there have been a few reports of the isolation of *M. pneumoniae* from joint fluid. Several of the cases of frank arthritis were reported in patients with hypogammaglobulinemia. Nonhuman mycoplasmas probably cause arthropathy in several animal species, and *M. hominis* has been associated with human arthritis. Rhabdomyolysis has also been increasingly reported and may be associated with very high muscle enzyme, interleukin-18, and tumor necrosis factor-α levels.[4]

Renal complications associated with immune complex deposition and high-titer cold agglutinins have been reported. There are several case reports of *M. pneumoniae*–associated aplastic anemia.

Conditions Leading to Increased Susceptibility

Several reports have emphasized the unusual severity of *M. pneumoniae* infection in patients with sickle cell disease or sickle-related hemoglobinopathies (Chapter 163). Large pleural effusions and marked respiratory distress may develop in these patients. Functional asplenia and its attendant opsonization deficiencies may contribute to overwhelming infection with *M. pneumoniae*, as they do with *S. pneumoniae* infection. Some patients with sickle cell disease and *M. pneumoniae* infection in whom extremely high cold agglutinin titers develop may experience digital necrosis, as they do with *S. pneumoniae* infection. A hypothesis about the pathogenesis is provided in the discussion on cold agglutinins in the Diagnosis section. Children with immunodeficiency syndromes have been the subjects of case reports of *M. pneumoniae* infection. Because *Mycoplasma* infections are so common in normal children, the contribution of immunodeficiency is unclear. *M. pneumoniae* is not a very common opportunistic agent in patients with acquired immunodeficiency syndrome (AIDS), but *M. fermentans* (*incognitus* strain) has been identified in these patients. Unusually severe but nonlethal *M. pneumoniae* infection has also been reported in children with Down syndrome.

DIAGNOSIS

The diagnosis of *Mycoplasma* pneumonia is made primarily on clinical grounds. The organism can be grown in cell-free media, but most hospital diagnostic laboratories are not prepared to culture mycoplasmas. Because of this, there is considerable interest in developing rapid diagnostic tests with high sensitivity and specificity. These assays fall into three categories: detection of *M. pneumoniae*–specific immunoglobulins in serum and detection of *M. pneumoniae*–specific antigens or nucleotide sequences directly in clinical specimens. Diagnostically, the most useful *M. pneumoniae*–specific immunoglobulin to detect is IgM because it is most likely to indicate recent infection. Enzyme-linked immunoassays have been developed to detect IgM and IgG directed against *M. pneumoniae*. When used in patients with positive assays for complement-fixing antibodies, the enzyme immunoassay had a specificity of more than 99% and a sensitivity of 98%. Specificity was retained but sensitivity dropped to only 46% when IgG alone was the target. Variations on this theme detect IgM antibodies directed at specific *M. pneumoniae* antigens. The tests are simple to perform and have high sensitivity and specificity, but because all these tests are designed to detect IgM antibody, results may be negative early in the course of infection (<7 to 10 days). Therefore, they do not provide the desired confirmation early enough to guide initial therapy.

Detection of *M. pneumoniae* antigens directly in sputum specimens has been accomplished with the use of an antigen capture, indirect enzyme immunoassay. The specificity of the assay was high, the reagents reacting only with *M. pneumoniae* and *M. genitalium.* Sensitivity was also relatively high (91%) when the assay was used on sputum and nasopharyngeal aspirates from patients who were shown by culture or serologically to have *M. pneumoniae* infection.

The high sensitivity and specificity of real-time PCR performed on sputum, nasopharyngeal aspirate, or throat swab material suggest that this test could serve as a specific and rapid diagnostic method. Detection of *M. pneumoniae*–specific nucleotide sequences directly in clinical material has been accomplished with the use of tests developed locally or by large reference laboratories. These tests, which can be completed in a few hours, detect either *M. pneumoniae* DNA (PCR) or ribosomal RNA (reverse transcriptase nucleic acid amplification).[5] Compared with PCR as the "gold standard" of proven infection, very few of the available antibody assays have acceptable sensitivity and specificity. Although the nucleic acid probe assays show excellent specificity, they fail to detect infection in some antibody-positive patients, and their sensitivity varies considerably, depending on the source of the specimen tested: highest for sputum, but lower for nasopharyngeal aspirate or throat swab material. This latter point is important in evaluating comparative studies, many of which use different specimen sources for their assays.[6]

In the course of *M. pneumoniae* infection, several classes of antibody are produced. Some of these fulfill the desired role of antibody production—neutralization of the agent—and others appear to be autoantibodies. The latter include agglutinins to lung, brain, cardiolipins, and smooth muscle. The best studied of these autoagglutinins are the cold isohemagglutinins. These agglutinins were found to be capable of clumping erythrocytes at 4° C. Agglutination was reversible by warming the serum-erythrocyte mixture to 37° C and, unlike hemagglutination by myxoviruses and paramyxoviruses, was repeatable with the same sample, indicating that receptor-destroying enzyme (neuraminidase) plays no role in the dissociation at 37° C.

The cold agglutinin phenomenon, when positive, occurs early, but it is neither sensitive nor specific. Other diseases that can give rise to cold agglutinins are mononucleosis caused by Epstein-Barr virus (anti-i), cytomegalovirus infection (anti-I), some other viral diseases, and lymphoma. A titer of 1 : 32 or greater is highly suggestive of infection with *M. pneumoniae.*

When this test is performed in a laboratory, the results will not be available for at least a day and in some cases a week, but a rapid version can be done at the bedside. In this test, 1 mL of the patient's blood is drawn into a tube containing anticoagulant. The type of tube used to collect specimens for prothrombin determination is preferred. Before cooling, examination shows a smooth coating of the tube by red cells. The blood is cooled to 4° C by placing it on liquid ice or in a standard refrigerator. After several minutes, the tube is examined for the presence of macroscopic erythrocyte agglutination. The tube is then rewarmed to 37° C in an incubator or by exposure to body heat and reexamined. The agglutination should dissociate at 37° C, and the appearance should be as it was before cooling. This temperature-associated agglutination and dissociation can be repeated many times on the same sample. A positive result in the bedside test correlates with a laboratory titer of 1 : 64 or greater and is therefore less sensitive than the laboratory test. It can be accomplished in minutes, however, and if positive, it is highly suggestive of *Mycoplasma*-related cold agglutination. The presence of cold agglutinins can also artifactually give rise to macrocytic indices secondary to in vitro clumping of erythrocytes, as measured by the Coulter counter method. In this case, the red cell distribution width would be high, indicative of heterogeneity in measured red cell size.

Finally, PCR should become the gold standard for diagnosis because of its high sensitivity and specificity and the rapidity with which results can be obtained. A multiplex assay kit for this test has been approved for rapid diagnosis of *M. pneumoniae* infection. However, the test may not be available in many medical centers. Widespread availability of real-time definitive diagnostic assays will enhance the ability to apply organism-specific treatment.[7]

TREATMENT

Rx

Despite the number and variety of tests for the diagnosis of *M. pneumoniae* infection, most cases are encountered in the ambulatory setting, and the institution of antimicrobial therapy is empirical and based on clinical recognition of the syndrome.

Antimicrobial therapy is not necessary for mycoplasmal upper respiratory tract infection, and the mycoplasmal cause of this syndrome most often goes undiagnosed. The pneumonia caused by *Mycoplasma* is self-limited and not life-threatening in most cases. However, treatment with effective antimicrobials may shorten the duration of illness[8] and, by reducing cough and the number of organisms per unit volume of sputum, may reduce the spread of infection to contacts. Because *Mycoplasma* pneumonia is sporadic, most of the studies of antimicrobial efficacy are directed not at this single agent but rather at the treatment of community-acquired pneumonia, of which *Mycoplasma* makes up a variable percentage. Retrospective analysis of specific causes then allows microbe-specific efficacy.

As would be predicted by the lack of a cell wall, all mycoplasmas, including *M. pneumoniae*, are unaffected by β-lactam antibiotics such as the penicillins and cephalosporins. Aminoglycosides are effective in vitro but have not been evaluated for efficacy in vivo. The mainstays of treatment of *M. pneumoniae* respiratory tract infection are macrolides and tetracyclines. Use of either drug class significantly shortens the duration of illness. The radiographic findings may take a week or longer to resolve, even with appropriate therapy (see Fig. 317-1), and organisms may continue to be cultured from sputum for several weeks after a complete course of clinically effective treatment. This may be a result of the fact that although *M. pneumoniae* causes respiratory disease as an extracellular parasite, it has the capacity to reside intracellularly as well, thus making it difficult to eradicate the organism in vivo as opposed to cell cultures. The effect of therapy on extrapulmonary manifestations is unknown. *M. hominis* is not sensitive to erythromycin.

Although the tetracyclines are very active against *M. pneumoniae*, their use is precluded in young children because of adverse effects on developing teeth and bones. Erythromycin is poorly tolerated by many people because of its gastrointestinal side effects, including nausea, vomiting, abdominal pain, and diarrhea. Erythromycin also raises theophylline levels, a consideration in the few asthmatic patients who may still be taking this drug.

Because of the adverse effects of erythromycin and tetracycline, there is considerable interest in the antimycoplasmal efficacy of other agents. Doxycycline is somewhat better tolerated than tetracycline and can be administered in two daily doses rather than three. In vitro, doxycycline is as effective as tetracycline against *M. pneumoniae*, but it is contraindicated in young children.

Several other classes of antimicrobials have significant in vitro and in vivo activity against *M. pneumoniae* and other *Mycoplasma* species, including the fluoroquinolones, broad-spectrum macrolides (azithromycin, clarithromycin), and members of the macrolide-lincomycin-streptogramin-ketolide (MLSK) class of antimicrobials. There are no good data on the optimal duration of therapy needed to minimize carriage and relapse with these agents.

The macrolides are more active in vitro than the tetracyclines are. Fluoroquinolones have adequate activity for the treatment of these infections. They are more active than the tetracyclines but are at least 100 times less active than the macrolides. The streptogramins are also less active than the macrolides but more active than the tetracyclines. There is a significant cost differential in the use of these drugs. The newer macrolides and quinolones are 50 to 60 times more expensive than the tetracyclines and 6 to 10 times more costly than erythromycin.

During the past decade, there have been increasing reports, first from Asia and later spreading to other areas including the United States,[9] describing decreasing susceptibility of *M. pneumoniae* isolates to the macrolides. By 2012, one study from China reported 95% macrolide resistance. Taking all this into account, recommended therapy includes doxycycline 100 mg every 12 hours in older children and adults,[10] or azithromycin 500 mg on day 1 and then 250 mg every 24 hours. Young children should be given erythromycin (10 mg/kg every 6 hours) or an extended-spectrum macrolide (10 to 12 mg/kg on day 1, followed by 5 mg/kg/day). The usual duration of therapy is 14 days; shorter courses may lead to relapse. The addition of corticosteroids (e.g., prednisolone 1 mg/kg twice daily for three days then tapered over one week) has been reported to shorten the duration of symptoms in patients with severe or refractory infections, especially when the serum lactate dehydrogenase level is above about 300 IU/L.[11] *M. hominis* is not sensitive to macrolides, but it is sensitive to the other antimicrobials recommended for *M. pneumoniae* infection. Azithromycin (1-g single dose) achieves a significantly higher cure rate for *Mycoplasma genitalium*–associated urethritis than does multidose doxycycline.

PREVENTION

Outbreaks of *M. pneumoniae* respiratory infection among military recruits led to interest in producing a vaccine to protect against this organism. The resulting vaccines induced specific antibody responses, but protection was limited to no more than 50% of vaccine recipients. Live vaccines using attenuated wild-type and temperature-sensitive mutant mycoplasmas have proved no more effective. In one study, volunteers who received vaccine but did not mount an antibody response had more severe disease when rechallenged with wild-type *Mycoplasma* than did nonvaccinated personnel.

Although *M. pneumoniae* is perhaps the leading cause of atypical pneumonia syndrome in closed populations, the enthusiasm for developing a vaccine for this disease has waned. New technology involving DNA expression library immunization has proved successful in animal studies with nonhuman mycoplasmas, and these methods may breathe new life into *M. pneumoniae* vaccine development.

Secondary Prevention

Prophylactic antibiotic use in family members exposed to *Mycoplasma* decreases clinical disease in these patients, but seroconversion is not prevented. One study showed that azithromycin prophylaxis, given as a 500-mg loading dose and 250 mg/day on days 2 through 5, significantly reduced the secondary attack rate of *M. pneumoniae* infection in a long-term care facility.

REVIEW QUESTIONS

1. *Mycoplasma pneumoniae* is one of the most common causes of the atypical pneumonia syndrome. Another organism that shares many of the characteristics of organisms causing this syndrome is

A. *Streptococcus pneumoniae*
B. *Chlamydophila pneumoniae*
C. *Staphylococcus aureus*
D. *Klebsiella pneumoniae*
E. *Acinetobacter baumannii*

Answer: B *Chlamydophila* does not show up on Gram stain or grow in common bacterial culture, two of the common characteristics of these "atypical" organisms. (See Definition section.)

2. Which of the following classes of antimicrobials would *not* be effective in treating pneumonia in a young adult caused by *M. pneumoniae*?

A. Fluoroquinolones
B. β-Lactamase–resistant penicillins
C. Extended-spectrum macrolides
D. Tetracyclines
E. MLSK class

Answer: B Mycoplasmas do not have cell walls, and the penicillins work by inhibiting cell wall synthesis. The other drugs all are effective in treating *M. pneumoniae.* (See section on treatment.)

3. Which of the following is true of cold agglutinins that occur in about 50 to 70% of patients with *M. pneumoniae* pneumonias?

A. They are IgG antibodies directed against the nucleic acid of the organism.
B. They are secreted by the organism as part of the infectious process.
C. They help to neutralize the organism and thereby protect the host.
D. They are IgM class antibodies directed at antigens on the host erythrocyte.
E. When present, they are pathognomonic of *Mycoplasma* infection.

Answer: D Mycoplasma-induced cold agglutinins are IgM antibodies directed at the I antigens of red cell membranes. They are detected by a positive direct antiglobulin test (DAT) result, also known as the direct Coombs' test. Although clinically significant hemolysis is rare, subclinical positivity for DAT is common in *Mycoplasma* pneumonia. (See Pathobiology section.)

4. Which of the following is true about *Mycoplasma hominis*?

A. Causes puerperal sepsis
B. Is sensitive to macrolides, as are the other mycoplasmas
C. Is a common cause of infectious carditis
D. Is the most common cause of nonbacterial urinary tract infection
E. Has, as its primary reservoir in nature, the feral cat

Answer: A *M. hominis* is a common genitourinary and oral commensal, but it has also been documented as a cause of endometritis and postpartum fever. (See section on epidemiology.)

5. Which of the following chest radiographic patterns would be most characteristic of *M. pneumoniae* pneumonia?

A. Pneumothorax
B. Dense, multilobar alveolar infiltrates
C. Dense unilobar infiltrate with ipsilateral pleural effusion
D. No infiltrate seen
E. Multifocal interstitial pattern

Answer: E The disparity between the paucity of physical findings and the radiographic appearance of pneumonia in this condition can be striking (see Fig. 317-2).

318 DISEASES CAUSED BY CHLAMYDIAE

WILLIAM M. GEISLER

DEFINITION

Chlamydiae are obligate intracellular bacteria that cause a variety of human and animal diseases and much morbidity. Chlamydiae were originally classified taxonomically into one genus, *Chlamydia*. On the basis of sequence analysis of 16S rRNA genes, it had been proposed that chlamydial taxonomy be revised to contain two genera: *Chlamydia* and *Chlamydophila.* However, on the basis of additional data on chlamydia genome sequences and meetings within the *Chlamydia* scientific community, it has been agreed that the family Chlamydiaceae will contain a single genus, *Chlamydia*. Within the family are now nine recognized species: *C. trachomatis, C. pneumoniae, C. psittaci, C. pecorum, C. muridarum, C. felis, C. abortus, C. suis,* and *C. caviae*. *C. trachomatis* is classified into a trachoma biovar and lymphogranuloma venereum (LGV) biovar. This chapter is limited to human diseases caused by chlamydiae.

The Pathogen

Chlamydiae have a gram-negative cell wall structure consisting of an outer membrane that contains lipopolysaccharide and an inner cytoplasmic membrane. The outer membrane contains a single 40-kD major outer membrane protein, OmpA (also known as MOMP), and two cysteine-rich minor outer membrane–associated proteins (OmcA and OmcB); through intermolecular and intramolecular disulfide bonding, these proteins form a complex that provides structural rigidity.

Chlamydiae grow only within intracellular membrane-bound vacuoles, termed inclusions,[1] that seclude the organism from extracellular and cytoplasmic environments. They share a distinct biphasic developmental cycle (Fig. 318-1) that includes an extracellular, metabolically inactive, infectious form (an elementary body) and an intracellular replicative form (a reticulate body). In vitro studies have shown that chlamydiae may enter a persistent state under certain conditions (penicillin treatment,[2] challenge with certain cytokines, restriction of select nutrients) in which they have reduced metabolic activity and may be more refractory to antibiotic treatment; whether this occurs in vivo is unclear. Chlamydiae are unable to synthesize adenosine triphosphate and therefore depend on the host cell for nutrients to meet their energy requirements.

Additional knowledge of chlamydial cell biology emerged after several chlamydial genomes were sequenced. Polymorphic outer membrane proteins were identified, but their role in pathogenesis is unclear. Chlamydiae were also found to express proteins that localize to the cytoplasmic surface of the inclusion membrane (e.g., Inc A). *C. trachomatis* was demonstrated to have type III secretion genes, which may encode a secretion apparatus providing a means for protein transport. Chlamydiae have small genomes (*C. trachomatis* contains 894 protein-coding genes, and *C. pneumoniae* contains 1052 genes). Most strains of *C. trachomatis* and some strains of *C. psittaci* contain a 7-kilobase cryptic plasmid.

PATHOBIOLOGY

Macrophages are the principal host cells for *C. psittaci* and *C. trachomatis* LGV biovar, whereas the principal host cells for *C. trachomatis* trachoma biovar and *C. pneumoniae* strains are columnar epithelial cells at mucosal sites. Host cell tropism correlates with the type of inflammation elicited by chlamydiae. The LGV biovar and *C. psittaci* produce granulomatous inflammation, characteristic of delayed hypersensitivity reactions. The trachoma biovar produces neutrophilic exudate during acute infection and submucosal mononuclear infiltration with lymphoid follicle formation during later stages of infection.

Chlamydiae elicit both humoral and cellular immune responses. Infection can persist or recur even after an adaptive immune response develops, suggesting that the organism has evolved strategies for immune evasion. Persistent or recurrent infections can elicit inflammatory cellular immune responses that cause tissue injury.

CHLAMYDIAL DISEASES

Table 318-1 summarizes the diseases caused by chlamydiae in humans and the associated clinical and laboratory characteristics.

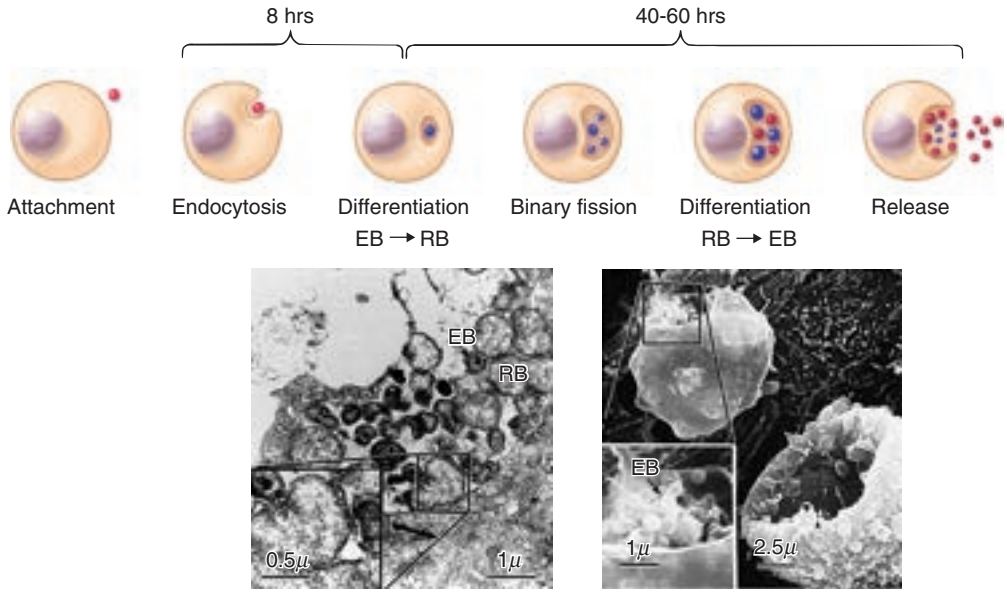

FIGURE 318-1. Developmental cycle of chlamydiae. The *top panel* shows the developmental cycle common to all chlamydiae. The *red circles* represent elementary bodies (EBs), and the *blue circles* represent reticulate bodies (RBs). Chlamydiae infect eukaryotic cells through multiple attachment mechanisms. After attachment, EBs enter the cell within a membrane-bound vacuole that remains unfused with lysosomes. EBs reorganize into RBs and asynchronously replicate 8 to 12 times, with a doubling time of 2 to 3 hours. At the conclusion of the growth cycle, RBs differentiate back to EBs, and each inclusion yields 100 to 1000 new infectious EBs. The *bottom left panel,* a transmission electron micrograph taken 40 hours after infection, shows the large RBs and the smaller EBs, which have a condensed nucleoid structure within their cytoplasm. The *bottom right panel,* a scanning electron micrograph taken 60 hours after infection, shows a membrane-bound vacuole containing many EBs exiting from an infected HeLa cell.

TABLE 318-1 MAJOR DISEASES CAUSED BY CHLAMYDIAE IN HUMANS AND ASSOCIATED CLINICAL AND LABORATORY FEATURES

SPECIES	SEROVAR	DISEASE	TRANSMISSION ROUTE	DIAGNOSIS	PREVENTION
C. trachomatis	A–C	Trachoma	Fomites, eye-seeking flies	Clinical criteria or culture/NAAT	SAFE strategy
	D–K	Urethritis, cervicitis, proctitis, epididymitis, PID	Sexual contact	NAAT	Abstinence or monogamy, education, condoms, partner treatment
	D–K	Inclusion conjunctivitis, infant pneumonia	Perinatal contact	Culture, DFA, NAAT, or serology (for pneumonia)	Prenatal chlamydia screening: treat infected mothers
	L1–L3	Lymphogranuloma venereum	Sexual contact	Serology or culture/NAAT plus OmpA typing	Abstinence or monogamy, education, condoms, partner treatment
C. pneumoniae	One	Upper respiratory infections, atypical pneumonia, asthma exacerbations	Respiratory droplet	Serology or culture/PCR	None
C. psittaci	Multiple	Psittacosis, atypical pneumonia, febrile illness	Aerosolized bird secretions, dust	Serology	Quarantine and chlortetracycline for imported birds, avoidance or precautions for at-risk subjects

DFA = direct fluorescent antibody test; NAAT = nucleic acid amplification test; PCR = polymerase chain reaction; PID = pelvic inflammatory disease; SAFE = World Health Organization's recommended strategy: acronym for surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement.

Chlamydia trachomatis

C. trachomatis infection is a common bacterial infection in humans and accounts for significant morbidity worldwide. *C. trachomatis* isolates have been differentiated into 18 major serovars (i.e., OmpA types) based on variations in OmpA that are identified on antigen cross-reactivity in the microimmunofluorescence test. The major diseases caused by *C. trachomatis* are trachoma, caused by serovars A, B, Ba, and C; sexually and perinatally transmitted diseases, caused by serovars D through K (and, rarely, serovars B and Ba); and sexually transmitted LGV, caused by serovars L1, L2, L2a, and L3. Sequencing of the *ompA* gene has led to the recognition of more OmpA variants, including L2b. Multilocus sequencing typing is a newer tool that has been used to further discriminate between *C. trachomatis* strains of the same OmpA genotype. Trachoma and LGV are endemic in developing areas of the world (although LGV outbreaks have also occurred in populations of men who have sex with men in developed countries), whereas sexually and perinatally transmitted non-LGV chlamydial infections occur worldwide.

TRACHOMA

EPIDEMIOLOGY

Trachoma is a chronic follicular conjunctivitis. The overall incidence is unknown, but it has been estimated by the World Health Organization (WHO) that 21.4 million people have active trachoma.[3] Trachoma is endemic in more than 50 countries and is especially common in poor areas of sub-Saharan Africa, where the disease prevalence in children may exceed 40%. According to the Trachoma Atlas provided by the International Coalition for Trachoma Control, there are an estimated 110 million people living in endemic areas and another 210 million living in suspected endemic areas. Trachoma is a major public health problem because scarring from trachoma causes blindness, affecting 7.2 million people by WHO estimates. Trachoma is the most common preventable cause of blindness worldwide. Active trachoma often occurs in the first few years of life. The inflammation from recurrent or persistent trachoma can lead to conjunctival scarring, which can ultimately cause corneal damage and blindness later in life. The *C. trachomatis* serovars that produce trachoma are spread by direct contact with fingers or fomites (e.g., washcloths, handkerchiefs) contaminated with eye discharge from an infected person or by eye-seeking flies. Because of this mode of transmission, trachoma often clusters in households. Risk factors for trachoma include poor facial hygiene, limited access to water, poor sanitation, and proximity to other infected persons or to a heavy density of eye-seeking flies.

CLINICAL MANIFESTATIONS

There are two stages of trachoma disease, and they can overlap. Initially, trachoma begins as an inflammatory follicular conjunctivitis (i.e., active trachoma). On eversion of the upper eyelid, white to pale yellow lymphoid follicles can be visualized on the superior tarsal conjunctival surface, and papillae may be noted between follicles. Minimal watery or mucoid ocular discharge may also be seen. In more severe active trachoma, the conjunctiva can be thickened and edematous. Subsequently, conjunctival inflammation can progress to cause scarring of the upper tarsal conjunctiva (the cicatricial stage of disease). Scarring deforms the eyelid and can lead to an inward turning of the eyelashes, which can result in corneal abrasion (trichiasis). Over time, trichiasis causes corneal edema, ulceration, vascularization (pannus), scarring, and opacification. The corneal damage leads to decreased vision or blindness, occurring mostly in young adults and middle-aged persons. Viral conjunctivitis (e.g., adenovirus) is manifested in a clinical fashion similar to active trachoma, but it is self-limited and usually resolves within a week. Trachoma can be complicated by superinfection with other bacterial pathogens (e.g., *Haemophilus influenzae*), which should be considered when purulent ocular discharge or significant inflammation of the bulbar conjunctiva is present.

DIAGNOSIS

Because the majority of trachoma cases occur in developing countries without access to laboratory testing or the necessary resources, trachoma is often diagnosed clinically on the basis of findings of active trachoma (follicles on the upper tarsal conjunctiva or pronounced inflammatory thickening of the tarsal conjunctiva) or cicatricial disease. When laboratories are available, detection of *C. trachomatis* provides definitive evidence of active trachoma and may identify infection in subjects with minimal clinical evidence of active trachoma. Isolation of the organism in cell culture is one means to detect *C. trachomatis*, but the test's sensitivity is less than 50% and the methods are labor-intensive. Nonculture tests have higher sensitivities in active trachoma. For instance, nucleic acid amplification tests (NAATs) are the most sensitive diagnostic tests, but they are not widely available in many trachoma-endemic areas. It is uncommon for adults with late scarring to have *C. trachomatis* detected by any of these assays.

TREATMENT

Rx

Active trachoma can be treated with a tetracycline eye ointment twice daily for 6 weeks or oral macrolide therapy. The latter is preferred in part because extraocular sites such as the nasopharynx may be infected in young children. Single-dose oral azithromycin (20 mg/kg; maximum of 1 g) is as effective as tetracycline ointment and is more advantageous in terms of compliance and side effect profile; tetracycline application can irritate the ocular surface.

Surgical intervention is the only effective management for trichiasis. Eyelid rotation surgery prevents the eyelashes from abrading the cornea, preventing blindness and other nonvisual symptoms. Trichiasis recurrence after surgery is a major concern, and recurrence rates are highly variable across studies. Other concerns include accessibility to surgery and the patient's acceptance.

PREVENTION

The WHO is committed to eliminating blinding trachoma by 2020 and recommends that all countries with endemic trachoma adopt the SAFE strategy: surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement. Mass treatment

of a community with single-dose oral azithromycin is safe and has dramatically reduced the prevalence of infection for up to 1 year after treatment, without an increase in antimicrobial resistance; it has also been shown to reduce mortality in children. Annual azithromycin treatment is recommended for trachoma-endemic areas. Reintroduction of trachoma after mass treatment has been demonstrated, which may be due in part to decreased herd immunity. Repeated mass treatment (every few months) provides herd protection to the entire community.

Mass antibiotic treatment as the sole intervention for eliminating trachoma is unlikely to be successful if other factors that facilitate transmission are not addressed. Face washing and good hygiene help reduce the risk of transmission through contact with fingers and flies. Although the promotion of facial cleanliness through educational campaigns may be one of the most important interventions, sustaining such behavioral changes can be challenging. Achieving better environmental conditions through measures that reduce household and community fly density and improve waste management and access to clean water can also limit transmission. Improvement in socioeconomic conditions in a community correlates with a decline in trachoma prevalence.

SEXUALLY AND PERINATALLY TRANSMITTED CHLAMYDIAL INFECTIONS

EPIDEMIOLOGY

Chlamydia is the most prevalent bacterial sexually transmitted infection in the United States. Currently, more than 1.4 million infections are reported to the Centers for Disease Control and Prevention (CDC) annually.[4] The number of reported cases is increasing each year; this may reflect increased chlamydia screening efforts rather than a true increase in infection burden, but this remains unclear. Taking into account underreporting and underscreening, it is estimated that more than 2.8 million new chlamydial infections occur annually in the United States. Higher chlamydia prevalence rates have been associated with younger age (sexually active adolescents and young adults), select minority ethnic groups (especially African Americans), and new or multiple sexual partners.[5] Chlamydia prevalence is higher in women than in men; it is unclear whether this is due to higher screening rates in women or whether women may be more susceptible to infection acquisition or persistence. Chlamydia prevalence is highest in the southeastern United States. The estimated total cost attributable to chlamydial disease in the United States exceeds $2.4 billion annually. From a global perspective, WHO estimated from 2005 data that there were approximately 98 million adults with chlamydia. In addition to the adverse effects on the reproductive health of women, chlamydia has a substantial impact on perinatal outcomes and facilitates the transmission of human immunodeficiency virus (HIV).

CLINICAL MANIFESTATIONS

Urethritis

C. trachomatis is the most common cause of nongonococcal urethritis in men,[6] being responsible for 20 to 55% of cases. Although the majority of men with chlamydial urethritis are asymptomatic, studies in high-prevalence venues (e.g., sexually transmitted disease clinics) have reported that 40 to 60% of men with chlamydial urethritis are symptomatic. The most frequent symptoms are urethral discomfort (itching or pain) with urination and urethral discharge. On examination, a mild to moderate amount of clear or cloudy/mucoid (rarely purulent) urethral discharge may be visualized (Fig. 318-2A). Urethral discharge sometimes becomes apparent only after stripping the urethra from the base of the penis to the glans; this should be considered in men reporting urethral symptoms but without urethral discharge on initial inspection. Gram stain from a urethral swab specimen demonstrates

FIGURE 318-2. Clinical manifestations of genital *Chlamydia trachomatis* infection. A, Cloudy urethral discharge of urethritis. **B,** Urethral specimen Gram stain revealing nongonococcal urethritis findings: five or more polymorphonuclear cells per oil field (1000×) and the absence of intracellular gram-negative diplococci. **C,** Purulent endocervical discharge of mucopurulent cervicitis. (**A** courtesy James Sizemore, MD. **B** and **C** from *Practitioner's Handbook for the Management of Sexually Transmitted Disease*. http://depts.washington.edu/handbook. Accessed March 18, 2015.)

five or more polymorphonuclear leukocytes (PMNs) per oil field (1000×) in the majority of chlamydial infections (Fig. 318-2B). Chlamydial organisms cannot be visualized on Gram stain. Up to 20% of men with chlamydial urethritis have fewer than five PMNs per oil field on urethral Gram stain, reflecting the fact that minimal inflammation may be elicited in some cases of chlamydial urethritis. Urethral inflammation can also be detected by a positive urinary leukocyte esterase test result on unspun first-void urine.

C. trachomatis urethritis also occurs in women, who may be asymptomatic or present with an acute urethral syndrome characterized by dysuria, urinary frequency, and pyuria. This acute urethral syndrome mimics a urinary tract infection, and chlamydia should be suspected in women with pyuria but negative urine nitrite or negative urine culture, especially in sexually active adolescents and young adults; many urinary tract infection treatments are not effective against chlamydia. Mild urethral discharge may be seen. Pelvic examination should be performed in women with suspected chlamydia urethritis to search for other clinical findings of chlamydia (e.g., cervicitis).

Epididymitis

Chlamydia can spread from the urethra to the epididymis, causing epididymitis in up to 1 percent of infected men. Symptoms include testicular pain and scrotal erythema and swelling that are typically unilateral. On examination, there is palpable swelling and tenderness of the epididymis; accompanying findings may include testicular tenderness, scrotal erythema and swelling, urethral discharge, or hydrocele. In men younger than 35 years, *C. trachomatis* is the principal cause of epididymitis, whereas in men older than 35 years, complicated urinary tract infection with uropathogens is a more common cause, especially in those with prostate disorders. Up to 15% of epididymitis cases are complicated by chronic pain that is usually idiopathic and often unresponsive to antibiotics. Other complications include decreased fertility and, rarely, testicular abscess.

Cervicitis

C. trachomatis is the most common cause of cervicitis, being responsible for up to 50% of cases. The majority of women with endocervical chlamydial infection are asymptomatic. Symptoms, when present, are often mild and nonspecific for chlamydia and include the following: vaginal discharge, intermenstrual vaginal bleeding, dysuria, and pain during intercourse (dyspareunia). Approximately 10% of women with asymptomatic cervical chlamydial infection have mucopurulent cervicitis detected on pelvic examination (Fig. 318-2C); this is characterized by a purulent or cloudy endocervical discharge visible in the endocervical canal or on the tip of an endocervical swab. A similar proportion may have endocervical bleeding that is easily induced with passage of a swab through the cervical os. Nonspecific findings may include vaginal discharge and edematous ectopy (a darker red area of columnar epithelium visible on the face of the cervix). Gram stain of an endocervical sample usually shows more than 10 PMNs per oil field. A vaginal wet mount often shows more than 5 to 10 PMNs per 400× field.

Pelvic Inflammatory Disease

Chlamydia can spread from the cervix to the endometrium (causing endometritis), fallopian tubes (causing salpingitis), and peritoneum (causing peritonitis or perihepatitis). These upper genital tract infections are collectively referred to as pelvic inflammatory disease (PID). Estimates of the proportion of cervical chlamydial infections that progress to PID vary greatly but are most commonly around 10 to 20%. The majority of PID cases are subclinical or silent. PID symptoms include pelvic or lower abdominal pain (especially during menses or the first 2 weeks of the menstrual cycle) and nausea. Fever is less common. Examination findings include cervical motion tenderness and tenderness of the uterus or adnexa. Although most cases of chlamydial PID are due to the natural progression of infection, they may also occur post partum or after pregnancy termination. The long-term consequences of PID include infertility, ectopic pregnancy, and chronic pelvic pain.

Complications during Pregnancy

There is some evidence that genital chlamydial infection during pregnancy can lead to adverse outcomes, including preterm labor, low birthweight, miscarriage, and stillbirth.

Reactive Arthritis

Reactive arthritis, characterized by the classic triad of trigger infection (e.g., chlamydia), conjunctivitis, and arthritis, can complicate chlamydial infection (Chapter 265). There is a male predominance in reactive arthritis cases triggered by chlamydia, and it has been estimated that reactive arthritis occurs in about 1% of men presenting with chlamydial urethritis.

Proctitis

Proctitis caused by non-LGV *C. trachomatis* OmpA types is usually asymptomatic. Subjects with acute symptomatic proctitis may report rectal pain or bleeding, tenesmus, pruritus, rectal discharge, or diarrhea. Anoscopy or sigmoidoscopy may reveal friable mucosa and a mucoid or mucopurulent discharge. A rectal swab Gram stain often reveals many PMNs per oil field.

Conjunctivitis

An acute follicular conjunctivitis may rarely occur in adolescents or adults with genital chlamydial infection. The presumed mode of acquisition is autoinoculation with infected genital secretions. The typical clinical presentation is subacute or chronic infection characterized by unilateral conjunctival redness, mucoid or mucopurulent ocular discharge, a foreign body sensation, and preauricular adenopathy.

Oropharyngeal Infection

C. trachomatis has been detected in the oropharynx of sexually active subjects and is asymptomatic in most instances. Recent evidence suggests that *C. trachomatis* can be transmitted from oropharyngeal sites to the genital tract, providing rationale for treatment of oropharyngeal chlamydia. However, because oropharyngeal chlamydia prevalence is very low in most populations and the clinical significance of *C. trachomatis* detected in the oropharynx is unclear, routine oropharyngeal chlamydia screening is not recommended.

Infant Inclusion Conjunctivitis and Pneumonia

Because the prevalence of chlamydia in pregnant adolescents and young adults in the United States can be high (>5%), the morbidity associated with perinatally transmitted chlamydia is considerable. Neonates exposed to *C. trachomatis* during passage through the birth canal may develop inclusion conjunctivitis (≈20 to 40%) or pneumonia (≈10 to 20%). The conjunctivitis, termed inclusion conjunctivitis because the cytoplasmic chlamydia inclusion bodies demonstrated in neonatal conjunctival scrapings are the same as those seen in genital scrapings from adults with genital chlamydia, usually develops 5 to 12 days after birth but may occur as long as 4 to 6 weeks after birth. Clinical manifestations include conjunctival injection and thickening, a clear or mucopurulent ocular discharge, and eyelid swelling. Chlamydia pneumonia in infants usually occurs subacutely between 1 and 3 months of age. Characteristic clinical features include a repetitive staccato cough and absence of fever. Other clinical findings may include tachypnea, crackles on auscultation of the lungs, nasal discharge, and eosinophilia. Chest radiographs may reveal bilateral diffuse infiltrates.

Lymphogranuloma Venereum

LGV is a sexually transmitted infection caused by *C. trachomatis* LGV OmpA types. In contrast to infection with non-LGV strains, LGV is a more invasive systemic infection that involves lymphoid tissue (causing lymphadenitis) and can be ulcerative. LGV is endemic in Africa, India, Southeast Asia, South America, and the Caribbean. LGV had been uncommon in the United States, with fewer than 100 cases reported annually. However, in 2003, an LGV outbreak was reported in the Netherlands, and since then, the LGV epidemic has continued to spread throughout Europe and to North America and Australia. LGV outbreaks are primarily occurring in men who have sex with men with high-risk sexual behaviors (most are HIV infected) who are presenting with proctitis and are infected with LGV OmpA variant L2b.[7]

The clinical manifestations of LGV differ in early versus later stages of infection. In the early stage (3 to 30 days after acquisition) of genital LGV, a primary skin lesion or lesions may develop on the genital mucosa or adjacent skin in the form of a papule, ulcer, or herpetiform lesion. The lesion is usually asymptomatic and goes unnoticed, but it may be erosive; it heals quickly without scarring. Early genital LGV may also be manifested as a nonspecific inflammatory syndrome (e.g., urethritis and cervicitis), similar to infection with non-LGV strains. Genital LGV can progress to an inguinal syndrome 2 to 4 weeks later, characterized by painful, erythematous inguinal lymphadenopathy (buboes; see Fig. 312-3) and systemic manifestations including fever, headache, arthralgias, myalgias, and leukocytosis. The buboes are commonly unilateral, and about one third spontaneously rupture

and drain pus, which can be complicated by fistulas or sinus tracks; unruptured buboes usually heal. In later stages, genital tract fibrosis can lead to complications such as infertility, elephantiasis, strictures, fistulas, and subcutaneous sclerosis.

LGV may also be manifested as an anogenital syndrome with invasive proctitis. Symptoms include fever, tenesmus, anal pruritus, and a rectal discharge that may be mucoid or, less commonly, mucopurulent or bloody. Up to 20 to 30% of patients are asymptomatic. The rectal mucosa is friable, with multiple superficial ulcerations, and biopsy may reveal submucosal granulomas and crypt abscesses; these clinical and histopathologic findings resemble Crohn's disease (Chapter 141). Late complications include rectal strictures, anal fistulas, and lymphorrhoids (perianal growths of lymphatic tissue).

Natural History

The natural history of untreated genital *C. trachomatis* infection has not been fully elucidated, in part because ethical considerations limit such research. Outcomes of untreated genital chlamydia include spontaneous resolution (i.e., immune-mediated clearance) and persisting infection; the latter may be subclinical or may progress to clinical manifestations (e.g., urethritis, cervicitis), which can remain uncomplicated or lead to a complication (e.g., PID). On the basis of limited evidence in subjects with chlamydia detected initially by a screening test who returned within weeks to months for treatment and were retested, anywhere from 10 to 40% of infections resolve spontaneously before treatment.[8] Some patients with persisting infection develop clinical manifestations before returning for treatment, including a small proportion of females (up to 4%) who develop symptomatic PID. Other sparse data in females suggest that up to 50% of genital chlamydial infections resolve after a year, but a small percentage (<10%) could persist for several years. There is recent evidence to suggest that chlamydia resolution before treatment may lower the short-term risk for reinfection.[9] An improved understanding of the natural history of chlamydia could have an impact on screening and treatment recommendations.

DIAGNOSIS

C. trachomatis infections are difficult to diagnose clinically because the majority are asymptomatic, and even when symptoms or signs are present, they are nonspecific. Therefore, a definitive diagnosis relies on detecting the organism. Laboratory diagnosis confirms the clinical diagnosis in those with clinical manifestations and detects infection in asymptomatic individuals (i.e., screening). The CDC recommends annual chlamydia screening for sexually active women aged 25 years and younger as well as for older women with risk factors (e.g., new or multiple sexual partners). Select studies have demonstrated that chlamydia screening reduces the prevalence of chlamydia in women and the rate of PID. Surveillance data from the United States, England, and British Columbia during the last decade have demonstrated a steady decline in PID rates. Universal chlamydia screening in men is not recommended; selective chlamydia testing is appropriate in venues with high prevalences (e.g., sexually transmitted disease clinics, correctional facilities), for high-risk men, or for symptomatic men.

The reference standard for the detection of *C. trachomatis* has been isolation of the organism in cell culture. Development of nonculture tests was important because culture is technically demanding, expensive, and not widely available. Earlier nonculture tests included enzyme immunoassay, direct fluorescent antibody, and nucleic acid hybridization. These tests were less expensive and less technically demanding than culture but had lower sensitivities (lower limit of detection $\geq 10^3$ elementary bodies) and therefore detected fewer infections. These earlier tests have been replaced in most laboratories by NAATs, which are now the recommended diagnostic tests for chlamydia.[10] NAATs have the highest sensitivity (detecting a small number of elementary bodies) and can be performed on genital swabs and on noninvasively collected specimens (first-void urine or self-collected vaginal swabs) with similar accuracy. The CDC's recommended specimens for screening with NAATs are first-void urine in males and vaginal swabs in females. NAATs have not been cleared by the Food and Drug Administration for use with rectal, oropharyngeal, or conjunctival swab specimens; however, some laboratories have validated the assays to meet Clinical Laboratory Improvement Amendments (CLIA) requirements.

The role of serology in diagnosis of *C. trachomatis* infection is limited primarily to two indications: (1) infant pneumonia syndrome, the diagnosis of which is suggested by a *C. trachomatis* immunoglobulin M (IgM) antibody titer of 1 : 32 or greater with the microimmunofluorescence (MIF) assay; and (2) LGV, the diagnosis of which is suggested by a complement fixation (CF) antibody titer greater than 1 : 64 or MIF antibody titer greater than 1 : 256 in the appropriate clinical context. MIF has a higher specificity than CF. LGV can be more definitively diagnosed by demonstrating an LGV OmpA type on *C. trachomatis* DNA from infected material.

TREATMENT

C. trachomatis is susceptible to tetracyclines, macrolides, and select quinolones (ofloxacin and levofloxacin, but not ciprofloxacin). The CDC's recommended treatment for uncomplicated chlamydia is either doxycycline 100 mg orally twice daily for 7 days or azithromycin 1 g orally in a single dose.[11] A meta-analysis of genital chlamydia treatment trials that used primarily chlamydia culture revealed that these regimens are equally efficacious, with cure rates around 97 to 98%. A subsequent study in women using the more sensitive NAAT suggested that the cure rate in genital chlamydia may be slightly lower (≈92%).[12] Recent retrospective studies have raised concern about the efficacy of azithromycin for rectal chlamydia; however, these studies had limitations, and prospective clinical trials comparing azithromycin versus doxycycline regimens for rectal chlamydia are needed. Treatment compliance is higher with azithromycin. Alternative treatment regimens include erythromycin base 500 mg orally four times a day for 7 days, ofloxacin 300 mg orally twice daily for 7 days, and levofloxacin 500 mg orally once a day for 7 days. Azithromycin is the recommended treatment for chlamydia-infected pregnant women. *C. trachomatis* epididymitis and PID should be treated with doxycycline for 10 and 14 days, respectively. Treatment of these syndromes is usually empirical before test results are available; therefore, ceftriaxone 250 mg intramuscularly in a single dose is added to doxycycline to cover gonorrhea. LGV should be treated with doxycycline for 3 weeks; some experts recommend azithromycin 1 g orally weekly for 3 weeks as an alternative.[13] Infant chlamydial infections are treated with erythromycin base 50 mg/kg/day orally divided into four daily doses for 14 days; data on other macrolides are limited, but a shorter treatment course with azithromycin 20 mg/kg/day orally may be effective.

A test of cure (approximately 3 weeks after completion of chlamydia treatment) is recommended only for pregnant women. Sexual partners (including current partners and those with contact in the preceding 60 days) and parents of chlamydia-infected infants should be evaluated and treated empirically. Expedited partner therapy, whereby chlamydia-infected patients are offered medication or a prescription to give to their sexual partners, or clinicians provide medication to contacts without an examination, may reduce the risk for recurrent chlamydia.[14] Patients and their partners should remain abstinent until treatment is completed.

PREVENTION

Education and the provision of condoms are preventive measures that should accompany chlamydia treatment. Recurrent chlamydia occurs in approximately 10 to 20% of chlamydia-infected subjects within a few months of treatment; therefore, repeated chlamydia testing is recommended approximately 3 months after treatment. Routine screening may reduce the risk of pelvic inflammatory disease in sexually active young women.[15]

Chlamydia pneumoniae

In 1986, a new chlamydial pathogen that caused acute respiratory tract infections was identified and designated *Chlamydia* strain TWAR. It was initially thought to be a novel *C. psittaci* strain but was later recognized as the species *C. pneumoniae*. Pneumonia and upper respiratory tract infections (bronchitis, pharyngitis, laryngitis, and sinusitis) are the most frequently identified diseases caused by *C. pneumoniae*.[16] However, *C. pneumoniae* may also contribute to exacerbations of chronic bronchitis and asthma. There is evidence suggesting that *C. pneumoniae* may contribute to atherosclerosis, although large *C. pneumoniae* treatment trials have not demonstrated benefit in preventing adverse cardiovascular events. Select central nervous system disorders (e.g., Alzheimer's disease, multiple sclerosis) have been linked to *C. pneumoniae*, but a causal relationship has not been established.

EPIDEMIOLOGY

The majority of adults in the United States and other developed countries are seropositive for *C. pneumoniae*, up to 80% in some populations. Seroconversion often occurs during childhood or adolescence and may be subclinical. Studies incorporating culture or polymerase chain reaction (PCR) suggest that infection is not uncommon in children younger than 5 years. *C. pneumoniae* causes an atypical pneumonia syndrome, with an estimated annual

incidence of 1 case per 1000 population; epidemiologic studies suggest a 4-year cycle of increased pneumonia incidence. Up to 10% of community-acquired pneumonias are attributed to *C. pneumoniae*, and coinfection with other respiratory pathogens such as *Streptococcus pneumoniae* and *Mycoplasma pneumoniae* is not uncommon. The organism is believed to be acquired through the inhalation of infected respiratory droplets from persons with disease and possibly asymptomatic carriers. This mode of transmission can facilitate the spread of infection among household members and can cause epidemics in enclosed populations, such as persons in military barracks, nursing homes, and schools.

CLINICAL MANIFESTATIONS

Most *C. pneumoniae* infections occur in children, who often have mild clinical manifestations or are asymptomatic. Clinical manifestations are more evident in adults, especially the elderly, who have the highest incidence of *C. pneumoniae* pneumonia. *C. pneumoniae* causes an atypical pneumonia that is usually of mild to moderate severity. The incubation period may be several weeks, and the disease onset is gradual. A nonproductive cough is usually present and is often preceded or accompanied by nasal congestion, sore throat, and hoarseness. Headache may occur in up to half of patients. Fever and dyspnea occur less commonly. On examination, localized pulmonary crackles or rhonchi are often heard. Chest radiography shows pneumonitis, most often evident as a single subsegmental lower lobe infiltrate. The leukocyte count is usually normal. *C. pneumoniae* may also be manifested as isolated bronchitis, sinusitis, laryngitis, or nonexudative pharyngitis. The clinical course of these upper respiratory tract infections may be protracted for several weeks.

DIAGNOSIS

C. pneumoniae infection is usually diagnosed by serology or direct detection of the organism in respiratory specimens by cell culture or other nonculture methods. Serology is the test used in most clinical settings, with the MIF assay considered the reference standard for serodiagnosis. Acute infection is suggested by a four-fold rise in IgG from paired sera or a single high IgM (>1 : 16) or IgG (>1 : 512) titer. However, serology is limited by its specificity, reproducibility, and clinical correlation. *C. pneumoniae* can be isolated in cell culture, but culture is technically challenging and time-consuming. Antigen detection with use of fluorescent monoclonal antibodies has a lower sensitivity than culture and is also technically challenging. *C. pneumoniae* PCR is more sensitive than culture, and real-time PCR appears to have advantages over conventional PCR. Although there are still issues involving the standardization of PCR methods for *C. pneumoniae* detection, PCR is promising and will likely become the test of choice.

TREATMENT Rx

C. pneumoniae is susceptible to tetracyclines, macrolides, and fluoroquinolones. Treatment trials using culture have demonstrated that select macrolide and fluoroquinolone regimens eradicate *C. pneumoniae* in approximately 70 to 85% of subjects with pneumonia. The clinical response to treatment may be slow, and some patients may need re-treatment. The suggested treatment duration for most regimens is typically 10 to 14 days, except that shorter courses may be effective for azithromycin (10 mg/kg on day 1, followed by 5 mg/kg during the next 4 days; up to 1.5 g orally during 5 days). Chronic *C. pneumoniae* infections may require even longer courses of treatment (e.g., 6 weeks), and macrolides are suggested in this setting. Protective immunity after *C. pneumoniae* infection may not occur, and therefore reinfection is common.

Chlamydia psittaci

EPIDEMIOLOGY

C. psittaci naturally infects a variety of mammals and birds. *C. psittaci* strains appear to be host specific, and most human infections are linked to contact with an infected bird. *C. psittaci* infection in humans is termed psittacosis, in part because exposure to psittacine birds (parrots, parakeets, and budgerigars) is commonly implicated in infections. However, because human cases have been linked to exposure to finches, pigeons, pheasants, ducks, turkeys, chickens, seagulls, and other birds, ornithosis may be a more appropriate term. Psittacosis disease in birds ranges from an asymptomatic carriage state to a mild symptomatic illness manifested by ruffled feathers, anorexia, shivering, dyspnea, diarrhea, or depression. Infected birds shed *C. psittaci* in urine, feces, or secretions from their beaks or eyes. Their feathers and surrounding environment become contaminated. Transmission to humans is primarily by inhalation of aerosolized bird secretions or dust. Infected birds may shed the organism for months. Person-to-person transmission rarely occurs.

Human psittacosis is a rare infection, due in part to antibiotic-laced bird feed and a mandated quarantine for imported birds. The number of cases of psittacosis in the United States has been stable for the past 10 years, with fewer than 50 confirmed cases reported annually; a larger number of cases are reported but not confirmed.

CLINICAL MANIFESTATIONS

Psittacosis initially involves the lungs and then spreads to the reticuloendothelial system. The clinical spectrum of infection ranges from asymptomatic to fulminant, and clinical manifestations may resemble several other nonspecific febrile systemic illnesses, including Q fever, typhoid fever, and legionnaires' disease.[17] After an incubation period of 5 to 14 days, some patients may present with a nonspecific virus-like illness or a mononucleosis-like syndrome. The presentation most suggestive of psittacosis is an acute febrile atypical pneumonia.[18] Patients initially have an abrupt onset of shaking chills and a fever as high as 40.5° C. Temperature-pulse dissociation (i.e., elevated temperature with a normal pulse) may occur. Constitutional symptoms, including headache, myalgias, and arthralgias, are prominent. A cough, usually nonproductive, appears early in the illness and may accompany chest pain, which is usually nonpleuritic. Auscultation may be normal or reveal bilateral crackles. Chest radiograph findings are usually more dramatic than lung examination findings; the most common finding is single lower lobe consolidation, but multiple localized bronchopneumonic patches, diffuse ground-glass changes, and a miliary pattern have been described. Small pleural effusions may be seen. In contrast to *C. pneumoniae* pneumonia, psittacosis is more severe, with high fever and absent or minimal upper respiratory complaints.

Extrapulmonary findings frequently occur in psittacosis. Splenomegaly is common. A faint erythematous, blanching, maculopapular rash (Horder's spots), resembling the rose spots of typhoid fever, can occur, as can erythema nodosum. Signs of hepatitis, endocarditis (culture negative), pericarditis, myocarditis, meningoencephalitis, hemolytic anemia, or disseminated intravascular coagulation may be noted. *C. psittaci* infection has also been associated with nongastrointestinal extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue, including ocular and central nervous system sites.

DIAGNOSIS

Psittacosis should be suspected in patients with a febrile illness (especially atypical pneumonia) who report exposure to sick or imported birds or who have regular exposure to birds, including bird owners, pet shop workers, veterinarians, zookeepers, and poultry processing plant workers. The diagnosis can be made with serology or by isolating the organism in cell culture. *C. psittaci* is a biocontainment level 3 agent because of its stability in the environment and aerosol transmission. Because laboratory-acquired *C. psittaci* infections are well documented, culture is discouraged and serology is preferred. If culture is attempted, laboratory staff should be notified in advance so that appropriate precautions can be taken. A serologic diagnosis of psittacosis is made by demonstrating (1) a four-fold or greater rise in CF or MIF antibody against *C. psittaci* to a titer of at least 1 : 32 from acute to convalescent sera collected at least 2 weeks apart (3 to 6 weeks is recommended) or (2) an IgM titer of 1 : 16 or greater against *C. psittaci* by MIF.

TREATMENT Rx

Untreated psittacosis can be fatal, but mortality is rare with prompt antimicrobial treatment. Because of the delay in laboratory diagnosis of psittacosis, empirical therapy should be provided on the basis of clinical suspicion. *C. psittaci* susceptibility has been demonstrated to tetracyclines, macrolides, and some of the newer fluoroquinolones. The recommended treatment regimen, based on clinical experience, is either tetracycline 500 mg four times a day or doxycycline 100 mg twice a day for 10 to 21 days. Further studies on the clinical efficacy of azithromycin and newer fluoroquinolones are needed. The initial treatment response can be dramatic, with defervescence and marked clinical improvement within 24 to 48 hours. Full recovery may take several weeks, and relapse or reinfection can occur. Endocarditis treatment includes prolonged antibiotic therapy and consideration of valve replacement.

Association with Atherosclerosis

There is evidence that *C. pneumoniae* may cause or contribute to atherosclerosis (Chapter 70) and cardiovascular disease. Seroepidemiologic studies have demonstrated a higher prevalence of *C. pneumoniae* antibodies in patients with atherosclerosis, although the serologic tests used and seropositivity criteria varied across studies. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by culture, immunohistochemical staining, and PCR. Animal studies have demonstrated that *C. pneumoniae* infection can initiate or enhance the progression of atherosclerosis, and sparse animal studies have demonstrated that antibiotics prevent atherosclerosis. However, large-scale randomized treatment trials have failed to show that *C. pneumoniae* treatment prevents cardiovascular events or mortality; some of these studies differed in terms of study populations, macrolide used, and length of treatment. Currently, antibiotics are not recommended for the prevention of adverse atherosclerotic cardiovascular events.

Association with Asthma

Epidemiologic and clinical studies have demonstrated an association between *C. pneumoniae* infection and asthma, both acute exacerbations and more severe chronic asthma. It is thought that persistent *C. pneumoniae* infection contributes to airway inflammation and hyperresponsiveness. Select randomized clinical trials have demonstrated improvement in asthma disease (symptoms, inflammatory markers, or peak expiratory flow) after antimicrobial treatment of presumed or proven *C. pneumoniae* infection, especially during acute exacerbations. However, it is difficult to determine how much of the improvement may have been due to the immunomodulatory effects of the antibiotics rather than their antimicrobial activity. Although the role of antibiotic treatment for *C. pneumoniae* infection in asthmatics remains somewhat controversial, treatment for *C. pneumoniae* infection is currently recommended for patients with acute exacerbations of asthma and clinical evidence of infection.

Association with Chronic Neurologic Diseases

C. pneumoniae infection has been implicated in the pathogenesis of multiple sclerosis and Alzheimer's disease on the basis of some studies demonstrating detection of the organism at a higher frequency in affected neurologic tissue. However, to date, the studies are contradictory, and a causal relationship between *C. pneumoniae* infection and either multiple sclerosis or Alzheimer's disease has not been established.

PREVENTION

Epidemic psittacosis is preventable by a 30-day period of quarantine for all imported psittacine birds and their treatment with feed containing chlortetracycline. The U.S. Department of Agriculture recommends extending treatment for an additional 15 days after quarantine. Prevention of epidemic and endemic psittacosis also relies on avoidance of or protection from exposure to dust or body secretions from birds or their living areas as well as avoidance of the handling of sick birds. Environmental sanitation is another important preventive measure, considering the organism's resistance to drying.

REVIEW QUESTIONS

1. Which of the following is *not* a recommended strategy for the elimination of trachoma and its complications?

A. Surgery to correct trichiasis
B. Mass antibiotic treatments within a trachoma-endemic community
C. Face washing and good hygiene
D. Achieving better sanitary conditions in the environment
E. Education to promote safer sexual practices

Answer: E The World Health Organization is committed to the elimination of trachoma and its complications by 2020 and recommends that endemic countries adopt the SAFE strategy: surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental sanitation improvement. Trachoma is spread by direct contact with fingers or fomites (e.g., washcloths, handkerchiefs) contaminated with eye discharge from an infected person or by eye-seeking flies, not through sexual transmission.

2. Routine annual screening for genital chlamydial infection is recommended by the Centers for Disease Control and Prevention (CDC) for the following patient group:

A. All sexually active women
B. All sexually active men
C. Sexually active women 25 years of age and younger
D. Sexually active men 25 years of age and younger
E. None of the above

Answer: C Routine genital chlamydia screening (i.e., testing of asymptomatic persons for chlamydia) in women has been shown to reduce the rate of pelvic inflammatory disease. Surveillance data from the CDC have shown that the majority of chlamydia cases reported each year are in women 25 years of age and younger. Therefore, the CDC recommends routine annual screening for genital chlamydial infection in women within this age group. Screening in women older than 25 years of age is recommended only if risk factors (e.g., new sexual partner, multiple sexual partners) are present. Routine chlamydia screening is not recommended for men; however, screening should be considered for men in venues with a high prevalence of chlamydia (e.g., STD clinics).

3. The recommended treatment for lymphogranuloma venereum (LGV) infection is

A. Doxycycline 100 mg twice daily orally for 7 days
B. Doxycycline 100 mg twice daily orally for 21 days
C. Azithromycin 1 g orally single-dose therapy
D. Erythromycin 500 mg four times a day for 21 days
E. Ciprofloxacin 500 mg twice daily for 7 days

Answer: B *Chlamydia trachomatis* strains of the LGV serovar/genotype cause more invasive disease than the non-LGV strains do, and therefore a course of doxycycline 100 mg twice daily for 21 days is recommended. There is insufficient clinical experience with macrolides to recommend them as a first-line agent for LGV. Some experts do recommend azithromycin 1 g weekly for 3 weeks as an alternative to the 3-week doxycycline regimen, but a single dose of azithromycin is believed to be insufficient to reliably cure invasive LGV infections. Ciprofloxacin has poor in vitro activity against *C. trachomatis* and is not recommended for treatment of LGV or non-LGV *C. trachomatis* infections.

4. Which of the following statements regarding *Chlamydia pneumoniae* is most accurate?

A. The seroprevalence of *C. pneumoniae* in adults in the United States is estimated to be around 15%.
B. Pneumonia caused by *C. pneumoniae* usually is manifested as an acute-onset illness with cough productive of purulent sputum.
C. *C. pneumoniae* causes upper respiratory tract infections, including pharyngitis and bronchitis.
D. Penicillin is a highly effective treatment for *C. pneumoniae* respiratory infections.
E. Large clinical trials have consistently demonstrated a reduction in adverse cardiovascular events in patients receiving antibiotic treatment directed against *C. pneumoniae.*

Answer: C The majority of adults in the United States and other developed nations are seropositive for *C. pneumoniae.* It is well known that *C. pneumoniae* can cause upper and lower respiratory tract infections. Pneumonia caused by *C. pneumoniae* usually develops gradually with a nonproductive cough, referred to as a walking pneumonia, in contrast to pneumococcal pneumonia, which is more likely to be acute in onset with a productive cough. *C. pneumoniae* respiratory infections are most effectively treated with an antibiotic from the tetracycline, macrolide, or respiratory fluoroquinolone (levofloxacin, moxifloxacin) class and are not adequately treated by a β-lactam antibiotic such as penicillin. Even though *C. pneumoniae* has been associated with atherosclerosis, large *C. pneumoniae* treatment trials have not demonstrated benefit in preventing adverse cardiovascular events.

5. Which of the following statements regarding *Chlamydia psittaci* is *not* true?

A. *C. psittaci* infection has been associated with exposure to psittacine birds (parrots, parakeets, and budgerigars).
B. *C. psittaci* infection has been associated with exposure to turkeys.
C. Birds may be carriers of *C. psittaci* but do not develop clinical disease.
D. *C. psittaci* infection can be manifested as an abrupt-onset febrile illness in humans.
E. *C. psittaci* has been classified as a biocontainment level 3 agent.

Answer: C *C. psittaci* infection has been associated with exposure to psittacine birds and several other nonpsittacine birds, including turkeys. Whereas birds may be asymptomatic carriers of *C. psittaci*, they may also develop a mild symptomatic illness manifested by ruffled feathers, anorexia, shivering, dyspnea, diarrhea, or depression. *C. psittaci* infection can be manifested as an abrupt-onset febrile illness in humans with pulmonary and extrapulmonary manifestations. *C. psittaci* has been classified as a biocontainment level 3 agent because of its stability in the environment and aerosol transmission. Because laboratory-acquired *C. psittaci* infections are well documented, culture is discouraged and serology is preferred for diagnosis.

SYPHILIS

EDWARD W. HOOK III

DEFINITION

Syphilis, which is a chronic infectious disease caused by the bacterium *Treponema pallidum* subspecies *pallidum*, is usually acquired by sexual contact with another infected individual. Syphilis is remarkable among infectious diseases for its large variety of clinical manifestations. If untreated, it progresses through primary, secondary, and tertiary stages. The early stages (i.e., primary and secondary), when lesions are present, are infectious. Spontaneous healing of early lesions occurs, followed by a long latent period. In about 30% of untreated patients, late disease of the heart, central nervous system (CNS), or other organs may develop years after the initial infection. Although the disease is less common now than previously, it remains a challenge to clinicians because of its protean manifestations, and it is of interest to biologists because of the prolonged, tenuous balance between the host and the invading spirochete.[1,2]

The Pathogen

The causative agent of syphilis, *T. pallidum* subspecies *pallidum*, is closely related to other pathogenic spirochetes (Chapter 320), including those causing yaws (*T. pallidum* subspecies *pertenue*) and pinta (*Treponema carateum*). *T. pallidum* is a thin, helical bacterium approximately 0.15 µm wide and 6 to 15 µm long. The organism has 6 to 14 spirals and is tapered on either end. It is too thin to be seen by ordinary Gram stain microscopy but can be visualized in wet mounts by dark-field microscopy or in fixed specimens by silver stain or fluorescent antibody methods.

Unlike most bacteria, which have protein-rich outer membranes, the *T. pallidum* outer membrane appears to be composed of predominantly phospholipids, with few surface-exposed proteins. It has been hypothesized that because of this structure, syphilis can progress despite the brisk antibody response to non–surface-exposed internal antigens, which is the basis for serologic tests for the diagnosis and management of syphilis. Between the outer membrane and the peptidoglycan cell wall are six axial fibrils; three are attached at each end, and they overlap in the center of the organism. They are structurally and biochemically similar to flagella and are in part responsible for the organism's motility.

It is possible to culture *T. pallidum*, but sustained in vitro cultivation is not yet possible, and yields are very low. Culture is of limited use in research and of no use in clinical practice. All isolates studied have been susceptible to penicillin and are antigenically similar. The only known natural hosts for *T. pallidum* are humans and certain monkeys and higher apes.

EPIDEMIOLOGY

With the exception of congenital syphilis, syphilis is acquired almost exclusively by intimate contact with the infectious lesions of primary or secondary syphilis (e.g., chancres, mucous patches, condylomata lata). Disease is usually acquired through sexual intercourse, including anogenital and orogenital intercourse. Health care workers are sometimes infected during the unsuspecting examination of patients with infectious lesions. Infection by contact with fomites is extremely uncommon. Before the advent of modern blood banking techniques, syphilis was occasionally transmitted through the transfusion of blood from persons with *T. pallidum* bacteremia, and occasional parenteral transmission still occurs as a result of the sharing of contaminated needles.

Syphilis is most common in large cities and in young, sexually active individuals. The highest rate is found in men between the ages of 20 and 29 years. In 2012, 67% of the 3142 U.S. counties reported no cases of primary or secondary syphilis, and just 28 locales accounted for about 50% of all reported infections.[3] The disease is most prevalent in the Southeast and California.

Syphilis spares no class, race, or group but is more prevalent among persons living on the margins of society. U.S. syphilis rates are about six-fold greater in African Americans than in non-Hispanic whites. In 2012, more than 75% of reported early syphilis occurred in men who acknowledged sex with other men. Increased numbers of different partners and perhaps indiscriminate choice of partners increase the risk of acquiring sexually transmitted disease (Chapter 285). A traditional cornerstone of syphilis control has been the epidemiologic investigation and treatment of sexual contacts of patients with primary or secondary lesions and patients with early latent disease. Patients with primary and secondary syphilis name, on average, nearly three different sexual contacts within the previous 90 days. As syphilis has become associated with drug use and anonymous sex, epidemiologic investigations have become less efficacious.

The incidence of syphilis has generally declined worldwide for more than 100 years, with the exception of periods of war or social upheaval. With the introduction of penicillin, there was a rapid decline in primary and secondary syphilis, to approximately 4 cases per 100,000 people in 1957. This decline was followed by reductions in federal expenditures for syphilis control, which resulted in resurgence of infectious primary and secondary syphilis in the United States; peaks of more than 12 cases per 100,000 people were attained several times from 1965 through the mid-1990s. Because many cases of syphilis are not reported, the true incidence may be much higher.

During the past 40 years, syphilis epidemics have occurred serially in at least three U.S. population subgroups. In the 1970s and 1980s, men who had sex with other men accounted for a disproportionate number of the total cases of infectious syphilis. Similar trends occurred in other countries. Then, after a period of decline, U.S. syphilis rates nearly doubled from 1986 to 1990, with 50,578 cases reported in 1990 in an epidemic disproportionately affecting multiracial heterosexual men and women and occurring contemporaneously with an epidemic of crack cocaine use. After 1990, syphilis rates again declined; in 2001, there were 6103 cases of primary and secondary syphilis reported, one of the lowest numbers since 1959. The epidemic of the late 1980s probably contributed to the spread of human immunodeficiency virus (HIV) infection (see Syphilis-HIV Interactions) and to dramatic increases in the rate of congenital syphilis. Since 2001, syphilis rates have again begun to increase in men, and now especially men infected with HIV.

In 2013, the rate of reported primary and secondary syphilis in the United States was 5.3 cases per 100,000 population, more than double the lowest-ever rate of 2.1 in 2000. During 2005 to 2013, primary and secondary syphilis rates increased among men of all ages, races, and ethnicities across all regions. Recent years have shown an accelerated increase occurring among men who have sex with men. Among women, rates increased during 2005 to 2008 and decreased during 2009 to 2013.[4]

Patients with clinically evident late syphilis, particularly those with cardiovascular or gummatous syphilis, are becoming less common, perhaps as a result of the effectiveness of penicillin therapy for early syphilis. However, surveys indicate that there are still significant numbers of patients with untreated neurologic syphilis, especially in older age groups.

FIGURE 319-1. Syphilis lesions. A, Chancre in primary syphilis. **B,** Palmar lesions of a coppery color in secondary syphilis. **C,** Mucous patch in secondary syphilis. **D,** Condylomata lata in secondary syphilis. (**A, C, and D** from Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003. **B** from Habif TP, Cambell JI, Quitadamo MJ, et al. *Skin Disease: Diagnosis and Treatment.* St. Louis: Mosby; 2001.)

Natural Course of Untreated Syphilis

The incubation period from the time of exposure to development of the primary lesion averages approximately 21 days (range, 10 to 90 days). Initially, a painless papule develops at the site of inoculation and soon breaks down to form a clean-based ulcer—the chancre—with raised, indurated margins (Fig. 319-1A). The chancre persists for 2 to 6 weeks and then heals spontaneously. Several weeks later, a secondary stage characterized by low-grade fever, headache, malaise, generalized lymphadenopathy, and a mucocutaneous rash typically develops. There may be involvement of visceral organs. The secondary eruption may occur while the primary chancre is still healing or up to several months after disappearance of the chancre. Secondary lesions also heal spontaneously within 2 to 6 weeks, and the infection then becomes latent. In more than 20% of patients with untreated latent syphilis, relapsing lesions later develop, similar to those of the secondary stage; rarely, the relapse takes the form of recurrence of the primary chancre. In the era before antibiotics, late, destructive tertiary lesions involving the eyes, the CNS, the heart, and other organs, including the skin, eventually developed in about a third of untreated patients. These lesions may occur a few years to as long as 25 years after infection.

The incidence of late complications of untreated syphilis is currently unknown, but it seems to be less than that seen previously. Cases of gumma are now so rare as to be reportable.

PATHOBIOLOGY

T. pallidum may penetrate through normal mucosal membranes and minor abrasions on epithelial surfaces. The first lesions appear at the site of direct, primary inoculation. The minimal number of treponemes needed to establish infection is not known but may be as low as one. Multiplication of organisms is slow, with a division time in rabbits of approximately 33 hours. The slow growth of treponemes in humans probably accounts in part for the protracted nature of the illness, the relatively long incubation period, and the need for relatively long duration of therapy.

Syphilis is a systemic disease from the onset. Treponemes are capable of specific attachment to host cells, but it is not known whether attachment results in damage to the host cells. Most treponemes are found in the intercellular spaces, but they are occasionally seen within phagocytic cells. However, there is no evidence of prolonged intracellular survival of treponemes. *T. pallidum* is not known to produce toxins.

The primary pathologic lesion of syphilis is a focal endarteritis with an increase in adventitial cells, endothelial proliferation, and the presence of an inflammatory cuff around affected vessels. Lymphocytes, plasma cells, and monocytes predominate in the inflammatory lesion, and polymorphonuclear cells are seen in some cases. The vessel lumen is frequently obliterated. With healing, there is considerable fibrosis. Treponemes may be seen in most early lesions of syphilis and in some of the late lesions, such as the meningoencephalitis of general paresis.

Granulomatous reaction is common in secondary and late syphilis. The granulomas are histologically nonspecific, and cases of syphilis have been incorrectly diagnosed as sarcoidosis or other granulomatous diseases. Human inoculation studies suggest that the pathogenesis of the gumma, which is a granulomatous lesion, involves hypersensitivity to small numbers of virulent treponemes introduced into a previously sensitized host.

Intracutaneous inoculation of partially purified antigens of *T. pallidum* into patients with syphilis in various stages has shown that delayed cellular hypersensitivity develops only late in secondary syphilis but is uniformly present in latent syphilis. There may be temporary hyporesponsiveness of lymphocytes to treponemal antigens in patients with primary and secondary syphilis. It is possible that the waxing and waning of lesions in early syphilis depend on the balance between the development of effective cellular immunity and the suppression of thymus-derived lymphocyte function.

The host responds to infection by producing numerous antibodies; in some instances, circulating immune complexes may be formed as well. For example, nephrotic syndrome has occasionally been recognized in secondary syphilis, and renal biopsy specimens from such patients have shown membranous glomerulonephritis characterized by focal subepithelial basement membrane deposits containing immunoglobulin G, C3, and treponemal antibody.

CLINICAL MANIFESTATIONS

Primary Syphilis

The typical lesion of primary syphilis, the chancre, is a painless, clean-based, indurated ulcer (Fig. 319-1A). The chancre starts as a papule, but then superficial erosion results in ulceration. The borders of the ulcer are raised, firm, and indurated. On occasion, secondary infections change the appearance and cause a painful lesion. Most chancres are single, but multiple ulcers are sometimes seen, particularly when skinfolds are apposed (i.e., kissing chancres). An untreated chancre heals in several weeks and leaves a faint scar. The chancre is usually associated with regional adenopathy, which may be unilateral or bilateral. The regional nodes are movable, discrete, and rubbery. If the chancre occurs in the cervix or the rectum, the affected regional iliac nodes are not palpable.

Chancres can occur at any site of potential inoculation by direct contact, with most occurring in anogenital locations. Chancres may also be seen in the pharynx, on the tongue, around the lips, on the fingers, on the nipples, and in other diverse areas. The morphology depends in part on the area of the body where they occur and on the host's immune response. Chancres in previously infected individuals may be small and remain papular. Chancres of the finger may appear more erosive and can be quite painful. Chancres of the anal canal may be missed in men who have sex with men unless a careful examination is undertaken.

Secondary Syphilis

Between 4 and 8 weeks after the appearance of the primary chancre, signs and symptoms of secondary syphilis typically develop. Symptoms may include malaise, fever, headache, sore throat, and other systemic complaints. Most patients have generalized lymphadenopathy, including involvement of the epitrochlear nodes. Approximately 30% of patients have evidence of a healing chancre, although many patients (including a disproportionate number of women and of men who have sex with men) give no history of a primary lesion.

At least 80% of patients with secondary syphilis have cutaneous or mucocutaneous lesions at some point in their illness. The diagnosis is frequently first suspected on the basis of the cutaneous eruption. The rash is often minimally symptomatic, and many patients with late syphilis do not recall primary or secondary lesions. The rashes are varied in appearance but have certain

characteristic features. The lesions are usually widespread, are symmetrical in distribution, and are frequently pink, coppery, or dusky red (particularly the earliest macular lesions). They are generally nonpruritic, although occasional exceptions have been reported, and they are rarely vesicular or bullous in adults. They are indurated, except for the very earliest macular lesions, and frequently have a superficial scale (i.e., papulosquamous lesions). The lesions tend to be polymorphic and rounded, and on healing, they may leave residual pigmentation or depigmentation. They may be faint and difficult to visualize, particularly on dark-skinned individuals.

The earliest pink macular lesions are typically seen on the trunk, with later spread to the rest of the body. The face is often spared, except around the mouth. Subsequently, a papular rash appears that is usually generalized but is marked on the palms and soles (Fig. 327-1B). These rashes are often associated with a superficial scale and may be hyperpigmented. When the rash occurs on the face, it may be pustular and resemble acne vulgaris. On occasion, the scale may be so great that it resembles psoriasis. Ulceration may occur and produce lesions resembling ecthyma. In malnourished or debilitated patients, extensive and destructive ulcerative lesions with a heaped-up crust may occur, the so-called rupial lesions. Lesions around the hair follicles may result in patchy alopecia of the beard or scalp.

Ringed or annular lesions may occur, especially around the face and particularly on dark-skinned individuals. A lesion at the angle of the mouth or the corner of the nose may have a central linear erosion, the so-called split papule.

The palate and pharynx may be inflamed. In approximately 30% of secondary syphilis patients, so-called mucous patches (Fig. 319-1C) develop; these slightly raised, oval areas are covered by a grayish white membrane that, when raised, reveals a pink base that does not bleed. These lesions may be seen on the genitalia, in the mouth, or on the tongue.

In warm, moist areas such as the perineum, large, pale, flat-topped papules may coalesce to form condylomata lata (Fig. 319-1D). Papules may also be seen in the axilla and rarely occur in a generalized form. These papules are not to be confused with the common venereal warts (i.e., condylomata acuminata), which are small, often multiple, and more sharply raised than condylomata lata. Like mucous patches, condylomata lata are highly infectious.

Other manifestations of secondary syphilis include hepatitis, which has been reported in up to 10% of patients in some series. Jaundice is rare, but an elevated alkaline phosphatase level is common. Liver biopsy reveals small areas of focal necrosis and mononuclear infiltrate or periportal vasculitis. Spirochetes can often be visualized with silver stains. Periostitis with widespread lytic lesions of bone has been reported occasionally; bone scanning appears to be a sensitive test for early syphilitic osteitis. An immune complex type of nephropathy with transient nephrotic syndrome has been documented rarely. There may be iritis or an anterior uveitis. Between 10 and 30% of patients have pleocytosis in cerebrospinal fluid (CSF), but symptomatic meningitis is seen in less than 1% of patients. Symptomatic gastritis may occur.

Relapsing Syphilis

After resolution of the primary or secondary skin lesions, 20 to 30% of patients experience cutaneous recurrences. Recurrent lesions may be fewer or more firmly indurated than the initial lesions. Like the typical lesions of primary or secondary syphilis, they are infectious for exposed sexual partners.

Latent Syphilis

By definition, latent syphilis is the stage at which there are no clinical signs of syphilis and the CSF is normal. Latency, which begins when the first attack of secondary syphilis has passed and may last for a lifetime, is usually detected by reactive serologic tests for syphilis (see Diagnosis). Congenital syphilis must also be excluded before the diagnosis of latent syphilis can be made. Patients may or may not have a clinical history of earlier primary or secondary syphilis manifestations.

Latency has been divided into two stages: early and late. Most infectious relapses occur in the first year, and epidemiologic evidence shows that the most infectious period is during the first year of infection. Early latency is therefore defined as the first year after resolution of the primary or secondary lesions or as a newly reactive serologic test response for syphilis in an otherwise asymptomatic individual who has had a negative serologic test result within the preceding year. Late latent syphilis, or, more accurately, latent syphilis of unknown duration, is ordinarily not infectious, except for pregnant women, who can transmit infection to the fetus despite long-standing infection.

TABLE 319-1 NEWLY DIAGNOSED TERTIARY SYPHILIS IN 105 PATIENTS IN DENMARK, 1961-1970

TYPE OF TERTIARY SYPHILIS	NO. OBSERVED*
Neurosyphilis	72
Asymptomatic	45
Tabes dorsalis	11
General paresis	13
Meningovascular	1
Optic atrophy	2
Cardiovascular syphilis	44
Aortic insufficiency	16
Aortic aneurysm	13
Uncomplicated aortitis†	15
Late benign syphilis (gumma)	4

*Some patients had more than one form of late syphilis.
†Autopsy diagnoses only.

Late Syphilis

Late syphilis (Table 319-1) is usually slowly progressive, although certain neurologic syndromes may have a sudden onset because of endarteritis and CNS thrombosis. Late syphilis is not infectious through sexual contact. Any organ of the body may be involved, but three main types of disease can be distinguished: late benign (gummatous), cardiovascular, and neurosyphilis.

Late Benign Syphilis

In the penicillin era, gummas are rare. They typically develop 1 to 10 years after initial infection and may involve any part of the body. Although gummas may be destructive, they respond rapidly to treatment and are therefore relatively benign. On histologic evaluation, the gumma is a granuloma.

Gummas may be solitary or multiple and most often come to medical attention as space-occupying lesions. They are usually asymmetrical and are often grouped. Gummas may start as a superficial nodule or as a deeper lesion that breaks down to form punched-out ulcers. They are ordinarily indolent, slowly progressive, and indurated on palpation. Cutaneous gummas may resemble other chronic granulomatous ulcerative lesions caused by tuberculosis, sarcoidosis, leprosy, and other deep fungal infections. Precise histologic diagnosis may not be possible. However, syphilitic gummas are the only such lesions to heal dramatically with penicillin therapy.

Gummas may also involve deep visceral organs, particularly the respiratory tract, gastrointestinal tract, and bones. In addition, they may involve the larynx or the pulmonary parenchyma. Gummas of the stomach may masquerade as carcinoma of the stomach or lymphoma. Gummas of the liver were once the most common form of visceral syphilis and often manifested as hepatosplenomegaly and anemia and occasionally as fever and jaundice. Skeletal gummas typically produce lesions in the long bones, skull, and clavicle; a characteristic symptom is nocturnal pain. Radiologic abnormalities, when present, include periostitis and lytic or sclerotic, destructive osteitis.

Cardiovascular Syphilis

The primary cardiovascular complications of syphilis are aortic insufficiency (Chapter 75) and aortic aneurysm (Chapter 78), usually of the ascending aorta. Less commonly, other large arteries may be affected, and involvement of the coronary ostia rarely results in coronary insufficiency. All these complications are caused by obliterative endarteritis of the vasa vasorum, with resultant damage to the intima and media of the great vessels. This damage results in dilation of the ascending aorta, but the valve cusps remain normal. An aneurysm occasionally is manifested as a pulsating mass bulging through the anterior chest wall. Syphilitic aortitis[5] may also involve the descending aorta proximal to the renal arteries.

Cardiovascular syphilis usually begins within 5 to 10 years of the initial infection but may not be manifested clinically until 20 to 30 years later. Cardiovascular syphilis does not occur after congenital infection, a phenomenon that remains unexplained.

Asymptomatic aortitis is best diagnosed by visualizing linear calcifications in the wall of the ascending aorta by radiography. The signs of syphilitic aortic insufficiency are the same as for aortic insufficiency of other causes. In aortic insufficiency resulting from dilation of the aortic ring, the decrescendo murmur is often loudest along the right sternal margin. Syphilitic aneurysms may be fusiform but are more typically saccular and do not lead to aortic dissection. Between 10 and 20% of patients with cardiovascular syphilis have coexistent neurosyphilis.

Neurosyphilis

CNS involvement occurs throughout the natural history of syphilis. Neurosyphilis[6] can be divided into five groups: asymptomatic, syphilitic meningitis, meningovascular syphilis, tabes dorsalis, and general paresis. Asymptomatic neurosyphilis can occur at any time, whereas syphilitic meningitis is most common during the secondary stage of infection. Meningovascular syphilis, tabes dorsalis, and general paresis are typically manifestations of late syphilis. The divisions are not absolute, and overlap between syndromes is typical. Current cases of neurosyphilis are likely to be variants of the classic syndromes, possibly as a result of the use of antimicrobial agents for other diseases.

Syphilitic Meningitis

Acute to subacute aseptic meningitis can occur at any time after the primary stage, but it usually occurs within the first year of infection. It frequently involves the base of the brain and may result in unilateral or bilateral cranial nerve palsies. Mild aseptic meningitis may be relatively common in patients with early syphilis, but severe disease occurs in only about 1.5% of untreated patients. Syphilitic meningitis typically resolves without treatment.

Meningovascular Syphilis

Some patients have sufficient endarteritis and perivascular inflammation to result in cerebrovascular thrombosis and infarction, generally 5 to 10 years after the initial infection. However, case reports suggest that in syphilis patients with coexistent HIV infection, meningovascular syphilis may be manifested earlier or may be a manifestation of treatment failure. Patients frequently have associated aseptic meningitis. Most cerebrovascular accidents are not caused by syphilitic arteritis, even in patients with a reactive serologic test result for syphilis. However, syphilis should be considered a potential cause in relatively young patients with a history of syphilis and without other risk factors for cerebrovascular accidents.

Tabes Dorsalis

Tabes dorsalis, which appears to be far less common than in the prepenicillin era, is a slowly progressive, degenerative disease that involves the posterior columns and posterior roots of the spinal cord and results in progressive loss of peripheral reflexes, impairment of vibration and position sense, and progressive ataxia. Sensory changes may lead to chronic destructive changes in the large joints of the affected limbs in advanced cases (i.e., Charcot's joints). Incontinence of the bladder and impotence are common. Sudden and severely painful crises of uncertain origin are a characteristic part of the syndrome. Severe, sharp abdominal pain may lead to exploratory surgery.

Optic atrophy is seen in 20% of cases. In 90% of patients, the pupils are bilaterally small and fail to constrict further in response to light, but they do respond normally to accommodation (i.e., Argyll Robertson pupils).

The onset of tabes dorsalis is usually first noticed 20 to 30 years after the initial infection. Its cause is unclear, and spirochetes cannot be demonstrated in the posterior column or dorsal root.

General Paresis

This form of neurosyphilis is a chronic meningoencephalitis resulting in the gradual and progressive loss of cortical function. It typically occurs 10 to 20 years after the initial infection. On pathologic examination, there is a perivascular and meningeal chronic inflammatory reaction, with thickening of the meninges, granular ependymitis, degeneration of the cortical parenchyma, and abundant spirochetes in tissues.

In its early stages, general paresis results in nonspecific symptoms of early dementia, such as irritability, fatigability, headaches, forgetfulness, and personality changes. Later, there is impaired memory, defective judgment, lack of insight, confusion, and often depression or marked elation. Patients may be delusional, and seizures sometimes occur. There may also be loss of other cortical functions, including paralysis or aphasia.

Physical signs are primarily those of the altered mental status. Cranial nerve palsies are uncommon, and optic atrophy is rare. The complete Argyll Robertson pupil is also uncommon, but irregular or otherwise abnormal pupils are not infrequent. Peripheral reflexes are often somewhat increased.

Syphilis-HIV Interactions

Syphilis, like other genital ulcer diseases, is associated with a three- to fivefold increased risk for acquisition of HIV infection. Presumably, genital ulcers act as portals of entry through which HIV may more readily infect exposed individuals. As a result, HIV serologic testing 3 months after a diagnosis of syphilis is recommended for all patients. Conversely, in individuals with HIV infection who acquire syphilis, the natural history of the infection may be modified. HIV-infected syphilis patients are somewhat more likely than non–HIV-infected patients to present initially with secondary syphilis. HIV-infected secondary syphilis patients are also more likely than HIV-negative secondary syphilis patients to have coexistent chancres, suggesting that the healing of chancres is delayed or the appearance of secondary manifestations is accelerated in the presence of HIV coinfection.

Congenital Syphilis

Congenital syphilis results from the transplacental, hematogenous spread of syphilis from the mother to the fetus. In 2012, 322 cases of congenital syphilis were reported in the United States. A serologic test for syphilis should be performed in all expectant mothers at the beginning of pregnancy and should be repeated near the end of pregnancy in women living in areas where syphilis is relatively common.[7]

The risk for fetal infection is greatest in the early stages of untreated maternal syphilis and declines slowly thereafter, but the untreated mother can infect her fetus during at least the first 5 years of her infection. Adequate treatment of the mother before the 16th week of pregnancy usually prevents clinical illness in the neonate. Later treatment may not prevent late sequelae of the disease in the child. Untreated maternal infection may result in stillbirth, neonatal death, prematurity, or syndromes of early or late congenital syphilis in surviving infants.

Manifestations of early congenital syphilis are often seen in the perinatal period but may not develop until the infant has been discharged from the hospital. The disease resembles secondary syphilis in adults, except that the rash may be vesicular or bullous. The child often has rhinitis, hepatosplenomegaly, hemolytic anemia, jaundice, and pseudoparalysis (i.e., immobility of one or more extremities) as a result of painful osteochondritis.

Late congenital syphilis is defined as congenital syphilis diagnosed more than 2 years after birth. The disease may remain latent, with no manifestations of late damage. Cardiovascular alterations have not been observed in patients with congenital syphilis. Neurologic manifestations are common and may include eighth cranial nerve deafness and interstitial keratitis. Periostitis may result in prominent frontal bones of the skull, depression of the bridge of the nose (saddle nose), poor development of the maxilla, and anterior bowing of the tibia (saber shins). There may be late-onset arthritis of the knees (Clutton's joints). The permanent dentition may show characteristic abnormalities known as Hutchinson's teeth; the upper central incisors are widely spaced, centrally notched, and tapered in the manner of a screwdriver. The molars may show multiple poorly developed cusps (mulberry molars).

DIAGNOSIS

Dark-Field Examination

The most definitive means of syphilis diagnosis is finding typical spirochetes in lesions of early acquired or congenital syphilis. Dark-field examination is often positive in cases of primary syphilis and in patients with the moist mucosal lesions of secondary and congenital syphilis. The result may occasionally be positive for aspirates of lymph nodes in secondary syphilis. False-negative results may occur in primary syphilis because of the application of soaps, antiseptics, or other compounds toxic to *T. pallidum* to the lesions. A single negative result is therefore insufficient to exclude syphilis. For high-risk individuals (e.g., drug users, homosexually active men), it is appropriate to treat presumptively on the basis of suspicious lesions after performing serologic tests. Confusion may also arise because of the presence of spirochetes that are morphologically indistinguishable from *T. pallidum* organisms in the mouth, particularly around the gingival margins. Living *T. pallidum* organisms demonstrate gradual motion to and fro, rotational movement around the long axis, and rather sudden 90-degree flexing near the center of the organism. Because most physicians do not have the proper equipment and are not familiar with dark-field microscopy techniques, public health authorities can

be called for assistance. *T. pallidum* may also be demonstrated in biopsy or pathologic specimens by fluorescent antibody stains or by silver stains.

Serologic Tests

Two basic types of serologic tests (Table 319-2) are widely used to diagnose infection with *T. pallidum:* (1) nontreponemal tests that detect antibodies reactive with diphosphatidylglycerol (cardiolipin), which is a normal component of many tissues; and (2) tests that detect antibodies to specific treponemal antigens.

Nontreponemal Tests

The standard tests to detect anticardiolipin antibody are the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests, which are slide flocculation tests. The RPR and VDRL are readily quantified, so they are the tests of choice for monitoring patients' responses to treatment. The relative proportion of patients with a false-positive RPR result depends on the prevalence of syphilis in the community; the lower the prevalence of syphilis, the higher the proportion of reactive RPR test results from nonsyphilitic causes.

The RPR test result begins to turn positive less than 1 week after onset of the chancre; thus, a nonreactive RPR test result does not exclude primary syphilis, particularly if the lesion is less than 1 week old. The RPR test result is positive in 99% of patients with secondary syphilis (Table 319-3). Patients with advanced HIV infection may have negative test results, and some patients have such high titers of antibody that they are in antibody excess; dilution of their serum paradoxically results in conversion of a negative test result to a positive one, the so-called prozone reaction. RPR reactivity tends to diminish in later stages of syphilis, and only about 70% of patients with cardiovascular syphilis or late neurosyphilis have positive RPR test results.

The *quantitative titer* of the RPR or VDRL test is somewhat useful in diagnosis and is quite useful for monitoring of the therapeutic response. Most patients with secondary syphilis have titers of at least 1 : 16. Most patients with false-positive RPR test results have titers of less than 1 : 8. No single titer is diagnostic by itself. Significant rises (four-fold or greater) in paired sera, however, strongly indicate acute syphilis.

Treponemal Tests

Several types of treponemal tests are widely used. Recently, treponemal enzyme immunoassays (EIAs) using cloned treponemal antigens for treponemal antibody detection have become available from several manufacturers and have gained favor because of their low cost and ease of use. In addition to EIA tests, agglutination of particles to which *T. pallidum* antigens have been fixed is the basis of the widely used *T. pallidum* particle agglutination (TP-PA) test. The fluorescent treponemal antibody absorption (FTA-ABS) test has been widely used as well and is reported in terms of relative brilliance of fluorescence, from borderline to 4 plus; most laboratories report only test results with 2 plus or greater reactivity as positive. For patients lacking historical or clinical evidence of syphilis but with a reactive FTA-ABS test result, the test should be repeated. Use of another treponemal test may be helpful in problem cases. The TP-PA test is slightly less sensitive than the RPR or FTA-ABS test in primary syphilis. Its sensitivity and specificity are otherwise nearly identical to those of the FTA-ABS test.

Because EIA serologic tests permit the screening of large numbers of sera and have performance characteristics (sensitivity, specificity, predictive values) similar to those of other treponemal tests, they have been increasingly used recently for syphilis screening.[8,9] Persons with reactive treponemal antigen EIAs should be tested with a quantitative nontreponemal test, such as the RPR or VDRL test, for confirmation and to permit the use of that test to evaluate the subsequent response to therapy. It is not unusual for patients to have a reactive EIA test result for syphilis and a nonreactive RPR or VDRL test result. A substantial proportion of these EIA-only positive test results are falsely positive or are detecting long-standing, often previously treated syphilis, but occasionally they may detect very recent infection before RPR or VDRL test results become positive.

When nontreponemal tests such as the RPR and VDRL are used for screening, treponemal tests are used to confirm that persons with reactive nontreponemal test results have antibodies to *T. pallidum.* Results of treponemal tests are not reliably quantified. They are sensitive and have a high degree of specificity, in that only approximately 1% of normal individuals have reactive treponemal test results. They are reactive in 85% of patients with primary syphilis, 99% with secondary syphilis, and at least 95% with late syphilis. They may therefore be the only test with a positive result in patients with cardiovascular or neurologic syphilis. For patients with late syphilis, treponemal test results often remain reactive for life, despite adequate therapy.

TABLE 319-2 SEROLOGIC TESTS FOR SYPHILIS

TYPE	USE
NONTREPONEMAL (ANTICARDIOLIPIN) ANTIBODIES	
VDRL (slide flocculation)	Screening, quantitation of response to treatment
RPR (circle card) (agglutination)	Screening, quantitation of response to treatment
SPECIFIC TREPONEMAL ANTIBODIES	
FTA-ABS (immunofluorescence with absorbed serum)	Confirmatory, diagnostic; not for routine screening
TP-PA (microhemagglutination)	Similar to FTA-ABS but can be quantified and automated
EIA	Confirmatory and increasingly used for screening; automated

EIA = enzyme immunoassay; FTA-ABS = fluorescent treponemal antibody absorption test; RPR = rapid plasma regain test; TP-PA = *Treponema pallidum* particle agglutination; VDRL = Venereal Disease Research Laboratory.

TABLE 319-3 FREQUENCY OF POSITIVE SEROLOGIC TEST RESULTS IN UNTREATED SYPHILIS

STAGE	VDRL (%)	FTA-ABS (%)	TP-PA (%)
Primary	70	85	50-60
Secondary	99	100	100
Latent or late	70	98	98

FTA-ABS = fluorescent treponemal antibody absorption test; TP-PA = *Treponema pallidum* particle agglutination; VDRL = Venereal Disease Research Laboratory.

Differential Diagnosis

The differential diagnosis of a genital ulcer (Chapter 285) includes genital herpes (Chapter 374), chancroid (Chapter 301), lymphogranuloma venereum (Chapter 318), and a number of other ulcerative processes. Classically, herpetic ulcers are multiple, painful, superficial, and, if seen early, vesicular. However, atypical manifestations may be indistinguishable from a syphilitic chancre. Genital herpes is much more common than syphilis and is now the most common cause of a "typical chancre" in North America. Syphilitic chancres may also be coinfected with herpes simplex virus in about 15% of cases. The ulcers of chancroid are usually painful, often multiple, and frequently exudative and nonindurated. Lymphogranuloma venereum may produce a small, papular lesion associated with regional adenopathy. Other conditions that must be distinguished include granuloma inguinale (Chapter 316), drug eruptions, carcinoma, superficial fungal infections (Chapter 438), traumatic lesions, and lichen planus (Chapter 438). In most cases, the final distinction is based on dark-field examination, which is positive only in syphilis, and on serologic test results.

The differential diagnosis of the skin lesions of secondary syphilis includes pityriasis rosea (Chapter 438), which can be differentiated by the occurrence of lesions along lines of skin cleavage and frequently by the presence of a herald patch. Drug eruptions, acute febrile exanthems, psoriasis, lichen planus, scabies, and other diseases must also be considered in some cases. A mucous patch may superficially resemble oral candidiasis (i.e., thrush). Infectious mononucleosis (Chapter 377) may appear similar to secondary syphilis, with sore throat, generalized adenopathy, hepatitis, and a generalized rash. Hepatitis (Chapter 148) may also cause confusion.

False-Positive Serologic Test Results for Syphilis

The RPR or VDRL test result is reactive in patients with other treponemal diseases, such as pinta, yaws, and endemic syphilis (Chapter 320). These test results may also be falsely reactive in persons who do not have treponemal infections based on a negative clinical history or negative results of serum treponemal tests.[10]

The origins of false-positive results are better studied for nontreponemal tests than for treponemal tests. Acute (<6 months) false-positive RPR test results occur with low frequency in patients with atypical pneumonia, malaria,

and other bacterial or viral infections, and they may occur after smallpox or other vaccinations as well. Chronic false-positive RPR test results (persisting >6 months) are relatively common in patients with autoimmune disorders such as systemic lupus erythematosus (Chapter 266), parenteral drug users, HIV-infected patients, patients with leprosy, and the aged. Between 8 and 20% of patients with systemic lupus erythematosus have false-positive RPR test results. Chronic false-positive RPR test results in female patients 20 years or younger indicate a significant risk for the future development of systemic lupus erythematosus, thyroiditis, or other autoimmune disorders. As many as a third of parenteral drug users have false-positive RPR test results. More than 1% of persons 70 years old and 10% of those older than 80 years also have low-titer, false-positive RPR test results. In most cases of false-positive RPR test results, the titer is less than 1 : 8, although a few patients with lymphoma and other diseases have very high-titer, false-positive results.

There is also an increased incidence of false-positive treponemal test results in other chronic inflammatory diseases associated with hyperglobulinemia, including rheumatoid arthritis and biliary cirrhosis. On occasion, reproducible positive FTA-ABS results are obtained in patients with no clinical or historical evidence of syphilis and no evidence of diseases typically associated with false-positive FTA-ABS results. If the diagnosis is in doubt and if the patient is not allergic to penicillin, it is often prudent to treat for possible syphilis.

Neurosyphilis

Asymptomatic neurosyphilis is diagnosed when there are CSF abnormalities, such as lymphocytic pleocytosis, protein elevation, or a reactive VDRL test result, in a syphilis patient in the absence of signs and symptoms of neurologic disease. Unlike serologic tests, the VDRL and RPR tests do not perform equally for CSF, and only the VDRL is recommended. Although numerous other processes can cause CSF pleocytosis or protein elevations, false-positive CSF VDRL test results are rare in the absence of a traumatic tap. If the CSF is normal 2 years or longer after the initial infection, a positive CSF finding is not likely to develop later. Routine lumbar punctures to examine CSF are not indicated in early syphilis unless the patient is known to have HIV infection. Lumbar puncture in HIV-infected persons with early syphilis is the subject of controversy. Although a nonreactive CSF FTA-ABS result may be useful to rule out the diagnosis, no diagnosis of neurosyphilis should be based solely on the CSF FTA-ABS test.

In syphilitic meningitis, the CSF shows a lymphocytic pleocytosis, with increased protein and usually normal glucose concentrations. The CSF VDRL test is nearly always reactive. Rarely, the CSF glucose concentration is decreased. Without treatment, syphilitic meningitis generally resolves, similar to the course of other manifestations of early syphilis. This syndrome can mimic tuberculous or fungal meningitis or nonpurulent meningitis of various causes.

In tabes dorsalis, the VDRL test for serum is nonreactive in as many as 30 to 40% of patients, and 10 to 20% of patients (even before the advent of penicillin) have normal CSF VDRL results. The FTA-ABS test for serum is nearly always reactive. In general paresis, the CSF is nearly always abnormal, with lymphocytic pleocytosis and an increased total protein concentration. The VDRL test is usually reactive for CSF and serum.

Congenital Syphilis

Because many infants with congenital syphilis may be clinically normal at birth but develop serious, symptomatic disease some weeks later, it is important to determine whether a newborn with a reactive serologic test result for syphilis has passively transferred maternal antibody or is actively infected. If the mother has been adequately treated for syphilis during pregnancy and the infant is clinically normal at birth, one option is to monitor the infant carefully by serial examinations and RPR titers. If the reactive RPR result for the infant is caused by passively transferred maternal antibody, the titer will fall markedly in the first 2 months of life; a rising titer indicates active disease and the need for treatment. However, the risk of improper follow-up of RPR-positive but clinically normal neonates makes the immediate empirical administration of effective therapy an attractive alternative.

TREATMENT

Rx

T. pallidum is inhibited by less than 0.01 μg/mL of penicillin G. Because treponemes divide slowly and penicillin acts only on dividing cells, it is necessary to maintain serum levels of penicillin for many days (Table 319-4).

Early Infectious Syphilis

Early syphilis (<1 year) can be treated with a single injection of 2.4 million units of benzathine penicillin G, which provides low but effective serum levels for about 2 weeks and cures approximately 95% of patients.[11] It is not necessary to examine CSF at this stage because penicillin prevents the later development of neurosyphilis.[12]

Individuals with other sexually transmitted diseases may have been exposed to syphilis at the time they became infected. Treatment with a single dose of β-lactam antibiotics (penicillins, cephalosporins), which provide relatively high serum levels for a brief period, is ineffective in established early syphilis but is curative if the disease is still in the incubating stage. The ceftriaxone regimen used for gonorrhea (Chapter 299) is probably curative for incubating syphilis, but careful follow-up is indicated if there is reason to suspect exposure to syphilis in a patient treated for gonorrhea with ceftriaxone. Single-dose therapy with 2.0 g of azithromycin administered orally was as effective as benzathine penicillin therapy in several studies of early syphilis,[13] but treatment failures have been reported in persons with coexistent HIV infection. Currently, azithromycin should not be used for the treatment of early syphilis unless close follow-up can be ensured.

For patients allergic to penicillin, 100 mg of doxycycline orally twice daily for 14 days is recommended. Particularly careful follow-up is necessary for patients treated with drugs other than penicillin because they may not be fully compliant with these prolonged courses of oral therapy and these regimens have been less fully evaluated clinically. Ceftriaxone, given in doses of 500 mg to 1.0 g intramuscularly daily for 10 days, may be effective but has been studied only in small numbers of patients with syphilis. Quinolone antibiotics have essentially no effect on syphilis.

Syphilis of More than 1 Year in Duration

Prolonged therapy with intramuscular injections of 2.4 million units of benzathine penicillin G weekly for 3 weeks is recommended for the treatment of late latent syphilis and latent syphilis of unknown duration. Limited evidence suggests that treatment of latent syphilis with a total dose of 7.2 million units of benzathine penicillin during a 3-week period is curative, even if the patient has asymptomatic neurosyphilis. However, because of the possible lack of efficacy of benzathine penicillin G in some patients with CNS syphilis, CSF examination should be considered in those with latent syphilis to exclude asymptomatic neurosyphilis, particularly in HIV-positive patients, in whom the prevalence of asymptomatic neurosyphilis is higher. Alternatively, a lumbar puncture can be performed at the conclusion of the follow-up period (2 years); if the CSF is normal, the patient can be reassured that neurosyphilis will not develop.

Larger doses of penicillin are recommended for persons with proven neurosyphilis (see Table 319-4). General paresis responds well to penicillin therapy if it is administered early, although progressive neurologic decline may develop later in as many as a third of treated patients. Carbamazepine in doses of 400 to 800 mg/day reportedly treats the lightning pains of tabes dorsalis effectively. Published studies show that a total of 6.0 to 9.0 million units of penicillin G results in a satisfactory clinical response in approximately 90% of patients with neurosyphilis who do not have HIV infection. There are anecdotal reports of increased treatment failures in patients with concomitant HIV infection, and there is considerable rationale to treat these patients with intravenous penicillin G (20 million units/day for at least 10 days). Therapy for neurosyphilis can result in increased CSF pleocytosis for 7 to 10 days after treatment is started and may transiently convert a normal CSF to abnormal.

Although there is no evidence that therapy with antimicrobial drugs is clinically beneficial in patients with cardiovascular syphilis, treatment is recommended to prevent further progression of disease and because approximately 15% of patients with cardiovascular syphilis have associated neurosyphilis. If patients are allergic to penicillin, it is mandatory that the CSF be examined before therapy is undertaken; if the CSF is abnormal, desensitization to penicillin is generally recommended. With a normal CSF, tetracycline (500 mg orally four times a day) or doxycycline (100 mg orally two times a day) taken for 4 weeks is probably effective.

Syphilis in Pregnancy

Because of the risk to the fetus, evaluation and treatment of a pregnant RPR-positive patient must be rapid, particularly for those patients first seen in the later stages of pregnancy. If a confirmatory treponemal test result is positive and the patient has not been treated, penicillin should be administered in doses appropriate for early or late syphilis, as outlined earlier. For penicillin-allergic patients, penicillin desensitization is preferred; patients should not be treated with tetracycline or erythromycin because of toxicity (tetracycline) or lack of efficacy (erythromycin). For patients who are RPR positive but treponemal test negative and have no clinical signs of syphilis, treatment may be withheld; a quantitative RPR test and another treponemal test should be repeated in 4 weeks. If the treponemal titer has risen four-fold or more, or if clinical signs of syphilis have developed, the patient should be treated. If, after repeated examination, the diagnosis remains equivocal, the patient should be

TABLE 319-4 PENICILLIN TREATMENT FOR SYPHILIS AS RECOMMENDED BY THE U.S. PUBLIC HEALTH SERVICE

INDICATIONS FOR SYPHILIS THERAPY*	DOSAGE AND ADMINISTRATION†	
	Benzathine Penicillin G	*Aqueous Benzylpenicillin G or Procaine Penicillin G*
Primary, secondary, and early latent syphilis (<1 year); epidemiologic treatment	Total of 2.4 million units; single IM dose of two injections of 1.2 million units in one session	Total of 4.8 million units IM in doses of 600,000 units/day for 8 consecutive days
Late latent (>1 year) or when CSF was not examined in "latency"; cardiovascular syphilis, late benign (cutaneous, osseous, visceral gumma)	Total of 7.2 million units IM in doses of 2.4 million units at 7-day intervals during a 21-day period	Total of 9 million units IM in doses of 600,000 units/day during a 15-day period
Symptomatic or asymptomatic neurosyphilis	2-4 million units aqueous (crystalline) penicillin G IV q4h for at least 10 days	2-4 million units procaine penicillin IM daily and probenecid 500 mg orally four times daily, for 10-14 days
Congenital		
Infants	CSF normal: total of 50,000 units/kg IM in a single or divided dose at one session	CSF abnormal: total of 50,000 units/kg/day IM for 10 consecutive days‡
Older children	CSF normal: same as for early congenital syphilis, up to 2.4 million units	CSF abnormal: 200,000-300,000 units/kg/day aqueous crystalline penicillin IV for 10-14 days

*In *pregnancy,* treatment depends on the stage of syphilis.
†Individual doses can be divided for injection in each buttock to minimize discomfort.
‡For aqueous penicillin, give in two divided intravenous doses per day; for procaine penicillin, give as one daily dose intramuscularly.
CSF = cerebrospinal fluid.

treated to prevent possible disease in the neonate. After treatment, a quantitative RPR titer should be monitored monthly; if it rises four-fold, the patient should be treated a second time.

Congenital Syphilis

Proper treatment of the mother usually prevents active congenital syphilis in the neonate. However, infected infants may be clinically normal at birth, and the infant may be seronegative if the mother's infection was acquired late in pregnancy. The infant should be treated at birth if the mother has received no treatment or inadequate treatment or has been treated with drugs other than penicillin, if the mother has not yet responded to possibly effective therapy, or if the infant cannot be carefully monitored for several months after birth. The infant's CSF should be examined before treatment. If the CSF is normal, the child can be treated with a single intramuscular injection of 50,000 units/kg (up to 2.4 million units) of benzathine penicillin G. If the CSF is abnormal, the infant should be treated with 50,000 units/kg of aqueous penicillin G given intramuscularly or intravenously twice daily for a minimum of 10 days. Alternatively, a single daily intramuscular injection of 50,000 units/kg of procaine penicillin may be given for 10 days. Antimicrobial agents other than penicillin are not recommended for treatment of congenital syphilis.

Jarisch-Herxheimer Reactions

Up to 60% of patients with early syphilis and a significant proportion of patients with later stages of syphilis experience a transient febrile reaction after therapy for syphilis. The pathogenesis is unclear, but it may be caused by the liberation of antigens from spirochetes.

This reaction usually occurs in the first few hours after therapy, peaks at 6 to 8 hours, and disappears within 12 to 24 hours of therapy. On occasion, Jarisch-Herxheimer reactions are mistaken for allergic reactions to syphilis therapy. Temperature elevation is usually low grade, and there is often associated myalgia, headache, and malaise. The skin lesions of secondary syphilis are frequently exacerbated during the Jarisch-Herxheimer reaction, and cutaneous lesions that were not visible may become visible. The reaction is generally of no clinical significance and in most cases can be treated with salicylates. Corticosteroids have been used to prevent adverse effects of the Jarisch-Herxheimer reaction, but there is no evidence that they are clinically beneficial (other than reducing fever) or necessary. Institution of treatment with small doses of penicillin does not prevent the reaction.

PREVENTION

All patients with syphilis should be reported to public health authorities. In the absence of an effective vaccine, control of syphilis depends on finding and treating persons with infectious lesions of primary and secondary syphilis before they can transmit the disease as well as finding and treating individuals with incubating syphilis before infectious lesions develop. All patients with early syphilis (primary, secondary, or early latent) should be carefully interviewed by qualified persons to determine the nature of their recent sexual contacts. Approximately 16% of the named recent contacts of patients with early syphilis are found to have active, untreated syphilis on examination, and a similar proportion of individuals named as suspects or associates also have active syphilis.

Treatment of the sexual contacts of patients with early syphilis with 2.4 million units of benzathine penicillin G intramuscularly is recommended even if the contacts are clinically and serologically normal on examination. This is because syphilis eventually develops in 30% of clinically normal contacts who are untreated. In general, preventive treatment is given to all sexual contacts in the past 90 days, although nearly all cases of syphilis in contacts develop within 60 days of exposure.

PROGNOSIS

Follow-up Examinations

All HIV-seronegative patients with early or congenital syphilis should return for quantitative VDRL titers and clinical examination 6 and 12 months after treatment. For HIV-positive patients, serologic tests should be repeated at 1, 2, 3, 6, 9, and 12 months. Patients with late latent syphilis should also be examined 24 months after therapy.

In about 80 to 85% of patients with early (i.e., primary, secondary, or early latent) syphilis, quantitative RPR titers decline two or more dilutions (four-fold) by 6 and 12 months after therapy. In serofast patients, prolonged reactive RPR test results are associated with older age, lower initial RPR titers, prolonged infection, or more advanced stage (primary < secondary < early latent) infection.[13] Re-treatment of patients with serofast RPR results at 6 months leads to serologic response to syphilis in a minority of patients.[14] Chronic, low-titer RPR reactivity after therapy is much more common in cases of late syphilis and should not be viewed with alarm. Treponemal test results may remain positive for years despite adequate therapy. A four-fold or greater rise in RPR titer after therapy is sufficient evidence for repeated treatment. Patients with treated early syphilis are susceptible to reinfection, and many clinical and serologic relapses after therapy are probably reinfections. As such, they represent failures of proper epidemiologic case finding and preventive therapy for the patient's sexual contacts.

Patients with neurosyphilis should be monitored with serologic tests for at least 3 years and with repeated CSF examinations at 6-month intervals. CSF pleocytosis is the first abnormality to disappear, but cell counts may not be normal for 1 to 2 years. Elevated CSF protein levels fall even more slowly, followed by a change in the positive CSF VDRL test result, which may take years to become negative. It is not known whether high-dose intravenous penicillin therapy accelerates the return of CSF to normal. Rising CSF cell counts, protein level, and CSF VDRL titer obtained at follow-up are an indication for repeated treatment.

Antibiotic therapy should ultimately cure essentially all patients with early or secondary syphilis, although treatment failures may occur in patients with concomitant HIV infection. In tabes dorsalis, penicillin usually arrests progression but does not reverse the symptoms. Meningovascular syphilis generally responds well, except for residual damage resulting from ischemic infarcts.

REVIEW QUESTIONS

1. A 33-year-old man is referred to you after receipt of notification that a blood test result for syphilis performed at the time of a recent blood donation was positive. You learn that the test was a treponemal enzyme immunoassay (EIA). A rapid plasma reagin (RPR) test performed in follow-up was nonreactive. He reports being in a long-standing, mutually monogamous sexual relationship. Physical examination shows no evidence of syphilis. Possible explanations for his reactive EIA and nonreactive RPR syphilis test results are

A. Residual antibody reactivity after successful treatment of syphilis in the past
B. Previously undetected latent syphilis of unknown duration
C. A falsely positive test result
D. He has acquired syphilis so recently that his RPR test result is not yet positive
E. All of the above

Answer: E Results of recently developed treponemal antigen EIA tests for syphilis are not uncommonly positive while results of nontreponemal tests, such as the RPR and Venereal Disease Research Laboratory (VDRL) tests, are negative. In most settings (and in this patient), unless there is a history of prior treated syphilis, this typically reflects a falsely positive test result; more uncommonly, it could represent previously undetected latent syphilis or, very rarely, recently acquired syphilis before the development of a reactive RPR or VDRL test result (lesions of primary syphilis are typically present in these situations).

2. You are asked to recommend management for a 27-year-old woman with secondary syphilis who is midway through her second trimester of pregnancy. The patient has a well-documented history of penicillin allergy. The recommended therapy for this patient is

A. Doxycycline 100 mg twice daily for 14 days
B. Azithromycin 2.0 g orally as a single dose
C. Ceftriaxone 500 mg IM or IV once daily for 10 days
D. Penicillin desensitization followed by a single intramuscular injection of 2.4 million units of benzathine penicillin
E. Penicillin desensitization followed by two intramuscular injections of 2.4 million units of benzathine penicillin administered a week apart

Answer: D For treatment of syphilis in pregnancy, there are no recommended alternatives to penicillin for therapy. Doxycycline could cause dental staining in her child, and neither doxycycline nor azithromycin has been studied in this situation. As a result, pregnant, penicillin-allergic patients should be desensitized and treated as recommended for the stage of disease they have. There is no evidence that pregnant patients need treatment with higher doses or prolonged therapy.

3. In 2013, early syphilis was most common among minority groups and particularly common among

A. Persons who use illicit drugs, such as cocaine or heroin
B. Men who have sex with other men
C. Adolescents
D. Commercial sex workers
E. Heterosexuals in monogamous relationships

Answer: B During the past 50 years, the epidemiology of syphilis has periodically shifted. Following an epidemic of syphilis in heterosexual men and women in the 1990s associated with a contemporary epidemic of crack cocaine use, the epidemiology of early syphilis again shifted. Since the beginning of the 21st century, syphilis in the United States has disproportionately occurred among men who have sex with men, including those infected with human immunodeficiency virus (HIV). As a result, annual (or more frequent, depending on sexual history) screening for syphilis is recommended for men who have sex with men and all persons with HIV infection.

4. A 34-year-old man with HIV infection well controlled by antiviral therapy presents with the acute onset of right-sided weakness. His CD4 lymphocyte count is 540/mm^3. In the course of his evaluation, he is found to have reactive RPR (positive at a 1 : 64 dilution) and *T. pallidum* particle agglutination (TP-PA) test results. Lumbar puncture reveals the following cerebrospinal fluid (CSF) findings: cell count, 32 cells (100% mononuclear); protein level, 54 mg/dL; glucose concentration, 63 mg/dL (simultaneous serum glucose concentration, 10 mg/dL); and a nonreactive CSF VDRL test response. The most likely diagnosis in this man is

A. Latent syphilis with CSF abnormalities attributable to his HIV infection
B. Meningovascular syphilis
C. Embolic stroke
D. Hypertensive stroke

Answer: B This patient is a member of a group at risk for acquisition of syphilis (HIV-infected men who have sex with other men), is relatively young to have atherosclerotic stroke, and has CSF abnormalities consistent with neurosyphilis. His RPR test result is consistent with active syphilis. The CSF VDRL test response is reactive in less than 70% of persons with neurosyphilis and need not be present for diagnosis of neurosyphilis. Whereas HIV infection can lead to elevations of CSF mononuclear cells, this rarely exceeds 20 cells unless other pathologic processes are present. Although other possibilities for stroke in relatively young persons should be considered, the most likely diagnosis in this man is meningovascular neurosyphilis.

5. A patient presents to you reporting that he was just notified that a casual sex partner he had sex with about 6 months ago was diagnosed with secondary syphilis shortly afterward. His exposures included multiple episodes of genital and oral intercourse. On physical examination, there is no clinical evidence of syphilis. At this point, in addition to serologic testing for syphilis, recommended management is

A. Preventive treatment with intramuscular injections of 2.4 million units of benzathine penicillin G
B. Serologic testing at this time and again 6 months in the future (treatment based on serologic test results)
C. Serologic testing at this time; no subsequent testing is needed (treatment based on serologic test results)
D. Reassurance that based on the fact that there is no history of lesions and his negative test results, there is no reason for concern and no further follow-up or treatment is needed

Answer: C Because lesions of syphilis may be painless and subtle, serologic testing is recommended for all persons reporting exposure to a partner with syphilis. Preventive penicillin is recommended treatment for persons exposed to sex partners within the preceding 90 days. In this patient, the exposure was 6 months ago, so only serologic testing is recommended. There is no need for treatment if the serologic test result for syphilis is negative and no need for testing beyond this time.

320 NONSYPHILITIC TREPONEMATOSES

EDWARD W. HOOK III

DEFINITION

The nonsyphilitic treponematoses—yaws, endemic syphilis (previously known as bejel), and pinta—are the spirochetal diseases caused by *Treponema pallidum* subspecies (yaws and endemic syphilis) or by the closely related organism *Treponema carateum* (pinta). Like syphilis, the nonsyphilitic treponematoses are usually transmitted through direct contact with an infectious cutaneous or mucosal lesion. The natural history of the nonsyphilitic treponematoses also has a number of similarities to that of syphilis (Chapter 319).

The Pathogen

Yaws is caused by *T. pallidum* subspecies *pertenue*, endemic syphilis is caused by *T. pallidum* subspecies *endemicum*, and pinta is caused by *T. carateum*. The *T. pallidum* subspecies causing nonsyphilitic treponematoses are closely related to *T. pallidum* subspecies *pallidum*, which causes venereal syphilis; there is a high degree (more than 99%) of DNA homology, and they share unique pathogen-restricted antigens.[1] Analyses of recently described genetic sequence variations among *T. pallidum* subspecies promise the eventual clarification of pathophysiologic differences among the subspecies as well as answers to the age-old question of the origins of syphilis. Like *T. pallidum*, these treponemes are spirochetal bacteria with helical structures and measure about 0.2 µm in diameter and 10 µm in length. They are visible by dark-field microscopy but cannot be cultivated for prolonged periods in vitro.

EPIDEMIOLOGY

Worldwide, the nonsyphilitic treponematoses are rare. However, rates are increasing (particularly for yaws) in some regions where previous World Health Organization (WHO)–coordinated control programs had dramatically reduced disease prevalence. Yaws is prevalent in moist, humid regions, including rural areas of tropical Africa, the Americas, Southeast Asia, and Oceania. The highest incidence occurs in children between 2 and 5 years of age. Endemic syphilis occurs in more arid climates, including Africa, eastern Mediterranean countries, the Arabian peninsula, central Asia, and Australia. Pinta occurs in rural areas of tropical Central and South America and affects mostly older children and adolescents. Humans are the only known carriers of the nonsyphilitic treponematoses, although *T. pallidum* strains associated with genital lesions have recently been described in African baboons, potentially providing a clue to the origin of human treponemal infections, including syphilis.[2] The spirochete enters the skin only after it is broken, such as by a scratch or an insect bite. Transmission is believed to occur by contact of the skin directly or by indirect contamination through hands or fomites; it is facilitated by conditions of poor personal hygiene and crowding.

PATHOBIOLOGY

Primary nodular or ulcerative lesions typically develop at sites of inoculation after an incubation period of several weeks. Untreated primary lesions serve as a source for local spread through scratching or for hematogenous dissemination, which gives rise to a secondary stage of infection characterized by the development of widespread manifestations involving the skin, lymph nodes, and bone or cartilage. Without therapy, the primary and secondary manifestations of infection resolve, and the infection becomes latent, detectable only with serologic testing; however, periodic recurrent secondary manifestations may occur for several years. A proportion of persons with long-standing untreated infection are at risk for late sequelae, which may include bone deformity, destruction of nasal cartilage, or chronic skin changes. Unlike syphilis, the nonsyphilitic treponematoses are primarily diseases of children, are not transmitted across the placenta, and do not invade the central nervous system to cause clinical disease.

CLINICAL MANIFESTATIONS

Yaws,[3] the most common nonsyphilitic treponematosis, produces a skin papule at the inoculation site after an incubation period of 3 to 4 weeks. The most common sites are the legs and buttocks. The papule enlarges, ulcerates, and forms a serous crust from which treponemes can be recovered. Regional lymphadenitis may accompany the papule, which heals spontaneously within 6 months. A generalized secondary rash occurs before or after the initial lesion heals; this rash is also papular and is often covered with brown crusts. Relapsing crops of lesions can occur. Papillomas may result, and the plantar surfaces of the feet are involved with hyperkeratotic lesions. Periostitis of the long bones leads to tenderness, and fever may be present. Relapsing lesions of early yaws may occur during a period of several years and result in chronic ulcerations and destructive gummatous lesions affecting the skin and bones.

Endemic syphilis produces patches on the mucous membranes of the oral cavity and pharynx and can cause split papules at the mucocutaneous junction of the oral angles. Anal, genital, and other intertriginous skin areas can be affected by lesions that resemble secondary syphilis. Regional lymphadenitis is common, and generalized rashes are rare. Healing of these early lesions is followed by latency, manifested as seropositivity, or by late lesions that resemble gummatous tertiary syphilis (Chapter 319). Lesions include nodular skin ulcers, bone deformities, and ulcerative lesions that can perforate the palate.

Pinta starts similarly as a cutaneous papule with regional lymphadenitis, followed by a generalized maculopapular eruption. One to 3 years after healing of the initial lesion, large hyperpigmented brown or blue macules develop; they subsequently lose their pigment and become white. The time required for lesions to pass through these stages varies, so the same patient may have coexisting areas of increased pigment and loss of pigment.

DIAGNOSIS

The clinical differentiation of the nonsyphilitic treponematoses from one another and from syphilis may be challenging, requiring the integration of epidemiologic features, clinical findings, and supportive but not diagnostic laboratory test results. The skin lesions of the endemic treponematoses may resemble other cutaneous processes, including impetigo (Chapter 439), scabies, cutaneous fungal infections (Chapter 438), and other diseases. By dark-field microscopy, the causative spirochetes from early skin lesions can be observed directly; however, dark-field microscopy is rarely available in settings where nonsyphilitic treponematoses are seen. There is no specific test for any of the nonsyphilitic treponematoses, but serologic tests for syphilis detect cross-reacting antibodies in these diseases. The rapid plasma reagin (RPR) test, the Venereal Disease Research Laboratory (VDRL) test, and the fluorescent treponemal antibody absorption (FTA-ABS) test as well as other specific treponemal tests give positive results if serum is obtained at least 2 weeks after the lesions initially appear.

PREVENTION

The prevalence of these diseases was reduced dramatically in the 1950s by mass penicillin treatment campaigns. The WHO campaign treated about 53 million cases of yaws and 350,000 cases of pinta in the 1950s, with good results. These campaigns, however, were not adequate to eradicate the disease, and in recent years, the prevalence of yaws has increased, with foci of infection now reported in sub-Saharan Africa, several Pacific islands including Indonesia, and the Amazon region of South America. Current estimates are that as many as 2.5 million persons are infected worldwide, 75% of whom are younger than 15 years. Whereas penicillin is effective for both treatment and prevention of infection, requirements for cold chain transport, parenteral administration, and allergies sometimes compromise the utility of the drug.

Recent studies demonstrating the efficacy of single-dose oral azithromycin have expanded practical intervention strategies and led to renewed emphasis on yaws eradication by the WHO with targeted mass therapy.[4]

TREATMENT AND PROGNOSIS

Rx

Single-dose, long-acting benzathine penicillin G, 1.2 million units intramuscularly, has been the preferred treatment in patients with early lesions. For patients with late manifestations, this therapy should be repeated twice at approximately 7-day intervals. The early lesions heal rapidly, and most seropositive cases convert to seronegative status. Late destructive lesions take longer to show improvement. A randomized trial demonstrated oral azithromycin, 30 mg/kg up to a maximal dose of 2.0 g, to be as effective as penicillin for yaws therapy, providing the first readily administered, single-dose alternative to penicillin for treatment and prevention of nonsyphilitic treponematoses.

REVIEW QUESTIONS

1. Nonsyphilitic treponematoses can be differentiated from syphilis by

A. Serologic testing
B. Response to therapy
C. Clinical and epidemiologic characteristics
D. Dark-field microscopy

Answer: C Traditionally, the human treponematoses have been differentiated on the basis of their clinical manifestations and epidemiologic characteristics because the etiologic agents are indistinguishable in the laboratory. They all respond to penicillin therapy.

2. The clinical course of untreated nonsyphilitic treponematoses is characterized by

A. Lesions at the site of inoculation that resolve without therapy
B. Risk for congenital transmission
C. Risk for central nervous system disease
D. Uniform progression to chronic, deforming disease in all untreated persons

Answer: A Unlike syphilis, the nonsyphilitic treponematoses are not transmitted across the placenta and do not invade the central nervous system to cause clinical disease. Only a proportion of individuals with long-standing untreated infection are at risk for late sequelae like bone deformities, nasal cartilage destruction, or chronic skin changes.

321

LYME DISEASE

GARY P. WORMSER

DEFINITION

Lyme disease (also known as Lyme borreliosis) is a zoonotic infection that is transmitted by certain *Ixodes* tick species and caused by a group of related spirochetes referred to formally as *Borrelia burgdorferi* sensu lato, or more simply as Lyme borrelia.[1] Lyme disease was first described in 1977 after an investigation of a cluster of cases of arthritis among children living in the area of Lyme, Connecticut. With more than 25,000 cases reported annually, it is the most common vector-borne infection in the United States; Lyme disease is also an infection of public health importance in both Europe and Asia. The most common clinical manifestation is a characteristic skin lesion called erythema migrans. This lesion is a result of inflammation associated with the centrifugal spread of the spirochete within the skin from the site where the tick deposited the microorganism. The spirochete may also spread hematogenously to other skin locations, resulting in secondary erythema migrans skin lesions, or to non-skin sites, such as the joints, nervous system, or heart, leading to a variety of extracutaneous clinical manifestations.[2]

The Pathogen

In the United States, the only species of Lyme borrelia known to cause human infection is *B. burgdorferi* (also referred to as *B. burgdorferi* sensu stricto). Although *B. burgdorferi* also causes Lyme disease in Europe, collectively other species of Lyme borrelia that can be distinguished genotypically account for the majority of infections there, especially *Borrelia afzelii* and *Borrelia garinii*. The fact that at least six species of Lyme borrelia may cause infection in Europe has created serodiagnostic challenges and accounts for a wider variety of possible clinical manifestations there than in the United States (see later). *B. garinii* appears to be the most neurotropic and *B. burgdorferi* the most arthritogenic among the species of Lyme borrelia.

Lyme borrelia are motile, microaerophilic, spirochetal bacteria with 3 to 10 loose coils arranged in a helical shape. The cells are 10 to 30 µm in length and 0.2 to 0.5 µm in width and contain at least seven periplasmic flagella that are responsible for the organism's motility. Borrelia are too thin to be seen by Gram stain, but live organisms can be visualized by dark-field or phase contrast microscopy. In tissues, they can be recognized by light microscopy after application of silver stains or by fluorescent microscopic methods. *B. burgdorferi* was the first spirochete for which the complete genome was sequenced. Genetic studies suggest the nearly complete absence of biosynthetic pathways, making the microorganism dependent on its environment for nutritional requirements.[3] Lyme borrelia can be grown in vitro in a highly enriched culture medium.

EPIDEMIOLOGY

In the United States, more than 95% of cases of Lyme disease are concentrated in just 14 states: 12 eastern states and two in the North Central region. The states with the largest number of cases are Pennsylvania, Massachusetts, New York, New Jersey, and Connecticut. *Ixodes scapularis* (also known as the deer tick or black-legged tick) is the tick vector in these states. *Ixodes pacificus* is the vector for cases that occur in the Northwest region. Lyme disease also occurs in limited areas of Canada. Cases of Lyme disease occur throughout the temperate regions of Europe and are especially common in Scandinavia and countries of central Europe such as Slovenia, Austria, and Germany. *Ixodes ricinus* transmits the infection in Europe, and *Ixodes persulcatus* is the vector in the Asian region of Russia, China, and Japan.

The principal reservoirs for Lyme borrelia (i.e., source of infection for ticks) in the United States and Eurasia are small mammals such as mice and certain species of birds. Deer play an essential role in the life cycle of the *I. scapularis* tick species but are not a competent reservoir for *B. burgdorferi.*

Although Lyme borrelia exist in enzootic cycles in the southern United States, cases of Lyme disease arising indigenously have not been well documented in states south of Virginia. A skin lesion that resembles erythema migrans does occur in the southern United States, however, but it is associated with the bite of the *Amblyomma americanum* tick, a tick species that is not a competent vector for *B. burgdorferi*. This condition is of unknown etiology and is referred to as southern tick-associated rash illness (STARI).

The likelihood of acquiring Lyme disease is directly related to exposure to environments in which infected ticks are present. Of the three feeding stages in the life cycle of *I. scapularis*, the second or nymphal stage is the most important epidemiologically for transmission of infection to humans. The first or larval stage is uninfected and cannot transmit this infection. Although the third stage (i.e., the adult stage of the tick) is more likely to be infected with *B. burgdorferi* than the nymphal stage is, it is less important in transmission to humans because this stage is present in smaller numbers in the environment and because there is less human activity outdoors during the time periods in the spring and fall when this stage is seeking a blood meal. In addition, adult ticks are larger and their bites cause more skin irritation than bites of nymphal ticks do, thereby increasing the likelihood that they will be noticed and detached by a person who has been bitten. If they are not removed, *Ixodes* ticks will usually feed for at least 3 days (Fig. 321-1). Transmission of *B. burgdorferi* by *I. scapularis* or *I. pacificus* ticks is typically delayed for more than 36 hours from the start of the blood meal, providing the opportunity to prevent infection simply by finding and removing the tick.[4] Transmission of *B. afzelii* by the European tick *I. ricinus* is considerably faster, however, often occurring within the first 24 hours of feeding.

Most cases of erythema migrans in the United States occur during June through August. There is a bimodal age distribution, with the highest incidences in children 5 to 9 years old and in adults 45 to 54 years of age, but individuals of all ages are at risk. The reported incidence of Lyme disease in the United States is rising, partially as a result of expansion of the deer population and the spread of infected *I. scapularis* ticks to new geographic areas.

Extracutaneous manifestations are somewhat less likely than erythema migrans to occur during June to August because the time from the tick bite until the onset of these manifestations is longer. Because adult *I. scapularis* ticks may become active on warm days during the winter, cases of erythema migrans may occasionally occur even in the colder months.

PATHOBIOLOGY

B. burgdorferi resides in the midgut of the *Ixodes* tick through attachment of its outer surface protein A (OspA) to the cells lining this site. With the onset

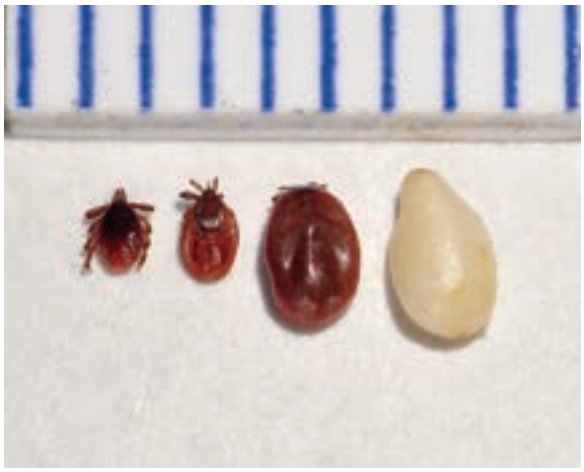

FIGURE 321-1. From left to right is an unfed nymphal stage *Ixodes scapularis* tick, a nymphal stage *I. scapularis* tick after about 48 hours of feeding, a nymphal stage *I. scapularis* tick after about 126 hours of feeding, and a sesame seed. The distance between the ruler marks is 1 mm. (Courtesy Kam Truhn of Fordham University.)

FIGURE 321-3. Acrodermatitis chronica atrophicans. This late cutaneous manifestation of Lyme borreliosis is characterized by slowly expanding red violaceous lesions that typically involve the dorsal surfaces of acral sites and do not heel spontaneously. The lesions are initially inflammatory and later on more and more atrophic. (Courtesy Dr. Franc Strle.)

of the blood meal, because of changes in temperature, pH, and probably other factors, the spirochete increases in number and undergoes a sequence of phenotypic changes including downregulation of OspA expression and upregulation of another outer surface protein, OspC.[5] This set of events releases the spirochete from the midgut and permits migration to the salivary gland. At that site, OspC binds to a salivary protein, Salp15, that is induced during the blood meal in borrelia-infected ticks; this protects the spirochete from antibody-mediated killing and aids in transmission to a vertebrate host. *Ixodes* tick saliva also contains other components with anti-inflammatory and immunomodulatory actions that serve to promote infection with Lyme borrelia and other tick-transmitted pathogens. Expression of OspC by the spirochete in the mammalian host is essential for infection to be established because in some manner this protein protects the microorganism from immediate elimination by the innate immune system.

The spirochete is deposited by the tick into the skin rather than directly into the blood stream. Hematogenous dissemination seems to be an important mechanism responsible for spread of the spirochete to other sites. Alternatively, spread of the spirochete to other sites might occur through tissue planes. The likelihood of entry into the blood stream is affected by the strain of Lyme borrelia causing the infection.[6] Unlike patients who are bacteremic with more conventional pathogens, patients with spirochetemia rarely appear "septic." In one study, only 5% of 93 spirochetemic patients were febrile when the blood culture specimen was obtained, and almost none was found to have leukocytosis. The lack of fever and other clinical signs of sepsis may be due to the absence of lipopolysaccharide within the borrelial cell wall.

Infection of humans or animals elicits innate and adaptive immune responses resulting in both macrophage and antibody-mediated killing of the spirochete. The inflammatory response in tissue typically shows an infiltration of lymphocytes, macrophages, and plasma cells, although granulocytes predominate in synovial fluid samples of Lyme arthritis patients. The potential for persistence of infection despite a robust humoral and cellular immunologic response is, however, typical of infection with Lyme borrelia, as it is with *Treponema pallidum* infection. The virulence factors responsible for persistence of infection include the spirochete's ability to downregulate expression of certain immunogenic surface-exposed proteins, including OspC, and to alter rapidly and continually by recombination the antigenic properties of a surface lipoprotein known as variable major protein–like sequence expressed (VlsE). In addition, the ability of the spirochete to bind avidly to various components of the extracellular matrix may also contribute to persistence.

All of the objective clinical manifestations of Lyme disease are thought to be due to an inflammatory response to live spirochetes or to their undegraded antigens. Obliterative endarteritis has been seen histologically in synovial tissue, but its importance in pathogenesis is unclear. Lyme borrelia are not known to produce toxins. In humans, the only role so far established for host genetic factors is in the development of antibiotic-refractory Lyme arthritis, which is seen most often in patients with certain HLA DR alleles, some of which coincide with those associated with rheumatoid arthritis.

CLINICAL MANIFESTATIONS

The clinical manifestations are often categorized as follows:

- Early localized infection, typically manifested by a single erythema migrans (Fig. 321-2) skin lesion, with or without viral infection–like symptoms, but without objective extracutaneous manifestations
- Early disseminated infection, usually manifested by multiple erythema migrans skin lesions or by an objective manifestation of early neurologic Lyme disease or Lyme carditis
- Late disease, usually manifested by arthritis but may also include certain rare neurologic manifestations or the skin condition known as acrodermatitis chronica atrophicans (Fig. 321-3)

Children and adults have similar clinical manifestations. The expected frequency of the various clinical presentations is well illustrated by a study of 313 cases of Lyme disease diagnosed in Wurzburg, Germany, during a 12-month period. In this series, erythema migrans by itself was seen in 89% of cases, early neurologic manifestations in 3%, cardiac manifestations in less than 1%, borrelial lymphocytoma in 2%, arthritis in 5%, and acrodermatitis chronica atrophicans in 1%. None of the patients had late neurologic Lyme disease. A similar distribution of cases has been seen in recent case series in the United States, except for the absence of borrelial lymphocytoma and acrodermatitis chronica atrophicans. In earlier studies in the United States from the 1980s, there was a much higher proportion of patients who had neurologic, cardiac, or joint manifestations. This may have been due to a bias of ascertainment in the older studies or to improved recognition and

TABLE 321-1 CLINICAL SYMPTOMS AND SIGNS PRESENT IN AT LEAST 20% OF PATIENTS WITH ERYTHEMA MIGRANS

CHARACTERISTIC	UNITED STATES (95% CI)
Viral infection-like	65% (52-76%)
Fatigue	47% (37-58%)
Headache	36% (27-46%)
Myalgias	35% (26-45%)
Arthralgias	35% (25-46%)
Fever	33% (23-43%)
Stiff neck	31% (21-43%)
Lymphadenopathy	22% (13-33%)
Dysesthesia	20% (12-32%)
	EUROPE (95% CI)
Viral infection-like	37% (27-49%)
Dysesthesia	35% (25-47%)
Headache	20% (14-29%)

CI = confidence interval.

treatment of patients with erythema migrans more recently, thereby preventing the development of extracutaneous complications because they occur later.

Early Localized Infection

Single Erythema Migrans Skin Lesion

Erythema migrans is by far the most common clinical manifestation of Lyme disease. Although the appearance of the skin lesion is often distinctive (see Fig. 321-2), it is not pathognomonic for Lyme disease. Erythema migrans appears 7 to 14 days (range, 3 to 30 days) after tick detachment and is characterized by an expanding, flat to slightly raised, erythematous skin lesion (usually ≥5 cm in diameter) that is round or oval. The bite mark from the preceding tick bite can sometimes be identified at or near the center of the lesion and is called a punctum. Approximately 80% of patients in the United States with erythema migrans have just a single skin lesion. Nonspecific viral infection–like symptoms or signs, such as malaise, neck pain, headache, fatigue, migratory arthralgias, or chills and fever, may be present (Table 321-1) but are more common in patients infected with *B. burgdorferi* or *B. garinii* compared with *B. afzelii*. Prominent respiratory or gastrointestinal symptoms are highly atypical for Lyme disease. An acute febrile illness in the absence of a skin lesion or other objective clinical manifestation has been attributed to early Lyme disease, but the possibility of misdiagnosis is greater in this situation because of the potential for false-positive serologic test results.

Erythema migrans skin lesions can vary in appearance. Some (especially lesions of short duration) are nearly uniform in color, whereas others may show central clearing or a target-like appearance. About 5% have a vesicular-pustular center. Erythema migrans on the lower extremities may sometimes be purpuric. Erythema migrans lesions may be scaly when they are long-standing and fading or after topical corticosteroid creams have been applied. The most common locations include the thigh, back, shoulder, and calf. Lesions are often asymptomatic but can be mildly painful or pruritic, and tender regional lymphadenopathy may be present. The majority of U.S. patients with erythema migrans, as for all other clinical manifestations, do not recall a preceding tick bite.

Certain signs and symptoms that have been described in small numbers of patients with erythema migrans in early case series, such as hepatomegaly, splenomegaly, sore throat, conjunctivitis, or testicular swelling, may have been coincidental findings. There has been no microbiologic confirmation of borrelia infection at these sites.

Borrelial Lymphocytoma

Borrelial lymphocytoma is a rare cutaneous manifestation of Lyme disease that almost never occurs in the United States. It often is manifested at or near a preceding tick bite as a solitary bluish red swelling with a diameter of up to a few centimeters. The most common locations are the earlobe in children and the breast in adults (Fig. 321-4). Histologic examination shows a dense polyclonal infiltration of the cutis and subcutis by predominantly B lymphocytes, frequently with germinal center formation. Histologic evaluation may be necessary to exclude malignant disease for patients with suspected borrelial lymphocytoma at a location other than the earlobe.

Early Disseminated Infection

Multiple Erythema Migrans Skin Lesions

In the United States, approximately 20% of patients with erythema migrans have multiple skin lesions at the time of presentation. Secondary erythema migrans skin lesions can be smaller than 5 cm, do not have a punctum, and are usually not tender or pruritic. They arise from hematogenous dissemination to the skin rather than from additional tick bites.

Early Neurologic Lyme Disease

Within weeks to several months after infection, patients may develop neurologic manifestations, the most common of which are cranial neuropathy (particularly peripheral seventh nerve palsy that may be bilateral), lymphocytic meningitis, and sensory (often painful) radiculopathy.[7] Less common manifestations, among others, include mononeuritis multiplex (multifocal involvement of anatomically unrelated nerves) and brachial or lumbosacral plexopathies. A pseudotumor cerebri–like picture has been reported occasionally in children. The presence of a concomitant erythema migrans lesion or the patient's recollection of a recent lesion consistent with erythema migrans may be helpful diagnostically. Studies suggest that approximately 90% of children with Lyme meningitis in the United States have at least one of the following three findings: concomitant erythema migrans, cranial nerve palsy, or papilledema.

Cardiac Lyme Disease

Weeks to months after infection, patients may develop cardiac manifestations of Lyme disease, most often fluctuating degrees of atrioventricular heart block or other manifestations of a myopericarditis, which may cause the patient to complain of lightheadedness, palpitations, dyspnea, chest pain, or syncope. Heart block is typically at or above the atrioventricular node.

Erythema migrans is often but not invariably present concurrently. Valvular dysfunction is not known to occur, and chronic cardiomyopathy has been reported only rarely in Europe.

Late Lyme Disease

Lyme Arthritis

If patients with erythema migrans in the United States are not treated with antibiotics, approximately 60% will develop a monarticular or oligoarticular arthritis at a mean time of 6 months after disease onset (range, 4 days to as long as 2 years). In untreated patients, Lyme arthritis is characterized by intermittent attacks of synovitis that last for a few weeks to several months. One or two joints are involved at a time. Primarily large joints are affected,[8] but there may be involvement of the temporomandibular joint, small joints, and periarticular sites. The most commonly involved joint is the knee. Baker's cysts may form and rupture. Joint swelling is often pronounced, but pain is usually relatively modest. Particularly in children, there may be concomitant fever, but adults are often minimally symptomatic aside from the arthritis.

In about 10% of adult patients with Lyme arthritis in the United States, involvement of a large joint (almost always the knee) may persist despite appropriate antibiotic treatment. Erosion of cartilage or bone may develop in such cases.

Late Neurologic Lyme Disease

After months to years of infection, late neurologic manifestations may develop. These include encephalomyelitis, peripheral neuropathy, and encephalopathy. Because most patients with Lyme disease are now diagnosed and treated early in the course of infection, these more indolent forms of neurologic Lyme disease are rare.

In untreated patients, encephalomyelitis has been monophasic and slowly progressive, mainly involving white matter. It is the most severe neurologic manifestation and, although infrequent, is probably more common in Europe than in the United States. Cerebrospinal fluid (CSF) examination typically shows a lymphocytic pleocytosis, a moderately elevated protein level, and a normal glucose level, with evidence of intrathecal production of antibody to borrelia. Magnetic resonance imaging of the affected part of the brain or spinal cord can demonstrate areas of inflammation, typically with increased signal on T2 and fluid attenuation inversion recovery imaging and enhancement after administration of contrast material.

In the United States, peripheral neuropathy typically is manifested as a mild, diffuse "stocking-glove" process. Patients typically complain of intermittent limb paresthesias and sometimes radicular pain. The most common abnormality on neurologic examination is reduced vibratory sensation of the distal lower extremities. Electrophysiologic studies show a patchy axonal neuropathy. Nerve biopsy shows axonal loss and small perivascular collections of lymphocytes without spirochetes. CSF findings are often normal without evidence of intrathecal antibody production.

Encephalopathy is an imprecisely defined clinical entity characterized by mild abnormalities of memory or other cognitive functions that are demonstrable on either a careful mental status examination or on formal neuropsychological testing. CSF examination findings may be completely normal or may show intrathecal antibody production, mild CSF protein elevation, or a mild pleocytosis. Cranial imaging studies may occasionally demonstrate focal areas of presumed parenchymal inflammation, but findings are most often normal.

Acrodermatitis Chronica Atrophicans

Acrodermatitis chronica atrophicans is a late skin manifestation of Lyme disease that is most commonly seen in women older than 40 years.[9] This skin lesion develops insidiously several years after initial infection, usually on the extensor surfaces of the hands and feet. Early lesions are characterized by a slight bluish red discoloration and doughy swelling. Histologic examination shows lymphocytes and plasma cells in the skin and sometimes in the subcutis, with or without atrophy. Initially unilateral, the lesion may later become bilateral. Over time, there is resolution of the edema with development of skin atrophy. Nodules may develop over bone prominences. About two thirds of patients have an associated peripheral neuropathy of the affected extremity, manifested primarily as local sensory loss.

Although presumably any of the species of Lyme borrelia may cause acrodermatitis chronica atrophicans, by far the most common etiologic agent is *B. afzelii*.[1] Therefore, this manifestation is rarely seen in the United States.

DIAGNOSIS

General Laboratory Testing

White blood cell count, hemoglobin and hematocrit levels, and platelet count are usually normal in Lyme disease, unless coinfection with *Anaplasma phagocytophilum*, *Babesia microti*, or a tick-borne encephalitis virus is present (see later). Lymphopenia, however, may be found in the absence of a recognized coinfection.[10] In patients with erythema migrans, mild abnormalities of liver function tests (particularly elevations of aspartate and alanine aminotransferase levels) can be seen in approximately 35% of patients. The erythrocyte sedimentation rate may be modestly elevated in all stages of Lyme disease, but values greater than 80 mm/hour are distinctly uncommon.

CSF examination in Lyme meningitis typically shows a pleocytosis with more than 90% lymphocytes, a modestly elevated protein level, and a normal glucose level. Synovial fluid examination in Lyme arthritis typically shows approximately 25,000 white cells/mm^3 (range, 500 to 110,000/mm^3) with a polymorphonuclear predominance.

Serologic Testing

Erythema migrans skin lesions may go unnoticed by the patient because of the absence of prominent local symptoms and occurrence on parts of the body that are difficult for the patient to visualize. Therefore, a complete skin examination should be performed for any patient thought to have early localized or disseminated Lyme disease. Erythema migrans is the only clinical manifestation sufficiently distinctive to allow a clinical diagnosis in the absence of a supporting laboratory test. Erythema migrans is diagnosed on the basis of recognition of the characteristic appearance of the skin lesion in persons who live in or have recently traveled to areas endemic for Lyme disease. Because of the short duration of infection at this stage, serologic assays for antibodies to Lyme borrelia are infrequently positive and thus should be obtained only in atypical cases, then in conjunction with convalescent-phase serologic testing 2 to 4 weeks after the acute sample is obtained (Table 321-2).

For non–erythema migrans presentations of Lyme disease, the mainstay of laboratory diagnosis is two-tier serologic testing in which the first tier test is usually a sensitive enzyme-linked immunosorbent assay (EIA). If the EIA result is positive or equivocal, separate IgM and IgG immunoblots are performed on the original serum sample. If symptoms have persisted for at least 4 weeks, then specifically the IgG immunoblot should be positive for the results to be interpreted as evidence of seropositivity. Untreated patients who remain seronegative for 6 to 8 weeks are unlikely to have Lyme disease, and other possible diagnoses should be pursued.

Omitting the first-tier EIA or interpreting the immunoblot with alternative criteria that are not evidence based will potentially decrease the specificity of testing and is not recommended. False-positive results on the IgM immunoblot may be due to cross-reactive antibodies that arise from polyclonal B-cell

TABLE 321-2 DIAGNOSIS OF LYME DISEASE

DIAGNOSTIC MODALITY	APPLICATION	COMMENT
Visual inspection	Erythema migrans	Usually seronegative at time of presentation
Two-tier serology with a positive IgM and/or IgG immunoblot	Lyme carditis	Look for concomitant erythema migrans
	Early neurologic Lyme disease	Look for concomitant erythema migrans; intrathecal antibody may be detectable before serum antibody in Europe; PCR sometimes positive in CSF
	Borrelial lymphocytoma	Biopsy may be needed to exclude malignant neoplasm
Two-tier serology with a positive IgG immunoblot	Lyme arthritis	PCR often positive in synovial fluid
	Late neurologic Lyme disease	Intrathecal antibody positivity expected in Lyme encephalomyelitis
	Acrodermatitis chronica atrophicans	

CSF = cerebrospinal fluid; Ig = immunoglobulin; PCR = polymerase chain reaction.

stimulation. Probably the most common cause of false-positive results, however, is the overreading of nonspecific weak bands.[11] Background rates of seropositivity, which may exceed 4% in highly endemic areas of the United States with even higher rates than this in Europe, may also confound the interpretation of seroreactivity. Therefore, a positive serologic test result does not mean that the patient necessarily has active Lyme disease. The positive predictive value is most informative when the pretest probability based on the clinical features is at least 20%. Serologic testing is not indicated in routine follow-up of patients after treatment as either IgM or IgG borrelial antibodies may persist for many years in successfully treated patients.

Testing for borrelial antibody that is produced locally in the central nervous system (i.e., intrathecal antibody) may be helpful in the diagnosis of neurologic Lyme disease and has been reported to precede detection of serum antibody in a minority of European patients. Positive test results for intrathecal antibody may persist, however, for long periods after successful antibiotic treatment.

Other Diagnostic Modalities

Culture for Lyme borrelia is not routinely done or available to diagnose Lyme disease. It is unnecessary for patients with erythema migrans and too insensitive for patients with extracutaneous manifestations of Lyme disease. In contrast, polymerase chain reaction (PCR) for detection of borrelial DNA is positive on synovial fluid specimens in up to approximately 80% of untreated patients with Lyme arthritis, and a positive result lends support for this diagnosis in a patient who is IgG seropositive. The sensitivity of PCR in CSF tends to be much lower, however, and was only approximately 5% in a study of children from the United States with early neurologic Lyme disease. A negative PCR result on either type of fluid does not exclude Lyme disease.

Differential Diagnosis

Erythema Migrans

Tick-bite hypersensitivity reactions can be mistaken for erythema migrans, but these reactions occur within 48 hours of a tick bite, are usually pruritic, and tend to wane within a few days. In contrast, erythema migrans skin lesions in untreated patients will last for a median time of approximately 4 weeks in the United States and even longer in Europe. Bacterial cellulitis rarely occurs at the most frequent skin sites for erythema migrans and would not be expected to demonstrate central clearing or a target-like appearance. Erythema migrans, unlike erythema multiforme, does not involve the mucous membranes, palms, or soles. Southern tick-associated rash illness (STARI) is the most likely diagnosis in patients with erythema migrans–like skin lesions who were bitten by an *A. americanum* tick or developed this lesion in the southern United States (see under Pathobiology). Other considerations in the differential diagnosis of erythema migrans that usually can be readily distinguished include tinea (often pruritic with a thin, raised, scaly border), nummular eczema (symmetrical pruritic lesions with a tendency to scale and crust), granuloma annulare (acral location, especially on the dorsum of hands and feet, relatively fixed in size and <5 cm in diameter), contact dermatitis (pruritic with streaking along the area of contact and a vesicular component), urticaria (raised, pruritic, and usually <5 cm in diameter), fixed drug eruption (usually on genitals, hands, feet, or face and fixed in size), pityriasis rosea (multiple, moderately pruritic lesions with peripheral scale and relatively fixed in size), and spider bite (often very painful and necrotic with a central eschar).

Extracutaneous Lyme Disease

Included in the differential diagnosis of early neurologic Lyme disease is Bell's palsy. Even in highly endemic areas of the United States, other causes of seventh nerve palsy outnumber Lyme disease by a margin of 3 : 1. Viral meningitis and mechanical radiculopathy can also potentially be confused with manifestations of early neurologic Lyme disease. Viral or other causes of myopericarditis may resemble cardiac Lyme disease. Many causes of synovitis might be considered in the differential diagnosis of Lyme arthritis, but the pattern of joint involvement, such as symmetrical small joint involvement in rheumatoid arthritis, is often distinctly different from that found in Lyme arthritis. Lyme encephalomyelitis may occasionally be confused clinically with a first episode of relapsing-remitting multiple sclerosis or primary progressive multiple sclerosis. Testing for borrelial antibody in serum (and CSF for the last condition) usually suffices to differentiate these conditions from Lyme disease.

TREATMENT

Rx

In vitro studies have shown that Lyme borrelia are highly susceptible to tetracyclines, most penicillins, and many second- and third-generation cephalosporins. *B. burgdorferi* is resistant to certain fluoroquinolones, rifampin, and first-generation cephalosporins. Whether macrolides are active in vitro depends on the borrelial strain tested and the assay technique used. Although most manifestations of Lyme disease will resolve spontaneously without treatment, antibiotic therapy may hasten resolution and prevent progression.

Oral antibiotic therapy is used to treat patients with erythema migrans (Table 321-3). Doxycycline, amoxicillin, and cefuroxime axetil are each highly effective and are the preferred agents for this indication. Macrolides such as azithromycin are somewhat less effective than other oral antibiotics and consequently are not recommended as first-line therapy.

Doxycycline alone among the first-line agents is effective against *A. phagocytophilum* coinfection and is the only agent for which a prospective clinical trial has demonstrated that just 10 days of treatment is effective. Doxycycline, however, may cause photosensitivity, which is a concern because early Lyme disease occurs most commonly during the summer months; in addition, this drug is relatively contraindicated in children younger than 8 years and in women who are pregnant or breast-feeding. When erythema migrans cannot be reliably distinguished from community-acquired bacterial cellulitis, either cefuroxime axetil or amoxicillin–clavulanate potassium (Augmentin) is preferred because these antimicrobials are generally effective against both types of infection.

Within 24 hours of initiation of antimicrobial therapy, up to 15% of patients treated for erythema migrans will experience a Jarisch-Herxheimer–like reaction characterized by an increase in the size or intensity of erythema in the skin lesion and more intense viral infection–like systemic symptoms. Fever, if present, should resolve within 48 hours and the skin lesion itself within 7 to 14 days. Other symptoms, such as fatigue or arthralgia, tend to improve but not invariably to resolve within this time frame, lasting for more than 3 months in one quarter of patients. Extending the initial course of treatment does not cause faster relief of symptoms. Oral antibiotic therapy is also used as first-line treatment for the other cutaneous manifestations of Lyme disease discussed elsewhere in this chapter and as initial treatment of patients with Lyme arthritis.

The preferred parenteral agent for Lyme disease is ceftriaxone because it is highly active against Lyme borrelia in vitro, crosses the blood-brain barrier well, and has a long serum half-life, allowing the convenience of once-daily administration. Alternative choices for parenterally administered antibiotics are cefotaxime and intravenous penicillin. Parenteral antibiotic therapy is recommended to treat patients with late neurologic Lyme disease and those with cardiac Lyme disease who are admitted to the hospital for monitoring (see Table 321-3). Parenteral antibiotics are often given to patients with Lyme arthritis who have failed to respond to one or more courses of oral antibiotic treatment.

TABLE 321-3 RECOMMENDED THERAPY FOR ADULT PATIENTS WITH LYME DISEASE*

THERAPY	MANIFESTATION	DURATION
Doxycycline 100 mg PO bid *or*	Erythema migrans	14 days
	Borrelial lymphocytoma	14 days
Amoxicillin 500 mg PO tid *or*	Acrodermatitis chronica atrophicans	21 days
	Lyme arthritis	28 days
Cefuroxime axetil 500 mg PO bid	Lyme carditis—mild	14 days
	Cranial neuropathy	14 days†
Doxycycline 100 mg PO bid	Lyme meningitis or radiculopathy in Europe and possibly in the United States	14 days
Ceftriaxone 2 g IV daily	Lyme arthritis that failed to respond to oral therapy	14-28 days
	Late neurologic Lyme disease	14-28 days
	Lyme carditis requiring hospitalization	14 days
	Lyme meningitis or radiculopathy in the United States	14 days
Azithromycin 500 mg PO daily	Erythema migrans in a patient intolerant of doxycycline and β-lactam antibiotics	6-10 days

*Regardless of the clinical manifestations of Lyme disease, complete response to treatment may be delayed beyond the treatment duration. Relapse may occur with any of these regimens; patients with objective signs of relapse may need another course of treatment.

†Although any one of first-line oral antibiotics appears to be effective in patients with cranial neuropathy, there is only limited experience in patients with a cranial neuropathy other than seventh nerve palsy or with agents other than doxycycline.

Modified from Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis*. 2006;43:1089-1134.

In the United States, parenteral therapy has been the preferred management strategy for early neurologic Lyme disease, especially for meningitis and radiculitis, with oral therapy reserved for patients with uncomplicated seventh nerve palsy. Studies conducted in Europe, however, have provided convincing evidence that oral doxycycline is just as effective as ceftriaxone for any of the primary manifestations of early neurologic Lyme disease.[A1,A2] Although the same may be true in the United States, studies are lacking. Other oral antibiotics, such as amoxicillin, have been used successfully to treat patients with uncomplicated seventh nerve palsy, but published data on efficacy are much more limited for these agents. Available data indicate that seventh nerve palsy will resolve, with or without antibiotic treatment, and that the rate of recovery is not accelerated by antibiotics. Therefore, the primary reason to treat such patients is to prevent the subsequent development of later complications, particularly Lyme arthritis.

The presence of either papilledema or sixth cranial nerve palsy may indicate the presence of increased intracranial pressure in patients with neurologic Lyme disease. The elevated pressure will typically fall in response to antibiotic therapy, but other measures conventionally used to lower pressure may need to be considered in individual cases.

Symptomatic patients with cardiac Lyme disease and those with high-grade first-degree atrioventricular heart block (PR interval of ≥300 msec) and second- or third-degree block should be hospitalized and closely monitored. Temporary cardiac pacing may be required. In treated patients, complete heart block generally resolves within 1 week, and lesser conduction disturbances resolve within 6 weeks.

Lyme arthritis typically responds to antibiotic treatment. Patients whose arthritis is improved but not resolved after an initial course of oral therapy may be re-treated with a second course of oral antibiotics, with parenteral antibiotic therapy reserved for those without any significant clinical response. Approximately 10% of adult patients in the United States, however, do not respond clinically to antibiotic therapy and are said to have antibiotic-refractory Lyme arthritis; this condition has been defined as persistent synovitis for at least 2 months after completion of a course of intravenous ceftriaxone (or 1 month after completion of two 4-week courses of an oral antibiotic) in conjunction with negative PCR test results on synovial fluid and on synovial tissue if it is available. Because these patients are no longer believed to be actively infected, they are customarily treated with nonsteroidal anti-inflammatory agents, intra-articular injections of corticosteroids, or disease-modifying antirheumatic drugs. Arthroscopic synovectomy has also been used successfully for patients with this condition.

Pregnant patients with Lyme disease are generally treated similarly to nonpregnant patients except that doxycycline should be avoided because of the potential for adverse effects to both the fetus and the mother. No published data convincingly support a congenital Lyme disease syndrome.

Post–Lyme Disease Symptoms and Syndrome

The outcome of treatment in most patients with erythema migrans is excellent. Studies show, however, that when questioned at 6 months or more after treatment of erythema migrans, approximately 5 to 15% of patients will report purely subjective symptoms such as fatigue or musculoskeletal pains. These subjective symptoms are typically mild and may wax and wane in intensity. Patients who have them are referred to as having post–Lyme disease symptoms or syndrome, depending on the symptom duration and severity. The cause of these symptoms is currently unknown. Carefully done microbiologic evaluations in the United States have failed to find evidence of either persistent *B. burgdorferi* infection or a coinfection with a second *Ixodes*-transmitted pathogen. Furthermore, re-treatment has provided either no measurable benefit or a benefit so modest or ambiguous that it was outweighed by the risks associated with the antibiotic therapy.[A3,A4] Therefore, symptomatic treatment is recommended for such patients. In addition, a prospective study conducted in Europe that for the first time also incorporated a "healthy control" group has challenged the notion that such a syndrome even exists. In this study, the frequency of unexplained subjective symptoms in the Lyme disease group was no higher than that in the control group by 6 months into follow-up.[12]

Chronic Lyme Disease

The term *chronic Lyme disease* is poorly defined but widely used. In Europe, the term has been used to refer to the objective manifestations that most authorities prefer to call late Lyme disease. Others have used the term to refer to patients with post–Lyme disease subjective complaints. Most often, chronic Lyme disease is used as a diagnosis for patients with persistent pain, neurocognitive complaints, or fatigue, without objective clinical or serologic evidence of past or present *B. burgdorferi* infection. In this usage, the term is a misnomer and has become the latest in a series of postulated syndromes that attempt to attribute "medically unexplained symptoms" to particular infections.[13]

Coinfections

Ixodes ticks may be coinfected with and transmit Lyme borrelia along with other pathogens, such as *A. phagocytophilum*, *B. microti* (the primary cause of babesiosis), and a tick-borne encephalitis virus. The likelihood of coinfection is dependent on the particular species of *Ixodes* tick and on the geographic area. Thus, bites from *I. scapularis* ticks in certain areas may lead to the development of Lyme disease, human granulocytic anaplasmosis, or babesiosis as a single infection or less frequently as a coinfection. In addition, this tick species can potentially transmit the deer tick virus subtype of the Powassan virus, an *Ehrlichia* species referred to as the *Ehrlichia muris*-like agent, and *Borrelia miyamotoi*.[14-16] In Europe, the most common coinfection is Lyme disease with tick-borne encephalitis virus infection.

Coinfection should be considered in patients from geographic areas endemic for these pathogens who present with more severe initial symptoms than are commonly observed with Lyme disease alone. In this situation, coinfection should be considered especially in those who have high-grade fever for more than 48 hours despite antibiotic therapy appropriate for Lyme disease; those who develop recurrent fever; and those who have unexplained leukopenia, thrombocytopenia, or anemia. Coinfection might also be considered in the situation in which there has been resolution of the erythema migrans skin lesion but either no improvement or worsening of the viral infection–like symptoms.

Reinfection

Patients treated for early Lyme disease do not appear to develop an immunologic response that is adequate to protect against reinfection with a different strain of *B. burgdorferi*.[17] Therefore patients with erythema migrans may become reinfected at a different skin site if they get a bite from another infected tick.[18] Reinfection has been well documented only in patients who were treated for early infection (nearly always erythema migrans) and not after late manifestations of Lyme disease, such as Lyme arthritis. Clinical manifestations of reinfection appear to be similar to those of the primary infection.

PREVENTION

Lyme disease can be prevented by avoiding tick-infested environments and by covering bare skin and using tick repellents on skin and clothing when in such environments. The tick density around individual residences can be reduced by removing leaf litter, placing wood chips where lawns abut forests, applying acaricides to property, and constructing fences to keep out deer. Bathing within 2 hours of tick exposure has been shown to decrease the risk of Lyme disease. Daily inspections of the entire skin surface (including scalp) to remove attached ticks is recommended because of the grace period between the time of tick attachment and transmission of *B. burgdorferi*. Removal is accomplished by grasping the tick as close to its mouth parts as possible with a forceps (or tweezers) and then gently pulling it out. Clinical studies have demonstrated that without any other intervention, more than 96% of patients who find and remove an attached *I. scapularis* tick will remain free of Lyme disease, even in highly endemic geographic regions. If the tick is not found or removed, the probability of infection approaches the infection rate in the regional tick population (typically >20% of nymphal stage *I. scapularis* ticks are infected in highly endemic areas of the Northeast and Midwest United States).

Evidence shows that doxycycline chemoprophylaxis can further reduce the chance for development of Lyme disease after removal of an *I. scapularis* tick. A single 200-mg dose of doxycycline is about 90% effective in preventing erythema migrans at the tick bite site.[A4] Use of a single dose of doxycycline within 72 hours of tick removal should be considered for persons in highly endemic areas who are known to have been bitten by a nymphal or adult *I. scapularis* tick that was estimated to have been attached for at least 36 hours. Given the uncertain efficacy of a short course of amoxicillin in this situation, observation rather than chemoprophylaxis has been recommended for individuals for whom doxycycline is contraindicated. No vaccine is currently available to prevent Lyme disease in humans.

REVIEW QUESTIONS

1. Aside from the egg, there are three feeding stages of the deer tick, *Ixodes scapularis*: the larval, nymphal, and adult stages. Adult deer ticks have higher infection rates with *Borrelia burgdorferi* than the other stages do. Which stage is the most important epidemiologically for transmission of *B. burgdorferi* to humans?

A. Egg
B. Larval
C. Nymphal
D. Adult
E. Egg and larval stages

Answer: C The nymphal stage is the most important epidemiologically for transmission of infection to humans. The larval stage, which is the first stage, is uninfected and cannot transmit the infection. The adult stage, which is the third stage, is infected with *B. burgdorferi*, but it is less important in transmission to humans because this stage is present in smaller numbers in the environment. (See Epidemiology section.)

2. A single 200-mg dose of doxycycline should be considered to prevent Lyme disease under which circumstance?

A. Documented *I. scapularis* tick bite in which the tick had been attached for 36 hours or more and doxycycline can be given within 72 hours after tick removal
B. Clinical suspicion of a tick bite based on the presence of a scab on the leg
C. Any documented *I. scapularis* tick bite regardless of duration of attachment
D. Any documented tick bite
E. In patients with suspected erythema migrans

Answer: A Doxycycline is particularly effective for prevention of Lyme disease when there has been a documented *I. scapularis* tick bite in an area highly endemic for Lyme disease in which the tick had been attached for 36 hours or more and doxycycline can be given within 72 hours after tick removal. (See Epidemiology and Prevention sections.)

3. Which of the following would be least consistent with early or late neurologic Lyme disease?

A. Cerebrospinal fluid (CSF) with 150 white cells, 95% lymphocytes
B. Peripheral unilateral seventh nerve palsy with an 8 × 10-cm erythematous skin lesion on the right thigh
C. Bilateral peripheral seventh nerve palsies
D. CSF with 1000 white cells, 85% polymorphonuclear leukocytes
E. Six months of chronic headache with CSF showing 35 white cells, 95% mononuclear cells; test result for intrathecal production of antibody to *B. burgdorferi* is positive, and IgG antibody to *B. burgdorferi* is present in serum

Answer: D Neither early nor late neurologic Lyme disease is associated with a neutrophilic pleocytosis in the CSF. (See Clinical Manifestations section.)

4. Serologic testing to support a diagnosis of Lyme disease is usually not recommended in patients with possible

A. Erythema migrans
B. Lyme arthritis
C. Early neurologic Lyme disease
D. Lyme carditis
E. Late neurologic Lyme disease

Answer: A Because of the short duration of infection at the erythema migrans stage, serologic assays for antibodies to Lyme borrelia are rarely positive when this finding is noted. (See Diagnosis section.)

5. Which of the following antimicrobials is ineffective for Lyme disease?

A. Doxycycline
B. Ceftriaxone (third-generation cephalosporin)
C. Cefuroxime (second-generation cephalosporin)
D. Amoxicillin
E. Cephalexin (first-generation cephalosporin)

Answer: E *B. burgdorferi* is resistant to first-generation cephalosporins as well as to certain fluoroquinolones and rifampin. (See Treatment section.)

322 RELAPSING FEVER AND OTHER *BORRELIA* INFECTIONS

WILLIAM A. PETRI, JR.

DEFINITION

Relapsing fever is a spirochetal infection with bacteria of the genus *Borrelia*. There are two modes of transmission: epidemic louse-borne and endemic tick-borne relapsing fever. Disease is characterized by recurrent bouts of fever and spirochetemia separated by short fever-free periods.

The Pathogen

Members of the genus *Borrelia* are motile spirochetes that measure 0.5 µm in diameter and 5 to 40 µm in length. They are aerophilic and require long-chain fatty acids for growth. Louse-borne relapsing fever is caused by *Borrelia recurrentis*. Tick-borne relapsing fever organisms are named after their tick vector and include the closely related species *Borrelia duttonii* (Old World); *Borrelia hermsii*, *Borrelia turicatae*, and *Borrelia parkeri* (North America); and *Borrelia miyamotoi* (Old and New World).[1]

EPIDEMIOLOGY

Louse-borne epidemic relapsing fever is caused by *B. recurrentis* and is carried from person to person by the human body louse (*Pediculus humanus*). There is no animal reservoir. The spirochete lives in the louse hemolymph; infection is transmitted to humans when the louse is crushed on human skin and infective spirochetes penetrate the skin or mucous membranes. Epidemics have occurred during famines and at wartime when breakdown in sanitation favors the transmission of body lice. Louse-borne disease remains endemic in central and east Africa (Ethiopia, Somalia, Chad, and the Sudan) and in the South American Andes (Bolivia and Peru).

Tick-borne endemic relapsing fever occurs throughout the world and is transmitted to humans by *Ornithodoros* soft ticks. The ticks become infected by feeding on wild rodents (including mice, rats, squirrels, and chipmunks), which serve as natural reservoirs for the organisms. In the United States, relapsing fever is limited to humid mountainous areas of the West at altitudes of 1500 to 8000 feet, where the tick vector *Ornithodoros hermsii* resides in forests of ponderosa pine and Douglas fir trees. A key diagnostic clue has been a history of sleeping in rodent-infested rustic cabins in western U.S. national parks.[2] In Tanzania, where house infestation with *Ornithodoros* tick vectors can be very high, relapsing fever was identified in 11% of children seen at a clinic with fever. In the northeastern U.S., the prevalence of antibodies to *Borrelia miyamotoi* is nearly 50%, as high as for *Borrelia burgdorferi* (Chapter 321).[3]

PATHOBIOLOGY

Borrelia infection begins in the skin at the site of the louse or tick bite and is followed by rapid dissemination of the spirochetes through the blood stream. Spirochetes are visible on Wright-stained peripheral blood smears during the initial febrile episode and during each febrile relapse in most patients. The spirochete burden in blood positively correlates with symptom severity. Clearance of spirochetes from blood is associated with the production of serotype-specific immune sera; anti-*Borrelia* antibodies have been shown in animal models to be the major mechanism of immune clearance of infection.

Relapses are associated with cyclic antigenic variation in the variable major proteins (VMPs), which are the abundant outer membrane proteins of the spirochete that carry the serotype-specific epitopes. Antigenic variation is the consequence of recombination events that occur between VMP genes at silent and expression sites on linear plasmids. A single *B. hermsii* bacterium may produce as many as 40 distinct serotypes. Because spirochetes undergo one or several antigenic phases during infection, no specific or standard procedure has been developed for routine serodiagnosis of relapsing fever.

CLINICAL MANIFESTATIONS

An abrupt onset of fever (temperature > 39° C in most patients), headache, myalgia, and shaking chills characterizes the onset of illness. Cough, nausea and vomiting, and fatigue are less frequent complaints. Signs include fever, tachycardia, lethargy or confusion, conjunctival injection, and epistaxis. Hepatosplenomegaly, jaundice, and often a truncal petechial rash are common signs in louse-borne relapsing fever. Neurologic findings may occur,[4] including meningitis, meningoencephalitis, and facial palsy, although these entities are more common with tick-borne relapsing fever. Untreated louse-borne disease lasts 6 days, and relapses occur once after an afebrile period of 9 days. The initial illness of tick-borne relapsing fever lasts about 4 days without antibiotic treatment, with an average of two relapses (each after an average 10-day afebrile period) before the diagnosis is made.

Relapsing fever in pregnancy can cause placental damage and intrauterine growth retardation and results in miscarriage in a third of patients. Neonatal infection by both the tick- and louse-borne forms is accompanied by jaundice, hepatosplenomegaly, and often sepsis and hemorrhage. Fever and hepatosplenomegaly are also common signs in children. It has been also recognized in immunocompromised patients.[5]

DIAGNOSIS

The diagnosis should be considered in patients with fever who are returning from a stay in cabins in the mountainous and high-elevation areas of the western United States. Only a few patients will remember tick exposure, because *O. hermsii* is a night feeder, has a painless bite, and remains attached for only 15 minutes. Internationally, relapsing fever can occur sporadically wherever dwellings are infected with *Ornithodoros* ticks, as well as in epidemics with louse-borne disease.

Because the number of organisms in blood is extremely high, the diagnosis is most often made by direct visualization of the organism in a blood smear (Fig. 322-1), although the diagnosis can also be made with polymerase chain reaction and serodiagnostic tests. Spirochetes can be demonstrated in peripheral blood smears taken during febrile episodes in 70% of patients. Additional sensitivity may be gained by examination of a buffy coat preparation of peripheral blood. Because of their characteristic locomotion, spirochetes can be readily detected by direct visualization of thick blood films under low-power microscopy. Culture of the organism requires a special medium and is not practical in a clinical laboratory setting. The white blood cell count is generally normal, but platelet counts of less than 50,000/mm^3 occur in up to 90% of cases of louse-borne disease. Prothrombin and activated partial thromboplastin times are often prolonged. In louse-borne disease, elevations in liver function test results (serum transaminases and bilirubin) and blood urea nitrogen are common. Urinalysis may reveal proteinuria and microscopic hematuria. Examination of cerebrospinal fluid may show a lymphocytic pleocytosis, and spirochetes may be directly visualized.

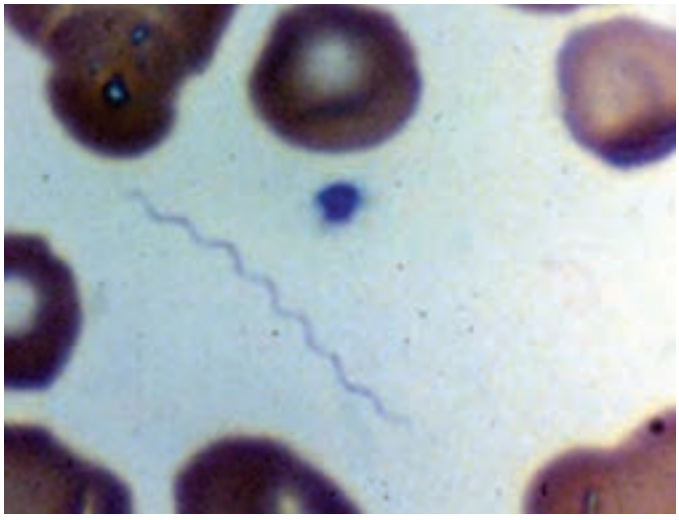

FIGURE 322-1. A single spirochete is seen in a Wright-stained thin blood smear from a patient with relapsing fever.

TREATMENT

Borrelia is generally quite sensitive to antibiotics, which has led to recommendations for single-dose treatments. Although this may be sufficient, especially for louse-borne disease, recent reports suggest that silent residual infections occur and may best be addressed by longer treatments. For tick-borne relapsing infection, treatment should extend for 7 days to reduce the risk for persistent infection. Tetracycline, doxycycline, and erythromycin are all effective antibiotics. Erythromycin should be used in pregnant women and children younger than 7 years (in whom tetracyclines can stain the permanent teeth). Penicillin treatment has been reported to clear the spirochetemia more slowly than tetracycline does.

The Jarisch-Herxheimer reaction (typically characterized by a rise in body temperature of 1°C, rigors, a rise in blood pressure followed by a fall, and transient leukopenia) occurs 2 to 3 hours after treatment in many patients with louse-borne disease, less commonly in tick-borne disease, and should be anticipated and managed supportively. Death as a result of shock from the Jarisch-Herxheimer reaction occurs rarely. The Jarisch-Herxheimer reaction has been associated with accelerated phagocytosis of spirochetes by neutrophils and transient elevations in tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-8, and IL-10. In small numbers of patients with louse-borne relapsing fever, anti–TNF-α antibodies have been effective in prevention.

PREVENTION

Prevention of louse-borne relapsing fever hinges on improving hygienic conditions, delousing affected areas, and antibiotic treatment of patients and close contacts. Tick-borne relapsing fever can be prevented by reducing the risk of contact with rodents and ticks, including repair of structural flaws in cabins and other residences so rodents cannot nest in or around them, as well as spraying infested indoor environments. Tick-bite screening and prophylactic treatment with doxycycline in highly endemic areas has been reported to be a practical, safe, and effective policy in preventing tick-borne relapsing fever.[6]

PROGNOSIS

Epidemics of louse-borne relapsing fever have been reported, with mortality rates approaching 40%; as much as 5% of the mortality is related to Jarisch-Herxheimer reactions with treatment. Mortality from tick-borne disease is less than 5%. Autopsies of patients with louse-borne disease have documented intracranial hemorrhage, brain edema, bronchopneumonia, hepatic necrosis, and splenic infarcts.

REVIEW QUESTIONS

1. The differential diagnosis for a patient presenting with an undifferentiated febrile illness, chills, headache, and recent tick exposure include ***all but one*** of the following:

A. Lyme disease
B. Rocky Mountain spotted fever (RMSF)
C. Ehrlichiosis
D. Tick paralysis
E. Anaplasmosis

Answer: D Not tick paralysis, which is not an infection but in fact an intoxication due to a tick neurotoxin. An undifferentiated febrile illness with recent tick exposure could include Lyme disease, RMSF, ehrlichiosis, and anaplasmosis.

2. Causes of a peripheral facial nerve palsy include ***all but one*** of the following:

A. Lyme disease
B. Herpes simplex virus (HSV)
C. Sarcoidosis
D. Babesiosis
E. Relapsing fever

Answer: D Not babesiosis. HSV is the most likely cause of Bell's palsy, with the borrelial infections, Lyme disease, and relapsing fever not uncommon, and sarcoidosis rare.

3. Diagnosis of relapsing fever can include ***all but one*** of the following:

A. Serology (acute and convalescent)
B. Positive blood smear for a spirochete
C. Polymerase chain reaction (PCR) assay of blood
D. Sleeping in rustic cabins in the U.S. West
E. Blood cultures

Answer: E Blood cultures cannot culture the *Borrelia* bacteria that cause relapsing fever; however, the number of organisms per milliliter of blood is so high they can be seen on a blood smear and detected by PCR.

4. Treatment of relapsing fever is:

A. Tetracycline
B. Ceftriaxone
C. Complicated by Jarisch-Herxheimer reaction
D. A and B
E. A, B, C

Answer: E Tetracycline and ceftriaxone are equally effective, and either can cause the Jarisch-Herxheimer reaction.

5. Complications of relapsing fever include:

A. Jarisch-Herxheimer reaction
B. Meningitis
C. Jaundice
D. A and C
E. All of the above

Answer: E Relapsing fever can be complicated by meningitis, jaundice (especially the louse-borne form), and the Jarisch-Herxheimer reaction, which is treatment associated and probably due to accelerated phagocytosis of spirochetes by neutrophils and the consequent elevation in levels of tumor necrosis factor (TNF)-α and interleukin (IL)-6, IL-8, and IL-10.

323

LEPTOSPIROSIS

ATIS MUEHLENBACHS AND SHERIF R. ZAKI

DEFINITION

Leptospirosis is a zoonotic disease caused by pathogenic *Leptospira* species spirochetes. Leptospirosis is distributed worldwide and is most prevalent in tropical developing countries. Leptospires frequently infect wild and domestic mammals. Humans are infected directly by contact with infected animals or indirectly through contact with urine-contaminated soil or water. Disease severity ranges from mild and self-limiting to severe with life-threatening manifestations including massive pulmonary hemorrhage and Weil's disease (the triad of jaundice, acute renal failure, and bleeding).

The Pathogen

Leptospires are thin, coiled, highly motile spirochetes measuring 6 to 20 microns in length. They are obligate aerobes that can survive for several weeks in the environment. *Leptospira* is currently genetically classified into nine pathogenic species (*L. interrogans, L. kirschneri, L. borgpetersenii, L. santarosai, L. noguchii, L. weilii, L. alexanderi, L. alstoni, L. kmetyi*) and those of intermediate pathogenesis (*L. inadai, L. broomii, L. fainei, L. wolffii, L. licerasiae*). Pathogenic leptospires are further classified into over 25 serogroups and 250 serovars that differ by geographic range and host specificity, which is useful information for outbreak and other epidemiologic investigations.

EPIDEMIOLOGY

Over 350,000 cases of leptospirosis are estimated to occur each year and are generally underreported. In the United States, around 100 to 200 leptospirosis cases are identified each year, with most occurring in Hawaii and Puerto Rico; the incidence is likely higher.[1] The majority of infections are mild and self-limiting, but case fatality in reported cases may be as high as 10%. In endemic areas, up to 20 to 30% of acute undifferentiated fever cases may be due to leptospirosis,[2] and seroprevalence can range from 5 to 15%. The major groups at risk are slum dwellers, subsistence farmers, and animal workers, owing to exposure to rodent, domestic, and wild animal reservoirs. In both tropical and temperate climates, the urban poor are an underrecognized population at risk.[3] Fresh water exposure is a risk factor, particularly during heavy rainfall and natural disasters, in addition to exposure during travel, extreme outdoor sports activities, and military operations. Humans are considered accidental hosts; rare human-to-human transmission by transplacental infection and breast-feeding has been reported.

PATHOBIOLOGY

Leptospires can directly penetrate abraded skin and mucous membranes and spread hematogenously to target organs. The classic illness is biphasic, with the first phase characterized by leptospiremia and the second phase with organism clearance by agglutinating antibodies and an associated host response that can be immunopathogenic.[4,5] Leptospires can persist for a period of time in target organs. In asymptomatic reservoir animals, leptospires can reach massive densities within the renal tubules, resulting in continued urinary excretion.

Pathologic findings (Fig. 323-1) may include pulmonary hemorrhage, diffuse alveolar damage, mild to marked hepatocellular dissociation, mild portal hepatitis, lymphohistiocytic interstitial nephritis, renal tubular necrosis, and mild renal glomerular mesangial hyperplasia. Hemorrhage in other organs, multifocal myocarditis, myositis, and hemophagocytosis may also be present. By immunohistochemistry or silver stains (Fig. 323-2), leptospires can be seen within the renal interstitium, hepatic parenchyma, and within the walls of small, medium, and large pulmonary blood vessels.

Leptospire tissue penetration may be mediated by a burrowing motion and secreted enzymes including collagenase and sphingomyelinase. Leptospiral proteins interact directly with host extracellular matrix components such as collagen, fibronectin, and laminins. Leptospires are resistant to the alternative pathway of complement-mediated lysis and can bind inhibitory complement factor H. Leptospiral lipopolysaccharides and lipopeptides have low endotoxic potency but can activate innate immune response through toll-like receptor (TLR)-2 signaling and are thought to generate a cytokine response. Immunity is considered to be primarily humoral and serotype specific. Circulating immune complexes may contribute to renal damage and endothelial dysfunction. An expansion of γδ T cells occurs during infection. Leptospires may also directly activate plasminogen to plasmin, the main enzyme of the fibrinolytic system, which could promote hemorrhage.[6]

Genomic studies of pathogenic intermediate and saprophytic *Leptospira* species have revealed a relatively large genome that contains genes involved in environmental survival, chemotaxis, and motility that may be involved in pathogenesis.[7] Little is known about host genetic risk factors, although the HLA-DQ6 allele has been associated with increased susceptibility to infection.

CLINICAL MANIFESTATIONS

The incubation period is typically 7 to 12 days (range, 2 to 30 days). During the early phase of illness (first 3 to 7 days), the majority of patients present with high fever (38° to 40° C) and myalgia. Cough, nausea and vomiting, diarrhea, headache, photophobia, and rash may be seen. Conjunctival suffusion is a characteristic finding (Fig. 323-3), but it is only seen in a third of patients near the end of early-phase illness. Myalgia may be pronounced and most frequently involves the calves and lumbar musculature, with creatine phosphokinase elevation. Severe cervical and abdominal myalgia may mimic nuchal rigidity or an acute abdomen, respectively. Rash occurs in 10 to 20% of patients and may be urticarial, maculopapular, or purpuric in a typically

pretibial and truncal distribution. Hepatosplenomegaly and lymphadenopathy may also be present. Resolution of symptoms coincides with the presence of agglutinating immunoglobulin (Ig)M antibodies and reduction in leptospiremia. As a classic biphasic disease, fever may recur 3 to 4 days after remission. In this later immune phase, severe headache is often present and can be associated with photophobia, meningeal signs, and cerebrospinal fluid (CSF) pleocytosis.

Severe disease may occur progressively at initial presentation or during late-phase leptospirosis and result in 10 to 50% mortality. Life-threatening manifestations are renal failure, hypotension, hemorrhage, and respiratory failure. Jaundice occurs in 5 to 10% of patients, and serum bilirubin levels can be elevated up to 40 to 80 mg/dL, with only moderate and minor elevations in transaminase and alkaline phosphatase levels, respectively. Leptospirosis may present as acute cholecystitis. Long-term hepatic sequelae are typically not seen. Renal findings are typically of nonoliguric hypokalemic renal insufficiency and impaired tubular sodium reabsorption. Volume loss may result in oliguric renal insufficiency and acute tubular necrosis, and renal failure occurs in about half of severe cases. Common urinalysis findings are proteinuria, white blood cells, hematuria, and hyaline and granular casts.

Pulmonary findings may include cough, dyspnea, and hemoptysis. Leptospirosis-associated pulmonary hemorrhage and acute respiratory distress syndrome is now recognized as a common clinical presentation. Radiographic findings may show a patchy alveolar infiltrate to large areas of consolidation due to hemorrhage.[8] Cardiac conduction abnormalities can be seen and tend to be nonspecific in mild disease. First-degree atrioventricular block and features of pericarditis are the most common findings in severe disease. Arrhythmias including ventricular fibrillation may also occur.

Thrombocytopenia is frequent and does not appear to be due to platelet consumption, but disseminated intravascular coagulopathy can occur. Prothrombin and partial thromboplastin times are typically normal or only mildly elevated. Petechiae, conjunctival hemorrhage, and purpura can be seen in addition to the more severe hemorrhagic manifestations.

Aseptic meningitis is the most frequent neurologic manifestation. CSF findings include pleocytosis with neutrophil predominance in early disease, followed by lymphocyte predominance in later disease. Glucose is generally normal, and CSF pressure may be elevated. Less common are intracerebral hemorrhage, encephalitis, myelitis, and peripheral neuropathy. Ocular leptospirosis, including chronic uveitis, is thought to be primarily caused by an immunopathogenic mechanism and occurs late in the disease process.

DIAGNOSIS

Few clinical signs differentiate early stage leptospirosis, and severe leptospirosis may be recognized in the form of Weil's disease. Reference tests require specialized laboratories, and there is a need for point-of-care testing in tropical areas. Culture and serologic assays may provide false negatives.[9-11]

Culture of the organism requires specialized media (Ellinghausen-McCullough-Johnson-Harris (EMJH) or Fletcher media, with often more than 4 weeks needed with observation under darkfield microscopy. Cultures generally have low sensitivity, with the best yield obtained from peripheral blood during days 1 through 4 of the acute illness; urine may be positive for up to day 10. Direct darkfield microscopy of clinical specimens can also be attempted but has low sensitivity and specificity.

The gold standard serologic test is the microagglutination test (MAT), available at the Centers for Disease Control and Prevention. MAT is considered positive if there is a four-fold rise in titer between acute and convalescent sera. This assay requires cultured *Leptospira*; it provides serotype data and has a very high specificity but lower sensitivity. U.S. Food and Drug Administration–approved IgM enzyme-linked immunosorbent assay (ELISA) and indirect hemagglutination assays are also available. Multiple lateral flow rapid diagnostic "dipstick" tests are manufactured and used in other countries; however, their performance may not be well characterized. Diagnostic polymerase chain reaction (PCR) assays are being investigated and hold promise for diagnostic accuracy.[12,13] Organisms within tissues can be detected by Warthin-Starry silver stain or immunohistochemistry. In the United States, leptospirosis is a nationally notifiable disease.

DIFFERENTIAL DIAGNOSIS

As previously discussed, few clinical or laboratory findings differentiate leptospirosis from other causes of acute fever. Differential diagnosis depends on other diseases in the geographic area, most frequently malaria, dengue, typhoid fever, and rickettsial diseases including scrub typhus. Other diseases in the differential include influenza, acute viral hepatitis, yellow fever, bacterial and viral meningitis, bacterial sepsis, and hantavirus infection. A high index of suspicion is needed in endemic areas. Useful diagnostic clues are conjunctival suffusion, muscle tenderness, and pulmonary bleeding. High serum bilirubin in the presence of relatively mild transaminitis would argue against viral hepatitis and favor leptospirosis. Hypokalemia, elevated creatinine, elevated creatine phosphokinase, and thrombocytopenia are nonspecific but may also suggest leptospirosis.

TREATMENT

Rx

The World Health Organization guidelines and widespread clinical practice are to treat patients early with antibiotics for leptospirosis. Penicillin, doxycycline, or a cephalosporin appear to be equally efficacious, and doxycycline has the advantage of also treating rickettsial infections. Of note, a recent meta-analysis of seven randomized trials over the past 30 years concluded there is insufficient "grade A" evidence to recommend for or against the use of antibiotics to treat leptospirosis[A1]; antibiotic therapy may decrease the duration of clinical illness by 2 to 4 days; however, in severely ill patients, penicillin may be associated with a higher rate of dialysis. Additional randomized controlled trials are needed.

Treatment regimens for mild leptospirosis include doxycycline (100 mg PO bid), ampicillin (500 mg PO q6h), amoxicillin (500 mg orally [PO] q8h), or azithromycin (1 g followed by 500 mg daily for 2 days); and for severe disease, intravenous (IV) penicillin (1.5 million units q6h), ceftriaxone (1 g daily), cefotaxime (1 g q6h), or doxycycline (100 mg IV q12h). Treatment duration is typically 7 days. The Jarisch-Herxheimer reaction, a febrile inflammatory reaction that occurs with initiation of treatment and results from clearance of the organism from the circulation (Chapter 319), can occur shortly after antimicrobial therapy is started,[14] so patients require monitoring at initiation of antibiotics.

Prompt triage of high-risk patients and aggressive supportive care are essential. Hypotension should be treated, and volume repletion is useful in limiting renal damage. Patients with nonoliguric hypokalemic renal insufficiency may be treated by volume and potassium repletion. Prompt dialysis is indicated for oliguric renal insufficiency, either by continuous hemofiltration or by peritoneal dialysis. Serial electrocardiograms are helpful to monitor for arrhythmia. Aggressive therapy may be needed to treat hemorrhage and respiratory failure.

PREVENTION

Preventive measures include sanitation to prevent population exposure to contaminated water, and limiting water contamination by animal reservoirs such as dogs, pigs, and cattle. Vaccination is available for domestic and livestock animals. Rodent control is important.[15] Workers with occupational exposure to animals or contaminated water or soil are encouraged to use protective equipment such as gloves and boots. Travelers to endemic areas should be counseled on fresh water exposure. A vaccine is not available for human use within the United States. Vaccine trials have been performed in Cuba, Russia and China, however vaccine safety and efficacy are uncertain.

Prophylaxis with doxycycline (200 mg PO weekly) is widely used for persons with exposure to contaminated water or at high risk for leptospirosis. Prophylaxis may work better in reducing risk of clinical disease for short-term travelers with high risk, rather than residents in an endemic area. Of interest, a recent meta-analysis concluded that there is insufficient grade A evidence to recommend for or against the use of antibiotic prophylaxis[A2]; additional randomized controlled trials are needed.

PROGNOSIS

The majority of infections are self-limiting, but there may be 10% case fatality among patients who seek medical attention. Severe leptospirosis is associated with a 10 to 50% risk of death. Death is more frequent during infection if there is renal failure, altered mental status, older age, oliguria, pulmonary hemorrhage, or respiratory insufficiency. Ocular disease, including chronic uveitis, may result in severe visual impairment.

REVIEW QUESTIONS

1. Which group is least at risk for leptospirosis?

A. Hospital workers
B. Veterinarians
C. Farmers
D. Sewage workers
E. Urban homeless

Answer: A Health care workers are at low risk for leptospirosis because human-to-human transmission is rare and primarily involves vertical transmission from mother to infant. Because *Leptospira* species are zoonoses that can persist in the environment, persons with exposure to domestic or wild animals, soil, or fresh water are at greatest risk. The urban poor of both temperate and tropical climates are an underappreciated population at risk.

2. Which is the least likely presentation of leptospirosis?

A. High fever and headache
B. Aseptic meningitis
C. Cough and hemoptysis
D. Localized seizure
E. Acute cholecystitis

Answer: D Localized seizure would be an atypical presentation of leptospirosis, which is generally not considered to be associated with focal neurologic findings. Hemoptysis and renal and hepatic failure are classic presentations of severe leptospirosis. Fever is very common, and aseptic meningitis is well described. Leptospirosis can be associated with acute abdominal pain, and acute cholecystitis has been described as a disease presentation.

3. What is the most likely renal finding in leptospirosis?

A. Cortical necrosis
B. Massive proteinuria
C. Hyperkalemic nonoliguric renal failure
D. Pyelonephritis
E. Allergic nephritis

Answer: C Hyperkalemic nonoliguric renal failure is the typical renal presentation of leptospirosis, which can progress to oliguric renal failure. Hypokalemia is an important laboratory value that can support the diagnosis of leptospirosis. Treatment involves volume resuscitation to prevent oliguric renal failure, electrolyte replacement, and prompt consideration of dialysis. Massive proteinuria would be atypical and suggests a different etiology. The pathologic findings are of interstitial nephritis; cortical necrosis, pyelonephritis, and eosinophilic infiltrates are typically not seen.

4. Of the following, what is the most likely clinical presentation and associated finding in leptospirosis?

A. Jaundice with markedly elevated transaminases
B. Myalgia with elevated creatine kinase
C. Petechiae and markedly prolonged prothrombin time
D. Fever and pancytopenia
E. Severe headache and papilledema

Answer: B Myalgia in leptospirosis is associated with elevated creatine kinase. Myalgia can be extremely painful and mimic an acute abdomen or the nuchal rigidity seen in meningitis. Jaundice is classically seen in leptospirosis, but transaminases are generally low despite markedly elevated bilirubin; these findings can be an important clue to support the diagnosis of leptospirosis. Petechiae and a bleeding diatheses, including massive pulmonary hemorrhage, can be present, but coagulation parameters are typically not markedly abnormal. Fever and headache are very common, but pancytopenia and papilledema would be unusual.

5. Of the following, which are the most likely pathologic findings in leptospirosis?

A. Massive hepatic necrosis and acute renal tubular injury
B. Pulmonary hemorrhage, interstitial nephritis, and hepatocellular dissociation
C. Neutrophilic bronchopneumonia and interstitial nephritis
D. Vasculitis with abundant intravascular spirochetes
E. Pulmonary and renal infarction

Answer: B Massive pulmonary hemorrhage, interstitial nephritis, and hepatocellular dissociation are the typical findings seen at autopsy. Massive hepatic necrosis is generally not seen and would suggest dengue or yellow fever virus infection (depending on the geographic location) or other causes of acute fulminant liver failure. Leptospiral organisms do not cause neutrophilic bronchopneumonia. Vasculitis is generally not a prominent feature of leptospirosis, although a degree of inflammation has been described within pulmonary vessel walls. *Leptospira* species spirochetes are not intravascular but associated with the interstitium; these organisms have several well-defined mechanisms to bind collagen and other components of the extracellular matrix. Infarcts are not a typical feature and would suggest a thromboembolic process.

324 TUBERCULOSIS

JERROLD J. ELLNER

DEFINITION

Tuberculosis (TB) is a chronic granulomatous disease with a unique latent stage usually caused by the acid-fast bacillus (AFB) *Mycobacterium tuberculosis* (Mtb). The most common site of disease is the lung; frequent extrapulmonary sites are the lymph nodes, pleura, bones, and joints. TB is spread from person to person by inhalation of infectious droplet nuclei aerosolized by patients with pulmonary TB (PTB). TB is a major cause of morbidity and mortality worldwide, with over 95% of cases and 99% of deaths occurring in resource-limited settings. The human immunodeficiency virus (HIV) pandemic led to a resurgence of TB and promoted explosive nosocomial outbreaks of multiple-drug resistant TB. The result was increased attention to TB as a global public health emergency and increased funding for TB control and research. The problems posed for TB control are compounded by increasing drug-resistant disease that is expensive to treat and may be refractory to available drugs.

The Pathogen

TB is caused by infection with one of the three members of the Mtb complex: Mtb, *Mycobacterium africanum*, or *Mycobacterium bovis*. The causative organism is a slender, non-motile, non–spore-forming, non–toxin-producing bacillus that may be beaded and is approximately 2 to 4 μm in length. It is a slow-growing (doubling time of 18 to 24 hours) facultative aerobe that can persist intracellularly for prolonged periods. The organism is identified in clinical specimens as an acid-fast bacillus (AFB). Mtb can be stained with carbol fuchsin by either alkalinization (Kinyoun) or heat (Ziehl-Neelsen) methods. The waxy coat of Mtb, composed of mycolic acid and other complex

TABLE 324-1 RISK FACTORS FOR TUBERCULOSIS

RISK FACTOR	INCREASED RISK OF RECENT INFECTION*	INCREASED RISK OF PROGRESSION FROM INFECTION TO DISEASE	TST CUT POINT
Household contact of PTB	X		>5 mm
Solid organ transplant recipients, immunosuppressive treatment (TNF inhibitors, prednisone > 15 mg/day for > 1 month), fibrotic lesions on chest radiograph consistent with prior TB		X	>5 mm
HIV infection	X	X	>5 mm
Foreign-born, injecting drug users, TST-positive children, adolescents, young adults	X		>10 mm
Residents or workers in hospitals, homeless shelters, correctional facilities, nursing homes, residences for the HIV-infected	X		>10 mm
Underweight (>15%), silicosis, diabetes mellitus (particularly insulin-dependent or poorly controlled), renal failure, hemodialysis, gastrectomy, jejuno-ileal bypass, carcinoma of the head and neck, lung cancer, lymphoma, leukemia		X	>10 mm
None			>15 mm

*Recent infection per se increases risk of progressing from infection to disease (12.9 cases per 1000 person-years in the first year compared to 1.6 per 1000 person-years in the subsequent 7 years).
HIV = human immunodeficiency virus; PTB = pulmonary TB; TNF = tumor necrosis factor; TST = tuberculin skin test.

lipopolysaccharides, precludes decolorization of the stain with a mixture of acid and alcohol.

DNA sequencing of Mtb and genetic manipulations have promoted basic understanding of the metabolism and virulence of the organism, its immunodominant antigens, and capacity to survive adverse conditions and persist intracellularly. Clinical isolates of Mtb differ in their virulence in experimental models, potential for transmission in humans, and interaction with the host (immunopathology, induction of host cytokines, delayed-type hypersensitivity [DTH]). For example, the hypervirulent Beijing strain family overexpresses a phenolic glycolipid that inhibits innate immunity and may thereby contribute to its pathogenicity.

There are six main phylogeographic lineages of Mtb, each associated with a specific human population. The families differ in geographic distribution and in some cases the potential for transmission and pathogenesis. Strain typing is particularly useful in outbreak investigations and can be performed by several techniques, restriction fragment length polymorphism (RFLP) of the insertional element IS 6110 or spoligotyping. The finding that multiple cases of TB are caused by the same strain and constitute a "cluster" suggests that they are epidemiologically linked. Whole-genomic sequencing has emerged as a more powerful tool to establish transmission even in the absence of epidemiologic links.

TB caused by *M. africanum* is clinically identical to that caused by Mtb. *M. bovis* has greater than 95% DNA homology with Mtb and causes disease in humans, cattle, deer, badgers, and other animals. The main route of transmission of Mtb is person to person through respiratory aerosols generated by coughing. Bacilli in small droplet nuclei (1 to 5 μm in diameter) remain suspended in air for long periods and once inhaled can reach the airways, where only 1 to 5 organisms are sufficient to cause infection. Laryngeal involvement renders the patient highly infectious. Direct cutaneous inoculation ("prosector's wart") does occur. *M. bovis* can be transmitted by the gastrointestinal route, usually through ingestion of contaminated milk.

EPIDEMIOLOGY

In 2012, there were an estimated 8.6 million new cases of TB (13% in HIV-infected persons) and 1.3 million deaths as a result of TB.[1] Fifty-eight percent of cases of TB occurred in Asia and 25% in Africa. The largest number of cases was in India (26% of all cases) and China (12%). Worldwide, TB occurs more commonly in males than females, but 210,000 women died of TB; the prevalence of disease peaks in young adults, with major economic consequence. Globally, both TB incidence (declining 2% per year) and case-fatality rates have been falling.

HIV infection has a profound effect on the epidemiology of TB, promoting and accelerating progression from infection to active TB and both reactivation and reinfection disease. Some 80% of HIV-infected TB cases are in sub-Saharan Africa, resulting in TB case rates as high as 1% in South Africa and Swaziland.

In the United States in 2013, the incidence of TB was 3.0 per 100,000, with 9588 new cases reported (6.8% were HIV-infected, 5.7% homeless, and 3.8% incarcerated).[2] The incidence rate in foreign-born individuals was 13-fold higher than in those born in the United States and foreign-born individuals accounted for 64% of new cases. Rates were 26-fold higher in non-Hispanic Asians than non-Hispanic whites. The age-specific prevalence of TB in the United States is skewed toward older adults, presumably representing reactivation disease in the foreign born and U.S. born that were infected when TB was more common.

Country of origin is a large determinant of both the risk of latent TB infection (LTBI) and of disease. In a low-prevalence setting such as the United States, the prevalence of LTBI (defined as a positive tuberculin skin test [TST] or interferon-γ release assay [IGRA] and no active disease) is approximately 4%. Those infected are at markedly increased risk of disease compared to uninfected, a risk that is further increased by medical comorbidities and other factors shown in Table 324-1. The risk is not homogeneous within groups affected, for example, by extent of immunosuppression in HIV or duration, severity, and control of diabetes. Smoking and alcoholism also confer an increased risk for TB, although smaller than the conditions listed.

TB caused by drug-resistant organisms is a particular and emerging threat to public health.[3] Multidrug-resistant (MDR) TB (resistant to isoniazid [INH] and rifampin [RIF]) and extensively drug-resistant (XDR) TB (MDR plus resistance to fluoroquinolones [FQs] and a second-line injectable (kanamycin, amikacin, or capreomycin) are much more difficult and expensive to treat and in some cases may be incurable. There are 450,000 incident cases of MDR TB each year, with an increasing prevalence because most are untreated, and 170,000 deaths. About 5 to 10% of these new cases of MDR TB are XDR. Twenty-seven countries account for 85% of the cases of MDR TB, with most occurring in India, China, and the Russian Federation. Eighty-six U.S. cases of MDR TB and two cases of XDR TB were reported in 2012. Most cases of MDR TB are not treated, which results in increasing transmission and prevalence.

PATHOBIOLOGY

Typically, the chain of transmission of TB begins with an infectious case of pulmonary TB (PTB) (Fig. 324-1). Infectiousness of a patient is determined by sputum smear status (3 to 4+ AFB), cough strength and frequency, the presence of cavitary lung disease, and the characteristics of the physical space shared with the source (ventilation and air recirculation). However, not all strongly AFB smear–positive patients with PTB are equally infectious, and there may be high transmitters, owing to host or bacterial factors or both. Recent studies, in fact, show that only about 50-60% of strongly sputum smear–positive persons with PTB generate aerosols that contain viable organisms.[4]

In both low- and high-prevalence countries, exposure/infection usually occurs in the household. In this setting, where exposure may be intense and protracted, 50 to 75% of contacts become infected. The higher numbers result from studies in which repeated testing identifies all TST convertors. In outbreaks occurring in residential shelters, hospitals, and prisons, Mtb infection or disease has been documented after brief exposure. Important variables that may explain differences in transmission include virulence of the organism, innate immunity, and susceptibility of the exposed populations (e.g., HIV infected). Human genetic factors such as polymorphisms in expression or regulation of toll-like receptors (TLR), pattern recognition

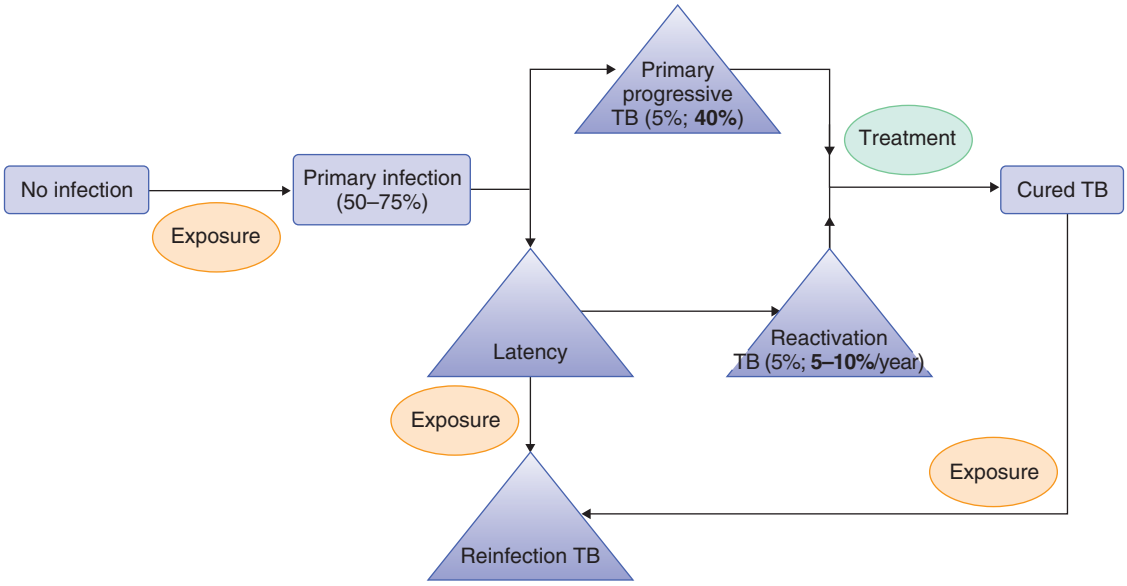

FIGURE 324-1. Natural History of TB. The proportion of individuals affected are shown in parentheses. Bolded figures are for HIV infection with severe immunosuppression. A number of medical risk factors besides HIV promote progression from *Mycobacterium tuberculosis* infection to disease (see Table 324-1).

receptors important to innate immunity, may modulate risk of infection and expression of infection (TST) as well as risk and expression of disease. Predisposition to disease is seen with defects in interferon (IFN)-γ and interleukin (IL)-12 receptors, consistent with their role in immunity. Polymorphisms that modify inflammation (e.g., by affecting leukotriene A_4 hydrolase) also may affect disease manifestations and response to therapy.

Two models of the natural history of TB are shown in Figures 324-1 and 324-2. There is increasing evidence that that the natural history represents a continuum rather than distinct entities of latent and active TB.[5] Diagnostic biomarkers that stratify risk of progression from LTBI to active TB would be of enormous value for targeting public health interventions.

The lung is the site of most cases of reactivation TB. The hallmark of the pathology is granuloma formation with caseation necrosis and multinucleated Langerhans giant cells. The caseous material found in necrotic cavities contains AFB. Mtb multiplies exuberantly in the liquid caseum. Immunologically, expectorated sputum contains cytokines and both upregulators and downregulators of the immune and inflammatory response, the downregulation being dominant. Bronchoalveolar lavage shows a lymphocytic alveolitis, with an influx of immature macrophages representing monocytes attracted from blood.[6] In sum, there is an active but downregulated immune response concomitant with bacterial replication. As a consequence of the inflammation, extensive apoptosis occurs and may lead to the deletion of Mtb-responsive T cells, which may play a role in the requirement for a long duration of therapy and in the susceptibility to reinfection TB. In HIV-infected persons with advanced immunosuppression, granulomas may be poorly formed or absent. Lung tissue is infiltrated with foamy epithelioid cells, which are macrophages laden with AFBs. Caseation may or may not be present, but there is extensive inflammation and necrosis.

Extrapulmonary TB can involve any organ. Persistence of organisms in areas that are relatively well oxygenated may explain the more frequent sites of reactivation, such as the apices of the lung, cortices of the kidney, and vertebral bodies.

Several forms of extrapulmonary TB have a shared pathogenesis: discharge of a contiguous tuberculous focus into a serosal cavity, a brisk inflammatory reaction based on preexisting delayed-type hypersensitivity (DTH), fever, frequently negative smears of exudative fluid for AFBs, and sometimes a transiently negative TST. The focus that discharges may be a long-standing focus or one seeded during recent dissemination associated with primary infection. This basic scenario also occurs in pleural TB, TB pericarditis, TB meningitis (the parameningeal focus is called a "Rich focus"), TB peritonitis, and TB arthritis.

Pleural TB represents an in situ DTH reaction with activation of T_H1 helper T cells, abundant cytokines, including IFN-γ and tumor necrosis factor (TNF)-α, and apoptosis. In non–HIV-infected individuals, organisms are sparse, which may be why self-cure of pleural TB can take place. However, in the absence of chemotherapy for TB, there is a high risk for TB recurrence, usually as PTB on the side contralateral to the effusion.

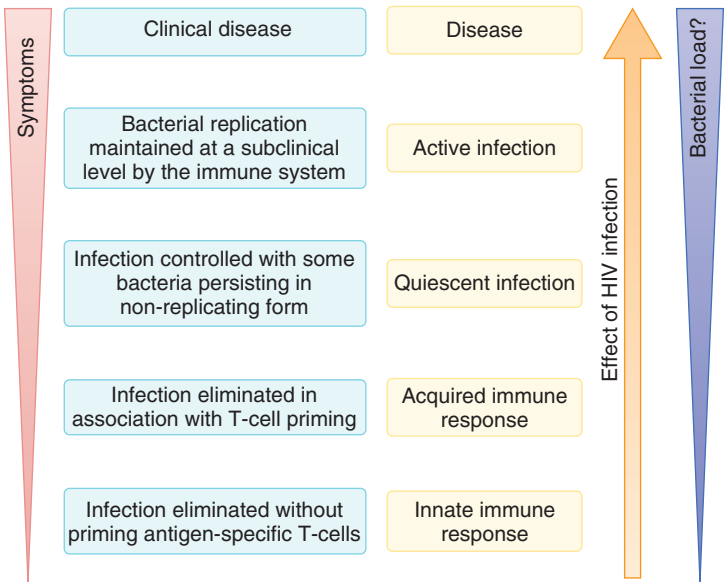

FIGURE 324-2. Tuberculosis infection as a spectrum. The outcome of infection by *Mycobacterium tuberculosis* is generally represented as a bimodal distribution between active tuberculosis (TB) and latent TB on the basis of the presence or absence of clinical symptoms. It is proposed that latent TB is usefully represented as part of a spectrum of responses to infection. One consequence of this model is that there may be a subpopulation within the group that is currently defined as having latent TB that should be preferentially targeted for preventive therapy. A second consequence is that efforts to develop drugs for effective treatment of latent TB would overlap the search for drugs that shorten treatment times for active TB. (From Barry CE 3rd, Boshoff HI, Dartois V, et al. The spectrum of latent tuberculosis. Rethinking the biology and intervention strategies. *Nat Rev Microbiol.* 2009;7:845-855, Figure 1.)

In addition to reactivation of a latent focus, reinfection with Mtb may occur and progress to disease. Reinfection is more likely if the host is immunosuppressed or there is repeated or intense exposure. Treated cases of PTB also are predisposed to reinfection disease as discussed earlier. LTBI is over 70% protective against reinfection TB.

CLINICAL MANIFESTATIONS

Primary Tuberculosis

Most cases of primary TB are unrecognized clinically except for conversion of the TST. There may be fever, shortness of breath, nonproductive cough, and rarely erythema nodosum. Crepitations and focal wheezes may be present. Chest radiographs show small patchy opacities in the mid-lung fields, often with unilateral hilar lymphadenopathy. Upper or middle lobe collapse may also be seen as a result of bronchial compression by enlarged nodes or transient pleural effusion. Recent studies with positron emission

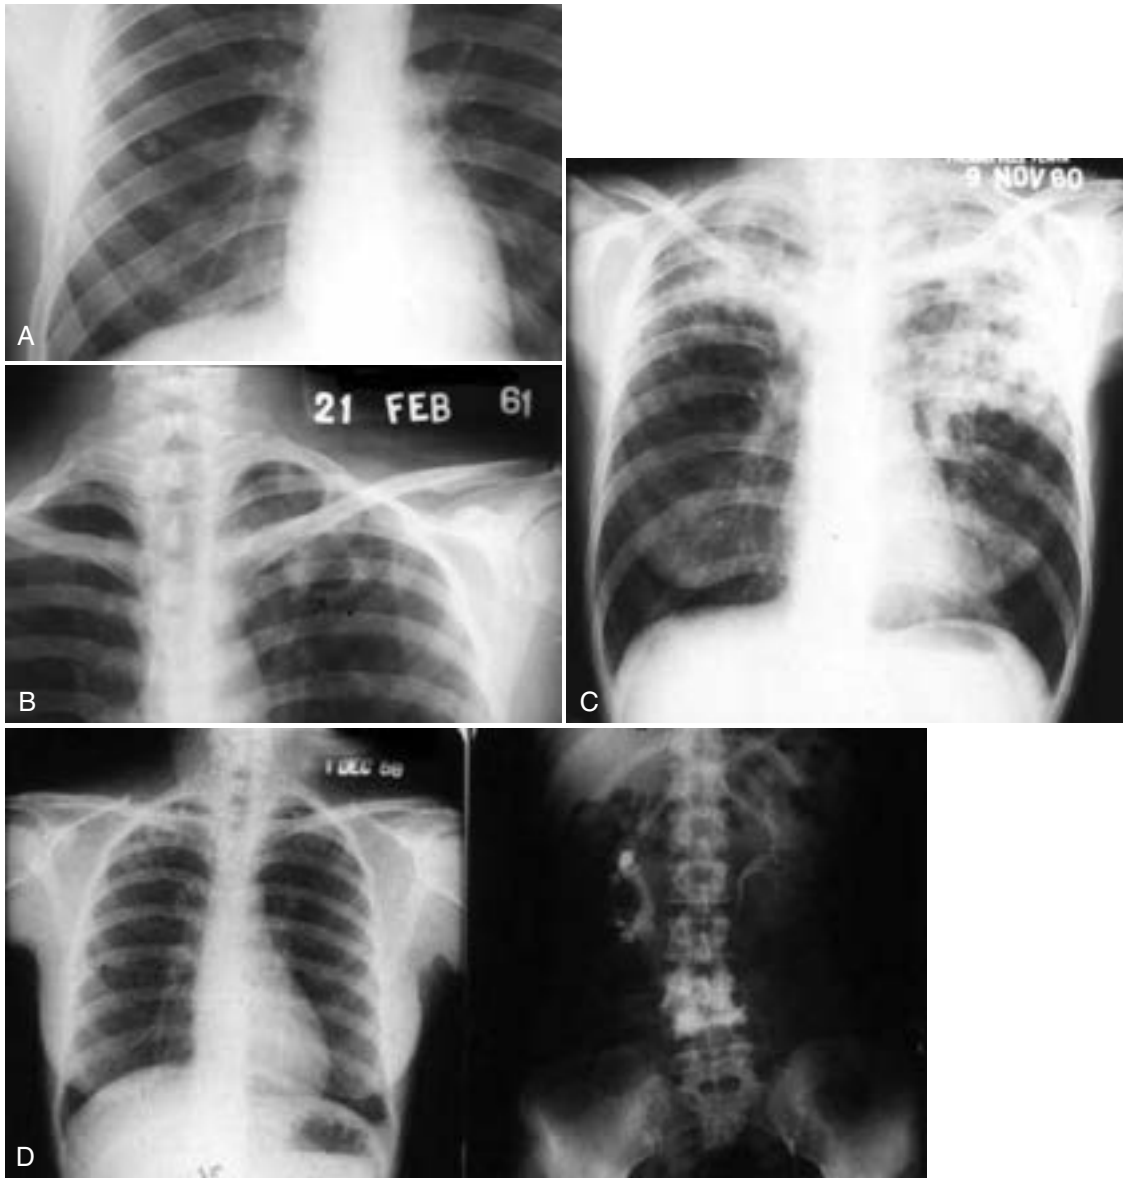

FIGURE 324-3. **A, Ghon complex. B, Moderately advanced pulmonary tuberculosis (TB). C, Far advanced pulmonary TB. D, Pulmonary (*left*) and extrapulmonary (*right*) TB. (Radiographs courtesy Thomas M. Daniel, MD.)**

tomographic computed tomography (PET-CT) scan show that most household contacts of infectious TB cases with a positive TST have mediastinal adenopathy that resolves with INH preventive therapy. HIV-infected persons with LTBI studied with this modality may show parenchymal uptake consistent with subclinical disease. In most individuals (immunosuppression being the exception), the manifestations of primary TB resolve without treatment, concurrent with the development of an adaptive immune response. During the subsequent period of clinical latency, evidence of the primary infection may be found as a small calcified parenchymal scar in the mid-lung fields (Ghon complex), sometimes associated with similar findings in the draining hilar nodes (Ranke complex) (Fig. 324-3A). A small scar caused by an arrested lesion in the apices of the lung is called a Simon focus.

Progressive Primary Tuberculosis

Failure to develop adaptive immunity is most common in young children, the elderly, and the immunocompromised. Progressive primary TB manifested as TB meningitis may develop in this setting. Primary infection also may progress to PTB within the first 1 to 2 years. In this case, PTB usually is upper lobe and cavitary, distant from the site of primary infection. Recent data indicate that in high-prevalence areas, most PTB cases represent progressive primary disease. Clinically, it is not possible to distinguish between progressive primary and "post-primary" or reactivation TB.

Reactivation Tuberculosis

The terms *reactivation TB* and *post-primary TB* are used interchangeably to connote that primary TB is followed by a variable period of at least 2 years of clinical latency, after which TB develops in the setting of existing DTH/adaptive immunity, which contributes importantly to the pathogenesis and clinical manifestations.

PTB is the most common form of reactivation TB. Typical clinical findings in PTB consist of the insidious onset of a productive cough, night sweats, anorexia, and weight loss. Fever is present in approximately half of those affected. Patients may be asymptomatic and the diagnosis suggested by a chest radiograph obtained for other reasons (subclinical TB). The sputum may be purulent, blood streaked, or frankly bloody. Pleuritic chest pain may occur when there is subpleural inflammation. Dyspnea is not a hallmark of PTB, in part because thrombosis of vessels limits the perfusion of inflamed areas, so hypoxemia is not a prominent clinical feature. Physical examination may show dullness to percussion, low-pitched amphoric (hollow-sounding) breath sounds, and occasionally crepitations that may be post-tussive. Chest radiographs often reveal more disease than suggested by physical examination (see Fig. 324-3B and C). Typically (>95% of cases), lesions are found in the apical and posterior segments of the upper lobes and the superior (dorsal) segment of the lower lobe. There is a progression from patchy opacities and consolidation to cavitation reflective of caseation and liquefaction. Advanced imaging with PET-CT shows a heterogeneity in metabolic activity of different lesions within the same patient (Fig. 324-4), which may be associated with variable response to treatment. Rupture and discharge into bronchi and intrabronchial spread may lead to disease in multiple areas, including the other lung (so-called TB bronchopneumonia). There may be involvement of the larynx and middle ear. Early cavities are thin walled and evolve into characteristic chronic thick-walled cavities. Ten percent of all cavities have an

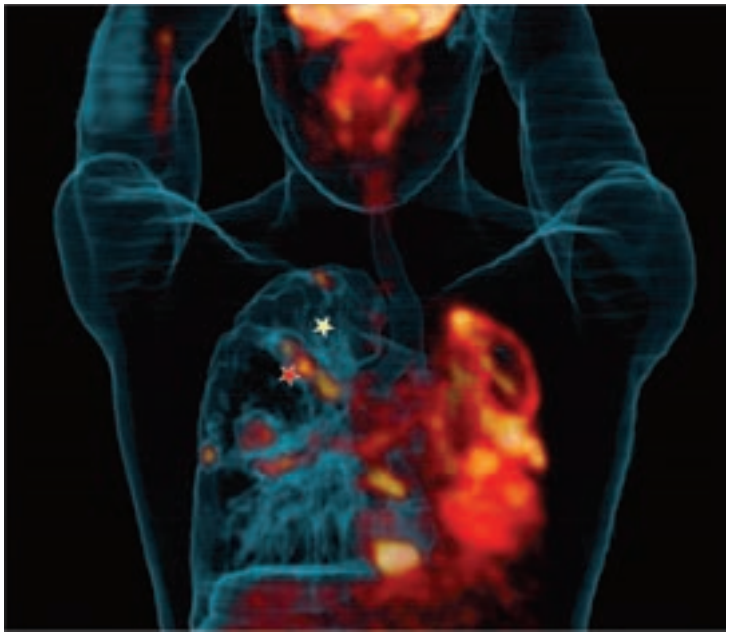

FIGURE 324-4. Positron emission tomographic computed tomography (PET-CT) imaging. An ^{18}F-fluorodeoxyglucose (FDG) PET-CT scan of a patient with tuberculosis with extensive bilateral disease and a complete collapse of the left lung. The right lung also shows extensive disease throughout and illustrates the variability of FDG-PET uptake among lesions within even a single infected patient. The yellow star illustrates one lesion that fails to take up FDG that lies immediately adjacent to a string of three lesions that take up label avidly (*red star*). These different types of lesions respond to chemotherapy with different kinetics, indicating that they represent distinct bacterial subpopulations in different microenvironments. (From Barry CE 3rd, Boshoff HI, Dartois V, et al. The spectrum of latent tuberculosis. Rethinking the biology and intervention strategies. *Nat Rev Microbiol.* 2009;7:845-855, Figure 2.)

air-fluid level. There may be an associated pleural effusion or rarely, with rupture of cavities into the air space, pyopneumothorax. If the disease is minimal, it may best be seen on apical lordotic chest radiographs or on CT. Rarely, chest radiographs are normal, and the accompanying symptoms and positive sputum smears may be the result of endobronchial lesions or rupture of a tuberculous node into bronchi. Healing, fibrosis, and contraction obliterate small cavities, although large cavities may persist and even become the eventual nidus for an aspergilloma or a "scar" carcinoma.

In immunocompromised persons, the opacities may be located in the mid- and lower lung fields and be manifested as poorly resolving lobar or segmental pneumonitis, atelectasis, nodules, and cavities. Early in the course of HIV infection when the $CD4^+$ count exceeds 200/μL, PTB may be typical in its manifestation. At lower $CD4^+$ counts, mid- and lower lung abnormalities are more common. At a $CD4^+$ count below 100/μL, the findings may be quite atypical, with prominent hilar and mediastinal adenopathy, pleural disease, interstitial or miliary opacities, or any combination of these manifestations. This picture resembles primary TB and, in fact, may represent progressive primary TB or reinfection disease. Chest radiographs are normal in up to 20% of persons with culture-confirmed TB, sometimes in the presence of a smear that contains AFB. In this CD4 strata, disseminated and extrapulmonary TB are the rule, with or without concurrent PTB.

Reinfection Tuberculosis

Reinfection TB is clinically indistinguishable from other forms and an important pathogenetic mechanism in high transmission settings. A shift in the drug susceptibility profile, a documented change in the DNA fingerprint or sequence, or occurrence in an outbreak setting may be the only evidence supporting the diagnosis of reinfection TB. Reinfection TB typically affects those with preexisting LTBI or following treatment of PTB.

Extrapulmonary Tuberculosis

Approximately 20% of cases of TB in non–HIV-infected populations are extrapulmonary (see Fig. 324-3D). In areas endemic for TB, extrapulmonary TB often occurs concurrently with PTB and is more common in children and young adults, in whom it represents progressive primary infection. By contrast, in low-prevalence areas, isolated extra-pulmonary TB is more common, and there is a shift to the elderly that represents reactivation TB. HIV infection is associated with a higher frequency of extrapulmonary disease, including the more serious forms, disseminated TB and TB meningitis.

Pleural Tuberculosis

Pleural TB occurs by direct extension when a subpleural caseous focus discharges into the pleural space or through hematogenous seeding. There may be concurrent PTB. Its peak occurrence is 3 to 6 months after primary infection. The typical manifestation is abrupt onset of fever, pleuritic chest pain, and cough. Occasionally there is an insidious presentation consisting of fever, weight loss, and malaise. If the pleural effusion is large enough, shortness of breath may be seen. Physical examination shows dullness to percussion and decreased breath sounds. Above the area of dullness there may be true egophony. Chest radiographs typically show unilateral pleural effusion, more frequently in the right hemithorax. Bilateral disease occurs in 10% of cases. Pleural effusions may be medium-sized, large, or, uncommonly, massive.

Miliary Tuberculosis

Miliary TB usually has an insidious manifestation consisting of fever, weight loss, night sweats, and little in the way of localizing symptoms or signs. There may be concurrent TB meningitis with associated symptoms. Physical examination may show choroidal tubercles (raised white-yellow plaques on funduscopic examination, present in 15% of cases), lymphadenopathy, and hepatomegaly. Chest radiographs may show multiple bilateral small opacities termed *miliary infiltrates* because of their resemblance to millet seeds. The findings on initial chest radiographs are often subtle and may be clear-cut only in retrospect after 3 months of follow-up. Performance of CT or high-resolution CT is useful because of its increased sensitivity (Fig. 324-5). A variant of miliary TB is disseminated are active TB, as may occur in HIV-infected patients or those treated with TNF inhibitors. In this entity, chest radiographic findings may be even more minimal. In the HIV-infected individual with advanced immunodeficiency, blood cultures are positive for Mtb in 20 to 40% of patients and may be the only manifestation of TB.

Tuberculous Meningitis

TB meningitis is usually characterized by less than 2 weeks of fever, headache, and meningismus. There may be depressed levels of consciousness, diplopia, and (rarely) hemiparesis. Physical examination shows a stiff neck and occasionally cranial neuropathy (VI, III, IV, VII in order of frequency) and long-tract signs. Chest radiographs may be consistent with PTB or miliary TB. CT of the head may show contrast enhancement over the basilar meninges, hypodense areas consistent with infarcts, hydrocephalus, and sometimes focal inflammatory lesions (tuberculomas). CT angiography may show entrapment of vessels or vasculitis.

Tuberculous Lymphadenitis

Lymphadenitis may be the sole manifestation of TB or, more frequently, particularly in the HIV infected, may accompany PTB. Patients with isolated lymph node disease may be afebrile. The supraclavicular and posterior cervical lymph nodes are most frequently involved. This is in contrast to scrofula caused by atypical mycobacteria or *M. bovis* and often seen in children, in whom submandibular and high anterior cervical adenopathy predominates. The lymphadenitis is not usually painful, and aspiration of the lymph node with the finding of AFB is an excellent approach to establish the diagnosis.

Tuberculous Pericarditis

The usual manifestation of TB pericarditis is chronic but may occasionally be subacute with fever, night sweats, chest pain, shortness of breath, pedal edema, and other signs of right heart failure. Physical examination shows signs of pericardial disease, right-sided heart failure, and tamponade (in ≈ 10%). Pericardial aspiration and biopsy are the diagnostic procedures of choice. When tamponade is present, a pericardial window can be both diagnostic and therapeutic.

Tuberculous Peritonitis

TB peritonitis may be accompanied by abdominal pain and fever, at times mimicking an acute abdomen. Alternatively, there may be an insidious manifestation consisting of abdominal pain, swelling, night sweats, and weight loss. The clinical syndrome is caused by discharge of tuberculous lymph nodes into the peritoneal space. Exudative ascites is usually present unless TB is superimposed on preexisting transudative ascites, as in alcoholic liver

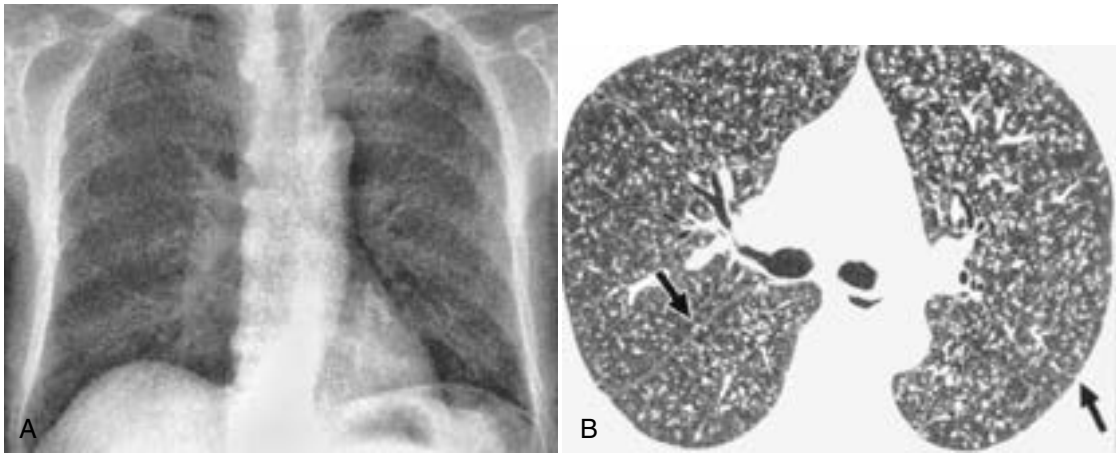

FIGURE 324-5. Miliary tuberculosis in a 70-year-old man. **A**, Posteroanterior chest radiograph shows evenly distributed, discrete, uniformly millet-sized nodular opacities in both lungs. **B**, High-resolution computed tomography (1.0-mm section thickness) at the level of the right upper lobar bronchus shows uniformly sized small nodules randomly distributed throughout both lungs. Note the subpleural and subfissural nodules (*arrows*). (From Jeong YJ, Lee KS. Pulmonary tuberculosis: up-to-date imaging and management. *AJR Am J Roentgenol.* 2008;191:834-844.)

disease. On physical examination, the abdomen has been described as "doughy," because matted loops of bowel may be palpable. A variant of this syndrome is perhaps best termed *abdominal TB*. In this case, the abdominal pain is subacute, the associated findings on physical examination less striking, and ascites less prominent or absent. The best method for diagnosis when ascites is present is laparoscopically guided peritoneal biopsy. In areas endemic for TB and HIV, the finding of intra-abdominal lymphadenopathy on abdominal ultrasound or CT is often used to support the diagnosis of abdominal TB.

Gastrointestinal Tuberculosis

Patients with gastrointestinal TB have fever, abdominal pain, diarrhea, and gastrointestinal bleeding or obstruction. Roentgenograms of the small bowel and abdominal CT show involvement of the terminal ileum, similar to Crohn's disease. The diagnosis is made on clinical suspicion in areas endemic for TB and HIV or by the finding of TB elsewhere. Occasionally, intraluminal biopsy of the terminal ileum or other involved sites is used to establish the diagnosis.

Renal Tuberculosis

There may be few symptoms and signs associated with renal TB, although occasionally dysuria, hematuria, and flank pain are present. The diagnosis is often suggested by the finding of sterile pyuria or hematuria as initial abnormalities that trigger evaluation. Physical examination is usually unremarkable. CT shows renal cortical scarring, occasionally with mass or cavitary lesions, papillary necrosis with calyceal and ureteral dilation, or "beading" of the ureter because of ureteral strictures.

Vertebral Osteomyelitis

The initial site of disease is the subchondral region of the anterior portion of the vertebral body. The lower thoracic and lumbar vertebrae are involved most commonly. The disc space is initially spared but becomes involved late with spread to adjacent vertebrae. Paravertebral "cold abscesses" may dissect through tissue planes. Patients have back and sometimes radicular pain. Occasionally and more often with cervical disease, there may be weakness of the legs and incontinence of stool and urine. Physical examination may show a gibbus deformity caused by anterior compression fractures or paraparesis. Radiographs of the spine, as well as CT and magnetic resonance imaging, may show abnormalities in adjacent vertebrae, with anterior compression (see Fig. 324-3D). Cold abscesses may be appreciated as well.

Other Forms of Extrapulmonary Tuberculosis

TB of the bone or joints may be manifested subacutely as a combination of synovitis and osteomyelitis. The joints involved may have sustained previous trauma. TB of the female genital tract may result in pelvic pain, menorrhagia, vaginal discharge, or infertility. Males may have an epididymal mass, sometimes seen in patients with miliary TB. TB can cause granulomatous uveitis.

DIAGNOSIS

Infection with *Mycobacterium Tuberculosis*

The diagnosis of latent TB infection (LTBI) is one of exclusion, based on the finding of delayed-type hypersensitivity (DTH) and the absence of active TB. The tuberculin skin test (TST) has been used widely, and there is strong epidemiologic evidence supporting its interpretation. Tuberculin purified protein derivative (PPD) derived from autoclaved culture filtrates of Mtb is used to elicit DTH. The response elicited by PPD is nonspecific because of broad cross-reactivity among tuberculous and nontuberculous mycobacteria and other organisms as well. The TST is performed by injecting 5 tuberculin units of PPD in 0.1 mL intradermally. The reaction is assessed as induration after 48 to 72 hours. Problems with the TST are legion. It is the only bioassay used in clinical medicine, and there is no quality control of the application or reading of the TST. The sensitivity of the TST is less in immunosuppressed patients, such as those with HIV infection, and also less in the presence of active TB. The TST may revert to negative over time, and it may be boosted by the application of PPD. On repeat testing the result is a "pseudoconversion" that does not represent new infection with Mtb. The greatest limitation of the TST is its nonspecificity. There has been uncertainty in its interpretation, particularly in the setting of previous vaccination with *M. bovis* bacille Calmette-Guérin (BCG). In fact, BCG administered once at birth has little effect on the TST beyond the first year. By 10 years of age, only 1% of positive TSTs can be ascribed to previous BCG administration.

The TST remains of value in the diagnosis of LTBI in at-risk individuals who are candidates for treatment (preventive therapy). Interpretation of the TST is based on a "sliding scale" that takes into account an individual's a priori risk for Mtb infection and, if infected, the risk for progressing to disease (see Table 324-1). Changing the cut point for positives, in effect, modifies the sensitivity and specificity of the TST. Routine testing is not recommended for low-risk populations; however, testing may be performed because of employment. Certain populations should undergo annual testing, including staff or individuals living or working in congregate settings (incarcerated, homeless, HIV-infected, correctional facility staff), injection drug users, and others at risk because of sociodemographic factors. For individuals who will undergo an annual TST, a true baseline should be established by two-step skin testing. After the initial negative TST, the test is repeated in 1 to 3 weeks (there is no need to repeat the test if the first TST is positive). An increased reaction size on the second TST is known as "boosting" and may be due to previous infection with non-tuberculous mycobacteria or Mtb or vaccination with BCG. TST conversion from negative to positive is the best indicator of intervening new infection with Mtb and is defined as an increase in reaction size of 6 mm or greater from less than 10 mm to 10 mm or greater. It also may be of value to perform a two-step TST on individuals older than 60 years and therefore at risk for TST reversion.

In HIV infection, the TST may be negative before administration of antiretroviral therapy (ART) and convert to positive with treatment. For this reason, it is recommended that the TST be repeated in TST-negative

HIV-infected persons once their $CD4^+$ count reaches 200/μL and annually thereafter.

The sensitivity of the TST is decreased in individuals with active TB, more so in certain forms of extrapulmonary TB. Though insensitive for the diagnosis of active TB, the TST has another application in low-prevalence areas. If the differential diagnosis of a clinical condition includes TB, establishment of previous Mtb infection increases the likelihood that the clinical findings represent TB. The TST is of particular value in the evaluation of smear-negative patients with pulmonary disease suggestive of PTB and in patients suspected of having extrapulmonary TB. Confirmatory findings such as positive culture or histology, response to therapy, and lack of an alternative diagnosis are necessary to establish the diagnosis of TB.

Interferon gamma releasing assays (IGRAs) (QuantiFERON-TB Gold test) have also been approved for the diagnosis of LTBI, and the CDC considers them interchangeable with the TST.[7] The assays represent in vitro cell culture in which blood cells are stimulated with a mix of antigens present in Mtb but not in BCG and most nontuberculous mycobacteria. The main advantage of IGRAs is specificity. The antigens used to stimulate cells are present in Mtb but not BCG. IGRAs also require only a single patient visit. The disadvantages of IGRAs are expense, technical requirements, and controversy over test sensitivity in certain situations such as HIV infection and in household contacts of patients with PTB. Another issue has been instability of the result in individuals undergoing annual testing with IGRAs close to the cut point. The main indication for performing an IGRA, therefore, is to diagnose LTBI in a person who received BCG vaccination beyond the first year of life. There are several other situations in which IGRAs may be useful, for example, confirmation of a positive TST.

Because treatment of LTBI is effective in TST-positive HIV-infected persons, and the risk for progression of infection is inordinately high in such individuals, it is important to perform tests with high negative predictive value. Therefore, both a TST and IGRA should be performed in HIV-infected persons and others at high risk of progression from Mtb infection to disease or of a poor outcome. If either TST or IGRA is positive, the individual is a candidate for treatment of LTBI. Recent studies indicate that IGRAs may be less sensitive than TST in household contacts recently infected with Mtb, a particularly high-risk group.[8] This may be due to delayed conversion of IGRAs relative to TST. Mathematical modeling suggests IGRAs should replace TST in immunocompromised and perhaps all individuals, and that despite their increased cost, they are cost-effective in the United States. Unfortunately, modeling currently is based on data that are quite variable between studies. A fourth-generation test, Quantiferon-Gold Plus will undergo evaluation shortly and may show improved and stable accuracy.

In high TB–prevalence areas, the World Health Organization (WHO) recommends preventive therapy for all HIV-infected persons because of the difficulty in implementing a TST program that would identify those that will achieve the greatest benefit of INH preventive therapy.

Active Tuberculosis

In countries with a high TB burden, the diagnosis of TB is often based on clinical symptoms and sputum microscopy. Clinical diagnosis without the benefit of culture confirmation or radiography is the norm in endemic countries where access to diagnostics is limited. The diagnosis is also made on clinical grounds alone when smears are negative and suspicion for TB is high. Cultures, if available, require several weeks to months, and the decision to begin therapy must be made promptly. Clinical diagnosis is particularly important in HIV-infected persons because of the risk for rapid progression of the TB if left untreated, the more frequent occurrence of AFB smear–negative PTB, and in those with forms of TB that are "paucibacillary" (pediatric, meningeal, miliary, abdominal, pleural, pericardial), in which bacteria are few and AFB smears typically negative. The diagnosis of miliary, abdominal, pleural, and pericardial TB may be confirmed by the finding of AFBs in biopsied tissue or by culture. In the absence of bacteriologic confirmation, either because cultures are negative or because they are unavailable, the final diagnosis often relies on response to therapy or establishment of an alternative diagnosis. It should be noted that the empirical approach, taken of necessity in resource-limited settings, leads to overdiagnosis and overtreatment of TB, which expends TB program resources and delays treatment of other infections. It is therefore preferable to attempt to establish a definite diagnosis based on demonstration of Mtb by smears, cultures, or nucleic acid amplification tests of infected secretions or tissue specimens.

Sputum microscopy is the standard approach to the diagnosis of PTB. A smear requires 1000 to 10,000 bacilli/mL to be read as positive. Both hot and cold carbol fuchsin methods (Ziehl-Neelsen and Kinyoun) are used extensively. The use of fluorochrome stains such as auramine-rhodamine allows more rapid screening of sputum smears and improves sensitivity by about 10%. Three specimens, preferably early morning samples, should be examined to establish the diagnosis. Yield is higher in the presence of cavitary lung disease. Approximately half of individuals with PTB are AFB sputum smear negative, and this proportion is higher in the HIV infected. The quantity of AFBs present in the sputum smear is a rough measure of the infectiousness of patients with PTB, and it is a convenient way to monitor response to treatment. On this basis, additional roles have evolved for the sputum smear as a tool to monitor the potential for transmission and response to therapy.

HIV-infected persons with PTB carry a particular risk for transmission to health care workers and have been documented as sources of nosocomial outbreaks. Therefore, in the United States, in areas of high prevalence of TB, HIV-infected persons with pulmonary symptoms may be placed into respiratory isolation until infectious TB can be reasonably excluded by three negative sputum smears for AFB on specimens separated by at least 8 hours.

The diagnosis of pediatric TB has always been problematic. Children do not produce sputum readily, and TB is often noncavitary, extrapulmonary, or both. Sputum samples may not be readily obtained from infants and children. Options in this case include sputum induction and gastric aspiration. The sensitivity of AFB smears of gastric aspirates and induced sputum is 25 to 30%. Therefore, the diagnosis often is based on clinical and epidemiologic features as well as response to therapy.

Bronchoscopy with bronchoalveolar lavage or transbronchial biopsy is another option for the diagnosis of TB and is useful in all severely ill individuals and the immunocompromised, in whom the diagnosis of TB or an alternative infection must be made quickly if treatment is to have an impact on patient outcome.

AFB smears should be performed on normally sterile fluid obtained from all patients suspected of having TB. The yield of smears from pleural fluid, pericardial fluid, ascitic fluid, and cerebrospinal fluid (CSF) is low in patients with TB but may be higher in those with HIV coinfection, particularly if immunodeficiency is advanced. In TB meningitis, CSF may clot spontaneously, and AFB stains of the clot have increased yield. Rapid diagnosis of some forms of extrapulmonary TB may be made by biopsy of tissue (pleural, pericardial, peritoneal, synovial, terminal ileum); the presence of granulomas, particularly if necrotizing, virtually confirms the diagnosis. Necrotizing granulomas are seen in TB and fungal diseases (particularly histoplasmosis, blastomycosis, coccidioidomycosis, and sporotrichosis). AFBs may also be seen in tissue histology, and Mtb cultured from the specimen.

The diagnosis of miliary TB can be suggested by CT of the chest and confirmed by transbronchial lung biopsy (highest yield), as well as biopsy of the liver, bone marrow, or abnormal lymph nodes. If TB meningitis is suspected and the patient is immunosuppressed, it is particularly important to exclude cryptococcal meningitis by performing a cryptococcal polysaccharide antigen test, as well as an India ink preparation on CSF sediment.

The diagnosis of TB from specimens of normally sterile fluid can be difficult and is increased by culturing relatively large volumes. In addition, the yield of biopsy and culture of tissue (pleura, pericardium) is additive. There are particular diagnostic features for various forms of extrapulmonary TB. In TB meningitis, the initial CSF examination may show neutrophil predominance, but this evolves into a lymphocytic meningitis (100 to 500 cells/μL) with high protein and depressed glucose. TB of the pleura, pericardium, and peritoneum is associated with an exudative effusion, often with a lymphocyte predominance. Low glucose may be found in 20% of TB effusions but limits the differential diagnosis considerably. For example, malignancy, empyema, and rheumatoid arthritis are the other causes of pleural effusion with low glucose. Pericardial fluid in patients with TB pericarditis may be bloody. Eosinophilic meningitis and chylous pleural effusions or ascites may also be seen in TB.

Currently, the gold standard for the diagnosis of TB is culture on solid (Löwenstein-Jensen) or in liquid (BACTEC MGIT 960 system) media. The mycobacteria growth indicator tube (MGIT) system, which has replaced BACTEC, is non-radiometric and based on oxygen quenching in the presence of replicating mycobacteria. When compared with solid media, culture with liquid media is more sensitive and growth is more rapid (1 to 3 weeks vs. 3 to 8 weeks for solid media). Once an isolate is available, drug susceptibility testing should be performed to guide therapy. This takes an additional 2 to 4 weeks on solid media, although isoniazid (INH) and rifampicin (RIF) susceptibility results are available in several days when the molecular line probe assay (described later) is used. Liquid medium can be inoculated with smear-positive specimens for direct drug susceptibility testing, which also accelerates the process. Once mycobacterial growth occurs, speciation is possible

within hours with commercially available DNA probes. Nuclear acid amplification tests are approved and commercially available for use in TB diagnostics. Their sensitivity is somewhat higher than that of AFB smears, and their specificity is excellent. Expense precludes routine use of such tests, however.

The Xpert MTB-RIF has transformed TB diagnosis globally, although there is limited uptake in the United States because of delays in approval. Through in situ DNA amplification reaction, this test allows a specific diagnosis of TB and determination of susceptibility to rifampicin within 90 minutes.[9] After minimal processing, sputum is added to a cartridge. Gene amplification is done with primers based on the *rpoB* gene, which encodes the target of RIF, and resistance-conferring mutations are detected. This method is capable of establishing the diagnosis of TB in 97% of patients with PTB, including 98% of AFB sputum smear–positive and 73% of smear-negative individuals, thus rivaling the sensitivity of solid culture. It does not require molecular expertise by the technician and is not subject to amplicon (DNA) contamination, because it is a closed system. The uptake of GenXpert has been remarkable. The government of South Africa is replacing sputum smear analysis with GenXpert for the diagnosis of TB. The government of Brazil is developing a similar policy. In Uganda, there will be a single reference laboratory for culture and drug susceptibility testing (DST). GenXpert will be available regionally and used mainly for the diagnosis of smear-negative cases. GenXpert is priced differently for low-income countries, but cost still may be prohibitive in some settings. The test allows more rapid diagnosis and initiation of treatment but may not affect the outcome of treatment depending on a site's effectiveness in treating smear-negative patients.[10]

There are other candidate nucleic acid amplification tests (NAATs) about to undergo evaluation that are less expensive than GenXpert and may be truly point of care. Diagnostics for pediatric and extrapulmonary TB more sensitive than NAATs are likely to be based on host responses. As regards host-based diagnostics, there are promising data based on transcriptomics, proteomics, and metabolomics.

TB in the HIV-infected patient poses particular diagnostic issues because of increased likelihood of smear-negative PTB, and in advanced HIV, atypical presentation and extrapulmonary disease.

The HIV-infected TB suspect poses unique difficulties in diagnosis. Recent data indicate that a dipstick to detect lipoarabinomannan, the major cell wall glycolipid of Mtb, has a sensitivity of 60% when $CD4^+$ cell count is below 100 cells/μL.[11] This would be the first point-of-care test.

The development of new diagnostics also targets rapid determination of drug susceptibility. The Xpert MTB-RIF test described earlier is promising in this regard. The commercially available molecular line probe assay (Hain Genotype MTBDR plus) has been approved in Europe and is recommended by the WHO. This assay is based on probing for mutations in the targets of INH and RIF. The assay requires the technician be trained in molecular methods, and results require several days. This assay also is useful for rapidly establishing drug susceptibility once cultures are positive.

TREATMENT

Comprehensive reviews of TB treatment have been published and provide complete information on drugs for TB, monitoring of therapy, management of adverse events, and treatment of pregnant women, children, and other special populations:

- http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5211a1.htm (treatment)
- http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm (treatment and prevention in HIV-infected persons)

Treatment of TB is both a clinical and a public health issue. The goals are to cure the patient and minimize transmission. For that reason, the treating physician has the obligation to ensure that treatment is completed with good adherence to medications. Because of the declining number of TB cases in the United States, with subsequent decline in expertise in TB management, treatment is more likely to occur in a public health clinic than in the private sector. The cornerstone of TB treatment is multidrug therapy. This is necessary because Mtb undergoes spontaneous mutation to drug resistance at a frequency such that most patients with cavitary lung disease—and therefore patients with a high burden of organisms—are likely to harbor resistant mutants.

For the treatment of TB caused by drug-susceptible organisms, there is an intensive phase of therapy for the first 2 months aimed at the rapidly dividing and metabolizing organisms and usually resulting in sterilization of sputum in those with PTB. This is followed by a 4- to 6-month continuation phase that kills the slowly metabolizing persisting organisms. The five first-line anti-TB drugs, INH, RIF, ethambutol (EMB), pyrazinamide (PZA), and streptomycin (SM), form the foundation of chemotherapy for TB. The precepts of therapy have been largely defined by controlled clinical trials. Standard short-course therapy for PTB requires a 2-month intensive phase of four drugs (INH, RIF, EMB, and PZA), followed by a 4-month continuation phase with INH and RIF.

The use of intermittent dosing regimens increases the feasibility of directly observed therapy (DOT) but is controversial. Intermittent regimens may be slightly less effective than daily 5/7 regimens (5 weekdays observed, 2 weekend days self-administered). For patients with extensive cavitary disease and the severely immunosuppressed, daily therapy should be administered throughout the entire course. For HIV-infected persons with TB who are not severely immunosuppressed, treatment should be daily during the intensive phase and at least three times weekly during the continuation phase. Non–HIV-infected persons without extensive cavitary disease can be treated with intermittent regimens throughout. Originally, EMB was perceived to be a "place holder" should the isolate prove to be resistant to INH, and the recommendation was to eliminate its use once drug susceptibility test results were available. There is recent evidence that EMB may be important because of its synergistic or additive activity with other first-line drugs, thereby providing an argument against its premature discontinuation before a full 2 months of therapy has been received.

The problem of nonadherence has led to the directive to provide DOT. The addition of PZA to the intensive phase allows for the so-called short-course chemotherapy; if PZA is not tolerated, comparable outcomes can be obtained with 9 months of INH-RIF. Treatment of drug-susceptible TB with this standard regimen can be expected to cure approximately 90 to 95% of cases. Routine monitoring of liver function test results is not recommended unless there is preexisting liver disease. Patients should return to the clinic promptly with any signs of drug toxicity, particularly those of early hepatotoxicity (nausea, malaise, anorexia, upper abdominal discomfort). Visits should be scheduled monthly and include clinical assessment and sputum examinations. For those with PTB, sputum cultures are continued until two consecutive cultures are negative. In uncomplicated PTB, defervescence is expected within 2 weeks, and there should be weight gain and diminution of cough and chest pain. About 20% of patients with cavitary PTB remain sputum culture positive after 2 months of therapy. A positive sputum culture at 3 months or failure to improve on chest radiographs suggests nonadherence with therapy, drug-resistant TB, or an alternative or complicating diagnosis. Positive sputum culture at 4 months is defined as treatment failure.

Extrapulmonary TB is usually associated with a smaller bacterial burden than is the case with PTB and can be treated with standard short-course regimens of 6 to 9 months' duration. However, because of the serious ramifications of treatment failure, more prolonged treatment of at least 9 to 12 months is recommended for miliary, meningeal, and skeletal TB. Adjunctive surgical débridement and stabilization may be necessary for skeletal TB. Adjunctive corticosteroids are indicated for TB pericarditis and severe pleurisy, as well as extensive PTB with clinical toxicity or respiratory failure. In TB meningitis, dexamethasone improves survival but has not had an impact on the proportion surviving with severe neurologic sequelae. Ventricular shunting may be necessary to relieve hydrocephalus.

HIV-TB coinfection creates additional management issues. Fortunately, the response to treatment of TB is comparable to that in HIV-uninfected individuals, except for higher early mortality. Intermittent regimens have a tendency to lead to RIF resistance; therefore, daily administration of drugs is recommended in the intensive phase, and drugs should be administered no less than three times weekly in the continuation phase. In resource-limited settings, the administration of cotrimoxazole prophylaxis is associated with improved survival. Integration of the treatment of TB and HIV rather than sequential treatment of first TB and then HIV is associated with a 56% reduction in mortality. The results of three randomized controlled trials support the current Department of Health and Human Services and Infectious Diseases Society of America guideline to start ART 2 weeks after initiation of TB treatment if $CD4^+$ count is below 50 cells/μL. Early initiation of ART does incur a risk for paradoxical reaction, a form of immune reconstitution inflammatory syndrome (IRIS) (Chapter 395). TB-IRIS is more likely to occur when the $CD4^+$ count is low, the viral load is high, and the interval between starting TB drugs and ART is short.[12] Immune reconstitution is associated with inflammation and transient exacerbation of disease mimicking progression of TB. There may, for example, be fever, lymphadenitis, and pleural or worsening parenchymal disease, including consolidation and new or progressing nodular opacities on chest radiographs. In about one third of dually infected patients, IRIS will develop within the first 2 months of treatment and often within the first 2 to 3 weeks of starting ART. TB-IRIS usually is not an important cause of mortality. A controlled trial has shown that corticosteroid therapy limits morbidity, although it is not useful for treating tuberculous pericarditis. More problematic is IRIS associated with respiratory failure or neurologic involvement. Initiation of ART in HIV-infected persons may also be associated with "unmasking TB," which occurs within 3 months. This may be due to a missed diagnosis of TB in screening, the development of inflammation at sites of mycobacterial replication in tissue, or progression of latent infection consequent to ART. Unmasking TB is common in countries endemic for TB (5 to 10% in Uganda, for example, but about 25% in South Africa) and associated with morbidity, mortality, and risk for nosocomial transmission.

In general, TB does not affect the response of HIV to ART. A major issue, however, is the interactions between rifamycins that induce CYP3A hepatic microsomal enzymes and protease inhibitors and some non-nucleoside reverse transcriptase inhibitors (NRTIs). Because of its potency, simplicity, and proven clinical efficacy, efavirenz 600 mg with two NRTIs, along with rifampin-based TB regimens, is the preferred strategy for co-treatment of HIV and TB. Rifabutin is off-patent and increasingly available as a less potent inducer of cytochrome enzymes, but its own pharmacokinetics can be affected by certain ARTs. Rifampin is the preferred rifamycin for efavirenz containing regimens, whereas rifabutin should be used at a does of 150 mg daily with a boosted protease inhibitor. Guidelines for other drug combinations for managing adverse events were updated June 2013 and are available at http://www.cdc.gov/tb/TB_HIV_Drugs/default.htm.[13]

Management of TB-HIV coinfection may be complicated for the clinician. For example, a new fever may be due to drug reaction, TB-IRIS, drug resistance, or a complicating opportunistic infection.

Drug-resistant TB is more difficult to cure than drug-susceptible TB and in some instances may be incurable. DOT is particularly important to prevent acquisition of additional drug resistance. Selection and monitoring of treatment for drug-resistant TB should be the responsibility of those experienced with the unique drug regimens and issues involved. General issues concerning the management of drug-resistant TB are listed in Table 324-2. A major problem, however, is the lack of information on drug susceptibility at the time of initiation of treatment. In resource-limited settings, drug susceptibility testing may not be available at all. Drug resistance is more likely in retreatment cases, so standardized retreatment regimens are administered. The risk for drug resistance is greater if the initial regimen was not administered in a DOT program. For patients who relapse, did not receive DOT, were not treated with a RIF-containing regimen, were known or presumed to have irregular treatment, or have severe disease, an expanded regimen should be started. An example would be INH, RIF, and PZA plus an injectable (streptomycin if not previously used) and a fluoroquinolone, with or without an additional oral agent (ethionamide, para-aminosalicylic acid [PAS], or cycloserine). Ideally, the retreatment regimen should contain at least three drugs to which the isolate is likely to be susceptible. In resource-poor environments, streptomycin alone is often added to INH, RIF, EMB, and PZA. Although most retreatment cases remain drug susceptible, about 25% do not respond adequately to the standard regimen.[14] This approach is clearly inadequate for MDR or XDR TB. Ideally, drug susceptibility testing should be performed for all patients being retreated to ensure success of treatment and prevent acquisition of additional resistance.

Monoresistance to INH or streptomycin has little effect on the outcome of TB treatment. INH-resistant TB can be treated with RIF, PZA, and EMB for 6 months. Ofloxacin may be added for extensive or refractory disease. RIF-resistant TB can be treated with 12 to 18 months of INH, EMB, ofloxacin, and PZA (plus an injectable for the first 2 months if there is extensive disease). Acquisition of additional drug resistance is more likely if the initial isolate was resistant to one drug (6%) or more than one drug (14%) versus being pansusceptible (0.8%).

MDR TB represents a problem of a different order of magnitude. Not only is cure difficult and extremely expensive, but unrecognized MDR TB can also lead to nosocomial outbreaks and rapid and high rates of fatality in the HIV infected.

TABLE 324-2 PRINCIPLES OF MANAGEMENT OF TUBERCULOSIS CAUSED BY DRUG-RESISTANT ORGANISMS

- Do not add a single drug to a failing regimen.
- When starting or modifying therapy, add three previously unused drugs (one an injectable) to which there is susceptibility.
- In MDR TB where there is resistance to first-line drugs, in addition to INH and RIF, treat with 4-6 drugs.
- Patients with MDR TB have highest priority for DOT, because treatment failure may mean XDR TB.
- Intermittent therapy should not be used (except for injectables after 2-3 mo).
- Do not use drugs to which the Mtb isolate is resistant. Low-level INH resistance may be the exception.
- There is cross-resistance among rifamycins but not between streptomycin and other aminoglycosides.
- There may be susceptibility to moxifloxacin but resistance to other fluoroquinolones.
- Drug susceptibility testing for PZA is complex technically and not performed in most laboratories. Monoresistance to PZA suggests *Mycobacterium bovis*.
- Always consult with an expert. There is predisposition to acquisition of additional drug resistance that will decrease the chances of cure.

DOT = directly observed therapy; INH = isoniazid; MDR TB = multidrug-resistant tuberculosis; Mtb = *Mycobacterium tuberculosis*; PZA = pyrazinamide; RIF = rifampin; XDR TB = extensively drug-resistant tuberculosis.

There is no substitute for performing drug susceptibility testing that includes all first-line and available second-line drugs. MDR TB is not a homogeneous entity. Frequently, the first diagnosis of MDR TB occurs in the setting of residual susceptibility to most other drugs. However, after repeated treatments, the isolate usually acquires additional drug resistance and, regardless of whether it fulfills the definition, is essentially XDR.

The cornerstone of treatment of MDR TB is administration of at least four drugs to which the isolate is susceptible (see Table 324-2). Typically, the regimen will include first-line drugs with retained activity, a fluoroquinolone (FQ), an injectable (amikacin, kanamycin, or capreomycin), and a second-line drug if disease is extensive (ethionamide, cycloserine, PAS). The duration of treatment is set at 12 to 18 months (12 to 15 months after sterilization of sputum). Residual susceptibility to FQ treatment and capreomycin has been shown to be a determinant of treatment outcome. Surgical resection is a consideration if the disease is localized, sputum remains culture positive, medical therapy is not tolerated, or massive hemoptysis is present. A recent review of published case series and cohort studies showed that surgical resection is beneficial in the adjunctive treatment of drug-resistant TB; however, the results might not be applicable in all settings, and well-designed studies are needed. Cure rates of 60 to 80% can be expected if therapy is targeted to drug susceptibility test results and MDR organisms remain sensitive to enough chemotherapeutic drugs that a reasonable regimen can be established. The U.S. Food and Drug Administration (FDA) recently approved both bedaquiline and delamanid for the treatment of MDR TB.[15] Bedaquiline, a diarylquinoline, targets mycobacterial ATP synthase, and delamanid, a nitrodihydroimidazooxazole inhibits Mtb mycolic acid synthesis. Both accelerate sterilization of sputum when added to regimens for treatment of MDR TB. It is recommended that bedaquiline be added to three drugs active against the isolate. These are the first new classes of TB treatment drugs to be approved by the FDA in 40 years. They should revolutionize management of MDR TB. Spectinamides, a new class of semisynthetic anti-TB agents, have been shown to overcome the efflux pump that is upregulated in MDR strains.[16]

The definition of XDR TB requires that an organism be MDR with additional resistance to an FQ plus at least one of three injectables (amikacin, kanamycin, capreomycin). The outcome of treatment of XDR TB has been variable. The best reported results have been obtained in Peru, with a comprehensive approach that included therapeutic regimens that were tailored according to drug susceptibility testing. Effective regimens included cycloserine, capreomycin, and PAS. Moxifloxacin may be active even if the isolate is resistant to first-generation FQs. Adjunctive surgery should be considered. A recent study indicates that linezolid has remarkable activity against XDR TB,[ ] and other oxazolidinones are in development for TB treatment.

The emergence of drug resistance has emphasized the need for new drugs and new drug regimens. A drug regimen that shortens the course of TB would lessen the emergence of drug resistance, because adherence would increase and DOT would be simplified. Once MDR TB develops, particularly in the setting of XDR TB, new drugs are necessary to improve efficacy and shorten treatment.

There are promising developments with existing classes of drugs, as well with as new classes about to enter or already in clinical trials. Rifapentine, a rifamycin with a longer half-life than RIF, shows remarkable enhancement of sterilization of sputum at 2 months. Moxifloxacin has increased activity against Mtb, although data of its efficacy in 4-month regimens have been disappointing to date. PA-824 and delamanid are nitroimidazole derivatives that are active against slowly replicating bacilli. Also in development are SQ-109 (ethylenediamine), an ethambutol derivative, and sutezolid (an oxazolidinone more active than linezolid).

PREVENTION

The issues surrounding prevention are presented in a comprehensive statement published in 2000 (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr4906a1.htm), and prevention in HIV-infected persons is presented at the website http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm.

The approach taken in a low-prevalence setting such as the United States is to target tuberculin skin testing to those at high risk for recent Mtb infection and to those with comorbid conditions that predispose to progression from infection to disease. In either category, a positive TST becomes an indication for treatment of LTBI. The cut point of TST is adjusted according to risk of MTB infection and risk of progressing from infection to disease (see Table 324-1).

LTBI can be treated with rifampicin for 3 to 4 months, INH for 6 to 12 months, or the combination for 3 to 4 months,[17] thereby decreasing the lifetime risk for development of TB by approximately 75 to 90%, depending on the level of adherence to treatment. Pyridoxine should be administered to prevent INH-induced peripheral neuropathy. Monitoring of liver function is indicated in older individuals (the risk for hepatotoxicity increases beyond the age of 35 years) and in those with significant alcohol intake or underlying

liver disease (or both). INH should be discontinued if symptoms develop (see Treatment) or hepatic transaminase levels rise to more than three to five times the upper limit of normal. Rifapentine plus INH once weekly for 3 months (12 doses) is as effective as 9 months of INH alone in preventing active TB in patients with latent infection.[A7] Administration of this regimen should be directly observed. In HIV-infected persons, treatment of LTBI confers short-term efficacy (≈1 year), but this may be extended if ART is administered. Treatment for 3 years confers an additional benefit that is most marked in the TST positives. Unfortunately, treatment of LTBI has not been applied broadly. This is in part due to the concern that if screening is inadequate, patients with active TB will be treated with a single drug and thereby acquire drug resistance. The available data do not support this concern. In a recently reported cluster-randomized study, a trial of mass screening and INH preventive therapy for TB control among gold mine workers in South Africa (where TB is epidemic) had no significant effect on TB control despite the successful use of INH in preventing TB during treatment.[A8] In a low-resource setting in the HIV infected, the absence of current fever, weight loss, or night sweats has a negative predictive value of 97%, may obviate the need for chest radiography if it is not routinely available, and identifies a group that should be treated with INH preventive treatment regardless of TST status. Although INH preventive therapy is the preferred regimen, there is renewed interest in the possibility that rifamycin-containing regimens may confer more sustained protection. There are no data on how to treat LTBI caused by a known or probably drug-resistant isolate. PZA plus EMB or ofloxacin has been used after known exposure to MDR TB that is susceptible to the combination, but gastrointestinal intolerance is very common. Studies of linezolid are planned in this population.

Secondary preventive therapy after completion of TB treatment is indicated in HIV-infected persons in the setting of intense exposure to Mtb. Data demonstrating efficacy of secondary prevention largely result from studies of adults in Congo and gold miners in South Africa.

A randomized controlled trial has now demonstrated that in HIV-positive patients, early initiation of ART as compared with delayed treatment (where there was a decline in CD4 counts or AIDS-related illness had already occurred) led to a significant decrease in the development of TB.[A9]

Tracing of household contacts is a critical element of TB programs. The household is a major site of TB transmission, particularly in an area of low endemicity, so treatment of TST converters is an important strategy for elimination of TB. It is essential that transmission be limited in hospitals and other settings in which infectious PTB patients may comingle with susceptible hosts. The risk of transmission to health care workers should be ascertained annually by skin testing. The finding of excessive risk for new TB infection should lead to focused measures for reducing transmission. All TB suspects should be placed in respiratory isolation in negative-pressure rooms with at least six air exchanges per hour and high-efficiency particulate air (HEPA) filtration or ultraviolet irradiation. N-95 personnel respirator devices that are fit-tested are necessary for individuals entering areas with a known high risk for exposure.

BCG vaccine is widely used and relatively safe except in the setting of immunosuppression. Unfortunately, efficacy has been variable by age and by latitude. A meta-analysis indicated an overall efficacy of 50%. It is approximately 80% effective in preventing the severe forms of TB in childhood, miliary TB, and TB meningitis. However, its failure to prevent adult TB, particularly at low latitudes that include the most endemic areas, means that BCG vaccine does not have an impact on the public health problem of TB. The development of a more effective protective vaccine has been hampered by the absence of good animal models and the lack of correlates of protective immunity in humans. The issue is further compounded by the natural history of TB such that large, lengthy, and expensive trials may be needed to establish protective efficacy. Nonetheless, several vaccine candidates have been developed and their potential efficacy supported by preclinical studies in animal models. Two of the 12 currently in clinical trials are MVA85A, a recombinant modified vaccinia virus expressing the 85A antigen, a major secretory product of Mtb, and Mtb72f, a combination of two immunogenic antigens, Mtb 32a and Mtb 39a, in two adjuvants, ASO2a and ASO1B. A recent trial of the MVA85A vaccine in infants to boost the BCG response failed to show efficacy.

PROGNOSIS

In the pre-chemotherapeutic era, minimal PTB stabilized in about 50% of cases. Pleural TB also self-cured, with a risk for reactivation as noted previously. With treatment, the prognosis of patients with TB depends on the extent of PTB, the sites of extrapulmonary TB, drug susceptibility of the isolate, and the presence of HIV infection and other comorbid conditions. With extensive PTB, respiratory failure may supervene with a poor prognosis. There is also increased risk for serious, sometimes lethal, hemoptysis and pneumothorax. Miliary TB is associated with a high case-fatality rate, in part related to delays in diagnosis. TB meningitis is associated with serious neurologic residua, as well as high mortality. MDR TB and XDR TB are accompanied by high rates of treatment failure, morbidity, and mortality. TB in HIV-infected persons is associated with high early mortality that is poorly characterized. In the absence of ART, there is increased risk for other opportunistic infections and progression of HIV disease. The addition of ART, however, results in the morbidities associated with the concurrent administration of TB and HIV medications and with TB-IRIS. Long-term outcomes of patients with XDR TB were recently reported from South Africa. Their outcomes were poor irrespective of HIV status, and because of the scarcity of long-stay or palliative care facilities, substantial numbers of patients with XDR TB who had failed treatment and had positive sputum cultures were being discharged to likely transmit disease into the wider community.[18]

REVIEW QUESTIONS

1. The following is true of tuberculosis (TB) in the United States:

A. Most cases are in the foreign born.
B. Most cases are in the HIV infected.
C. The elderly are not at risk.
D. The period of greatest risk of progression is 5 years and longer after infection.
E. Outbreaks are a major source of multidrug-resistant (MDR) TB cases.

Answer: A Foreign-born individuals account for over 60% of U.S. TB cases. The greatest risk of progressing to disease is in the first and second years after infection. Outbreaks have been limited by application of infection control measures.

2. Advantages of interferon gamma release assays (IGRAs) such as Quantiferon-Gold for the diagnosis of latent TB infection include all the following ***except***:

A. More specific than tuberculin skin test (TST)
B. Reproducible results in health care workers
C. Does not require return visits
D. End points are objective.
E. Antigens are not found in BCG.

Answer: B There is lack of reproducibility in serial testing, particularly if the "positive" is close to end point.

3. The advantages of GenXpert MTB/RIF for the diagnosis of TB include all the following ***except***:

A. Useful in monitoring therapy
B. More sensitive than smear
C. Does not require proficiency in molecular technology
D. More rapid than culture
E. Provides rifampin susceptibility

Answer: A Not useful in monitoring therapy; the presence of *Mycobacterium tuberculosis* DNA in sputum does not indicate that there are viable organisms.

4. Which of the following is true concerning treatment of MDR TB:

A. The strategy of adding a single drug to retreatment regimens is cost-effective.
B. Empirical therapy is as good as tailoring regimen to drug susceptibility.
C. Acquisition of additional drug resistance is unlikely.
D. Standard duration of therapy (6 months) is adequate.
E. New drugs with potent activity now are available.

Answer: E Bedaquiline and delamanid have been approved by the FDA. Adding a single drug to a retreatment regimen is inadequate in one fourth of cases.

5. Which of the following is true regarding treatment of latent TB infection (LTBI)?

A. There is a prolonged effect in HIV-infected persons.
B. A 12-dose regimen of rifapentine-isoniazid is effective.
C. Treatment requires both a positive TST and IGRA.
D. There is no need to monitor for adverse events.
E. Screening in HIV-infected patients in resource-limited settings requires chest x-ray and culture.

Answer: B A 12-dose course of rifapentine-isoniazid is effective. The efficacy of isoniazid preventive therapy in HIV-infected patients in high-transmission settings wanes after 6 to 12 months.

325 THE NONTUBERCULOUS MYCOBACTERIA

STEVEN M. HOLLAND

DEFINITION

Nontuberculous mycobacteria generally include the growing number of mycobacteria other than *Mycobacterium tuberculosis* and its close relatives (Chapter 324) and *Mycobacterium leprae* (Chapter 326). Other names that have been used include *atypical mycobacteria, mycobacteria other than tuberculosis,* and *environmental mycobacteria*. The number of nontuberculous mycobacteria is growing rapidly as a result of the advent of DNA sequence typing for determining criteria for speciation. Accordingly, the number of species of nontuberculous mycobacteria has increased to almost 170 and will continue to increase for the near future.

The Pathogens

Identification of any mycobacterium requires that the appropriate tests be thought of ahead of time and be performed, because routine microbiological testing does not identify mycobacteria. Nontuberculous mycobacteria are typically first detected on acid-fast smears of sputum or other body fluids. When levels of organisms are high, mycobacteria may be seen on Gram stain

TABLE 325-1 COMMON NONTUBERCULOUS MYCOBACTERIA

ORGANISM	DISEASE
RAPIDLY GROWING NONTUBERCULOUS MYCOBACTERIA	
M. abscessus	Lung, disseminated, lymph node
M. chelonae	Skin
M. fortuitum	Line infections, lung
M. smegmatis	Almost never associated with disease
SLOWLY GROWING NONTUBERCULOUS MYCOBACTERIA	
M. avium complex	Lung, disseminated, lymph node
M. kansasii	Lung
M. marinum	Skin, tendons (fish tank granuloma)
M. xenopi	Lung
M. simiae	Lung
M. szulgai	Lung
M. malmoense	Lung
M. scrofulaceum	Lymph node
M. haemophilum	Disseminated, skin
M. genavense	Disseminated
M. ulcerans	Skin (Buruli ulcer; toxin producing)
M. neoarum	Disseminated
M. celatum	Disseminated
M. gordonae	Almost never causes disease
M. terrae complex	Disseminated

M = *Mycobacterium*.

as gram-positive beaded rods, but this finding is unreliable. The first step in identification is to request the appropriate smear (acid-fast or fluorochrome) and culture. Nontuberculous mycobacteria are broadly differentiated into rapidly growing (<7 days) and slowly growing (>7 days) forms. *M. tuberculosis*, by contrast, typically takes 2 or more weeks to grow. Formation of pigment in light (photochromogens) or dark (scotochromogens) and lack of pigment (nonchromogens) have also been used to help categorize nontuberculous mycobacteria. Current diagnostics use biochemical, nucleic acid, or cell wall composition on high-performance liquid chromatography for speciation (Table 325-1). For purposes of diagnosis, prognosis, and therapy, identification of nontuberculous mycobacteria should be taken to the species level.

EPIDEMIOLOGY

As a group, the nontuberculous mycobacteria are ubiquitous in soil and water and are often found in certain animals, but they rarely cause disease in humans. There are very few instances of human-to-human transmission of nontuberculous mycobacteria. However, *Mycobacterium massiliense* has caused outbreaks of infection in cystic fibrosis centers. Because these infections are not reported to health agencies and their identification is sometimes problematic, reliable data on incidence and prevalence are lacking. In the United States, however, isolates of nontuberculous mycobacteria have exceeded those for *M. tuberculosis* for many years. In patients with cystic fibrosis (Chapter 89), for example, rates of clinical nontuberculous mycobacterial infection range up to 40%, but even more patients harbor the organism. Differentiating active disease from commensal harboring of the organism remains problematic. Other patient groups, such as those with bronchiectasis, also have elevated rates of nontuberculous mycobacterial infection, but the rates are undefined.[1] The bulk of nontuberculous mycobacterial disease in North America is due to *Mycobacterium kansasii*, *Mycobacterium avium* complex (MAC), and *Mycobacterium abscessus*.

PATHOBIOLOGY

Because exposure is essentially universal and disease is rare, normal host defenses against nontuberculous mycobacteria must be highly effective. Therefore, otherwise healthy individuals in whom disease develops must have specific susceptibility factors that permit these infections to become established, multiply, and cause disease.

With the advent of human immunodeficiency virus (HIV) infection, $CD4^+$ T lymphocytes were identified as key effectors against nontuberculous mycobacteria. Much of the genetic basis of susceptibility to disseminated nontuberculous mycobacterial infection outside HIV infection has been found to be due to specific mutations in the interferon (IFN)-γ/interleukin (IL)-12 synthesis and response pathways. However, only about 70% of disseminated cases unassociated with HIV infection have a genetic diagnosis, and genetic causes of predisposition to nontuberculous mycobacterial lung disease are still very few.

Mycobacteria are typically phagocytosed by macrophages, which respond with the production of IL-12, a heterodimer composed of p35 and p40 moieties that together constitute IL-12p70 (Fig. 325-1). IL-12 activates T lymphocytes and natural killer (NK) cells through binding to its receptor (composed of IL-12Rβ1 and IL-12Rβ2/IL-23R) and results in phosphorylation of STAT4 (signal transducer and activator of transcription 4). IL-12 stimulation leads to production and secretion of IFN-γ, which activates neutrophils and macrophages to produce reactive oxidants and increase major histocompatibility complex display and Fc receptors. IFN-γ signals through its receptor (composed of IFN-γR1 and IFN-γR2), thereby leading to phosphorylation of STAT1, which in turn regulates IFN-γ–responsive genes such as those for the production of IL-12 and tumor necrosis factor (TNF)-α. Therefore, the positive feedback loop between IFN-γ and IL-12/IL-23 is pivotal in the immune response to mycobacteria and other intracellular infections (most importantly *Salmonella*, *Histoplasma*, *Coccidioides*). The advent of potent TNF-α inhibitors such as infliximab, adalimumab, certolizumab, etanercept, and golimumab (Chapter 36) has provided the ability to neutralize this critical cytokine, which has occasionally resulted in mycobacterial and fungal infections.

CLINICAL MANIFESTATIONS

Disseminated Disease

Disseminated nontuberculous mycobacterial disease secondary to MAC used to occur commonly in the setting of advanced acquired immunodeficiency syndrome (AIDS) but is now uncommon in North America because of MAC prophylaxis and improved treatment of HIV infection. The portal of entry was the bowel, with spread to bone marrow and the blood stream. Rapidly growing mycobacteria such as *Mycobacterium fortuitum* sometimes infect deep indwelling lines. The severe disseminated infection seen with immune defects is typically associated with malaise, fever, and weight loss, and it is often accompanied by organomegaly and lymphadenopathy. Disseminated (two or more organ) involvement in a child without an underlying iatrogenic cause should always prompt an investigation of the IFN-γ/IL-12 pathway.[2] Nontuberculous mycobacterial osteomyelitis is especially common with dominant negative mutations in IFN-γR1. A male with conical or peg teeth or an abnormal hair pattern and disseminated nontuberculous mycobacterial infection should be evaluated for defects in the pathway that activates nuclear factor (NF)κB. Some patients with disseminated rapidly growing infections (predominantly *M. abscessus*) have high-titer autoantibodies to IFN-γ.

Pulmonary Disease

Lung disease caused by nontuberculous mycobacteria is by far the most common form of the infection in North America. Predisposing factors include underlying lung disease, such as bronchiectasis (Chapter 90), pneumoconiosis (Chapter 93), chronic obstructive pulmonary disease (Chapter 88), primary ciliary dyskinesia, and cystic fibrosis.[3] The manifestations of *M. kansasii* infection can be very similar to those of tuberculosis (Chapter 324) and consist of hemoptysis, chest pain, and cavitary lung disease. MAC infection most commonly occurs in women in their sixth or seventh decade who have had months to years of nagging intermittent cough and fatigue, with or without sputum production or chest pain. Bronchiectasis and nontuberculous mycobacterial infection often coexist and progress in tandem, thus making causality difficult to determine. When compared with male smokers with upper lobe cavitary disease, who tend to carry the very same single strain of MAC indefinitely, nonsmoking females with nodular bronchiectasis tend to have several strains simultaneously and change them over the course of their disease process. Patients with pulmonary alveolar proteinosis (Chapter 91) are prone to pulmonary nontuberculous mycobacterial and *Nocardia* infections, likely reflecting their association with anti-GM-CSF autoantibodies and impaired alveolar macrophage function. Esophageal motility disorders such as achalasia (Chapter 138) have been associated with pulmonary disease, especially that caused by rapidly growing nontuberculous mycobacteria such as *M. abscessus*. It is important to note that lung disease rarely disseminates, illustrating that the defects leading to isolated pulmonary involvement are specific to the respiratory epithelium, whereas those defects leading to disseminated disease affect immune cells.

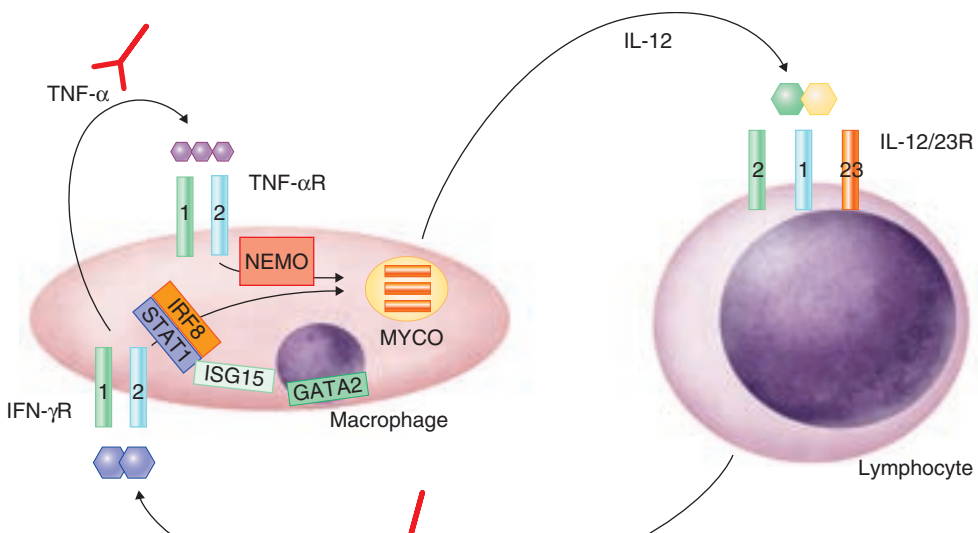

FIGURE 325-1. Schematization of the critical cytokine interactions between infected macrophages and T and natural killer lymphocytes. Organisms (MYCO) infect macrophages, which release heterodimeric interleukin (IL)-12. This acts on the IL-12/23 receptor complex and leads to the production of homodimeric interferon (IFN)-γ. IFN-γ acts on its receptor to stimulate the production of tumor necrosis factor (TNF)-α and kill intracellular organisms such as mycobacteria, salmonellae, and some fungi. Homotrimeric TNF-α acts on its own receptor and also contributes to killing of intracellular organisms. Both IFN-γ and TNF-α lead to upregulation of IL-12. TNF-α–blocking antibodies work either by blocking the ligand (infliximab, adalimumab, certolizumab) or by providing soluble receptor (etanercept). Mutations in both chains of IFN-γR, IL-12p40, and IL-12Rβ1, IL-12Rβ2 and signal elements for IFN-γR and TNF-αR have been identified through their predisposition to mycobacterial infections. IRF8 = interferon regulatory factor 8; ISG = interferon stimulated gene; NEMO = nuclear factor kappa-B essential modulator; STAT1 = signed transducer and activator of transcription 1.

Therefore, evaluation of isolated lung disease should focus on respiratory tract causes.[4]

Cervical Lymph Nodes

Isolated cervical lymphadenopathy, most frequently caused by MAC, is the most common form of nontuberculous mycobacterial infection in young children in North America. The organism is generally MAC, but other nontuberculous mycobacteria can also cause disease. The cervical swelling is often firm and relatively painless with a paucity of systemic signs. Because the differential diagnosis of painless adenopathy includes malignancy, many of these infections are incidentally diagnosed at biopsy. Local fistulas usually resolve completely with resection or antibiotic therapy or both.

Skin and Soft Tissue Disease

Mycobacterium marinum causes skin infections, usually papules or ulcers, associated with water exposure and is known as "fish tank granuloma." Numerous outbreaks of skin infections caused by rapidly growing mycobacteria (especially *M. abscessus*, *M. fortuitum*, and *Mycobacterium chelonae*) have been due to skin contamination from instruments used for surgical procedures (especially cosmetic surgery), injections, and other procedures.[5] These infections are typically accompanied by painful, erythematous, draining subcutaneous nodules, usually without associated fever or systemic symptoms.

FIGURE 325-2. Chest computed tomography in a patient with severe pulmonary *Mycobacterium abscessus* infection. Arrows indicate bronchiectasis. Note the extensive left upper lobe destruction and diffuse pleural reaction. In addition, the left lung is smaller than the right as a result of extensive loss of lung parenchyma.

DIAGNOSIS

With the continued decline in cases of tuberculosis, nontuberculous mycobacteria are now the most common mycobacteria isolated from humans in North America. The conventional tuberculin skin test (purified protein derivative [PPD]) evokes a cell-mediated response to secreted mycobacterial antigens. Unfortunately, the PPD test does not differentiate well between nontuberculous mycobacterial and tuberculosis infection, although large PPD reactions (>15 mm) more commonly signify tuberculosis. With the progressive decline in active tuberculosis in the United States, nontuberculous mycobacteria are likely to account for significant proportions of PPD reactivity. Newer IFN-γ release assays (IGRAs) incubate blood with relatively tuberculosis-specific recombinant proteins and elicit T-cell secretion of IFN-γ, thereby helping to clarify whether PPD reactivity is due to tuberculosis.

Isolation of nontuberculous mycobacteria from blood specimens is clear evidence of disease. However, because the slow-growing nontuberculous mycobacteria typically do not grow well in routine blood culture media, the diagnosis must be suspected. Isolation of nontuberculous mycobacteria from a biopsy specimen is strong evidence of infection, but cases of laboratory contamination do occur. Identification of organisms on stained sections of biopsy material confirms the authenticity of the culture. Some unusual nontuberculous mycobacteria require lower incubation temperatures or special additives for growth (e.g., *Mycobacterium hemophilum*).

The radiographic appearance of nontuberculous mycobacterial disease in the lung ranges from normal to nodules, bronchiectasis, air space disease, and extensive cavity formation, similar to that seen in tuberculosis (Fig. 325-2). Isolation of nontuberculous mycobacteria from respiratory samples presents special problems in both sensitivity and specificity. *Mycobacterium gordonae* is often recovered from respiratory samples and is almost never thought to be a real pathogen. Many patients, especially those with bronchiectasis, will occasionally have nontuberculous mycobacteria recovered from sputum culture without such mycobacteria being seen on smear. Specific criteria for definitive diagnosis of nontuberculous mycobacterial lung disease exist for MAC, *M. abscessus*, and *M. kansasii*, but they are probably good guidelines for other nontuberculous mycobacteria as well. A positive diagnosis requires

that two of three sputum samples grow nontuberculous mycobacteria, regardless of smear findings; a positive bronchoscopic alveolar sample, regardless of smear findings; or a biopsy specimen of pulmonary parenchyma with granulomatous inflammation or mycobacteria found on section and nontuberculous mycobacteria on culture.

Once isolated, identification of nontuberculous mycobacteria is important because it will determine the broad class of antimycobacterial therapy to be used. Many laboratories now use DNA probes to identify MAC, *M. gordonae*, and *M. kansasii*.[6] Drug susceptibility testing is of limited and largely unproven value, although clarithromycin susceptibility testing for MAC and rifampin susceptibility testing for *M. kansasii* are indicated. Initial isolates of MAC that have not been exposed to macrolides are almost always susceptible to macrolides. Any nontuberculous mycobacteria that have resisted a course of antimicrobials should probably be tested for antibiotic susceptibility as well.

PREVENTION

Prophylaxis of MAC disease in patients infected with HIV is started when the $CD4^+$ T-lymphocyte count is less than 50 cells/μL. Azithromycin 1200 mg weekly, clarithromycin 1000 mg daily, and rifabutin 300 mg daily are effective.

TREATMENT

Rx

It is rarely an emergency to initiate treatment of nontuberculous mycobacterial infections, which are relatively slow-growing chronic infections that evolve over a period of weeks to years, not hours to days. Therefore, empirical therapy is not usually needed, and identification of the species is advisable before starting complex, often poorly tolerated and potentially toxic, regimens. Similar to the case with tuberculosis, single-drug therapy is almost always associated with the emergence of antimicrobial resistance and is strongly discouraged.

MAC infection frequently requires complex multidrug therapy, the foundation of which is a macrolide (clarithromycin or azithromycin), ethambutol, and a rifamycin (rifampin or rifabutin). For disseminated nontuberculous mycobacterial disease in HIV-infected patients, the use of rifamycins poses special problems of drug interactions with protease inhibitors. For pulmonary MAC disease, three-times-weekly administration of drugs has been used successfully. The duration of therapy is prolonged, generally for 12 months after culture conversion and typically for a total of at least 18 months. Other drugs with activity against MAC include aminoglycosides, fluoroquinolones, and clofazimine.

M. kansasii lung disease is similar to tuberculosis in many ways and is also effectively treated with isoniazid (300 mg/day), rifampin (600 mg/day), and ethambutol (15 mg/kg/day). Treatment should continue until cultures have been negative for at least 1 year. Other drugs with very high activity against *M. kansasii* include clarithromycin, fluoroquinolones, and aminoglycosides.

Rapidly growing mycobacteria pose special therapeutic problems. Extrapulmonary disease in an immunocompetent host is usually due to inoculation (e.g., surgery, injection, trauma) or line infection and is often treated successfully with a macrolide and another drug (based on in vitro susceptibility), along with removal of the offending focus. By comparison, pulmonary disease, especially that caused by *M. abscessus*, is extremely difficult to eradicate, although repeated courses of treatment are usually effective in reducing the infectious burden and symptoms. Therapy generally includes a macrolide along with an intravenous agent such as amikacin, a carbapenem, cefoxitin, or tigecycline.[7] Other oral agents used according to in vitro susceptibility testing and tolerance include fluoroquinolones, doxycycline, and linezolid. Inhaled amikacin may be an option for treatment-refractory pulmonary infections.[8]

Treatment of the other nontuberculous mycobacteria is less well defined, but macrolides and aminoglycosides are usually effective, with other agents added as indicated. Expert consultation is strongly encouraged for difficult or unusual nontuberculous mycobacterial infections.

PROGNOSIS

The effect of nontuberculous mycobacterial infection on longevity is closely tied to the underlying condition (e.g., IFN-γ/IL-12 pathway defect, cystic fibrosis). With no or inadequate treatment, symptoms are intrusive, and the infections can lead to fatal complications, including overwhelming infection or severe lung destruction.

REVIEW QUESTIONS

1. Initial *Mycobacterium avium* complex (MAC) susceptibility testing is recommended and validated for which of the following?

A. Rifamycins
B. Macrolides
C. Aminoglycosides
D. Ethambutol
E. All of the above

Answer: B The only antibiotic class for which there is evidence for in vitro testing to predict in vivo value is macrolides. The other agents have limited predictive value in in vitro testing for MAC. Therefore, only macrolide testing is recommended and interpretable with break points.

2. Pulmonary MAC infection is associated with which of the following underlying conditions?

A. Cystic fibrosis
B. Primary ciliary dyskinesia
C. Bronchiectasis
D. Pneumoconiosis
E. All of the above

Answer: E Isolated pulmonary MAC infection has been clearly associated with defects in respiratory ciliary function and channel defects affecting the respiratory epithelium.

3. Disseminated MAC infection is associated with which of the following conditions?

A. Mutations in the interleukin (IL)-12 receptor
B. Mutations in the interferon (IFN)-γ receptor
C. Mutations in *STAT1*
D. Tumor necrosis factor (TNF)-inhibiting antibodies
E. All of the above

Answer: E The IL-12/IFN-γ pathway is critical for the control of intracellular organisms including nontuberculous mycobacteria. IFN-γ also induces TNF-α, linking these two pathways together.

4. Nontuberculous mycobacteria (NTM) are relatively ubiquitous in the environment. Which organism is the most common cause of nontuberculous mycobacterial infection in humans?

A. *Mycobacterium gordonae*
B. *Mycobacterium smegmatis*
C. MAC
D. *Mycobacterium abscessus* complex
E. *Mycobacterium kansasii*

Answer: C MAC is a compilation of *M. avium*, *M. intracellulare*, and *M. avium* X-cluster. The leading cause of disseminated NTM infection is *M. avium*, whereas the majority of isolated pulmonary NTM is due to *M. intracellulare*. *M. avium* X-cluster is a relatively infrequent cause of disease that is usually extrapulmonary.

5. Nontuberculous mycobacterial osteomyelitis is rare outside of genetic immunodeficiency. Which immunodeficiency is it most associated with?

A. Chronic granulomatous disease
B. Anti–TNF antibody therapy
C. Recessive deficiency of IFN-γR
D. Dominant negative deficiency of IFN-γR
E. Advanced HIV

Answer: D Osteomyelitis due to NTM and bacille Calmette Guérin (BCG) is strongly associated with the autosomal dominant form of IFN-γ receptor 1 deficiency. Isolated osteomyelitis due to NTM is much less common in the recessive forms of IFN-γ receptor 1 deficiency and very unusual in other genetic defects.

LEPROSY (HANSEN DISEASE)

JOEL D. ERNST

DEFINITION

Leprosy (Hansen disease) is a chronic infection caused by *Mycobacterium leprae*, an acid-fast slowly growing bacterium that cannot yet be cultured in vitro. Leprosy is found worldwide, although three countries of high prevalence (India, Brazil, and Indonesia) currently account for more than 80% of reported cases.[1] The primary manifestations of infection with *M. leprae* occur in the skin and peripheral nerves. The skin lesions of leprosy are classically hypopigmented, hypoesthetic or anesthetic, and nonpruritic. Peripheral nerves can be damaged by direct infection with *M. leprae* or by the immune response to the infection; the result is loss of sensation and motor function. Additional morbidity is due to the peripheral nerve dysfunction, including painless traumatic and burn injuries, secondary bacterial infections, and muscle atrophy and contractures. Leprosy per se is not a cause of death, but the debility associated with leprosy contributes to the severity of poverty and the likelihood of death from malnutrition or other infections. Despite the low transmissibility of *M. leprae* and the ability of multiple-drug therapy to cure leprosy, it remains a stigmatized disease that can pose a challenge to diagnosis and therapy.

The Pathogen

M. leprae is an acid-fast bacillus that contains a mycolic acid–rich cell wall and a single membrane. Despite nearly 150 years of effort, *M. leprae* remains uncultivatible in vitro. For biochemical and structural characterization, *M. leprae* can be grown in large quantities in nine-banded armadillos (*Dasypus novemcinctus*), and inoculation of the footpads of athymic mice allows semiquantitation of viable bacilli.

The genome of *M. leprae* consists of 3,268,203 base pairs (bp), compared with the *Mycobacterium tuberculosis* genome of 4,411,529 bp, and the number of expressed genes of *M. leprae* is approximately 60% fewer than that of *M. tuberculosis*. Because *M. leprae* and *M. tuberculosis* probably evolved from a common mycobacterial ancestor, *M. leprae* appears to have lost approximately 2000 genes since this divergence, leaving it dependent on specialized ecologic niches for its survival. Among the genes lacking in *M. leprae* are those of the *mbt* complex, whose products are involved in bacterial acquisition of iron. *M. leprae* also lacks many of the genes for lipid biosynthesis and modification that are characteristic of *M. tuberculosis*. The genome sequence has also allowed a directed approach to identification of 16 strains of *M. leprae* from geographically diverse sources. Genome sequence analyses have revealed that leprosy was introduced to the United States from Europe,[2] and also facilitated discovery that armadillos in the southeastern United States have the same unique strain as the U.S.-born leprosy patients have in the same region, suggesting that armadillos may be a reservoir for the pathogen in that region.

EPIDEMIOLOGY

Leprosy is found worldwide, although endemic leprosy is absent from northern Europe, where it was present in epidemic form as recently as the 19th century. The global prevalence of leprosy is about 180,000 known cases, and the current incidence is about 220,000. By definition of the World Health Organization (WHO) Strategic Plan for the Elimination of Leprosy, a newly diagnosed patient who has been treated with multidrug therapy is removed from the prevalence registry, which explains the lower prevalence than incidence of this chronic infection. Since initiation of the WHO Strategic Plan (whose goal is to eliminate leprosy as a public health problem, i.e., a prevalence of < 1 in 10,000 in all regions), an estimated 14 million people have been cured of leprosy.

The success of multidrug therapy notwithstanding, leprosy remains a public health problem in Brazil, Indonesia, Philippines, Democratic Republic of Congo, India, Madagascar, Mozambique, Nepal, and the United Republic of Tanzania. India and Brazil currently have the largest number of cases. Although domestic transmission of leprosy is extremely rare in the United States, 82 cases of leprosy were diagnosed in 2011, including cases in

immigrants from India, Brazil, the Philippines, the Dominican Republic, and Mexico. Because leprosy is not highly transmissible, it is not considered a disease of travelers other than immigrants.

Inability to culture *M. leprae* in vitro has been a major hindrance to understanding the modes of transmission and reservoirs of the organism. Observational studies reveal a low frequency of leprosy in casual travelers or temporary residents of high-incidence regions, thus indicating that *M. leprae* is not highly transmissible. Even in areas of high incidence, clusters of leprosy are rare outside families or others with prolonged close contact. It is believed that transmission of *M. leprae* commonly occurs through the respiratory route, because nasal secretions of people with lepromatous leprosy may contain 10^7 viable bacilli per milliliter. In addition, transmission of *M. leprae* is thought to occur through contact with contaminated soil, although soil has not been found to be a reservoir for the bacilli.

PATHOBIOLOGY

Immunology

There is an inverse correlation between the number of lymphocytes and the number of acid-fast bacteria present in skin lesions. Tuberculoid lesions have abundant lymphocytes, well-formed granulomas, and few bacteria (hence this form of leprosy is also termed *paucibacillary*). In contrast, lepromatous lesions have very few lymphocytes, poorly organized or no granulomas, and large numbers of bacteria (also termed *multibacillary leprosy*). Between these polar extremes are intermediate forms that represent a continuum of the histopathologic and bacteriologic findings, termed *borderline tuberculoid*, *borderline*, and *borderline lepromatous* (Fig. 326-1). In addition to correlating with the number of bacteria in individual lesions, the polar forms of leprosy correlate with the total number of skin lesions in an individual patient: tuberculoid leprosy exhibits few (<five) lesions, whereas lepromatous leprosy is characterized by multiple lesions (≥five, up to hundreds).

Leprosy provides a paradigm for the effect of the cellular immune response to a bacterial pathogen on the clinical manifestations of the infection.[3] Individuals in whom a T helper 1 (T_H1) immune response (characterized by antigen-specific T cells that produce interferon [IFN]-γ, lymphotoxin [LTA], or interleukin [IL]-2 and no IL-4 or IL-5) develops to *M. leprae* exhibit few skin lesions and few bacteria within the lesions (paucibacillary leprosy). In contrast, persons in whom a T_H2 immune response develops (T cells that produce little IFN-γ, lymphotoxin, or IL-2, but produce IL-4, IL-5, and IL-13) have larger numbers of skin lesions and large numbers of bacteria within lesions (multibacillary leprosy). The roles of other T-cell subsets, such as T_H17 or T-regulatory cells, remain to be defined in leprosy. The primary determinant of the differential immune response to *M. leprae* is incompletely understood, although substantial evidence indicates that host genetic polymorphisms contribute to the likelihood of paucibacillary versus multibacillary leprosy.

Pathogenesis of Nerve Damage

Peripheral nerve damage, the most important consequence of infection with *M. leprae*, occurs in all forms of leprosy and underlies the complications of the infection. *M. leprae* invades Schwann cells, the glial cells of peripheral nerves. Schwann cells form a functional unit with peripheral nerve axons and are surrounded by laminin-2, a neural-specific extracellular matrix protein. The G domain of laminin-2 can bind simultaneously to *M. leprae* and to the Schwann cell laminin receptor α-dystroglycan, which promotes binding of *M. leprae* to Schwann cells by use of laminin-2 as a bridging molecule. Laminin-2 interacts with two distinct molecules on the surface of *M. leprae*, a 21-kD protein and phenolic glycolipid-1 (PGL-1); either can mediate internalization by Schwann cells. Once *M. leprae* is bound and internalized by Schwann cells, it can cause direct demyelination of peripheral nerves in the absence of an immune response, apparently by signaling through ErbB2 and Erk1/2. *M. leprae*–mediated demyelination occurs without early cell death or toxicity, although Schwann cells and neurons can die by apoptosis later after infection. In addition, dead *M. leprae* or PGL-1 shed from live or dying *M. leprae* can mediate peripheral nerve demyelination and may contribute to the ongoing nerve damage that can follow initiation of chemotherapy. In addition to PGL-1–mediated demyelination, an *M. leprae* 19-kD lipoprotein can mediate Schwann cell apoptosis in vitro, and apoptotic Schwann cells can be found in human leprosy lesions. These mechanisms may be responsible for the nerve damage in multibacillary leprosy.

In addition to direct damage to peripheral nerves by *M. leprae*, the immune response in leprosy also contributes to nerve damage, especially in paucibacillary (tuberculoid) leprosy, in which the bacteria or PGL-1 or both are present in insufficient quantity to cause widespread nerve damage, and in reversal reactions, in which inflammation is particularly prominent.[4] Several distinct immunologic mechanisms probably contribute to the nerve damage in leprosy. Pro-inflammatory cytokines such as tumor necrosis factor (TNF)-α, IL-1β, and IFN-γ are especially prominent in lesions during reversal reactions, when irreversible nerve damage can occur. Because these molecules can contribute to inflammatory tissue damage and can induce apoptosis of Schwann cells in vitro, it is likely these mediators play an active role in nerve damage. Reversal reactions are also characterized by an increase in the number of $CD4^+$ T lymphocytes in lesions, and at least some of these $CD4^+$ cells exhibit a cytotoxic phenotype and kill *M. leprae*–infected Schwann cells through antigen- and major histocompatibility complex class II–dependent secretion of cytotoxic granule contents. Whether these mechanisms of nerve damage occur in chronic tuberculoid leprosy is not established, but similar cytokines and T lymphocytes are found in tuberculoid lesions.

Genetics

Cases of leprosy cluster in families, partly because of shared environments and similar exposure but also probably because of genetic determinants of susceptibility. Genetic loci whose allelic variants are related to altered susceptibility to infection with *M. leprae* include *PARK2*, *NRAMP1*, *TNF*, *TLR1*, *FCN2*, *LTA*, *NOD2*, *RIPK2*, *IL23R*, and *RAB32*. Parkin, the product of PARK2, is an E3 ubiquitin ligase that promotes autophagy and killing of intracellular bacteria, including mycobacteria. *NRAMP1*, *NOD2*, *RIPK2*, and *TNF* are expressed by macrophages, and quantitative or temporal differences in their expression may account for differences in innate susceptibility to infection. TLR1 and ficolin-2 are pattern recognition molecules that recognize bacterial lipopeptides and polysaccharides, respectively, whereas NOD2 and its downstream kinase RIPK2 are involved in responses to bacterial peptidoglycan. The overlap in susceptibility genes for leprosy and for Crohn's disease suggests one or more shared mechanisms of pathogenesis.[5] Genes with polymorphisms associated with a predisposition to distinct clinical forms of leprosy (i.e., lepromatous vs. tuberculoid) include HLA-DRB1*1501 and HLA-DRB1*1502, *NRAMP1*, *TNF*, *IL-10*, and *TAP2*.

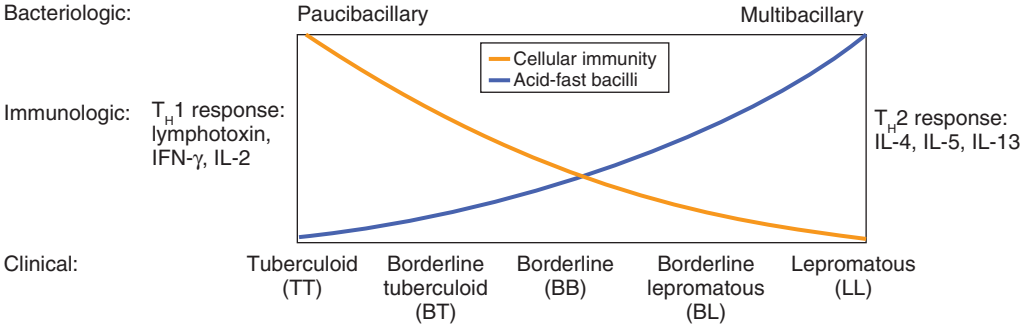

FIGURE 326-1. Bacteriologic, immunologic, and clinical spectrum of leprosy. Tuberculoid (paucibacillary) leprosy is characterized by a T_H1 immune response and few or no detectable bacilli in biopsy specimens of skin lesions or smears of skin slits. At the opposite pole of the spectrum, lepromatous (multibacillary) leprosy is accompanied by a T_H2 immune response, numerous skin lesions, and numerous acid-fast bacilli on skin biopsy specimens or smears. The intermediate forms can be classified according to their resemblance to tuberculoid or lepromatous leprosy. IFN = interferon; IL = interleukin.

FIGURE 326-2. Tuberculoid leprosy. A single large lesion with irregular, raised, erythematous borders and a depressed, hypopigmented center is shown. (From Hansen's disease [leprosy]. In: James WD, Berger TG, Elston DM, eds. *Andrews' Diseases of the Skin.* 10th ed. Philadelphia: Elsevier; 2006.)

FIGURE 326-3. Lepromatous leprosy. Numerous papules and nodules are apparent. Lepromatous macules have ill-defined borders, with normal sensation usually maintained. (From Hansen's disease [leprosy]. In: James WD, Berger TG, Elston DM, eds. *Andrews' Diseases of the Skin.* 10th ed. Philadelphia: Elsevier; 2006.)

CLINICAL MANIFESTATIONS

The most common manifestations of leprosy involve the skin and peripheral nerves and are determined by the polarity of the disease: paucibacillary (tuberculoid) or multibacillary (lepromatous). The onset of leprosy is usually insidious. Depending on the form of leprosy, numbness may be an initial complaint or finding, and skin lesions may become apparent only months or years later. The classification of leprosy as tuberculoid, lepromatous, or one of the borderline forms is based on the combination of clinical examination, the number of bacteria seen on skin slit smears or skin biopsy specimens, and the histologic appearance. Because the nature of the potential complications and the specific course of chemotherapy are determined by the form of leprosy, accurate diagnosis and classification are essential.

Tuberculoid Leprosy

Tuberculoid leprosy is characterized by the presence of fewer than five skin lesions, which are typically hypopigmented or erythematous macules with raised erythematous borders and an atrophic center (Fig. 326-2). The skin lesions in tuberculoid leprosy are usually hypoesthetic or anesthetic; when multiple lesions are present, their distribution is asymmetrical. The skin lesions may be large and are most commonly found on the face, trunk, or extremities; however, they are not found in the axillae, groin, perineum, or on the scalp, presumably because of the preference of *M. leprae* for lower temperatures.

Local peripheral nerve involvement is common in tuberculoid leprosy and is asymmetrical. In addition to hypoesthesia or anesthesia of the skin lesions, nerve involvement in tuberculoid leprosy is manifested as enlargement or tenderness (or both) of the peripheral nerves that serve the region of the skin lesions. Superficial nerves such as the ulnar, superficial peroneal, or greater auricular nerves may be visibly enlarged, depending on the location of the skin lesions. Functional complications of nerve involvement, such as muscle atrophy and contractures, may be present at the time of diagnosis of tuberculoid leprosy. Tuberculoid leprosy is a stable form; it does not convert to borderline or lepromatous forms.

Lepromatous Leprosy

Lepromatous leprosy is characterized by multiple skin lesions that are smaller than those observed in tuberculoid leprosy (Fig. 326-3). Although the sites of skin lesions are similar to those of tuberculoid leprosy, the multiple lesions of lepromatous leprosy are often symmetrically distributed. Lepromatous macules may have poorly defined borders and no loss of sensation; local nerve enlargement is not characteristic. In addition to macules, lepromatous skin lesions may be nodules or plaques, or they may diffusely infiltrate the skin, especially on the face (which may cause loss of eyebrows and "leonine facies").

Nerve involvement in lepromatous leprosy is characteristically symmetrical and exhibits a stocking-glove distribution unrelated to the location of skin lesions. Peripheral nerve involvement may initially be manifested as loss of temperature sensation, followed by loss of light touch, pain, and deep pressure sense. In addition, dysesthesia is common. Motor complications, including muscle weakness and atrophy of the muscles of the hands, feet, and face, develop in the absence of effective antileprosy chemotherapy. Involvement of the facial nerve may result in corneal exposure, ulceration, and blindness. Persons with lepromatous leprosy may also have prominent rhinorrhea as a result of nasal mucosal involvement, and they may shed large numbers of *M. leprae* in their nasal secretions—one of the major sources of bacilli for transmission to other individuals. Like tuberculoid leprosy, lepromatous leprosy is stable; conversion to other forms does not occur.

Borderline Forms of Leprosy

Borderline tuberculoid leprosy is characterized by skin lesions similar to those of tuberculoid leprosy, but they are more numerous and may be accompanied by satellite lesions around large lesions. In borderline leprosy, skin lesions are numerous but remain asymmetrical. The lesions are usually plaques rather than macules and exhibit satellite lesions. Nerve involvement in borderline leprosy is manifested as thickening or tenderness of local nerves, but the skin lesions retain sensation. Borderline lepromatous leprosy is characterized by numerous symmetrical small macules, papules, plaques, and nodules but not the diffuse skin infiltration found in full-blown lepromatous leprosy. Unlike tuberculoid and lepromatous leprosy, the borderline forms are unstable and progress to the lepromatous form over time unless effective treatment is provided. Reactional states, including both reversal reactions and downgrading reactions, occur in those with borderline forms of leprosy.

Reactional States

Individuals with leprosy who may otherwise avoid care may exhibit acute reactional symptoms and signs. Physicians in developed countries may encounter patients with reactional states in acute care settings.[6]

Type 1 reactions, which are mediated by cellular immune responses to *M. leprae* antigens in skin lesions and nerves, occur in borderline tuberculoid, borderline, and borderline lepromatous leprosy. Type 1 reactions are frequently accompanied by worsening of peripheral nerve manifestations and may result in permanent nerve damage; they should be considered medical emergencies. Reversal reactions, which are type 1 reactions that occur after

initiation of therapy for leprosy or for human immunodeficiency virus (HIV) infection, are associated with enhanced T_H1 immune responses that develop in patients with a large burden of *M. leprae*; they are most severe in those with borderline lepromatous leprosy. Downgrading reactions occur in association with the transition of borderline disease toward the lepromatous form. Although the immune mechanisms that underlie reversal reactions and downgrading reactions are believed to be distinct, their clinical manifestations are indistinguishable. Type 1 reactions may have an acute or insidious onset, and they are characterized by inflammation of preexisting skin and nerve lesions. Skin lesions, which become erythematous and edematous, may also become tender and thereby resemble cellulitis, but type 1 reactions are not accompanied by fever or other systemic symptoms or signs. Increased expression of TNF has been found in lesions during type 1 reactions and may contribute to the clinical and functional consequences. Moreover, type 1 reactions have been reported when TNF antagonist therapy has been withdrawn after diagnosis of borderline lepromatous leprosy. Recent transcriptomic analyses have also implicated the complement system in the pathogenesis of type 1 and type 2 leprosy reactions.[7]

Type 2 reactions, also known as erythema nodosum leprosum (ENL), occur in persons with borderline lepromatous and lepromatous leprosy; they may be mediated by immune complexes rather than cellular immune responses. Type 2 reactions, which occur most often after initiation of antileprosy chemotherapy or during pregnancy, are generally accompanied by fever and arthralgias. Additional signs of systemic inflammatory disease may appear, including hepatosplenomegaly, lymphadenopathy, arthritis, nephritis, keratitis, and iritis. The skin lesions of ENL resemble those of classic erythema nodosum (Chapter 440), with widely distributed erythematous dermal and subcutaneous nodules whose location is unrelated to the leprosy lesions. Biopsy of ENL lesions shows leukocytoclastic vasculitis.

Leprosy and Human Immunodeficiency Virus

$CD4^+$ T-cell–mediated immunity is essential for control of *M. leprae,* and the extent of T_H1 immunity determines whether an individual will have tuberculoid or lepromatous leprosy. However, coinfection with HIV and depletion of $CD4^+$ T lymphocytes does not affect the rate of progression of leprosy, nor does it cause conversion of tuberculoid leprosy to the lepromatous form. In contrast, type 1 reversal reactions may accompany immune reconstitution subsequent to initiation of effective antiretroviral therapy for HIV infection (Chapter 395). The manifestations of these reversal reactions are similar to those observed in patients who are not infected with HIV.

DIAGNOSIS

The diagnosis of leprosy should be considered in any patient with skin and peripheral nerve manifestations, especially those who have lived in countries where leprosy is endemic. Although leprosy is a chronic infection, its acute complications require prompt diagnosis and therapy to prevent irreversible peripheral nerve damage. It is also important to classify a patient's disease as tuberculoid, lepromatous, or one of the specific borderline forms, because correct classification is necessary for selecting optimal therapy and anticipating potential reactional states. Because *M. leprae* cannot be cultured in vitro and there is currently no reliable serologic test or other diagnostic biomarker for leprosy, diagnosis and classification of leprosy depend on the combination of clinical examination, histopathologic evaluation, and acid-fast staining of skin slit or biopsy specimens.

Clinical Examination

Examination of an individual with possible or confirmed leprosy must include evaluation and documentation of the number, location, and characteristics of skin lesions. In addition to descriptions of the skin lesions, accurate classification of leprosy depends on whether the lesions are distributed symmetrically and whether they are hypoesthetic or anesthetic. The examination must also include a search for (1) enlarged and tender peripheral nerves, (2) the presence of sensory deficits (especially temperature sensation and pain) and skin ulcerations, and (3) the nature and distribution of motor deficits, muscle atrophy, and contractures. Because some medications used for the treatment of leprosy are contraindicated in pregnancy, women of childbearing age should be evaluated for pregnancy.

Skin Smears and Biopsies

In developing countries, classification of multibacillary or paucibacillary leprosy is made by the combination of clinical examination findings and bacterial counts as determined on acid-fast–stained smears made from skin slits of lesions and skin from cool areas of the body, such as the earlobes. In developed countries, skin biopsies are usually performed instead of skin slits. Skin specimens should be obtained from the active borders of lesions and should include subcutaneous tissue. On hematoxylin-eosin staining, tuberculoid leprosy is characterized by granulomas with giant cells, aggregates of epithelioid macrophages that are neither vacuolated nor foamy, and lymphocytes at the periphery. Although granulomas may be found in other skin diseases, selective destruction of nerve trunks and perineural fibrosis are specific features of leprosy. Acid-fast stains (preferably done with the Fite procedure) show rare or undetectable bacilli in tuberculoid leprosy. Lesions of lepromatous leprosy show poorly organized granulomas without giant cells or lymphocytes; macrophages are foamy and lipid laden. Acid-fast staining of lepromatous leprosy lesions reveals abundant bacilli that usually appear in large clumps ("globi"). The borderline forms of leprosy exhibit less well-organized granulomas with fewer giant cells and lymphocytes but more foamy macrophages and acid-fast bacilli as the spectrum varies from borderline tuberculoid to borderline lepromatous.

Specialized immunohistochemistry stains, such as for $CD4^+$ T lymphocytes or cytokine expression, are useful in research studies but are not currently used for the diagnosis or classification of leprosy. Polymerase chain reaction amplification of *M. leprae* genomic DNA from skin slits or skin biopsy specimens has not yet contributed to enhanced sensitivity or specificity of diagnosis or classification.

Diagnosis of Reactional States

The diagnosis of type 1 reactions is based on clinical findings in a patient with borderline tuberculoid, borderline, or borderline lepromatous leprosy and acute inflammation of preexisting skin lesions, with or without worsening of nerve lesions. Type 1 reactions are not accompanied by systemic findings such as fever or arthritis. At highest risk for type 1 reactions are patients who have recently initiated antileprosy chemotherapy, although type 1 reactions can occur spontaneously. Diagnosis of a type 2 reaction (ENL) is also based on clinical findings of new erythematous subcutaneous or dermal nodules in a patient with borderline lepromatous or lepromatous leprosy. There are currently no diagnostic tests or biomarkers for ENL, and skin biopsy will not distinguish ENL from classic erythema nodosum.

TREATMENT Rx

Agents to Treat Leprosy

The first-line antimicrobial agents for leprosy are dapsone and rifampin. Clofazimine, minocycline, certain fluoroquinolones, and clarithromycin are also useful in specific contexts, including drug intolerance or resistance.

Dapsone is inexpensive and well tolerated, has a long serum half-life (≈28 hours), and is safe for use during pregnancy. Glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals (Chapter 161) are susceptible to dapsone-induced methemoglobinemia and hemolysis, and all patients should be screened for G6PD deficiency before starting dapsone. Patients with mild G6PD deficiency (the African type, caused by mutations that lead to instability of the enzyme) can begin dapsone at 25 mg/day but require close monitoring for hemolytic anemia. Dapsone can also cause bone marrow suppression and profound neutropenia. Other rare adverse effects of dapsone include hepatitis, cholestatic jaundice, and a hypersensitivity syndrome that usually occurs within 4 to 6 weeks of initiation of dapsone and is characterized by exfoliative dermatitis, generalized lymphadenopathy, fever, and hepatosplenomegaly. A recent study in China found that the presence of the HLA class I allele B*13:01 confers a seven-fold higher risk of the dapsone hypersensitivity syndrome, strongly implicating $CD8^+$ T cells in its pathogenesis.[8]

Rifampin, the most bactericidal drug against *M. leprae*, is well absorbed after oral administration and has a serum half-life of approximately 3 hours. Rifampin should never be used as monotherapy because resistance can develop with single point mutations in its target, RNA polymerase II. Because rifampin is bactericidal and rapid release of components from dead bacteria can have pro-inflammatory effects, some experts withhold rifampin during reversal reactions. Adverse effects of rifampin include maculopapular rash, hepatotoxicity, an influenza-like syndrome (most frequent with intermittent therapy), and orange discoloration of tears, urine, saliva, and sweat. Thrombocytopenia occurs occasionally but is not usually severe. Rifampin also induces metabolism and decreases serum concentrations of other drugs, including antiretroviral protease inhibitors and non-nucleoside reverse transcriptase inhibitors, methadone, and oral contraceptives. Rifampin decreases serum concentrations of dapsone, but this effect is not clinically significant with a dapsone dose of 100 mg/day.

Clofazimine is a lipophilic dye that is bacteriostatic against *M. leprae.* It has a very long (≈70 days) half-life and appears to have anti-inflammatory activity

as well as direct bacteriostatic activity. Because of its anti-inflammatory activity, clofazimine is useful in the treatment of type 1 reactional states. Clofazimine is generally well tolerated; its major side effect is discoloration of the skin, which occurs in nearly all clofazimine-treated patients. The skin discoloration can range from reddish tan to bluish black and can be blotchy, but it is reversible within 6 to 12 months of discontinuation of the drug. In chronic reactional patients maintained with high doses of clofazimine (200 to 300 mg/day), enteropathy with crampy abdominal pain, mild nausea, or diarrhea (or both) and even bowel obstruction can develop.

Regimens to Treat Leprosy

Chemotherapy for leprosy involves the use of multiple drugs to optimize the rate of cure and prevent emergence of drug resistance.[9] The regimen currently recommended in the United States for paucibacillary (tuberculoid and borderline tuberculoid) leprosy in adults consists of dapsone, 100 mg, and rifampin, 600 mg, both given daily for 12 months. The U.S. recommended regimen for multibacillary leprosy in adults is dapsone, 100 mg, plus rifampin, 600 mg, and clofazimine, 50 mg, each given daily for 24 months (available at http://www.hrsa.gov/hansensdisease/diagnosis/recommendedtreatment.html). Clofazimine is currently not commercially available, but it can be obtained in the United States through the National Hansen's Disease Program (1-800-642-2477). In resource-limited countries where the burden of leprosy is highest, the WHO regimen for paucibacillary leprosy is dapsone, 100 mg daily, plus rifampin, 600 mg once a month, for 6 months. The WHO regimen for adults for multibacillary leprosy (which differs from the U.S. recommendation) is dapsone, 100 mg daily, plus rifampin, 600 mg once a month, plus clofazimine, 50 mg daily, each given for 12 months, plus an additional dose of clofazimine, 300 mg once a month (available at http://www.who.int/lep/mdt/regimens/en/index.html). The monthly doses of rifampin and clofazimine should be administered under supervision. Alternative agents for patients with drug intolerance or drug resistance include clarithromycin (may be substituted for any of the first-line drugs), minocycline (may be substituted for dapsone or clofazimine), and ofloxacin (may be substituted for clofazimine).

Response to Therapy

Response to effective therapy for leprosy is seen clinically as flattening and resolution of the papules, nodules, or plaques, with or without improvement in nerve function. Clinical improvement may begin within the first months of therapy, but resolution of skin lesions is often delayed as long as 1 to 2 years after completion of therapy. Quantitation of the bacillary load to assess response to treatment is cumbersome, semiquantitative, and not recommended.

Patients who have been adequately treated may experience worsening of nerve and skin symptoms, perhaps because of a late reversal reaction or relapsed leprosy. If skin specimens do not reveal acid-fast organisms, a therapeutic trial of corticosteroids, which will ameliorate the symptoms of reversal reactions but not those of relapsed leprosy, can help make the distinction and assist in choosing subsequent therapy. Patients who experience relapse after treatment of paucibacillary disease should be treated for multibacillary disease, because the most likely cause of relapse is previous multibacillary disease that was misclassified. Patients with multibacillary disease who relapse should be retreated with a regimen containing dapsone and rifampin with the addition of at least two drugs that were not used in the initial treatment regimen, unless susceptibility testing is available and confirms that the organisms remain susceptible to dapsone and rifampin. The choices among additional drugs include minocycline, ofloxacin or moxifloxacin, and clarithromycin. Relapsed multibacillary patients may benefit from lifelong maintenance therapy after completing 2 years of a salvage regimen. Because susceptibility testing cannot be performed with in vitro assays, an alternative approach to determination of susceptibility by detecting mutations in the targets of dapsone and rifampin (*folP1* and *rpoB*, respectively) is beginning to be widely used and is commercially available. The mouse footpad assay has been used, but it is becoming less available.

Treatment of Reactional States

Type 1 reactions may develop before, during, or years after completion of antileprosy chemotherapy.[10] Type 1 reactions that involve worsening of nerve symptoms are medical emergencies because permanent nerve damage can occur. Type 1 reactions usually respond to prednisone at a daily dose of 60 to 80 mg, which can be tapered slowly once symptoms are controlled. Type 1 reactions can also respond to high-dose clofazimine (200 to 300 mg/day), although reactions with worsening nerve symptoms should be treated initially with prednisone. Patients who have type 1 reactions that occur before or during antileprosy chemotherapy and whose reactions include nerve involvement should have rifampin withheld until the worsened nerve symptoms resolve, because release of pro-inflammatory components from dying bacteria may contribute to inflammation and nerve damage. Dapsone and clofazimine should be continued during treatment of type 1 reactions.

The treatment of choice for severe type 2 reactions (ENL) is thalidomide, except in pregnant or potentially pregnant women. Thalidomide requires that patients and the prescribing physician be enrolled in the System for Thalidomide Education and Prescribing Safety (STEPS) program to avoid the drug's teratogenic effects. The mechanism of action of thalidomide is incompletely understood but is likely to include inhibition of TNF. The dose of thalidomide for ENL varies, depending on the severity of the reaction. In patients with ENL and high fever, frank arthritis, and large subcutaneous plaques, up to 100 mg four times daily may be required to achieve a clinical response. Once a clinical response is achieved, the dose of thalidomide may be tapered to a maintenance dose of 50 to 100 mg given once daily at night (because thalidomide is sedating). For milder cases of ENL, 50 to 100 mg per night may be sufficient to achieve and maintain control. ENL in women of childbearing age and thalidomide-unresponsive cases may respond to corticosteroids. Methotrexate may be efficacious in otherwise treatment-resistant ENL, but methotrexate has been assigned by the U.S. Food and Drug Administration to pregnancy category X (teratogenic risks "clearly outweigh" potential benefits) and is also contraindicated in nursing mothers. Antileprosy chemotherapy, including rifampin, should be continued in patients with ENL.

Other Therapy

Nerve damage in leprosy, which can result in muscle atrophy, contractures, and autoamputation, is the major cause of debility. Supportive care, reconstructive surgery, physical and occupational therapy, and rehabilitation can be extremely valuable in allowing patients to achieve and maintain optimal function.

PREVENTION

There is currently no effective specific vaccine for leprosy, but several trials have observed a partial protective effect of bacille Calmette-Guérin vaccination.[11] It is likely that improved understanding of transmission of *M. leprae* will be generated by the use of DNA-based strain typing, so better preventive measures are likely to become available in the near future.

PROGNOSIS

Multidrug chemotherapy cures a high proportion of people with paucibacillary and multibacillary leprosy. The currently recommended regimens provide high rates of response, with relapse rates of approximately 0.1% per year in paucibacillary cases and up to 5% per year in multibacillary cases. Some cases of paucibacillary leprosy may enter remission or even self-cure, but all cases of multibacillary leprosy are progressive. Because of its efficacy and low toxicity and to minimize long-term morbidity, multidrug chemotherapy should be used in all persons in whom leprosy is diagnosed.

REVIEW QUESTIONS

1. A 23-year-old Brazilian man was seen by a dermatologist for evaluation of multiple bilateral plaques and nodules; biopsy revealed poorly formed granulomas with multiple foamy cells, and Fite stain revealed multiple acid-fast bacteria. Additional investigation revealed glucose-6-phosphate dehydrogenase (G6PD) deficiency with the Mediterranean variant. What are the potential treatment options for this patient's leprosy?

A. Rifampin and dapsone
B. Rifampin and clarithromycin
C. Rifampin
D. Rifampin and clofazimine
E. Rifampin and ofloxacin

Answer: B The patient has lepromatous or borderline lepromatous leprosy with a high bacterial burden. His G6PD mutation is sufficiently severe (Chapter 161) that he is at high risk of significant hemolysis if he is treated with dapsone. Rifampin monotherapy is likely to select for rifampin-resistant variants, especially in someone with the high bacterial burden present in multibacillary leprosy. According to current guidelines, the only recommended drug to substitute for dapsone is clarithromycin. Reference: http://www.hrsa.gov/hansensdisease/diagnosis/recommendedtreatment.html

2. A 27-year-old Brazilian woman was diagnosed with borderline tuberculoid leprosy on the basis of clinical and histopathologic criteria and was begun on multidrug therapy with dapsone and rifampin. Six months after initiation of therapy, she complains of worsening of her skin lesions, which are now more erythematous, and worsening neuritic pain with weakness of her left hand. She is afebrile, and a complete blood count and urinalysis are normal. What is the most appropriate therapeutic intervention?

A. Add ofloxacin and clarithromycin for drug-resistant leprosy with progression.
B. Discontinue rifampin and treat with thalidomide.
C. Hold rifampin and add clofazimine and prednisone.
D. Continue rifampin and dapsone and treat with prednisone until symptoms resolve.
E. Biopsy the edge of one of the skin lesions and treat according to the results.

Answer: C The patient has typical symptoms and findings of a reversal reaction, which requires effective anti-inflammatory therapy to minimize progressive peripheral nerve damage. Reversal reactions are currently diagnosed clinically; a skin biopsy is not necessary. When there is evidence of nerve involvement during a reversal reaction, most experts recommend holding rifampin to minimize the ongoing release of pro-inflammatory components during bacterial death. The preferred treatment is clofazimine, owing to its anti-inflammatory activity; its additional antimycobacterial activity is thought to help minimize emergence of dapsone-resistant bacteria. When there is evidence of neural involvement, prompt addition of prednisone is indicated. Emergence of drug resistance during treatment of leprosy with a low bacterial burden, such as in borderline tuberculoid leprosy, occurs rarely and more often presents as a relapse rather than progression with evidence of increased inflammation. Thalidomide is used to treat erythema nodosum leprosum (ENL), not reversal reactions, and must be used with extreme caution and multiple methods of contraception in a woman of child-bearing age.

3. A 32-year-old man originally from Indonesia was found to have borderline tuberculoid leprosy during evaluation of a mononeuropathy. Results of a complete blood count, serum chemistry panel, and G6PD assay were all within normal limits. Four weeks after beginning treatment with dapsone and rifampin, he had gradual onset of malaise, fever, and diffuse rash. Physical examination is remarkable for a toxic appearance, fever (38.6° C), tachycardia, exfoliative dermatitis, diffuse lymphadenopathy, and hepatosplenomegaly. Lab studies are remarkable for leukocytosis, thrombocytopenia, and elevated transaminases. What intervention is most important for his recovery from the acute illness?

A. Addition of thalidomide to his current regimen.
B. Substitute clarithromycin for rifampin.
C. Add clofazimine for antimycobacterial and anti-inflammatory activity.
D. Add prednisone.
E. Discontinue dapsone.

Answer: E The patient has dapsone hypersensitivity syndrome, which is an immunologically mediated reaction that is likely due to activation of $CD8^+$ T cells. This syndrome has a case fatality rate as high as 10%, and when it occurs, dapsone must be discontinued immediately. A syndrome of systemic toxicity with the acute onset of rash in a patient receiving treatment for leprosy could also be erythema nodosum leprosum, but ENL occurs rarely if ever in patients with a low bacterial burden, as in tuberculoid or borderline tuberculoid leprosy.

4. A 72-year-old man from the Philippines was diagnosed with borderline lepromatous leprosy; treatment with rifampin, dapsone, and clofazimine was initiated. After 4 weeks, a reference laboratory reported that polymerase chain reaction (PCR) amplification of two separate skin biopsy samples revealed mutations in *Mycobacterium leprae polB* that are diagnostic of high-level rifampin resistance. How should his treatment be altered?

A. Rifapentine should be substituted for rifampin.
B. The dapsone dosage should be increased.
C. Clarithromycin should be substituted for rifampin.
D. Ofloxacin should be substituted for rifampin.
E. Minocycline should be substituted for rifampin.

Answer: C Multidrug treatment of leprosy is essential for optimal relapse-free outcomes, especially in multibacillary leprosy, which includes borderline lepromatous leprosy. Although experience is limited, it is unlikely that treatment with dapsone and clofazimine is adequate for an optimal outcome. Mutations in *polB* that confer resistance to rifampin also confer resistance to other rifamycins, including rifabutin and rifapentine. Of the alternative drugs, clarithromycin is the only one currently recommended to substitute for rifampin.

5. In patients with lepromatous leprosy, in whom lesions contain very few T lymphocytes, nerve damage is thought to be due to which of the following mechanisms?

A. Demyelination of peripheral nerve fibers by interaction of phenolic glycolipid with Schwann cells
B. Autoantibody destruction of peripheral nerve axons
C. T_H1-mediated inflammatory tissue damage
D. Cytolytic $CD8^+$ T-cell expression of granzyme B
E. Complement-mediated cytotoxicity

Answer: A In multibacillary (including lepromatous) leprosy, existing evidence is most consistent with nerve fiber damage by products of *M. leprae* rather than by host-mediated mechanisms. *M. leprae* phenolic glycolipid interacts with Schwann cell laminin 2 and activates the receptor tyrosine kinase ErbB2. Downstream signaling that requires activation of the Erk1/2 kinase(s) results in demyelination. In contrast, nerve damage in paucibacillary leprosy is believed to be mediated by host T-cell responses.

RICKETTSIAL INFECTIONS

DIDIER RAOULT

DEFINITION

Rickettsioses are emerging infectious diseases. Because of better diagnostic tools and changes in tick exposure, many new rickettsial diseases have been described in the past 20 years. Three families of diseases are grouped under this name: (1) rickettsioses, (2) ehrlichioses and anaplasmoses, and (3) Q fever.

The Pathogens

The agents of rickettsial diseases (formerly grouped in the order Rickettsiales) are small gram-negative bacteria that grow within eukaryotic cells. They have never been grown in axenic media thus far and for culture require living hosts such as cell cultures, embryonated eggs, or susceptible animals. With the exception of *Rickettsia prowazekii*, the agent of epidemic typhus, these

bacteria infect humans incidentally and are mainly animal pathogens. On the basis of molecular phylogeny, the bacteria causing rickettsial diseases have been reclassified into three phyla (Table 327-1).

Because of their difficult growth in vitro, the main diagnostic tool for rickettsioses is serology. Serologic evaluation is frequently hampered by late positivity and cross-reactivity. The development of direct staining in blood smears or skin biopsy samples, as well as polymerase chain reaction (PCR) amplification of DNA in blood samples or biopsy specimens, has considerably helped identification at the species level and led to the description of emerging pathogens.[1]

RICKETTSIOSES (DISEASES CAUSED BY *RICKETTSIA* SPECIES AND *ORIENTIA TSUTSUGAMUSHI*)

DEFINITION

Rickettsia species are small gram-negative bacteria that multiply free in the cytoplasm of their host cells. The target cells in humans are endothelial cells or monocytes, and vasculitis is the most prominent clinical manifestation. These bacteria invade cells by phagocytosis and escape the phagosome vacuole.[2]

The genome of *Rickettsia* is small, between 1.1 and 1.6 Mb; some have plasmids and potential for conjugation. These bacteria have a family of outer membrane proteins of the surface cell antigen family, including rOmpA (lacking in typhus group) and rOmpB. These proteins are major antigens that help identify the rickettsial species, and their encoding genes are used for amplification and sequencing for diagnostic or taxonomic purposes. Among rickettsiae, two subgroups, the typhus group and the spotted fever group, were identified on the basis of growth conditions and antigenicity. A specific group antigen determined to be lipopolysaccharide has been identified. The optimal growth temperature is 37° C for the typhus group and 32° to 35° C for the spotted fever group. The complete genome sequencing of *R. prowazekii* (from the typhus group) showed that it is mainly a subset of *Rickettsia conorii* (a member of the spotted fever group).

Tick-Borne Rickettsioses

ROCKY MOUNTAIN SPOTTED FEVER

EPIDEMIOLOGY

Rocky Mountain spotted fever (RMSF), the most severe of the rickettsioses, is caused by *Rickettsia rickettsii* (Table 327-2).[3] It is the major tick-transmitted rickettsiosis (Chapter 359) recognized in America, with *Rickettsia africae* in the West Indies, *Rickettsia parkeri* in the southern states of the United States,[4] and perhaps *Rickettsia amblyommii*. It was described first in the 19th century in the western United States. RMSF is prevalent in at least 44 U.S. states (Fig. 327-1) and in Central and South America (Argentina, Brazil, Colombia, Costa Rica, Mexico, and Panama).[5]

Rickettsia is transmitted transovarially to tick progeny from one generation to the next. The infecting ticks are mainly *Dermacentor andersoni* (a wood tick) in the western United States; *Dermacentor variabilis* (the American dog tick) in the East, the Midwest, and the South; and *Rhipicephalus sanguineus* in Arizona. In Central and South America, *Amblyomma cajennense* is the major vector. Humans are infected through infected saliva after a tick bite. The duration of attachment is critical in any tick-borne rickettsiosis, and transmission is unlikely when the tick feeds for less than 20 hours. The tick

American sylvatic typhus	*R. prowazekii*	Flying squirrel ectoparasites	United States	Yes	No	No	Yes	Low
Brill-Zinsser disease (relapse of epidemic typhus)	*R. prowazekii*		Worldwide	Yes, could lack	No	No	No	Low
MITE-TRANSMITTED DISEASE								
Rickettsialpox	*R. akari*	*Liponyssoides sanguineus*	Worldwide	Yes, vesicular	Yes	Yes	Yes	Low
Scrub typhus	*Orientia tsutsugamushi*	*Leptotrombidium* sp. (chiggers)	Central and eastern Asia, Australia	Yes	Yes	Yes	Yes	High, may relapse

bite is painless and frequently unnoticed. Rarely, an eschar at the site of the tick bite is observed in RMSF. The epidemiology of RMSF undergoes largely unexplained yearly variations. This temporal repartition is determined by tick activity and human encounter. More than 500 cases occur each year, and more than 90% are reported from April to September. The disease is more prevalent in children younger than 10 years. A recent increase has been reported, but the current diagnostic tools do not allow discrimination between RMSF and other rickettsioses.

CLINICAL MANIFESTATIONS

Two to 14 days after the tick bite, fever and headaches appear. The fever is high (temperature > 102°F) and associated with nonspecific symptoms

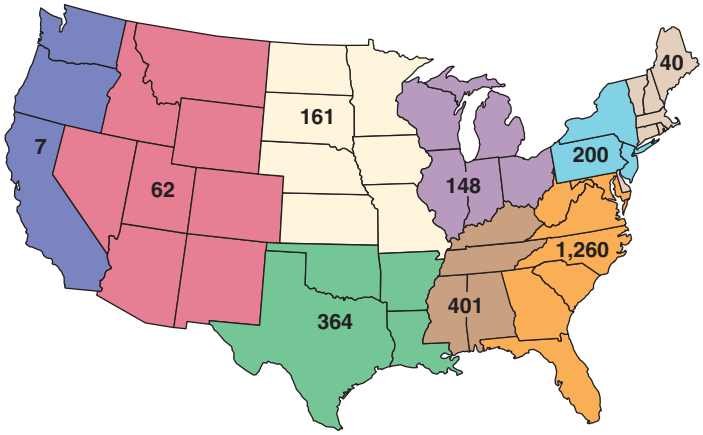

FIGURE 327-1. Number of reported cases of Rocky Mountain spotted fever by region, 1994 to 1998.

including malaise, myalgias, nausea, vomiting, anorexia, and diarrhea. At this stage, RMSF is not frequently diagnosed, but during the "tick season," patients with high fever who live in or have a history of travel to an endemic location and possibly a history of tick bite should be considered as possibly having RMSF.

The most characteristic feature is a rash. However, the classic triad of fever, headache, and rash is present in only 44% of confirmed cases. Rash is found in 14% of cases on the first day of disease and in less than 50% in the first 3 days. The rash is macular; it appears first on the ankles and wrists and then generalizes. Spots are 1 to 5 mm in diameter and can evolve from pink to purpuric. A rash can appear later or even not at all; Rocky Mountain "spotless" fever represented 34% of cases in a series from the Centers for Disease Control and Prevention (CDC). Involvement of the palms and soles theoretically differentiates the typhus diseases (in which it is absent) from the spotted fevers.

Untreated patients worsen progressively. The disease is associated in various degrees with general manifestations related to vascular inflammation and increased vascular permeability and with multiple organ involvement that can lead to multiple organ dysfunction syndrome (MODS). In severe forms, patients suffer from edema, hypovolemia, hypoalbuminemia, and hypotension leading to shock. In very severe cases, necrosis and gangrene of the extremities occur. In some instances, noncardiogenic pulmonary edema develops; pulmonary involvement leading to respiratory distress can cause death. Renal failure can result either from hypovolemia and shock and be reversible or from acute tubular necrosis and require hemodialysis. The usual neurologic symptoms are confusion, lethargy, and stupor. In severe cases, delirium, coma, and seizures are observed. Cerebrospinal fluid (CSF) sampling exhibits meningitis in a third of cases; in general, a few monocyte cells (10 to 100) are observed, along with increased protein but normal glucose levels. Heart involvement can cause arrhythmia. Liver involvement is manifested as an increase in transaminases in a third of patients and jaundice in 8%. Jaundice can also reflect hemolysis. Intestinal tract involvement is manifested as abdominal pain, diarrhea, vomiting, and severe bleeding (upper gastrointestinal hemorrhage can cause death). Ocular involvement consists of conjunctivitis and retinal abnormalities, including hemorrhages, papilledema, and arterial occlusion.

The blood cell count shows a normal number of white blood cells but often immature myeloid cells. Thrombocytopenia is observed in 30 to 50% of cases and may be marked in severe cases. Anemia develops in 30% of patients. Coagulopathy with decreases in clotting factors (including fibrinogen) and prolonged coagulation times may contribute to bleeding; serum albumin may be low and proteins of the acute phase response increased (C-reactive protein, ferritin, fibrinogen). Hyponatremia and hypocalcemia may be noted and correlate with severity, as with an increase in creatinine. Increased concentrations of serum enzymes such as aminotransferases (aspartate [AST] and alanine [ALT] aminotransferase), lactate dehydrogenase (LDH), and creatine kinase usually reflect the severity of organ involvement—including the lung, heart, and liver—and multifocal rhabdomyolysis.

DIAGNOSIS

The diagnosis of RMSF should be based on clinical and epidemiologic findings and lead to early use of doxycycline. The most important clue is unexplained fever in a patient with a history of tick exposure in an endemic area. When a rash is present, RMSF should be suspected and the patient treated accordingly unless another cause is demonstrated. The differential diagnosis includes other rickettsioses (e.g., those caused by *R. parkeri* in southeastern states), meningococcemia, enterovirus infections, typhoid, leptospirosis, ehrlichiosis, gonococcemia, toxic shock syndrome, syphilis, rubella, measles, and the Kawasaki syndrome. Drug hypersensitivity, especially after antimicrobial use for febrile illness, is sometimes confused with RMSF.

The main diagnostic test relies on serology, and treatment should never be delayed to obtain diagnostic confirmation. Criteria for laboratory confirmation include a four-fold or greater change in antibody titer determined by serology (measured by immunofluorescence assay [IFA], complement fixation, or latex agglutination) and direct detection of the bacterium by demonstration of specific antigens by immunodetection, genomic amplification by PCR, or culture. A biopsy specimen of a skin lesion is the best sample for this purpose. Culture of *Rickettsia* takes 3 to 7 days and is restricted to specialized laboratories. It is performed on cell lines such as Vero, L929, or HEL cells. Immunodetection by IFA or immunohistochemistry is sensitive and specific. It can be performed with frozen or fixed and paraffin-embedded material and allows retrospective diagnosis. PCR amplification and identification give promising results in rickettsioses in general but have not been properly evaluated for diagnosis of RMSF. Skin biopsy and direct detection in removed ticks yield the best results because blood contains inhibitors and only few copies of rickettsial DNA.

Two serum samples should be tested (early and convalescent). The early serum is usually negative because patients seroconvert between the 7th and 15th days. IFA is highly sensitive and specific. A cutoff value of 1 : 64 for total immunoglobulin and 1 : 32 for IgM antibodies is required for diagnosis. The latex agglutination cutoff is 1 : 64 or 1 : 128. Cross-reactive antibodies have been reported with infections caused by other rickettsioses, *Ehrlichia*, *Bartonella*, *Legionella*, and *Proteus*. False-positives, including IgM, may be observed when rheumatoid factor is present in serum and in patients with viral infection generating nonspecific B-lymphocyte proliferation (cytomegalovirus, Epstein-Barr virus). Complement fixation (which lacks sensitivity) and the Weil-Felix test (using antibodies that cross-react with *Proteus* strains) should not be used.

TREATMENT

Rx

The prognosis for patients with RMSF depends on the timing of antimicrobial treatment. Doxycycline saves patients with RMSF. The recommended dose is 100 mg twice daily, and treatment should be continued for at least 3 days after the fever resolves. Oral treatment is effective, but in patients with gastric intolerance or coma, the intravenous route is advised. Several antimicrobials are effective in vitro against *R. rickettsii*, including fluoroquinolones, rifampin, and new macrolide antimicrobials (but not erythromycin), but lack of clinical experience precludes their use for RMSF. β-Lactam antimicrobials, aminoglycosides, and cotrimoxazole are not effective.

Severely ill patients should be treated in intensive care units and fluid administration carefully monitored. Mechanical ventilation is used in case of respiratory distress, hemodialysis in patients with renal insufficiency, and antiseizure drugs in patients with seizures. Anemia and coagulation abnormalities may also be corrected. For patients with gangrene of the extremities, amputation may be necessary. Glucocorticoids have not proved useful.

PREVENTION

Prevention is based on avoidance of tick bites (Chapter 359) by use of repellents, protective garments, or both. To discourage tick attachment, repellents containing permethrin can be sprayed on boots and clothing and will last for several days. Repellents containing DEET (*N,N*-diethyl-*m*-toluamide) can be applied to the skin but will last only a few hours before reapplication is necessary. It is also useful to check for ticks after exposure. Careful examination of the scalp, groin, and axillae is recommended. The tick can be removed by forceps, and the skin should be disinfected (Fig. 327-2).

PROGNOSIS

The evolution of RMSF depends strongly on the timing of diagnosis and antimicrobial treatment. The current fatality rate is 2.4% on the basis of a 4-year national survey in the United States (27 deaths were attributable to RMSF during this period). This rate is currently declining, but this may result

from reporting of confounding rickettsial diseases. No significant difference in outcome was observed between blacks and whites, but the case-fatality rate was highest in individuals older than 70 years (9%). Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are more susceptible to severe infection. Treatment with chloramphenicol has been associated with a poorer outcome than treatment with doxycycline. Recovery from RMSF is usually complete, but neurologic sequelae can remain, and amputation of extremities may be necessary after gangrene.[6]

OTHER TICK-BORNE RICKETTSIOSES

EPIDEMIOLOGY

Like other tick-transmitted diseases (Chapter 359), rickettsioses have a limited geographic distribution that is determined mainly by the tick vector ecology (Fig. 327-3). *R. parkeri* has recently been identified in the United States and South America. *R. conorii* is found in Europe around the Mediterranean and Caspian seas (*caspia* subspecies); *Rickettsia slovaca*, *Rickettsia raoultii*, and possibly *Rickettsia helvetica* in western and central Europe; and *Rickettsia sibirica mongolotimonae* in France and Greece. Elsewhere, a number of specific agents of rickettsial disease have been identified (see Table 327-2).

CLINICAL MANIFESTATIONS

R. conorii comprises different but closely related subspecies. Many names are given to the infection caused by *R. conorii:* Mediterranean spotted fever (MSF), boutonneuse fever, Marseilles fever, Kenya tick typhus (caused by the subspecies *R. conorii conorii*), Astrakhan fever (caused by *R. conorii caspia*), Israeli spotted fever (caused by *R. conorii israeli*), and Indian tick typhus (caused by *R. conorii indica*). *R. conorii* is closely related to *R. rickettsii*, with which it shares many common antigens that generate cross-reactive antibodies. MSF resembles RMSF but has several distinct characteristics. The spontaneous evolution is milder, but a fatality rate of 1.5 to 2.5% in hospitalized patients is still observed. A malignant form of the disease that includes purpuric rash, shock, and MODS has been described in alcoholic, diabetic, human immunodeficiency virus (HIV)-infected, and elderly or debilitated patients. The typical clinical manifestation is that of a patient with fever, a rash, and a tache noire (i.e., a black eschar at the site of the tick bite). A tache noire is found in 50 to 80% of cases. Multiple lesions do not occur because the dog tick vector, *R. sanguineus*, seldom bites humans. The rash is frequently clearly papular, which led to one of the names of the disease, boutonneuse fever. Israeli tick bite fever and Astrakhan fever appear to be milder than typical MSF, and tache noire is usually lacking.

R. africae, which causes African tick bite fever, may be responsible for most of the rickettsioses worldwide. It is extremely common in travelers visiting southern Africa. It is transmitted by African ticks, *Amblyomma hebraeum* and *Amblyomma africanum.* These ticks are often infected; as many as 60% can harbor *R. africae.* They usually feed on ungulates but attack human beings in groups and cause a high prevalence of infection in rural Africa (60% of tested patients exhibit antibodies) and in travelers. The tick attacks typically generate clusters of cases in Safari tourists. The disease differs from MSF in that it is much milder, fever is frequently absent, a rash is observed in only half the patients, and the rash may be vesicular (which has never been reported in confirmed MSF). Moreover, several taches noires are frequently observed. They are prevalently found on the lower limbs and often associated with draining lymphadenopathy in the groin.

Japanese spotted fever (caused by *Rickettsia japonica*) and Siberian tick typhus (caused by *R. sibirica*) resemble MSF. Infections caused by *R. sibirica mongolitimonae* resemble MSF but in some cases exhibit specific clinical features, including a tache noire, groin lymphadenopathy, and lymphangitis joining these two lesions. The disease has recently been named lymphangitis-associated rickettsiosis. *Rickettsia australis* (Queensland tick typhus) and *Rickettsia honei* (Flinders Island spotted fever) cause diseases resembling MSF, but their rash can be vesicular.

R. slovaca and *R. raoultii* cause a disease apparently common in Europe named scalp eschar and neck lymphadenopathy transmitted by ticks (Hungary, Germany, France, Spain). Its tick vectors, *Dermacentor marginatus* and *Dermacentor reticulatus*, preferentially bite in cold months and bite the scalp because they prefer hairy prey. In contrast to other tick-borne rickettsioses, the disease is more prevalent in children and women. It is rarely exanthematic; the typical clinical picture consists of an erythematous skin lesion at

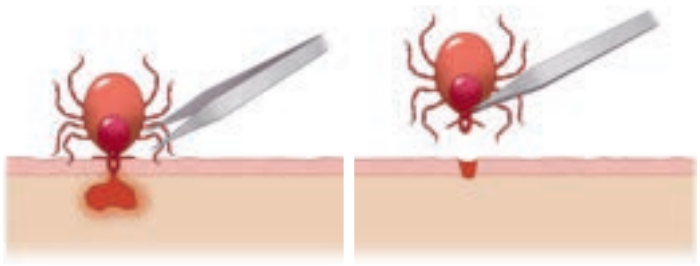

FIGURE 327-2. Tick removal technique.

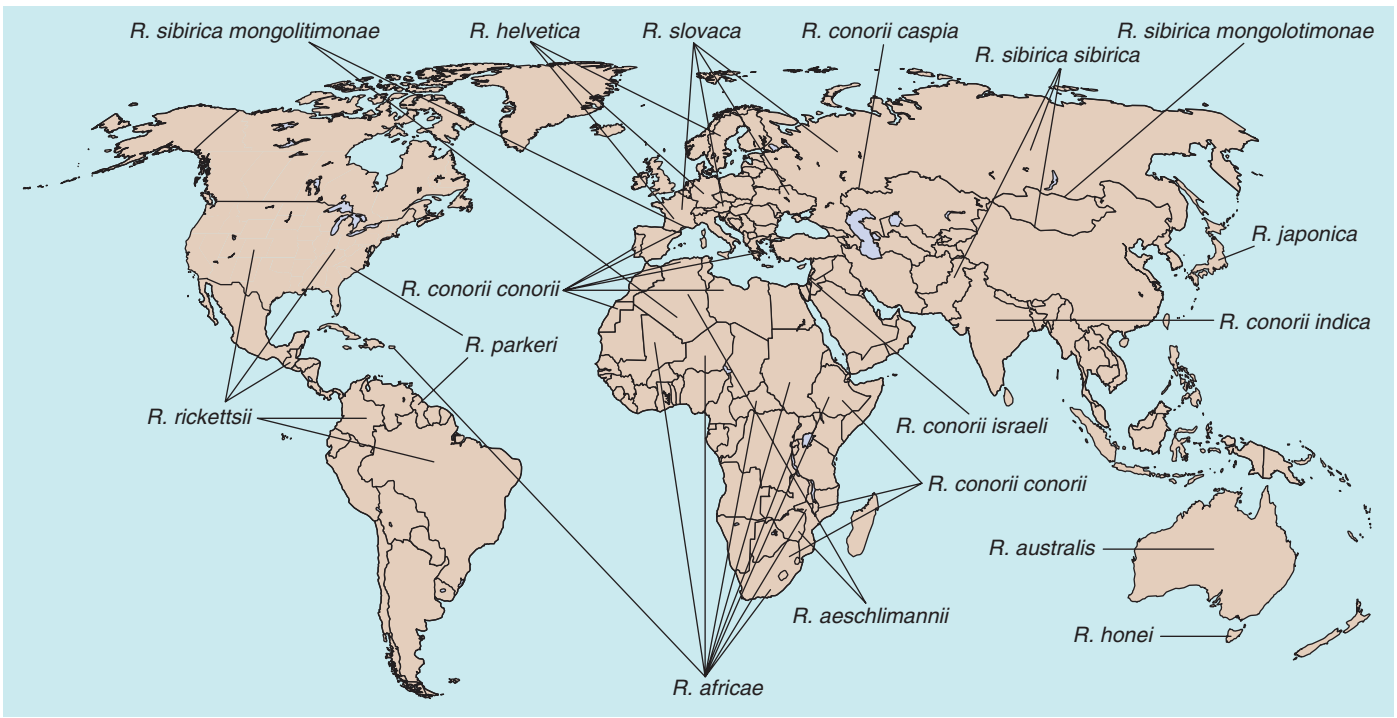

FIGURE 327-3. Geographic distribution of tick-borne rickettsioses.

the site of the tick bite on the scalp that ranges from 2 to 8 cm in diameter, and a draining neck lymphadenopathy that may be painful. Rarely, patients may exhibit fever and a rash. Deep postinfectious asthenia and residual alopecia at the site of the tick bite can be observed. The occurrence of this rickettsiosis without rash may stimulate research on other new rickettsial diseases with only localized manifestations.

DIAGNOSIS

The diagnosis of other tick-borne rickettsioses is similar to that of RMSF, mainly by serology (IFA; see earlier). An exception is *R. slovaca* infection, in which the serologic response is weak, possibly because of its lack of general infection; in this case, PCR of a skin lesion sample by a swab or a lymph node aspirate is the best solution. In *R. africae* infection, the serologic response occurs later than in RMSF and MSF, and late serum samples are therefore recommended.

TREATMENT Rx

Doxycycline (100 mg twice daily for adults or 4.4 mg/kg body weight per day in two divided doses for children under 45.4 kg [100 lb]) is the drug of choice for treatment. A single day of therapy usually suffices, but in adults with more severe disease, it should be administered until the patient is afebrile for 24 hours. In pregnant women, josamycin, a macrolide antimicrobial, has proved efficient at a dose of 3 g daily for 7 days for MSF; quinolones and newer macrolide antimicrobials give results comparable to those of doxycycline but with longer regimens.

Flea-Transmitted Diseases

Fleas (Chapter 359) can harbor two rickettsial species: *Rickettsia typhi*, the agent of murine typhus, and *Rickettsia felis*, the agent of flea-borne spotted fever. Both rickettsiae can be transmitted transovarially in the flea. Vectors are *Xenopsylla cheopis* and *Pulex irritans* but also *Ctenocephalides felis*, a cat flea. Rats, cats, opossums, and dogs can propagate infected fleas. These reservoirs and vectors are distributed worldwide, and thus these diseases have a global distribution. Fleas can be infected by both species at the same time.

MURINE TYPHUS

DEFINITION

Fleas are usually infected by *R. typhi* when feeding on apparently healthy rats that have blood-borne infection. Humans and other mammals are infected through autoinoculation by scratching a fleabite that is contaminated with feces from an infected flea. Murine typhus, because of its cycle, is more prevalent in hot and humid areas when rats proliferate.

EPIDEMIOLOGY

In the United States, 50 to 100 cases are reported yearly, mainly in southern California and southern Texas. In California, a transmission cycle involving opossums and cat fleas has been demonstrated. Murine typhus is extremely common in Southeast Asia and North Africa and is a common cause of fever in travelers.

CLINICAL MANIFESTATIONS

On the basis of studies of infected volunteers, the incubation period is generally 8 to 16 days. The disease begins with abrupt fever, nausea, vomiting, myalgias, arthralgias, and headache. A rash is observed in 40 to 50% of patients about 6 days after the onset.[7] It is detected even less frequently in patients with dark skin. The rash begins as pink maculae that can evolve to be maculopapular. It is often discrete, starting in the axilla; it generalizes to the trunk but does not usually involve the face, palms, and soles. In severe cases, it can become purpuric. The most frequently involved organ is the lung. A third of patients have a cough, and in a fourth, a nonspecific interstitial pneumonia develops that is sometimes associated with a pleural effusion. In severe forms, respiratory failure occurs. In patients with severe disease, neurologic symptoms range from confusion and stupor to coma and seizures. Cerebral hemorrhages may occur. Gastrointestinal involvement can be manifested as vomiting, abdominal pain, jaundice, and in severe cases, hematemesis.

The white blood cell count initially shows leukopenia and then leukocytosis. Thrombocytopenia can be noted as well as anemia, specifically when hemolysis is observed (frequently in patients with G6PD deficiency). A moderate increase in serum liver enzymes is common. In patients with severe disease, hyponatremia and hypoalbuminemia are observed.

DIAGNOSIS

The diagnosis of murine typhus is based mainly on serology (IFA), with titers similar to those of RMSF. On serologic evaluation, *R. typhi* cross-reacts with *R. prowazekii*; it can be differentiated either by comparing titers (two dilutions or more if IgG and IgM titers are discriminative) or by cross-adsorption. In this technique, the serum is absorbed with either antigen and then retested, and the causative agent is that removing antibodies to both bacteria. Skin biopsies and blood samples for culture and PCR may be valuable.

TREATMENT Rx

Treatment is the same as that for RMSF.

PROGNOSIS

The prognosis is usually favorable, but 10% of patients require intensive care and 1% die. Older patients and those with G6PD deficiency (Chapter 161) or chronic debilitating conditions are at higher risk.

FLEA-BORNE SPOTTED FEVER CAUSED BY *RICKETTSIA FELIS*

R. felis is mainly transmitted transovarially. Its genome comprises one or two plasmids, one being apparently conjugative. This is a new, incompletely defined disease. The bacterium is found in fleas in the Americas, Asia, Europe, Africa, and New Zealand. Isolated cases have been reported from Texas, Mexico, Brazil, France, and Germany. Reported cases all exhibited fever, a rash in six of seven cases, and inoculation eschar in some cases. The diagnosis can be based on serologic evaluation using specific *R. felis* antigen or PCR of blood or skin biopsy samples. Treatment has not been established, but the bacterium is highly susceptible to doxycycline and resistant to erythromycin. *R. felis* has been found at very high prevalence in the blood of febrile sub-Saharan Africans and is suspected to be transmitted by mosquitoes.

Louse and Mite Infections

EPIDEMIC LOUSE-BORNE TYPHUS

EPIDEMIOLOGY

The human body louse (Chapter 359) lives in clothes and multiplies rapidly when cold weather and lack of hygiene allow it to. The body louse transmits three bacterial diseases: (1) trench fever (caused by *Bartonella quintana*), (2) relapsing fever (caused by *Borrelia recurrentis*), and (3) exanthematic typhus (caused by *R. prowazekii*). The name *typhus* is derived from the Greek *tuphos*, which describes the neurologic condition associated with this disease and with typhoid. The body louse is prevalent during war, in poor countries, and in the homeless population of rich countries, including the United States and Europe. A 100,000-person outbreak of typhus was reported during the civil war in Burundi in 1997, and cases were reported in Russia, Peru, the United States, Algeria, and France in the 1990s. Louse-transmitted diseases killed more people than weapons did during central and eastern European wars in the 19th and 20th centuries.

The epidemiology of *R. prowazekii* is mainly related to humans as reservoirs and lice as vectors. In the United States, the eastern flying squirrel *(Glaucomys volans volans)* is also a reservoir, and its fleas, lice, and mites can be infected.

R. prowazekii has also been found in *Amblyomma* ticks, but their role is not known. The louse is infected when feeding on blood, which it does five times a day. *R. prowazekii* multiplies in the gut of the louse and is released in feces; after a few days, it destroys intestinal epithelium, which causes bright red blood to spread from the gut (typhus was also named the red louse disease). The patient is usually contaminated by infected feces (in which *R. prowazekii* survives for weeks), through aerosols, or by skin autoinoculation after scratching. Patients who recover from typhus may harbor the bacterium in a dormant form and suffer relapses under stressful conditions years later; this relapsing form is called Brill-Zinsser disease. During the relapse, a bacteremia occurs that may allow the start of a new outbreak if lice bite the patient.

CLINICAL MANIFESTATIONS

Typhus begins abruptly with fever, headaches, and myalgias, which may have led to the crouched posture termed *sutama* in the largest recent outbreak in Burundi. Cough and neurologic signs (stupor, confusion, or coma) are common. A rash is observed in 20 to 80% of patients, depending on the population studied; it is probably commonly underobserved on dark skin. It generally starts in the axilla and then spreads. The rash is usually macular but can be papular or purpuric in severe cases. In some cases, diarrhea and jaundice are reported. Splenomegaly is infrequently found. In severe cases, shock occurs and the fatality rate is 20 to 30%. Leukopenia, thrombocytopenia, and anemia as well as an increase in serum hepatic enzymes may be noted.

Sylvatic typhus in the United States is caused by an *R. prowazekii* variant and is a milder disease. The most prominent clinical features are neurologic. Few cases have been described, and nearly all occurred in areas where the eastern flying squirrel is found, east of the Mississippi.

Brill-Zinsser disease is difficult to diagnose because rash is rare and recent exposure to lice can be lacking. Interviewing the patient may reveal prior exposure to lice, associated or not with a diagnosis of typhus in previous years. The disease is mild and the prognosis is good.

DIAGNOSIS

The diagnosis of typhus should be considered when grouped cases of high fever with confusion are observed in patients exposed to lice. The most common diagnostic error is to attribute the findings to typhoid, which can have fatal consequences because the antimicrobials typically prescribed for that condition (β-lactams, cotrimoxazole, and quinolones) are ineffective treatment of typhus. In tropical countries, typhus is frequently confused with malaria, hemorrhagic fever, and dengue. In persons with lice, it can be confused with trench fever and relapsing fever, but treatment for both can be prescribed.

The diagnosis of typhus should be clinical because the fatality rate is high and the treatment safe and efficient. Any outbreak of unexplained fever in unhygienic environments may suggest typhus, including outbreaks during civil wars (such as in Algeria, Rwanda, and Burundi), during social collapses (such as in Russia and Ukraine), in jails (such as in Rwanda and Burundi), and in chronically poor and cold countries. The diagnosis is based mainly on serology, in which there is cross-reaction with *R. typhi* (see earlier). When the investigation is performed under difficult field conditions, a drop of blood applied on filter paper and sent to a reference laboratory is valuable for serologic testing. Culture and PCR are helpful and can be performed with a skin biopsy sample or blood. Lice are good diagnostic tools because they can be tested even when dry and can be sent in closed containers without specific temperature conditions.

TREATMENT Rx

Treatment of typhus is extremely simple, cheap, and effective; 200 mg of doxycycline orally in two divided doses is life-saving. Comatose patients should be treated parenterally. In allergic patients, chloramphenicol is the only known alternative, prescribed at a dose of 2 g/day for 10 days. There is no current vaccination, and the fight against lice is the major prevention strategy. Because lice are fragile, changing and boiling clothes are efficient. When this is not possible, insecticides (primarily permethrin) or ivermectin orally should be used.

SCRUB TYPHUS (*ORIENTIA TSUTSUGAMUSHI*)

EPIDEMIOLOGY

Scrub typhus is transmitted by the bite of trombiculid mite (Chapter 359) larvae infected by *O. tsutsugamushi.* These mites, also named chiggers, are vertically infected through their mother. Scrub typhus distribution is limited to a triangle extending between northern Japan, eastern Australia, and eastern Russia and includes the Far East, China, and the Indian subcontinent. All together, 1 billion people may be exposed. Seasonality is determined by the emergence of larvae. It is one of the three most common causes of prolonged fever in rural Asia; in temperate zones, it occurs mainly in autumn and to a lesser extent in spring. *O. tsutsugamushi* species have a wide heterogenicity that may allow the definition of several species, but a single species is currently recognized with many serotypes.

CLINICAL MANIFESTATIONS

The disease occurs in patients exposed to rural or urban foci of scrub typhus after a delay of 10 or more days. The onset is usually sudden and includes fever, headache, and myalgias. Attentive examination may reveal an inoculation eschar at the site of the mite bite and tender draining lymph nodes. Generalized lymphadenopathy and rash may be observed. The symptoms vary according to organ involvement. Neuromeningeal symptoms are relatively common. Severe forms can be manifested as septic shock. Abortion commonly occurs in pregnant women.

Leukopenia, thrombocytopenia, and increased levels of hepatic enzymes can occur. Evolution depends on the hosts and strains, and the fatality rate ranges from 0 to 30%. Scrub typhus is not more severe in HIV-infected patients, and surprisingly, HIV suppressive factors appear to be produced during infection. Relapses may occur in this disease.

DIAGNOSIS

Diagnosis may be difficult. Because the clinical features are frequently not specific, epidemiologic factors are critical.[8] A diagnosis of infectious mononucleosis has erroneously been made in patients with scrub typhus. The bacterium can be detected by culture (in cells or mice) or by PCR in blood and biopsy specimens. The serologic technique first used was agglutination of *Proteus mirabilis* serotype OXK in the Weil-Felix reaction. This test lacks sensitivity and specificity and should be replaced by IFA or enzyme-linked immunosorbent assay tests using the three or four major serotypes.

TREATMENT Rx

Chloramphenicol was the mainstay of treatment for many years, but now doxycycline is recommended. Single-day treatment with doxycycline is followed by relapses, and even repeated treatment for 2 days at a 7-day interval does not prevent all relapses. Hence, the currently recommended regimen is doxycycline, 100 mg orally twice a day for 7 days. Cases resistant to doxycycline have been reported, and rifampin (600 mg orally daily) is a reasonable alternative. Quinolones should be avoided. Prophylaxis is based on the use of repellents.

RICKETTSIALPOX (*RICKETTSIA AKARI*)

EPIDEMIOLOGY

Rickettsialpox was first described by a general practitioner in 1946 in New York City, where it is still prevalent. *R. akari*, the causal agent, is transmitted by the bite of the mouse mite (*Liponyssoides sanguineus*). Its prevalence is probably underestimated; an active search revealed 13 cases in a New York hospital in the 1980s. Cases have been reported in Arizona, Utah, and Ohio. After the terrorist attacks of 9/11/01, cases of black skin eschars were investigated as possible anthrax in New York but were in fact rickettsialpox. High seroprevalence was reported among intravenous drug users in Baltimore. Cases have also been reported from Russia, Ukraine, Slovenia, and Korea.

CLINICAL MANIFESTATIONS

Ten days after the mite bite, the beginning of the illness is marked by fever, headache, and myalgia. Careful examination reveals an inoculation eschar and a draining lymphadenopathy that could be mistaken for cutaneous anthrax. Two to 6 days later, a rash appears and comprises 5 to 40 macular then papular and vesicular spots. This aspect led to the name of the disease. It is frequently mistaken for chickenpox. The disease is usually mild.

DIAGNOSIS

The diagnosis can be made by serologic testing with IFA. Specific antigens react with high titer, but antibodies to other *Rickettsia* may be detected. The diagnosis may also be made on skin specimens by culture, immunodetection, or PCR.

TREATMENT Rx

Doxycycline is highly effective in these patients. Prevention is based on the control of mice.

EHRLICHIOSES AND ANAPLASMOSES

DEFINITION

The index case of modern ehrlichiosis was reported in the United States in 1987.[9] The patient died of fever, presumably acquired after a tick bite in Arkansas, despite receiving chloramphenicol. The patient had several initially confusing diagnostic features; on blood smears, morulae in polymorphonuclear (PMN) cells were seen, and antibodies to *Ehrlichia canis*, a pathogen of dogs but not humans, were detected. He was then thought to have *Ehrlichia chaffeensis*, but this bacterium infects monocytes, not PMN cells. A diagnosis of *Anaplasma phagocytophilum* infection (or human granulocytic ehrlichiosis [HGE]) was considered, but the tick vector of this disease is absent in Arkansas. The most likely diagnosis is currently believed to be infection with *Ehrlichia ewingii*, an agent transmitted by *Amblyomma americanum* that is prevalent in Arkansas, infects PMN cells, and cross-reacts with *E. canis*, although it typically affects immunocompromised hosts. This case illustrates the progress in knowledge on ehrlichioses and how difficult it is to conclude the etiology of an atypical infection definitively on the basis of serology alone.

All *Ehrlichia* pathogenic for humans—except *E. ewingii*—can be cultured.[10] The ehrlichiae have been reclassified into four genera, mainly on the basis of 16S ribosomal RNA–derived phylogenetic analysis. Two are the tick-associated genera *Ehrlichia* and *Anaplasma* (*A. phagocytophilum*, or the HGE agent that was formerly named *Ehrlichia phagocytophila*). One is a helminth-associated genus, *Neorickettsia*, including *Neorickettsia sennetsu* (formerly *Rickettsia sennetsu*, then *Ehrlichia sennetsu*). The fourth is *Wolbachia pipientis*, a bacterium associated with arthropods (insects, crustaceans, and acarids) and helminth worms (mainly filaria). These organisms elicit cross-reactive antibodies.

Ehrlichiae multiply exclusively in vacuoles of their eukaryotic cell host, where they form clusters known as morulae. The vacuoles are derived from phagosomes and help the organism escape bactericidal lysosomal fusion. In humans, ehrlichiae are associated with monocytes (*E. chaffeensis*, *E. canis*, *N. sennetsu*) or PMN cells (*A. phagocytophilum*, *E. ewingii*).

Ehrlichioses can be acquired through tick bites, by ingestion of nematodes through contaminated water or animals (fish, snails), or as a consequence of filariasis.

American Human Monocytic Ehrlichiosis (*Ehrlichia chaffeensis*)

EPIDEMIOLOGY

Human monocytic ehrlichiosis (HME) is caused by *E. chaffeensis.* This organism has been isolated or identified by PCR mainly in the United States in the southeastern, south central, and mid-Atlantic states and California (Table 327-3). In the United States, *A. americanum* (Lone Star tick) is the vector (Chapter 359), and the white-tailed deer is the main mammalian reservoir. Immature ticks are infected by blood while feeding on persistently bacteremic reservoirs. *E. chaffeensis* is transmitted transstadially (remaining with the same vector from one life stage to the next) in the tick and infects its next host (deer or human) during its next blood meal. The disease epidemiology reflects the tick habitat and activity, with most cases being contracted in the southern United States, in rural areas, and from April to September. In highly endemic areas, the incidence can reach 100 cases per 100,000 inhabitants. The severity is age dependent, which may explain the lower incidence reported in children. Males are more often affected than females, with a sex ratio of 4 : 1.

TABLE 327-3 EHRLICHIOSES AND ANAPLASMOSES

DISEASE	AGENT	VECTOR	GEOGRAPHIC REPARTITION
American monocytic ehrlichiosis	*Ehrlichia chaffeensis*	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
Human granulocytic ehrlichiosis	*Anaplasma phagocytophilum*	*Ixodes ricinus*	Europe, China
		Ixodes scapularis	Northeast, upper Midwest, northern California
E. ewingii	*Ehrlichia ewingii*	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
Japanese monocytic ehrlichiosis	*Neorickettsia sennetsu*	Helminth of the gray mullet?	Japan
E. canis	*Ehrlichia canis*	*Rhipicephalus sanguineus*	Venezuela

CLINICAL MANIFESTATIONS

The incubation lasts for 7 to 10 days after an identified tick exposure in 80% of cases. Patients have fever, headache, malaise, nausea, and anorexia. Untreated patients worsen and may require intensive care. Gastrointestinal tract involvement consisting of nausea, vomiting, diarrhea, and abdominal pain is common. Central nervous system infection is manifested in many forms from confusion to coma. A rash is observed in a third of cases and lymphadenopathy in a fourth. In severe forms, sepsis syndrome and multiple organ dysfunction syndrome may occur.

The white blood cell count typically shows leukopenia, caused by both lymphopenia and neutropenia. Thrombocytopenia is also frequently found; anemia may appear later. Coagulopathy may be observed in severe forms. Increases in serum enzymes, including AST, ALT, and LDH, may reflect organ involvement, as does an elevated serum creatinine. CSF examination in patients with neurologic symptoms reveals pleocytosis and increased protein levels. Cells may be monocytic or PMN. The prognosis depends on early antimicrobial treatment, but the fatality rate is still high at 2.5%. In persons coinfected with HIV, it may be most severe; in one series, 6 of 13 patients died.

DIAGNOSIS

The diagnosis of HME should be considered in patients with a history of tick exposure and unexplained fever. HME resembles RMSF, but rash is less frequent. Later in the disease, it can be misdiagnosed as anything that causes severe sepsis.

Leukopenia associated with thrombocytopenia and an increase in liver enzyme levels may establish the etiology. Careful examination of blood and CSF smears may help identify typical morulae. Treatment should be started in any suspected case. The diagnosis can be confirmed by culture in specialized laboratories using a canine cell line, DH82. However, PCR is more practical; confirmatory PCR using a second target gene is useful. Most cases are currently diagnosed serologically by a four-fold or greater increase in antibody titer or by seroconversion. The reference technique is IFA. A single titer of 25 is indicative of the diagnosis. There are cross-reactive antibodies among *Ehrlichia* species and with *A. phagocytophilum.* Western blotting may be valuable to distinguish among these bacteria.

TREATMENT

Rx

Doxycycline (100 mg twice daily for adults) is the drug of choice for patients with ehrlichiosis. The optimal duration of therapy has not been established, but current regimens recommend continuation of treatment for at least 3 days after the fever subsides and until evidence of clinical improvement, for a minimum total course of 5 to 7 days. Severe or complicated disease may require longer treatment courses. Because tetracyclines are contraindicated in pregnancy, rifampin has been used successfully in a limited number of pregnant women with documented HME.

Human Granulocytic Ehrlichiosis (*Anaplasma phagocytophilum*)

EPIDEMIOLOGY

The first human case of *A. phagocytophilum* infection was recognized in 1990. The disease is found in America, Asia, and Europe (Fig. 327-4). It is transmitted by *Ixodes scapularis* (eastern North America), *Ixodes pacificus* (western North America), *Ixodes ricinus* (Europe), and *Ixodes persulcatus* (Asia), the vectors of Lyme disease (Chapter 321), and its epidemiology is similar. Coinfection with the two diseases may occur. The temporal distribution of the disease parallels that of nymph tick activity, with two peaks in spring and autumn. Ticks are born free of *Ehrlichia* and are infected while feeding on bacteremic small mammals. Deer play a major role as hosts of adult ticks and reservoirs. In highly endemic areas, the incidence can reach 50 per 100,000

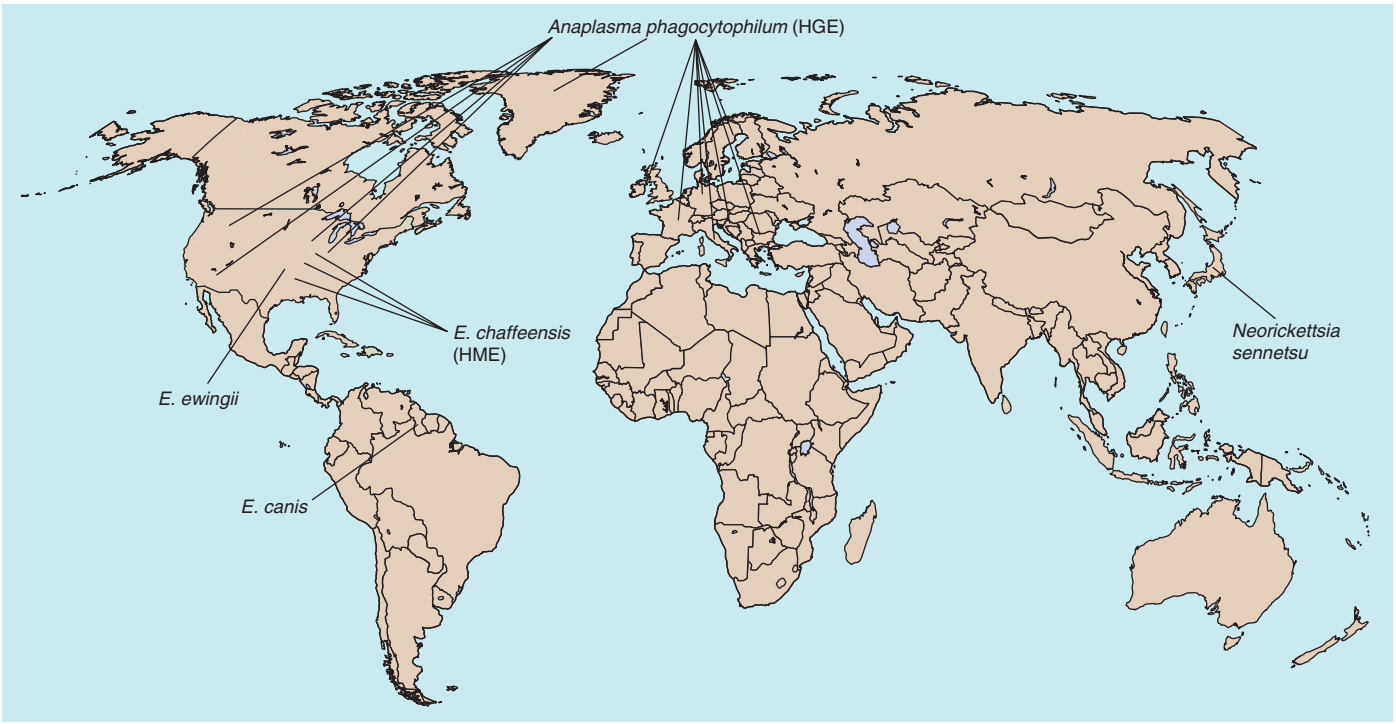

FIGURE 327-4. Geographic distribution of ehrlichioses. HGE = human granulocytic ehrlichiosis; HME = human monocytic ehrlichiosis.

inhabitants per year. The mean age of diagnosed patients is high, and males are more frequently infected than females, with a sex ratio of 3 : 1.

CLINICAL MANIFESTATIONS

The incubation time is usually between 7 and 10 days, and 80% of patients report a history of tick exposure. Many infections may be asymptomatic or too mild to require a diagnostic procedure. The disease frequently begins abruptly, with fever, headache, malaise, and myalgias that may be particularly severe. Rash is found in less than 10% of cases. Visceral involvement may be observed and includes digestive symptoms such as nausea, vomiting, and diarrhea. Neurologic symptoms may include confusion, meningitis, and meningoencephalitis.

The evolution of the disease is favorable in most cases, even without specific therapy, but the disease may evolve to septic shock in some individuals. Patients with underlying diseases are more at risk of dying. Most deaths are the consequence of *Anaplasma*-induced immunosuppression, and patients may experience invasive aspergillosis, candidiasis, cryptococcosis, or herpes esophagitis.

DIAGNOSIS

Laboratory findings consist of the association of thrombocytopenia and leukopenia (lymphopenia or neutropenia). An increase in serum transaminases is also frequent. The diagnosis can be made by careful examination of blood smears for morulae within PMN cells (Fig. 327-5). Culture from blood is possible in appropriate cells (HL-60), and PCR is useful as for HME. Most cases are diagnosed by serologic testing with IFA, which is comparable to that in HME (see earlier).

TREATMENT

Rx

Treatment is also similar to that of HME except that *A. phagocytophilum* is susceptible to fluoroquinolones in vitro, but these drugs have not been tested in patients.

Ehrlichia ewingii

Canine granulocytic ehrlichiosis, reported in the United States in 1972, is caused by *E. ewingii.* This bacterium was characterized by amplification and sequencing of the 16S ribosomal RNA gene. The vector of *E. ewingii* is *A. americanum* (Chapter 359), which also transmits *E. chaffeensis.* Among 60 cases of ehrlichiosis in Missouri in 1999, four were caused by *E. ewingii;* four other cases have been reported since by the CDC. The disease was prevalent in immunocompromised hosts (seven of eight) coinfected with HIV or receiving immunosuppressive drugs. Patients who report tick exposure are noted to have fever, thrombocytopenia, leukopenia, and various symptoms, including meningitis. Morulae may be seen on blood smears in PMN cells. The evolution in reported cases was good; patients responded dramatically to doxycycline. Patients have antibodies to *E. chaffeensis*, and PCR has been shown to be useful when it is applied to blood samples. This diagnosis should be considered when ehrlichiosis is suspected in immunocompromised patients exposed to *A. americanum* ticks.

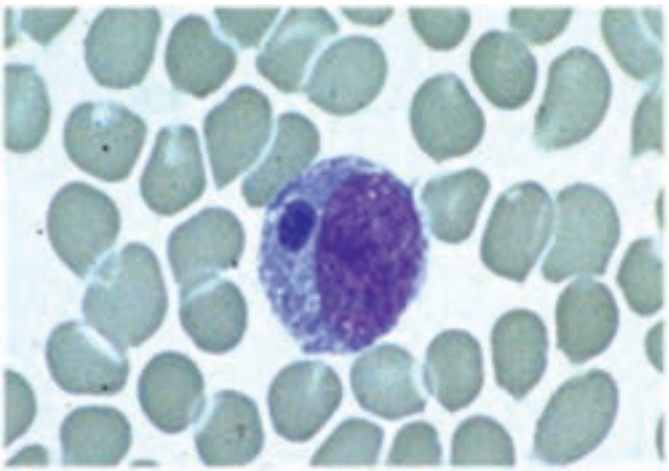

FIGURE 327-5. Peripheral blood leukocyte (monocyte) containing ehrlichial morula in a patient with human monocytic ehrlichiosis. (Courtesy Centers for Disease Control and Prevention. http://www.cdc.gov/ehrlichiosis/symptoms.)

Ehrlichia canis

Canine monocytic ehrlichiosis was reported first in Algeria in the 1930s. It is caused by *E. canis* and transmitted by the dog tick *R. sanguineus* (Chapter 359). This tick is found worldwide and is prevalent in temperate and hot areas. In 1996, a single case of infection was reported in an asymptomatic

man from Venezuela who owned an infected dog. Recently, cases have been reported in patients in South America.

A New *Ehrlichia* in Wisconsin

In four patients from Wisconsin, a new *Ehrlichia* species closely related to *E. muris* was cultured and identified[11] as *Ixodes scapularis* ticks. All patients had fever, malaise, headache and lymphopenia, and some also had thrombocytopenia and elevated transaminases.

Candidatus Neoehrlichia mikurensis

Candidatus Neoehrlichia mikurensis, transmitted by Ixodes ticks, has been reported based on PCR on the blood of febrile immunocompromised European patients and in China.

Wolbachia Species

Wolbachia bacteria are endosymbionts of arthropods and nematodes. They were known to be present in filarial worms, but it was later shown that they may play a role in human disease. These bacteria manipulate the fertility of their host. Eradication of *Wolbachia* in filariae may lead to infertility and stop the microfilariae from spreading. This effect was demonstrated by field treatment with doxycycline in patients with onchocerciasis. The patients improved when treated with this drug, which is effective on *Wolbachia* and subsequently on the worm's fertility but not on the worm itself. In 2001, it was shown that the adverse reactions observed after treatment of lymphatic filariasis may be caused by the release of *Wolbachia* from destroyed worms. Some authors suggested that eradicating *Wolbachia* before the anthelmintic prescription would avoid these reactions. For some reason, *Loa loa* (Chapter 358) do not harbor *Wolbachia*, and the genome of *Wolbachia* integrated in the *Brugia malayi* genome makes it inaccessible to therapy.

Q FEVER

DEFINITION

Q fever is a worldwide zoonosis caused by *Coxiella burnetii*. The name Q fever is derived from "query" to emphasize the surprising aspect of the disease first described in Queensland, Australia, in 1935 by Derrick. The infection in humans is variable in its severity, clinical expression, and natural course (i.e., acute or chronic). It is considered by the CDC to be a potential agent of bioterrorism. Ungulates and pets are the major sources of human infection.[12]

The Pathogen

C. burnetii is a gram-negative bacterium that naturally infects its host's monocytes. It multiplies in an acidic vacuole. Strains are heterogeneous genetically and antigenically and are associated with acute infections of variable severity. *C. burnetii* in vitro generates a deleted avirulent mutant also named phase II. This mutant exhibits diagnostic antigens that are useful because they are more reactive during acute infection.

C. burnetii is incompletely eliminated after acute infection. In immunocompromised hosts and patients with cardiac valve lesions, *C. burnetii* continues to multiply despite high levels of antibodies and causes chronic infection. Control of the disease in acute Q fever is associated with formation of a granuloma.

EPIDEMIOLOGY

C. burnetii infects a wide range of animals, including mammals, birds, and ticks. Ungulates and pets (cats and dogs) are the most common source of the disease. Mammals are infected through aerosols and may shed *Coxiella* in feces, urine, milk, and birth products. Humans are usually infected by aerosols or less frequently by exposure to milk products. Interhuman infections through sexual intercourse, during delivery, or by blood transfusion have been reported. *Coxiella* survives in the environment and can be spread far by the wind. In the past few years, major outbreaks were related to sheep and goats. The disease is partly seasonal and related to lambing time. The current geographic repartition is largely unknown. Males have more severe disease but are not more often exposed to Q fever, and middle-aged people are more frequently affected and hospitalized. The number of reported cases recently increased dramatically in Europe and Asia. Many American soldiers were infected during the war in Iraq. A giant outbreak was observed more recently in the Netherlands.

CLINICAL MANIFESTATIONS

After contamination by *C. burnetii,* 60% of patients seroconvert without apparent disease, 38% experience a self-limited disease, and only 2% require diagnostic evaluation. Months to years after the primary infection, a chronic infection associated with an immunocompromised situation, a cardiac valve lesion, or a vascular prosthesis or aneurysm develops in 0.2 to 0.5% of patients.

TABLE 327-4 SITUATIONS THAT SHOULD PROMPT SEROLOGIC TESTING FOR Q FEVER

ACUTE Q FEVER (PHASE II ANTIGEN AND IgG ≥ 200 AND IgM ≥ 50)
Fever in a patient in contact with ungulates
Unexplained prolonged fever (>7 days)
Granulomatous hepatitis
Fever and thrombocytopenia
Meningoencephalitis
Myocarditis
Erythema nodosum
Fever during pregnancy
Fever in a patient in contact with a parturient pet
Unexplained atypical pneumonia
Fever and an increase in transaminases (2-5 times the normal level)
Aseptic meningitis
Guillain-Barré syndrome
Pericarditis
Spontaneous abortion
CHRONIC Q FEVER (PHASE I ANTIGEN AND IgG ≥ 800 AND IgA ≥ 100)
Blood culture–negative endocarditis
Patient with a valvulopathy and unexplained
Fever
Weight loss
Fatigue
Increased erythrocyte sedimentation rate
Increased transaminases
Thrombocytopenia
Patient with unusually rapid degradation of a prosthetic valve
Fever in a patient with a vascular aneurysm or prosthesis
Aseptic osteomyelitis
Chronic pericarditis
Multiple spontaneous abortions

Patients with diagnosed acute infection may have a variety of symptoms (Table 327-4). Isolated prolonged fever was observed in 14% of more than 1000 patients. Pneumonia was found in 37% and was the only symptom in 17%. This percentage may vary according to the place of study and reach 90% of diagnosed cases. Some cases may be associated with respiratory distress. Hepatitis is found in 60% of patients and is the sole manifestation in 40%. The association of fever and a moderate increase in transaminases is an important clue. Some hepatitides, specifically in middle-aged men, are associated with an inflammatory syndrome and autoantibodies and may be resistant to antimicrobial treatment. Liver biopsy, when it is performed, exhibits granulomas that may be typified by a lipid vacuole and surrounded by a fibrinoid ring in the form of a doughnut. Less frequently (1.5% of cases), patients exhibit a rash. Patients can have specific neurologic manifestations such as meningitis, encephalitis, meningoencephalitis, or peripheral neuropathy. In 1 to 2% of cases, patients have cardiovascular manifestations such as pericarditis or, more rarely, myocarditis.

Evolution is usually favorable even without treatment, except in special hosts. In pregnant women, symptomatic or not, Q fever compromises the pregnancy. When infected during the first trimester, the patient usually aborts spontaneously. When the patient is infected later, the disease can result in fetal death or prematurity, or the outcome may be normal. Chronic uterine infection may develop in half the patients infected during pregnancy, and they may later experience multiple spontaneous abortions. From 30 to 50% of patients with heart valve or vascular lesions may experience chronic endocarditis within 2 years. This evolution is not prevented by regular treatment.

Patients with Q fever endocarditis have a chronic infection with low-grade fever, progressive degradation of valve function, and progressive heart failure. Fever is intermittent, and vegetations are frequently absent on echocardiography. Endocarditis is therefore not frequently considered in the initial differential diagnosis. If it is not diagnosed, the disease progressively worsens, and emboli (mainly cerebral) as well as renal insufficiency, splenomegaly, and hepatomegaly may be observed. Digital clubbing may also be seen. The main clue to the diagnosis in a patient with a valvulopathy is unexplained sickness (unexplained fatigue, weight loss, fever), a biological abnormality (leukopenia, increased erythrocyte sedimentation rate, thrombocytopenia, increase in

hepatic enzymes), or rapid degradation of a prosthetic valve. Chronic osteomyelitis, hepatitis, and infection of an aneurysm and vascular prosthesis have been reported.

Leukopenia may be observed; thrombocytopenia is frequent, as are increases in hepatic enzymes. Circulating anticoagulant associated with antiphospholipid antibodies may be observed, as may anti–smooth muscle antibodies. During endocarditis, antinuclear antibodies, microhematuria, and rheumatoid factor are frequently found.

DIAGNOSIS

The diagnosis is based mainly on serology (see Table 327-4). Direct detection by culture and PCR or immunochemistry in valve, liver, or blood samples is also useful, but serologic evaluation by IFA is the best method. Two antigens (phase I and phase II) can be tested. Acute Q fever is diagnosed when seroconversion or a four-fold increase is obtained with phase II antigen. A single serum test exhibiting IgG antibodies of 200 or greater and IgM of 50 or greater against phase II is also diagnostic. During chronic Q fever, antibodies are at higher titer and directed against both phase I and phase II. IgG against phase I at a titer of 800 or 1600 is diagnostic of chronic infection, as is IgA at 100 or greater. Serology is useful for follow-up of patients with acute Q fever and underlying disease and those with treated chronic Q fever.

TREATMENT

Rx

Treatment is easy during acute Q fever. Doxycycline is the most efficient antimicrobial and should be prescribed for 2 weeks. Some patients with hepatitis do not respond well because of an excessive immune response. They rapidly improve with a short course of glucocorticoids. In pregnant women, cotrimoxazole during the entire pregnancy may decrease the chance of an unfavorable outcome. As for endocarditis, bactericidal treatment is necessary. In vitro, antimicrobial efficacy is impaired by the low pH of the vacuoles in which *C. burnetii* resides. Hydroxychloroquine increases the pH of these vacuoles and restores the bactericidal effect of doxycycline. In patients with endocarditis, the recommended treatment is a combination of doxycycline (200 mg daily) and hydroxychloroquine (600 mg/day, then adjusted to reach a 1-mg/mL plasma concentration). This regimen is prescribed for 18 to 36 months according to serologic results. We recently observed that a more rapid favorable outcome was obtained with doxycycline serum levels higher than 5 µg/mL. Some strains may be resistant to doxycycline, and new macrolides may be an alternative. The major problem with this treatment is photosensitivity; sun exposure should be avoided. An alternative treatment is a combination of doxycycline and ofloxacin for 3 years or more.

PREVENTION

Prevention is based on veterinary control in animals. A vaccine is currently available in Australia.

REVIEW QUESTIONS

1. A 50-year-old man with acute Q fever presents after 7 days of fever, when he became spontaneously afebrile. You should:

A. Prescribe 15 days of doxycycline.
B. Evaluate clinically and/or echocardiographically if he has an underlying cardiovascular predisposing factor to chronic endocarditis.
C. Perform hepatic echography to detect hepatomegaly.
D. Explain to the patient that as he is spontaneously cured, he does not need to follow up.
E. Investigate the possible environmental source of the disease.

Answer: B It is critical in such patients to determine the risk of endocarditis. Progression to chronic endocarditis may be accompanied by only low-grade or intermittent fever, but if it is not diagnosed it can cause severe valve dysfunction, heart failure, and embolic complications.

2. A 6-year-old boy is diagnosed with Rocky Mountain spotted fever and presents with high fever. You should prescribe:

A. Treatment with doxycycline adjusted to weight
B. Chloramphenicol intravenously
C. Ciprofloxacin orally
D. Erythromycin intravenously
E. Ceftriaxone intravenously

Answer: A Doxycycline is recommended even in children for the treatment of potentially severe diseases. Oral treatment is effective.

3. A patient with body lice exposure and fever returns from Eastern Congo and you suspect louse-borne typhus. You should:

A. Immediately prescribe two pills of 100 mg doxycycline.
B. Prescribe intravenous chloramphenicol.
C. Sample blood for serology and wait for the result to treat.
D. Sample blood for polymerase chain reaction and wait for the result to treat.
E. Sample a stain biopsy and wait for the result to treat.

Answer: A This situation is an emergency; the patient should be treated as soon as the diagnosis is suspected. The diagnosis of typhus should be clinical because the fatality rate is high and the treatment safe and effective.

4. A pregnant women who travelled in Thailand received a diagnosis of scrub typhus. You should treat with which of the following:

A. Doxycycline
B. Ciprofloxacin
C. Chloramphenicol
D. Rifampicin
E. Streptomycin

Answer: D Because doxycycline is a U.S. Food and Drug Administration Pregnancy Category C drug ("use not recommended unless essential for the patient's welfare."), rifampicin is the reference treatment for scrub typhus when doxycycline is contraindicated.

5. Which of these tick bite diseases may be commonly superinfected by yeast or opportunistic bacteria?

A. Human monocytic ehrlichiosis
B. Infection by *E. canis*
C. Rocky Mountain spotted fever
D. Human granulocytic anaplasmosis
E. African tick bite fever

Answer: D Granulocytopenia favors superinfection by opportunistic pathogens.

328

ZOONOSES

STUART LEVIN AND KAMALJIT SINGH

DEFINITION

Zoonoses are classically defined as infections or diseases naturally transmitted between humans and vertebrate animals. There are approximately 1400 human pathogens, of which about 800 species are zoonotic. Zoonoses may be bacterial, viral, fungal, parasitic, or due to unconventional agents such as prions.[1] Of the approximate 400 emerging or reemerging pathogens in the past 70 years, 60% are known to be zoonotic, with a disproportionate number of the new zoonoses being caused by RNA viruses. Arthropod-transmitted diseases are prototypic zoonoses, but whereas infections such as West Nile fever, *Schistosoma japonicum*, *Trypanosoma rhodesiense*, and *Plasmodium knowlesi* malaria are zoonoses, other related diseases such as *Schistosoma mansoni*, *Trypanosoma gambiense*, and *Plasmodium vivax* malaria are not zoonoses, because these pathogens are transferred from human to human and do not depend on vertebrate reservoirs. Human infestations with ectoparasites are likewise not considered to be zoonoses.

We have little ability to predict how an emerging zoonotic pathogen will act. Most zoonotic pathogens like rabies enter a human and cause disease; however, in these cases, humans are dead-end hosts and are unlikely to transmit the disease to others. Less commonly, pathogens such as human immunodeficiency virus (HIV) or recombinant swine H1N1 (pH1N1/2009) enter the human population with great difficulty but are then successfully transmitted from human to human to cause global epidemics. The recent emphasis on emerging infections that are predominantly zoonoses and the potential for new pandemics markedly enhance the need for human medicine to be integrated with veterinary medicine and veterinary research. This is the concept of One Health, which calls for enhanced collaboration between physicians, veterinarians, and environmental health professionals for the optimal health of all species on the planet.[2,3]

EPIDEMIOLOGY

During the course of evolution, humans have sought the company of vertebrates for many reasons, including their companionship as pets. In the United States, fewer than 60% of households have pets; a surprising 56% of dog owners sleep with their dog next to them, whereas among cat owners, 75% sleep with their pets.[4] The over 100 million dogs and cats in the United States facilitate the transmission of more than 250 different infectious species and cause more than 1 million bite injuries each year. Other pets include birds, fish, and reptiles (particularly common are small pet turtles that can transmit salmonellosis). Another popular trend is the keeping of exotic animals as pets, many of which are important reservoirs of a variety of viral and bacterial human pathogens.

Almost all arthropod-transmitted infectious agents acquired from vertebrates in the United States are due to either ticks or mosquitoes. Ticks are the more common villain,[5] and Lyme disease is the most frequent arthropod-transmitted infectious disease in the United States (Chapter 321). At least five tick-borne pathogens are known to be transmitted by *Ixodes scapularis* (the principal tick vector for Lyme disease): *Borrelia burgdorferi*, *Anaplasma phagocytophilum* (an agent for anaplasmosis, previously known as human granulocytic ehrlichiosis), *Babesia microti* (an agent of human babesiosis), *Borrelia miyamotoi* (an agent of relapsing fever), and the Powassan encephalitis virus. Two or more of these pathogens can be transmitted by a single tick bite, resulting in 30 different permutations of mixed infections. In addition, two geographically distinct species of *Borrelia* (Chapter 322) cause relapsing fevers in the United States, with *Borrelia hermsii* described in the mountain states west of the Mississippi River and *Borrelia turicatae* in the southwest plains states. Threats from mosquito bites include almost all the vector-borne encephalitides, such as St. Louis encephalitis and West Nile virus (Chapter 383).

The recognition of novel zoonoses such as Hendra and Nipah (henipaviruses) and the SARS (severe acute respiratory syndrome) coronavirus has intensified research in wildlife reservoirs especially among the more than 1000 species of Chiroptera or bats. Bats have been known as the origin of a number of "old" viruses such as yellow fever virus (Chapter 381) and Japanese encephalitis virus but are now also recognized as the source of a succession of highly pathogenic emerging zoonoses, including Ebola, Marburg, and MERS (Middle East respiratory syndrome) coronavirus. (Dromedary camels have also been identified as hosts for MERS.) Another area of great interest is in the highly pathogenic avian influenza viruses (HPAIV) that spread from wild birds and ducks to chickens and humans, such as A/H5N1, with over 640 cases and 380 deaths since 2003, and other avian viruses, such as A/H7N9, with 132 laboratory-confirmed cases and 38 fatalities since March 2013. Emerging swine zoonoses include the 2009 novel swine-origin A/H1N1 virus that began in February 2009 in Veracruz, Mexico. Other novel swine influenza virus infections (e.g., vH3N2) have been documented in fairgoers and pigs in agricultural fairs in the United States since 2007.[6] In addition, living in close contact with swine, a common husbandry practice in Asia, has been associated with an emerging rapidly fatal meningitis due to *Streptococcus suis*.

The risk of contracting a zoonosis is increased by direct animal contact in meat handlers, poachers, hunters, exotic animal smugglers, and international travelers; by exposure to and inhalation of infectious air particles; by insect

TABLE 328-1 NEWER ZOONOSES IN THE UNITED STATES (EMERGING INFECTIONS)

DISEASE*	INFECTIOUS AGENT	CLINICAL FINDINGS	VECTOR/ACQUISITION
Ehrlichiosis, monocytic	*Ehrlichia chaffeensis* (Chapter 327)	Fever, myalgia, leukopenia; monocyte inclusions not often seen; maculopapular rash in a minority	*Amblyomma* (Lone Star) tick bite

STARI (Southern tick-associated rash illness)	Unknown	Lyme disease–like illness	*Amblyomma*
Relapsing fever	*Borrelia hermsii* & *Borrelia turicatae* (Chapter 322)	Fever, headaches, myalgias	*Ornithodorus* ticks
Cat-scratch disease	*Bartonella* spp. (there are 8 identified zoonotic *Bartonella* spp.) (Chapter 315)	Cervical lymphadenopathy in normal hosts and cutaneous and hepatic angiomatosis in AIDS patients	Cat scratch or bite
Hemorrhagic diarrhea	Enterohemorrhagic *Escherichia coli* O157:H7 (other Shiga toxin–producing strains) (Chapter 304)	Rectal bleeding, dysentery, hemolytic-uremic syndrome	Contaminated undercooked meat
Hantavirus pulmonary syndrome	*Hantavirus*—Sin Nombre (Chapter 381)	Noncardiac pulmonary edema, elevated hematocrit	Fomites of wild rodents
Cryptosporidium diarrhea	*Cryptosporidium parvum* (Chapter 350)	Prolonged watery diarrhea	Contaminated water—cattle and sheep
Paragonimiasis	*Paragonimus kellicotti* (Chapter 356)	Diarrhea, cough, pleuritic chest pain, hemoptysis	Freshwater crayfish
Dysentery	*Campylobacter jejuni* (Chapter 303)	Dysentery, reactive arthritis, Guillain-Barré syndrome	Contaminated chicken
Pyogenic skin ulcer	*Capnocytophaga canimorsus* (Chapter 280)	Sepsis, skin infection	Dog bites
West Nile fever encephalitis	West Nile virus (Chapters 382 and 383)	Encephalitis, myelitis, Guillain-Barré syndrome, West Nile fever	Mosquito bite, birds
SARS	Coronavirus (Chapter 366)	Severe lower respiratory tract infection	Horseshoe bats
Cutaneous leishmaniasis	*Leishmania mexicana* (Chapter 348)	Skin nodules and ulcers	Wood rat

*See table of contents and index to locate a more detailed discussion of each disease.
AIDS = acquired immunodeficiency syndrome; SARS = severe acute respiratory syndrome.

bites, contact with previously infected human blood products, contact with and ingestion of infectious agents transmitted by animal-contaminated water; by insufficiently cooked meat, eggs, dairy products, and fish; and by acts of bioterrorism. Patrons of petting zoos, pet owners, farmers, hunters, laboratory researchers, cave explorers, hikers, and veterinarians, among others, are at higher risk for a zoonosis than the general population is. Infectious agents transmitted by these routes from animal sources essentially include members of all microbial classes: viruses and prions, bacteria and rickettsia, fungi, helminths, and protozoa. Immunocompromised hosts, such as splenectomized individuals, transplant recipients, patients with acquired immunodeficiency syndrome (AIDS), patients on chemotherapeutic agents (including biologics used in rheumatology and oncology), and pregnant women and their fetuses, are at higher risk for clinical disease when exposed to these various infectious agents. Chagas disease, a protozoal infection, is a zoonosis in South America but is not endemic to the United States (with only seven Autochthonous cases described since 1955); however, immigration from Latin America has led to "globalization" of this disease, with an estimated 300,000 persons with *Trypanosoma cruzi* infection in the United States and the potential for transmission of the infection through blood, birth, or organ donations. *Leishmania donovani* is almost always a small-animal reservoir zoonosis, but in India, it has become established in the human population, with female sandflies as the vector for human-to-human transmission.

As the world shrinks, warms, flattens, and remains in conflict, new infectious diseases seem inevitable, and previously rare ones are seen in unexpected places (Table 328-1) because of global warming, human intrusion into previously underexplored or never explored sites, world travel, deforestation, and the increasing threat of biological terrorism or warfare. Tens of thousands of years ago, human communities consisted of small groups of people living in vastly disparate regions that posed a very low risk for global epidemics. Increasing urbanization, intermingling of humans and domestic animals, and lack of adequate sanitation threaten to dramatically increase the incidence and severity of epidemic infectious diseases.

CLINICAL MANIFESTATIONS

Zoonoses can manifest as a variety of clinical syndromes, including respiratory disease (Table 328-2), central nervous system disease (Table 328-3), and rash or skin lesions (Table 328-4). Other zoonotic clinical syndromes may present as sepsis, polyarthritis, jaundice, acute renal failure, endocarditis, or diarrhea (Table 328-5).

Emerging zoonotic infectious diseases include Nipah virus and Hendra virus encephalitis, *Hantavirus* pneumonia and *Hantavirus* fever with renal failure, the SARS and MERS coronaviruses, West Nile encephalitis (which spread coast to coast in the United States in 3 years and is now apparently a permanent resident), monkeypox (an outbreak of which in the upper Midwest was caused by pet prairie dogs housed next to an imported Gambian rat infected with the virus), *Leishmania mexicana* in Texas, and at least 8 to 10 newly identified tick-borne rickettsial spotted fevers worldwide, including the flea-borne *Rickettsia felis* in California and tick-borne *Rickettsia parkeri* in the Gulf Coast states. Avian H5N1 and A/H7N9, pH1N1/2009 (swine) influenza, SARS and MERS coronaviruses, and West Nile fever have recently exposed the fragility of our world village. Nevertheless, exotic zoonoses remain a less frequent cause of fever in travelers than the well-known ordinary gastrointestinal and pulmonary pathogens.

DIAGNOSIS

Non–animal-associated environment- or travel-related infectious diseases can be confused with zoonoses. The vast majority of clinical diseases caused by *Legionella pneumophila*, *Entamoeba histolytica*, *Giardia lamblia*, *Burkholderia pseudomallei*, *Chromobacterium violaceum*, *Aeromonas hydrophila*, and airborne fungi such as *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* are acquired through environmental exposure and are only rarely related to animal hosts. *Sporothrix schenckii*, almost always an environmentally acquired pathogen stemming from vegetation-related injuries, has also been transmitted from cats with draining cutaneous ulcers to owners and animal handlers. Histoplasmosis has been acquired by explorers (spelunkers) in caves contaminated by bat guano.

Unfortunately, some descriptive disease titles can be misleading to clinicians and interfere with reaching the correct diagnosis. The transmission of tick-borne Rocky Mountain spotted fever actually occurs much more commonly in the southeastern United States than in the Rocky Mountains and has even occurred in the middle of New York City. In turn, the geographic range of Southern tick-associated rash illness (STARI), a Lyme disease–like infection transmitted by the Lone Star tick, *Amblyomma americanum*, has expanded to areas where *Ixodes scapularis* transmission of *B. burgdorferi*

TABLE 328-2 RESPIRATORY TRACT ZOONOSES

DISEASE*	MICROORGANISM†	CLINICAL FINDINGS	RESERVOIR AND/OR VECTOR
Psittacosis‡	*Chlamydophila psittaci* (Chapter 318)	Pneumonia, often severe	Aerosols from parrots, ducks, turkeys
Q fever	*Coxiella burnetii* (Chapter 327)	Pneumonia, hepatitis, myocarditis	Airborne from soil contaminated by sheep, goats, and cats, particularly if parturient
Tularemia	*Francisella tularensis* (Chapter 311)	Cutaneous ulcer and regional node, pneumonia and hilar node, pleural effusion	Rabbit contact (winter) and tick/fly bites
Plague	*Yersinia pestis* (Chapter 312)	Inguinal nodes, bubonic plague (basilar pneumonia develops in 10%), hilar node enlargement	Fleas from prairie dogs, rock squirrels, rats
Hantavirus cardiopulmonary syndrome	*Hantavirus* (Chapter 381)	Upper respiratory to lower respiratory to adult respiratory distress syndrome (ARDS) to death	Deer mouse fomites: urine, feces, saliva
Rhodococcus pneumonia	*Rhodococcus equi*	Pneumonia often cavitates in those with AIDS and in other immunosuppressed patients.	Horse manure, soil
Mycoplasma arginini pneumonia	*Mycoplasma arginini* (Chapter 317)	Pneumonia, sepsis, neutropenia	Sheep, goats
Foot-and-mouth disease	*Aphthovirus*	Nonspecific upper respiratory tract infection, oral vesicles	Cloven-footed mammals
Whooping cough	*Bordetella bronchiseptica* (Chapter 313)	Pneumonia, bronchitis, whooping cough	Dogs
Histoplasmosis	*Histoplasma capsulatum* (Chapter 332)	Pneumonia or fever of unknown origin	Bats
Anthrax	*Bacillus anthracis* (Chapter 294)	Mediastinal widening with CT scan; pneumonia often absent	Herbivore mammals
Glanders	*Burkholderia mallei* (Chapter 306)	Pneumonia, erosive tracheobronchitis	Horses, mules

*See table of contents and index to locate a more detailed discussion of each disease.
†Because of the fastidious nature of some organisms, the rapid development of diagnostic tools, and the risk some agents pose to laboratory workers, a clinical microbiologist should be consulted if these agents are considered in a patient's differential diagnosis.
‡Occurs in more than 1000 animal species.
AIDS = acquired immunodeficiency syndrome; CT = computed tomography.

TABLE 328-3 CENTRAL NERVOUS SYSTEM ZOONOSES

DISEASE*	ORGANISM	CLINICAL FINDINGS	ACQUISITION
Listeriosis	*Listeria monocytogenes* (Chapter 293)	Purulent meningitis during pregnancy, in patients > 65 yr, in neonates, and immunosuppressed	Unpasteurized cheese and other dairy products; cattle, goats
Leptospirosis	*Leptospira interrogans* (Chapter 323)	Aseptic meningitis, hepatorenal syndrome	Asymptomatic dogs, cattle; common water source
Herpes B encephalitis	Cercopithecine herpesvirus (herpes B virus) (Chapter 414)	Diffuse progressive encephalitis	Macaca monkey bites or scratches
Lyme disease	*Borrelia burgdorferi* (Chapters 321 and 322)	Lymphocytic meningitis, motor-sensory neuropathy, facial palsy	Tick bite
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis virus (Chapter 412)	Lymphocytic meningitis, occasionally with pneumonia	Inhalation of mouse secretions: urine, feces, saliva
Mosquito-borne encephalitis (U.S.)	Eastern, Western equine, St. Louis, California encephalitis; West Nile virus (Chapter 383)	Diffuse encephalitis least severe; California encephalitis most severe; Eastern equine encephalitis, myelitis, meningitis	Mosquito-borne from horses, birds
Rabies encephalitis	Rabies virus (Chapter 414)	Encephalitis; almost always fatal	Bites from dogs, skunks, bats, raccoons, foxes
Toxoplasmosis	*Toxoplasma gondii* (Chapter 349)	Multiple brain masses in AIDS patients	Cat feces or ingestion of undercooked lamb or pork
Cerebral cysticercosis	*Taenia solium* (Chapter 354)	Epilepsy, CNS cysts, eosinophilic meningitis, hydrocephalus	Fecal-oral; contamination of food with pork tapeworm eggs
New-variant Creutzfeldt-Jakob disease	Prion (proteinaceous infectious particle) (Chapter 415)	Dementia, ataxia, myoclonus	Beef from cattle fed scraps from contaminated sheep carcasses
Nipah virus (Chapter 414)	Paramyxovirus	Acute encephalitis, death	Pig contact, fruit bats
Hendra virus	Paramyxovirus	Pneumonitis, encephalitis	Horses, fruit bats

*See table of contents and index to locate a more detailed discussion of each disease.
AIDS = acquired immunodeficiency syndrome; CNS = central nervous system.

occurs, resulting in misdiagnosis as Lyme borreliosis. Urban New York City continues to be a major source of rickettsialpox, where it was first described 60 years ago.[7] Vegetarians and other strict non–pork-eating persons have been seriously infected with the pig tapeworm *Taenia solium* as a result of fecal contamination of food from infected human food handlers. Recent outbreaks of food-borne zoonotic disease with Shiga toxin–producing *Escherichia coli*–infected brussels sprouts in Germany and *Listeria*-infected cantaloupes in the United States in 2011 highlight the difficulties in identifying the original source of the disease outbreak. The separation of an infection from the source of transmission, or a lack of knowledge, often blurs the diagnosis of a zoonoses. For example, unexpected outbreaks of leptospirosis among triathlon athletes exposed to water bodies that are contaminated by animal urine may not be recognized by physicians in a nonendemic setting. Emerging parasitic zoonosis such as the lung fluke, *Paragonimus kellicotti* (acquired by ingestion of contaminated crayfish from the Mississippi River basin), although unknown to most physicians and microbiologists, is well recognized by veterinarians in North America.

Until recently, human influenza A was not well recognized as a zoonosis; however, interspecies spread and mixing of swine, avian, and human influenza viruses can occur in unique geographic areas such as southern China or Mexico (pH1N1/2009), where dense concentrations of ducks, pigs, and people cohabit. Viral incubation of the three influenza species in the pig, with

TABLE 328-4 ZOONOSES CAUSING RASH OR SKIN NODULE, ULCER

DISEASE*	MICROORGANISM†	CLINICAL FINDINGS	RESERVOIR AND/OR VECTOR
Ehrlichiosis (monocytic)	*Ehrlichia chaffeensis* (Chapter 327)	Macular rash (seen in < half of patients) with a central distribution; prevalent in south-central United States	Tick bite
Leptospirosis	*Leptospira interrogans* (Chapter 323)	Central macular rash in 20%; occasional enanthem, conjunctival suffusion, hepatorenal syndrome	Urine-contaminated water; dogs, cattle
Lyme disease	*Borrelia burgdorferi* (Chapters 321 and 322)	Erythema migrans; 20% have multiple lesions	Mouse reservoir—tick bite
Rocky Mountain spotted fever	*Rickettsia rickettsii* (Chapter 327)	Acral or peripheral distribution of maculopapular to hemorrhagic rash to gangrenous lesions—no eschar	Tick bite
Typhus (epidemic)	*Rickettsia prowazekii* (Chapter 327)	Macular rash with a central distribution (can be hemorrhagic)	Flying squirrel fleas or fomites
Spotted fever	*Rickettsia parkeri* (Chapter 327)	Eschar, fever, headache, generalized rash involving palms and soles	*Amblyomma maculatum*
Cat-scratch disease	*Bartonella* spp. (Chapter 315)	Bacillary angiomatosis, peliosis hepatis in HIV patients, cervical adenopathy, subacute bacterial endocarditis, fever of unknown origin	Cat scratch or bite
Tularemia	*Francisella tularensis* (Chapter 311)	Ulcer and node, typhoidal syndrome, pneumonia	Rabbit contact and tick bite
Anthrax	*Bacillus anthracis* (Chapter 294)	Painless, edematous, nonpurulent ulcer that becomes black and necrotic over days; mediastinitis	Herbivore animal products, including animal hides
Rickettsialpox (spotted fever *Rickettsia*)	*Rickettsia akari*, *Rickettsia conorii*, *Rickettsia africae* (8 others found on all continents) (Chapter 327)	Fever, rash, eschar (multiple), tache noire (*R. africae*, often multiple)	House mouse mite
Monkeypox	Orthopoxvirus (Chapter 372)	Multiple maculopustular lesions with lymphadenopathy	Prairie dog (U.S.), African rodents
Erysipeloid	*Erysipelothrix rhusiopathiae* (Chapter 295)	Red, tender, swollen finger; subacute bacterial endocarditis	Skin pricked while cleaning fish, domestic meat animals

*See table of contents and index to locate a more detailed discussion of each disease.
†Because of the fastidious nature of some organisms, the rapid development of diagnostic tools, and the risk some agents pose to laboratory workers, a clinical microbiologist should be consulted if these agents are considered in a patient's differential diagnosis.

*See table of contents and index to locate a more detailed discussion of each disease.

a reassortment of antigens and subsequent spread of virulent "new" influenza strains to humans, can lead to massive influenza pandemics that in sheer numbers (billions) surpass any past epidemics of smallpox or plague.[8] Initially, HIV-1 and HIV-2 were transmitted as simian immunodeficiency viruses from chimpanzees and mangabey primates, respectively, to humans. As with influenza, the subsequent 60 million (and counting) cases of HIV no longer require an animal reservoir for continuing transmission. Because these pandemics of AIDS and influenza now spread from human to human without the help of the initiating animal host, the World Health Organization no longer considers them zoonoses.

Leprosy, an illness of biblical notoriety transmitted from human to human, is endemic in at least three animal species, including the armadillo. This animal has rarely been implicated in the transmission of leprosy to humans in the United States.

Despite the large number of zoonoses described, clinicians evaluating an individual patient usually need to consider only a limited number of historical details to arrive at an appropriate differential diagnosis:

1. A history of direct contact with animals or animal products, animal bites, arthropod exposure, and food ingestion may offer clues to the correct cause.
2. All hobbies such as hunting and pet exposures (including contact with other owners' pets) should be elicited. Ownership of exotic pets or reptiles is often denied.
3. The patient's travel history must be considered because a number of zoonoses are still quite limited in geographic distribution.
4. Occupational and recreational high-risk activities such as cave exploration must be ascertained.
5. The patient's clinical manifestations (course and organ involvement) are used to focus on the most likely cause (see Tables 328-2 through 328-5).
6. Though neither specific nor sensitive, the inoculation nodule (eschar, tache noire, chancre, necrotic ulcer), with or without fever, rash, or local lymphadenopathy, is the only general clue from the physical examination that might alert the physician to a zoonosis when the history does not.
7. Significant unilateral hilar adenopathy in the presence of acute pneumonia can be a clue to anthrax, plague, or tularemia.

TREATMENT

Rx

The approach to treatment of the various zoonoses is presented in their respective chapters.

PREVENTION

Guidelines have been published to help prevent nosocomial transmission of zoonotic diseases. Preventive measures to decrease infection in compromised hosts include the routine immunization of pets, neutering of pets, use of caution when handling pet fomites, rigorous handwashing practices, and avoidance of ingesting undercooked meat, fish, shellfish, and eggs.

Isolation is recommended for anthrax, Andes *Hantavirus* disease, herpes B, monkeypox, Q fever, rabies, plague, SARS and MERS coronavirus (Chapter 366), influenza, and the hemorrhagic fever illnesses (Chapter 381)

TABLE 328-6 HIGHLY FATAL ZOONOSES

DISEASE*	FATALITY RATE (%)
Creutzfeldt-Jakob disease (new variant)	100

caused by Argentine, Bolivian, Crimean-Congo, Ebola, Lassa, and Marburg viruses.

PROGNOSIS

The prognosis of zoonoses varies widely, but a number of these diseases have very high case-fatality rates (Table 328-6).

REVIEW QUESTIONS

1. The deer tick (*Ixodes scapularis*) is a known vector for which of the following infections:

A. Babesiosis
B. Human monocytic ehrlichiosis (HME)
C. Rocky Mountain spotted fever (RMSF)
D. Leishmaniasis
E. Chagas Disease

Answer: A HME and RMSF are transmitted by the bite of the Lone Star tick. Leishmaniasis is transmitted by the bite of a sandfly, and Chagas disease is spread by the kissing bug (Triatome).

2. Which of the following viral infections is associated with bats?

A. Henipaviruses
B. Dengue fever
C. West Nile virus
D. Avian H5N1 influenza
E. Herpes simiae

Answer: A Henipaviruses, which include the Hendra virus and Nipah virus, are paramyxoviruses found in fruit bats in Australia and Asia, respectively.

3. A 32-year-old man with a history of Hodgkin's lymphoma in remission presents to the emergency department with a 3-day history of fever, cough, and left-sided pleuritic chest pain. He reports no recent travel or pets. One week prior to presentation, he had Thanksgiving dinner at his mother's house, where he remembered feeding table scraps to her dog. On admission, he is found to be febrile with a left lower lobe pneumonia and pleural effusion. Blood cultures drawn on admission are positive for a fastidious gram-negative rod that is most likely:

A. *Streptococcus* pneumonia
B. *Haemophilus influenzae*
C. *Pseudomonas aeruginosa*
D. Methicillin-resistant *Staphylococcus aureus*
E. *Pasteurella multocida*

Answer: E Transient contact with pets, including being licked by an animal, can result in transmission of pet-associated zoonoses such as *Pasteurella multocida*. Presumably in this case, the patient contacted the dog's saliva with his feeding hand and proceeded to eat without washing his hands. Patients with prior hematologic malignancies may be slow to fully recover immune function after completion of chemotherapy, and this may represent an added risk factor for infection.

4. A 12-year-old Kenyan boy presents with a necrotic ulcer on his right arm that has been present for approximately 2 weeks. The lesion started as a nonpainful papule, which gradually enlarged and eroded to leave a painless ulcer with a black necrotic-appearing base. He does not recall any trauma and works on the family farm herding cattle. On examination, the patient also has a low-grade fever with associated swollen right axillary lymph nodes. The most appropriate treatment would be:

A. Penicillin
B. Trimethoprim-sulfamethoxazole (TMP-SMX)
C. Clindamycin
D. Azithromycin
E. Pentavalent antimony

Answer: A The patient has cutaneous anthrax, probably acquired from contact with cattle, and the treatment of choice is penicillin. TMP-SMX and clindamycin are reasonable treatment options for community-associated methicillin-resistant *Staphylococcus aureus* skin–soft tissue infections and impetigo. Azithromycin is used for treatment of cat-scratch disease or *Mycobacterium marinum* infection. Pentavalent antimony is generally used for treatment of cutaneous leishmaniasis (particularly New World cutaneous leishmaniasis).

5. A 50-year-old woman is admitted to the hospital for fevers and diffuse arthralgias and myalgias. She denies recent travel or pets. On examination, the patient has a faint diffuse rash over the extremities. Blood cultures drawn on admission are positive only at day 5 for a pleomorphic branching gram-variable rod that fails to grow on routine media. On further questioning, the patient admits to keeping a pet python and feeds it with rats. The most likely cause of her infection is:

A. *Neisseria gonorrhoeae*
B. *Streptococcus suis*
C. *Bacillus anthracis*
D. *Streptobacillus moniliformis*
E. *Borrelia burgdorferi*

Answer: D The patient has rat-bite fever due to *Streptobacillus moniliformis*.

329

ACTINOMYCOSIS

ITZHAK BROOK

DEFINITION

Actinomycosis is an uncommon, subacute to chronic bacterial infection that induces both suppurative and granulomatous inflammation. Localized swelling with suppuration, abscess formation, tissue fibrosis, and draining sinuses characterize this disease. The infection spreads contiguously and often forms draining sinuses that extrude characteristic but not pathognomonic "sulfur granules." Infections of the oral and cervicofacial regions are the most common, but any site in the body can be infected, including the thoracic region, abdominopelvic region, and central nervous system (CNS). Musculoskeletal or disseminated disease is rare but does occur.

The Pathogen

Actinomycetes of the genera *Actinomyces, Propionibacterium,* and *Bifidobacterium* act as the principal pathogens. However, 98 to 99% of actinomycoses are caused by non–spore-forming anaerobic or microaerophilic bacterial species of the genus *Actinomyces,* family Actinomycetaceae, order Actinomycetales.[1] Of the 30 *Actinomyces* spp, 8 may cause disease in humans: the strictly anaerobic *A. israelii, A. gerencseriae* (formerly known as *A. israelii* serotype II), *A. odontolyticus, A. naeslundii, A. meyeri, A. viscosus, A. pyogenes,* and *A. georgiae. A. israelii* is the most common species causing human disease. *Propionibacterium propionicum* (formerly known as *Arachnia propionica*) and *Bifidobacterium dentium* (formerly known as *Actinomyces eriksonii*) also are associated with clinically indistinguishable infection. The organisms are filamentous, branching, gram-positive, pleomorphic, non–spore-forming, non–acid-fast anaerobic or microaerophilic bacilli. *Actinomyces* organisms are fastidious bacteria that require enriched culture media; 6 to 10% ambient CO_2 may aid in their growth, which takes up to 2 to 3 weeks in culture. Most actinomycotic infections are polymicrobial and involve other aerobic and anaerobic bacteria. The most common co-isolates depend on the infection site and are *Actinobacillus actinomycetemcomitans, Aggregatibacter aphrophilus, Eikenella corrodens, Bacteroides, Fusobacterium, Capnocytophaga,* aerobic and anaerobic streptococci, *Staphylococcus,* and Enterobacteriaceae.

EPIDEMIOLOGY

Actinomyces spp are members of the endogenous mucous membrane flora in the oral cavity, lower gastrointestinal tract, bronchi, and female genital tract. No external environmental reservoir, such as soil or straw, has been documented, nor has person-to-person transmission of pathogenic *Actinomyces* spp been demonstrated. Although infection can occur in all age groups, it is rarely seen in children or patients older than 60 years. Most cases are encountered in individuals in the middle decades of life. A male-to-female infection ratio of 3 : 1 is reported in most series. The explanation for this ratio is the higher prevalence of poor oral hygiene and oral trauma in men. The annual reported incidence in the United States is fewer than 100 cases. However, because of the fastidious nature of the organism, many cases are undiagnosed and the true incidence is probably much higher.

PATHOBIOLOGY

Actinomyces spp are agents of low pathogenicity and require mucosal barrier disruption to cause disease.[2] Actinomycosis usually occurs in immunocompetent persons but may afflict those with diminished host defenses. Risk factors include steroids, bisphosphonates, leukemia with chemotherapy, human immunodeficiency virus (HIV), alcoholism, lung and renal transplant receipt, and local tissue damage caused by trauma, recent surgery, or irradiation. Oral and cervicofacial diseases are commonly associated with dental caries and extractions, gingivitis and gingival trauma, infection in erupting secondary teeth, chronic tonsillitis, otitis or mastoiditis, diabetes mellitus, immunosuppression, immunodeficiency, malnutrition, and neoplastic disease. Pulmonary infections generally arise after aspiration of oropharyngeal or gastrointestinal secretions and has been reported in patients with underlying lung disorders, such as emphysema, chronic bronchitis, and bronchiectasis. Gastrointestinal infection frequently follows loss of mucosal integrity, such as with surgery, trauma, foreign bodies, perforated appendix or diverticulitis, neoplasia, foreign bodies, and emergency colonic surgery. Extended use (>2 years) of intrauterine contraceptive devices (IUDs) increases risk for the development of actinomycosis of the female genital tract.

Other bacterial species that are frequently copathogens with *Actinomyces* spp may assist in the spread of infection by inhibiting host defenses and reducing local oxygen tension. Once the organism is established locally, it may spread progressively to surrounding tissues. The infection tends to spread without regard for anatomic barriers, including fascial planes and lymphatic channels. The end result is a chronic, indurated, suppurative infection (usually with draining sinuses and fibrosis, especially in pelvic and abdominal infection). The fibrotic walls of the mass before suppuration are "wooden" in nature and may be confused with a neoplasm. Hematogenous spread can be fulminant but is rare.

Actinomyces spp grow in microscopic or macroscopic clusters of tangled filaments surrounded by neutrophils. Plasma cells and multinucleated giant cells are often observed with lesions, as are large macrophages with foamy cytoplasm around purulent centers. When visible, these clusters are pale yellow and exude through sinus tracks; they are called sulfur granules (originally called drusen). These granules (1 to 2 mm in diameter) are made of aggregates of organisms and contain calcium phosphate. A central purulent loculation surrounds the granules. Their centers have a basophilic staining property, with eosinophilic rays terminating in pear-shaped "clubs." One to six granules can be present per loculation, and up to 50 loculations can be present in a lesion. Multicenter giant cells can be seen as well.

CLINICAL MANIFESTATIONS

Cervicofacial

Cervicofacial infection is the most common manifestation of actinomycosis (Fig. 329-1).[3] It is generally odontogenic and evolves as a chronic or subacute painless or painful soft tissue slowly progressive, nontender swelling or mass involving the submandibular or paramandibular region. However, the submental and retromandibular spaces, temporomandibular joint, cheek, chin, and upper jaw can be involved. The swelling may have a ligneous consistency caused by tissue fibrosis. Depending on the composition of the concomitant synergistic flora, the onset of actinomycosis may be acute, subacute, or chronic. When *Staphylococcus aureus* or β-hemolytic streptococci are involved, an acute painful abscess or a phlegmatous cellulitis may be the initial manifestation. Pain and trismus can be disproportionate to the degree of inflammation apparent. The chronic form of the disease is the most common form and is characterized by painless infiltration and bluish or reddish induration that generally progresses to form multiple abscesses and draining sinus tracts discharging pus that may contain sulfur granules in up to 25% of instances. Periapical infection, trismus, dyspnea, dysphagia, fever, pain, and leukocytosis may be present. The infection can extend to the carotid artery, tongue, sinuses, ears, mastoid, orbit, salivary glands, pharynx, masseter muscle, thyroid, larynx, trachea, or thorax. Bone (most commonly the mandible) may be invaded from the adjacent soft tissue and results in periostitis or osteomyelitis. Cervical spine or cranial bone infection may lead to subdural empyema and invasion of the CNS. The differential diagnosis includes tuberculosis (scrofula), fungal infections, nocardiosis, suppurative infections by other organisms, and neoplasms.

Thoracic

Thoracic actinomycosis is an indolent, slowly progressive process involving the pulmonary parenchyma and pleural space.[4,5] This form accounts for 15 to 30% of actinomycosis cases and is caused by aspiration of infective material from the oropharynx, as well as rarely after esophageal perforation, by extension into the mediastinum from the neck, by spread from an abdominal site, or by hematogenous spread to the lung. Infection can spread from a pneumonic focus across lung fissures to involve the pleura and the chest wall, with eventual fistula formation and drainage containing sulfur granules (Fig. 329-2). The mediastinum, pericardium, and myocardium also rarely can be affected. Granules are seldom present in sputum. The incidence of this complication, as well as the destruction of thoracic vertebrae and adjacent ribs, has declined in the antimicrobial era.

The complaints of patients with thoracic actinomycosis are nonspecific. The most common are chest pain, productive cough, dyspnea, weight loss, and fever. Anemia, mild leukocytosis, and elevated sedimentation rate are relatively common. There is often a history of underlying lung disease, and patients are rarely initially seen in an early stage of infection. The pulmonary lesion is either a mass lesion or pneumonitis and may resemble tuberculosis, especially when cavity formation occurs, or blastomycosis, which may destroy ribs posteriorly but rarely forms sinuses.[6] Nocardiosis, bronchogenic carcinoma, cryptococcosis, aspiration pneumonia, pulmonary infection, and lymphoma also can mimic thoracic actinomycosis. Pleural thickening, effusion, or emphysema is common.

Abdominal

Abdominal actinomycosis makes up approximately 20% of actinomycosis.[7] It is a chronic, localized inflammatory process that can occur weeks, months, or years after the integrity of the gastrointestinal mucosa is breached by surgery or trauma. Extension from the thorax or pelvis or through hematogenous dissemination also can occur. The ileocecal region is involved most frequently (usually after a perforated appendix) with the formation of a mass lesion. The infection extends slowly to contiguous organs, especially the liver, and may involve retroperitoneal tissues, the spine, or the abdominal wall. Hepatic, renal, or splenic dissemination is an uncommon complication. Persistent draining sinuses may form, and those involving the perianal region can simulate Crohn's disease (Chapter 141) or tuberculosis. The extensive fibrosis of actinomycotic lesions, recognized by the examiner as a mass, often suggests tumor. A frequent finding on computed tomography (CT) is an infiltrative mass with dense inhomogeneous contrast medium enhancement. Constitutional symptoms and signs are nonspecific, the most common being fever, diarrhea or constipation, weight loss, nausea, vomiting, pain, and sensation of a mass.

Pelvic

Pelvic infection is observed in patients with prolonged use of IUDs and also may occur from extension of intestinal infection, commonly from indolent ileocecal disease.[8] Manifestations may range from a chronic vaginal discharge

to pelvic inflammatory disease with tubo-ovarian abscesses or pseudomalignant masses. Patients generally have abnormal vaginal bleeding or discharge, abdominal or pelvic pain, menorrhagia, fever, and weight loss.

Endometritis is the earlier form of the infection, followed by tubo-ovarian abscesses. Extension to the uterus, bladder, rectal area, abdominal wall, peritoneum, pelvic bones, thorax, and systemic circulation also can occur.

Central Nervous System

Infections of the CNS are very rare and generally manifest as single or multiple encapsulated brain abscesses that appear as ring-enhancing lesions with a thick wall that may be irregular or nodular on contrast-enhanced CT scans. There are no features that readily distinguish actinomycosis from other causes of brain abscesses. Rarely, solid nodular or mass lesions termed *actinomycetomas* or *actinomycotic granulomas* are found. Headache and focal neurologic signs are the most common finding. Most actinomycotic infections of the CNS are seeded hematogenously from a distant primary site, but direct extension of cervicofacial disease also occurs. Sinus formation is not a characteristic of CNS disease. The rare meningitis caused by *Actinomyces* is chronic and basilar in location, and the cerebrospinal fluid pleocytosis is usually lymphocytic. Thus, it may be misdiagnosed as tuberculous meningitis. Extension to the cranial epidural or subdural space and spinal epidural space also can occur from adjacent foci.

DIAGNOSIS

Appropriate microbiologic and pathologic studies are essential for diagnosis. A high index of suspicion should be communicated to the microbiology laboratory, along with material from draining sinuses, from deep-needle aspiration, or from biopsy specimens. CT or ultrasound needle aspiration can be used to obtain a biopsy specimen. It is important to avoid contamination of the specimen by normal flora and administration of antimicrobial therapy before a specimen is obtained. Anaerobic culture is required, and no selective media are available to restrict overgrowth of the slow-growing *Actinomyces* by associated microflora. The presence, in pus or tissue specimens, of non–acid-fast, gram-positive organisms with filamentous branching is suggestive of the diagnosis. The characteristic morphologic features of sulfur granules within are helpful. In tissue sections stained with hematoxylin-eosin, sulfur granules are round or oval basophilic masses with a radiating arrangement of eosinophilic terminal clubs. However, *Actinomyces* spp are infrequently visible in sections stained with hematoxylin-eosin; visualization is facilitated by special stains such as Gomori methenamine silver, *p*-aminosalicylic acid, McCallen-Goodpasture, and Brown-Brenn. Multiple biopsy sections from different tissue levels are recommended to improve the histopathologic diagnosis. The granules must be distinguished from similar structures that are sometimes produced in infections caused by *Nocardia, Monosporium, Cephalosporium, Staphylococcus* (botryomycosis), and others. *Actinomyces* and *Arachnia* can generally be differentiated from other gram-positive anaerobes by means of their growth rate (slow), by catalase production (negative, except for *A. viscosus*), and by gas-liquid chromatographic detection of the acetic, lactic, and succinic acids produced in peptone-yeast-glucose broth. Specific staining with fluorescent-conjugated monoclonal antibody testing can be used, but this method is not readily available to clinical microbiology laboratories.

Imaging methods such as conventional radiography, CT, and magnetic resonance imaging do not provide a specific diagnosis but allow more accurate definition of the dimensions and extension of the infection.

TREATMENT

Rx

Prolonged antimicrobial therapy (i.e., 6 to 12 months) has typically been recommended for patients with all clinical forms of actinomycosis to prevent disease recrudescence. However, individualization of courses of therapy is recommended because the duration of treatment depends on the initial burden of disease, the site of infection, and the clinical and radiologic response. Adequate drainage is indicated if abscesses are present.

Penicillin G is the drug of choice for treatment of an infection caused by any of the *Actinomyces.* It is given in high dosage during a prolonged period because the infection has a tendency to recur. Most deep-seated infections can be expected to respond to intravenous penicillin G, 18 to 24 million units/day given for 2 to 6 weeks, followed by an oral phenoxypenicillin in a dosage of 2 to 4 g/day. A few additional weeks of oral penicillin therapy may suffice for uncomplicated cervicofacial disease; complicated cases and extensive pulmonary[9] or abdominal disease may require treatment for 12 to 18 months. Little evidence exists of acquired resistance to penicillin G by *Actinomyces* during prolonged therapy. The combination of a penicillin (i.e., amoxicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanate, tazobactam) offers the advantage of coverage against penicillin-resistant aerobic and anaerobic copathogens. Alternative first-line antibiotics include amoxicillin, tetracycline, erythromycin, and clindamycin. Ceftriaxone, imipenem, and fluoroquinolones have also been used successfully. Metronidazole, aminoglycosides, oxacillin, and cephalexin are not effective. In vitro antimicrobial susceptibility testing of *Actinomyces* is difficult, and the results may not be predictive of antimicrobial effects in vivo.

The need to use combination antimicrobial therapy to eradicate microorganisms that are isolated in association with *Actinomyces* has not been established. However, because many of these organisms are known pathogens, treatment is usually appropriate, especially with lower abdominal infections. Surgical removal of infected tissue also may be necessary in some cases, especially if extensive necrotic tissue or fistulas are present, if malignant disease cannot be excluded, and if large abscesses cannot be drained by percutaneous aspiration. When well-defined IUD-related symptoms and Papanicolaou smears demonstrate *Actinomyces* by specific fluorescence-labeled antibody, the IUD should be removed. Antimicrobial administration for a 2-week period may be indicated. More serious infections require prolonged therapy.

PROGNOSIS

The availability of antimicrobial treatment has greatly improved the prognosis for all forms of actinomycosis. At present, cure rates are high and neither deformity nor death is common.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding treatment of actinomycosis?

A. Treatment should be guided by in vitro antimicrobial susceptibility testing.
B. Prolonged therapy with penicillin is limited by increasingly frequent acquisition of resistance to it.
C. Cervicofacial and thoracic actinomycosis generally requires combination antimicrobial therapy.
D. Penicillin G is the drug of choice and should be given in high doses for a prolonged period because the infection has a tendency to recur.
E. Surgical intervention is almost never required if antibiotic therapy selection and duration are correctly prescribed.

Answer: D Penicillin G is the drug of choice for treatment of an infection caused by any of the actinomycoses. The infection has a tendency to recur, so high doses for prolonged periods are generally required. Little if any evidence exists for significant acquired resistance to penicillin G during prolonged therapy. The need for combination antimicrobial therapy to eradicate actinomycosis has not been established; however, it is often considered clinically appropriate, especially with lower abdominal infections. Effective antibiotic therapy does not replace the need for surgical intervention when needed, such as removal of necrotic tissue, fistula repair, and drainage. In vitro antimicrobial susceptibility testing of *Actinomycosis* is difficult and the results may not be predictive of in vivo effects.

2. Cervicofacial actinomycosis is:

A. A rare manifestation of the infection.
B. Usually caused by extension of primary intrathoracic involvement.
C. Acutely accompanied by disproportionately severe symptoms of pain and trismus.
D. Not prone to spread beyond the soft tissues of the neck, although its extension to those soft tissues can be extensive.
E. A chronic disease.

Answer: C Cervicofacial infection is the most common manifestation of actinomycosis. It is generally odontogenic (not intrathoracic) in origin. Actinomycosis can be acute, subacute, or chronic. In its acute form, the symptoms of pain and trismus are disproportionate for the signs of inflammation that is apparent. Chronic actinomycosis can extend widely, including to the carotid arteries, tongue, sinuses, mastoid, orbit, thyroid, larynx, trachea, and contiguous muscle and bone.

3. Which of the following statements is correct regarding the epidemiology of actinomycosis?

A. There is no person-to-person transmission.
B. External reservoirs include soil and straw.
C. Most diagnosed individuals are elderly.
D. Males and females are comparably affected.
E. It predominantly occurs in tropical climates.

Answer: A There is no evidence for person-to-person transmission or for any external environmental reservoirs (e.g., soil or straw) for actinomycosis. Ages of infected patients can range from childhood to old age, but peak incidence is in the middle decades of life. A male-to-female predominance (3 : 1 ratio) has been attributed to the increased prevalence of poor oral hygiene and oral trauma in males (because *Actinomyces* spp are endogenous flora of the oral cavity).

330

NOCARDIOSIS

FREDERICK S. SOUTHWICK

DEFINITION

Nocardiosis refers to infections caused by *Nocardia* spp. *Nocardia* most commonly causes pneumonia but also can infect the central nervous system (CNS) and the skin. Less commonly, this organism can disseminate throughout the body. These infections usually occur in patients with defective immunity.

Etiology

Nocardia spp are thin, aerobic, gram-positive bacilli that form branching filaments. The bacteria stain irregularly and appear beaded on Gram stain. The speciation of *Nocardia* has been problematic. The original classification was based on the ability to use specific nutrients and decompose substrates such as adenine, casein, urea, gelatin, and xanthine. However, gene sequencing and DNA-DNA hybridization have now defined the true taxonomy. The species called *N. asteroides* was previously reported to be the most common cause of human disease. However, the majority of these bacteria were misidentified by today's standards. The number of species causing human disease is large and includes *N. abscessus, N. brevicatena/paucivorans* complex, *N. nova* complex, *N. transvalensis* complex, *N. farcinica, N. cyriacigeorgica, N. otitidiscaviarum, N. veterana, N. brasiliensis,* and *N. pseudobrasiliensis*.

EPIDEMIOLOGY

Nocardia spp are ubiquitous and primarily originate in soil. Despite being found throughout the environment, they rarely cause symptomatic infection in humans. Because nocardiosis is not a reportable disease, the frequency of this disease is unknown. The annual incidence has been estimated to be 0.4 in 100,000. The risk for symptomatic *Nocardia* infection is greatly increased

(estimated to be 140 to 340 times greater) in individuals who are immunocompromised, including patients who are receiving immunosuppressive agents following bone marrow or solid organ transplant, and patients with acquired immunodeficiency syndrome (AIDS). Corticosteroids are the most frequent immunosuppressant associated with nocardiosis[1]; however, cases also have been reported in patients receiving anti–tumor necrosis factor-α antibody (infliximab) as well as other immunosuppressants. It is important to keep in mind that trimethoprim-sulfamethoxazole prophylaxis does not always protect against *Nocardia*. Other risk groups include patients with cancer, Cushing's disease, chronic granulomatous disease, and dysgammaglobulinemia. Patients with chronic pulmonary disorders, particularly alveolar proteinosis, are also more susceptible to this infection. In approximately one third of patients with nocardiosis, no predisposing condition can be identified.

PATHOBIOLOGY

Most *Nocardia* spp gain entry to the host via the respiratory tract or less commonly by skin inoculation. Invading bacteria elicit a neutrophil response that inhibits but does not kill the organism. The bacteria are phagocytosed by neutrophils and macrophages and become enclosed in a membrane-bound phagolysosome. In this closed environment neutrophils and macrophages are able to kill many species of bacteria by synthesizing superoxide and hydrogen peroxide. However, *Nocardia* are able to survive in this hostile environment by producing superoxide dismutase, an enzyme that inactivates these toxic oxygen byproducts. In addition, *Nocardia* spp produce a mycolic acid called cord factor that inhibits the fusion of lysosomes with the phagolysomal compartment, preventing toxic proteases and other antibacterial products from reaching the intracellular bacteria. Cell wall extractable lipids impair phagocytosis and also inhibit bacterial killing.[2] In addition to neutrophils and macrophages, cell-mediated[3] and humoral immunity also play roles in protecting the host against *Nocardia* invasion, explaining the wide range of immunocompromised patients that are at increased risk for contracting nocardiosis.

CLINICAL MANIFESTATIONS

Nocardiosis has no pathognomonic characteristics, and delays in diagnosis are common. Failure of a pulmonary or skin infection to respond to conventional antibiotic therapy should raise the possibility of a *Nocardia* spp infection. Nocardiosis always should be considered in the immunocompromised patient.

Pulmonary Nocardiosis

Approximately two thirds of patients with nocardiosis present with pulmonary infection.[4,5] Pulmonary disease is usually subacute in onset, mimicking a fungal or mycobacterial infection, and is most commonly misdiagnosed as tuberculosis. The most common complaints are a persistent cough producing purulent sputum, fever, anorexia, and weight loss. Less commonly, patients may report pleuritic chest pain and dyspnea. Hemoptysis is rare but can develop in patients with large cavitary lesions. Acute onset of pneumonia has occasionally been reported in the immunocompromised host.

Central Nervous System Infection

Approximately 5% of patients with a *Nocardia* infection have CNS involvement.[6] Multilocular brain abscess is the most common CNS manifestation[7] and is usually the consequence of transient bacterial dissemination from the lung. Lesions can occur in any region of the brain, and symptoms depend on location. Headache is the usual initial complaint and frequently localized to the site of the abscess. Patients also may present with neurologic deficits and seizures. The combined findings of a lung nodule on chest x-ray and a ring-enhancing CNS lesion are often mistaken for metastatic lung carcinoma. Other diagnoses that should be considered when the immunocompromised host presents with both a lung and CNS focus are disseminated aspergillosis and toxoplasmosis. Meningitis is a less common CNS manifestation and is often associated with brain abscess (40% of meningitis cases). The CSF cell count usually reveals neutrophils and the CSF culture may be positive, particularly if the culture is held for a prolonged period.

Cutaneous Infection

Skin infection is usually caused by *N. brasiliensis* and typically follows a break in the skin that is contaminated by soil. Cutaneous disease has been reported in association with trauma, a postoperative wound, insect bites, thorn bush scratches, or even a cat scratch. Initially a pustule or a moderately erythematous, nonfluctuant nodule develops at the site of inoculation. Erythema can extend along the lymphatic system and is associated with tender lymphadenopathy.[8] This form of cutaneous infection has been termed *lymphocutaneous* or *sporotrichoid* disease. Similar skin manifestations are seen with other etiologies, including cat scratch disease, tularemia, *Mycobacterium marinum*, and sporotrichosis. In the immunocompromised host, disseminated infection may be manifest by multiple erythematous raised nodules and is an ominous finding. In tropical regions of South and Central America *Nocardia* spp can cause ulcerations and large tumor-like lesions called *mycetomas* that are usually found on the lower legs.

DIAGNOSIS

Radiology

In pulmonary disease, chest x-ray findings are variable, with pulmonary nodules or mass lesions being seen most often (Fig. 330-1). Less frequently, consolidation, cavitary lesions with air-fluid levels, interstitial infiltrates, and pleural effusions are found. Chest CT often demonstrates areas of low attenuation within consolidations, multiple nodules, and chest wall extension of the infection. Patients with AIDS are more likely to have multiple pulmonary nodules, cavitary lesions, and upper lobe infiltrates. In some patients the infiltrate may resolve, particularly in patients with normal immune function. However, the patient may present with brain abscess several months later as a consequence of transient dissemination. In CNS infection CT or magnetic resonance imaging with contrast usually demonstrates one or more ring-enhancing lesions (Fig. 330-2). *Nocardia* brain abscess is more commonly multiloculated; otherwise the radiologic findings are similar to those in other

FIGURE 330-1. Chest computed tomography showing a peripheral nodular lung lesion (*arrow*) caused by *Nocardia* infection.

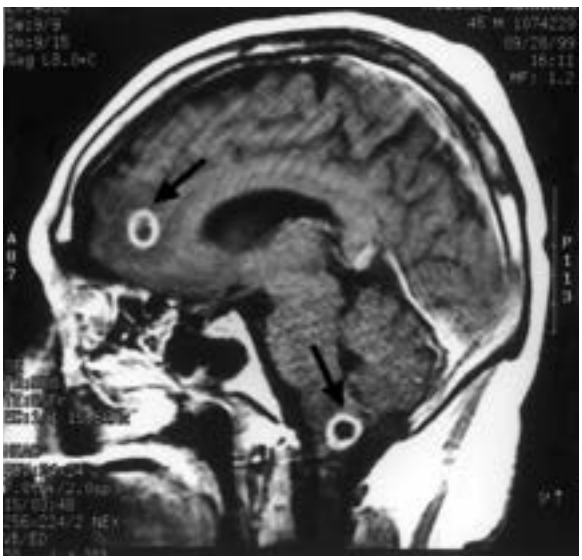

FIGURE 330-2. Multiple, gadolinium-enhanced brain lesions (*arrows*) caused by *Nocardia* infection.

bacterial causes of brain abscess. Positron emission tomography is not helpful in differentiating *Nocardia* brain abscess from tumor; both demonstrate increased uptake.

Histopathology

Invasive procedures are generally required for specific diagnosis. For pulmonary infection, bronchoscopy with transbronchial biopsy or skinny needle biopsy is recommended. CT-guided needle aspirate is the diagnostic procedure of choice for brain abscess. Histopathologic examination usually reveals an acute inflammatory response with a predominance of neutrophils. Micronodular abscesses with minimal capsular formation are usually found. Gram stain or Brown-Brenn stains reveal gram-positive, beaded, branching forms. The morphology is identical to that of *Actinomyces;* however, the high lipid content of its cell wall often renders *Nocardia* modified acid-fast positive, whereas *Actinomyces* spp are modified acid-fast negative. However, acid fastness may be variable when staining *Nocardia* colonies from cultures and is unreliable for direct clinical samples.

Culture

Isolation of the organism on culture provides a definitive diagnosis from needle aspirate samples of brain abscess, and a presumptive diagnosis when grown from respiratory and cutaneous samples. *Nocardia* grows best under aerobic conditions with 5 to 10% carbon dioxide. Because the organism grows slowly on blood agar, taking 3 to 5 days to form colonies, other organisms can overgrow. When *Nocardia* is suspected the clinical laboratory should be notified to allow the use of selective media and prolonged incubation. 16S ribosomal RNA gene sequencing allows rapid speciation of isolates. Antibiotic susceptibility testing always should be performed to guide the choice of therapy.

TREATMENT

Rx

Because of the rarity of nocardiosis, no prospective treatment trials have been performed, and all recommendations are based on retrospective studies and in vitro sensitivity testing. Sulfonamides remain the treatment of choice for pulmonary and cutaneous disease. Trimethoprim-sulfamethoxazole given orally at a dose of 160/800 mg (one double strength) three times daily is the most commonly used adult regimen. When patients with disseminated and/or CNS *Nocardia* are treated with sulfonamides alone, survival has been less than 50%. One of the most common species to cause disseminated diseases, *N. farcinica,* is also one of the most common *Nocardia* spp to be resistant to sulfonamides. In these more serious conditions combination therapy is generally recommended, the exact regimen being guided by antibiotic susceptibility testing. One recommended empirical regimen is trimethoprim-sulfamethoxazole 15 mg/kg/day IV of the trimethoprim component divided into 2 to 4 doses, amikacin (7.5 mg/kg every 12 hours), and either ceftriaxone (2 g twice daily) or imipenem (500 mg four times daily). In a retrospective study, patients failing trimethoprim-sulfamethoxazole responded to imipenem with or without amikacin.[9] Linezolid (600 mg twice daily) has been used successfully in a small number of CNS infections. However, prolonged therapy with this agent can lead to bone marrow toxicity and warrants weekly monitoring of the peripheral cell counts.[10] The newer fluoroquinolone moxifloxacin (400 mg/day PO) has been shown to have activity against several strains of *Nocardia,* including *N. farcinica* and *N. brasiliensis,* and this agent may prove useful in patients who cannot tolerate sulfonamides; however, relapse has been reported. Minocycline (100 mg PO twice daily) and amoxicillin-clavulanate (875/125 mg PO twice daily) are other potentially effective alternative treatments for *Nocardia.* Because of the intracellular nature of *Nocardia* and the slow rates of bacterial growth, antibiotic treatment for 6 to 12 months in the immunocompromised host and 4 to 6 months in the normal host is usually required to prevent relapse.

In addition to antibiotics for patients with brain abscess or subcutaneous abscesses, surgical drainage is required for cure.

PROGNOSIS

The overall mortality for nocardiosis is approximately 25%. In otherwise healthy individuals pulmonary nocardiosis has a better prognosis (15% mortality). The survival rate is worse in patients with bacteremia, patients with acute infection (symptoms for < 3 weeks), patients receiving corticosteroids or cytotoxic agents, patients with disseminated disease involving two or more noncontiguous organs, and patients with meningitis.

REVIEW QUESTIONS

1. How can *Nocardia* be contracted by humans?

A. Spread from person to person
B. Spread from animals to humans (zoonotic infection)
C. By inhaling dust
D. By being bitten by mosquitoes
E. By being bitten by ticks

Answer: C *Nocardia* usually gains entry through the lungs. Patients inhale dust contaminated with *Nocardia,* a common soil organism.

2. A 50-year-old male bicycler fell on a dirt path, scraping his arm. Over the next 2 weeks he noted progressive swelling of his arm associated with swollen lymph nodes and streaks of erythema. He also developed a fever to 101° F. His peripheral WBC was 12,500 (90% PMN). How should you manage this patient (*best* answer)?

A. Begin an antistaphylococcal antibiotic
B. Swab the surface of his erythematous skin for culture
C. Draw blood cultures
D. Obtain a tissue biopsy for histopathologic examination and culture
E. Obtain a urine antigen test for histoplasmosis

Answer: D Diagnosis of *Nocardia* is difficult and often delayed. Obtaining a biopsy sample for histopathologic examination and staining, as well as culture, is the primary method for making the appropriate diagnosis. Empirical antibiotics often fail to treat *Nocardia*. A surface swab culture is likely to grow only normal skin flora because *Nocardia* is slow growing. *Histoplasma* rarely causes soft tissue infection, and therefore urine antigen is highly likely to be negative.

3. A 55-year-old renal transplant recipient, who has been receiving high-dose corticosteroids for transplant rejection, develops severe headaches that persist for 2 weeks. His headaches are sharp and localized to the left temporal region. They are not relieved by Tylenol or aspirin. He is admitted to the hospital after having a grand mal seizure that began with tonic-clonic movements of the right arm and leg. CT with contrast shows a multiloculated ring-enhancing abscess in the left temporal region. A CT-guided needle biopsy is performed. Gram stain of the sample demonstrates gram-positive beaded branching forms accompanied by many PMNs. What is the simplest and most rapid way to differentiate whether your patient has nocardiosis or actinomycosis?

A. Modified acid-fast stain *Nocardia* is acid-fast positive
B. Modified acid-fast stain *Actinomyces* spp are acid-fast positive
C. Polymerase chain reaction of the sample
D. Aerobic and anaerobic culture
E. PET scan

Answer: A The *Nocardia* cell wall has a high lipid content that tightly binds carbol fuchsin (the red stain used for acid-fast staining) and is resistant to acid decolorization while *Actinomyces* spp is readily decolorized. PCR is most useful for speciation. It is more complicated to perform and is not readily available in most hospital-based diagnostic laboratories. *Nocardia* is slow growing and may take over a week to grow. PET scan can falsely diagnose *Nocardia* brain abscess as a brain tumor and is not a helpful diagnostic tool.

4. What would be the best treatment plan for a patient with a *Nocardia* brain abscess?

A. Ceftriaxone and metronidazole combined with surgical drainage
B. High-dose penicillin alone
C. Trimethoprim-sulfamethoxazole combined with imipenem
D. Clindamycin combined with surgical drainage
E. Trimethoprim-sulfamethoxazole combined with imipenem and surgical drainage

Answer: E Trimethoprim-sulfamethoxazole continues to cover many strains of *Nocardia;* however; combination therapy is favored for brain abscess. Outcome is better when the abscess is also surgically drained. Penicillins have limited activity against *Nocardia,* as does ceftriaxone. Metronidazole has no activity and clindamycin fails to cross the blood-brain barrier and is not recommended for CNS infections.

5. How long should a patient with a *Nocardia* soft tissue infection be treated?

A. 7 to 10 days
B. 2 weeks
C. 1 month
D. 2 months
E. 6 months

Answer: E *Nocardia* is an intracellular pathogen that grows slowly. Relapses have been observed if treatment is not extended for 6 months. In patients who are severely immunocompromised, 12 months of treatment may be required.

331

SYSTEMIC ANTIFUNGAL AGENTS

DAVID A. STEVENS

Methods for in vitro susceptibility testing are available as standardized tools. A variety of assays are available for therapeutic drug monitoring of serum and other body fluids. As more common mutations inducing resistance are uncovered,[1] it becomes possible to develop molecular screening methods that can detect the resistance genes in clinical isolates, in advance of susceptibility test results.[2]

AMPHOTERICIN B–BASED PREPARATIONS

Mechanism of Action

Amphotericin B is a lipophilic molecule that exerts its antifungal effect by insertion into the fungal cytoplasmic membrane. Amphotericin B causes membrane permeability to increase. Loss of intracellular molecules impairs fungal viability. The onset of action is rapid. Amphotericin B also has effects on oxidation that may enhance antifungal activity and in vivo may activate endothelial cells.

Spectrum of Activity and Mechanisms of Resistance

Amphotericin B is active against most fungi, and its spectrum of activity is not influenced by the choice of formulation. When resistance occurs, it is generally attributed to reductions in ergosterol biosynthesis and the synthesis of alternative sterols that lessen the ability of amphotericin B to interact with the fungal membrane; oxidant scavengers also may be produced. Primary resistance is common for *Scedosporium* and *Trichosporon* spp. Among the *Candida* spp, primary resistance is noted at meaningful frequencies most often for *Candida lusitaniae*. Development of resistance in isolates of normally susceptible species is uncommon. In some studies, the principal pharmacodynamic driver of in vivo response has been the ratio of the peak serum concentration to the minimal inhibitory concentration (MIC).

Available Formulations

There are four commercially available amphotericin B formulations: amphotericin B deoxycholate (ABD) and three lipid-associated formulations—amphotericin B colloidal dispersion (ABCD), amphotericin B lipid complex, and liposomal amphotericin B. All formulations must be infused in 5% dextrose with no electrolytes added. Infusion bottles need not be protected from light. In attempts to produce less expensive lipid-associated formulations, some have advocated mixing ABD with a parenteral fat emulsion. Although less nephrotoxicity has been observed in adults given this preparation at a dose of 1 mg/kg/day compared with infusions of ABD in 5% dextrose, no advantage was found in children. Serum amphotericin B concentrations were also lower with the fat emulsion, raising the possibility that amphotericin B was simply aggregating in the fat emulsion, but the cloudiness could not be perceived in the milky-looking lipid. Use of such preparations should be reserved for investigational settings.

Amphotericin B Deoxycholate

Formulation

ABD for intravenous use is a colloidal suspension. If a filter with a 0.22-μm pore diameter is placed in the infusion line, considerable drug is removed by the filter. The addition of electrolyte aggregates the colloids, so the solution becomes cloudy; this is to be avoided. ABD is available from several generic manufacturers, and significant differences in the formulations have been reported, which may account in part for the intersubject variation in toxicities observed.

Pharmacology

Most of the drug leaves the circulation promptly, with only a small percentage being excreted in urine or bile. Amphotericin B is stored in the liver and other organs; the drug appears to re-enter the circulation slowly. Blood levels are not influenced by hepatic or renal failure. Hemodialysis does not alter blood levels, except in an occasional patient with lipemic plasma who may be losing drug owing to its adherence to the dialysis membrane. Concentrations of amphotericin B in fluid from inflamed areas, such as pleura, peritoneum, joint, vitreous humor, and aqueous humor, are roughly two thirds of the nadir serum level. Amphotericin B penetrates poorly into either normal or inflamed meninges, saliva, bronchial secretions, brain, pancreas, muscle, bone, vitreous humor, and normal amniotic fluid. Urine concentrations are similar to serum concentrations. Peak serum concentrations with conventional intravenous doses are roughly 0.5 to 2 μg/mL; these concentrations fall rapidly and then slowly approach a plateau of roughly 0.2 to 0.5 μg/mL. The initial half-life is approximately 24 hours; the β-phase half-life is roughly 15 days. Serum concentrations can be detected for at least 7 weeks after the end of therapy, presumably reflecting release from cell membranes. The drug also has complex immunomodulatory properties that are potentially of clinical significance.

Nephrotoxicity

ABD causes a dose-dependent decrease in the glomerular filtration rate. The direct vasoconstrictive effect of amphotericin B on afferent renal arterioles results in reduced glomerular and renal tubular blood flow. Other effects on the kidney include potassium, magnesium, and bicarbonate wasting and decreased erythropoietin production. Loss of renal function is due to the destruction of renal tubular cells, disruption of tubular basement membrane, and loss of functioning nephron units. Saline loading, such as the infusion of 1 L saline before ABD, has been associated with reduced nephrotoxicity in some studies. Potassium wasting often requires supplemental oral or intravenous potassium. Renal tubular acidosis from bicarbonate wasting rarely requires base replacement, but other drugs and diseases that promote acidosis may act synergistically.

Azotemia caused by amphotericin B is often worse in patients taking other nephrotoxic drugs. Hypotension, intravascular volume depletion, and other preexisting renal disease all magnify the management problems associated with amphotericin B–induced azotemia. These toxicities are lessened by use of the lipid-associated formulations of amphotericin B.

Early in the course of therapy with ABD, azotemia may increase rapidly; it often improves a little and then stabilizes after several days. Adults with no other renal disease have an average serum creatinine level of 2 to 3 mg/dL at therapeutic doses, and therapy should not be withheld unless azotemia exceeds this level. Attempting to give ABD to an adult without causing azotemia usually leads to inadequate therapy.

Other Chronic Toxicity

Nausea, anorexia, and vomiting are common. Phlebitis occurs if peripheral vein catheters are used. Normocytic normochromic anemia occurs gradually. The hematocrit rarely falls below 20 to 25% unless other causes of anemia are present. Rarely, thrombocytopenia, modest leukopenia, arrhythmias, coagulopathy, hemorrhagic enteritis, tinnitus, vertigo, encephalopathy, seizures, hemolysis, or dysesthesia of the soles of the feet may be observed. Amphotericin B remains the first choice parenteral agent in pregnancy despite its potential toxicities.[3]

Acute Reactions

Approximately 30 to 45 minutes after beginning the first few ABD infusions, chills, fever, and tachypnea may occur, peak in 15 to 30 minutes, and then slowly abate over 2 to 4 hours. A patient with underlying cardiac or pulmonary disease may have hypoxemia. These reactions are less common in young children or in patients receiving corticosteroids. Subsequent infusions of the same dose cause progressively milder reactions. Premedication with acetaminophen or the addition of hydrocortisone 25 to 50 mg to the infusion solution can diminish the reaction. Meperidine given early in a chill shortens the rigors but may induce nausea or emesis. Concern about this kind of reaction in an unstable patient has led some physicians to use a test dose of 1 mg given over a 15-minute period to assess the subsequent reaction over 1 hour before deciding whether to administer a full therapeutic dose. Patients with rapidly progressive mycoses should receive a full therapeutic dose within 24 hours. These reactions should not be mistaken for anaphylaxis or considered a contraindication to further amphotericin B. True allergic reactions are extremely rare.

Administration

ABD is infused over a 2- to 4-hour interval. Infusions 1 hour in duration generally appear to be safe for persons who have tolerated slower infusions. Rapid infusion in patients with severely compromised renal function may lead to acute, marked hyperkalemia and ventricular fibrillation.

Patients receiving a stable daily dose can be changed to a double dose on alternate days to reduce the frequency of infusion-associated toxicity, particularly anorexia, and to make outpatient therapy more convenient. Doses above 1.5 mg/kg are generally not given on this schedule because the toxicity of such infusions is not well described. Continuous infusion of amphotericin B with doses up to 2 mg/kg/24 hours is another approach (based on limited data) to reducing toxicity, but this is not consistent with the observation that the principal pharmacodynamic driver of efficacy for amphotericin B is peak drug concentration.[4]

Dosage

Daily ABD doses of 0.3 mg/kg often suffice for esophageal candidiasis. A dose of 0.5 mg/kg is appropriate for blastomycosis, disseminated histoplasmosis, and extracutaneous sporotrichosis. Patients with cryptococcal meningitis are generally given doses of 0.6 to 0.8 mg/kg; those with coccidioidomycosis may require doses of 1 mg/kg. Patients with mucormycosis or invasive aspergillosis are given daily doses of 1 to 1.5 mg/kg until improvement is clearly present. Doses of 0.5 to 1 mg/kg are often used in neutropenic patients receiving empirical amphotericin B. Local instillation of amphotericin B into cerebrospinal fluid (CSF), joints, or pleura is rarely indicated. One exception is coccidioidal meningitis, which may be treated with intrathecal ABD because it may produce superior results to systemic azole therapy, particularly in the long term, although with far greater toxicity. Intraocular administration for fungal endophthalmitis is occasionally used; doses of 10 μg appear to avoid retinal toxicity. Corneal baths with 1 mg/mL in sterile water are useful for fungal keratitis but are irritating.

Lipid-Associated Formulations of Amphotericin B

Pharmacology and Toxicity

The three lipid-associated formulations have quite different pharmacokinetic patterns. When compared on the basis of equal dosages (milligram/kilogram), the lipid-associated formulations produce tissue amphotericin B concentrations that range from 90% lower to 500% higher than those seen with ABD, with the most consistent relative reduction seen in the kidney. The lipid-associated formulations are typically given at doses that are 3- to 12-fold higher than those used for ABD. All three formulations generally require higher doses in experimental animals to achieve the same therapeutic effect as ABD.

These higher but equipotent doses are notably better tolerated than ABD, with reductions in both the frequency and the severity of acute infusion-related reactions and chronic nephrotoxicity. An exception is ABCD, which generally induces acute infusion-related reactions similar to those for ABD.

Randomized clinical trials comparing ABD as therapy for a defined mycosis are limited to demonstrations that liposomal amphotericin B has a similar efficacy for cryptococcal meningitis and a greater efficacy for histoplasmosis. Randomized comparisons with ABD in persistently neutropenic and febrile cancer patients consistently demonstrate a better tolerability profile, but few data on differential antifungal effect. The aggregate open-label data on efficacy rates for the lipid-associated formulations are similar to those for ABD. Although the lipid-associated formulations are notably more costly than ABD, the purchase cost of the compound must be balanced against the morbidity of ABD-related nephrotoxicity and the financial costs of monitoring, treating, and managing it.

FLUCYTOSINE

Formulation and Pharmacology

Flucytosine (5-fluorocytosine) is the fluorine analogue of a normal body constituent, cytosine. Flucytosine is marketed as 250- and 500-mg capsules. Absorption from the gastrointestinal tract is rapid and complete, and approximately 90% is excreted unchanged in the urine. CSF concentrations are approximately 74% of simultaneous serum concentrations; the drug also penetrates well into aqueous humor, joints, bronchial secretions, peritoneal fluid, brain, bile, and bone, and it is readily cleared by hemodialysis and peritoneal dialysis.

The half-life of the drug in the serum of patients with normal renal function is 3 to 5 hours and is longer in newborns. Abnormal hepatic function has no influence, but decreased renal function prolongs the half-life.

Mechanisms of Action and Resistance

Isolates of *Candida* spp are usually susceptible, as are most isolates of *Cryptococcus neoformans*. Flucytosine is often active against isolates of *Aspergillus* spp and against the melanin-pigmented molds that cause chromoblastomycosis. The mechanism of antifungal action appears to be deamination to 5-fluorouracil and then conversion through several steps to 5-fluorodeoxyuridylic acid monophosphate, a noncompetitive inhibitor of thymidylate synthetase, which interferes with DNA synthesis, or conversion to 5-fluouridine triphosphate, which is incorporated into RNA and causes aberrant transcription. In some studies, the principal pharmacodynamic driver of response was the proportion of time the blood level exceeded the minimum inhibitory concentration (MIC). Resistance may be due to loss of the cytosine permease that permits flucytosine to cross the fungal cell membrane or loss of any of the enzymes that lead to its conversion into forms that interfere with DNA or RNA synthesis.

Administration and Dosage

Flucytosine is administered orally, 100 to 150 mg/kg/day, in four divided doses. As an approximation, the total daily dose should be reduced to 75 mg/kg with a creatinine clearance of 26 to 50 mL/minute and to 37 mg/kg when the creatinine clearance is 13 to 25 mL/minute. Ideally, the blood level should be measured in azotemic patients 2 hours after the last dose and immediately before the next dose. These values should range between 10 and 100 μg/mL. Patients requiring hemodialysis can be given a single post-dialysis dose of 37.5 mg/kg. Further doses are adjusted by blood level.

Flucytosine given alone to patients with normal renal, hematologic, and gastrointestinal function is infrequently associated with adverse effects, including rash, diarrhea, and hepatic dysfunction. In the presence of azotemia (such as that caused by concomitant amphotericin B), leukopenia, thrombocytopenia, and enterocolitis may appear. These complications seem to be far more frequent among patients whose flucytosine blood levels attain, and especially if they exceed, 100 to 125 μg/mL. Patients receiving flucytosine whose renal function is changing should have their serum flucytosine concentrations determined twice weekly, and the leukocyte count, platelet count, alkaline phosphatase, and aminotransferase levels should be measured at a similar frequency. Patients in whom loose stools or dull abdominal pain suddenly develops or who have laboratory evidence consistent with flucytosine toxicity should have their flucytosine blood levels determined, and consideration should be given to withholding the drug until the situation is clarified. Patients with bone marrow and gastrointestinal toxicity from flucytosine often tolerate the drug at a reduced dosage. Uncommonly, vomiting, bowel perforation, confusion, hallucinations, headache, sedation, and euphoria have been reported. Flucytosine is contraindicated in pregnancy.

Conversion of flucytosine to 5-fluorouracil within the human body occurs to a sufficient degree to possibly account for the drug's toxicity to bone marrow and the gastrointestinal tract. It is likely that the drug is secreted into the gut, where flucytosine becomes deaminated by intestinal bacteria and is reabsorbed as 5-fluorouracil.

Flucytosine has a beneficial effect in patients with cryptococcosis, candidiasis, and chromoblastomycosis. It is not the drug of choice for any infection, however, because its clinical efficacy in the first two mycoses is inferior to that of amphotericin B, primary drug resistance is not uncommon in *Candida* infection, and secondary drug resistance is common in cryptococcosis and chromoblastomycosis.

Flucytosine and amphotericin B are at least additive in their effects. Flucytosine permits a lower dose of amphotericin B to be used to achieve the same therapeutic effect, and amphotericin B prevents the emergence of secondary drug resistance. These advantages have been confirmed in large multicenter studies of cryptococcal meningitis, and a more rapid antifungal effect has been shown.

Flucytosine therapy is more difficult to manage in patients with diminished bone marrow reserve. Intravenous flucytosine is no longer available in the United States, but it is used at the same dosage as the capsule formulation.

Flucytosine resistance has occurred, albeit uncommonly, during combination therapy. Use of combination therapy in such patients incurs the risk for toxicity without evidence that flucytosine adds to the therapeutic effect. An MIC of 20 μg/mL or less is considered susceptible.

AZOLE ANTIFUNGAL AGENTS

Mechanism of Action

The azole ring confers antifungal activity on a variety of synthetic organic compounds. *N*-substitution of imidazoles has created a family of drugs called *triazoles* that have the same mechanism of action as imidazoles, a similar or broader spectrum of activity, and less effect on human sterol synthesis. Both imidazoles and triazoles inhibit C-14α demethylation of lanosterol in fungi; this leads to reduced concentrations of ergosterol, which is essential for a normal fungal cytoplasmic membrane. In some studies, the principal pharmacodynamic driver for response to the triazole antifungal agents has been the ratio of total drug exposure (area under the curve) to the MIC. Because of their interaction with the cytochrome P-450 (CYP) system and, in some cases, the P-glycoprotein pumps, the azoles as a class have a large number of drug-drug interactions, only some of which are covered here. In any patient in whom azole therapy is contemplated, package inserts for the drug should be consulted to determine which of the patient's other medications could result in a significant drug-drug interaction.

Newer triazoles have properties that make them preferable to ketoconazole. These include not only less hormonal inhibition but also better distribution into body fluids, both parenteral and oral formulations, less hepatotoxicity, and a broader spectrum. Some have fewer drug interactions. Resistance to azoles in previously susceptible species is emerging. Resistance mechanisms include increased drug efflux and altered or increased C-14α demethylase. It has been speculated that some of the common mutations in this demethylase in *Aspergillus* isolates from certain geographic areas, resulting in resistance, may have arisen owing to the widespread agricultural use of azole fungicides. All agents in this class have the potential for embryotoxicity and teratogenicity and should be avoided during pregnancy, particularly the first trimester.

Ketoconazole

Formulations and Pharmacology

Ketoconazole is available in tablet form. It is metabolized in the liver and excreted as inactive drug in bile and, to a small extent, urine. The drug is not removed significantly by hemodialysis or peritoneal dialysis. Decreased renal or hepatic function does not alter plasma drug levels. The initial half-life is approximately 2 hours, with a β-phase half-life of approximately 9 hours commencing 8 to 12 hours after ingestion.

Oral absorption of ketoconazole differs among individuals. Serious gastrointestinal disease may lead to low blood levels. Inhibitors of gastric acid secretion should not be given to patients taking ketoconazole because blood levels of the latter drug are drastically reduced. The drinking of citrus fruit juices or cola beverages with ketoconazole improves absorption in hypochlorhydric patients. Patients who need antacids should take them 1 to 2 hours after ketoconazole. Low concentrations are found in vaginal secretions, saliva, and breast milk, but penetration into inflamed joints is better.

Uses

The main advantage of ketoconazole is its lower cost compared with the cost of triazoles. Although at a dose of 400 mg/day the drug is effective in many mycoses, usage has been supplanted by the triazoles, but least so in cutaneous mycoses. Therapy is continued for 6 to 12 months or longer, if the response is slow, to prevent relapse. Improvement may not be evident for weeks to months. Although the dose can be advanced to 600 or 800 mg/day in patients who are not responding to therapy, there is more evidence of increased toxicity than increased efficacy. Aspergillosis does not respond to ketoconazole; additionally, the subsequent use of amphotericin B may be antagonized.

Adverse Effects

The most frequent toxic effects are anorexia, nausea, and vomiting. Dividing doses greater than 400 mg/day is not recommended because hormonal suppression is prolonged. Ketoconazole causes a dose-dependent depression in the serum testosterone-stimulated and adrenocorticotropic hormone–stimulated cortisol response. The effect of doses of 800 to 1200 mg/day is profound enough to have prompted trials in the treatment of Cushing's syndrome and prostate cancer. Hypertension is seen in a few of these high-dose patients, associated with increased levels of mineralocorticoid precursors.

Gynecomastia, oligospermia, and menstrual irregularities may be seen during prolonged therapy. Allergic rash and pruritus have been noted.

Perhaps the most serious complication is hepatitis. Fortunately, this complication is estimated to occur in only 1 in 15,000 exposed individuals. A slight, asymptomatic elevation of transaminase levels occurs in 5 to 15% and is generally transient. Ketoconazole-associated hepatitis begins as anorexia, malaise, nausea, and vomiting. Eighty percent of cases occur within the first 3 months. Progression can be swift. If hepatotoxicity is suspected, serum transaminase and alkaline phosphatase levels should be measured. Some authorities have recommended that liver function be measured periodically. This procedure does not protect a patient who has a rapid onset of hepatitis in the interval between tests, but it does require that all patients with abnormalities be contacted to inquire about symptoms and to arrange for repeat testing.

Itraconazole

Formulations and Pharmacology

Itraconazole (Sporanox) is marketed as a capsule and as an oral suspension in cyclodextrin (an oligosaccharide ring). The ring entraps the hydrophobic, water-insoluble drug, thus making it soluble; it is then released either at the lipid membrane of the enterocyte after oral administration or directly into tissues after intravenous administration. The solution can be delivered through a nasogastric tube in intubated patients, and it makes the dosing of infants and small children more convenient. Oral absorption of the capsule is significantly enhanced by food, whereas absorption of the solution is best on an empty stomach. Coadministration of a cola beverage with itraconazole capsules increases absorption. Peak levels with either preparation are achieved 4 to 6 hours after a dose. Steady state is achieved only after 13 to 15 days, at which time the β-elimination half-life is approximately 19 to 22 hours. Absorption of the capsule is markedly depressed in bone marrow transplant recipients, probably because of hypochlorhydria, mucositis, and graft-versus-host intestinal changes, and in patients with acquired immunodeficiency syndrome (AIDS) because of enteritis, but this problem can be alleviated by using the solution.

For deep mycoses, an initial itraconazole dose of 200 mg three times daily is recommended for the first 3 days to quickly achieve high serum and tissue levels. Hydroxyitraconazole, a metabolite of itraconazole, appears in the blood in amounts roughly twice that of the parent drug; it has antifungal activity and pharmacokinetics similar to those of the parent compound.

Bioassays of itraconazole yield much higher concentrations than measurement by high-pressure liquid chromatography; the difference depends on the susceptibility of the bioassay organism to hydroxyitraconazole. Concentrations of itraconazole in tissue, pus, and bronchial secretions are generally higher than those in plasma. Ocular levels are low. Saliva concentrations persist for 8 hours after administration of the solution and may be beneficial in treating oral disease or eradicating oral colonization. The drug is metabolized in the liver and excreted in feces as metabolites. Of the liquid administered, less than 0.5% of the cyclodextrin is absorbed. No significant amount of bioactive itraconazole appears in urine. Plasma concentrations do not increase in patients with renal insufficiency or decrease with hemodialysis. The half-life is prolonged in those with cirrhosis.

Adverse Effects

The most common adverse effect is dose-related nausea and abdominal discomfort, but symptoms rarely necessitate stopping therapy. Dividing the dose and administering the drug twice daily can improve tolerance and raise blood levels. Hypokalemia and edema may occur at doses of 400 mg/day or higher. Allergic rash is seen occasionally. Itraconazole is rarely hepatotoxic. Diarrhea, nausea, and other gastrointestinal complaints are more frequent with the solution. A negative inotropic effect is rarely seen.

Drug Interactions

Blood levels are reduced by about half in patients taking drugs that decrease gastric acidity. Some of the most notable drug interactions are rifampin, rifabutin, isoniazid, phenytoin, carbamazepine, and phenobarbital, which decrease itraconazole blood levels. Itraconazole decreases rifampin blood levels and increases blood levels of some antihistamines, potentially causing polymorphic ventricular tachycardia (torsades de pointes), as well as increasing levels of warfarin, benzodiazepines, hepatic hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase cholesterol-lowering agents, dihydropyridine calcium-channel blockers, digoxin, quinidine, cyclosporine, tacrolimus, methylprednisolone, human immunodeficiency virus (HIV) protease inhibitors (ritonavir, indinavir), and vinca alkaloids (vincristine, vinblastine).

Uses

Itraconazole is useful for the treatment of invasive aspergillosis, allergic bronchopulmonary aspergillosis, blastomycosis, histoplasmosis, meningeal and nonmeningeal coccidioidomycosis, paracoccidioidomycosis, sporotrichosis, phaeohyphomycosis, mucosal candidiasis, ringworm (including onychomycosis), and tinea versicolor. Itraconazole is also useful for the prevention of relapse of disseminated histoplasmosis in patients with AIDS. Itraconazole may be useful for prophylaxis against fungal infections during neutropenia and as empirical therapy for febrile episodes in neutropenia.

Fluconazole

Formulations and Pharmacology

Fluconazole is currently available in oral and vaginal tablets, as a powder for oral suspension, and as an intravenous formulation. Fluconazole is well absorbed from the gastrointestinal tract. Of the oral dose, 60 to 75% appears unchanged in the urine. Oral absorption is not decreased in patients with AIDS or patients taking H_2-blocking agents. Fluconazole penetrates into the brain, saliva, sputum, and urine.

The half-life in patients with normal renal function is 27 to 34 hours; it increases to 59 and 98 hours in groups with creatinine clearances of 35 and 14 mL/minute, respectively. The normal dose should be reduced to 50% when the creatinine clearance is reduced to 50 mL/minute and to 25% when the creatinine clearance is below 20 mL/minute. A loading dose of twice the daily dose is recommended. Patients receiving hemodialysis should have one daily dose after each session.

Drug Interactions

Among other drug interactions, fluconazole can cause significant increases in the blood level of phenytoin, glipizide, glyburide, tolbutamide, warfarin, rifabutin, cisapride, quinidine, or cyclosporine. Rifampin lowers fluconazole blood levels by approximately one fourth.

Adverse Effects

Adverse effects are uncommon. Even with chronic therapy, including doses exceeding 400 mg/day, headache, hair loss, and anorexia were the most common symptoms; 10% of patients had rises in aspartate aminotransferase levels. Alopecia is reversible, in some cases, even when the drug is continued at lower doses. Neurotoxicity has been described after heroic doses of 2000 mg/day. Rarely, anaphylaxis after the first dose or Stevens-Johnson syndrome has been observed.

Indications

Candidiasis

Provided the infection is not caused by fluconazole-resistant *Candida,* fluconazole is effective for the treatment of oropharyngeal and esophageal candidiasis. A single dose of 150 mg is approximately as effective as topical treatment of vulvovaginal candidiasis. Patients with candidemia who are not neutropenic or otherwise seriously immunosuppressed respond as well to intravenous fluconazole therapy as to amphotericin B. A study comparing fluconazole with a combination of fluconazole plus amphotericin as initial therapy of candidemia found that the combination might produce more rapid clearance of the pathogen from the blood stream. In a few patients with *Candida* endocarditis, long-term fluconazole therapy has been used to prevent relapse after amphotericin B therapy. For immunosuppressed patients and for rapidly progressing or severely ill patients with deep-seated candidiasis, amphotericin B or an echinocandin is preferred.

Cryptococcal Meningitis

Clinical trials in AIDS have engendered the conventional practice of therapy with amphotericin B or amphotericin B plus flucytosine for at least the first 2 weeks. Therapy can then be changed to fluconazole 400 mg/day for 2 months if the patient is clinically stable. The propensity of patients with AIDS to relapse has led to maintenance therapy with fluconazole 200 mg/day, at least until antiretroviral therapy causes CD4 counts to approach normal. Itraconazole capsules are inferior to fluconazole for maintenance therapy. Relapse because of fluconazole resistance is rare. Fluconazole is effective for the eradication of genitourinary foci. For patients without AIDS, fluconazole is useful for those who have completed a course of amphotericin B and seem to be at high risk for relapse.

Other Mycoses

Fluconazole is useful for coccidioidal meningitis and disseminated nonmeningeal coccidioidomycosis, but a direct comparison with itraconazole found a trend favoring itraconazole owing to its superior efficacy for skeletal infections. The two drugs were similarly efficacious for soft tissue and pulmonary infections. Cutaneous sporotrichosis, ringworm, histoplasmosis, and blastomycosis may respond to fluconazole, but the results are inferior to those with itraconazole.

Prophylaxis in Neutropenic Patients

Fluconazole decreases the incidence of death from deep-seated candidiasis in bone marrow transplant recipients. In a long-term follow-up of one study, bone marrow transplant recipients who received at least 75 days of fluconazole prophylaxis also had improved survival. Use of this drug for prophylaxis may result in shifts to less susceptible species in patient flora.

Prophylaxis in Patients with Acquired Immunodeficiency Syndrome

Fluconazole has reduced the incidence of oral and vulvovaginal candidiasis and cryptococcosis in patients with advanced HIV infection, but it has negligible effects on other mycoses. Cost, lack of effect on survival, and the possibility of azole resistance have led the advisory committee of the Infectious Diseases Society of America to recommend against routine fluconazole prophylaxis in patients with AIDS.

Voriconazole

Formulations and Pharmacology

Voriconazole is marketed as a tablet and as a solution in sulfobutyl ether β-cyclodextrin for intravenous administration. Voriconazole is cleared by hepatic metabolism, with less than 2% of the dose excreted unchanged in the urine. Voriconazole exhibits nonlinear pharmacokinetics owing to saturation of the clearance pathways at higher doses. The principal enzyme involved in clearance is hepatic CYP2C19. This enzyme has significant genetic polymorphisms that affect the metabolism of this drug. Despite these differences in metabolism, the achieved plasma levels overlap, and an initial dose adjustment based on genotype or racial group is not necessary. Different studies have suggested that favorable outcomes correlate with serum concentrations greater than 1 to 2 μg/mL, and neurologic/psychiatric, hepatic or cardiac side effects occur with levels greater than 5 μg/mL, so therapeutic drug monitoring is recommended, with dose adjustments as necessary.

Standard loading doses followed by maintenance doses that are 50% of normal are recommended for individuals with mild-to-moderate hepatic cirrhosis. Dosage adjustments are not required for renal dysfunction, and voriconazole is not significantly cleared by hemodialysis. Because of nephrotoxicity from the cyclodextrin, the intravenous formulation should not be used in patients with a creatinine clearance less than 50 mL/minute.

Drug Interactions

Voriconazole has many drug interactions. Rifampin, carbamazepine, long-acting barbiturates, glucocorticoids, and ritonavir induce the hepatic enzymes responsible for the clearance of voriconazole and thereby reduce voriconazole levels. Sirolimus levels are increased dramatically. Reduction in the clearance of pimozide, quinidine, and some antihistamines may be sufficient to place the patient at risk for QTc prolongation. Reduction in the clearance of ergot alkaloids could lead to chronic ergot poisoning. Cyclosporine, tacrolimus, warfarin, oral coumarins, lipid-lowering statin agents, benzodiazepines, calcium-channel blockers, sulfonylureas, methadone, and vinca alkaloids can be coadministered, but the dosages of these drugs may need to be reduced, and clinical or laboratory monitoring is suggested. Voriconazole significantly reduces the rate of clearance of omeprazole. Voriconazole with rifabutin, phenytoin, or efavirenz results in lower voriconazole levels and elevated levels of the other drug. Other interactions are possible, and any cytochrome P450 (CYP 450) inhibitors, blockers, or inducers could have an interaction with voriconazole.

Adverse Effects

The most frequently reported adverse event is a transient, reversible visual disturbance beginning approximately 30 minutes after a dose. Patients should be advised to avoid activities that require keen visual acuity while experiencing visual changes. Hallucinations and confusion also have been reported, associated with higher blood levels. Liver enzyme abnormalities appear to correlate with higher blood levels. Photosensitivity can be severe and has been associated with skin cancers in rare instances. Prolongation of the QT interval and tachyarrhythmias have been noted in patients with proarrhythmic risk factors, such as electrolyte abnormalities. Periostitis has been noted after prolonged therapy, apparently related to the fluoride atoms in the molecule. Leukoencephalopathy has been rarely reported.

Indications

Aspergillosis

Voriconazole was licensed for the treatment of invasive aspergillosis[5] on the basis of a randomized, unblinded comparative trial in which patients were randomized to receive initial therapy with either voriconazole or amphotericin B. Following the initial randomization, patients could be switched to other licensed therapies, as dictated by clinical events. After 12 weeks, 53% of the patients randomized to voriconazole, but only 32% of those randomized to amphotericin B, had a successful outcome.

Other Mycoses

Voriconazole is also licensed for the treatment of invasive fusariosis and scedosporiosis, based on high response rates for these diseases. Infections by *Scedosporium apiospermum* complex may respond, but *Scedosporium prolificans* infections are commonly resistant. The drug is efficacious in esophageal candidiasis, invasive candidiasis, and refractory candidiasis. Although the drug has appeal for use in prophylaxis, there has been concern about breakthrough zygomycoses with long-term use.

Posaconazole

Formulations and Pharmacology

Posaconazole has been available as an oral suspension, and a tablet form has been introduced. Absorption of the suspension is usually maximized by dividing the daily dose into four administrations and enhanced by taking the suspension with or after fatty food. Some commercial dietary supplements have the same effect as fatty meals and are better tolerated. The half- life is 20 to 35 hours. Clearance is primarily by fecal excretion, with only 13% excreted via renal clearance. Hepatic metabolism via uridine diphosphate glucuronidation plays only a small role in clearance, and CYP-mediated oxidation does not occur. The drug is concentrated in phagocytes. The dose is 800 mg/day for treatment of deep-seated mycoses, although 600 mg has been used successfully for prophylaxis, and 100 to 200 mg has been used for mucosal candidiasis. At steady state, 800 mg/day produces a peak concentration (C_{max}) of 4.2 μg/mL. Blood levels appear to be rather unpredictable, and outcomes in the treatment of aspergillosis correlate with levels. Therapeutic drug monitoring is advisable, and levels greater than 0.7 μg/mL have correlated with efficacy in prophylaxis. Dosage adjustment is not needed for hepatic or renal failure or hemodialysis. The dosing for the 100-mg oral tablet is 300 mg twice daily as a first day loading dose, then 300 mg/day. Blood concentrations after administration of the tablets exceed those after optimal dosing of the solution and appear negligibly affected by food or by medications that affect gastric pH or motility. Side effects of the tablets reported include somnolence, diarrhea, and flatulence. An intravenous formulation of posaconazole was introduced in early 2014.

Drug Interactions

Although posaconazole has fewer interactions than itraconazole and voriconazole, there are many significant ones, including increased levels of calcium-channel blockers, cyclosporine, sirolimus, tacrolimus, quinidine, atazanavir, amiodarone, cisapride, corticosteroids, digoxin, benzodiazepines, and drugs for erectile dysfunction. Posaconazole levels are reduced by cimetidine, efavirenz, metoclopramide, rifampin, and, in some studies, with diarrhea and proton pump inhibitors. Posaconazole with phenytoin, carbamazepine, or rifabutin result in lower posaconazole levels and elevated levels of the other drug.

Adverse Effects

The paucity of side effects is similar to that of fluconazole. Gastrointestinal symptoms, headache, and acneiform rashes of the face are occasionally seen. Electrolyte abnormalities should be rectified before therapy to avoid arrhythmias.

Indications

Posaconazole appears to possess a very broad spectrum of activity against molds, including many zygomycetes, a unique property among azoles, and

the least cross-reactivity among the azoles to mutations in the ergosterol synthesis pathway that cause resistance to other azoles. The main interest in the drug has been as prophylaxis and for salvage therapy of refractory mycoses. Efficacy in preventing opportunistic mycoses has been shown in the patients at highest risk, transplant patients with graft-versus-host disease, and those with hematologic malignancies and neutropenia. Impressive results in salvage have been demonstrated in aspergillosis and coccidioidomycosis. Superficial candidiasis is also responsive.

ECHINOCANDIN ANTIFUNGAL AGENTS

General Features

The echinocandin antifungal agents act by inhibiting the synthesis of 1,3-β-D-glucan in the fungal cell wall. In studies, the principal pharmacodynamic driver of in vivo response has been the ratio of the peak concentration to the MIC. There are now three licensed echinocandins: caspofungin, micafungin, and anidulafungin. These agents are similar to one another, having very few drug interactions, an admirably low adverse event rate, and essentially identical antifungal spectra. Of the three drugs, caspofungin has the broadest array of approved indications and the most clinical data. Micafungin has the most detailed data on its use in neonates and children. Anidulafungin appears to have somewhat fewer drug-drug interactions. All are cyclic lipopeptides that must be given intravenously.

They are fungicidal against all *Candida* spp, including isolates resistant to other agents. Reduced activity against isolates of *Candida parapsilosis* and *Candida guilliermondii* and a paradoxical effect whereby high concentrations that permit growth in vitro have been noted in a minority of *Candida* isolates and do not appear to be clinically relevant. Resistance, while uncommon, is increasingly noted, and instances of resistance development on therapy have been described. All are active against *Aspergillus* spp, but activity is limited to growing and dividing hyphal elements. Their activity against other fungi is variable.

Caspofungin

Formulations and Pharmacology

Caspofungin is marketed for intravenous infusion. The clearance of caspofungin is through a combination of spontaneous chemical degradation, hydrolysis, and *N*-acetylation. Dose adjustments are not required for impaired renal function or hemodialysis. The clearance of caspofungin is modestly reduced in subjects with moderate hepatic insufficiency, and a reduction of the usual daily dose is recommended. Penetration into infected tissues appears to be good.

Drug Interactions

Caspofungin has few meaningful drug interactions. Cyclosporine coadministration increases caspofungin exposure and has been associated with increased hepatic transaminase levels, so concomitant use requires caution. Caspofungin reduces tacrolimus exposure by approximately 20%, and dosage adjustments may be required. Rifampin reduces caspofungin blood levels by approximately 30%, so the daily dosage of caspofungin should be increased from 50 to 70 mg if these drugs are co-administered. Likewise, limited data on other inducers of drug clearance (efavirenz, nevirapine, phenytoin, dexamethasone, carbamazepine) suggest that reduced caspofungin levels are possible and that increasing the daily dose to 70 mg should be considered.

Adverse Effects

Overall, the adverse reactions with caspofungin have been infrequent and minor. Symptoms possibly related to histamine release during rapid infusion have been reported.

Indications

Caspofungin is indicated for the treatment of invasive candidiasis and esophageal candidiasis. Caspofungin is also indicated for invasive aspergillosis in patients who are refractory to or intolerant of other therapies. With its activity against these two major opportunistic pathogens, the use of caspofungin for empirical therapy in high-risk situations is logical and is supported by clinical trials.

Micafungin

Micafungin has an in vitro spectrum and properties similar to those of caspofungin. It is similarly cidal for *Candida* spp and noncidal in vitro for *Aspergillus*.

Formulations and Pharmacology

The drug is light sensitive. After an intravenous infusion, the terminal half-life is approximately 15 hours. The recommended dose is 100 mg/day. Once daily dosing produces steady state in 3 days. Metabolism appears to be mostly through fecal excretion; less than 1% is excreted in the urine. The drug appears to penetrate particularly well into the lungs, liver, kidneys, and gastric mucosa. No adjustment for hepatic or renal insufficiency is needed.

Drug Interactions

Micafungin has fewer drug interactions than caspofungin. There is no interaction with cyclosporine or rifampin.

Adverse Effects

Micafungin has an excellent safety profile. Histamine release, manifested most prominently by erythema over the body, can be avoided by slow infusion. Phlebitis has been reported.

Indications

Efficacy is good in invasive candidiasis, similar to that of amphotericin or caspofungin. In clinical dose-finding studies against *Candida* esophagitis, doses of 75 to 150 mg/day were particularly effective. A trial of prophylaxis in neutropenic patients with hematopoietic stem cell transplant showed efficacy at 50 mg/day. Limited experience suggests comparable activity to caspofungin against aspergillosis.

Anidulafungin

Formulations and Pharmacology

Anidulafungin is slowly degraded by the chemical opening of its ring structure. A 100-mg dose produces a C_{max} (peak concentration achieved) of 8.6 μg/mL at a time of peak concentration (T_{max}) of 6 to 7 hours. The half-life is 30 to 50 hours. Steady state is achieved in 3 to 10 days. Dose adjustments are not required for renal or hepatic insufficiency.

Drug Interactions

Anidulafungin has no meaningful CYP enzyme interactions. It is not an inducer, inhibitor, or substrate and has no interaction with drugs cleared by these pathways or drugs that induce these pathways. The lack of metabolism suggests this would be the best echinocandin to use in the presence of liver failure.

Adverse Effects

Histamine-mediated symptoms (e.g., rash, urticaria, flushing, pruritus, dyspnea, hypotension) have been noted on occasion, but they are infrequent when the rate of infusion does not exceed 1.1 mg/minute. Other adverse reactions to anidulafungin have generally been infrequent and minor (diarrhea, hypokalemia, elevated liver function tests, neutropenia, nausea, headache, dermatitis).

Indications

Anidulafungin is indicated for the treatment of invasive candidiasis and esophageal candidiasis. Randomized trials indicate that anidulafungin is at least as efficacious as fluconazole. Inefficacy against *C. parapsilosis* may be of greatest concern with this echinocandin.

OTHER AGENTS

Combinations of antifungal agents are increasingly being used in an effort to improve the very poor response rates in some diseases and to combine drugs with different mechanisms of action. Although synergy in vitro may be relatively easy to demonstrate, there are few examples of synergy in animal model studies. In patients, the costs are high and the side effects are likely to be increased. The clinical advantages of the amphotericin-flucytosine combination in cryptococcosis have yet to be documented definitively in other situations.

Immunomodulators, particularly cytokines, hold promise, but insufficient clinical data exist to determine where and how these drugs might be used.[4] Granulocyte-macrophage colony-stimulating factor was shown to be effective in one trial when given prophylactically during induction therapy of patients with leukemia who are high risk.

Therapy of the various forms of tinea and of onychomycosis with systemic agents is discussed in Chapter 438. Although *Pneumocystis jiroveci* (formerly

Pneumocystis carinii) is now classified among the fungi, the drugs used to treat it are principally those used to treat parasitic infections (Chapter 344).

HISTOPLASMOSIS

CAROL A. KAUFFMAN

DEFINITION

Histoplasmosis is the most common endemic mycosis in the United States. Most infections are self-limited, but the organism has the ability to cause acute and chronic pulmonary infections and disseminated infection.[1,2]

The Pathogen

Histoplasma capsulatum var *capsulatum* is a thermally dimorphic fungus. In the environment and at temperatures lower than 35° C, it exists as a mold that produces conidia. It produces both tuberculate macroconidia, which are helpful for identification purposes in the laboratory, and microconidia, which are the infectious form. In tissues and at 35 to 37° C, *H. capsulatum* transforms into tiny 2- to 4-μm oval yeasts that reproduce by budding and parasitize macrophages. African histoplasmosis is caused by a different subspecies, *H. capsulatum* var *duboisii,* and has different disease manifestations, particularly involvement of skin, subcutaneous tissues, lymph nodes, and bone, and only rarely the lungs and other internal organs.

EPIDEMIOLOGY

Histoplasmosis, though found worldwide, is primarily a disease of North and Central America. *H. capsulatum* is endemic in the Mississippi and Ohio River valleys, with extension into the St. Lawrence basin; microfoci exist in discrete isolated areas in several eastern states. Soil, caves, and abandoned buildings containing high concentrations of bird or bat guano support luxuriant growth of the organism. Every year, hundreds of thousands of individuals who live in areas endemic for *H. capsulatum* are infected. Most cases are sporadic and the exact source of exposure is unknown. Point source outbreaks that have included as few as 4 persons and as many as 100,000 have been well described in association with disruption of soil; cleaning attics, bridges, or barns; renovating or tearing down old structures laden with guano; and spelunking.[3]

PATHOBIOLOGY

After inhalation of microconidia into the alveoli, a localized pulmonary infection ensues. Neutrophils and macrophages phagocytize the organism, now in the yeast phase; the organism is able to survive and travels within macrophages to the hilar and mediastinal lymph nodes and throughout the reticuloendothelial system by hematogenous dissemination. Such dissemination probably occurs in most persons who are infected and in normal hosts is associated with no symptoms. After several weeks, T cells specifically sensitized by *H. capsulatum* antigens activate macrophages, which are then able to kill the intracellular fungi. Histoplasmosis is a classic example of the pivotal importance of the cell-mediated immune system in containing intracellular pathogens.

The extent of disease is determined by both the number of conidia inhaled and the immune response of the host. A small inoculum can cause severe pulmonary infection or progress to acute symptomatic disseminated histoplasmosis in immunosuppressed patients. Conversely, severe life-threatening pulmonary infection may develop in a healthy individual if a large number of conidia are inhaled, as might occur during the demolition of old buildings or while spelunking in a heavily infested cave.

Reinfection can occur in persons who previously had histoplasmosis but is uncommon and almost always occurs in the setting of heavy exposure. Reactivation of latent infection takes place in patients who have deficient cell-mediated immunity, as evidenced by the occurrence of histoplasmosis in immunosuppressed persons who grew up in the endemic area but have not been back in that area for years.

CLINICAL MANIFESTATIONS

Acute Pulmonary Histoplasmosis

Infection is asymptomatic in most people infected with *H. capsulatum*. Those who do have symptomatic pulmonary infection usually have a self-limited illness that begins several weeks after exposure and is characterized by fever, chills, fatigue, nonproductive cough, anterior chest discomfort, and myalgias. A patchy lobar or multilobar nodular infiltrate is noted on chest radiographs.

The differential diagnosis of acute pulmonary histoplasmosis includes pneumonia from *Blastomyces dermatitidis, Mycoplasma pneumoniae, Legionella* sp, and *Chlamydia pneumoniae*. When enlarged hilar or mediastinal lymph nodes are present, histoplasmosis should be strongly considered. The most difficult to differentiate is acute pulmonary blastomycosis (Chapter 334) because the endemic areas overlap, a comparable history of outdoor activities is often obtained, and radiographs show similar findings.

In patients who have experienced heavy exposure to *H. capsulatum* and in those who are immunosuppressed, acute pulmonary histoplasmosis can be life-threatening. High spiking fevers, chills, prostration, dyspnea, and cough are prominent.[4] Chest radiographs show diffuse reticulonodular pulmonary infiltrates, and acute respiratory distress syndrome (ARDS) can occur.

Chronic Pulmonary Histoplasmosis

Chronic cavitary pulmonary histoplasmosis is a progressive, often fatal form of histoplasmosis that develops almost exclusively in older patients who have chronic obstructive pulmonary disease.[5] Symptoms include fever, fatigue, anorexia, weight loss, cough productive of purulent sputum, and hemoptysis. On chest radiography the usual findings are unilateral or bilateral upper lobe infiltrates with multiple cavities and extensive fibrosis in the lower lobes. Chronic pulmonary histoplasmosis mimics tuberculosis, other fungal pneumonias (especially blastomycosis and sporotrichosis), and nontuberculous mycobacterial infections with regard to symptoms, signs, and radiographic findings.

Complications of Pulmonary Histoplasmosis

The mediastinal and hilar lymph nodes frequently calcify as the infection resolves; years later they can erode into bronchi and cause hemoptysis and expectoration of broncholiths. Granulomatous mediastinitis is an uncommon syndrome characterized by continuing inflammation and necrosis in the mediastinal lymph nodes. The enlarged nodes are readily apparent on chest radiographs, and computed tomography (CT) shows central necrosis and, in some cases, impingement on adjacent structures, including the esophagus, airways, and blood vessels. Although the symptoms usually resolve without treatment, obstructive syndromes can be severe and the nodes can persist for years.

Fibrosing mediastinitis[6] is a rare complication of histoplasmosis in which the host responds to the infection with an inappropriate excessive fibrotic response. Obstruction of the airways, superior vena cava, or pulmonary arteries and veins can occur with resultant progressive right heart failure and respiratory insufficiency. Bilateral obstruction of the pulmonary vasculature is less common than unilateral involvement and carries a worse prognosis. Mediastinal widening is seen on chest radiographs, and CT and angiography define the extent of invasion and obstruction of mediastinal structures.

Pericarditis is a manifestation of a local inflammatory reaction to adjacent histoplasmosis. Patients respond promptly to anti-inflammatory medications without antifungal therapy. Hemodynamic compromise, though unusual, requires drainage of pericardial fluid; only rarely has progression to constrictive pericarditis been documented.

Disseminated Histoplasmosis

Symptomatic disseminated histoplasmosis occurs mostly in immunosuppressed patients. Patients with acquired immunodeficiency syndrome (AIDS) and CD4+ counts lower than 150/μL, infants, and those who have a hematologic malignancy, have received an organ transplant, or are taking corticosteroids or tumor necrosis factor antagonists are at greatest risk for acute disseminated histoplasmosis.[7] Symptoms and signs include chills, fever, anorexia, weight loss, hypotension, dyspnea, hepatosplenomegaly, and skin and mucous membrane lesions. Pancytopenia, diffuse pulmonary infiltrates

on chest radiography and CT, findings of disseminated intravascular coagulation, and acute respiratory failure are common. This syndrome is indistinguishable from sepsis of any bacterial or viral cause. In patients with acquired immunodeficiency syndrome (AIDS), the differential diagnosis includes cytomegalovirus, disseminated *Mycobacterium avium* complex infection, and tuberculosis.

Chronic progressive disseminated histoplasmosis is a fatal form of histoplasmosis that occurs mostly in middle-aged to elderly men who have no known immunosuppressive illness. The illness is characterized by fever, night sweats, weight loss, anorexia, and fatigue. Patients appear chronically ill, hepatosplenomegaly and mucocutaneous ulcerations are common, and adrenal insufficiency can develop. An increased erythrocyte sedimentation rate, elevated alkaline phosphatase, pancytopenia, and diffuse reticulonodular infiltrates on chest radiography and CT are typical. Patients with this form of histoplasmosis often have fever of unknown origin. Miliary tuberculosis, lymphoma, and sarcoidosis must be excluded.

Involvement of almost every organ system has been reported with disseminated infection. Adrenal insufficiency must be sought in any patient who has unexplained hypotension, hyponatremia, and hyperkalemia. Abdominal CT shows markedly enlarged adrenal glands. Central nervous system involvement manifests as either meningitis or focal lesions seen on magnetic resonance imaging and is more common in patients with AIDS. Skin lesions, also more common in patients with AIDS, can be papular, pustular, or ulcerated. *Histoplasma* endocarditis is a rare form of disseminated infection.[8]

DIAGNOSIS

The definitive diagnostic test for histoplasmosis is growth of the organism in culture. Unfortunately, *H. capsulatum* may take as long as 6 weeks to grow in vitro. Tissue samples, bronchoalveolar lavage fluid, sputum, and blood are appropriate for culture. For patients who have evidence of dissemination, blood cultures are best performed with the lysis-centrifugation (Isolator tube) system; bone marrow and liver biopsy material often yield *H. capsulatum* in the setting of dissemination. If pulmonary histoplasmosis is a diagnostic consideration, the laboratory should be informed so that a special medium that decreases the growth of commensal fungi can be used for the culture of pulmonary samples. As soon as growth of a mold has been detected, highly specific DNA probes for *H. capsulatum* allow rapid identification of the organism.

If the patient is acutely ill, tissue biopsy should be performed to search for the distinctive 2- to 4-µm oval yeasts with single buds, which allows a tentative diagnosis to be made as quickly as possible. Routine tissue stains do not show the tiny yeasts; biopsy material must be stained with methenamine silver or periodic acid–Schiff stains. In patients with disseminated disease, bone marrow, liver, skin, and mucocutaneous lesions usually reveal many organisms. The organisms also can be seen within neutrophils in peripheral blood smears from patients with acute disseminated infection. In patients with chronic pulmonary histoplasmosis or granulomatous mediastinitis, biopsy of the lung or lymph nodes may reveal the organism.

Serology plays an important role in the diagnosis of some forms of histoplasmosis. Complement fixation assays that use two different antigens—mycelial and yeast—and immunodiffusion tests are available. Serology is helpful in diagnosing acute pulmonary histoplasmosis when a four-fold rise in complement fixation titer, a complement fixation titer higher than 1:32, or the appearance of an M precipitin band by immunodiffusion assay is found. These tests also are useful in patients with chronic forms of pulmonary or disseminated histoplasmosis, but they are rarely helpful in immunosuppressed patients, who often cannot mount an antibody response. Because serologic tests are not definitive in patients with mediastinal lymphadenopathy, the results always should be confirmed by tissue biopsy. An enzyme immunoassay for *H. capsulatum* polysaccharide antigen in urine and serum is extremely helpful in patients with disseminated infection and in those with acute pulmonary histoplasmosis.[9] Almost 75% of patients who have experienced heavy exposure and demonstrate diffuse pulmonary infiltrates and more than 90% of patients who have disseminated histoplasmosis will have a positive urinary antigen test. However, the assay is not useful for patients who have chronic cavitary histoplasmosis, granulomatous mediastinitis, or fibrosing mediastinitis. False-positive reactions have been noted commonly with blastomycosis, paracoccidioidomycosis, and penicilliosis and occasionally with acute coccidioidomycosis. Antigen levels usually become undetectable with successful therapy. Polymerase chain reaction has been used for diagnosis in some cases, but the assays are not standardized.

TREATMENT

Rx

Guidelines for the treatment of histoplasmosis have been published by the Infectious Diseases Society of America (IDSA).[10] Itraconazole is the drug of choice for mild-to-moderate histoplasmosis, and lipid formulations of amphotericin B should be used as initial therapy for severe, life-threatening infections. Fluconazole is less active and should be considered a second-line agent. There is less experience using voriconazole or posaconazole, although both appear to be effective therapy. The echinocandins are not effective for histoplasmosis.

For all patients who are treated with itraconazole, serum levels should be determined when a steady state has been reached after 2 weeks of therapy to ensure adequate absorption. Serum concentrations should be greater than 1 µg/mL.

Pulmonary Histoplasmosis

Treatment is not usually given for acute pulmonary histoplasmosis; many times the diagnosis is not made until after the symptoms have resolved. However, if the patient remains symptomatic after 4 weeks, therapy with itraconazole, 200 mg once or twice daily for 6 to 12 weeks, should be given. All patients who have severe pulmonary histoplasmosis and all immunosuppressed patients should be treated with an antifungal agent. Lipid formulation amphotericin B, 3 to 5 mg/kg/day, is recommended for several weeks until a response is noted, at which time therapy can be changed to oral itraconazole, 200 mg three times daily for 3 days and then 200 mg twice daily. A short course of methylprednisolone is recommended in the IDSA guidelines for patients in whom respiratory distress develops in association with acute pulmonary histoplasmosis.

Antifungal therapy should be given to all patients with chronic pulmonary histoplasmosis. Itraconazole, 200 mg twice daily for 12 to 24 months, is recommended. A trial of itraconazole for 6 to 12 weeks is often given to patients with symptomatic granulomatous mediastinitis, although there are no data proving such therapy to be effective. Surgical resection of nodes causing obstructive symptoms may be beneficial. Antifungal therapy offers no benefit for patients with fibrosing mediastinitis. Surgery is not indicated and carries a high operative mortality rate. Intravascular stents have been used successfully in patients who have vascular obstruction.

Disseminated Histoplasmosis

All patients with symptomatic disseminated histoplasmosis should receive antifungal therapy. Patients who have only mild-to-moderate symptoms with acute disseminated disease and most patients with chronic progressive disseminated histoplasmosis can be treated with itraconazole, 200 mg twice daily after a loading dose of 200 mg three times daily for 3 days. A total of 12 months of therapy is generally adequate, but for those with chronic progressive disease, the duration of treatment may need to be longer.

Patients who have moderately severe to severe disseminated histoplasmosis should be treated with liposomal amphotericin B, 3 mg/kg/day. Therapy can be changed to itraconazole after the patient has responded to therapy, generally in a few weeks. Therapy should continue for a total of 12 months. For those who are immunosuppressed, therapy with itraconazole, 200 mg/day, should continue until the immunosuppression resolves. For patients with AIDS, suppressive therapy can be safely stopped in those who have had a year of therapy, are receiving antiretroviral therapy, and have CD4+ counts greater than 150 cells/µL.[11]

Prevention of histoplasmosis is difficult because exposure can occur without the person's knowledge in highly endemic areas. Persons who are immunosuppressed should be advised to avoid demolition areas, spelunking, and cleaning of farm buildings or attics. A randomized, blinded, placebo-controlled trial in patients with AIDS found that itraconazole, 200 mg/day, was effective in preventing infection. Recommendations are to use prophylaxis only for patients whose CD4+ counts are lower than 150/µL and who live in a highly endemic area with a rate of histoplasmosis that is greater than 10 cases per 100 patient years. There are no recommendations for prophylaxis for other immunosuppressed patients.

PROGNOSIS

Acute pulmonary histoplasmosis is usually a self-limited disease. Patients who require treatment generally respond promptly to antifungal agents. However, the response of patients with chronic cavitary pulmonary histoplasmosis is often poor, primarily because of their severe underlying pulmonary disease. Mediastinal fibrosis has a poor prognosis, but intravascular stenting has led to improvement in many patients. Patients with disseminated histoplasmosis, even those with advanced AIDS, usually respond promptly to antifungal therapy; most deaths in immunosuppressed patients occur when the diagnosis is delayed. Older patients with chronic progressive disseminated histoplasmosis have a slower, but usually complete response to therapy.

REVIEW QUESTIONS

1. A 72-year-old man from Kentucky who has emphysema and coronary artery disease comes in with fever, night sweats, 20-lb weight loss, cough, and sputum production with occasional hemoptysis for the last 4 to 5 months. Chest x-ray shows bilateral upper lobe cavitary infiltrates and emphysematous changes. The *most* likely diagnosis is:

A. Coccidioidomycosis.
B. Sporotrichosis.
C. Blastomycosis.
D. Histoplasmosis.

Answer: D. Any of the above fungal infections can manifest by upper lobe cavitary lesions. However, the most likely diagnosis is histoplasmosis because he is from Kentucky, where *H. capsulatum* is highly endemic. Blastomycosis is also endemic in Kentucky but is less common than histoplasmosis. Pulmonary sporotrichosis could manifest with a similar picture, but is very uncommon. Coccidioidomycosis occurs in the desert southwest and is not possible unless he had traveled to that area.

2. Which test would be most useful for the diagnosis of chronic cavitary pulmonary histoplasmosis in the patient noted in question 1?

A. Serum antigen assay for *H. capsulatum* cell wall polysaccharide
B. CT scan of the chest
C. Sputum culture for fungus
D. PCR for *H. capsulatum* on serum
E. Urine enzyme immunoassay

Answer: C. The definitive diagnostic test is growing *H. capsulatum* in culture, and in this form of histoplamosis, sputum cultures usually yield the organism. PCR tests can be useful when performed on a tissue biopsy, but not on serum. The serum and urine antigen assays are not sensitive for the chronic cavitary form of histoplasmosis. CT scan is useful to define the extent of pulmonary disease, but it does not define the causative agent.

3. Which form of histoplasmosis does not respond to antifungal therapy?

A. Chronic cavitary pulmonary
B. Mediastinal fibrosis
C. Disseminated infection in immunocompetent patients
D. Acute respiratory distress syndrome (ARDS)
E. Disseminated infections in patients with AIDS

Answer: B. Mediastinal fibrosis is characterized by an abnormal host response with the production of excessive fibrosis that can lead to obstruction of pulmonary arteries, the superior vena cava, and mainstem bronchi. The organism is rarely seen within the fibrous tissue, and it is thought that there is no longer active infection when the patient presents with obstructive symptoms. Disseminated histoplasmosis, including in patients with AIDS, and acute and chronic pulmonary histoplasmosis, including in patients with AIDS, respond to antifungal therapy.

4. A 65-year-old man is admitted with fevers and hypotension. He has a 3-month history of night sweats and weight loss, and he is found to have anemia (Hb 9.5 g/dL), thrombocytopenia (platelets 112,000/μL), and leukopenia (2600 WBC/μL). His serum sodium is 126 mEq/L and potassium is 5.2 mEq/L. What is the most likely fungal infection that could explain these findings?

A. Coccidioidomycosis
B. Sporotrichosis
C. Histoplasmosis
D. Cryptococcosis
E. Candidiasis

Answer: C. The patient has adrenal insufficiency, and the fungus that most often causes this is *H. capsulatum*. The other fungal infections have been reported very rarely to cause adrenal insufficiency. This manifestation is not uncommon in patients with AIDS who develop disseminated histoplasmosis and in older adults who develop the chronic progressive form of disseminated histoplasmosis.

5. A 37-year-old woman is being treated with etanercept for rheumatoid arthritis. She developed disseminated histoplasmosis 3 weeks after an old barn on her farm had been demolished. On admission to hospital, she has hypoxemia, pancytopenia, and signs of disseminated intravascular coagulation. She should be treated with:

A. Liposomal amphotericin B.
B. Itraconazole.
C. Amphotericin B deoxycholate.
D. Fluconazole.

Answer: A. Liposomal amphotericin B has been shown to be superior to amphotericin B deoxycholate for the treatment of severe disseminated histoplasmosis in patients with AIDS. Mortality was decreased, patients became afebrile sooner, and toxicity was less with the liposomal formulation. Any immunosuppressed patient who has severe histoplasmosis should be treated with this agent. Itraconazole is appropriate therapy for mild-to-moderate histoplasmosis and for step-down therapy after the patient has responded to amphotericin B. Fluconazole is less active against *H. capsulatum* and is a second-line agent.

333

COCCIDIOIDOMYCOSIS

JOHN N. GALGIANI

DEFINITION

Coccidioidomycosis is a systemic fungal infection caused by *Coccidioides* spp endemic to some arid regions of the Western Hemisphere (Table 333-1).

The Pathogen

Coccidioides immitis and *C. posadasii* are dimorphic fungi classified as Ascomycetes by ribosomal gene homology. In their vegetative state, mycelia with true septations mature to produce arthroconidia, single cells approximately 2 to 5 µm in diameter. After infection, an arthroconidium enlarges to a spherule up to 75 µm in diameter and undergoes internal septation to produce scores of endospores. When the spherules rupture, packets of endospores are released and produce more spherules in infected tissue or revert to mycelia if removed from the body.

EPIDEMIOLOGY

Coccidioides organisms can be recovered from the soil of the low deserts of Arizona; the Central Valley of California; parts of other states, including New Mexico and Texas; and parts of Central and South America.[1] Isolated pockets of endemnicity have been found unexpectedly elsewhere such as in Washington State.[2] Endemic regions follow the climatologic Sonoran life zone, which is characterized by modest rainfall, mild winters, and low humidity. However, even in the most highly endemic areas, fungal colonies are sparse and occupy only a tiny fraction of the total acreage. Mycelia bloom beneath the surface during periods of rain, and arthroconidia develop as the earth dries.[3] Rates of infection are highest during dry months, occasionally accentuated when soil is disturbed by windstorms or construction equipment. Exposure to contaminated bales of cotton or other fomites can rarely result in infection beyond the endemic regions. Person-to-person transmission of pulmonary infection has not been reported, and isolation precautions are unnecessary, even in acute care areas. As of 2013, *Coccidioides* spp are no longer listed and controlled by the Centers for Disease Control and Prevention as select agents.

TABLE 333-1 COCCIDIOIDOMYCOSIS: CLINICAL CHARACTERISTICS AND TREATMENT

CHARACTERISTIC	DESCRIPTION
Causative fungi	*Coccidioides immitis* and *Coccidioides posadasii*
Primary geographic distribution	Lower Sonoran deserts of the Western Hemisphere, including parts of Arizona, California, and New Mexico; western Texas; parts of Central and South America
Primary route of acquisition	Respiratory (inhalation of arthroconidia)
Principal site of disease	Lungs most common; spread to skin, bones, meninges, and other viscera uncommon but serious
Opportunistic infection in compromised hosts	Diffuse pneumonia and widespread infections common in patients with T-lymphocyte defects or during high-dose corticosteroid therapy
Drug of choice for most patients	No antifungal is required for uncomplicated pneumonia; fluconazole or itraconazole for progressive forms of infection
Alternative therapy	Amphotericin B (especially with diffuse pneumonia or rapidly progressive infections), voriconazole, posaconazole

Incidence and Prevalence

In general, the annual risk for infection within the most strongly endemic areas is 3%, resulting in approximately 150,000 new infections per year. Reported clinical illness following infection is increasing. For example, from 1998 to 2011, reported infections increased more than eight-fold.[4] With unusually intense exposure, such as at archaeology sites or during military maneuvers within endemic regions, infections can develop in the majority of persons exposed for only a matter of days. Arizona and California contribute 66% and 31%, respectively, of all U.S. infections.

PATHOBIOLOGY

Inhaling even a single arthroconidium to the level of the terminal bronchiole initiates virtually all coccidioidal infections. Fungal proliferation engenders both granulomatous inflammation, which is associated with intact spherules, and acute inflammation, including eosinophils, which is associated with spherule rupture and proliferation. Focal pneumonia is often associated with ipsilateral hilar adenopathy; less frequently, infection enlarges the paratracheal, supraclavicular, and cervical nodes. Lesions occurring elsewhere are the result of hematogenous dissemination, and most become apparent within 2 years of the initial infection. Although progressive dissemination occurs in less than 1% of infections, as many as 8% of persons with self-limited infection manifest asymptomatic chorioretinal scars, suggesting that subclinical hematogenous spread may be frequent. Within weeks after infection, durable T-cell immunity normally arrests fungal proliferation, which allows the inflammation to resolve and prevents reinfection in the future. However, control of the infection occurs without sterilizing lesions, and reactivation of the dormant infection is possible even many years later in patients whose cell-mediated immunity becomes deficient.

CLINICAL MANIFESTATIONS

Two thirds of infections are asymptomatic and are detected only by finding dermal hypersensitivity to coccidioidal antigens. Those who become ill usually experience pulmonary syndromes that eventually are self-limited. However, some patients develop complications or progressive forms of infection that display a broad variety of manifestations and pose difficult management problems.

Primary Pulmonary Infections

Symptoms develop within 5 to 21 days after exposure. For residents of or recent visitors to southern Arizona, coccidioidomycosis accounts for approximately one third of cases of community-acquired pneumonia.[5] Fever, weight loss, fatigue, dry cough, and pleuritic chest pain are common but nonspecific complaints. Arthralgia of multiple joints without significant effusion is also frequent and is referred to as "desert rheumatism." Occasionally, skin manifestations develop, including a short-lived nonpruritic maculopapular rash, erythema multiforme, or erythema nodosum. These arthritic and dermatologic manifestations are mediated by circulating immune complexes or other immunologic phenomena rather than by fungal dissemination and resolve without tissue destruction. Radiographs of the chest may not detect any abnormalities or may demonstrate pulmonary infiltrates that are either segmental or lobar. Hilar adenopathy is often a distinctive finding and may suggest lymphoma by its appearance. Peripneumonic pleural effusions may occur and generally resolve without intervention, although cultures of pleural biopsies usually yield *Coccidioides* spp. Eosinophilia may be a prominent finding in differential leukocyte counts of peripheral blood, and the erythrocyte sedimentation rate is generally elevated. Symptoms frequently persist for many weeks before improvement is clearly under way, and the illness, especially lassitude, may persist for months.[6]

The primary pulmonary process produces a variety of sequelae. The most frequent is the development of a pulmonary nodule (Fig. 333-1), typically measuring 1 to 4 cm and lying within 5 cm of the hilum. Despite their harmless nature, coccidioidal nodules may cause concern because of their similarity to a malignant mass (Chapters 84 and 191). Positron emission tomography scans are typically positive. For these reasons, management usually requires percutaneous needle aspiration or resection. Another consequence of pulmonary coccidioidomycosis is cavitation of the infiltrate, which occurs in approximately 5% of cases of pneumonia.[7] Most cavities are solitary and thin walled and reside in an upper lobe, close to the pleura. Occasionally, they produce pain, hemoptysis, or adjacent infiltrates. Cavities may acquire mycetomas from either *Coccidioides* spp or some other colonizing mold. Infrequently, a cavity ruptures and forms a pyopneumothorax. Half of the time,

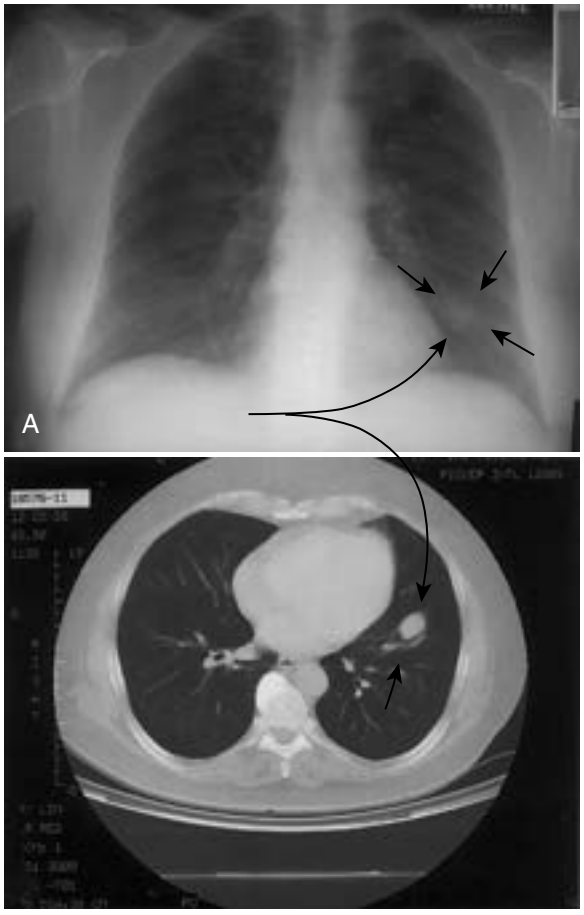

FIGURE 333-1. Coccidioidomycosis. A, Benign nodule secondary to coccidioidomycosis (*arrows*). **B,** Computed tomography scan of the nodule shown in **A** (*arrows*).

this is the first symptom of coccidioidal infection and typically occurs in otherwise healthy young men. An air-fluid level in the pleural space, detectable by roentgenography, often helps differentiate this problem from a spontaneous pneumothorax. Prompt surgical resection of the cavity is the preferred treatment of this complication. The least common pulmonary complication is persistent fibrocavitary infection that progresses to involvement of both lungs. Rarely, a mutation of the *STAT1* gene results in chronic progressive noncavitary pulmonary destruction.[8]

Extrapulmonary Dissemination

Coccidioidomycosis in patients with deficiencies in cellular immunity, such as solid organ recipients, those with acquired immunodeficiency syndrome (AIDS) or lymphoma, and women during their third trimester of pregnancy, usually results in dissemination beyond the lungs. Mutations of the genes for γ-interferon or the interleukin-12 receptor also predispose persons to dissemination.[9] However, disseminated infection occurs in some patients who have no underlying disease and do not manifest heightened susceptibility to other infections. Disseminated infection is more likely in men than in women and in persons of certain ancestry such as Africans, Filipinos, or Native Americans compared to Caucasians. The most common locations for disseminated lesions are the skin (cutaneous papules or subcutaneous abscesses); joints (especially the knee); bones, including the vertebrae; and basilar meninges.[10] Such infections may produce one or many lesions and are frequently subacute or chronic in their manifestation. In broadly immunosuppressed patients, coccidioidal infections may be more fulminant, with fungemia detectable in blood cultures and the development of diffuse reticulonodular embolic pulmonary infiltrates. Although the kidneys and the urinary bladder are rarely involved, *Coccidioides* may be recovered from concentrated specimens of urine, usually because of focal dissemination to the prostate. In contrast to histoplasmosis, the gastrointestinal tract is rarely involved in coccidioidomycosis.

DIAGNOSIS

The diagnosis is definitively established by recovering *Coccidioides* spp from clinical specimens. On direct examination of respiratory specimens or tissue, spherules appear as large structures with refractile walls and internal organization; they are also seen on hematoxylin-eosin, silver, or periodic acid–Schiff stains of histologic preparations. Gram stain does not detect spherules. In culture, mycelial growth is often evident within the first week of incubation, and DNA probing with commercially available kits allows rapid genus identification. Recovery of *Coccidioides* spp from patients with only scant respiratory secretions associated with the initial pneumonia and from the cerebrospinal fluid of patients with meningitis may be difficult.

A presumptive diagnosis of coccidioidal infection is often based on the detection of specific antibodies in serum. Within the first weeks of the initial infection, a precipitin-type antibody is detected, usually by immunodiffusion techniques. Later, complement fixation–type antibodies generally appear. However, these tests may be falsely negative as often as half the time during the first weeks of illness.[11] When reported quantitatively, concentrations of complement fixation antibodies are usually highest in the most extensive infections and decrease in patients whose infections are controlled. An important means of diagnosing coccidioidal meningitis is the detection of complement fixation antibodies in cerebrospinal fluid, along with other abnormalities such as leukocytosis, elevated protein concentration, or low glucose concentration. Newer enzyme immunoassay commercial kits are also available, are generally more sensitive than the older serologic tests, but occasionally produce falsely positive results. Coccidioidal antigens are sometimes found in the urine or serum of patients with widespread infection. A *Coccidioides* genus–specific, quantitative, real-time polymerase chain reaction assay has been developed for the early diagnosis of coccidioidomycosis.[12] In 2014, a coccidioidal skin test became clinically available and, if positive, indicates past infection.

TREATMENT

Rx

The role of antifungal therapy for primary uncomplicated infections is unsettled because clinical trials have not been performed to determine whether treatment either shortens the course of symptoms or diminishes the chance of complications.[13,14] However, the value of treatment is clear for patients with progressive illness.[15] Because many coccidioidal infections are chronic, initial treatment often consists of oral azole antifungal agents, such as fluconazole and itraconazole. Responses to these two drugs are similar, but itraconazole is preferred in patients with skeletal infections. Doses of these azoles are 400 mg/day or higher, and treatment is usually continued for a year or more. Satisfactory responses are obtained in approximately two thirds of patients. Fluconazole is effective therapy for coccidioidal meningitis and has greatly reduced the number of patients treated with intrathecal amphotericin B. Unfortunately, cessation of azole therapy is often followed by a recurrence of symptoms, especially in those with coccidioidal meningitis. Therefore, many patients need protracted or even lifelong therapy to control disease activity. The limited evidence available for the newer azole antifungals (voriconazole, posaconazole) indicates that they are also effective in some patients and are sometimes useful for refractory infections. Amphotericin B remains a rational choice when treatment with azole antifungals has failed. Daily doses range from 0.4 to 1 mg/kg for the original deoxycholate formulation and up to 5 mg/kg per day for newer lipid formulations. Occasionally, in a patient with rapid disease progression, amphotericin B may produce a more rapid therapeutic response and is therefore the preferred initial therapy. In addition to antifungal agents, surgical removal of necrotic tissue may be essential to control the progressive damage from specific lesions.

PROGNOSIS

After resolution of the initial infection, most patients maintain lifelong immunity, and infections after re-exposure are rare. However, cessation of symptoms is frequently accomplished without eradicating *Coccidioides* completely, and recurrence of the original infection many years after the original episode is a well-recognized risk for intercurrent profound immunosuppression. Re-treating patients with rheumatic disease with biologic response modifiers and/or disease-modifying antirheumatic drugs after coccidioidomycosis appears to be safe in some patients.[16] For patients in whom the initial infection cannot be resolved, the disease typically follows a protracted course. Although infection is more often debilitating than fatal, fulminant respiratory failure can occur, and, if untreated, coccidioidal meningitis is nearly always fatal within 2 years.

REVIEW QUESTIONS

1. A patient in Seattle, Washington is diagnosed with community-acquired pneumonia that developed 2 weeks after attending a business conference in Phoenix, Arizona. The likelihood that the etiology of the infection is *Coccidioides* is:

A. 80%
B. 30%
C. 15%
D. 5%
E. Less than 1%

Answer: B Two prospective studies demonstrate this frequency within the endemic region. It is equally applicable to visitors with symptoms soon after endemic exposure.

2. A 56-year-old man, a long-time smoker who lives in the California central valley, is found to have a 2.5-cm right middle lobe nodule. He was diagnosed with valley fever 5 years ago. Evaluation should include:

A. Repeated CT scans every 6 months to determine if the nodule is enlarging.
B. Initiation of fluconazole 400 mg/day and re-evaluation for regression of the nodule.
C. Obtain tissue for microscopic examination, either by bronchoscopy or percutaneous fine-needle aspiration.
D. Perform edge resection by thoracotomy.
E. Obtain a coccidioidal serology.

Answer: C There is insufficient information to assume the nodule is related to the prior coccidioidal diagnosis. It is too large to simply observe in a patient at risk for lung cancer. There is a high probability (perhaps 50%) that the nodule is not cancer, which would make the thoracotomy overly invasive without first establishing that the lesion is a cancer. Antifungal treatment would be unlikely to affect the nodule size. Whether the coccidioidal serologic test was positive should not change the need for tissue to exclude cancer.

3. A patient develops coccidioidal meningitis, is started on fluconazole 400 mg/day and over the next 6 months completely resolves her symptoms. An MRI of the brain was never abnormal, and a follow-up lumbar puncture produces CSF with essentially normal laboratory values. Treatment is continued unchanged for 2 years. At that point, management should be:

A. Stop treatment and follow-closely for possible relapse.
B. Stop treatment only if reevaluation shows no evidence of pulmonary or extrapulmonary infection.
C. Continue treatment at a reduced dose.
D. Continue treatment at the current dosage indefinitely

Answer: D Relapses are frequent and potentially lethal. Even reducing the dose may lead to recurrence of infection.

4. A patient is found to have a thin-walled pulmonary cavity, 2 cm in diameter, abutting the visceral pleura in the left upper lobe. He has no symptoms associated with this. A coccidioidal complement fixation antibody test of serum returns a positive result at a 1 : 4 dilution. Management of this situation should be:

A. No treatment, with periodic reassessment with chest x-ray.
B. Start fluconazole 400 mg/day to see if the cavity responds to treatment by decreasing.
C. Start amphotericin B intravenously.
D. Resect the cavity by visually assisted transthoracic surgery (VATS) to avert the risk for cavity rupture and consequent bronchopleural fistula formation.

Answer: A Such cavities often follow an uncomplicated course. Treatment with antifungal agents does not affect the likelihood of their getting smaller. Although rupture occurs in some, most do not.

5. A woman in El Paso, Texas develops arthralgias in both ankles and erythema nodosum. She has no pulmonary symptoms. An enzyme immunosorbant assay for coccidioidal antibodies is positive for IgG antibodies. Which of the following is the *best* assessment of this current illness?

A. Because the EIA IgG finding indicates past infection, the etiology still is not clear.
B. This is likely the "desert rheumatism syndrome" of coccidioidomycosis.
C. The skin lesions are likely to become progressive destructive lesions, and biopsy should be performed to determine how best to treat the patient.
D. This presentation increases the likelihood that the patient eventually will develop serious complications.

Answer: B Because coccidioidal serology findings usually return to undetectable levels months following a coccidioidal infection, B is the correct answer. Patients with *E. nodosum* seldom develop future complications. A biopsy sample of the skin lesions would show an inflammatory process that is not specific to a particular etiology.

334

BLASTOMYCOSIS

CAROL A. KAUFFMAN

DEFINITION

Blastomycosis (North American blastomycosis) is an endemic mycosis that primarily causes infection of the lungs and skin and, less commonly, infection of the osteoarticular and genitourinary systems.[1]

The Pathogen

Blastomyces dermatitidis is a thermally dimorphic fungus. In the environment in the mold phase, the organism produces conidia, which when aerosolized and inhaled cause infection. At 37°C on culture media and in tissues, the organism is a yeast that is 5 to 20 µm in diameter, has a thick refractile cell wall, and produces single broad-based buds (Fig. 334-1)

EPIDEMIOLOGY

B. dermatitidis exists in many diverse geographic areas worldwide, but most cases of blastomycosis are reported from the south central and north central regions of the United States[2] and the Canadian provinces surrounding the Great Lakes. The natural niche of *B. dermatitidis* is thought to be soil and decaying vegetation, especially in areas associated with rivers and lakes. Although most cases occur sporadically, several well-described outbreaks have occurred in association with activities along waterways. The largest community outbreak was reported in 2009 and 2010 in Wisconsin, with geographic and ethnic clustering likely related to multifocal environmental sources.[3] The typical patient in whom blastomycosis develops is a middle-aged man who has an outdoor occupation or hobby. The association of blastomycosis developing in both hunters and their dogs is well known in endemic areas.

PATHOBIOLOGY

After the inhalation of conidia, *B. dermatitidis* transforms into the yeast phase and causes pulmonary infection. Although many patients manifest only pulmonary symptoms, others have cutaneous lesions in the absence of other organ involvement or have disseminated infection. It is likely that most patients have asymptomatic hematogenous dissemination after the initial pulmonary infection. Thus, cutaneous lesions should be viewed as a manifestation of hematogenous spread of the organism. Except in rare instances, blastomycosis is not acquired by inoculation. Cellular immunity involving T lymphocytes and macrophages is an important component of the host response to infection with *B. dermatitidis,* but neutrophils also play a role. Most patients with blastomycosis are healthy hosts. Patients who are immunosuppressed are more likely to have severe disease. Infection in an immunosuppressed host can occur after new exposure to *B. dermatitidis* or from reactivation of a latent focus of infection acquired years earlier.[4]

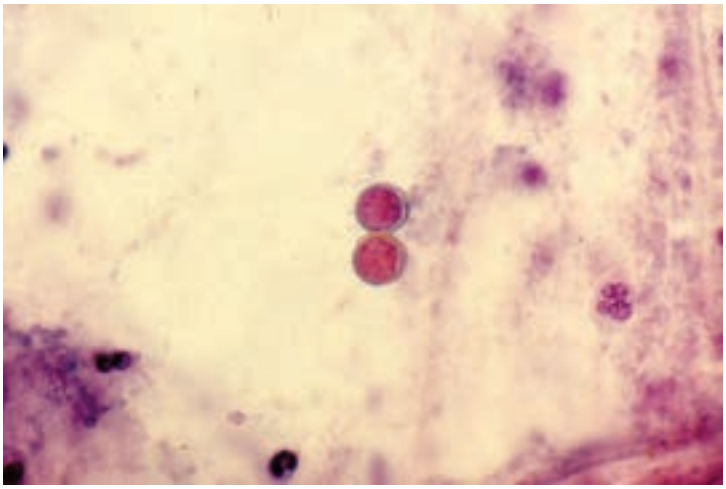

FIGURE 334-1. Papanicolaou stain of sputum showing a thick-walled yeast with broad-based budding typical of Blastomyces dermatitidis.

CLINICAL MANIFESTATIONS

Pulmonary

Most patients with acute pulmonary blastomycosis are asymptomatic or are thought to have community-acquired pneumonia. Patients with acute pneumonia have fever, malaise, a nonproductive cough, and a pulmonary infiltrate that shows lobar or multilobar patchy or nodular infiltrates on chest radiographs. Development of skin lesions is a strong clue for blastomycosis. Chronic pulmonary blastomycosis must be differentiated from tuberculosis, other fungal infections, and lung cancer.[5] Fever, night sweats, weight loss, fatigue, cough, sputum production, hemoptysis, and dyspnea are commonly noted. On chest radiograph the lesions are cavitary, nodular, fibrotic, or mass-like in appearance. Hilar and mediastinal lymphadenopathy and pleural effusions are not commonly seen. Overwhelming pulmonary disease with acute respiratory distress syndrome (ARDS) occurs infrequently but has a high mortality rate. Whether this is due to inhalation of a large number of conidia or to an exuberant host response is not known. Given improvement in some patients with corticosteroids, the latter may be important.

Disseminated Infection

Cutaneous lesions are the most common manifestation of disseminated blastomycosis. The lesions are usually well-circumscribed, painless papules, nodules, or plaques that become verrucous and develop multiple punctate draining areas in the center. Some patients have predominantly ulcerative lesions. Cutaneous lesions, sometimes single but more often multiple, are most common on the face and extremities but can appear anywhere. The skin lesions of blastomycosis clinically mimic those associated with nontuberculous mycobacteria, other fungal infections, pyoderma gangrenosum, and bromide use. An uncommon manifestation, seen more often in immunocompromised patients, is the appearance of hundreds of pustular lesions that readily reveal the organism when aspirated.

Another manifestation of disseminated blastomycosis is osteoarticular involvement. Osteomyelitis can be associated with contiguous skin lesions or can appear at sites distant from cutaneous lesions. It is helpful to obtain a bone scan in all patients with disseminated blastomycosis because of the propensity of the organism to infect bone. Genitourinary involvement may be asymptomatic or be associated with signs of prostatism and the presence of a nodule on digital examination. Infrequently occurring findings include laryngeal and oropharyngeal nodules; ocular lesions; central nervous system (CNS) involvement, either meningitis or intracerebral mass lesions; and dissemination to the liver, spleen, and lymph nodes.

DIAGNOSIS

The definitive diagnostic test for blastomycosis is growth of the organism from an aspirate, tissue biopsy specimen, sputum, or body fluid. Urine obtained before and after prostatic massage should be sent for fungal culture in those with disseminated blastomycosis. The mold phase takes several weeks to grow at room temperature. Once growth has occurred, the organism can be rapidly identified as *B. dermatitidis* with a highly specific and sensitive DNA probe. Histopathologic examination of cutaneous or pulmonary lesions, cytologic examination of sputum, bronchoalveolar lavage fluid, or other tissue fluids, and calcofluor fluorescent staining of sputum or purulent material from pustular lesions should be performed to look for the distinctive large, thick-walled yeast with a single broad-based bud. Identification of characteristic organisms allows a tentative diagnosis of blastomycosis and initiation of antifungal therapy before culture results are known. An enzyme immunoassay for *B. dermatitidis* cell wall antigens can be performed on urine and serum and is a useful rapid diagnostic test in patients who have severe pulmonary or disseminated blastomycosis.[6] Because *B. dermatitidis* and *H. capsulatum* share many cell wall antigens, this assay is often positive in patients with histoplasmosis, as well as in those with blastomycosis. Antibody tests for blastomycosis are neither sensitive nor specific. Polymerase chain reaction on tissue samples has proved useful if histopathology and culture are not diagnostic.[7]

TREATMENT Rx

Guidelines for the treatment of blastomycosis have been published by the Infectious Diseases Society of America (IDSA),[8] and the American Thoracic Society.[9] With the exception of patients who have acute pulmonary

blastomycosis that has totally resolved before the diagnosis is established, all patients with blastomycosis should be treated with an antifungal agent. Patients who have mild-to-moderate pulmonary or disseminated blastomycosis should be treated with itraconazole, 200 mg once or twice daily. The length of treatment is 6 to 12 months to achieve mycologic cure and prevent relapse. Fluconazole is not as effective as itraconazole. However, if the patient is unable to take itraconazole, fluconazole can be used, but the dosage should be 400 to 800 mg/day for 6 to 12 months. Voriconazole is increasingly reported to be effective in patients unable to tolerate itraconazole. Successful use of posaconazole has been reported in only a few patients. The echinocandins are not active against *B. dermatitidis* and should not be used.

Patients who have severe pulmonary or disseminated blastomycosis, all patients with CNS infection,[10] and most immunosuppressed patients should be treated initially with a lipid formulation of amphotericin B. The dosage is 3 to 5 mg/kg daily, except for CNS infection, for which 5 mg/kg daily should be used. After clinical improvement has occurred, usually within several weeks, therapy can be changed to itraconazole, 200 mg twice daily for a total of at least 12 months of therapy. For all patients who are treated with itraconazole, serum levels should be determined when steady state has been reached after 2 weeks of therapy to ensure adequate absorption. Serum concentrations should be greater than 1 µg/mL. Corticosteroids have been helpful as adjunctive therapy for patients with ARDS associated with blastomycosis, but this practice remains controversial.

PROGNOSIS

The prognosis for patients with pulmonary or disseminated blastomycosis treated with itraconazole is excellent; more than 90% are cured.[11] If relapse does occur, a second course of itraconazole is usually successful. Most reported deaths occur in patients with overwhelming pneumonia and ARDS.

REVIEW QUESTIONS

1. A 64-year-old previously healthy man from upper Michigan developed two skin lesions on his face and one on his thigh in late summer. He remembered having several days of feeling feverish with myalgias and a dry cough a few weeks before the first skin lesions appeared. He had been clearing brush around his home in early summer. On examination, he had three heaped-up, nontender lesions, two of which had punctate areas draining a small amount of purulent material on his face and left thigh. Chest radiograph revealed a left upper lobe infiltrate. Biopsy of one of the skin lesions revealed a pyogranulomatous tissue response and special stains showed thick-walled yeasts with a single broad-based budding daughter cell. The *most* likely etiology of this patient's skin lesions and pulmonary infiltrate is:

A. Coccidioidomycosis.
B. Histoplasmosis.
C. Blastomycosis.
D. Sporotrichosis.
E. Disseminated cryptococcosis.

Answer: C Blastomycosis occurs throughout the Mississippi River Valley, in the north central states around the Great Lakes, and along the St. Lawrence Seaway. Blastomycosis begins as a pulmonary infection, but this may cause few symptoms and go undetected until a skin lesion develops. The skin lesions can be ulcers, papules, nodules, or plaques and often evolve to become verrucous with punctate draining areas in the center. Biopsy of a skin lesion shows an exuberant epidermal reaction known as *pseudoepitheliomatous hyperplasia.* Special stains should be performed to look for the distinctive large round, thick-walled yeasts that have a single broad-based budding daughter cell attached, allowing a tentative diagnosis of blastomycosis. Coccidioidomycosis occurs in the desert Southwest and not the upper Midwest. The skin lesions of histoplasmosis are generally smaller papules and usually appear in patients with systemic symptoms of disseminated infection. The skin lesions of sporotrichosis are rarely disseminated; they usually occur in the distribution of the lymphatic drainage from the initial inoculation site. Skin lesions are a prominent clue to disseminated cryptococcal infection in individuals with AIDS and other immunocompromised conditions.

2. The treatment of choice for mild-to-moderate disseminated blastomycosis is:

A. Fluconazole.
B. Itraconazole.
C. Micafungin.
D. Voriconazole.
E. Amphotericin B.

Answer: B Itraconazole is the drug of choice for the treatment of most of the endemic mycoses, and the most experience has accrued with this agent. If itraconazole is not tolerated, the second choice for blastomycosis should be voriconazole, which is increasingly used for the treatment. Fluconazole is not as active, and high doses must be given if the patient is treated with this agent. Micafungin and the other echinocandins are not active against the endemic mycoses. Amphotericin B is reserved as initial therapy for severe blastomycosis.

3. A patient presents with a single skin lesion on her left cheek that yields *B. dermatitidis.* Chest radiograph reveals no pulmonary infiltrate. The most likely mechanism of infection with this organism was:

A. Inoculation when a twig scratched her cheek.
B. Ingestion of mold-contaminated unwashed vegetables.
C. Inoculation of conidia when she rubbed her face while gardening.
D. Inhalation of conidia of the mold phase from the soil.

Answer: D Blastomycosis results when conidia are inhaled into the lungs from the soil or decaying vegetation where the organism is growing. The organism is ingested by macrophages and converts into the yeast phase. Spread occurs by the hematogenous route, and the skin is the most common site of dissemination. The pulmonary infection may be healed by the time the patient presents with skin lesions. Even one skin lesion is a manifestation of hematogenous spread unless a clear-cut inoculation event has been documented. The organism is never acquired by ingestion.

4. Which is the most definitive diagnostic test for blastomycosis?

A. Culture of a skin lesion
B. PCR for *B. dermatitidis* in serum
C. Antigen detection in a sputum sample
D. Complement fixation antibody tests

Answer: A Culture is always definitive for the endemic mycoses, which are environmental organisms and never colonizers of humans. PCR can be useful if performed on tissue samples, but is not useful for serum. A *B.dermatitidis* antigen assay is available for urine and serum, but cannot be performed on sputum samples. Antibody assays are not specific or sensitive for infection with *B. dermatitidis.*

5. A patient presents with acute respiratory distress syndrome (ARDS) several weeks after returning from a hunting trip in northern Wisconsin. Bronchoalveolar lavage reveals large yeasts with single broad-based buds seen on calcofluor white stain. The most appropriate treatment would be:

A. Itraconazole, 200 mg PO twice daily
B. Lipid formulation amphotericin B, 5 mg/kg/day IV
C. Posaconazole, 400 mg PO twice daily
D. Caspofungin, 50 mg/day IV
E. Voriconazole, 200 mg PO twice daily

Answer: B Persons seriously ill with blastomycosis, which is the most likely diagnosis given the organism seen on the calcofluor stain of the BAL, require treatment with amphotericin B. Most physicians now use a lipid formulation to decrease the risks for nephrotoxicity. Oral azole agents should not be relied on for therapy in a seriously ill patient. Caspofungin and the other echinocandins are not active against *B. dermatitidis* or other endemic mycoses.

PARACOCCIDIOIDOMYCOSIS

CAROL A. KAUFFMAN

DEFINITION

Paracoccidioidomycosis (South American blastomycosis) is a subacute to chronic mycosis that is endemic in Central and South America. The disease is characterized primarily by pulmonary, mucous membrane, and cutaneous lesions, but disseminated disease also occurs.[1]

The Pathogen

Paracoccidioides brasiliensis is a thermally dimorphic fungus. In the environment and at temperatures below 35° C, the organism is a mold that produces conidia, the infectious form. In tissues and at 37° C in vitro, the organism assumes the yeast form with multiple narrow-based daughter cells attached to the mother cell.

EPIDEMIOLOGY

P. brasiliensis exists only in humid areas of Central and South America. More than 80% of cases are from Brazil. The presumed ecologic niche is in soil, but the exact conditions that favor growth of the organism have not been elucidated. The disease is most prevalent in middle-aged to elderly men from rural areas. The reason for the sexual imbalance (male-to-female ratio of 13 : 1 in many reports, but as high as 70 : 1 in one report from Colombia) is possibly related to the inhibitory effects of estrogens on transition from the mold to the yeast phase of the organism,[2] rather than solely environmental exposure. Although the disease classically develops later in life, it is likely that initial exposure occurs many years earlier. Cases seen in areas outside Central and South America have all been linked to previous residence in the endemic area.

PATHOBIOLOGY

Paracoccidioidomycosis develops after the inhalation of aerosolized conidia encountered in the environment. Once in the alveoli, the mycelial phase converts to the yeast phase. The infection may remain localized to the lungs, although it is likely that asymptomatic hematogenous dissemination occurs during most infections. In most patients, manifestations of disease do not develop at the time of the initial infection. The primary host defense mechanism against *P. brasiliensis* appears to be cell-mediated immunity, but neutrophils also play a role in host defense. The histopathologic picture includes both neutrophilic and granulomatous responses. There have been increasing reports of paracoccidioidomycosis in patients infected with human immunodeficiency virus (HIV)[3] and in other immunosuppressed patients; in these patients there is widespread dissemination, and histopathologic examination shows poorly formed granulomas. Reactivation of latent infection acquired years earlier is the presumed pathogenesis of most cases of the chronic adult form of paracoccidioidomycosis and cases that appear years after the patient has left the endemic area.

CLINICAL MANIFESTATIONS

Acute-Subacute (Juvenile) Paracoccidioidomycosis

The acute-subacute form of paracoccidioidomycosis occurs in less than 10% of patients. It is a disease of the reticuloendothelial system with widespread dissemination to the liver, spleen, lymph nodes, and bone marrow. Patients younger than 30 years typically have this form of paracoccidioidomycosis; however, older adults, especially those who are immunosuppressed, also can manifest this type of rapidly progressive disease. In patients with HIV infection, rapid progression occurs with multiple cutaneous lesions, lymphadenopathy, hepatosplenomegaly, and severe pulmonary involvement with hypoxemia.

Chronic (Adult) Paracoccidioidomycosis

Chronic paracoccidioidomycosis is slowly progressive over many years and is the form seen in more than 90% of patients. Most patients with this type of paracoccidioidomycosis are older men. Pulmonary involvement is prominent and clinically mimics tuberculosis and other chronic fungal pneumonias.[4] Radiographically, nodular, interstitial, or cavitary lesions are seen but differ from those of tuberculosis and histoplasmosis in that the infiltrates tend to be in the middle and lower lung fields rather than the apices. Many patients with the adult form of paracoccidioidomycosis also have ulcerative or nodular mucous membrane lesions, primarily in the anterior nares, the oral cavity, and the larynx; these are slowly destructive and can lead to dysphonia and stenosis of the airway. Cutaneous lesions, particularly on the face, are also common and may be papular, nodular, ulcerative, or plaquelike. The mucocutaneous lesions must be differentiated from mucocutaneous leishmaniasis and squamous cell carcinoma. Adrenal involvement has been reported in more than 90% of cases at autopsy, but adrenal insufficiency is only noted in about half.

DIAGNOSIS

Definitive diagnosis of paracoccidioidomycosis is established by growth of *P. brasiliensis* in culture. The organism may take as long as 4 weeks to grow. For seriously ill patients, direct examination of body fluids, sputum, or purulent material treated with potassium hydroxide or calcofluor fluorescent stain or histopathologic examination of tissue biopsy samples can provide a presumptive diagnosis while awaiting culture results. The characteristic appearance of *P. brasiliensis* consists of thick-walled yeast cells that have multiple small, circumferentially attached, narrow-based budding daughter yeast cells—a distinctive morphologic picture likened to a ship's steering wheel.

A variety of immunodiffusion assays, enzyme immunoassays, and complement fixation assays are available in endemic areas, but sensitivity and specificity vary greatly. The immunodiffusion assay appears to be most useful.[5] An assay for circulating cell wall antigens of *P. brasiliensis* has also been developed in endemic areas, but its role has not been established.

TREATMENT

Rx

The drug of choice for the treatment of paracoccidioidomycosis is itraconazole (200 mg/day for 6 to 12 months). Ketoconazole at a dosage of 200 to 400 mg daily for 1 year is effective and certainly less expensive than itraconazole, but the incidence of side effects is greater and relapses occur more

frequently than with itraconazole. Fluconazole is less effective and should not be used unless no other agent is available. Voriconazole has been shown to be as effective as itraconazole in a randomized open-label pilot study, and there are scattered reports of the successful use of posaconazole as salvage therapy. Sulfonamides have been used for years to treat paracoccidioidomycosis and are clearly the most inexpensive form of treatment. However, relapse rates are higher than with the azoles. Amphotericin B is effective but rarely required, except in immunosuppressed patients with life-threatening disseminated disease. Most HIV-infected patients with paracoccidioidomycosis have been treated with amphotericin B as initial therapy, followed by lifelong suppressive therapy with either itraconazole or trimethoprim-sulfamethoxazole. Adjunctive corticosteroids have been used in a few patients with severe infection and appeared to be useful, but this remains controversial.[6]

PROGNOSIS

Patients with paracoccidioidomycosis have an excellent response to antifungal therapy, with overall relapse rates of about 5% with itraconazole therapy.[7] Although HIV-infected patients respond less well. Patients who have extensive pulmonary involvement at the time of diagnosis are at high risk for progressive fibrosis despite antifungal therapy.

REVIEW QUESTIONS

1. To entertain a diagnosis of paracoccidioidomycosis, one should obtain a history of residence in:

A. The Mideast.
B. South America.
C. Southeaast Asia.
D. North America.
E. Africa.

Answer: B The geographic distribution of *Paracoccidioides brasiliensis* is in several countries in South America. It does not occur in any of the other areas listed.

2. The usual hosts in whom chronic paracoccidioidomycosis is seen are:

A. Infants.
B. Teenage girls.
C. Middle-aged men.
D. Older women.
E. Immunocompromised individuals.

Answer: C Chronic paracoccidioidomycosis is seen almost entirely in middle-aged to older men. The male-to-female ratio is usually quoted as 13 : 1, but has been reported to be as high as 70 : 1 in some countries of South America. The infection begins earlier in life but is slowly progressive, and symptoms appear in middle age. The propensity for infection to occur in men has been explained both by greater exposure to the organism and by the protective effect of estrogens on infection in women.

3. The treatment of choice for paracoccidioidomycosis is:

A. Posaconazole.
B. Amphotericin B.
C. Caspofungin.
D. Itraconazole.

Answer: D Itraconazole is the preferred treatment of paracoccidioidomycosis. There is little experience with posaconazole, but it has been shown to be effective. Caspofungin and other ecinocandins have no activity against *P. brasiliensis* or other endemic mycoses. Amphotericin B is reserved for treatment of severe infection, such as occurs in immunocompromised patients.

4. A major complication of chronic paracoccidioidomycosis in spite of antifungal therapy is:

A. Pulmonary fibrosis.
B. Granulomatous mediastinitis.
C. Constrictive pericarditis.
D. Pneumothorax.
E. Retroperitoneal fibrosis.

Answer: A Pulmonary fibrosis can progress in patients who have the chronic form of paracoccidioidomycosis, in spite of treatment. Progression is more likely in those who have more extensive pulmonary infection. Granulomatous mediastinitis occurs with histoplasmosis, but is uncommon with paracoccidioidomycosis. Constrictive pericarditis is not a complication of paracoccidioidomycosis, and pneumothorax is not commonly seen.

5. In patients who have HIV infection, paracoccidioidomycosis can be a life-threatening acute infection and should be treated with:

A. Itraconazole.
B. Voriconazole.
C. Amphotericin B.
D. Trimethoprim-sulfamethoxazole.
E. Combination antifungals.

Answer: C HIV-infected patients develop acute disseminated paracoccidioidomycosis and should be treated with amphotericin B initially. Step-down therapy to itraconazole can be given after they have improved. Trimethoprim-sulfamethoxazole is effective for paracoccidioidomycosis, but should not be used for severe infection as initial therapy. Voriconazole also is effective for paracoccidioidomycosis, but should not be used for severe infection as initial therapy.

336

CRYPTOCOCCOSIS

CAROL A. KAUFFMAN

DEFINITION

Cryptococcosis occurs most often in persons who are immunosuppressed, especially those infected with human immunodeficiency virus (HIV). Meningitis is the most common clinical manifestation, but pulmonary and other organ involvement occur as well.

The Pathogen

Among the approximately 40 species of *Cryptococcus, Cryptococcus neoformans* and, much less often, *Cryptococcus gattii* are the predominant pathogens in humans.[1] In the environment, *Cryptococcus* species exist as yeasts that have minimal capsules and are easily aerosolized and inhaled. In tissues, *C. neoformans* and *C. gattii* are enveloped by a large polysaccharide capsule that is a major virulence factor. *C. neoformans* is found in the soil and grows well in avian droppings that have high nitrogen content. *C. gattii* is more restricted geographically and has been described mostly in Australia and Southeast Asia, where the ecological niche is the eucalyptus tree. However, the epidemiology of *C. gattii* is evolving with its emergence in the past decade in the Pacific Northwest and now in other areas of North America; the ecologic niche has not been definitively established in these areas. Most of this chapter focuses on *C. neoformans,* which is more common and which has been studied extensively.

EPIDEMIOLOGY

Before the widespread availability of antiretroviral therapy (ART), cryptococcosis occurred in 5 to 10% of patients with acquired immunodeficiency syndrome (AIDS), and almost always in those with fewer than 50 CD4 cells/μL. Cryptococcosis is less commonly seen now in Europe and North America but is extremely common in Africa, where it is estimated that the prevalence among HIV-infected patients is as high as 30%.

In the non-AIDS population, cryptococcosis is a frequent opportunistic infection in patients who have received a solid organ transplant,[2] have been treated with corticosteroids, or have diabetes mellitus, renal failure, cirrhosis, or chronic pulmonary disease. For some patients, the only risk factor appears to be older age. In every reported series, separate from those dealing only with HIV infection, approximately 20% of patients have no known underlying illness. *C. gattii* most often causes illness in normal hosts.[3]

PATHOBIOLOGY

The organism is inhaled from the environment and causes pulmonary infection initially. The primary host defense at this stage is complement-dependent macrophage and neutrophil phagocytosis and killing. Natural killer cells also have the ability to kill the organism. Ultimately, however, T-cell immunity is the most important host determinant in limiting the replication of *C. neoformans*. In most normal hosts, the infection remains localized to the lungs and does not cause symptomatic infection. It is likely that a few organisms exist as walled-off subpleural granulomas in many who have had pulmonary infection. If the host becomes immunosuppressed, the organism can then reactivate and disseminate to other sites. *C. neoformans* is clearly neurotropic, and the primary disease manifestation is meningoencephalitis. However, dissemination to many organs is likely, especially in those with deficient T-cell immunity.

Virulence factors for *C. neoformans* include the capsule, which requires opsonization for efficient phagocytosis, and the production of melanin, which has been shown to occur in vivo and enables the organism to resist intracellular killing. Both of these factors may help explain the virulence of the organism once it has reached the central nervous system (CNS). Antibody and complement levels are low in the brain, and thus phagocytosis of the organism is minimal. Brain tissue provides high concentrations of substrates, such as catecholamines, for the phenol oxidase enzyme systems of *C. neoformans* that produce melanin, thereby aiding survival of the organism.

CLINICAL MANIFESTATIONS

Central Nervous System Infection

The most common manifestation of cryptococcosis is CNS infection.[4] The typical picture is subacute to chronic meningoencephalitis. Patients usually have increasingly severe headaches over a period of several weeks. Other symptoms and signs include nuchal rigidity, lethargy, personality changes, confusion, visual abnormalities (photophobia, diplopia, decreased visual acuity, papilledema, extraocular nerve palsies), and nausea and vomiting. Less commonly, hearing loss, ataxia, and seizures occur. Fever is present in only approximately half the patients. Elderly persons with cryptococcal meningitis may have just dementia, without other neurologic findings. AIDS patients often have subtle CNS symptoms but usually have fever and other constitutional symptoms and rapidly manifest signs of dissemination.

Pulmonary Infection

In non-HIV-infected patients, the most common underlying risk factor for pulmonary cryptococcal infection is chronic obstructive pulmonary disease, followed by corticosteroid use and receipt of a solid organ transplant. *C. neoformans* may merely be an airway colonizer in some patients; in others, symptomatic infection, manifested by fever, cough, and dyspnea, requires treatment with an antifungal agent. The typical lesion noted with pulmonary cryptococcosis is a pleural-based nodular lesion. However, patchy pneumonitis, multiple nodular lesions, cavitary lesions, masslike lesions, and diffuse pulmonary infiltrates have all been noted with pulmonary cryptococcosis. Patients with advanced HIV infection are likely to have diffuse infiltrates that can progress rapidly to acute respiratory insufficiency. All immunosuppressed patients who have pulmonary cryptococcosis and all patients with any CNS symptoms should undergo lumbar puncture to be certain that meningitis is not present. Whether normal hosts with isolated pulmonary cryptococcosis and negative serum antigen tests require lumbar puncture remains controversial.

Involvement of Other Organs

C. neoformans has been reported to infect most organs during the course of disseminated infection, especially in AIDS patients. Skin lesions are a prominent clue to dissemination. Papules that resemble molluscum contagiosum or an acneiform rash, nodules, ulcers, plaques, draining sinuses, and cellulitis have all been reported. Focal involvement can occur in the prostate and other organs of the genitourinary tract, in osteoarticular structures, in the breast, and in the eye, larynx, and other head and neck structures. The prostate, in particular, has been noted as a sanctuary from which persisting organisms can later disseminate.

DIAGNOSIS

The diagnosis of cryptococcosis is established when the yeast is grown in culture. Appropriate specimens for culture include cerebrospinal fluid (CSF),

blood, sputum, material from skin lesions, and other body fluids or tissues that appear to be infected. The organism grows in several days on most standard agar media. Most automated blood culture systems allow rapid growth of *C. neoformans*. Visualization of the capsule and performance of a few simple tests differentiate *C. neoformans* from other yeasts. Tissue biopsy shows the 5- to 10-µm yeast surrounded by the capsule. Definitive diagnosis of cryptococcosis can be made by mucicarmine staining, which selectively stains the polysaccharide capsule a deep rose color. In CSF or other body fluids, an India ink preparation allows visualization of the budding yeast cells surrounded by the large capsule, but this test is not currently done by many laboratories.

The latex agglutination assay for cryptococcal polysaccharide antigen (CRAG) is a highly sensitive and specific diagnostic test.[5] CRAG is positive in CSF in almost 100% and in serum in about 75% of patients who have meningitis. In AIDS patients, serum CRAG is almost always positive and is an excellent screening tool, and in these patients, titers in both CSF and serum are exceptionally high because of the enormous burden of organisms. In non-AIDS patients who have pulmonary cryptococcosis, the CRAG assay is positive in only 25 to 50% of cases. False-positive results with the CRAG assay are uncommon but have been reported in patients with *Trichosporon asahii* infections because of cross-reacting antigens shared by both fungi.

A newer technique, lateral flow analysis (LFA) to detect cryptococcal polysaccharide antigen has been developed as a dipstick assay, similar to that of pregnancy tests, that can be performed in serum or urine at the point of care by clinicians caring for the patient. This technique appears to be as sensitive and specific as the classic CRAG test.

The CSF of patients with cryptococcal meningitis typically has an increased number of white blood cells (but rarely >500/µL), a predominance of lymphocytes (although neutrophils are sometimes prominent early in the course), elevated protein, and decreased glucose. AIDS patients most often have normal or only mildly abnormal findings as a result of their markedly defective immune response. Despite normal CSF findings with regard to cells, protein, and glucose, every AIDS patient with a headache must have a CRAG or LFA test and culture performed on CSF. It is extremely important that an opening pressure be obtained when lumbar puncture is performed. Especially in AIDS patients, extremely high intracranial pressure (>350 mm H_2O) has been associated with poor outcomes and must be aggressively lowered.

All patients with cryptococcal meningitis should undergo computed tomography or magnetic resonance imaging of the brain to look for mass lesions and to assess ventricular size. Obstructive hydrocephalus is uncommon but requires a shunting procedure to decrease the pressure. More commonly, the increased intracranial pressure with cryptococcal infection is associated with normal-sized ventricles and is due to blockage at the arachnoid villi or increased brain edema (or both), perhaps related to the osmotic effect of the polysaccharide capsule. Different methods for reducing pressure are used in this situation.

TREATMENT

Rx

Guidelines for the treatment of cryptococcal infection have been published by the Infectious Diseases Society of America (IDSA).

Central Nervous System Infection

Early multicenter randomized trials in non-AIDS patients showed superiority of the combination of amphotericin B and flucytosine for 6 weeks over amphotericin B alone for 10 weeks. Subsequent randomized trials in the azole era have been performed only in the AIDS population. They have confirmed the benefit of flucytosine added to amphotericin B for induction therapy and have shown that initial therapy with fluconazole alone or with amphotericin B alone is not as effective as therapy with amphotericin B and flucytosine. The combination of amphotericin B and flucytosine has been shown to be the most rapidly fungicidal regimen, and increasing number of reports have documented that rapid fungicidal activity that clears the organism from the CSF is associated with improved outcomes. Regimens using amphotericin B with fluconazole or flucytosine with fluconazole are less effective but reasonable alternatives when the preferred regimen of amphotericin B plus flucytosine is not available.

Current recommendations for AIDS patients are to give induction therapy with intravenous amphotericin B deoxycholate, 0.7 to 1 mg/kg daily, combined with oral flucytosine, 100 mg/kg daily given in four divided doses for at least 2 weeks, followed by consolidation therapy with oral fluconazole, 400 mg daily for a minimum of 8 weeks, and then suppressive therapy with fluconazole, 200 mg daily. Lipid formulations of amphotericin B at daily dosages of 3 to 5 mg/kg daily are increasingly used because they are less nephrotoxic; however, they are often not available in developing countries. Induction therapy with amphotericin B (1 mg/kg per day for 4 weeks) plus flucytosine (100 mg/kg per day for 2 weeks) is associated with improved survival among HIV-positive patients with cryptococcal meningitis compared with either amphotericin B alone or amphotericin B plus fluconazole (400 mg twice daily for 2 weeks).

For patients who have undergone 12 months of antifungal therapy, who have $CD4^+$ counts higher than 100/µL, and whose HIV viral load is undetectable on antiretroviral therapy, the suppressive therapy can be stopped. Suppressive therapy with fluconazole for transplant recipients is recommended for 6 to 12 months. The IDSA guideline recommendations[6] for non-HIV-infected, non–transplant recipients are to treat with amphotericin B deoxycholate, 0.7 to 1.0 mg/kg daily, plus flucytosine, 100 mg/kg daily, in four divided doses for at least 4 weeks for induction therapy, followed by consolidation therapy with fluconazole, 400 mg daily for 8 weeks, and suppressive therapy with fluconazole, 200 mg daily for 6 to 12 months. Again, many physicians use lipid formulations of amphotericin B, 3 to 5 mg/kg daily, in this population, many of whom are older and have underlying medical illnesses.

Only one treatment trial used voriconazole in combination with amphotericin B, and there are just a few case reports on the use of voriconazole and posaconazole for salvage treatment of cryptococcal meningitis. These are reasonable alternatives if no other azoles can be used. The echinocandins are not active against *C. neoformans* and should not be used.

A significant observation from the AIDS treatment trials was the role of increased intracranial pressure as a cause of early death from cryptococcal meningitis. An aggressive approach to the diagnosis and treatment of increased intracranial pressure in both AIDS and non-AIDS patients is mandatory and should include daily lumbar puncture or placement of a temporary lumbar drain or ventriculostomy until the opening pressure remains lower than 190 mm H_2O. Treatment with corticosteroids, acetazolamide, or mannitol has not proved efficacious in this setting.

Another issue that has emerged is the development of immune reconstitution inflammatory syndrome (IRIS), which can occur in patients with AIDS who are receiving effective antiretroviral therapy (ART) that increases the CD4 count (Chapter 395). Symptoms of meningitis reappear and are due to the inflammatory response and not to a relapse of disease. In a recently reported trial, HIV-positive patients with cryptococcal meningitis who had not previously received ART were randomized to initiate either earlier ART (1 to 2 weeks after meningitis diagnosis) or deferred ART (5 weeks after diagnosis), with all patients treated for cryptococcal meningitis with amphotericin B (0.7 to 1.0 mg/kg/day) plus fluconazole (800 mg per day) for 14 days, followed by fluconazole consolidation therapy. Although the incidence of recognized cryptococcal IRIS did not differ significantly between the earlier and deferred ART groups, deferring ART for 5 weeks after diagnosis was associated with significantly improved survival, especially among patients with a paucity of CSF white cells. IRIS can also occur in transplant recipients in whom immunosuppressive therapy is decreased rapidly. Generally, no specific therapy is needed for mild IRIS, but sometimes corticosteroids are needed if increased intracranial pressure occurs.

Pulmonary and Other Nonmeningeal Infections

Treatment of nonmeningeal cryptococcosis depends on the severity of the infection. Many patients with isolated pulmonary or other focal infections are not severely ill, and oral fluconazole, 400 mg daily for 6 to 12 months, is recommended. For patients who are severely ill, therapy is the same as noted earlier for CNS infection.

PROGNOSIS

The outcome for both AIDS and non-AIDS patients with cryptococcal meningitis has improved markedly in the developed world. However, in Africa the mortality from cryptococcal meningitis in AIDS patients approaches 100% in some areas because of lack of access to specific therapy. Dementia, which usually occurs in older patients, hearing loss, and visual loss may not be reversed even though mycologic cure is achieved. Fluconazole, 200 mg three times per week, is safe and effective as primary prophylaxis against cryptococcal disease in cryptococcal antigen-negative, HIV-infected adults with CD4 counts lower than 200 cells/µL, both before and during early antiretroviral treatment.

REVIEW QUESTIONS

1. A patient with cryptococcal meningitis had improvement of headache and nausea following the initial diagnostic lumbar puncture. Amphotericin B and flucytosine were begun immediately after the tap, but 2 days later, he has recurrence of these symptoms and also has some blurring of vision. What is the likely reason for the return of his symptoms?

A. Reaction to amphotericin B
B. Secondary bacterial infection related to the lumbar puncture
C. Increased intracranial pressure
D. Resistance of the organism to amphotericin B
E. Resistance of the organism to flucytosine

Answer: C This is a typical picture in that the lumbar puncture takes off cerebrospinal fluid and relieves some of the pressure briefly. Increased intracranial pressure is most likely due to blockage of the arachnoid villi and/or increased brain edema and is thought to be secondary to the large capsule surrounding the yeast. Resistance to amphotericin B and flucytosine is very uncommon. The symptoms, especially blurring of vision, are unlikely due to amphotericin B toxicity. Secondary bacterial infection after a spinal tap is also rare.

2. What is the treatment for the condition noted in question 1?

A. Perform repeated lumbar punctures to bring down the increased pressure
B. Change therapy to fluconazole
C. Continue amphotericin B but stop flucytosine
D. Add ceftriaxone 2 g every 12 hours
E. Symptomatic treatment only

Answer: A Treatment of increased intracranial pressure, which is seen commonly with cryptococcal meningitis, is to perform repeated spinal taps until the pressure remains low. There is no reason to change antifungal therapy or add an antibiotic.

3. Which of the following is the preferred treatment for an AIDS patient with cryptococcal meningitis?

A. Fluconazole and flucytosine
B. Voriconazole and amphotericin B
C. Posaconazole and caspofungin
D. Amphotericin B and flucytosine
E. Fluconazole

Answer: D Several randomized blind and open-label treatment trials have shown the benefit of combined therapy with amphotericin B and flucytosine for cryptococcal meningitis. Echinocandins have no role in treating this infection. The other suggested regimens are inferior to amphotericin B and flucytosine.

4. What is the major host defense against *Cryptococcus* species?

A. Immunoglobulin A antibody
B. Natural killer cells
C. T lymphocytes
D. Complement
E. Neutrophils

Answer: C Patients who have deficient T-cell immunity, such as AIDS patients with low CD4 cell counts, transplant recipients, and patients on corticosteroids, are at high risk for developing infection with *Cryptococcus.*

5. The diagnosis of cryptococcal meningitis can be made in a few hours by performing which of the following?

A. Culture of cerebrospinal fluid
B. Magnetic resonance imaging
C. Lateral flow dipstick test for cryptococcal antigen
D. Cryptococcal immunoglobulin M antibody assay
E. Gram stain of cerebrospinal fluid

Answer: C Culture is definitive but takes several days. Antibody assays for *Cryptococcus neoformans* are not helpful for diagnosis. Magnetic resonance imaging may show brain abscesses and meningeal enhancement, but these are not specific for cryptococcosis. The dipstick method for detecting antigen in cerebrospinal fluid is a rapid, sensitive, and specific test to make the diagnosis of cryptococcal meningitis. An India ink preparation (but not Gram stain) allows visualization of the budding yeast cells surrounded by the large capsule, but this test is not currently done by many laboratories.

337

SPOROTRICHOSIS

CAROL A. KAUFFMAN

DEFINITION

Sporotrichosis is a subacute or chronic infection that is usually localized to cutaneous and lymphocutaneous structures, but pulmonary, osteoarticular, and disseminated infection can occur in patients who have certain underlying diseases.

The Pathogen

Sporothrix schenckii is a thermally dimorphic fungus. In the environment at temperatures lower than 35° to 37° C, the organism is a mold and produces conidia, the infectious form. In tissues and at 35° to 37° C, *S. schenckii* transforms into the yeast phase; the yeasts are 4 to 6 μm in diameter; are cigar shaped, round, or oval; and reproduce by budding.

EPIDEMIOLOGY

S. schenckii is found worldwide in climates ranging from temperate to tropical.[1] The organism exists in a variety of environmental niches, including soil, sphagnum moss, hay, decaying wood, and other vegetation. Infection is seen almost entirely in persons whose vocation, avocation, or living condition brings them into contact with the organism in the environment. Landscaping activities, gardening, farming, and motor vehicle collisions have been associated with sporotrichosis. Inhalation of *S. schenckii* conidia occurs less commonly and results in pulmonary and, rarely, disseminated sporotrichosis. Most cases of sporotrichosis are sporadic, but outbreaks have been described. An extensive outbreak extending over many years in Rio de Janeiro and occurring mostly in children and women has been traced to infected domestic cats.

PATHOBIOLOGY

Infection is almost always acquired by inoculation of conidia and remains localized to the immediate and contiguous cutaneous, subcutaneous, and lymphatic structures. Some strains of *S. schenckii* grow poorly at temperatures higher than 35° C; these strains usually cause fixed cutaneous lesions without lymphatic spread. The typical host response to infection with *S. schenckii* is a mixed neutrophilic and granulomatous reaction. Antibody is not protective; cell-mediated immunity is important in containing the infection. In individuals who have underlying illnesses, including alcoholism, diabetes mellitus, and chronic obstructive pulmonary disease, *S. schenckii* is more likely to involve osteoarticular structures and the lungs. Widespread dissemination develops in persons infected with human immunodeficiency virus (HIV) but is a distinctly unusual event in normal hosts.[2]

CLINICAL MANIFESTATIONS

Lymphocutaneous

Days to weeks after inoculation of *S. schenckii* conidia, a papular lesion develops at the inoculation site; the lesion becomes nodular and often ulcerates (Fig. 337-1). Drainage is not grossly purulent, and the lesion is not terribly painful. Similar lesions occur along the lymphatic distribution proximal to the primary lesion. Verrucous or ulcerative fixed cutaneous lesions do not exhibit lymphatic extension. The differential diagnosis of lymphocutaneous sporotrichosis includes *Nocardia* infections (Chapter 330), particularly *Nocardia brasiliensis*; atypical mycobacterial infections (Chapter 325), especially *Mycobacterium marinum*; *Leishmania brasiliensis* infections (Chapter 348); and tularemia (Chapter 311).

Visceral and Osteoarticular

Pulmonary sporotrichosis[3] occurs most often in middle-aged men who have chronic pulmonary disease and abuse alcohol. Fever, night sweats, weight loss, fatigue, dyspnea, cough, purulent sputum, and hemoptysis are common. Chest radiographs show unilateral or bilateral upper lobe cavities with variable amounts of fibrosis and nodular lesions. The disease mimics reactivation tuberculosis in many aspects. Osteoarticular sporotrichosis is found most often in middle-aged men and occurs more frequently in alcoholics. Infection may involve one or multiple joints; the joints most commonly affected are the knee, elbow, wrist, and ankle. Isolated bursitis, tenosynovitis, and nerve entrapment syndromes have been reported. Osteoarticular infection can follow local inoculation, but in most patients this occurs secondary to hematogenous spread. Isolated case reports document sporotrichosis involving the pericardium, eye, perirectal tissues, larynx, breast, epididymis, spleen, liver, bone marrow, lymph nodes, and meninges. Disseminated sporotrichosis, manifested as widespread ulcerative cutaneous lesions with or without visceral involvement, is uncommon; most cases have been reported in patients with advanced HIV infection.

DIAGNOSIS

Growth of *S. schenckii* from culture of material aspirated from a lesion, a tissue biopsy specimen, sputum, or body fluid is the most effective method of establishing the diagnosis of sporotrichosis. Growth of the mold phase of the organism is usually evident within a few days. Histopathologic examination of biopsy material shows a mixed granulomatous and pyogenic process; however, the organisms are often present in small numbers and are frequently not visualized. Serology is not useful in the diagnosis of sporotrichosis. Polymerase chain reaction testing has been used to confirm the diagnosis[4] but must be obtained at a fungal reference laboratory.

TREATMENT

Rx

Because sporotrichosis is usually a localized subacute to chronic infection, oral antifungal agents are preferred; amphotericin B is reserved for severe visceral infections. Guidelines for the management of sporotrichosis have been published by the Infectious Diseases Society of America.[5] Itraconazole is the drug of choice for lymphocutaneous sporotrichosis.[6] The usual dosage is 200 mg daily, and treatment should continue for several weeks after all lesions have disappeared, generally for a total of 3 to 6 months. Saturated solution of potassium iodide (SSKI) has been used to treat sporotrichosis for almost a century. The initial dose is 5 to 10 drops three times daily in water or juice, with the dose increasing over a period of several weeks to a maximum of 40 to 50 drops three times daily. SSKI has many side effects, including salivary gland swelling, metallic taste, rash, and fever; the only advantage is that it is inexpensive. Fluconazole is less effective than itraconazole but for occasional patients can be used at a dosage of 400 to 800 mg daily. Voriconazole is not active against *S. schenckii*, and there is minimal experience using

posaconazole. Terbinafine appears to be effective for sporotrichosis at a dosage of 500 mg twice daily. Local hyperthermia, induced by a variety of different warming devices or baths, has been shown to be effective in some patients with fixed cutaneous lesions.

Osteoarticular and pulmonary sporotrichosis are usually treated with itraconazole, 200 mg twice daily for 1 to 2 years. Other azoles are less effective, and SSKI is ineffective. In a seriously ill patient with pulmonary sporotrichosis, a lipid formulation of amphotericin B at a dosage of 3 to 5 mg/kg daily should be used as initial therapy. After the patient has shown improvement, therapy can be changed to itraconazole. A lipid formulation of amphotericin B, at a dosage of 3 to 5 mg/kg daily, is the drug of choice for disseminated sporotrichosis. Therapy can be changed to itraconazole, 200 mg twice daily, once the patient has stabilized. Patients with HIV infection and disseminated sporotrichosis should remain on lifelong maintenance therapy with itraconazole, 200 mg daily.

For all patients who are treated with itraconazole, serum levels should be determined when steady state has been reached after 2 weeks of therapy to ensure adequate absorption. Serum concentrations should be greater than 1 µg/mL.

PROGNOSIS

The prognosis for patients with cutaneous and lymphocutaneous sporotrichosis is excellent. Almost all patients are cured with one course of therapy; relapses occur in only a small proportion of patients. Extracutaneous forms of sporotrichosis do not respond well to therapy, partly because of delays in diagnosis and partly because of the underlying diseases that are frequently found in those who have extracutaneous sporotrichosis. The outcome of disseminated sporotrichosis in patients with HIV infection has improved in recent years with effective antiretroviral therapy.

REVIEW QUESTIONS

1. A 26-year-old man from Michigan had a motorcycle collision; he was thrown off and scraped his left shoulder in the dirt. Two weeks later, he developed a nodular lesion at the site of the injury. This ulcerated, and then several other nodular lesions that became ulcerated appeared proximal to the initial lesion over the next 3 weeks. He had no systemic symptoms or signs of infection. What is the most likely organism causing this infection?

A. *Leishmania brasiliensis*
B. *Mycobacterium marinum*
C. *Nocardia asteroides*
D. *Sporothrix schenckii*

Answer: D This is a typical picture of lymphocutaneous sporotrichosis due to inoculation of *S. schenckii* from soil into the skin and subcutaneous tissues. Days to weeks after inoculation, a papule develops at the site of inoculation. The primary lesion can become nodular, but most often, it ulcerates. The drainage is not grossly purulent and has no odor, and the lesion is not terribly painful. *M. marinum* is usually associated with water exposure. *L. brasiliensis* is not found in North America. *Nocardia* species usually cause infection in immunocompromised hosts.

2. Which of the following is the most appropriate method for establishing the diagnosis of sporotrichosis?

A. Culture of the fungus from a skin lesion
B. Polymerase chain reaction (PCR) on a serum sample
C. Antibody testing
D. Antigen assay in urine
E. Histopathology

Answer: A There is no sensitive or specific antibody or antigen assay for *S. schenckii*. PCR can be performed at reference laboratories on tissue, but not on serum. Histopathology of biopsy material shows a mixed granulomatous and pyogenic process, but the organisms are often present in small numbers and frequently not visualized. Culture of a lesion is the definitive diagnostic procedure for sporotrichosis.

3. Which of the following is the treatment of choice for lymphocutaneous sporotrichosis?

A. Posaconazole
B. Itraconazole
C. Voriconazole
D. Fluconazole
E. Saturated solution of potassium iodide (SSKI)

Answer: B Itraconazole is the treatment of choice for lymphocutaneous sporotrichosis. Fluconazole has some activity, but large doses are needed to be effective. Voriconazole does not have activity against *S. schenckii*, and there are minimal data with posaconazole. SSKI has been used to treat sporotrichosis for almost a century, but it has many side effects, and its only advantage is that it is not expensive.

4. Which animal is most often implicated in zoonotic transmission of *S. schenckii* to humans?

A. Armadillos
B. Dogs
C. Pigs
D. Cats
E. Birds

Answer: D Cats have been associated with an ongoing outbreak since 1998 of sporotrichosis in Rio de Janeiro; this outbreak involves mostly children and women who care for the cats, which are infected and generally have a high burden of organisms. Dogs have only occasionally been involved in transmission of sporotrichosis to humans. Armadillos can transmit *S. schenckii* to humans by inoculating the organisms from dirt on their claws. Pigs and birds have not transmitted *S. schenckii*.

5. Saturated solution of potassium iodide (SSKI) is effective in treating which manifestation of sporotrichosis?

A. Osteoarticular
B. Pulmonary
C. Lymphocutaneous
D. Disseminated
E. Breast

Answer: C SSKI has been used for a century to treat sporotrichosis but is only effective against the cutaneous and lymphocutaneous forms. Pulmonary, osteoarticular, and disseminated infection, including unusual sites like breast, must be treated with either itraconazole or amphotericin B.

338

CANDIDIASIS

CAROL A. KAUFFMAN

DEFINITION

Candidiasis encompasses a wide variety of clinical syndromes caused by yeasts of the genus *Candida.* Of the species that cause infection in humans, *Candida albicans* is the most common; *Candida glabrata, Candida parapsilosis,* and *Candida tropicalis* are responsible for most of the remaining infections. Organisms such as *Candida krusei, Candida lusitaniae,* and *Candida guilliermondii* are less common causes of infection.

The Pathogen

Candida species are 2- to 6-µm yeastlike organisms that reproduce by budding. Most species, with the exception of *C. glabrata,* form pseudohyphae (elongated buds that remain attached to the mother cell) and hyphae in tissues.

Candida species cause a wide spectrum of diseases ranging in severity from localized mucous membrane infection to life-threatening disseminated disease. The major determinant of the severity of infection is the host's immune response. Local infections are often related to overgrowth of *Candida* as a result of changes in the normal microbiota. Invasive infections that remain within an organ system, such as urinary tract infections, usually occur because of local anatomic abnormalities. In an immunosuppressed host, especially a patient with neutropenia, widespread visceral dissemination is common.

EPIDEMIOLOGY

Candida species reside normally in the gastrointestinal and genitourinary tracts and on the skin. As colonizers, *Candida* species do not cause infection unless there is a defect in host defense mechanisms or unless exogenous factors, such as antibiotic use, have upset the ecology of the normal microbiota. *C. albicans* is the species most commonly found colonizing humans; *C. glabrata* is the second most common species, and *C. tropicalis, C. parapsilosis,* and others are found less often. The species of *Candida* colonizing and infecting patients has changed in recent decades in that *C. glabrata,* a species that is increasingly resistant to fluconazole, has become a prominent pathogen in many hospitals.

Though uncommon, acquisition of *Candida* from environmental sources has been noted. The *Candida* species most often associated with transmission from contaminated fluids or devices, especially central intravenous catheters, has been *C. parapsilosis.*

Candidiasis is the most common opportunistic fungal infection as a result of both the organisms' ubiquity and the increasing number of patients with risk factors for infection with these organisms.[1] The classic immunosuppressed host at risk for serious *Candida* infections is a neutropenic patient with a hematologic malignancy who has received cytotoxic agents and corticosteroids. Increasingly, however, candidiasis is seen in patients in intensive care units (ICUs). Risk factors for the development of serious *Candida* infections in ICU patients include the use of broad-spectrum antimicrobials, indwelling central venous catheters, previous surgical procedures, renal failure, parenteral nutrition, and high Acute Physiology and Chronic Health Evaluation (APACHE) score. Certain ICU populations, especially very-low-birthweight neonates and burn victims, are at even higher risk for *Candida* infection than is the typical ICU patient.

The primary manifestation of *Candida* infection in patients with HIV/AIDS is mucocutaneous infection, primarily oropharyngeal candidiasis. The development of mucosal *Candida* infection is related to deficient T-cell immunity as reflected by a low CD4 lymphocyte count. With appropriate antiretroviral therapy, oropharyngeal candidiasis has become an uncommon opportunistic infection.

PATHOBIOLOGY

The usual mode of infection with *Candida* is egress from its normal niche into the bloodstream or other tissues; the source is usually the gastrointestinal tract, but the skin and genitourinary tract are other sources. The primary host defense in response to this event is phagocytosis and killing by neutrophils, monocytes, and macrophages. C-C chemokine receptor 2 (CCR2)-expressing inflammatory monocytes and their tissue-resident derivatives play an essential antifungal role, particularly in the first 48 hours after *Candida* infection.[2] Phagocytosis is enhanced in the presence of specific anti-*Candida* antibody and complement. Several different mechanisms are operative within neutrophils and macrophages that allow the killing of yeasts. Thus, patients who are leukopenic, especially those with chemotherapy-induced disruption of the gut mucosa, are at great risk for invasion with *Candida* species. Once *Candida* gains access to the bloodstream, widespread hematogenous dissemination is the rule. Biopsy of involved organs shows multiple microabscesses composed of neutrophils (in a host who has these cells), budding yeasts, and often pseudohyphae or hyphae. Over time, the lesions show a mixed neutrophilic and granulomatous response.

T-cell immunity is an important host defense against infection with *Candida* at mucosal surfaces. In contrast to those with neutropenia, patients with deficient T-cell immunity are at risk for persistent and recurrent mucocutaneous candidiasis, but invasive infection rarely develops.

CLINICAL MANIFESTATIONS

Mucocutaneous Candidiasis

Oropharyngeal Candidiasis

Local mucous membrane and cutaneous lesions are the most common forms of *Candida* infection. Oropharyngeal candidiasis, or *thrush* (Chapter 425), can be due to either local factors or T-cell dysfunction. Local factors include the use of broad-spectrum antimicrobials or inhaled corticosteroids, xerostomia, and radiation treatment of the head and neck. Denture stomatitis occurs frequently in persons who wear full upper dentures, especially those who do not remove their dentures at night.

Thrush secondary to T-cell dysfunction is most commonly seen in patients with HIV infection (Chapter 390) and is the most frequent opportunistic infection noted in patients with AIDS. The appearance of thrush in a

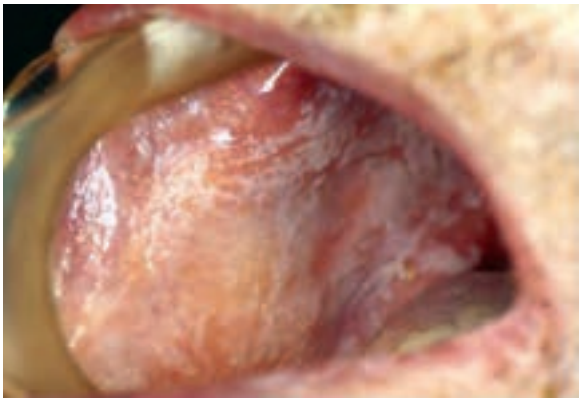

FIGURE 338-1. Thrush.

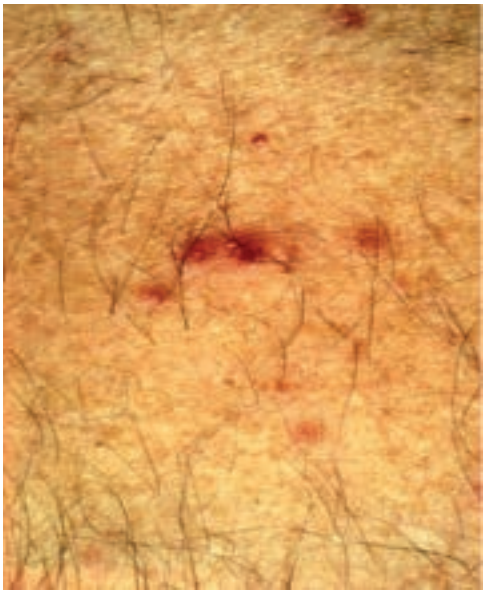

FIGURE 338-2. Skin lesions in invasive candidiasis.

previously healthy individual with no known risk factors should immediately raise suspicion of HIV infection.

Thrush manifests with white plaques on the buccal mucosa, palate, oropharynx, or tongue (Fig. 338-1). Scraping the lesions with a tongue depressor reveals an erythematous, nonulcerated mucosa under the plaques. Denture stomatitis almost always manifests as a painful erythematous palate without plaques. Angular cheilitis, or perlàche, which is the presence of painful cracks at the corners of the mouth, can occur with or without thrush.

Esophagitis

Esophagitis may accompany oropharyngeal candidiasis or may occur independently of lesions in the oropharynx (Chapter 138). The development of *Candida* esophagitis is almost always related to immune dysfunction and not simply to local factors. *Candida* esophagitis occurs in AIDS patients with low CD4 counts, patients with leukemia, and others taking immunosuppressive agents. The classic symptom of *Candida* esophagitis is odynophagia localized to a discrete substernal area. The differential diagnosis includes ulcerations due to herpes simplex or cytomegalovirus and, in AIDS patients, idiopathic ulcers.

Vulvovaginitis

Candida vulvovaginitis is a common infection in women of childbearing age and is the most frequent mucocutaneous manifestation of *Candida* infection.[3] Risk factors include conditions associated with increased estrogen levels, such as the use of oral contraceptives and pregnancy, diabetes mellitus, therapy with corticosteroids or broad-spectrum antimicrobials, and HIV infection. Symptoms include vaginal discomfort, discharge, and vulvar pruritus. The discharge is usually curdlike, but it can also be thin and watery. The labia are erythematous and swollen, and the vaginal walls show erythema and white plaques. Although most women have only a few episodes throughout their lives, a minority have frequent recurrences; in most of these patients, no discrete risk factor is found, and the cause is presumed to be local immune dysregulation.

Cutaneous Candidiasis

Candida infection of the skin (Chapter 441) occurs mostly in the intertriginous areas or under a large pannus or pendulous breasts. The lesions are erythematous, pruritic, and frequently pustular; have a distinct border; and are almost always associated with smaller satellite lesions, which helps distinguish candidiasis from tinea cruris or corporis. *Candida* onychomycosis results in thickened, opaque, and onycholytic nails. *Candida* can also cause paronychia, especially in those whose occupation involves frequent immersion of the hands in water.

Chronic Mucocutaneous Candidiasis

This uncommon syndrome usually begins in childhood and is characterized by recalcitrant and relapsing thrush, vaginitis, onychomycosis, and hyperkeratotic skin lesions on the face, scalp, and hands. Autosomal dominant chronic mucocutaneous candidiasis is associated with mutations in the CC domain of *STAT1* leading to defective T_H1 and T_H17 responses.[4] Some patients have associated autoimmune endocrinopathies, including hypoparathyroidism, hypothyroidism, and hypoadrenalism (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED], which is caused by a loss-of-function mutation of the autoimmune regulator gene, *AIRE*, and in these patients autoantibodies against interleukin-17 (IL-17) and IL-22 are found.[5] (See Autoimmune Polyglandular Syndrome Type 1 in Chapter 231.)

Disseminated Infections

Candidemia

The most common manifestation of disseminated *Candida* infection is candidemia. However, candidemia merely implies the presence of *Candida* in blood; it does not define the extent of visceral involvement. *Candida* obtained from a blood culture should never be considered a contaminant and should always prompt a search for the probable source and the extent of infection. Risk factors for candidemia include broad-spectrum antimicrobial therapy, central intravenous catheters, parenteral nutrition, renal failure, surgical procedures involving the gastrointestinal tract, neutropenia, and corticosteroid therapy. The attributable mortality from candidemia approaches 40%; overall mortality is higher in elderly patients and neonates.

Although candidemia is the most obvious manifestation of serious infection with *Candida* species, septic shock can occur, along with invasion of multiple viscera, in the absence of positive blood cultures.[6] The clinical picture of invasive candidiasis is indistinguishable from that of bacterial infection. The characteristic histologic picture consists of multiple microabscesses in many organs. The eyes, kidneys, liver, spleen, and brain are the most commonly involved sites, but virtually all organs can be involved. Clinical clues to the diagnosis of invasive candidiasis include the appearance of skin and retinal lesions. The nonpainful, nonpruritic skin lesions are papular to pustular and surrounded by a zone of erythema (Fig. 338-2). The eye lesions appear as distinctive white exudates in the retina (Fig. 338-3); with extension into the vitreous body, the retina becomes obscured.

Endocarditis

Candida endocarditis is an uncommon and often fatal complication of candidemia. It occurs most often in intravenous drug users, patients who have prosthetic cardiac valves, and those with central venous catheters in place. Blood cultures are usually persistently positive, and echocardiography reveals large vegetations that can readily embolize to major vessels.

Chronic Disseminated (Hepatosplenic) Candidiasis

This syndrome almost always occurs in leukemic patients who have had an episode of neutropenia. After the neutrophil count returns to normal, fevers that are often quite high, right upper quadrant tenderness, and nausea develop. The alkaline phosphatase level is generally elevated, and distinctive punched-out lesions are seen in the liver, spleen, and sometimes the kidneys on computed tomography (Fig. 338-4). Biopsy of these lesions shows microabscesses that contain budding yeasts.

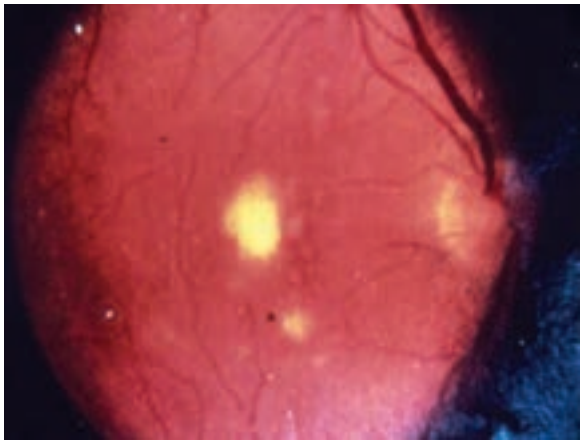

FIGURE 338-3. Retinal involvement.

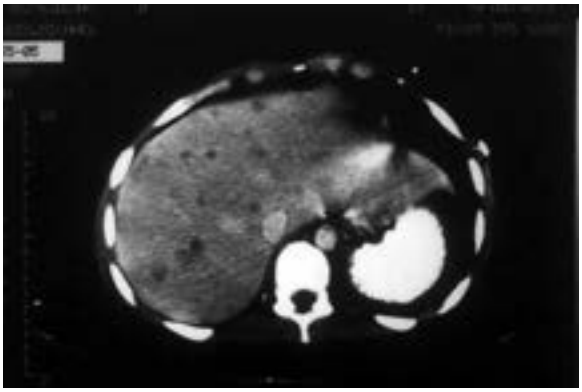

FIGURE 338-4. Computed tomography scan of a patient with chronic disseminated candidiasis (hepatosplenic candidiasis). Note the distinctive punched-out lesions in the liver.

Focal Invasive Infections

These forms of candidiasis result from local inoculation, contiguous spread, or hematogenous spread. Hematogenous spread, which often goes undetected, is probably the most common pathogenetic mechanism.

Urinary Tract Infections

Candiduria is a frequent finding in hospitalized patients and is related to factors such as diabetes mellitus, broad-spectrum antimicrobial treatment, indwelling urinary devices, and genitourinary tract structural abnormalities. Most patients with candiduria have only bladder colonization and not infection. Urinary tract infection with *Candida* species can arise by two mechanisms. Patients with candidemia can develop multiple microabscesses secondary to hematogenous spread to the kidneys. Other patients, who have the risk factors noted earlier, can develop cystitis or ascending infection with pyelonephritis. Patients with cystitis or pyelonephritis have symptoms indistinguishable from those of bacterial infections. A fungus ball composed of fungal hyphae can develop at any level of the collecting system and lead to obstruction, with subsequent infection.

Osteoarticular Infections

Osteoarticular infections arise secondary to hematogenous seeding or exogenous inoculation during intra-articular injection, a surgical procedure, or trauma. Vertebral osteomyelitis is the most common manifestation of osteoarticular candidiasis. The symptoms of back pain and fever may occur many weeks after an episode of fungemia.

Endophthalmitis

Exogenous endophthalmitis occurs secondary to trauma or ophthalmic surgery. Most often, the procedure involved is cataract extraction, with or without lens implantation, and the most common infecting species is *C. parapsilosis.* Primary infection occurs in the anterior chamber, but ultimately the posterior chamber is also involved. Endogenous *Candida* endophthalmitis results from hematogenous seeding of the choroid and retina and is one of the most serious complications of candidemia. Characteristic white lesions are visible in the retina, and with progression of the infection, vitritis occurs; the risk for loss of vision is quite high.

Peritonitis

Candida peritonitis can follow bowel surgery or perforation. Symptoms are the same as those noted in bacterial peritonitis. Usually, this type of infection is polymicrobial, and abscess formation is common. In patients maintained on continuous ambulatory peritoneal dialysis, *Candida* peritonitis generally develops as a late infection after previous episodes of bacterial peritonitis. A cloudy dialysate, abdominal pain, and fever are typically noted.

Meningitis

Acute *Candida* meningitis occurs as part of disseminated infection, especially in low-birthweight neonates. Chronic meningitis, an uncommon manifestation of candidiasis, resembles cryptococcal or tuberculous meningitis with regard to symptoms and cerebrospinal fluid findings.

DIAGNOSIS

The diagnosis of mucocutaneous candidiasis is often made clinically. Culture is rarely indicated. Confirmation can be sought by scraping the lesions and performing either a potassium hydroxide preparation or a Gram stain to look for budding yeasts (Chapter 436). In cases in which the disease is recurrent or unresponsive to standard therapy, lesions should be cultured to establish whether a more resistant species, such as *C. glabrata* or *C. krusei,* is the causative agent. In the event of suspected esophagitis, endoscopy shows plaque-like lesions or ulcerations, and biopsy shows mucosal invasion with budding yeasts and pseudohyphae.

The diagnosis of invasive candidiasis is more difficult. Evidence of dissemination is usually sought by culturing blood or other sterile body sites. The automated blood culture systems used by most hospitals are as sensitive as the lysis-centrifugation system for growing *Candida* from blood. However, no system is sensitive enough for clinicians to rely on blood cultures to establish the diagnosis of invasive candidiasis in all cases or to rule out candidiasis as a diagnostic possibility. In addition, 1 to 4 days is required for growth to occur; in a desperately ill patient, this delay is problematic.

The tips of intravenous catheters that have been removed should be sent for culture. However, no studies have evaluated the number of yeasts that is indicative of infection, and many physicians accept the growth of any yeast as affirming infection that requires treatment. Many focal forms of candidiasis are indistinguishable from bacterial infection, and biopsy should be performed for histopathologic and culture studies.

In a seriously ill patient suspected of having candidiasis, the development of pustular skin lesions or typical retinal lesions can be helpful. Budding yeasts typical of *Candida* species should be sought by smearing material from a pustule on a slide and staining it with Gram stain or by performing a biopsy of a lesion and staining the tissue section with a silver stain. All patients who are candidemic or suspected of having disseminated *Candida* infection should undergo a dilated ophthalmologic examination, preferably by an ophthalmologist, to look for typical retinal lesions.

Imaging studies are invaluable for certain forms of candidiasis, especially chronic disseminated candidiasis, and they can be of major help in defining the extent of infection in other types of *Candida* infection, such as osteoarticular and urinary tract infections and endocarditis.

There are increasing reports of using an assay for β-D-glucan, a cell wall component of fungi, or polymerase chain reaction (PCR) as diagnostic aids for invasive candidiasis.[7,8] The β-D-glucan assay is commercially available; sensitivity and specificity vary depending on the patient populations studied and further studies need to be performed to establish its role in diagnosis. PCR is not standardized, but some studies show that it is more sensitive than β-D-glucan and it may prove useful for earlier diagnosis.

TREATMENT

Rx

Guidelines for treatment of the various forms of candidiasis have been published by the Infectious Diseases Society of America (IDSA).[9] Mucocutaneous disease is obviously treated in a much different fashion than disseminated

life-threatening infection. Because diagnostic tests are not sensitive, empirical therapy is indicated in some circumstances, and for patients at the highest risk for *Candida* infection, antifungal prophylaxis can decrease that risk.

Mucocutaneous Infections

Most mucocutaneous infections should initially be treated with local creams, solutions, troches, or suspensions.[10] For thrush, clotrimazole troches (10 mg four or five times daily) are preferred to nystatin suspension (commonly given as "swish and swallow" four times daily). Patients with AIDS may not respond to local therapy, especially when their CD4 counts are low; in this situation, oral fluconazole 100 to 200 mg daily is given. For vaginitis, a variety of creams and vaginal tablets (miconazole, clotrimazole, and others) are effective, but many women prefer to take a single 150-mg fluconazole tablet orally. Recurrent vaginitis is a more complicated therapeutic issue and often requires chronic suppressive therapy with fluconazole. Esophagitis should always be treated with a systemically absorbed agent; the usual treatment is fluconazole 200 mg/day for 14 days.

In patients with advanced AIDS and low CD4 counts, who are often taking fluconazole to prevent recurrent candidiasis, fluconazole-refractory disease may develop. For these patients, increasing the dosage of fluconazole or switching to itraconazole suspension 200 mg daily, voriconazole 200 mg twice daily, or posaconazole suspension 400 mg daily should be effective. If oral tablets and solutions are no longer effective, intravenous amphotericin B, caspofungin, anidulafungin, and micafungin are alternative agents that can be used. Patients with the syndrome of chronic mucocutaneous candidiasis require lifelong suppressive therapy with oral azole agents.

Candidemia and Invasive Candidiasis

All patients with candidemia should be treated with an antifungal agent, including patients who have only one blood culture that yields *Candida* and those with a vascular catheter tip that yields *Candida*. The rationale for this recommendation is related to the high rate of metastatic foci in major organs associated with hematogenously disseminated candidiasis. Randomized controlled trials have shown the effectiveness of the following antifungal agents for the treatment of candidemia: fluconazole 400 or 800 mg/day; the three echinocandins—caspofungin 50 mg/day, anidulafungin 100 mg/day, and micafungin 100 mg/day; voriconazole 3 mg/kg twice daily; amphotericin B 0.7 mg/kg/day; and a lipid formulation of amphotericin B 3 to 5 mg/kg/day. The IDSA guidelines recommend fluconazole for patients who are not severely ill and have not had recent azole exposure and an echinocandin for severely ill patients and those who have had recent azole exposure. Patients who have stabilized clinically and are found to have an isolate, such as *C. albicans*, that is likely to be susceptible to fluconazole can be transitioned to fluconazole from an echinocandin. Voriconazole is recommended for step-down therapy rather than initial therapy, and amphotericin B formulations are used infrequently, except for patients who are neutropenic and for neonates.

All vascular catheters should be removed because removal has been shown to help clear *Candida* from blood more quickly. Repeated blood cultures should be obtained to ascertain that the fungemia has resolved, and treatment should continue for 2 weeks after the date of the first negative blood culture. An individual patient-level quantitative review of seven randomized trials for the treatment of invasive candidiasis found an overall mortality in the entire data set of 31.4%.[11] Significant predictors of mortality included increasing age; use of immunosuppressive therapy; and infection with *C. tropicalis*. Improved survival and clinical success was found with the use of an echinocandin and the removal of central venous catheters.

Because diagnostic tests are not sensitive, seriously ill patients who could have invasive candidiasis may need to be treated before culture confirmation. This approach is used frequently in neutropenic patients and is increasingly used in the ICU setting.[12] Liposomal amphotericin B, caspofungin, and voriconazole have been shown to be effective for empirical use in neutropenic patients. A placebo-controlled, randomized trial of fluconazole empirical therapy in ICU patients failed to show a benefit; however, there were acknowledged problems with the chosen end point, and the rate of candidemia was too low to allow a proper evaluation of empirical therapy. The IDSA guidelines recommend that empirical therapy be reserved for febrile, critically ill patients who have risk factors for invasive candidiasis. The agents recommended are either fluconazole or an echinocandin, with the caveats noted earlier for treating patients with documented candidemia. Compelling data for early treatment come from a study of 224 candidemic patients who had septic shock. Mortality rates as high as 98% were found in patients in whom there was a delay beyond 24 hours of the onset of shock in initiating antifungal therapy and in effecting source control, defined as draining abscesses and removing central venous catheters.

Endocarditis should be treated with a lipid formulation of amphotericin B, with or without flucytosine. Echinocandins are an acceptable alternative. Infected valves should be replaced. In a few patients for whom valve replacement was not an option, lifelong suppression with fluconazole appeared to be effective.

Chronic disseminated candidiasis generally requires months of therapy for cure. Most patients begin therapy with a lipid formulation of amphotericin B and are then switched to fluconazole and treated until the lesions disappear on computed tomography scanning.

Focal Invasive Infections

Treatment of focal infections depends on the organ system involved. Perhaps the simplest to treat are urinary tract infections. Most patients with candiduria are not infected but merely colonized; removing the selective pressure of antimicrobials and indwelling catheters eliminates candiduria in many of these patients. For those who have infection, oral fluconazole at a dosage of 200 mg/day for 2 weeks is recommended. Bladder irrigation with amphotericin B should not be used because it eradicates only bladder colonization, requires that a catheter be placed in the bladder, and is associated with a high recurrence rate. None of the newer antifungal agents has a role in the treatment of urinary tract infections.

Osteoarticular infections require months of therapy; a lipid formulation of amphotericin B or an echinocandin can be given initially, followed by long-term therapy with an azole. Peritonitis associated with chronic ambulatory peritoneal dialysis can be treated with amphotericin B, fluconazole, or an echinocandin, depending on the species of *Candida* causing infection. Intraperitoneal administration of amphotericin B can be extremely irritating and should not be attempted. The dialysis catheter should be removed. Meningitis should be treated initially with a lipid formulation of amphotericin B and flucytosine; patients with more chronic disease can be switched to fluconazole for a longer duration of therapy.

Treatment of *Candida* eye infections varies with the extent of ocular involvement.[13] Lesions discovered early at the stage of choroidal or retinal involvement perhaps can be treated effectively with systemic antifungal agents (amphotericin B, an echinocandin, fluconazole, or voriconazole) alone. Many experts prefer to use an agent, such as voriconazole or fluconazole, that achieves higher concentrations in the eye. Lesions extending into the vitreous require more aggressive therapy. The best results have been obtained with pars plana vitrectomy, injection of amphotericin B or voriconazole into the vitreous; and a systemic antifungal agent such as fluconazole or voriconazole. Management must be individualized and performed in concert with an ophthalmologist experienced in the treatment of this infection. Treatment of endophthalmitis associated with an intraocular lens implant requires removal of the implant, vitrectomy, and local amphotericin B injections, as well as therapy with fluconazole or voriconazole.

PREVENTION

For certain populations at the highest risk for invasive fungal infection, prophylactic antifungal agents can prevent infection. The populations for whom prophylaxis is recommended include stem cell transplant recipients, patients with acute leukemia who are undergoing induction chemotherapy, high-risk liver transplant recipients, and pancreas and small bowel transplant recipients; in these groups, a variety of different agents are effective. In the ICU population, prophylaxis with fluconazole can be effective, but it is recommended only in units that have a high rate of invasive candidiasis, and only in those patients at the highest risk for infection. In a placebo-controlled trial of caspofungin as antifungal prophylaxis in adults who were in the ICU for at least 3 days, were ventilated, received antibiotics, had a central line, and had at least one additional risk factor, caspofungin was safe and tended to reduce the incidence of invasive candidiasis when used for prophylaxis, but the difference was not statistically different.[A1] Restricting the use of prophylaxis is essential to prevent the widespread use of azoles, with subsequent selection of resistant species.

PROGNOSIS

The prognosis for patients with mucocutaneous infections is excellent. The prognosis for focal invasive infections depends on the organ involved and the patient's immune status. For example, whereas pyelonephritis may respond well to antifungal therapy, endocarditis and meningitis are more difficult to treat and have poor outcomes. Invasive candidiasis has a high mortality rate. Early treatment with an effective antifungal agent is extremely important for a favorable outcome.

REVIEW QUESTIONS

1. *Candida glabrata* infections are more difficult to treat for which of the following reasons?

A. *C. glabrata* is more virulent.
B. *C. glabrata* cannot be phagocytized by neutrophils.
C. *C. glabrata* is resistant to azole antifungals.
D. *C. glabrata* readily forms hyphae and invades tissues.

Answer: C *C. glabrata* infections are difficult to treat because of both inherent and acquired resistance to fluconazole and other azoles. It is not more virulent and may actually be less so. It does not form hyphae in contrast to the other species of *Candida*. Phagocytosis of *C. glabrata* occurs just as it does with other *Candida* species.

2. An AIDS patient comes in because he has retrosternal pain when he swallows. He does not have thrush, and there is no cervical lymphadenopathy. What is the most likely diagnosis?

A. Gastroesophageal reflux disease
B. Pericarditis
C. Pulmonary embolus
D. Esophageal candidiasis
E. Angina

Answer: D Odynophagia is the classic symptom shown by AIDS patients who have *Candida* esophagitis. The other diseases generally do not cause pain when swallowing food. Esophagitis can occur without thrush, although frequently both are present concomitantly. Response to treatment with fluconazole can be used as a diagnostic test for *Candida* esophagitis; endoscopy can be done, also, but is usually reserved for patients who do not respond to fluconazole therapy.

3. Which is *not* a risk factor for candidemia?

A. High APACHE II score
B. Central venous catheter
C. Deficient T-cell immunity
D. Prior surgical procedure
E. Neutropenia

Answer: C The risk factors for candidemia include everything noted above except deficient T-cell immunity. T cells are important in protection against mucosal infection with *Candida* species but do not play a role in prevention of invasive candidiasis and candidemia.

4. A 70-year-old man who is in the intensive care unit after having abdominal surgery for a perforated bowel becomes hypotensive and febrile. He has a central catheter in place, is receiving parenteral nutrition and broad-spectrum antibiotics, and has kidney failure requiring renal replacement therapy. What is the most appropriate approach to treatment after you obtain blood cultures?

A. Treat with fluconazole when the laboratory tells you that yeasts are growing in the cultures.
B. Treat with an echinocandin after the laboratory identifies the yeast in the blood cultures as *C. glabrata.*
C. Treat with amphotericin B immediately after obtaining the blood cultures.
D. Treat with fluconazole after the laboratory identifies the yeast in the blood culture as *C. glabrata.*
E. Treat with an echinocandin immediately after obtaining the blood cultures.

Answer: E In a patient at great risk for candidemia, as is this patient (who is on renal replacement therapy, has a central venous catheter plus another central line for dialysis, is receiving broad-spectrum antibiotics and parenteral nutrition, has a perforated bowel, and has undergone recent abdominal surgery), empirical treatment with an antifungal agent should be started as soon as the blood cultures and any other pertinent cultures have been obtained. Amphotericin B is rarely used in this setting, and echinocandins or fluconazole are generally used. In a patient who is not stable and is hypotensive, an echinocandin is preferred. Waiting for the cultures to grow, which will take 1 to 3 days, and for identification of species, which may add another 2 to 3 days, increases the mortality rate enormously in candidemic patients.

5. Which finding is helpful in directing the clinician to a diagnosis of invasive candidiasis?

A. Nonpainful papular skin lesions on an erythematous base on the chest and left arm
B. Painful erythematous nodules developing on the shins
C. Bilateral spreading erythema over the lower legs and feet
D. Molluscum-type lesions on the forehead accompanied by fever
E. Pruritic blisters appearing in crops over the trunk

Answer: A Candidemia and invasive candidiasis can present with the sudden appearance of nonpainful, nonpruritic papules that evolve to become pustules on an erythematous base. These can occur anywhere on the body. All of the other lesions do not occur with candidemia.

339

ASPERGILLOSIS

THOMAS J. WALSH

DEFINITION

Aspergillosis is defined as an infection with one or more of the species of the genus *Aspergillus.* Sporelike structures called *conidia* are aerosolized from the mold form of the organism growing in the environment. When conidia reach tissue, they germinate to form invasive filaments called *hyphae.*

The Pathogens

The most common species infecting humans are *Aspergillus fumigatus, Aspergillus flatus, Aspergillus terreus, and Aspergillus niger.* The species are usually identified in culture by characteristic microscopic features of hyphae and the structures producing conidia. When some species are not readily identifiable, they may be reported by the clinical laboratory as "*Aspergillus* species or *Aspergillus* sp." Molecular methods are increasingly used for identification. *Aspergillus fumigatus* may be reported as "*A. fumigatus* species complex." Some species within *A. fumigatus* complex may be particularly drug resistant. *Aspergillus terreus* is resistant to amphotericin B. Aspergilli within tissue appear as dichotomously branched (Y-shaped) septate hyphae. *Scedosporium* and *Fusarium* species also may produce septate hyphae in tissue. The presence of septa and dichotomous branching differentiates *Aspergillus* species from the Mucorales, which are the causative organisms of mucormycosis (Chapter 340).

EPIDEMIOLOGY

Aspergillus species. are ubiquitous organisms in the external environment, including soil, decaying matter, and air in temperatures as high as 40 to 50° C.[1] Aspergilli are easily isolated from houses, particularly from basements, crawl spaces, bedding, humidifiers, ventilation ducts, potted plants, dust, condiments (e.g., pepper), and marijuana samples. Aspergilli cause abortion in cattle and are important pathogens of marine organisms, insects, and domesticated and wild birds. Aflatoxin, which is one of the most potent carcinogens known, is produced by strains of *Aspergillus flavus* at ambient temperature on stored grain, spices, and nuts. Foodborne ingestion of preformed aflatoxin may cause hepatic necrosis or hepatocellular carcinoma (Chapter 196) in animals and humans.

Aspergillus species may be acquired from airborne conidia in inpatient and outpatient settings. Nosocomial aspergillosis is associated with building renovation, new construction, unfiltered air, contaminated ventilation systems, and fireproofing materials.[2] Hospital water, which may become aerosolized during activities such as showering, is a newly described potential source of aspergilli. As human pathogens, *Aspergillus* species may cause acute invasive disease, chronic infection, or allergic symptoms. A classification of aspergillosis is presented in Table 339-1.

Acute invasive aspergillosis develops in immunocompromised patient populations, particularly those with hematologic malignancies, hematopoietic stem cell transplantation (HSCT), severe aplastic anemia, primary immunodeficiencies, and solid organ transplantation, especially of heart, lung, and liver.[1] Genetic deficiency of the soluble pattern-recognition receptor called PTX3 (long pentraxin 3) caused by homozygous haplotype (h2/h2) in the *PTX3* gene of donor cells has been found to lead to impaired neutrophil antifungal capacity and increased risk for invasive aspergillosis in recipients of HSCT.[3] Persistent neutropenia, corticosteroids, other immunosuppressive agents, graft versus host disease (GVHD), and cytomegalovirus (CMV) disease are the most frequently observed clinical risk factors. The mortality of acute invasive aspergillosis varies from as much as 100% with central nervous system (CNS) infection to approximately 65% with pulmonary infection in HSCT recipients. Early recognition of clinical manifestations followed by initiation of antifungal therapy may improve the ominous prognosis of acute invasive aspergillosis.

TABLE 339-1 CLASSIFICATION OF ASPERGILLOSIS

CATEGORY	SPECIFIC FORMS OF ASPERGILLOSIS
Acute invasive aspergillosis	Invasive pulmonary aspergillosis Empyema Tracheobronchial infection Extrapulmonary aspergillosis Acute sinusitis Focal rhinitis Cerebral, cerebellar, or brain stem infarction Endophthalmitis Osteomyelitis Epidural abscess Cardiac aspergillosis Myocarditis Endocarditis Pericarditis Gastrointestinal aspergillosis Renal infection Cutaneous lesions (nodules, ulcers) Disseminated aspergillosis
Chronic aspergillosis	Aspergilloma Chronic necrotizing pulmonary aspergillosis Chronic cavitary pulmonary aspergillosis *Aspergillus* otomycosis
Allergic forms of aspergillosis	Allergic bronchopulmonary aspergillosis Extrinsic allergic alveolitis Allergic *Aspergillus* sinusitis

CLINICAL MANIFESTATIONS

Invasive Aspergillosis

The classic clinical manifestations of *invasive pulmonary aspergillosis* (IPA) in immunocompromised hosts are fever and focal pulmonary infiltrates, nodules, or wedge-shaped densities resembling infarcts (see Table 339-1).[4] Cough, pleuritic pain, and hemoptysis also may be present. Focal pulmonary infiltrates may progress to a cavity on recovery from neutropenia. Pulmonary infiltrates may also present as bronchopneumonia in an immunosuppressed patient. The pulmonary pathology in all these entities is that of hemorrhagic infarction caused by the organism's capacity to invade blood vessel walls (angioinvasion). These processes lead to formation of a necrotic center surrounded by a ring of hemorrhage and edema, which correlates with a "halo sign" surrounding the nodular density. Concomitant pleural effusion may develop and represent *Aspergillus* empyema. Tracheobronchial aspergillosis in immunocompromised patients presents as ulcerative, pseudomembranous, or plaquelike large airway disease that may presage pulmonary parenchymal invasion.

Acute Aspergillus sinusitis may occur concomitantly or independently of IPA. Although symptoms may include fever, localized pressure, and pain, they may be absent in severely immunocompromised patients. Eschar may be observed by speculum examination or endoscopy on the nasal septum and turbinates. Acute *Aspergillus* sinusitis of the ethmoid and sphenoid sinuses may progress to cavernous sinus thrombosis with symptoms referable to cranial nerves III, IV, $V_{1,2}$, and VI. *Aspergillus flavus* has a high propensity for causing acute sinus infection.

The tissue targets of *extrapulmonary* and *disseminated aspergillosis* most commonly include the CNS, where abscesses and infarcts are characteristic.[5] Patients with CNS aspergillosis present with focal paresis, cranial nerve deficits, and seizures. The glucose level in cerebrospinal fluid (CSF) is usually normal, and cultures of CSF are negative. Other extrapulmonary manifestations include endophthalmitis, myocardial infarction, gastrointestinal disease, renal infarction, cutaneous lesions, and Budd-Chiari syndrome. Esophageal ulcers and mesenteric thrombosis may produce gastrointestinal bleeding. Renal infection may present as flank pain and hematuria.

Aspergillus endocarditis usually begins as an isolated infection in intravenous drug users or after cardiac valvular surgery.[6] *Aspergillus* endocarditis most commonly presents as major arterial emboli. Blood cultures, which are

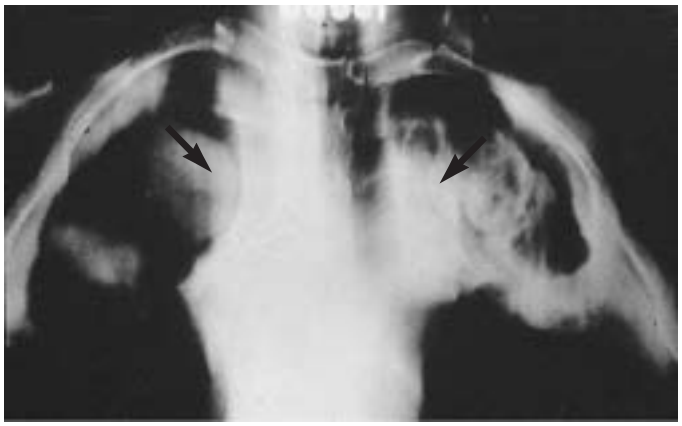

FIGURE 339-1. Tomogram of pulmonary aspergillomas *(arrows)*.

seldom positive, may be delayed in growth by as much as 14 to 21 days. Diagnosis is difficult, and despite valve replacement with antifungal therapy, mortality approaches 100%. *Aspergillus pericarditis* may arise from contiguous pulmonary lesions or through transmural infection from endocardial infection.

Locally invasive aspergillosis usually develops in immunocompromised patients as cutaneous ulcers, focal rhinitis, osteomyelitis, and septic arthritis.[7] Cutaneous ulcers have been associated with use of contaminated adhesive tape and arm boards. Blood-borne infection in illicit intravenous drug users may present as foci of dissemination in brain, lung, kidney, and bone. Keratitis, endophthalmitis, and infection of burn wounds may develop from traumatic inoculation in otherwise immunocompetent patients.

Chronic Pulmonary Aspergillosis

Aspergilloma appears on chest radiograph as a ball in a cavity. The fungus ball consists of matted hyphae and debris in a preformed cavity from previous pulmonary tuberculosis, histoplasmosis, or fibrocystic sarcoidosis (Fig. 339-1). Symptomatic patients present with cough, hemoptysis, dyspnea, weight loss, fatigue, chest pain, or fever. Sputum culture is typically positive for *Aspergillus* species, particularly *Aspergillus niger*. Pleural aspergillosis may complicate surgical resection of aspergilloma or develop spontaneously as a bronchopleural fistula or concomitantly with tuberculosis.

As a stage in the repair process of infarcted lung tissue in neutropenic patients, one or more apparent "aspergillomas" may develop in consolidated lesions during recovery from neutropenia. These apparent aspergillomas do not develop in preexisting cavities and create an "air-crescent sign," or Monod sign, during their formation.

Chronic necrotizing pulmonary aspergillosis (CNPA) and *chronic cavitary pulmonary aspergillosis* (CCPA) occur in patients with underlying chronic lung disease, chronic immunosuppression, such as that due to prolonged use of systemic corticosteroids, or both. CNPA characteristically causes a slowly progressive inflammatory destruction of lung tissue superimposed on chronic lung disease. Clinical manifestations of worsening pulmonary function, cough, and dyspnea in CNPA may be indistinguishable from concomitant primary chronic respiratory disease.

CCPA is defined as the presence of multiple *Aspergillus*-related cavities, which may or may not contain an aspergilloma. Patients with CCPA may have genetically mediated deficits in innate host defenses. Occurring in association with symptoms of cough, hemoptysis, and dyspnea, the progressive cavities of CCPA tend to coalesce with the loss of functional lung tissue.

Aspergillus otomycosis is a chronic infection that usually involves the external auditory canal with symptoms of pain, pruritus, hypoacusis, and otic discharge in patients with impaired mucocutaneous immunity, such as those with chronic eczema, hypogammaglobulinemia, diabetes mellitus, or HIV infection and those receiving corticosteroids. *Aspergillus* may involve the middle ear and extend into the mastoid sinus if the tympanic membrane has been perforated.

Allergic Forms of Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) develops most frequently in patients with a history of chronic asthma or cystic fibrosis.[8,9] Occurring in genetically susceptible patients exposed to specific *Aspergillus* antigens, ABPA is characterized by episodic airway obstruction, fever, eosinophilia, positive sputum cultures, mucous plugs containing hyphae, the presence of grossly visible brown flecks in sputum (hyphae), transient infiltrates and parallel "tramline" or ring markings on chest radiographs, proximal bronchiectasis, upper lobe contraction, and elevated levels of total immunoglobulins G and E (IgG and IgE). Eosinophilia may be present in blood, sputum, and lung tissue. Mucous plugs contribute to development of pulmonary infiltrates, atelectasis, and peribronchial inflammation. The parallel or ring markings are caused by thickened ectatic bronchi, whereas the upper lobe changes are due to progressive apical fibrosis. Pulmonary infiltrates in ABPA may be nonsegmental and transient in association with eosinophilia and asthma; alternatively, they may be segmental and associated with bronchial obstruction by mucous plugs, wherein asthma and eosinophilia may be absent.

Extrinsic allergic alveolitis is an unusual allergic form of *Aspergillus* lung disease that has been most frequently associated with *Aspergillus clavatus* in malt workers. A hypersensitivity pneumonitis with dyspnea and fever develops approximately 4 hours after exposure. Diffuse reticulonodular interstitial infiltrates may be present at the time of symptoms. Patients have IgG precipitins and cell-mediated immune reactions against *Aspergillus* antigens. Granulomas are present in lung tissue. In comparison to ABPA, eosinophilia is not a feature of *Aspergillus* extrinsic allergic alveolitis.

Allergic Aspergillus sinusitis (AAS) is a noninvasive form of sinus disease that typically presents in patients with asthma, nasal polyps, sinus opacification, and eosinophilia. Sinus aspirate yields mucinous material containing eosinophils, Charcot-Leyden crystals, and hyphal elements. AAS and ABPA may coexist in some patients. Advanced forms of AAS may present with proptosis and optic neuropathy, necessitating prompt surgical intervention.

DIAGNOSIS

Invasive Aspergillosis

Diagnosis of IPA and disseminated aspergillosis is difficult. None of the aforementioned clinical manifestations are diagnostic for invasive aspergillosis. Advances in computed tomography (CT) have revealed characteristic features of nodules, halo signs, wedge-shaped infiltrates, and air-crescent signs during IPA in immunocompromised patients (Fig. 339-2). However, infections caused by *Fusarium* species, *Scedosporium* species, the Mucorales, as well as *Pseudomonas aeruginosa* may be radiologically indistinguishable from IPA. Microbiologic confirmation, where possible, is important to differentiate aspergillosis from other filamentous fungal infections. Bronchoalveolar lavage (BAL), percutaneous needle aspiration, video-assisted thoracoscopic (VATS) biopsy, and if necessary, open lung biopsy are standard procedures for establishing a microbiologic diagnosis of invasive aspergillosis. Specimens obtained from these procedures may demonstrate dichotomously branching septate hyphae by direct microscopy or grow *Aspergillus* species in culture. Each of these procedures is associated with false-negative results, as well as with complications. Conversely, the presence of *Aspergillus* by direct examination or culture in an immunocompromised host with pulmonary nodules or well-circumscribed infiltrates carries a high probability for diagnosis of invasive aspergillosis.

Galactomannan, which is a heteropolysaccharide of the *Aspergillus* cell wall, is a useful biomarker that is released into the circulation and alveolar spaces during IPA.[10] Detection of galactomannan by enzyme immunoassay (EIA) in serum or BAL above certain thresholds is strong microbiologic evidence for a diagnosis of invasive aspergillosis in immunocompromised patients with characteristic clinical manifestations. Nonetheless, false-positive results have been reported in patients who have received piperacillin-tazobactam or amoxicillin-clavulanate, in cases in which Plasmalyte was used for BAL, and in other deeply invasive mycoses such as blastomycosis and histoplasmosis. Serum galactomannan may be falsely negative in patients receiving antifungal prophylaxis or empirical therapy.

(1→3)-β-D-glucan is another *Aspergillus* cell wall polysaccharide that is detected in serum during invasive disease. The sensitivity of the *Limulus* spectrophotometric assay for detection of (1→3)-β-D-glucan in patients with invasive aspergillosis appears to be comparable to that of the galactomannan EIA. However, because (1→3)-β-D-glucan also is present in the cell wall of other medically important fungi, including *Candida* species, the specificity of (1→3)-β-D-glucan for *Aspergillus* species is less than that of galactomannan.

Although molecular diagnostic tools, such as quantitative polymerase chain reaction (PCR), for diagnosis of invasive aspergillosis are promising, they also remain investigational for this infection. Ultimately, the combined use of improved diagnostic imaging, microscopy, culture methodology, cell

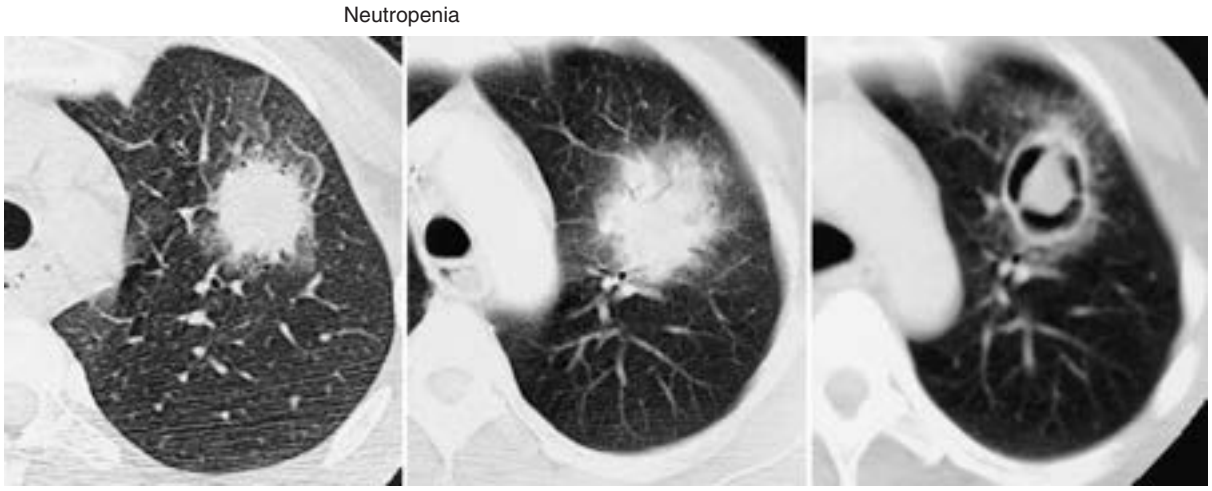

FIGURE 339-2. Evolution of radiography of invasive aspergillosis in an immunocompromised host. D = days after the lesion is first noted.

wall biomarkers, and possibly PCR in conjunction with careful bedside assessment of risk factors and clinical manifestations will improve the diagnosis of invasive aspergillosis and early initiation of therapy.

Diagnosis of locally invasive extrapulmonary aspergillosis causing mucocutaneous lesions, osteomyelitis, and septic arthritis is best accomplished with biopsy, direct microscopy, and culture. A diagnosis of *Aspergillus* keratitis is established by careful culture of corneal lesions by an ophthalmologist.

Allergic Forms of Aspergillosis

Diagnosis of ABPA is based on the presence of a combination of clinical, biologic, and radiologic, criteria (Fig. 339-3). The consensus criteria for establishing a diagnosis of ABPA differ depending on the presence of cystic fibrosis. For patients with ABPA without the presence of cystic fibrosis (Chapter 89), criteria for ABPA include asthma, an immediate cutaneous reaction to *A. fumigatus* antigen, total serum IgE concentration higher than 1000 ng/mL, elevated *A. fumigatus*–specific serum IgE levels, precipitating serum antibodies to *A. fumigatus*, central bronchiectasis, peripheral blood eosinophilia, and characteristic pulmonary infiltrates. The latter two features (eosinophilia and pulmonary infiltrates) are considered nonessential because they only may be present during an acute phase of ABPA.

Among patients with cystic fibrosis, distinguishing between ABPA and an episode of clinical deterioration with colonization by *Aspergillus* species is challenging. The current criteria of the Cystic Fibrosis Foundation help to define ABPA in that setting: clinical deterioration (coughing, wheezing, increased sputum production, exercise intolerance, and decrease in pulmonary function); immediate hypersensitivity to *A. fumigatus* (positive skin test or IgE response); total serum IgE concentration higher than 1000 kUI/L; precipitating antibodies to *A. fumigatus*; abnormal chest radiograph (infiltrate, mucous plugs, or unexplained changes compared with previous chest radiograph).

A biphasic skin test response may assist in the diagnosis. A scratch test with *Aspergillus* antigens produces an immediate wheal-and-flare reaction that is mediated by IgE and blocked by antihistamines but not by corticosteroids. An intracutaneous test with the antigens produces a later (6 to 8 hours) reaction that is mediated by IgG and complement and blocked by corticosteroids.

An occupational history of exposure is critical to the diagnosis of *extrinsic allergic alveolitis*. A typical history of recurrent episodes developing within 24 hours after inhalation of conidial antigens in an agricultural environment in conjunction with a negative scratch test, a positive intradermal test, and granulomas with immunoglobulins and complement in tissue is diagnostically consistent with *Aspergillus* extrinsic allergic alveolitis.

Recurrent sinusitis in a patient with asthma, nasal polyps, eosinophilia, sinus opacification, and a sinus aspirate yielding mucinous material containing eosinophils, Charcot- Leyden crystals, and hyphal elements establishes a diagnosis of AAS.

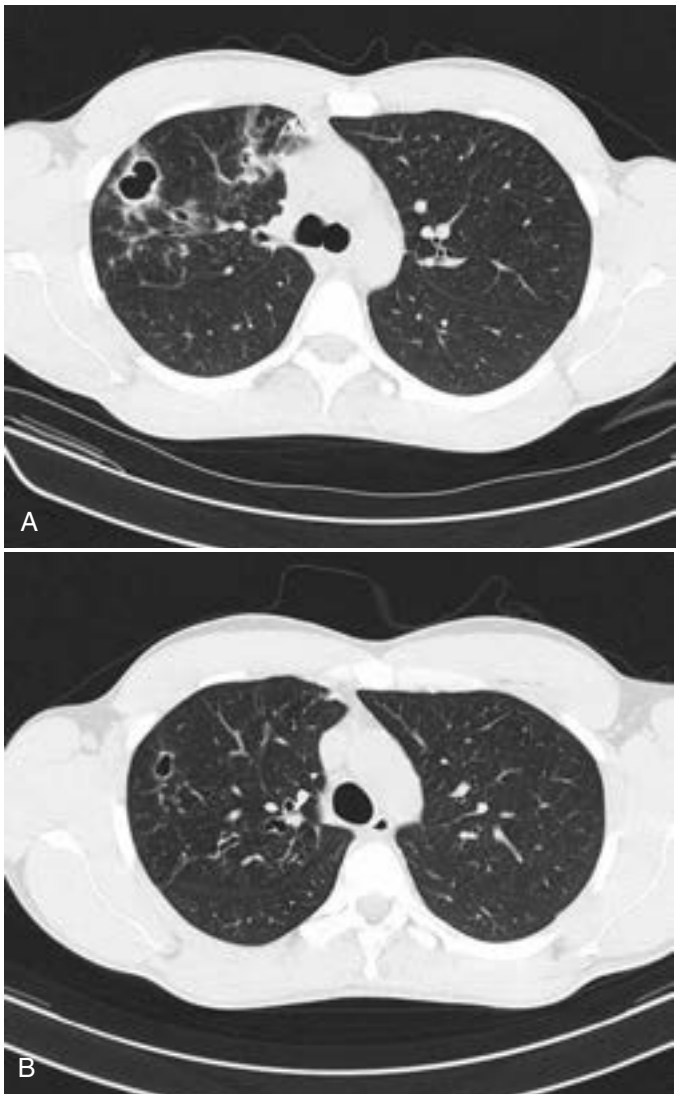

FIGURE 339-3. **Allergic bronchopulmonary aspergillosis in a patient with a long history of asthma. (A)** is a thin slice CT image showing bronchiectasis with cystic changes in the right upper lobe. This patient had an underlying history of asthma and a markedly elevated IgE level and other findings consistent with allergic bronchopulmonary aspergillosis. **(B)** is the same patient after treatment with systemic steroids; the cystic bronchiectasis has markedly improved. TABLE 339-2 ANTIFUNGAL THERAPY OF INVASIVE ASPERGILLOSIS*

FIRST-LINE TREATMENT IN ADULTS†	
Drug of choice:	
Voriconazole	IV therapy: 6 mg/kg q12h for two doses, then 4 mg/kg q12h Oral therapy: 300 mg or 4mg/kg bid
Alternate (see text for conditions):	
Liposomal amphotericin B	3-5 mg/kg IV daily
SECOND-LINE OR SALVAGE TREATMENT IN ADULTS†	
Amphotericin B lipid complex	5 mg/kg IV daily
or	
Caspofungin	70 mg IV daily for first dose, then 50 mg IV daily
or	
Posaconazole	200 mg PO qid or 400 mg PO bid
or	
Itraconazole	400 mg PO (capsules) daily (in either one or two doses); or 2.5 mg/kg PO (solution) bid

*Refer to package insert for dosage modification of antifungal agents in liver disease or renal impairment.
†Duration of antifungal therapy depends on therapeutic response of documented lesions, burden of disease, host immunocompetence, and type of aspergillosis (e.g., acute invasive vs. chronic, vs. allergic). Guidelines of Infectious Diseases Society of America recommend at least 6 to 12 weeks for invasive pulmonary aspergillosis. Patients who are immunosuppressed continue treatment throughout the period of immunosuppression and until resolution of lesions. In patients with previously diagnosed invasive aspergillosis, antifungal therapy should be continued or reinitiated during subsequent periods of immunosuppression (e.g., chemotherapy, stem cell transplantation, graft vs. host disease) to prevent recrudescence
(see Walsh TJ, Anaissie EJ, Denning DW, et al. Treatment of aspergillosis: clinical practice guidelines of the Infectious Diseases Society of America (IDSA). *Clin Infect Dis.* 2008: 46:327-360.)

TREATMENT

Rx

Invasive Aspergillosis

The foundation of treatment of invasive aspergillosis consists of (1) antifungal medical therapy (Table 339-2), (2) reversal of immunosuppression and, where appropriate, (3) surgical resection of infected lesions (see Table 339-2).[11,12] Dosages of antifungal agents are listed in Table 339-2. Voriconazole is recommended in most patients for the primary treatment of invasive aspergillosis, including pulmonary, disseminated, and extrapulmonary isolated infection. This recommendation is based on the randomized controlled trial showing that voriconazole is superior to deoxycholate amphotericin B (D-AmB) as primary treatment for invasive aspergillosis. However, not all patients are candidates to receive voriconazole. This includes patients with substantially elevated hepatic transaminases, hepatic dysfunction, and a history of hypersensitivity to or intolerance of voriconazole. Such patients should receive liposomal amphotericin B (L-AmB) as primary therapy. This recommendation is based on the randomized trial that demonstrated comparable efficacy of approximately 70% using dosages of 3 mg/kg/day and 10 mg/kg/day of LAmB in patients who had predominantly hematologic malignancies. L-AmB also is indicated as primary therapy for patients in whom there is a suspicion for or documentation of concurrent mucormycosis.

Second-line or salvage antifungal therapy is indicated in patients who are intolerant of or whose infection is unresponsive to primary therapy. Among the antifungal agents used in this setting are a lipid formulation of amphotericin B, posaconazole, itraconazole, or an echinocandin (caspofungin is the only agent licensed for this indication). For patients who are already receiving voriconazole, a change of class to a lipid formulation, addition of an echinocandin, and use of another azole are alternative possibilities. Such decisions are complicated and warrant infectious diseases consultation with consideration of pharmacokinetic and host factors.

Antifungal therapy for invasive aspergillosis should be continued until lesions have resolved, cultures and biomarkers are negative, and reversible underlying predispositions have abated. Reinstating therapy in patients who have previously responded should be considered if immunosuppression is reinstituted or if neutropenia recurs.

Preliminary reports of a randomized multicenter study demonstrate that a new antifungal triazole known as isavuconazole is as effective but better tolerated than voriconazole in the primary treatment of invasive aspergillosis.

Reversal of immunosuppression is a critical factor in the successful management of invasive aspergillosis. Recovery from neutropenia and decreasing the daily dosage or discontinuation of corticosteroids, where feasible, are two of the most important forms of improving host response. Depending on the protocol used, granulocyte transfusions may stabilize *Aspergillus* lesions until recovery from neutropenia. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may accelerate recovery from neutropenia. The role of GM-CSF, G-CSF, or interferon-γ in immunocompromised non-neutropenic patients with invasive aspergillosis remains to be further defined.

Surgical management of infected lesions is an important adjunctive component of primary therapy for several forms of invasive aspergillosis: endocarditis, pericarditis, osteomyelitis, epidural abscess, infected vascular catheters and prosthetic devices, and skin and soft tissue infection. Surgical management also is important for several conditions of invasive pulmonary aspergillosis: recurrent hemoptysis from a single cavitary lesion, invasion of a pulmonary lesion into the chest wall, and pulmonary lesions contiguous with great vessels or the pericardium. *Aspergillus* empyema requires closed chest tube drainage and possibly débridement of the infected pleural cavity. Débridement of sinus aspergillosis, particularly when the ethmoid and frontal sinuses are infected, may prevent extension into the orbit or into the cavernous sinus. Surgical resection of selected lesions of the CNS may be indicated for establishing a diagnosis, reducing increased intracranial pressure, and/or protecting critical neural centers. Location of CNS lesions and neurologic sequelae after resection are critical factors in neurosurgical management of aspergillosis.

Local infusion of antifungal agents, particularly intravitreal therapy for endophthalmitis, provides high concentrations to compartments that may not be reached by systemic therapy. Topical irrigation with voriconazole, amphotericin B, or if available, pimaricin is an important adjunct to management of *Aspergillus* keratitis.

Chronic Aspergillosis

Medical therapy has limited benefit in treatment of aspergilloma; however, some patients may benefit from extended use of an antifungal triazole. Lifelong commitment to an antifungal triazole should be balanced against the natural history of approximately 10% of aspergillomas resolving spontaneously. By comparison, medical therapy with itraconazole or voriconazole is the standard of treatment for CCPA. Patients with CCPA typically achieve improvement of symptoms and stabilization or improvement of radiologic changes. Patients with CNPA also receive an antifungal triazole; however, assessment of response is more difficult because of the underlying chronic lung disease. The role of surgical resection in patients with solitary aspergilloma or CCPA is limited because of development of bronchopleural fistula, *Aspergillus* infection of the pleural space, and potentially further worsening of already compromised pulmonary function. However, surgical resection may have a more important role in treating patients with recurrent and severe hemoptysis, for which the benefits of removing the cavity usually outweigh the known risks. Bronchial artery embolization and transthoracic direct intracavitary instillation of antifungal agents for aspergilloma have only transient benefits but substantial risk.

Topical irrigating solutions of boric acid, acetic acid, or an antifungal azole cream may be effective in treating *Aspergillus* otomycosis. Voriconazole, posaconazole, or itraconazole may be necessary for refractory cases or perforated tympanic membranes.

Allergic Forms of Aspergillosis

ABPA is treated with a combination of corticosteroids and itraconazole. This recommendation is based on two double-blind, randomized, placebo-controlled trials for treatment of ABPA. These studies demonstrated that itraconazole (200 mg twice daily orally for 16 weeks) resulted in significant amelioration of disease, as evidenced by improvement in exercise tolerance and pulmonary function, reduction in corticosteroid dose, increased interval between corticosteroid courses, as well as decreased eosinophilic inflammatory parameters and IgE concentration. Although corticosteroid therapy is the mainstay of treatment of ABPA, chronic administration of corticosteroids causes severe immunosuppression and multisystem metabolic abnormalities. Addition of itraconazole reduces organism burden, attenuates antigenic stimulus for destructive bronchial inflammation, and provides a corticosteroid-sparing effect. Intermittent use of corticosteroids or substantially raising the dose in patients receiving chronic therapy can produce rapid resolution of marked symptomatic episodes or deteriorating forced expiratory volume in 1 second (FEV_1).

Extrinsic allergic alveolitis is best managed by removing patients from the allergenic environment. An accurate occupational history is critical to this intervention.

AAS is treated by endoscopic drainage to relieve obstruction by tenacious mucin. Itraconazole, nasal corticosteroids, and systemic corticosteroids, alone or in combination, may be beneficial in some patients with AAS. Caution is warranted with chronic use of systemic or nasal corticosteroids. Itraconazole may have a corticosteroid sparing effect.

Combination Antifungal Therapy

Combinations of polyenes, triazoles, and echinocandins are being explored. The aggregate of well-conducted in vitro, in vivo, and clinical observational

studies support the additive or synergistic interaction of a triazole and echinocandin in primary treatment of invasive pulmonary aspergillosis. In a randomized trial designed to study combination therapy for invasive aspergillosis, patients with hematologic malignancies and/or allogeneic HSCT were randomized at study entry to receive initial treatment with a combination of voriconazole and anidulafungin or voriconazole monotherapy.[A1] Combination therapy was associated with reduced all-cause mortality at 6 weeks compared with voriconazole monotherapy, but this difference did not reach statistical superiority. In patients with probable invasive aspergillosis, combination therapy was associated with a significant survival benefit.

PREVENTION

Several strategies may be used for prevention of invasive aspergillosis in immunocompromised patients: primary prophylaxis, empirical therapy, and secondary prophylaxis. Posaconazole is licensed for prophylaxis of invasive aspergillosis in patients with hematologic malignancies and in HSCT recipients.[A2] This recommendation in hematologic malignancies is based on a randomized clinical trial in patients undergoing chemotherapy for acute myelogenous leukemia or myelodysplasia. Posaconazole significantly prevented invasive fungal infections more effectively than did either fluconazole or itraconazole and improved overall survival. There were, however, more adverse events with posaconazole. Voriconazole also is used for this indication but with less evidence.[A3] A multicenter, randomized, double-blind trial comparing fluconazole versus voriconazole in HSCT recipients for the prevention of mycoses found nonsignificant trends of fewer *Aspergillus* infections with voriconazole. The study also demonstrated that in the context of intensive monitoring and structured empirical antifungal therapy, 6-month fungal-free survival did not differ in allogeneic HSCT recipients given prophylactic fluconazole or voriconazole. Empirical antifungal therapy provides early treatment for persistently febrile immunocompromised patients and systemic prophylaxis for high-risk hosts with or without pulmonary infiltrates. Liposomal amphotericin B (D-AmB), caspofungin, and voriconazole have been used for this strategy. Secondary prophylaxis of invasive aspergillosis with voriconazole is used for patients with a history of previous aspergillosis who are scheduled for a subsequent cycle of immunosuppression that may increase the risk for recurrence.

Reduction of exposure to airborne conidia, such as by HEPA filtration of hospital air, avoiding activities that increase conidial aerosols (room maintenance, dust exposures, and contaminated materials (e.g., potted plants), as well as providing clean water distribution systems, may reduce acquisition of *Aspergillus* by immunosuppressed or neutropenic patients.

For patients with allergic forms of aspergillosis, use of corticosteroids and itraconazole, alone or in combination, may prevent debilitating exacerbations. The toxicity of chronic administration of prednisone warrants strategies for intermittent administration of prednisone or corticosteroid-sparing use of itraconazole.

PROGNOSIS

Untreated invasive aspergillosis is associated with severe morbidity and high mortality in immunocompromised patients. Prognosis is improved by both early initiation of antifungal therapy, reversal of immunosuppression, and successful treatment of the underlying primary disease. For patients with chronic aspergillosis, multidisciplinary specialized supportive care may improve outcome and quality of life.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding the treatment of invasive aspergillosis?

A. Reversal of immunosuppression is critical for successful therapy.
B. Combination antifungal therapy, including a triazole, is the treatment of choice because monotherapy is usually not effective.
C. There are no biomarkers that can be clinically used for following response to treatment.
D. Surgical treatment is rarely needed when long-term, uninterrupted antifungal treatment can be administered.
E. Systemic antifungal therapy is sufficient to treat ocular involvement.

Answer: A Invasive aspergillosis characteristically occurs in immunocompromised hosts. In these individuals, reversal of immunosuppression (e.g., recovery from neutropenia, discontinuation of corticosteroids) is a critical factor in successful management. The antifungal treatment of choice for invasive aspergillosis, according to Infectious Diseases Society of America clinical practice guidelines, is monotherapy with voriconazole; the alternate drug is liposomal amphotericin B. Second-line and salvage treatments likewise involve monotherapy. Surgical treatment is an important adjunctive component of primary therapy for several forms of invasive aspergillosis (e.g., endocarditis, osteomyelitis, epidural abscess, soft tissue infection, and others). Intravitreal antifungal therapy for endophthalmitis and topical irrigation with an antifungal agent for keratitis can provide high concentrations of these agents to ocular compartments that may not be reached by systemic therapy. Galactomannan and (1→3)-β-D-glucan in serum or bronchoalveolar lavage are useful biomarkers.

2. Which of the following statements is correct regarding treatment of different forms of chronic aspergillosis?

A. Long-term voriconazole has a high success rate in curing aspergilloma.
B. Bronchial artery embolization is an effective alternative for curing aspergilloma.
C. Response to antifungal therapy for chronic necrotizing pulmonary aspergillosis is conveniently monitored by serial computed tomography (CT).
D. Surgical resection is recommended for definitive therapy of solitary aspergilloma and chronic cavitary pulmonary aspergillosis.
E. Surgical resection plays an important role in treating disease complicated by hemoptysis.

Answer: E Surgical resection may have an important role in treating patients with recurrent and severe hemoptysis. However, in general, surgical resection in patients with solitary aspergilloma or chronic necrotizing pulmonary aspergillosis is limited by complications of bronchopleural fistula development, *Aspergillus* infection of the pleural space, and potential further worsening of already compromised pulmonary function. Medical therapy has limited benefit in the treatment of aspergilloma. Although some benefit may be derived from extended use of an antifungal triazole, lifelong commitment to it should be balanced against the natural history of spontaneous resolution in about 10% of patients. Bronchial artery embolization (or transthoracic direct intracavitary instillation of antifungal agents) for aspergilloma has only transient benefits but substantial risk. CT or radiologic assessment of response to antifungal therapy in chronic necrotizing pulmonary aspergillosis is difficult because of the underlying chronic lung disease.

3. Allergic bronchopulmonary aspergillosis (ABPA) occurs most frequently in patients with which of the following?

A. Intravenous drug abuse
B. Immunocompromised status
C. Asthma
D. α_1-Antitrypsin deficiency
E. Occupational exposure (e.g., malt workers)

Answer: C ABPA characteristically develops in patients with a history of chronic asthma or cystic fibrosis (not α_1-antitrypsin deficiency). ABPA is characterized by episodic airway obstruction, fever, eosinophilia, mucous plugs containing hyphae, transient infiltrates and parallel "tramline" or ring markings on chest radiographs, bronchiectasis, and upper lobe contraction. Extrinsic allergic alveolitis, an unusual allergic form of *Aspergillus* lung disease, is associated with *Aspergillus clavatus* in malt workers. In contrast, invasive aspergillosis is seen in immunocompromised patients and those with intravenous drug abuse.

340

MUCORMYCOSIS

D.P. KONTOYIANNIS

DEFINITION

Mucormycosis is the accurate unifying term used to describe infections caused by fungi belonging to the order Mucorales. Zygomycosis, an alternative term used to describe these life-threatening infections, has become less accurate based on a recent taxonomic reclassification (using molecular methods) that abolished Zygomycetes as a class (and placed the order Mucorales in the subphylum Mucormycotina).[1] Mucorales typically cause aggressive, acute-onset, frequently fatal angioinvasive infections, especially in immunosuppressed hosts.

EPIDEMIOLOGY

Mucorales fungi are distributed worldwide and found in decaying organic substrates. The true incidence of mucormycosis is not known and probably is underestimated because of difficulties in antemortem diagnosis. The relative frequency of Mucorales families causing infection differs. In a recent review of more than 900 reported cases, the most common microbiologically confirmed infecting species were *Rhizopus* (47%), *Mucor* (18%), *Cunninghamella bertholletiae* (7%), *Apophysomyces elegans* (5%), *Absidia* (5%), *Saksenaea* (5%), and *Rhizomucor pusillus* (4%). Some Mucorales causing infection have specific geographic and host associations. For example, the thermophilic Mucorales *Saksenaea vasiformis elegans* have specific geographic distributions, as recently shown in victims of combat-related injuries from Afghanistan who developed necrotizing soft tissue infections.[2] Also, major natural disasters have been associated with rapidly progressing necrotizing soft tissue infections by infrequently isolated species, such as those caused by *Apophysomyces elegans* in the Joplin tornado victims in 2011.[3]

The classic risk factors for mucormycosis include hematologic malignancy, hematopoietic stem cell or solid organ transplantation, poorly controlled diabetes mellitus, chronic acidemia, prematurity, profound chronic debilitation, trauma, burns, and very rarely intravenous drug use.[4] Nosocomial cutaneous infections can develop at surgical wound and intravenous catheter insertion sites. Finally, breakthrough mucormycosis has been increasingly observed in patients with leukemia and in recipients of hematopoietic stem cell transplants receiving *Aspergillus*-active drugs such as voriconazole (which has no anti-Mucorales activity). This association has been a topic of debate.

PATHOBIOLOGY

Mucorales species are saprophytic, rapidly growing fungi. Angioinvasive growth results in infarction and necrosis of surrounding tissue, which is the hallmark of mucormycosis. The major modes of transmission are inhalation, ingestion, and cutaneous inoculation, with inhalation of spores from environmental sources being the most common. Cutaneous or percutaneous transmission occurs with traumatic disruption of skin barriers, and it is the most important mode of transmission in immunocompetent hosts. Gastrointestinal acquisition, while less common, has occurred in patients with repeated ingestion of spores during severe malnutrition, non-nutritional substances (pica), contaminated herbal/homeopathic products, or allopurinol tablets.

Host immunity in healthy hosts prevents germination of fungal spores unless the inoculum is heavy.[5] To establish invasive infection, spores must overcome both innate and adaptive immune responses to germinate into hyphae. Defects in phagocytic activity caused by insufficient numbers (i.e., neutropenia) and functional defects caused by glucocorticoids, hyperglycemia, and/or acidosis allow unimpeded proliferation of fungi because of the absence of coordinated, effective host responses. Unsurprisingly, mucormycosis is often disseminated in severely immunosuppressed patients, with high

mortality rates. However, lymphopenia may not be as critical in patients with acquired immunodeficiency syndrome.

Free iron is an essential component of the pathogenesis of mucormycosis, as suggested by the predisposition of patients with iron overload and ketoacidosis to such infections. These patients often receive the iron chelator deferoxamine. Both iron overload and use of deferoxamine (which is also used to treat aluminum overload in dialysis recipients) are risk factors for angioinvasive mucormycosis. *Rhizopus oryzae* can utilize deferoxamine as a xenosiderophore to form a ferrioxamine complex and to obtain more iron for use. Reassuringly, the newer iron chelators agents (e.g., deferasirox) are not associated with increased risk for mucormycosis; on the contrary, in preclinical models, deferasirox has exhibited direct fungicidal effects against Mucorales via iron starvation.

Historically, poorly controlled diabetes mellitus (types 1 and 2) has been a major predisposing factor, reported in 36 to 88% of all cases of mucormycosis. In particular, diabetic patients with ketoacidosis are susceptible to mucormycosis. Normal human serum cannot support the growth of *R. oryzae*, whereas serum in diabetic patients can do so. Acidosis disrupts the normal inhibitory activity of serum by attenuating the ability of transferrin to bind iron from the fungus. In addition, quantitative and qualitative neutrophil and phagocytic cell dysfunction occurs in diabetic patients with ketoacidosis and may play a role in the pathogenesis.

CLINICAL MANIFESTATIONS

The clinical presentation of mucormycosis depends on the host's underlying immune and medical condition. Hence, pulmonary mucormycosis is most common in neutropenic or corticosteroid-treated patients (e.g., hematopoietic stem cell and solid organ transplant recipients). In contrast, rhino-orbital or rhinocerebral mucormycosis is the characteristic presentation in patients with diabetic ketoacidosis. Finally, cutaneous mucormycosis in both immunocompetent and immunocompromised hosts is typically seen following local trauma or burns resulting in breakdown of skin integrity and/or subcutaneous tissue injuries. Infectious syndromes associated with Mucorales are grouped based on clinical presentation into one of six categories: (1) rhinocerebral, (2) pulmonary, (3) cutaneous, (4) gastrointestinal, (5) disseminated, and (6) unusual presentations, as follows:

Rhinocerebral Mucormycosis

Rhinocerebral mucormycosis describes an infection originating in the paranasal sinuses after inhalation of Mucorales spores and extending to the orbit (sino-orbital) or brain (rhinocerebral), particularly in patients with diabetic ketoacidosis or those with profound neutropenia.[6] Rhinocerebral mucormycosis is the most common manifestation. Early signs and symptoms of sinus invasion may be indistinguishable from common causes of sinusitis. Common symptoms include sinus pain, congestion, headache, mouth pain, otologic symptoms, and hypo-osmia/anosmia. Involved tissues become red and then violaceous and, finally, black with thrombosis, and tissue necrosis. Necrotic eschar of the nasal cavity and turbinates, facial lesions, and exophytic or necrotic lesions of the hard palate are signs of extensive, rapidly progressing infection. A painful black eschar on the palate or nasal mucosa is a classic diagnostic but late sign. Absence of this finding does not rule out rhinocerebral infection, as necrotic nasal or palate lesions occur in only 50% of patients within 3 days of onset of infection. Extension into the periorbital region is not uncommon at presentation. Signs and symptoms of periorbital and orbital involvement include periorbital swelling, preseptal and/or orbital cellulitis, proptosis, chemosis, blurred vision or rapidly progressing external ophthalmoplegia, diplopia, eyelid gangrene, retinal detachment, and endophthalmitis. Also, patients with extensive rhino-orbital or rhinocerebral disease may present with trigeminal or other cranial nerve palsy, which is consistent with frequent histologic findings of perineural invasion. Infection can rapidly progress through the cavernous sinuses into the central nervous system, resulting in cavernous sinus and internal carotid artery thrombosis. A bloody nasal discharge may be the only sign indicating that the infection has invaded through the nasal turbinates and into the brain. Patients with advanced infection may have cranial neuropathies and/or altered consciousness; bone destruction; retinal artery, internal carotid artery, cavernous, and less often, sagittal sinus, thrombosis; frontal lobe necrosis; epidural and subdural abscesses; and/or basilar artery aneurysm.

Plain films and cerebrospinal fluid findings lack sensitivity in diagnosing rhinocerebral mucormycosis. Computed tomography (CT) and magnetic resonance imaging (MRI) are more useful for revealing soft tissue involvement around the nerve sheaths and bone destruction. CT frequently shows mucosal thickening, air-fluid levels, and bony erosion. Orbital thickening may be detected earlier by using MRI. CT and MRI scans of the orbits may be unremarkable during the initial stages of mucormycosis, highlighting the importance of serial radiographic imaging in monitoring disease progression. Extraorbital muscle thickening is often the first sign of orbital involvement and should prompt empirical antifungal therapy followed by surgical exploration or biopsy.

Accurate diagnosis and prompt medical and surgical intervention are critical because of the rapid progression of the infection. Definitive diagnosis of necrotic lesions using biopsy and rapid histologic assessment of frozen sections should be performed as soon as possible because it directly impacts outcome. In a review of 929 documented mucormycosis cases, the mortality rate was as follows: 62% in rhinocerebral mucormycosis, 24% in sino-orbital involvement, and 16% in isolated sinus disease. Isolated sinusitis is curable by following timely surgical intervention and systemic antifungal therapy.

Pulmonary Mucormycosis

The clinical manifestations of pulmonary mucormycosis are indistinguishable from those of invasive pulmonary aspergillosis. Patients may present with fever refractory to broad-spectrum antibiotics, nonproductive cough, and progressive dyspnea. Less commonly, pleuritic chest pain, hemoptysis, and pleural effusion are seen. If the major pulmonary blood vessels are invaded by fungal hyphae, massive, potentially fatal hemoptysis can occur. Pulmonary mucormycosis can progress and invade adjacent organs via traverse tissue planes, including the diaphragm, chest wall, and pleura (Fig. 340-1). Clues for distinguishing pulmonary mucormycosis from invasive pulmonary aspergillosis include the presence of pansinusitis, a history of prophylaxis with antifungals against *Aspergillus* but not Mucorales (e.g., voriconazole, echinocandins), and possibly continual absence of detectable *Aspergillus galactomannan* antigen in serum. In rare circumstances, pulmonary mucormycosis can present as an endobronchial or tracheal lesion with a less fulminant course, especially in diabetics. Endobronchial mucormycosis may cause airway obstruction or erosion of major pulmonary blood vessels and fatal hemoptysis. In more immunocompetent hosts, pulmonary mucormycosis may present with more atypical, slowly progressing forms. Like *Aspergillus* species, Mucorales can form mycetomas in preexisting lung cavities and cause slowly necrotizing pneumonia and hypersensitivity syndromes. Investigators have also implicated *Rhizopus* species in allergic alveolitis among farm workers or sawmill workers (wood-trimmer's disease).

Because the first-line antifungal typically used for aspergillosis is voriconazole, which lacks activity against Mucorales, failure to achieve a timely diagnosis of pulmonary mucormycosis and delayed antifungal therapy (e.g., amphotericin B) rapidly worsens outcome.

Skin and Soft Tissue Mucormycosis

Cutaneous mucormycosis typically occurs in victims of severe skin or muscular injury. It starts as erythema and a skin induration at a puncture site and progresses to necrosis with a black eschar. Cutaneous infections can quickly extend into the deep fascia and muscle layers. Necrotizing fasciitis is rare and has a poor prognosis. Neutropenic patients in particular are susceptible to lymphatic and blood vessel invasion, infarction, and necrosis with eventual dissemination. Interestingly, the skin appears to be a less common site of secondary involvement with disseminated mucormycosis than of infections by other hyaline molds such as *Fusarium* or *Scedosporium* species. Even so, skin lesions in patients with suspected mucormycosis should raise concerns about disseminated disease and prompt, careful clinical work-up. Because the differential diagnosis of necrotic skin lesions is broad, especially in neutropenic patients, biopsy specimens should be obtained from the center of the lesion down to the subcutaneous fat. Excision and wide débridement of cutaneous lesions, coupled with systemic antifungal therapy and, on occasion, hyperbaric oxygen therapy, can further reduce mortality rates.

Gastrointestinal Mucormycosis

Primary gastrointestinal mucormycosis is rare and can present as necrotizing enterocolitis and involve any part of the alimentary system with mortality rates of more than 85%. It occurs primarily in malnourished patients and premature infants, in which the stomach is the most commonly affected site, followed by the colon and ileum. The liver, spleen, and pancreas also can be involved. Physicians have described liver abscesses following ingestion of herbal products contaminated by *Mucor indicus*. Fungi can invade the bowel wall and blood vessels, resulting in bowel perforation, peritonitis, and massive gastrointestinal hemorrhage. In neutropenic patients, seeding of the gastrointestinal tract is likely more common than previously thought because 75% of gastrointestinal mucormycoses are diagnosed postmortem. Symptoms and

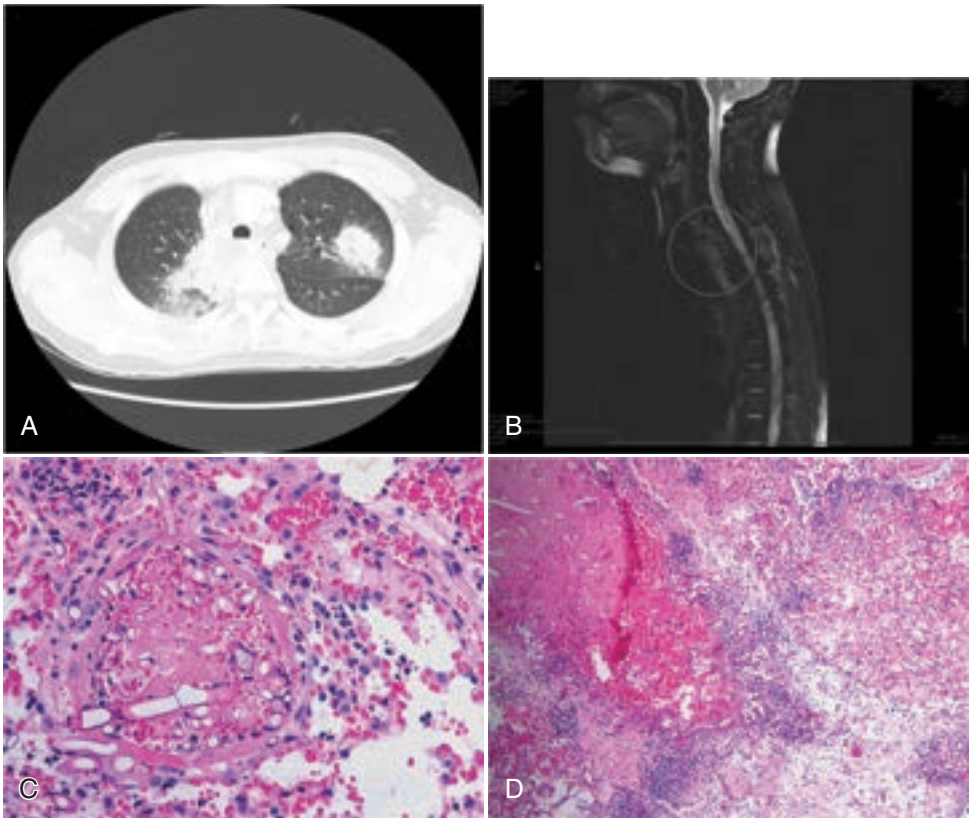

FIGURE 340-1. Extensive, progressive pulmonary mucormycosis in a patient with active leukemia and neutropenia. Characteristic extension of the infection across tissue planes to trachea (producing a fistula) and mediastinum (**A**) and adjacent spine (**B**) are shown. The histopathologic characteristics of profound necrosis and hemorrhage and pauciseptate, broad-based, ribbon-like Mucorales are also shown (**C** and **D**). Culture of a tissue biopsy specimen remained negative. The patient died 3 weeks after diagnosis, despite aggressive use of a high-dose lipid formulation of amphotericin B (AMB) and adjunct immune therapy.

signs of gastrointestinal mucormycosis include fever, abdominal distention, nausea, vomiting, abdominal pain, diarrhea, melena, hematemesis, hematochezia, and masslike appendiceal and ileal lesions.

Disseminated Mucormycosis

Disseminated mucormycosis is rarely apparent antemortem. Severely immunosuppressed patients (e.g., those with prolonged and profound neutropenia, allogeneic stem cell transplant recipients with severe graft-versus-host disease) and patients receiving deferoxamine are at the highest risk. Symptoms vary depending on the site of dissemination and degree of vascular infarction of the affected organs. The most common organ as source of dissemination is the lung, and the most common site of spread is the brain. Diagnosis of disseminated mucormycosis is challenging and requires a high level of suspicion because the infection may present as an unexpected acute vascular event. Biopsy of suspected sites is critical because of the low yield of blood cultures and suboptimal recovery of the fungus from respiratory specimens. Without appropriate timely treatment, virtually all patients with disseminated mucormycosis die.

Rare Clinical Presentations of Mucormycosis

Mucormycosis has protean manifestations that involve any organ. Authors have reported isolated cases of tracheal, mediastinum, bone, heart, kidney, otitis externa, and corneal involvement. More recently, there have been reports of renal mucormycosis in patients with intravenous drug abuse and/or those receiving corticosteroids. Cerebral mucormycosis often presenting as brain abscess involving the basal ganglia, and in conjunction with infective endocarditis, has been typically observed in patients using illicit intravenous drugs. Reports of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis have been rare. In all cases of device-related mucormycosis, prompt removal of the device and several weeks of systemic antifungal therapy are essential for resolution of the infection.

DIAGNOSIS

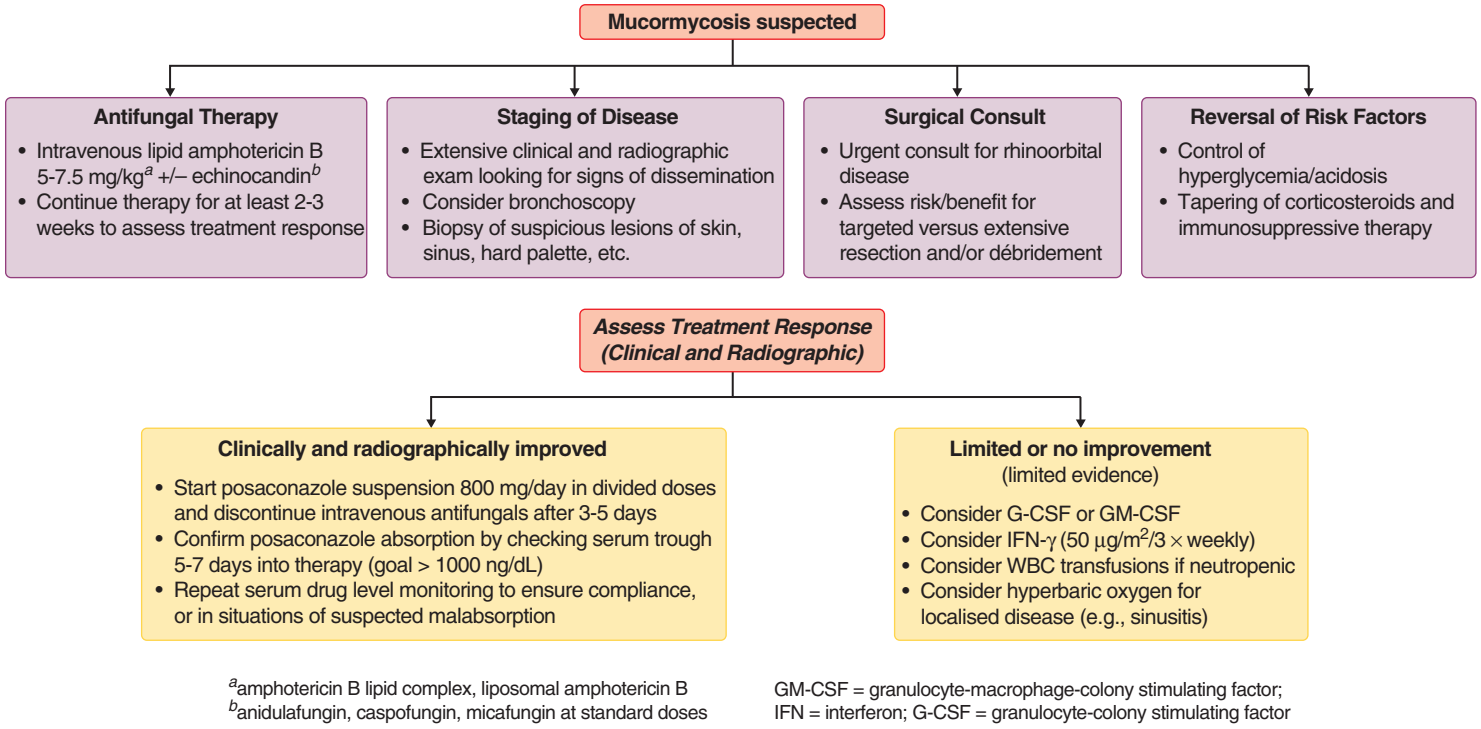
The clinical signs and symptoms of mucormycosis are nonspecific. Therefore, a high level of suspicion in susceptible patient populations is of paramount importance.[7] Biopsy analysis and culture from sterile sites remain critical. Tissue swabs and cultures of sputum, sinus secretions, and bronchoalveolar lavage fluid are usually nondiagnostic. For example, fungal contamination of clinical specimens occurs because the small size of sporangiospores (approximately 6 μm in width) allows easy dispersion via the airborne route. Particles of this size may remain airborne even with very slight movements in air and contaminate clinical samples. Therefore, growth in culture may not represent clinically significant invasive mucormycosis. However, the value of Mucorales-positive cultures (especially repetitive cultures) as an important indication of infection in immunocompromised patients is quite high. The site of infection has a major impact on the likelihood of histopathologic diagnosis. With their ease of accessibility, sinuses are the major site of definite infection.

Histopathology

A variety of stains, including hematoxylin and eosin, Grocott-Gomori methenamine-silver nitrate, and periodic acid–Schiff, reveal characteristic hyphal elements in tissue. Histopathologic examination of infected tissue typically shows characteristic broad (3 to 25 μm in diameter), thin-walled, primarily aseptate hyphae; focal bulbous dilation; and nondichotomous irregular branching at occasional right angles accompanying tissue necrosis and fungal angioinvasion (see Fig. 340-1). Perineural invasion is found in 90% of tissues containing nerves. The inflammatory responses to mucormycosis can range from neutrophilic, granulomatous, and/or pyogranulomatous to minimal inflammation with hemorrhage. Also, fungal hyphae can be examined directly using a potassium hydroxide preparation of a tissue specimen or bronchial alveolar lavage fluid. Although contamination is always a possibility, discovery of fungal elements in a specimen obtained from an immunocompromised host is considered significant. Treatment with fluorescent stains such as Calcofluor White and Blankofluor may enhance detection of hyphal elements during microscopic examination. Improved staining procedures may be important when the number of organisms is small or the amount of tissue is limited.

Culture

Mucorales fungi characteristically produce large, ribbon-like hyphae with irregular diameters and only occasionally septa, resulting in characterization of these organisms primarily as aseptate fungi. Identification can be



[a]amphotericin B lipid complex, liposomal amphotericin B
[b]anidulafungin, caspofungin, micafungin at standard doses

GM-CSF = granulocyte-macrophage-colony stimulating factor; IFN = interferon; G-CSF = granulocyte-colony stimulating factor

FIGURE 340-2. Diagram of the management approach to patients with suspected mucormycosis.

confirmed by observing the characteristic saclike fruiting structures (sporangia), which produce internally spherical yellow or brown spores (sporangiospores). Spores range from 3 to 11 μm in diameter and are easily aerosolized. Blood cultures are rarely positive for these pathogens despite their angioinvasive nature. Paradoxically, even when fungal hyphae are seen in histopathologic analysis, fungal cultures may not be positive because of the friability of nonseptated hyphae, making them more susceptible to damage during tissue manipulation. However, collection of several proper clinical specimens is important. Recovery of Mucorales from tissue can be improved by mincing (not homogenizing) tissue specimens and using culture techniques that simulate in vivo fungal growth, including incubation at 35° to 37°C under relatively semianaerobic conditions.

Morphologic identification of Mucorales requires their cultivation to examine reproductive fruiting structures. Most of these fungi grow rapidly on most fungal media (e.g., Sabouraud dextrose agar) when incubated at 25° to 30° C. These fungi are sensitive to the protein inhibitor cycloheximide, and addition of this agent to fungal media may not ensure optimal recovery. Morphologic features alone, especially when assessed by individuals with expertise in fungal identification, can provide a high level of accuracy comparable to that of molecular methods.

Data on the antifungal susceptibility of Mucorales species. are limited, and minimal inhibitory concentration (MIC) testing is rarely available outside research or research laboratories. The MIC end points for these rapidly growing fungi are inconsistent, not standardized, and at times difficult to interpret. Because interpretive MIC break points for Mucorales have yet to be defined, the correlation between clinical responses and MIC values is uncertain. Mucorales are resistant to many antifungals, including flucytosine, ketoconazole, fluconazole, voriconazole, and the echinocandins. Also, they have variable susceptibility to itraconazole. Amphotericin B (AMB) and posaconazole, a new triazole, are the most active agents in vitro, although their activities differ among different Mucorales families. The activity of antifungal combinations against these fungi has yet to be proved in vivo.

The importance of early differentiation of Mucorales from more common opportunistic molds such as *Aspergillus* species has generated considerable interest in development of culture- or histopathology-independent diagnostic tests such as detection of specific antigens or nucleic acids using polymerase chain reaction or in situ hybridization techniques. Molecular techniques for detecting Mucorales are few, not widely available, and investigational. This is an important unmet need for the management of mucormycosis.

TREATMENT

Approach to the management of suspected mucormycosis and assessment of treatment response are shown in Figure 340-2. Successful treatment of mucormycosis relies on a multifaceted strategy that includes (1) aggressive attempts at diagnosis and rapid initiation of effective antifungal therapy and (2) extensive surgical débridement, and (3) rapid control of underlying medical conditions.[8]

Again, early diagnosis is critical to the outcome. Small focal lesions can be surgically resected before they progress to involve critical structures or distal organs. Patients often have indolent clinical presentations until extensive invasion or dissemination of the infection occurs.[9]

Antifungal Therapy

Delayed administration of systemic antifungal therapy increases the probability of patient death. Most of the knowledge about the activity of currently used antifungals comes from small case series, anecdotes, and animal models of infection. Therefore, the optimal treatment approach is uncertain.[10] Most of the clinical experience has been with AMB. Previously, the recommended antifungal therapy for mucormycosis included AMB deoxycholate at the maximum tolerated dosage, usually 1.0 to 1.5 mg/kg/day. The nephrotoxic and systemic toxic effects of regular AMB led to the development of the lipid formulations of AMB (liposomal AMB, AMB lipid complex, AMB colloidal dispersion). These agents are less nephrotoxic than regular AMB and can be given at higher doses (e.g., 5 to 10 mg/kg per day). Lipid formulations of AMB are now considered the drugs of choice for mucormycosis. Furthermore, use of percutaneous or aerosolized AMB in conjunction with concomitant systemic therapy has been successful in selected patients with pulmonary mucormycosis. Topical therapy with AMB as well as other polyenes (natamycin) may be effective against primary cutaneous and ocular mucormycosis. Treatment of mucormycosis with AMB-based combinations has been successful in small retrospective case series. In particular, a benefit has been suggested for echinocandin-liposomal AMB combination in 41 diabetic patients with rhino-orbital mucormycosis compared with the ones who received amphotericin B lipid complex (ABLC) or liposomal AMB alone. This benefit was most pronounced in patients with cerebral involvement.

Although azoles traditionally have been inactive against Mucorales, the new broad-spectrum triazole posaconazole demonstrated promising activity. Among open-label studies and retrospective surveys evaluating posaconazole suspension as salvage therapy (800 mg/day) in patients with refractory mucormycosis, the agent showed a response rate approaching 70%. Furthermore, posaconazole has been well tolerated. Determining whether posaconazole alone or combined with a lipid formulation of AMB or other agent (e.g., deferasirox) is of value requires further study. Posaconazole has limitations because absorption of the oral suspension is suboptimal in patients with mucositis,

severe diarrhea, acid suppression therapy, or poor oral intake. Absorption of oral posaconazole is maximized when administered with high-fat foods in separate doses (four times daily). Finally, steady-state plasma concentrations of posaconazole are not reached until around 1 week of therapy. The new formula of posaconazole (posaconazole tablets 300 mg/daily) has not been studied adequately in mucormycosis.

The duration of antifungal therapy should be determined on an individual basis. Near normalization of radiographic imaging, negative follow-up biopsy specimens, and cultures from the affected site, as well as recovery from immunosuppression, are important indicators for stopping antifungal therapy.

Surgery

Surgical débridement of cutaneous lesions is crucial and must be done without delay because of the aggressively invasive nature of mucormycosis. A coordinated effort among all subspecialties involved (surgery, infectious diseases, head and neck, ophthalmology, pathology, clinical microbiology, and plastic surgery) is crucial, and the internist can play a vital role coordinating it.

Repeated removal of necrotic tissue or aggressive surgical measures such as enucleation of the eye may be required for control of the infection. Decisions regarding the extent of débridement are often made at the bedside. A CT or MRI scan before surgery and intraoperative frozen section analysis help determine the extent of tissue and tissue margin involvement. Low platelet counts, as may be seen in patients with underlying hematologic malignancies, must be corrected with transfusions before surgical intervention. Unfortunately, bleeding problems can limit surgical options. Surgery in conjunction with systemic antifungal therapy has been shown to significantly improve survival rates.

Management of Comorbidity and Adjunct Treatments

Adjunct measures have been proposed to improve host immunity, tissue viability, and impeding fungal proliferation. Rapid correction of underlying conditions, such as control of hyperglycemia, reversal of ketoacidosis, rapid tapering of glucocorticoid therapy, and discontinuation of deferoxamine-based treatment, can influence outcomes. Hyperbaric oxygen is a beneficial adjunct therapy for mucormycosis, particularly in diabetic patients with rhinocerebral disease. Specifically, the increased oxygen pressure achieved seems to improve neutrophil activity and oxidative killing by polyene antifungals. Also, high concentrations of oxygen can inhibit growth of the organism in vitro and improve the rate of wound healing by increasing the release of tissue growth factors. However, this treatment has not been studied vigorously to determine efficacy and cannot be routinely recommended. Investigators have proposed several immune augmentation strategies as adjunct therapy, including administration of cytokines (e.g., granulocyte colony-stimulating factor [G-CSF], interferon). In refractory neutropenic patients, granulocyte transfusion may be beneficial until granulocyte recovery. These adjunct measures, although promising, are yet to be studied sufficiently. Finally, the new iron chelator deferasirox has been considered as an adjunct antifungal agent based on preclinical studies and very limited human experience with patients with refractory mucormycosis. Results of the small randomized, double-blinded DEFEAT Mucor trial were published in 2012.[A1] Twenty patients with proven or probable mucormycosis were randomized to treatment with liposomal amphotericin B plus deferasirox (20 mg/kg per day for 14 days) or liposomal amphotericin B plus placebo. Although reported adverse events were similar between the two study groups, significantly higher mortality rates were found in patients randomized to receive deferasirox at 30 (45% vs. 11%) and 90 days (82% vs. 22%, $P = .01$). However, patients in the deferasirox arm were more likely than patients in the placebo arm to have active malignancy, neutropenia, and/or corticosteroid therapy, and less likely to have received additional antifungals, making the results of this pilot trial less conclusive. Nevertheless, currently available data do not support a role for initial deferasirox therapy for mucormycosis. Further knowledge of the unique virulence attributes of Mucorales based on genomic analysis might aid the development on novel therapeutic targets.

REVIEW QUESTIONS

1. What is the best way to diagnose mucormycosis?

A. Serum galactomannan
B. Serum β-D-glucan
C. Anti-Mucorales antibodies
D. Polymerase chain reaction (PCR)
E. Tissue for biopsy and culture

Answer: E Unfortunately, there are no biomarkers to diagnose mucormycosis, and this is a major unmet need for the management of the disease. Specifically, galactomannan and β-D-glucan do not detect Mucorales. PCR, although promising, remains investigational. There are no data about the value of anti-Mucorales antibodies for diagnosis. Tissue for histopathologic analysis and culture remains the only method for documenting invasive disease. (See Skiada A, Lanternier F, Groll AH, et al. Diagnosis and treatment of mucormycosis in patients with haematological malignancies: guidelines from the 3rd European Conference on Infections in Leukemia [ECIL 3]. *Haematologica.* 2013;98[4]:492-506; and Tacke D, Koehler P, Markiefka B, Cornely OA. Our 2014 approach to mucormyocis. *Mycoses.* 2014;57[9]:519-524.)

2. All the conditions below are common risk factors for mucormycosis *except* which one of the following?

A. Iron overload
B. Poorly controlled diabetes
C. Crowding conditions
D. Severe trauma of soft tissues
E. Chronic severe immune suppression

Answer: C Classic risk factors for the disease include iron overload that results in increased availability of host iron to support invasive fungal growth, significant and chronic immunosuppression such as severe cytopenia, systemic corticosteroids, crushing soft tissue injury (e.g., following severe trauma), and poorly controlled diabetes, especially in the setting of acidosis. Mucorales are extremely rare causes of catheter related infections not known to be associated with crowding conditions in the absence of trauma. (See Epidemiology.)

3. What is the most common Mucorales species causing mucormycosis?

A. *Mucor* spp
B. *Cunninghamella bertholletiae*
C. *Rhizomucor* spp
D. *Rhizopus* spp
E. *Apophysomyces* spp

Answer: D Although there is notable geographic and host-related variability of infecting Mucorales, on a global scale *Rhizopus* species are the most common cause of mucormycosis, accounting for nearly 50% of such cases. (See Epidemiology.)

4. Which of the following azoles has the most potent activity against Mucorales?

A. Fluconazole
B. Posaconazole
C. Voriconazole
D. Itraconazole
E. Ketoconazole

Answer: B Mucorales are innately resistant to most antifungal drugs. Specifically, the only agents that have activity are amphotericin B and the triazole posaconazole. (See Skiada A, Lanternier F, Groll AH, et al. Diagnosis and treatment of mucormycosis in patients with haematological malignancies: guidelines from the 3rd European Conference on Infections in Leukemia [ECIL 3]. *Haematologica.* 2013;98[4]:492-506; Tacke D, Koehler P, Markiefka B, Cornely OA. PNEUMOCYSTIS PNEUMONIA

JOSEPH A. KOVACS

DEFINITION

Pneumocystis jirovecii is a fungus that causes pneumonia almost exclusively in immunodeficient patients. In the 1950s, it was recognized as the cause of an epidemic interstitial plasma cell pneumonia that occurred primarily in premature and malnourished infants. During the 1960s and 1970s, *Pneumocystis* pneumonia (PCP) was seen with increasing frequency in immunodeficient patients, especially those receiving immunosuppressive chemotherapy. In the early 1980s, an epidemic of PCP in previously healthy adults heralded the onset of the HIV/AIDS epidemic; in the United States and in many other parts of the world, PCP has been the most common life-threatening opportunistic infection in this population. Although the frequency of PCP decreased in HIV-infected patients first in association with the widespread use of anti-*Pneumocystis* prophylaxis and later with the introduction of effective combination antiretroviral therapy for HIV/AIDS, it continues to be seen with regularity in HIV-infected and other immunodeficient patients.[1] Over the past decade, there has been a marked increase in outbreaks of PCP among renal transplant recipients, especially in Europe and Australia.

The Pathogen

Pneumocystis, which was long thought to be a protozoan, has now been definitively classified as an ascomycete fungus, based primarily on molecular studies demonstrating that a large number of genes have a high level of homology to other fungi rather than to protozoa. Molecular as well as antigenic studies have further demonstrated that the genus *Pneumocystis* includes a group of closely related organisms that are unique species, each of which can infect only a single host species. This has led to the application of species names to the group of organisms previously called *Pneumocystis carinii*. *P. carinii* is reserved for a species that infects rats (there is also a second species, *P. wakefieldiae*, that can infect rats). The organism infecting humans has been renamed *P. jirovecii,* in honor of Otto Jirovec, one of the investigators who recognized that this organism is the causative agent of interstitial plasma cell pneumonia. Despite the name change, the acronym PCP (for *Pneumocystis* pneumonia) continues to be used to designate the disease in humans.

Pneumocystis species show a strict host specificity: attempts to transmit, for example, rat or human *Pneumocystis* to mice have been unsuccessful. Molecular evolutionary studies suggest that *Pneumocystis* species coevolved with their hosts, with rat and mouse *Pneumocystis* diverging an estimated 33 million years ago, similar to the time rat and mouse species diverged.

Studies of *Pneumocystis* have been substantially hampered by an inability to grow any species in culture for a sustained period. Thus, the life cycle of *Pneumocystis* is unknown, although putative life cycles based on morphologic studies have been proposed; there is accumulating evidence supporting a sexual phase in the life cycle. There are two easily recognized forms of the organism: trophic forms (≈2 to 6 μm in diameter) and cysts (also called asci; ≈6 to 8 μm in diameter), which can contain up to eight intracystic bodies (ascospores); additional intermediate forms are also seen. Trophic forms, which have an amorphous shape, are estimated to outnumber cysts, which are spherical, by approximately 10 : 1 in an infected lung. β-1,3-Glucan is found in the cyst form only, where it contributes to the rigidity of the cell wall. The estimated genome size is approximately 8 million base pairs.[2] The most abundant surface protein of *Pneumocystis*, the major surface glycoprotein, is found on both cysts and trophic forms and is encoded by a multicopy gene family, only one of which is apparently expressed in a given organism; this provides *Pneumocystis* with the potential for antigenic variability. Although, to date, only a single *Pneumocystis* species has been found that infects humans, molecular typing techniques have demonstrated a high level of diversity among human *Pneumocystis* isolates.

EPIDEMIOLOGY

Pneumocystis has a worldwide distribution. Serologic studies show a high prevalence of anti-*Pneumocystis* antibodies in all populations studied to date.

In America and Europe, serologic studies have demonstrated that most humans develop antibodies to *Pneumocystis* by an early age, suggesting that this is a ubiquitous organism. In support of this, an autopsy study in infants younger than 1 year with no major underlying medical problems identified *Pneumocystis* infection in lung tissue by polymerase chain reaction (PCR) in 100% of cases.

Animal studies have demonstrated that *Pneumocystis* is transmitted by the respiratory route. Human infection appears to be transmitted in the same manner. There is no evidence that water or fomites play a role in transmission. A small number of animal studies and very limited human data suggest that transmission can occur transplacentally, although the clinical relevance is unknown.

Given the strict host specificity of *Pneumocystis*, the source of organisms infecting humans is presumably other humans, by either direct or indirect exposure; *Pneumocystis* is not a zoonosis. PCR-based studies have identified *Pneumocystis* DNA in air sampled in close proximity to patients with PCP, and outbreaks, especially in renal transplant patients, have been linked to a single strain of *Pneumocystis*, both of which suggest that patients with PCP can transmit it to other susceptible patients.[3] Because clinically apparent PCP is rare, and given the high penetration of infection into healthy human populations at a young age, *Pneumocystis* infection is also likely acquired from apparently healthy humans, in whom subclinical infection (either asymptomatic or minimally symptomatic) must be quite common to allow such rapid and broad dissemination. The high frequency of detection in infants suggests an important role in transmission.

Although infection with *Pneumocystis* is widespread, in immunocompetent hosts, it does not appear to cause significant disease. Clinically significant PCP occurs exclusively in patients with severe levels of immunodeficiency that are usually associated with a high risk for other opportunistic pathogens. Populations at risk include those with congenital immunodeficiencies (Chapter 250), especially severe combined immunodeficiency (SCID) and hyper–immunoglobulin M (IgM) syndrome; patients with HIV infection (Chapter 384) and human T-lymphotropic virus-1–associated lymphoma (Chapter 378); patients receiving chemotherapy for the treatment of malignancies, especially lymphoma; transplant patients receiving immunosuppressive therapy; and patients being treated with prolonged courses of immunosuppressive drugs (Chapter 35), especially corticosteroids, for inflammatory diseases such as Wegener's granulomatosis or systemic lupus erythematosus. Biologic agents such as rituximab and those targeting tumor necrosis factor-α (TNF-α) are also associated with an increased, though low, absolute risk for PCP (e.g. 0.18 to 0.4% in patients receiving anti-TNF-α agents in Japan).[4] Among patients with HIV infection, the best predictor of the risk for developing PCP is the CD4 count: patients with CD4 counts less than 200 cells/mm^3, and especially those with CD4 counts less than 100 cells/mm^3, are at greatest risk. Patients with a prior history of PCP and those with unexplained fever, weight loss, or thrush are also at increased risk. Among other patient populations, laboratory parameters are not as useful in quantifying risk, although non-HIV patients with CD4 counts less than 200 cells/mm^3 may be at increased risk. Additional information on risk is provided in the section on prophylaxis.

For many years, development of PCP was thought to result from a reactivation of latent infection by organisms that remained viable following infection at an early age, similar to tuberculosis. However, recent molecular epidemiologic studies based on the detection of mutations in the dihydropteroate synthase (DHPS) gene of *Pneumocystis*, as well as genotyping of isolates from outbreaks of PCP primarily in renal transplant patients, have provided compelling evidence that the infecting strain is often recently acquired. Molecular studies have further documented that in the majority of non-outbreak cases of PCP, more than one strain can be identified in respiratory samples. In patients who develop recurrent PCP, this recurrence can be due to relapse, especially for early recurrences, or to reinfection with a novel strain. Recurrent PCP occurs almost exclusively in HIV-infected patients, in whom the risk was greater than 50% early in the AIDS epidemic, before the availability of highly active antiretroviral therapy (HAART) and the broad use of anti-*Pneumocystis* prevention.

PATHOBIOLOGY

Animal studies have provided important insights into the pathogenesis of *Pneumocystis* infection. Exposure for as little as 1 day to a *Pneumocystis*-infected animal results in transmission of infection. In healthy animals, an adaptive immune response develops by approximately 5 to 6 weeks, which leads to control and clearance before the organism burden produces symptoms. CD4 cells are critical to this control, although other populations, including B cells and macrophages, also play important roles. CD8 cells can contribute to the associated inflammation. In immunodeficient animal models, inability to control *Pneumocystis* replication leads to severe pneumonia by 2 to 3 months. Limited human data suggest a similar time course. Host inflammatory responses appear to play a critical role in the development of pulmonary symptoms. This may account for the development of symptoms of PCP in patients in whom corticosteroids are being tapered, as well as the exacerbation of hypoxia that develops approximately 4 days after the initiation of anti-*Pneumocystis* therapy (in the absence of concomitant corticosteroid therapy).

The lung pathology in patients with PCP is characteristic. Staining with hematoxylin and eosin demonstrates an acellular, foamy, eosinophilic, intra-alveolar exudate associated with mild interstitial inflammation (Fig. 341-1). With disease progression, hyaline membrane formation and interstitial as well as intraluminal fibrosis develop. Although methenamine silver stain highlights cysts scattered throughout the eosinophilic exudate, based on Giemsa staining of thin sections as well as electron micrographs, this exudate is composed almost entirely of *Pneumocystis* organisms. Atypical pathology, including noncaseating granulomas and intrapulmonary cystic changes, can also be seen.

As noted earlier, patients with certain congenital immunodeficiencies, especially SCID patients, who have global T- and B-cell defects, and hyper-IgM syndrome patients, whose primary defect is in CD40-CD40L signaling,

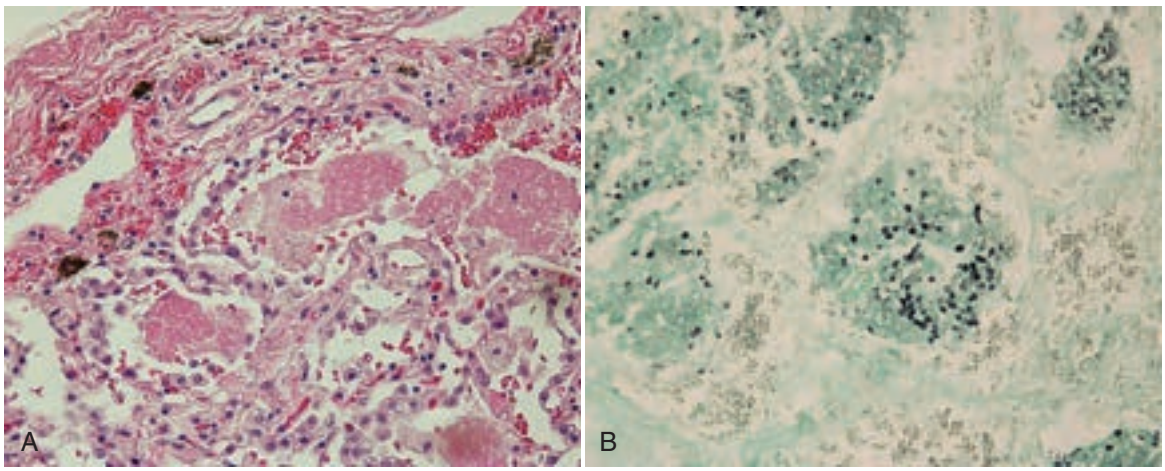

FIGURE 341-1. Histopathology of the lung of a patient who died from *Pneumocystis* pneumonia (PCP). A, The hematoxylin and eosin–stained section shows the characteristic acellular, eosinophilic, intra-alveolar exudate that is typical of PCP. **B,** Methenamine silver staining of lung tissue from the same patient demonstrates black-staining cysts scattered throughout the intra-alveolar exudates.

are at increased risk for developing PCP. Among HIV-infected patients, polymorphisms in the FcγRIIa gene and in the chemokine receptor gene for CCRL2 were each associated with an increased risk for developing PCP in single studies.[5]

CLINICAL MANIFESTATIONS

In nonimmunosuppressed humans, no well-defined clinical syndrome is associated with *Pneumocystis* infection. *Pneumocystis* has been identified in infants by PCR and may be associated with a mild respiratory syndrome, but a postulated association with sudden infant death syndrome has not been supported by data from well-controlled studies. *Pneumocystis* has been detected by PCR in pulmonary samples from patients with chronic obstructive pulmonary disease (COPD), but what role, if any, it plays in the development or progression of COPD (Chapter 88) remains to be elucidated.[6]

Pneumonia is the primary clinical manifestation of *Pneumocystis* infection in immunosuppressed patients. PCP typically presents with a fever, nonproductive cough, and shortness of breath that initially occurs only on exertion but, without therapy, inevitably progresses to dyspnea at rest. Only one or two of these symptoms may be present initially. Development of symptoms may be insidious, over the course of a few weeks, as is common in patients with HIV infection; a more rapid onset, over the course of only a few days, is more common in non-AIDS patients. Purulent sputum production is unusual, and chills and chest pain occur in a minority of patients. Patients with HIV infection may present with other manifestations of immunodeficiency, including weight loss and thrush.

In non-AIDS patients, corticosteroids are a common risk factor.[7] Clinical manifestations may develop as corticosteroids are being tapered, which presumably represents the unmasking of an inflammatory response to the infection as immunosuppression is decreased.

Rarely, extrapulmonary disease can involve the skin, eye (choroiditis), central nervous system, bone marrow, thyroid, spleen, liver, gastrointestinal tract, lymph node, or multiple organs in disseminated disease. Extrapulmonary disease can occur with or without concurrent pneumonia. Use of aerosol pentamidine for prophylaxis has been associated with an increased risk for extrapulmonary disease in HIV-infected patients, but even in that circumstance, it remains extremely rare. Symptoms are related to the specific site involved and may be nonspecific; diagnosis is often made at autopsy.

DIAGNOSIS

Given the nonspecific symptoms, especially early in the disease process, clinicians must have a high index of suspicion for PCP even in patients not known to be immunosuppressed; many patients with HIV infection are unaware of their status until they present with an opportunistic infection. Knowledge of the most recent CD4 count is helpful in assessing HIV-infected patients because PCP is rare in those whose CD4 counts are above 200 cells/mm^3.

Physical examination and routine laboratory tests are usually not helpful in making the diagnosis because many pulmonary processes, both infectious and noninfectious, can present in a similar manner. Moreover, even though patients may be tachypneic and appear to be in respiratory distress, those presenting early in the disease course may have an entirely normal lung examination. Lymphopenia is common but is a manifestation of the underlying disease rather than PCP. Lactate dehydrogenase levels may be elevated but have poor specificity.

The initial evaluation should include a chest radiograph and assessment of arterial oxygenation, either by blood gas measurement or by pulse oximetry. The chest radiograph typically shows perihilar or diffuse bilateral interstitial infiltrates that progress to a diffuse alveolar pattern (Fig. 341-2). However, PCP has been associated with unilateral disease, focal disease, consolidation, nodules, cavities, pneumothorax, and, rarely, pleural effusions. In up to 30% of patients with HIV infection, the chest radiograph appears normal; in this situation, a computed tomography (CT) scan of the chest, especially high-resolution CT, is invariably abnormal, usually showing a patchy or diffuse ground-glass pattern (see Fig. 341-2).[8]

Arterial oxygenation at rest is often abnormal, although in 30% or more of cases, it is within normal limits. Exercise testing induces desaturation and an increase in the alveolar-arterial oxygen (A-a O_2) gradient in the majority of patients with PCP, even those with normal oxygenation at rest or a normal chest radiograph. An abnormal resting diffusing capacity is also common. However, although many of these tests have a high sensitivity for PCP, their specificity is poor because other respiratory processes show similar abnormalities.

Serologic tests are not helpful in diagnosing PCP. Although antibody titers against recombinant *Pneumocystis* proteins such as major surface glycoprotein may be increased in patients with PCP, such tests have not shown utility for diagnosis in individual patients. Although serum and bronchoalveolar lavage (BAL) β-D-glucan levels are elevated in many patients, this again is a nonspecific test because other fungal infections can also lead to elevations, and conditions unrelated to fungal infection can lead to false-positive results. To date, there are inadequate data from well-conducted prospective trials to support routine use of this assay for definitive diagnosis of PCP.

Because *Pneumocystis* cannot be cultured, a definitive diagnosis of PCP requires detection of the organism in a pulmonary sample. This can be accomplished by any number of colorimetric or immunologic stains or by molecular techniques. Until the development of anti-*Pneumocystis* monoclonal antibodies in the 1980s, colorimetric stains were routinely used, and they continue to be used at many centers owing to cost considerations. Such stains include Gomori methenamine silver, toluidine blue O, Gram-Weigert, and cresyl echt violet, which stain the cyst wall of *Pneumocystis*, as well as Giemsa-type stains, including Diff-Quik, which can stain both trophic forms, the more abundant form of the organism, and intracystic bodies within cysts, but not the cyst wall. *Pneumocystis* can also be detected by Calcofluor white, Papanicolaou, periodic acid–Schiff, and, rarely, Gram stain. None of the colorimetric stains is specific for *Pneumocystis*. Cyst wall stains such as Gomori methenamine silver and toluidine blue O can stain other fungi, and Giemsa-type stains also stain background cells and cellular debris. The latter requires substantial expertise for correct interpretation.

Immunofluorescent assays using anti-*Pneumocystis* monoclonal antibodies provide a number of advantages over colorimetric stains. They are specific for *Pneumocystis* and do not show cross-reactivity with other organisms, including fungi; they can be performed and interpreted rapidly; and they have increased sensitivity, especially when examining induced sputum samples (Fig. 341-3).

Molecular techniques, primarily PCR-based assays, have been extensively evaluated for diagnosing PCP. PCR assays are 10- to 100-fold more sensitive than stains for the detection of *Pneumocystis;* this may allow for diagnosis using samples such as oral washes, which have a lower organism burden than induced sputum or BAL.[9] This increased sensitivity, however, is associated with decreased specificity because it allows the detection of organisms in patients ultimately shown not to have PCP.[10] The latter situation presumably reflects colonization or subclinical infection that does not require specific anti-*Pneumocystis* therapy. PCR-based assays are currently not broadly used because of limited availability, lack of standardization among laboratories, and the lack of a commercial product with U.S. Food and Drug Administration approval.

As detection methods for *Pneumocystis* improved, there was a parallel improvement in sample acquisition. Before the AIDS epidemic, open lung biopsy was required for diagnosis. During the 1980s, bronchoscopy, initially with brushings and biopsy, and subsequently with BAL, was shown to have a greater than 90% sensitivity for diagnosing PCP; BAL continues to be the primary diagnostic modality at many centers today. Although expectorated sputum has a low diagnostic yield, induced sputum, especially when combined with immunofluorescent staining, can have a sensitivity approaching 90%, although in many centers the diagnostic yield is much lower, likely due in part to variability in the methods used for induction and processing. Ideally, sputum induction should be the first step in diagnosis, followed by bronchoscopy with BAL (Fig. 341-4). Bronchoscopic or open lung biopsy is only rarely needed to make the diagnosis.

The differential diagnosis of pulmonary infiltrates in immunosuppressed patients is very broad and includes infections such as adenovirus, cytomegalovirus, tuberculosis, cryptococcosis, histoplasmosis, aspergillosis, and toxoplasmosis, as well as noninfectious processes such as tumor, congestive heart failure, pulmonary emboli, radiation- and chemotherapy-induced pneumonitis, and, especially in HIV-infected patients, nonspecific interstitial pneumonitis and Kaposi's sarcoma.

TREATMENT

Rx

Specific anti-*Pneumocystis* therapy should be initiated promptly when the diagnosis is suspected in a potentially susceptible patient. Dosing regimens with documented efficacy are listed in Table 341-1. Although there are no controlled studies defining the optimal duration of therapy, HIV-infected patients should be treated for 21 days and non-HIV patients for at least 14

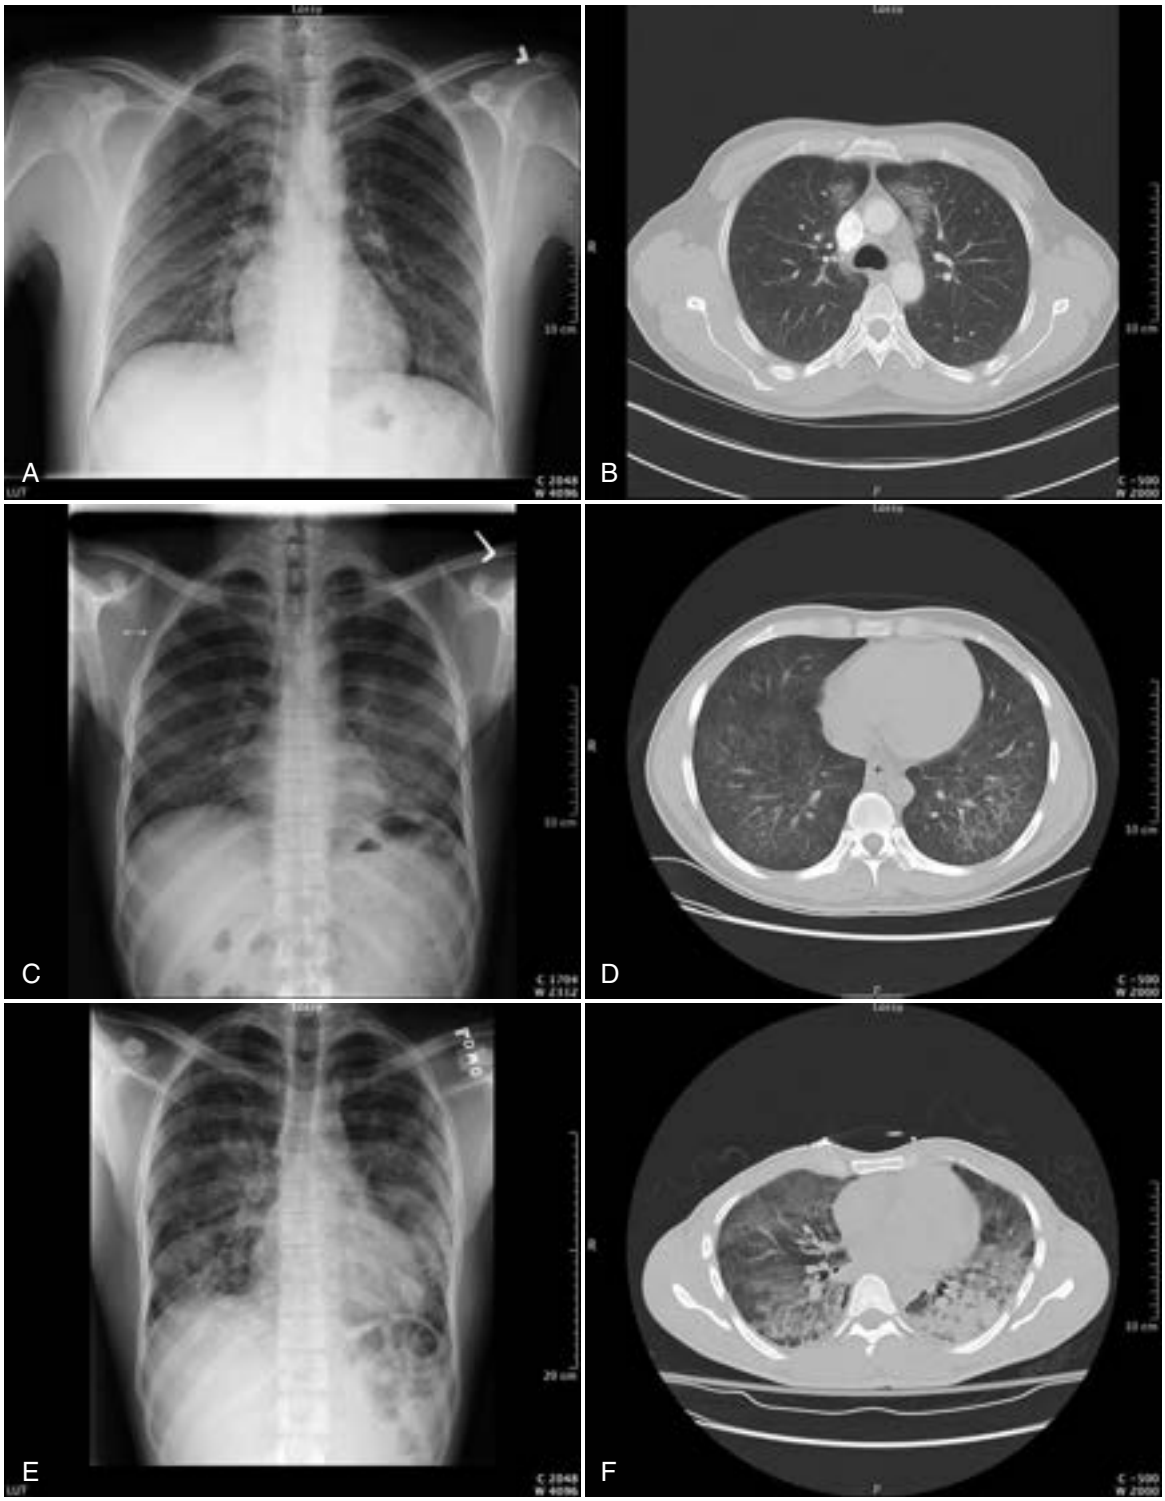

FIGURE 341-2. **Chest radiographs (A, C, E) and corresponding computed tomography (CT) scans (B, D, F) from three HIV patients diagnosed with laboratory-confirmed *Pneumocystis* pneumonia. Patient 1 presented with no symptoms; had minimal abnormalities on an incidental chest radiograph (A), suggesting an interstitial process; and had focal infiltrates on CT (B). Patient 2 presented with fever and weight loss but no shortness of breath. Pulse oximetry demonstrated 99% saturation at rest, with a decrease to 89% with exercise. Chest radiograph (C) showed bilateral lower lobe infiltrates, and CT (D) showed bilateral lower lobe interstitial infiltrates with patches of ground-glass attenuation. Patient 3 presented with a 2-week history of fever, night sweats, shortness of breath, and weakness. His Pao_2 at diagnosis was 67 mm Hg, and his A-a O_2 gradient was 53 mm Hg. Chest radiograph (E) showed bilateral mid and lower lung field infiltrates, and CT (F) showed bilateral infiltrates with lower lung consolidation.**

days.[11,12] For HIV-infected patients with moderate to severe disease (Pao_2 <70 mm Hg or A-a O_2 gradient >35 mm Hg), concomitant corticosteroid therapy should be administered. In contrast, the use of corticosteroids in non-HIV patients is not well defined, as discussed later. The diagnosis should be definitively confirmed by sputum induction or bronchoscopy as soon as possible; however, delaying such confirmation for a few days after the initiation of therapy will not decrease the diagnostic yield because organisms can be detected in clinical samples for more than 3 weeks after the initiation of therapy. Empirical therapy in the absence of a confirmed diagnosis runs the risk of delaying appropriate therapy for another infection, giving inappropriate therapy with known toxicities, and performing a definitive procedure such as bronchoscopy when the patient is failing therapy and consequently has more severe pulmonary compromise.

The treatment of choice for PCP or extrapulmonary disease, regardless of severity, is trimethoprim-sulfamethoxazole, which combines inhibitors of two enzymes in the folate synthetic pathway of *Pneumocystis*: sulfamethoxazole, an inhibitor of DHPS, and trimethoprim, an inhibitor of dihydrofolate reductase (DHFR). Trimethoprim-sulfamethoxazole is available in both oral and intravenous formulations. Oral therapy should be reserved for patients with mild to moderate disease in whom poor absorption is not a concern.

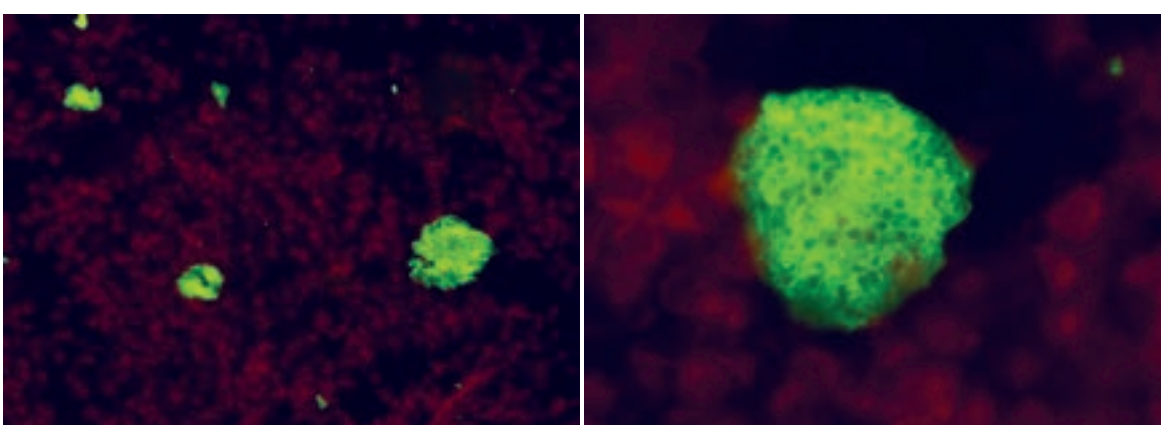

FIGURE 341-3. **Immunofluorescent detection of *Pneumocystis* using a direct fluorescent antibody test to examine an induced sputum sample. A,** Low power (100× original) allows visualization of multiple clusters of organisms staining bright green. **B,** Under high power (400× original), individual organisms can be seen within a single cluster.

TABLE 341-1 DRUG REGIMENS FOR TREATMENT OF *PNEUMOCYSTIS PNEUMONIA* (PCP)

INDICATION	REGIMEN PREFERENCE	DRUG	ROUTE	DOSE	COMMENTS
Mild PCP: PaO_2 ≥70 mm Hg or (A-a) O_2 gradient ≤35 mm Hg	Preferred	Trimethoprim-Sulfamethoxazole (TMP-SMX)	PO	2 double-strength (160 TMP+800 SMX) tablets TID	
	Alternative	Trimethoprim plus	PO	5 mg/kg TID (15 mg/kg/d)	
		Dapsone	PO	100 mg QD	If possible test for G6PD deficiency before use
	Alternative	Clindamycin plus	PO	450 mg QID or 600 mg TID	
		Primaquine	PO	30 mg (base) QD	If possible test for G6PD deficiency before use
	Alternative	Atovaquone	PO	750 mg BID with food	
Moderate to severe PCP: PaO_2 <70 mm Hg or (A-a) O_2 gradient >35 mm Hg; moderate PCP ((A-a) O_2 gradient 35 to 45 mm Hg); can be treated with an oral regimen	Preferred	Trimethoprim-Sulfamethoxazole (TMP-SMX)	IV	5 mg/kg Q8H TMP and 25 mg/kg Q8H SMX (15 mg/kg/d TMP and 75 mg/kg/d SMX)	May switch to oral therapy following clinical improvement
	Alternative	Pentamidine	IV	3-4 mg/kg QD	Infuse over >60 minutes
	Alternative	Clindamycin plus	IV	600 mg Q6H or 900 mg Q8H	May switch to oral therapy following clinical improvement
		Primaquine	PO	30 mg (base) QD	No parenteral formulation is available
Adjunctive therapy for moderate to severe PCP: PaO_2 <70 mm Hg or (A-a) O_2 gradient >35 mm Hg	Preferred	Prednisone	PO	40 mg BID, days 1-5; 40 mg QD, days 6-10; 20 mg QD days 11-21	Begin as early as possible and within 72 hours; efficacy if started later has not been demonstrated
	Preferred	Methylprednisolone	IV	30 mg BID, days 1-5; 30 mg QD, days 6-10; 15 mg QD days 11-21	Use if parenteral therapy is necessary

Note: HIV-infected patients should receive 21 days of therapy; non-HIV patients should receive at least 14 days of therapy.

Outpatient therapy should be reserved for patients with mild to moderate disease who will reliably return for follow-up.

The efficacy of trimethoprim-sulfamethoxazole for both the treatment and the prevention of PCP was first demonstrated in a pediatric cancer population in the 1970s; it has been the first-line therapy since then, when the only alternative was pentamidine. The high incidence of PCP during the early years of the AIDS epidemic led to the identification of a number of new agents with anti-*Pneumocystis* activity, and these were extensively evaluated in randomized controlled trials, primarily in HIV-infected patients. In patients with mild to moderate disease (A-a O_2 gradient <45 mm Hg), trimethoprim-sulfamethoxazole has superior efficacy compared with atovaquone and similar efficacy compared with trimethoprim-dapsone and clindamycin-primaquine. In patients with moderate to severe disease (A-a O_2 gradient >30 mm Hg), it showed superior efficacy to trimetrexate, a potent inhibitor of *Pneumocystis* DHFR that is approved for the treatment of PCP but is no longer commercially available. In smaller, lower power studies, trimethoprim-sulfamethoxazole and pentamidine showed similar efficacy.

The major toxicities associated with trimethoprim-sulfamethoxazole include fever, rash, neutropenia, thrombocytopenia, nausea, vomiting, and transaminase elevations. Hyperkalemia and crystalluria have also been reported, and hyponatremia is seen primarily in association with intravenous administration. Toxicities usually appear after the first week of therapy. Toxicities are much more common in HIV-infected patients, occurring in about 50 to 60%; 15 to 35% of these patients discontinue therapy because of the adverse events. Although folinic acid can decrease the toxicities associated with some DHFR inhibitors such as pyrimethamine, it should not be administered with trimethoprim-sulfamethoxazole; in one placebo-controlled trial, it did not decrease side effects but was associated with an increased risk for therapeutic failure and death.

Alternative regimens for patients with mild to moderate disease include trimethoprim-dapsone, clindamycin-primaquine, and atovaquone. Like sulfamethoxazole, dapsone is an inhibitor of *Pneumocystis* DHPS. Adverse reactions to trimethoprim-dapsone include rash, fever, nausea and vomiting, transaminase elevations, methemoglobinemia, anemia, and mild hyperkalemia. Approximately 20 to 30% of patients with adverse reactions to trimethoprim-sulfamethoxazole experience adverse reactions to trimethoprim-dapsone. Toxicities associated with clindamycin-primaquine include fever, rash, diarrhea, anemia, neutropenia, transaminase elevations, and methemoglobinemia. For both dapsone and primaquine and, to a lesser extent, sulfamethoxazole, glucose-6-phosphate dehydrogenase deficiency (Chapter 161) can increase the risk for hemolytic anemia and methemoglobinemia. In a randomized trial comparing trimethoprim-sulfamethoxazole, trimethoprim-dapsone, and clindamycin-primaquine in 181 HIV-infected patients with mild to moderate disease, response rates and toxicities were similar among the three arms, with an overall therapeutic failure rate of 9% by day 21 and a dose-limiting toxicity rate of 31%. Serious transaminase elevations were more common in the trimethoprim-sulfamethoxazole group, and serious hematologic toxicities were more common in the clindamycin-primaquine group.

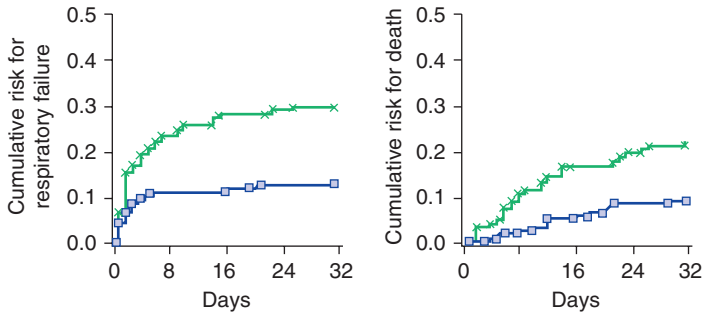
Atovaquone is a hydroxynaphthoquinone with activity against *Toxoplasma* and malaria as well as *Pneumocystis*. Atovaquone (tablet formulation) was less effective than trimethoprim-sulfamethoxazole in a randomized trial in HIV-infected patients with mild to moderate disease and showed a trend toward lesser efficacy compared with pentamidine in another study. Low serum atovaquone levels and preexisting diarrhea were associated with therapeutic failure. The current formulation is a suspension that has approximately 50% greater bioavailability than the tablet formulation, which may result in improved responses. Atovaquone should be taken with food because this increases its bioavailability, and it should be avoided in patients with potentially decreased gastrointestinal absorption (e.g., diarrhea). Toxicities of atovaquone include rash, fever, transaminase elevations, nausea, vomiting, diarrhea, neutropenia, and anemia.

Therapeutic alternatives to trimethoprim-sulfamethoxazole for patients with disease requiring parenteral therapy are limited to clindamycin-primaquine (but only clindamycin is available for intravenous administration) and pentamidine. Caspofungin and other echinocandins, which are β-1,3-glucan synthase inhibitors, cannot be recommended because there have been no clinical trials documenting their efficacy; β-1,3-glucan is present in the cyst but not in the trophic form of the organism.

Pentamidine was the first drug demonstrated to have anti-*Pneumocystis* activity. Available data suggest that trimethoprim-sulfamethoxazole and pentamidine have similar efficacy; trimethoprim-sulfamethoxazole is the preferred regimen because the toxicities associated with pentamidine are more frequent and potentially more severe. Intravenous pentamidine was originally associated with severe hypotension, but a slow (>1 hour) infusion is usually well tolerated. Intramuscular administration is associated with a high frequency of sterile abscesses at the injection site. Toxicities associated with pentamidine, which occur in about 50 to 60% of patients and frequently result in discontinuation of the drug, include nephrotoxicity, hypoglycemia, hyperglycemia, fever, neutropenia, thrombocytopenia, hypotension, hyperkalemia, transaminase elevations, and pancreatitis. Hypoglycemia may be life-threatening and may precede the development of hyperglycemia; hyperglycemia may be irreversible. Torsades de pointes (Chapter 65) has also rarely been reported.

Adjunctive Corticosteroid Therapy

Initiation of specific anti-*Pneumocystis* therapy is associated with deterioration in oxygenation after approximately 3 to 4 days; this likely results from a host inflammatory response to organisms damaged by therapy. Randomized controlled trials have demonstrated that the early addition of corticosteroids to specific anti-*Pneumocystis* therapy in HIV-infected patients can prevent this deterioration and improve survival, without a significant increase in opportunistic complications other than localized herpes simplex infection. In the largest such study, corticosteroid therapy was associated with a 50% decrease in respiratory failure and mortality; this benefit was limited to patients with moderate to severe disease (E-Fig. 341-1). For HIV-infected patients, corticosteroids and specific anti-*Pneumocystis* therapy should be started at the same time; the addition of corticosteroids after 72 hours has shown no benefit,



E-FIGURE 341-1. Cumulative risks for an unfavorable outcome during a randomized trial of corticosteroid therapy in patients with HIV infection and *Pneumocystis* pneumonia measured over a period of 31 days. The risk for respiratory failure *(left)* was 0.14 in the corticosteroid group (*blue square*) and 0.30 in the standard-treatment group (*green*) ($P = .004$). The risks for death *(right)* were 0.11 and 0.23, respectively ($P = .009$). Corticosteroid therapy was associated with a significant decrease in both outcomes. (Modified from Bozzette SA, Sattler FR, Chiu J, et al. A controlled trial of early adjunctive treatment with corticosteroids for *Pneumocystis carinii* pneumonia in the acquired immunodeficiency syndrome. *N Engl J Med*. 1990;323:1451-1457. Copyright 1990, Massachusetts Medical Society. All rights reserved.)

although it is reasonable to add them if patients exhibit deterioration after this time. Although the optimal regimen has not been defined by controlled trials, the tapering regimen from the largest study is most commonly used (see Table 341-1).

The optimal utilization of corticosteroids in non-HIV patients who are often receiving them as part of the treatment regimens for their underlying disease is less clear because data from randomized controlled trials are not available; dosing may need to be individualized to balance the immunosuppressive effects that potentially contributed to the development of PCP against the anti-inflammatory effects that may ameliorate life-threatening pulmonary dysfunction. One retrospective analysis of 31 patients suggested that increasing corticosteroids to a prednisone equivalent of 60 mg/day or more was associated with clinical benefit. It is reasonable to administer corticosteroids to non-HIV patients with moderate or severe disease if they were not receiving corticosteroids, using the same regimen as for HIV-infected patients; for patients already taking corticosteroids at lower doses, the dosage can be increased to those levels.[13]

Initiation of Antiretroviral Therapy

Given that many patients with HIV infection who are diagnosed with PCP are not receiving antiretroviral therapy, an important issue is how soon to start HAART after a diagnosis of PCP. Retrospective and prospective studies have suggested that, in general, it is safe to initiate HAART while patients are being treated for PCP, and early HAART may be associated with an improved outcome. In a randomized 282-patient trial that examined early versus late initiation of HAART in patients with acute opportunistic infections, 63% of whom had PCP, the early initiation arm (HAART started a median of 12 days after starting therapy for the opportunistic infection) had a decreased rate of AIDS progression or death. Similar findings for tuberculosis in developing countries have emphasized the benefit of early initiation of HAART.

Major concerns about initiating HAART include the risk for adverse drug reactions, which may be confused with adverse reactions to anti-PCP therapy; the risk for overlapping toxicities, which may complicate management; and the risk for immune reconstitution. There are several reports describing apparent immune reconstitution inflammatory syndrome (Chapter 395), which can be life-threatening, in patients who started HAART soon after being diagnosed with PCP. Thus, many clinicians initiate HAART during or immediately after completion of anti-*Pneumocystis* therapy, assuming the patient has shown clinical improvement, is able to tolerate oral medications, and accepts the commitment to lifelong therapy. However, the parameters for such an approach are difficult to define precisely. Patients who start HAART early should be closely monitored for a recurrence of symptoms that may represent immune reconstitution.

Treatment Failure

The optimal approach to the management of patients who are failing therapy has not been well defined. In patients with progressive respiratory deterioration, it is critical that the diagnosis of PCP be confirmed rather than presumptive and that other concurrent processes (e.g., other infections, congestive heart failure, pulmonary emboli) have been ruled out; bronchoscopy should be considered to facilitate these determinations. Parenteral therapy should be used to eliminate absorption concerns, and corticosteroid medications should be added if this has not already been done. Because patients who will ultimately respond can show clinical deterioration at 3 to 4 days, as noted earlier, it is reasonable to wait 5 to 8 days before considering a change in drug therapy.

Only trimethoprim-sulfamethoxazole and pentamidine are available in parenteral formulations. Parenteral clindamycin is available, but primaquine is available only as a tablet. No randomized trials have examined the relative efficacy of these agents in patients who are failing therapy. For patients who have not received trimethoprim-sulfamethoxazole, this should be the first choice as an alternative agent, assuming the patient did not have a life-threatening adverse reaction previously. Rapid desensitization (similar to penicillin desensitization), ideally in consultation with an allergy specialist, can be considered in patients with prior adverse reactions; however, patients with a history of Stevens-Johnson syndrome or toxic epidermal necrolysis should not be rechallenged. Although retrospective cohort studies and meta-analyses have found that clindamycin-primaquine is superior to pentamidine in patients failing a first-line regimen, there are potential biases in such analyses (e.g., severity of illness or ability to take oral medications may have affected the choice of salvage regimen). There are no data to recommend switching to an alternative agent rather than adding an alternative agent (if toxicity is not an issue); both approaches have been used.

Resistance

Although *Pneumocystis* cannot be cultured, molecular studies have identified mutations in genes that are the targets of anti-*Pneumocystis* therapy, and these mutations appear to represent the development of resistance by *Pneumocystis* to these agents. The best-characterized mutations have been identified in the DHPS gene of *Pneumocystis*, which is the target of sulfamethoxazole and dapsone. Two mutations at the active site of this enzyme, which can occur either individually or together, have been identified with greater frequency in patients receiving trimethoprim-sulfamethoxazole or dapsone for prophylaxis; in vitro studies suggest that these mutations confer resistance. The clinical relevance of these mutations remains uncertain; some studies have found worse outcomes in patients with these mutations, but others have found no such association.[14] Most patients in whom these mutations were identified retrospectively were successfully treated with sulfa-containing drugs. In contrast to DHPS, there are very limited reports suggesting that the DHFR gene of *Pneumocystis*, which is the target of trimethoprim and pyrimethamine, has developed potential drug-resistant mutations.

Atovaquone presumably binds to the mitochondrial bc_1 complex of *Pneumocystis* and thus inhibits electron transport. Multiple mutations have been identified in the cytochrome B gene of *Pneumocystis,* which presumably represent resistance in patients receiving atovaquone for prophylaxis; these mutations have not, however, been associated with clinical outcome.

Because the presence of these mutations has not been definitively associated with worsening prognosis, clinical decisions should not be based on their identification. Methods for identifying these mutations are not readily available, and their detection should remain a research tool until their clinical relevance can be better defined.

PREVENTION

Although *Pneumocystis* is transmitted by the airborne route, exposure to the organism appears to be ubiquitous in humans, suggesting that avoidance of exposure may be difficult. In animal models, it takes 2 to 3 months following exposure to develop a heavy infection. If the pattern of growth were similar in humans, clinical symptoms would develop only months after exposure to a source that is likely unknown. Currently, respiratory isolation of patients with active PCP is not required, although it is reasonable to avoid having a susceptible patient share a room with a PCP patient. Recent outbreaks in renal transplant patients strongly suggest a common source of infection; a better understanding of the patterns of transmission in these settings may lead to improved guidelines for preventing the spread of infection. It is noteworthy that in these outbreaks, broad institution of anti-*Pneumocystis* prophylaxis was the intervention that terminated the outbreaks.

A major advance in the management of patients at risk for the development of PCP was the demonstration that trimethoprim-sulfamethoxazole was highly effective in preventing the disease in a susceptible pediatric population. Subsequent studies, primarily in HIV-infected patients, demonstrated that additional drug regimens were also effective. This has led to the broad use of anti-*Pneumocystis* prophylaxis in a wide range of susceptible populations.

Two important issues in administering prophylaxis are identifying populations at risk and defining the period of risk during which prophylaxis should be provided. AIDS patients are at especially high risk; before the use of prophylaxis or HAART, the lifetime incidence of PCP in this population was estimated at 60 to 80%. The most recent CD4 count is a validated surrogate marker for HIV-infected patients: patients with CD4 counts below 200 cells/mm^3 are at substantially increased risk for developing PCP, and prophylaxis is recommended for this group.[15] Although 10 to 15% of patients who develop PCP have higher CD4 counts, the incidence is very low in this population, given the large number of patients who fall in this category. Patients with CD4 counts greater than 200 cells/mm^3 but a CD4 percentage of less than 14% or a history of an AIDS-defining illness are also candidates for prophylaxis. For pediatric patients with HIV infection, in whom the normal CD4 count changes with age, guidelines are based on age. Prophylaxis is recommended for children older than 6 years with CD4 counts below 200 cells/mm^3 or 15%, for children between 1 and 5 years old with CD4 counts below 500 cells/mm^3 or 15%, and for all children younger than 12 months.[16]

Before the availability of HAART, when patients with HIV infection initiated prophylaxis, they were committed to continuing it for life because immunologic decline was irreversible. With HAART, however, control of HIV replication leads to an increase in the CD4 count, which is associated with a concomitant decrease in the risk for developing PCP. Multiple studies have shown that when the CD4 count has been above 200 cells/mm^3 for at least 3 months (ideally in the setting of controlled HIV replication), prophylaxis can be safely discontinued because the risk for developing PCP is no greater than in patients whose CD4 counts never fell below 200 cells/mm^3. In most of these studies, the median CD4 count was greater than 300 cells/mm^3, and HIV viral loads were below detection limits in the majority of patients. Recent uncontrolled studies have suggested that prophylaxis can also be safely discontinued in patients with CD4 counts between 100 and

200 cells/mm^3 who have virologically suppressed HIV, but specific criteria for discontinuation (e.g., duration of viral suppression) were not defined in these studies.[17]

Among non-HIV-infected patients, the CD4 count is not routinely measured, and it has not been shown to have the same predictive value for the development of PCP as in HIV-infected patients; however, CD4 counts below 200 cells/mm^3 do appear to increase their susceptibility. Recommendations for PCP prophylaxis in these populations are based on clinical parameters, including empirical identification of periods of risk and estimation of levels of immunosuppression. Very broad prophylaxis has not been implemented because of the side effects associated with these regimens; for example, there is concern that trimethoprim-sulfamethoxazole might cause bone marrow suppression that would interfere with engraftment or cause nephrotoxicity that would damage a transplanted kidney.

Risk factors for non-HIV-infected patients include underlying disease, older age, use of immunosuppressive drugs, radiation therapy, graft-versus-host disease, and concomitant cytomegalovirus infection (Chapter 376). Patients with malignancies, especially hematologic malignancies, but increasingly solid tumors as well, are at risk for PCP primarily owing to the therapies they receive; the incidence can range from 1 to 43% in the absence of prophylaxis and is highly dependent on the intensity and duration of immunosuppression. In the absence of prophylaxis, the risk for developing PCP in transplant patients, whether hematopoietic stem cell or solid organ transplants, is reportedly about 5 to 15%, although lung and heart-lung transplant patients appear to have a higher incidence (up to 43%). Among patients with collagen vascular disease, the reported risk is less than 2% without prophylaxis, although patients with Wegener's granulomatosis (Chapter 270) reportedly have a risk up to 12%, presumably because of the use of more immunosuppressive treatment regimens.[18] In patients with inflammatory bowel disease, the incidence in one large retrospective cohort study, was about 1% per year, with a greater risk for Crohn's disease compared with ulcerative colitis.[19] The current risk for developing PCP in non-HIV populations is difficult to quantify because of the widespread use of prophylaxis and because immunosuppressive regimens are evolving.

To facilitate the management of prophylaxis in at-risk populations, a number of guidelines have been developed by expert panels that have made recommendations based on the strength of the available data. HIV guidelines have already been summarized. For allogeneic stem cell transplant recipients, prophylaxis is recommended from the time of engraftment to at least 6 months after transplantation, and longer for patients who continue receiving immunosuppressive therapy or who have chronic graft-versus-host disease. For autologous stem cell transplant recipients, who have a lower risk for PCP, prophylaxis for 3 to 6 months should be considered if the degree of immunosuppression is substantial owing to underlying disease or therapy (e.g., patients with leukemia or lymphoma receiving intensive conditioning or immunosuppressive therapy).

For solid organ transplant patients, prophylaxis has not been universally adopted; it has been used primarily in centers with a known incidence greater than 3%. Guidelines recommend the administration of prophylaxis for 3 to 12 months in renal transplant patients and for longer periods, up to lifelong, in heart, lung, liver, and intestine transplant recipients. As noted earlier, a number of outbreaks of PCP have recently been reported in renal transplant centers, and many of those patients developed disease more than 1 year after transplantation. Risk factors identified in case-control studies have included older age, recent or concurrent cytomegalovirus infection, and treatment for rejection. Specific immunosuppressive drugs, such as mycophenolate mofetil and cyclosporine, have not been consistently implicated.

For patients with inflammatory bowel disease (Chapter 141), who appear to be at increased risk as newer immunosuppressive agents are used, data are limited; however, consensus-based guidelines recommend prophylaxis for patients receiving triple immunomodulators that include either a calcineurin inhibitor or an anti-TNF agent. No consensus was reached for less intensive regimens. For patients with connective tissue disorders or vasculitis, there are currently no consensus guidelines.

Corticosteroid therapy (Chapter 35) is a well-described risk factor in non-HIV-infected patients, with approximately 90% of patients receiving such therapy before developing PCP in some studies. Higher dose and longer duration increase the risk. Not all patients who receive corticosteroids are at risk, however; for instance, asthmatic patients receiving corticosteroid therapy are at low risk. Although there are no consensus guidelines on the use of prophylaxis for patients receiving corticosteroids, one reasonable approach is to provide prophylaxis to patients with an underlying immunosuppressive or inflammatory disease who receive at least 20 mg of prednisone or equivalent for longer than 1 month. Other immunosuppressive agents (Chapter 35), such as calcineurin inhibitors, sirolimus, TNF antagonists, and rituximab, also appear to increase the risk for developing PCP, primarily in the patient populations noted earlier. Based on the manufacturer's recommendations, patients receiving temozolomide plus radiotherapy for glioblastoma multiforme should receive anti-*Pneumocystis* prophylaxis.

Trimethoprim-sulfamethoxazole is the first-line agent for prophylaxis in all populations (Table 341-2). Alternatives include dapsone alone or combined with pyrimethamine plus leucovorin, atovaquone, and aerosol pentamidine administered by the Respirgard II nebulizer. In a randomized trial of 843 HIV-infected patients comparing trimethoprim-sulfamethoxazole with dapsone and aerosol pentamidine, no significant differences were seen on an intent-to-treat basis, but the lowest failure rates were seen while patients were receiving trimethoprim-sulfamethoxazole. Conversely, trimethoprim-sulfamethoxazole was superior to aerosol pentamidine in another randomized study. In other large randomized trials in HIV-infected patients, the following regimens showed similar efficacy: atovaquone suspension and dapsone, atovaquone suspension and aerosol pentamidine, and dapsone-pyrimethamine and aerosol pentamidine. No randomized trials of these regimens have been conducted in non-HIV-infected populations, but clinical experience suggests that they are effective in these populations as well. Patients receiving pyrimethamine plus sulfadiazine plus leucovorin for treatment of toxoplasmosis do not require additional anti-*Pneumocystis* prophylaxis as this regimen also prevents PCP.

Although the combination of sulfadoxine and pyrimethamine is also efficacious, it is contraindicated in patients with sulfonamide allergies. Moreover, because Stevens-Johnson syndrome and other potentially life-threatening cutaneous reactions are more common with this combination than with trimethoprim-sulfamethoxazole, and because its long half-life results in slow

TABLE 341-2 DRUG REGIMENS FOR PREVENTION OF *PNEUMOCYSTIS PNEUMONIA* (PCP)

INDICATION	DRUG	ROUTE	DOSE	COMMENTS
Preferred	Trimethoprim-Sulfamethoxazole (TMP-SMX)	PO	1 double-strength tablet (160 mg TMP+800 mg SMX) or one single-strength tablet (80 mg TMP+400 mg SMX) QD	Also active in preventing toxoplasmosis
Alternative	Trimethoprim-Sulfamethoxazole (TMP-SMX)	PO	1 double-strength tablet (160 mg TMP+800 mg SMX) 3 times weekly	Also active in preventing toxoplasmosis
Alternative	Dapsone	PO	100 mg QD or 50 mg BID	Test for G6PD deficiency before use
Alternative	Dapsone plus	PO	50 mg QD	Also active in preventing toxoplasmosis
	Pyrimethamine plus	PO	50 mg once weekly	
	Leucovorin	PO	25 mg once weekly	Should be administered with pyrimethamine to minimize toxicity
Alternative	Atovaquone	PO	1,500 mg QD with food	Likely active in preventing toxoplasmosis
Alternative	Pentamidine	Aerosol	300 mg via the Respirgard II nebulizer once monthly	Not active in preventing toxoplasmosis

Note: Patients receiving pyrimethamine-sulfadiazine and atovaquone therapy for toxoplasmosis do not appear to need additional prophylaxis for PCP; patients receiving clindamycin-pyrimethamine therapy for toxoplasmosis will need additional prophylaxis for PCP. GGPD = glucose-6-phosphate dehydrogenase.

clearance after the drug is discontinued, sulfadoxine plus pyrimethamine should probably not be used in sulfa-tolerant patients if trimethoprim-sulfamethoxazole is available.

HIV-infected patients with a prior history of a mild sulfa allergy (e.g., mild rash, excluding those with prior Stevens-Johnson syndrome or toxic epidermal necrolysis) can often be safely rechallenged with trimethoprim-sulfamethoxazole. Randomized trials have demonstrated that dose escalation over a 6- to 13-day period is associated with better tolerance than direct rechallenge with full-dose trimethoprim-sulfamethoxazole, and that up to 75% of patients can continue to receive trimethoprim-sulfamethoxazole for at least 6 months.

PROGNOSIS

Mortality for untreated PCP approaches 100%. With therapy, the survival rate for HIV-infected patients with confirmed PCP is now as high as 95%, but a poorer survival rate of 75% has been reported in patients without HIV infection.[20] Risk factors for death in HIV-infected patients include more severe hypoxia, older age, recurrent episodes of PCP, low hemoglobin, and the presence of comorbid conditions. Although mortality for patients admitted to an intensive care unit is high, survival for HIV-infected patients has improved in recent years, now approaching 75%.[21]

REVIEW QUESTIONS

1. A 47 year old previously healthy male comes into the emergency room complaining of a 2 week history of shortness of breath, non-productive cough, and fevers to 103° C. On physical exam he is tachypneic, with no rales or rhonchi, and has thrush on his buccal mucosa. His chest X-ray and pulse oximetry are normal. Which of the following is true?

A. The normal chest X-ray and pulse oximetry rule out *Pneumocystis* pneumonia.
B. A chest CT can help in the diagnosis of *Pneumocystis* pneumonia since it is almost invariably abnormal, even in the setting of a normal chest X-ray.
C. A positive PCR test for *Pneumocystis* definitively confirms the diagnosis of *Pneumocystis* pneumonia as the specificity of the PCR test for PCP approaches 100%.
D. Culture of induced, but not expectorated, sputum on Sabouraud agar will confirm the diagnosis of *Pneumocystis* pneumonia in 2 to 3 days.
E. Bronchoscopy with bronchoalveolar lavage is helpful if positive for *Pneumocystis* but has a low sensitivity (~40-50%); open lung biopsy is required to confirm the diagnosis of PCP in about 50% or patients.
