Chemoradiotherapy is now standard first-line treatment for squamous cell cancer of the anal canal. Current radiation protocols most frequently use 45-Gy external beam radiation therapy in 25 fractions, with a boost to the primary tumor and involved inguinal nodes to a total dose of 54 to 59 Gy. Standard chemotherapy uses 5-fluorouracil (1000 mg/m^2 per 24 hours continuous infusion for 96 hours, starting on days 1 and 29) in combination with mitomycin C (most commonly 10 mg/m^2 intravenous bolus on days 1 and 29). Abdominoperineal resection with permanent colostomy is reserved for tumors that fail to respond to chemoradiation and those that recur. Similarly, groin dissection is performed only when involved inguinal nodes fail chemoradiation.

Early squamous cell cancers of the anal margin can be locally excised if a satisfactory margin can be obtained without injuring the anal sphincter and if

there is no evidence of nodal spread. More advanced anal margin tumors are treated with chemoradiotherapy as described for anal canal tumors. Combined chemoradiation therapy is the primary treatment for most squamous cell carcinomas of the anal canal.

PREVENTION

In a randomized trial, use of an HPV vaccine reduced anal intraepithelial neoplasm by about 50% in men who have sex with men.[A9] Vaccination is warranted in all such individuals.

Other Sexually Transmitted Anorectal Diseases

A number of sexually transmitted diseases (Chapter 285) of the anorectum occur most frequently in individuals who practice anoreceptive intercourse. Common causative agents include *Treponema pallidum* (Chapter 319), *Neisseria gonorrhoeae* (Chapter 299), *Chlamydia trachomatis* (Chapter 318), herpes simplex (Chapter 374), and HIV (Chapter 384). Other sexually transmitted pathogens are *Shigella* (Chapter 309), *Campylobacter jejuni* (Chapter 303), *Haemophilus ducreyi* (Chapter 301), *Calymmatobacterium granulomatis* (Chapter 316), *Entamoeba histolytica* (Chapter 352), *Giardia lamblia* (Chapter 351), and *Isospora belli* (Chapter 353).

The widely variable presentations range from asymptomatic to anal pain, pruritus, discharge, fever, cramps, and bloody diarrhea. Clinical suspicion followed by appropriate and specific testing is necessary to make the correct diagnosis, and clinicians should consider the possibility of simultaneous infections. Treatment addresses the specific infection.

REVIEW QUESTIONS

1. A 34-year-old man presents with perianal pain, fever, and leukocytosis. Physical examination demonstrates no obvious source. Which of the following is the most appropriate next step?

A. Repeat examination in 24 hours
B. 10-day course of oral antibiotics
C. Digital rectal examination
D. Office-based needle aspiration
E. Examination under anesthesia

Answer: E Supralevator, intersphincteric, and deeper abscesses may present with symptoms but no obvious source on physical examination. Although adjunctive radiological testing can be considered, the best approach to this potentially serious and urgent problem is examination under anesthesia. Antibiotics alone will not resolve an abscess that needs to be drained. Digital rectal examination and blind needle aspiration in the office should be avoided.

2. A 55-year-old otherwise healthy woman complains of a mass at her anal verge with straining. Which of the following is the most characteristic for differentiating rectal prolapse from other anorectal disorders?

A. Presence of radial folds
B. Concomitant bleeding
C. Presence of concentric mucosal folds
D. A patulous anal sphincter
E. Associated incontinence

Answer: C The diagnosis of rectal prolapse is made clinically, with the major finding of concentric mucosal folds—the so-called "bulls eye." The presence of radial folds is seen in mucosal and hemorrhoidal prolapse. Although bleeding, incontinence, and a patulous anus may be seen in rectal prolapse, each may be also present in many other anorectal disorders and none are specific for rectal prolapse.

146 APPROACH TO THE PATIENT WITH LIVER DISEASE

PAUL MARTIN

The liver serves multiple key functions, including metabolism of the products of ingested food, production of amino acids to form proteins, detoxification of ingested drugs, conversion of nitrogenous substances from the gut into urea, formation of clotting factors, metabolism of bilirubin, processing of lipids absorbed from the intestine, and excretion of its products as bile. The liver also stores glycogen, which is a source of glucose, and helps contain infections by removing bacteria from the blood stream. These diverse functions reflect the activities of hepatocytes, bile duct cells called cholangiocytes, Kupffer cells, endothelial cells, and portal fibroblasts.

The liver has a dual blood supply: 70% delivered by the portal vein, which drains the intestine, and the remainder by the hepatic artery. After arrival in the liver, nutrient-rich portal blood passes along the hepatic sinusoids in close contact with lining hepatocytes before draining into the hepatic vein. The hepatocytes detoxify, metabolize, and synthesize the products of digestion. Bilirubin, which is produced by breakdown of red cells and other hemoproteins by reticuloendothelial cells predominantly in the liver and spleen, is transported to the hepatocytes, bound to albumin, and solubilized by them for biliary excretion.

Liver disease causes loss of hepatocellular activity, with diminished detoxification, excretory, and synthetic functions. Hepatocyte dysfunction results in impaired production of clotting factors, albumin, and other proteins, as well as reduced endogenous formation of lipids. Hepatocyte injury from a variety of causes, including viruses, alcohol, autoimmune disorders, and drug hepatotoxicity, is accompanied by leakage of cellular enzymes into the systemic circulation (Chapter 147). Coagulopathy, decreased serum albumin, and hyperbilirubinemia are observed in more profound hepatocellular injury. Portal hypertension occurs because of disruption of the low-pressure intrahepatic blood flow from the portal to the systemic venous circulation owing to hepatic fibrosis. Consequences of portal hypertension include accumulation of abdominal ascites and the development of portal-systemic venous collaterals with portal-systemic shunting, thereby resulting in the formation of varices and hepatic encephalopathy. Vascular disorders, including portal vein thrombosis, can result in portal hypertension in the absence of parenchymal liver disease.

The diversity of the liver's functions, its complicated blood supply, and its intimate relationship with the biliary tree contribute to the divergent manifestations of liver diseases. The initial complaint often reflects whether the cause is diffuse, such as acute viral hepatitis with widespread hepatocyte injury that manifests as malaise or fatigue, or whether the cause is discrete, such as when biliary obstruction from a gallstone in the common bile duct manifests with severe abdominal pain. Patients may present with multiple complaints, such as nausea and anorexia owing to hepatocellular disease accompanied by right upper quadrant discomfort due to stretching of the hepatic capsule by parenchymal cell edema and inflammation. Patients with more advanced liver disease, such as decompensated cirrhosis (Chapter 153), may have marked hepatocellular dysfunction with jaundice and coagulopathy in addition to portal hypertension with ascites and bleeding esophageal varices. Many patients who present with hepatic symptoms or signs may have extrahepatic disease; for example, a tender, enlarged liver may be caused by a systemic disorder, such as heart failure with hepatic congestion, rather than a primary hepatic disorder. In patients with cirrhosis, the initial presentation of previously unrecognized liver disease may be a major complication such as variceal hemorrhage, which in turn can precipitate hepatic encephalopathy and other features of frank hepatic decompensation.

HISTORY

Patients with liver disorders come to medical attention for a variety of reasons, ranging from the incidental discovery of abnormal liver chemistries to decompensated cirrhosis. Many complaints related to liver disease, such as fatigue, are nonspecific; unless liver disease is considered in the differential diagnosis, recognition of the hepatic origin of these complaints may be delayed.

In clinical practice, a frequent manifestation of asymptomatic liver disease is discovery of abnormal liver biochemistries during a life insurance application, annual physical examination, or attempt to donate blood.[1] It is important to inquire about occasions when liver biochemistries may have been obtained, to determine whether hepatic dysfunction is long-standing or more recent. In a patient with hepatic dysfunction, inquiry should be made about the presence of malaise, anorexia, fatigue, and weight change. Jaundice (Chapter 147) is a dramatic manifestation of possible liver disease. A patient may first notice lighter-colored stools or dark urine rather than scleral icterus. The absence of these latter changes suggests that unconjugated hyperbilirubinemia is due to hemolysis rather than intrinsic liver disease. Not infrequently, a patient may be unaware of jaundice until it is noted by others.

Abdominal pain (Chapter 132) related to liver disease can have a variety of causes. Symptomatic gallstones (Chapter 155) can manifest with the abrupt onset of severe epigastric or right upper quadrant discomfort, often after a large meal and frequently associated with nausea and vomiting. The pain is often steady rather than colicky and can radiate widely, including to the chest and back. A patient may not be able to achieve a position that lessens the pain, which may last several hours. More persistent pain, particularly if associated with weight loss and jaundice, raises concern about malignant bile duct obstruction. Pain is also common in parenchymal liver disease in the absence of biliary tract disease. Many patients with chronic hepatocellular disorders, such as chronic hepatitis C (Chapter 149) or nonalcoholic fatty liver disease (Chapter 152), complain of vague right upper quadrant discomfort that has no particular relieving or aggravating factors. Abdominal pain, which can be severe, is also frequent in acute viral hepatitis (Chapter 148), as well as with the hepatic congestion that results from back pressure in heart failure or hepatic vein occlusion, as in Budd-Chiari syndrome (Chapter 143).

Fatigue, anorexia, and malaise can be present in both acute and chronic liver disease. In acute liver disorders such as acute viral hepatitis (Chapter 148), drug-induced liver disease (Chapter 150), or an acute manifestation of autoimmune hepatitis (Chapter 149), patients may report profound fatigue, nausea, and malaise with decreased appetite and substantial associated weight loss. Distaste for cigarettes is said to be characteristic of acute viral hepatitis. Fatigue is also prominent in chronic liver disease such as chronic hepatitis C (Chapter 149). Pruritus is a prominent feature of cholestatic disorders, such as primary biliary cirrhosis, sclerosing cholangitis, or cholestatic drug reactions, particularly when patients are frankly icteric; however, pruritus also occurs in chronic parenchymal liver disease, most notably chronic hepatitis C, and in acute viral hepatitis. Easy bruisability in those with liver disease reflects coagulopathy and thrombocytopenia.

Fever in a patient with hepatic dysfunction is experienced in the prodrome of acute hepatitis A, as well as in alcoholic hepatitis and drug-induced liver disease. In a patient with suspected biliary obstruction, fever suggests complicating bacterial cholangitis or acute cholecystitis. Ascites is most frequently a manifestation of cirrhosis and portal hypertension in a patient with liver disease. Patients note increasing abdominal girth, which may be preceded by ankle edema. Weight gain owing to fluid retention may be masked by concomitant loss of muscle mass. The onset of ascites in the absence of a history of liver disease suggests a vascular event, such as hepatic vein occlusion (Chapter 143), or a nonhepatic cause of ascites, such as nephrotic syndrome or heart failure. Accumulation of ascites in a patient with liver disease may be subtle, with a slowly increasing waist circumference, or it may be more rapid, such as in a cirrhotic patient who receives fluid resuscitation after gastrointestinal bleeding. Although ascites in a patient with liver disease implies the presence of cirrhosis, ascites also can complicate severe acute liver disease, including alcoholic hepatitis and viral hepatitis, in which it suggests a poor prognosis.

Hepatic encephalopathy (Chapter 153), which is a neuropsychiatric disorder in patients with liver disease, can range from subtle cognitive impairment to deep coma. Early symptoms include a disturbed sleep pattern with nocturnal insomnia and daytime somnolence. More advanced encephalopathy can result in impairment of memory, confusion, and difficulty completing routine tasks. However, new-onset confusion or coma in a patient with liver disease should not be presumed to reflect hepatic encephalopathy unless other explanations, such as sedative overdose or subdural hematoma, have been excluded. Important precipitants of hepatic encephalopathy in a cirrhotic patient include gastrointestinal bleeding, bacterial infection (e.g., spontaneous bacterial peritonitis), electrolyte imbalance, and renal insufficiency,

all of which need to be excluded during the initial clinical evaluation. In a patient with acute liver failure, coma as a consequence of cerebral edema may be impossible to distinguish from advanced hepatic encephalopathy unless the increased intracranial pressure results in papilledema.

Gastrointestinal hemorrhage resulting from bleeding varices is usually profuse and often abrupt in onset. It classically manifests with hematemesis or melena (Chapter 135), and coexisting postural hypotension and presyncope can reflect profound blood loss. The increased protein load in the gut can precipitate hepatic encephalopathy. Nonvariceal causes of gastrointestinal bleeding in a patient with liver disease include portal gastropathy (Chapter 135).

RISK FACTORS FOR LIVER DISEASE

An important aspect of the history is identification of possible risk factors for liver disease. The history should include directed questioning about alcohol consumption, including frequency and pattern (Chapter 33). The age of initial alcohol use and whether consumption has increased with age should be ascertained. Family members also should be asked about their perception of the patient's alcohol use and whether it has resulted in difficulties in personal relationships or work performance. Other clues to alcohol abuse are a history of convictions for driving under the influence of alcohol, motor vehicle accidents, and physical symptoms of alcohol dependence (Chapter 33). More circumspect questioning may be required to elicit a history of recreational drug use, especially given societal disapproval of this activity. Not infrequently, a patient with suspected viral hepatitis admits to smoking marijuana or snorting cocaine but does not acknowledge intravenous drug use. With the increasing frequency of nonalcoholic fatty liver disease as a cause of hepatic dysfunction (Chapter 152), comorbid conditions such as diabetes mellitus, hyperlipidemia, or weight gain should be noted.[2]

Medication use, whether prescription or over the counter, must be assessed because drug-induced liver disease is an important cause of apparently cryptogenic hepatic dysfunction and is not limited to therapeutic drugs (Chapter 150). Increasingly, herbal and "natural" products (Chapter 39) are ingested for a variety of maladies, and patients may fail to disclose their use because they do not perceive these agents to have side effects or may sense that the physician does not endorse their use.[3] As with alcohol, it is important to quantify the amount of medication ingested and over what period. The social history should include details about recent travel and contact with individuals with viral hepatitis through intimate, household, or occupational contact. It is also important to ask about vigorous physical activity that can result in elevated aminotransferase levels of nonhepatic origin.

ASSESSING DURATION OF LIVER DISEASE

The differential diagnosis in a patient with liver disease is determined to a large extent by manifesting symptoms, such jaundice or ascites. In many patients, however, the timing of more subtle findings such as elevated aminotransferases is difficult to determine. Prior blood test results should be retrieved to determine whether hepatic dysfunction is long-standing or more recent. Hepatic dysfunction of less than 6 months' duration is regarded as acute and is frequently self-limited, whereas abnormalities that persist for more than 6 months are unlikely to resolve spontaneously. If the patient has had a cholecystectomy, it is important to determine the indication. Incidental gallstones are sometimes assumed to be the cause of abnormal liver chemistries in a patient with parenchymal liver disease and can lead to an unnecessary operation. Thrombocytopenia owing to portal hypertension in a patient with unrecognized cirrhosis may have been investigated in the past without a firm conclusion being reached.

REVIEW OF OTHER ORGAN SYSTEMS

While focusing on liver-related symptoms, it is important not to overlook other diagnostic clues, associated disorders, and complications. Sicca symptoms, including dry eyes and mouth, are common in primary biliary cirrhosis (Chapter 155); florid features of scleroderma and CREST syndrome (Chapter 267) are other associations. Dyspnea in a patient with hepatic dysfunction may reflect cardiac failure with hepatic congestion (Chapter 58). Other explanations include hepatopulmonary syndrome (Chapter 153), with the characteristic complaint of platypnea–dyspnea (often with chest tightness) that is worse in the upright position owing to aggravation of the ventilation-perfusion mismatch because of intrapulmonary shunting. A hydrothorax in decompensated cirrhosis can cause dyspnea, as can emphysema in patients with liver disease caused by α_1-antitrypsin deficiency. A history of premature menopause is common in middle-aged women with cirrhosis, as is decreased libido and sexual potency in cirrhotic men. Arthralgias are often reported in viral hepatitis, and hemochromatosis (Chapter 212) may manifest with involvement of the proximal interphalangeal joints or chondrocalcinosis of the knees; increased skin pigmentation and diabetes mellitus are other features of this disorder. Accelerated osteopenia occurs in many liver diseases, including primary cirrhosis, primary sclerosing cholangitis, and alcoholic cirrhosis; osteopenia may be aggravated by corticosteroid use in autoimmune chronic active hepatitis. Alcoholic peripheral neuropathy (Chapter 416) can manifest with pain and paresthesia. Tremor and inattentiveness in a younger patient with hepatic dysfunction suggests Wilson disease (Chapter 211). Diarrhea and rectal bleeding in a patient with cholestatic liver disease suggests associated inflammatory bowel disease (Chapter 141).

FAMILY HISTORY

The family history should inquire not only about relatives with liver disease but also associated extrahepatic conditions. Hereditary hepatic conditions (see later), such as Wilson disease and hemochromatosis, may occur in several members of a sibship. In α_1-antitrypsin deficiency, some family members may experience predominantly emphysema rather than cirrhosis. Similarly, renal failure in a family member of a patient with hepatic cysts suggests adult polycystic disease (Chapter 127). A family history of inflammatory bowel disease may be a clue to primary sclerosing cholangitis in a patient with cholestatic liver chemistries. The history in patients with suspected alcoholic liver disease may reveal other family members with alcoholism.

PHYSICAL EXAMINATION

General Condition

In a patient with suspected liver disease, it is crucial to resist the temptation to palpate the abdomen immediately, thus potentially ignoring other important diagnostic clues. Apart from seeking icterus, the initial observation should note whether muscle wasting, cutaneous stigmata of liver disease, abdominal distention, and peripheral edema are present. The vital signs may reflect the hyperdynamic circulation characteristic of cirrhosis, with a resting tachycardia, wide pulse pressure, and low blood pressure resulting from peripheral vasodilation. Fetor hepaticus, which is described as a musty smell, may be detected when a cirrhotic patient exhales and must be distinguished from more frequent halitosis caused by poor dental hygiene.

Mucocutaneous Findings

Icterus (Fig. 146-1) is best confirmed by examination of the sclera or, if necessary, under the tongue, where elastin tissue retains bilirubin. Grayish skin discoloration in hemochromatosis may be most evident in the skin folds in the groin or axilla. Acanthosis nigricans can be observed in nonalcoholic fatty liver disease (Chapter 152). A Kayser-Fleischer ring (see Fig. 211-2), caused by the deposition of copper in Descemet membrane, is a brownish circle around the periphery of the iris and may require slit lamp examination to detect; it always should be sought in a patient with suspected Wilson disease (Chapter 211). Poor dentition is characteristic in alcoholic or drug-abusing individuals, and excessive dental caries may result from decreased saliva production in sicca syndrome. Parotid gland swelling is occasionally observed in alcoholic patients. Central cyanosis and clubbing are found in the hepatopulmonary syndrome. Temporal muscle wasting and "paper money" facial skin,

FIGURE 146-1. Scleral icterus.

FIGURE 146-2. Palmar erythema.

FIGURE 146-3. Caput medusae. Photograph shows caput medusae accentuated by a large amount of ascites in a patient being prepared for liver transplantation. An extensive plexus of veins is seen emanating from the umbilical region and radiating across the anterior abdominal wall. Note the large vein coursing inferiorly along the right flank (*arrows*). This is the superficial epigastric vein, which drains into the external iliac vein. (From Henseler KP, Pozniak MA, Le FT, et al. Three-dimensional CT angiography of spontaneous portosystemic shunts. *Radiographics.* 2001;21:691-704.)

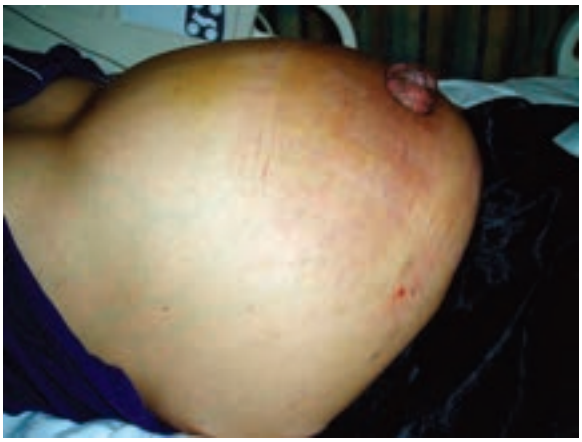

FIGURE 146-4. Ascites.

owing to atrophy with telangiectasia, are signs of advanced liver disease. Xanthelasma from lipid deposits may be observed on the eyelids and skin around the orbits in patients with cholestatic liver disease. Spider nevi on the face and thorax are not pathognomonic of liver disease, especially in women, but they are suggestive if more than a few are present. Palmar erythema (Fig. 146-2) may be normal in women but suggests liver disease in men. Dupuytren contracture (see Fig. 152-1), the retraction of the palmar fascia with subsequent contracture of the palms and fingers can be a sign of alcoholic liver disease, although it is also described in patients with epilepsy or diabetes mellitus, as well as in individuals who have work-related contractures. Petechiae and ecchymoses reflect impaired production of clotting factors and hypersplenism in advanced liver disease. Patches of white discoloration on the nails may be present in advanced liver disease. Scratch marks from pruritus may be observed on the trunk and extremities of patients with cholestatic liver disease. Sparing of the center of the back can lead to a less pigmented butterfly-shaped area because patients cannot reach that area with their fingernails.

Examination of the Abdomen

Abdominal distention with ascites and dilation of collateral veins owing to portal hypertension represent florid signs of advanced liver disease. Caput medusae (Fig. 146-3) in the periumbilical area implies recanalization of the umbilical vein with portal hypertension.

Abdominal percussion may confirm the presence of ascites (Fig. 146-4). Shifting dullness results from movement of ascites to the most dependent portion of the abdomen. The subject should be examined in the supine position, with percussion of the abdomen from the midline toward the right or left flank. A change from a tympanic sound to a dull sound signifies a change from air to fluid, and the location of that change identifies the surface of the fluid pool. Next, the examiner should percuss below the point at which dullness is elicited and ask the subject to turn toward the examiner. With the subject on his or her side, the examiner percusses again at the same point where tympany converted to dullness. If that spot is now tympanic, shifting dullness has been detected as a result of movement of the air-fluid boundary; this finding supports the presence of ascites. This maneuver should be performed sequentially on each side for confirmation. A fluid wave can be felt by placing the medial border of one hand on the abdomen and tapping the right or left lateral abdominal walls; the resulting wave is felt by the first hand. Scrotal edema and abdominal wall hernias are often present in patients with long-standing ascites. Abdominal tenderness in a patient with ascites suggests peritonitis (e.g., spontaneous bacterial peritonitis or the result of a perforated viscus). However, it is important to note that abdominal tenderness is frequently absent in spontaneous bacterial peritonitis.

The liver is dull to percussion. Percussion of the right upper quadrant can determine the liver span, normally 6 to 12 cm in the midclavicular line. The liver span may be diminished in a patient with cirrhosis, whereas hepatomegaly (Fig. 146-5) is detected in hepatic congestion resulting from heart failure, nonalcoholic fatty liver disease, and cholestatic forms of cirrhosis. The liver is best examined with the patient in the supine position, arms parallel to the side of the body, and knees bent to relax the abdominal muscles. Palpation should begin in the right lower quadrant of the abdomen and move upward toward the rib cage so that the liver edge is felt on the way up. A normal liver edge is smooth and sometimes slightly tender when palpated. In general, a liver edge that is felt up to 2 cm below the right costal margin is considered normal, but a normal-sized liver can be displaced downward by other abnormalities, such as emphysema. In thin subjects, the liver edge may be felt on deep inspiration, even if it is normal in size.

The liver can feel hard and irregular, as in cirrhosis, or slightly tender, enlarged, and smooth, as in acute viral hepatitis, alcoholic hepatitis, or hepatic congestion owing to congestive heart failure. The liver can extend across the midline, and the left lobe can be felt in the epigastrium. When the location of the edge of the liver is unclear, the scratch test may be helpful. The bell of the stethoscope is placed on the right upper quadrant over the rib cage while scratching the surface of the abdominal wall from the mid-abdomen toward the liver; the sound of the scratch is amplified in an area under which the liver lies.[4] In the presence of ascites, the liver edge may be detected by exerting quick pressure with the fingertips below the rib cage.

A palpable gallbladder suggests obstruction of the biliary system, whereas tenderness elicited by palpation during inspiration (the Murphy sign) suggests acute cholecystitis. Marked hepatic tenderness with hepatomegaly is observed in patients with a hepatic abscess (Chapter 151).

Splenomegaly (Chapter 168) is suggested by dullness to percussion between the 9th and 11th ribs in the left midaxillary line. A palpable spleen tip implies portal hypertension in a patient with chronic liver disease, although an enlarged spleen also can be detected in acute viral hepatitis and infiltrative disorders that involve both the liver and the spleen (see Table 168-7). Rectal examination is obligatory if gastrointestinal bleeding is suspected because of melena, anemia, or unexplained hepatic encephalopathy.

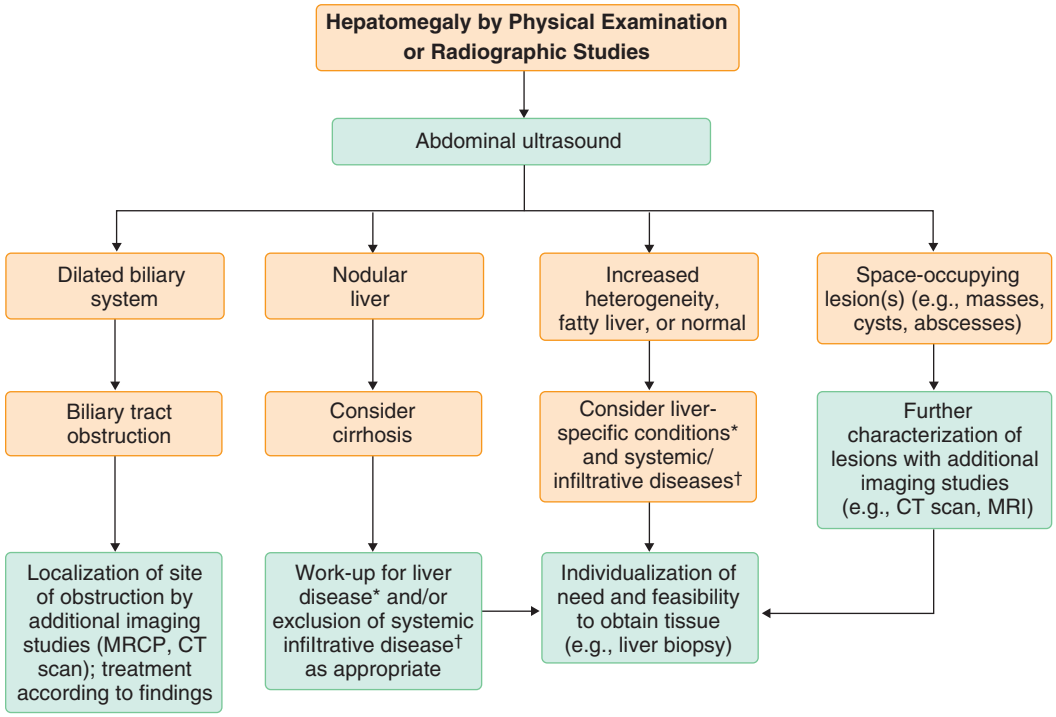

FIGURE 146-5. Diagnostic approach to hepatomegaly. *Conditions to be excluded include viral hepatitis; alcohol- and drug-induced liver disease; steatohepatitis; autoimmune liver diseases; and metabolic disorders, including hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency. †Systemic and infiltrative diseases include amyloidosis, lymphoma, sarcoidosis, and infectious processes such as disseminated tuberculosis and fungemia. CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging.

TABLE 146-1 APPROACH TO COMMON HEPATIC COMPLAINTS

PRESENTATION	COMMON SYMPTOMS	COMMON PHYSICAL SIGNS	DIAGNOSTIC STUDIES	COMMON DIAGNOSES
Ascites	Abdominal distention and pain, ankle edema	Flank dullness Shifting dullness Fluid wave	Ultrasound with Doppler Diagnostic paracentesis Urinalysis	Cirrhosis Budd-Chiari syndrome Heart failure Nephrotic syndrome
Hepatic encephalopathy	Sleep disorientation, confusion, coma	Asterixis Altered mentation Fetor hepaticus	Serum ammonia Blood cultures Stool Hemoccult Serum creatinine and electrolytes	Decompensated cirrhosis Acute liver failure Other metabolic encephalopathies (renal, respiratory)
Hepatic mass	None or abdominal pain	Hepatic bruit or rub	α-Fetoprotein Ultrasound CT scan MRI Biopsy	Benign lesions: Hemangioma, adenoma, focal nodular hyperplasia Malignant lesions: Hepatocellular carcinoma, cholangiocarcinoma, metastases
Abdominal pain	Nausea, vomiting, fever	Right upper quadrant tenderness Palpable gallbladder Murphy sign	Ultrasound HIDA scan Paracentesis for ascites if present	Biliary colic Acute cholecystitis Hepatic congestion Hepatic metastases

CT = computed tomography; HIDA = hepatobiliary iminodiacetic acid; MRI = magnetic resonance imaging.

Complete Physical Examination

The presence of rales and elevation of the jugular venous pressure suggest heart failure or pericardial disease as a cause of hepatic congestion. Loss of secondary sexual characteristics in liver disease is reflected by a loss of axillary and pubic hair, as well as feminization of body habitus in a male patient. Testicular atrophy also may be present. Peripheral edema is common in decompensated cirrhosis and may occur before ascites is obvious.

Neuropsychiatric alterations can include subtle changes in personality or more overt hepatic encephalopathy. Constructional apraxia (e.g., inability to draw a five-pointed star or to write legibly) in a fully conscious patient is a typical finding in hepatic encephalopathy. Asterixis, which is characterized by a series of extensor and flexor wrist movements,[5] can be elicited by having the patient extend the arms, with dorsiflexion of the wrists, while separating the fingers for at least 15 seconds. Tremors (Chapter 410) are nonspecific but are also common in advanced cirrhosis.

DIAGNOSTIC STUDIES (TABLE 146-1)

Laboratory Studies

The initial evaluation of liver disease involves a battery of blood tests, which can assess hepatic necroinflammation (serum aminotransferases), cholestatic biliary tract dysfunction (alkaline phosphatase, γ-glutamyl transpeptidase), excretory function (bilirubin), and synthetic function (coagulation factors, albumin) (Chapter 147). In hepatocellular dysfunction caused by viral hepatitis (Chapter 148), aminotransferase levels are elevated, with the serum alanine aminotransferase (ALT) level higher than the aspartate aminotransferase (AST) level. In alcoholic hepatitis (Chapter 152), AST elevation exceeds that of ALT. In patients with biliary obstruction or cholestatic liver diseases (Chapter 155), such as primary biliary cirrhosis or a cholestatic drug reaction, bilirubin and generally alkaline phosphatase levels are elevated. Impairment of synthetic function leads to a decreased serum albumin level

over days to weeks. The prothrombin time, expressed as the international normalized ratio (INR), is a more sensitive test of hepatic synthetic function and becomes prolonged within several hours after a major hepatic insult. Portal hypertension owing to advanced hepatic fibrosis or cirrhosis results in a decreased platelet count resulting from hypersplenism. Although these general patterns of liver dysfunction are helpful in initial evaluation of liver disease, they are nonspecific. For example, a patient with a predominantly hepatocellular process commonly has elevated bilirubin and alkaline phosphatase levels and a low serum albumin level if the injury is severe. Nevertheless, these blood tests should identify the predominant pattern of abnormality and direct further diagnostic evaluation with serologic studies and abdominal imaging. A variety of approaches have attempted to incorporate readily available tests, such as the ratio of AST to platelet count, or serum markers of fibrosis, such as type IV collagen, to assess hepatic fibrosis, but none of these alternatives can substitute for the accuracy of liver biopsy.

Abdominal Imaging

Plain abdominal radiographs generally do not have a major role in the evaluation of suspected liver disease. An exception is a patient with severe abdominal pain, in whom it is important to exclude a perforated viscus with free air under the diaphragm.

Ultrasonography should be the initial investigation in patients with obstructive jaundice. It can confirm dilated bile ducts in patients with biliary obstruction and often can identify the cause, such as a pancreatic mass or a gallstone lodged in the common bile duct. Ultrasonography also can determine whether the hepatic parenchyma is diffusely abnormal, such as in acute viral hepatitis; it can identify bright hepatic echo texture in nonalcoholic fatty liver disease or a coarsened echo texture in cirrhosis. In addition to confirming the presence of ascites, ultrasonography can identify other signs of portal hypertension, such as splenomegaly or intra-abdominal varices. A Doppler flow study can evaluate blood flow through the portal and hepatic vessels. An ultrasound study can identify hepatic masses and distinguish a cystic mass from a solid lesion (see later). Computed tomography (CT) and magnetic resonance imaging (MRI) add greater detail to the assessment of the hepatic vasculature, hepatic masses, and hepatic vascular structures. MRI can obtain a detailed cholangiogram, thereby avoiding a more invasive endoscopic retrograde cholangiopancreatography in many patients with suspected bile duct obstruction or disease (Chapters 133 and 134). Liver elastrography assesses hepatic fibrosis by measuring liver stiffness by propagation of waves in liver tissue. Generally liver stiffness correlates with fibrosis. *Fibroscan,* which uses high-frequency shear waves, can predict the amount of fibrosis in most patients, but it is less accurate in patients with a high body mass index or extensive steatosis.[6]

Liver Biopsy

Liver biopsy remains the definitive test to assess the severity of hepatic inflammation and fibrosis extent in diffuse hepatocellular disease. In addition, it can confirm certain diagnoses suspected by noninvasive testing, such as autoimmune hepatitis, or it can suggest other diagnoses, such as drug hepatotoxicity. However, because of its potential complications, such as intra-abdominal bleeding, biopsy is recommended only when less invasive testing does not yield a definitive diagnosis or prognosis or when additional information, such as quantitative determination of hepatic copper in Wilson disease or hepatic iron in hemochromatosis, is necessary for definitive diagnosis (see later).

Transjugular pressure measurements are indicated in patients with atypical presentations of portal hypertension (e.g., when it is unclear whether liver disease is the cause) or to titrate medications to reduce portal pressure. A catheter is advanced under fluoroscopy into the hepatic vein, and the free hepatic venous pressure is measured. The catheter is then advanced further until it becomes "wedged" in a small hepatic vein venule. A small balloon occludes the venule, and the wedged hepatic vein pressure, which reflects hepatic sinusoidal pressure, is obtained. The portal pressure gradient, which is derived by subtracting the free pressure measurement from the wedged pressure measurement, is normally less than 5 mm Hg. Varices form at a gradient greater than 10 mm Hg, whereas ascites and variceal hemorrhage occur only when the gradient greater than 12 mm Hg. A transjugular approach also increases the safety of liver biopsy in the presence of ascites, coagulopathy, or thrombocytopenia when standard percutaneous liver biopsy is hazardous. Endoscopy is indicated to screen for varices in any patient suspected of having cirrhosis to determine the need for prophylaxis against hemorrhage.

APPROACH TO A HEPATIC MASS

A hepatic mass may be discovered under a number of different circumstances and is often an incidental finding on abdominal imaging performed for another indication.[7,8] The initial evaluation is directed as to whether the mass is cystic or solid (Fig. 146-6).

Hepatic Cysts

Most hepatic cysts are benign and incidental. Simple hepatic cysts are usually solitary and asymptomatic, although larger cysts may cause abdominal discomfort. Ultrasonography, which is usually diagnostic, shows an anechoic fluid-filled space, an imperceptible wall, and posterior acoustic enhancement (Fig. 146-7A and B). Worrisome features, including the presence of symptoms or increasing size, require exclusion of a cystadenoma. On ultrasound a cystadenoma is hypoechoic with irregular walls and septations. Hepatic resection is indicated because malignant transformation can occur.

Multiple hepatic cysts may suggest the presence of autosomal dominant adult polycystic disease.[9] Polycystic liver disease can occur in conjunction with polycystic kidney disease (Chapter 127) or without it. Isolated polycystic liver disease is associated with mutations in the *PRCKSCH* gene, which encodes the glucosidase 2 subunit β enzyme, and in Sec63, which is part of a large protein complex involved in protein translocation in the endoplasmic reticulum. Adult polycystic liver disease typically is symptomatic, although some patients note dull right upper quadrant pain, fullness, sense of a mass, and increasing abdominal girth. Rupture of a cyst, hemorrhage into a cyst, infection of a cyst, or torsion of a cyst may cause severe pain. Physical examination may include hepatomegaly, cachexia due to weight loss, and ascites. As cysts increase in number and size with age, they may become palpable. On ultrasound, multiple fluid-filled cysts are present without internal echoes unless bleeding or infection has occurred. Interventions indicated for symptoms include aspiration or resection. Polycystic liver disease usually does not result in clinical hepatic impairment, and prognosis depends on the severity of any concurrent polycystic renal disease. In some cases, however, large, symptomatic, or bleeding cysts may raise the consideration of liver transplantation, often with combined kidney transplantation (Chapter 131) for associated renal cysts and failure.

Caroli disease, which is a rare congenital abnormality with cystic dilatation of the intrahepatic biliary tree, can be associated with cholangitis and biliary stones. Many patients ultimately develop cholangiocarcinoma (Chapter 155). Magnetic resonance cholangiopancreatography demonstrates intrahepatic dilatations with normal ducts in between and a normal common bile duct. Endoscopic treatment is indicated for cholangitis, although resection or liver transplantation may ultimately be required.

Solid Hepatic Mass

Most solid hepatic masses are asymptomatic, but some patients may have vague right upper quadrant discomfort. The abrupt onset of more severe pain suggests a complication, such as hemorrhage or rupture. The approach to a solid hepatic mass (Fig. 146-8) is influenced by the presence or absence of underlying chronic liver disease, such as chronic viral hepatitis, as well whether an extraheptic malignancy with possible hepatic metastases is a concern. If chronic liver disease is present, a solid mass must be assumed to represent primary hepatocellular carcinoma (Chapter 196) until proved otherwise. By comparison, a solid lesion in the absence of underlying liver disease is more likely to be benign and incidental. Benign hepatic adenomas are commonly discovered in young to middle-aged women and are not associated with hepatic dysfunction. With modern contrast studies, it is usually possible to make a confident radiologic diagnosis about the nature of a solid hepatic mass. Important examples include the initial peripheral filling and retention of contrast dye by a hemangioma (see Fig. 146-8A, B, and C), the rapid arterial filling of a hepatocellular carcinoma with subsequent "washout" of contrast during the portal venous phase (see Fig. 196-5), or the central scar typical of focal nodular hyperplasia (see Fig. 146-8D), although biopsy is indicated if it is not possible to exclude malignancy.

Hepatic hemangiomas are the most common benign solid hepatic mass. On ultrasound, the lesion is hyperechoic. It has a typical hypervascular appearance on contrast CT or MRI. Generally, no intervention is required unless there is a clear association with abdominal symptoms, increasing size, or a complication such as rupture.

Hepatic adenomas (Chapter 196) are benign epithelial hepatic tumors associated with use of oral contraceptives with a higher estrogen content. On ultrasound, adenomas are hyperechoic, reflective of their fat content,

but become anechoic if hemorrhage has occurred. Contrast CT and MRI show arterial enhancement and varying signal intensity reflecting steatosis and hemorrhage if present. Biopsy may be needed for diagnosis. Potential complications of adenomas, especially if greater than 5 cm, include spontaneous hemorrhage and rupture, as well as rare malignant transformation. Discontinuation of oral contraceptives may lead to a decrease in size. Prophylactic hepatic resection is indicated for adenomas greater than 5 cm.

Focal nodular hyperplasia, which is a benign lesion characterized by a central scar and is thought to represent a hyperplastic response due to a vascular malformation. Identification of the scar by ultrasound, CT, or MRI is diagnostic (see Fig. 146-8D). Observation in the absence of symptoms is advised.

Nodular regenerative hyperplasia is characterized by multiple regenerative 1- to 3-mm nodules clustered around portal triads. It is associated with a variety of systemic disorders, predominantly autoimmune, including rheumatoid arthritis, systemic lupus erythematosus, and polymyalgia rheumatica, neoplastic such as myeloproliferative syndromes, and medications including thiopurines. Symptoms, if present, reflect associated portal hypertension. Diagnosis is by biopsy, which shows hypertrophied hepatocytes clustered around the center of the nodules with peripheral atrophy. Management is directed to the associated portal hypertension (Chapter 153).

Hepatocellular carcinoma (Chapter 196) is a frequent complication of cirrhosis of any cause as well as chronic hepatitis B infection even in the absence of cirrhosis. Patients usually will have evidence of cirrhosis with hepatic dysfunction. Because surveillance for hepatocellular carcinoma is now recommended in individuals at risk, this tumor is increasingly identified when asymptomatic and potentially curable.[10] On ultrasound, hepatocellular carcinoma appears solid. Owing to its predominantly arterial blood supply compared with that of normal hepatic parenchyma, intravenous contrast is

rapidly taken up by a hepatic cellular carcinoma and then "washes out" on CT scan or MR imaging (see Fig. 196-5). Serum α-fetoprotein is elevated in approximately 60% of cases. Therapeutic options depend on the tumor's size and severity of associated liver disease.

APPROACH TO THE PATIENT WITH INHERITED LIVER DISEASE

The major inherited liver diseases in adults are hemochromatosis, Wilson disease, cystic fibrosis, and α_1-antitrypsin deficiency. These disorders may be suspected by their extrahepatic manifestations or may be detected during evaluation of unexplained hepatic dysfunction.

Hereditary hemochromatosis (Chapter 212), which is the most common inherited liver disorder, is most frequently due to mutations in the *HFE* gene (located on chromosome 6p22.2), typically at C282Y and H63D. Approximately 1 in 250 individuals of Northern European descent are homozygous for C282Y, the major *HFE* mutation, although only a minority develop phenotypic manifestations.[11] Liver blood test abnormalities, if present, are nonspecific. Definitive diagnosis is confirmed by detection of C282Y homozygote or compound heterozygote (C282Y/H63D). MRI or CT scan can confirm excessive hepatic iron. Liver biopsy is unnecessary for diagnosis but is advised for a serum ferritin greater than 1000 μg/L because the patient is likely to be cirrhotic. Iron accumulates in hepatocytes but not Kupffer cells in a periportal to pericentral gradient (Fig. 146-9). By comparison, secondary iron overload accumulates in Kupffer cells in conditions such as ineffective erythropoiesis. Quantitative iron measurement in liver tissue, calculated as the μmol of iron/g dry weight liver/age, can confirm the diagnosis. Treatment of hemochromatosis is by phlebotomy (Chapter 212).

α_1-Antitrypsin deficiency, which results from inherited mutations in this serine protease inhibitor, prevents its export from hepatocytes, where its accumulation causes liver inflammation, fibrosis, and cirrhosis. Deficiency of circulating α_1-antitrypsin results in panlobular emphysema (Chapter 88) even in nonsmokers. The disease is most frequent in persons of European ancestry. Inheritance is autosomal recessive with codominant inheritance because each allele provides 50% of circulating α_1-antitrypsin. A large number of alleles have been identified in the proteinase inhibitor (Pi) gene,

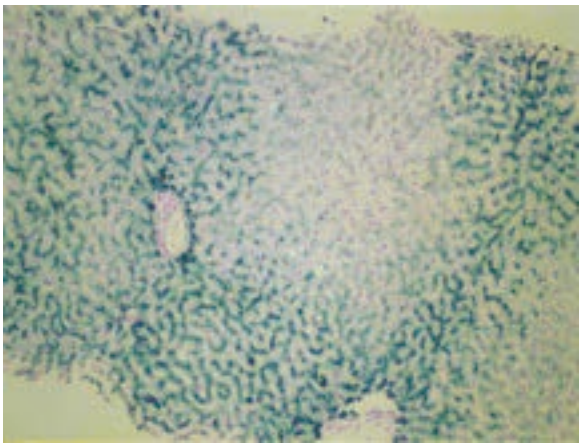

FIGURE 146-9. Liver biopsy in hemochromatosis (Perls Prussian blue stain for iron). Iron deposition is found in a periportal distribution, predominantly in parenchymal cells (hepatocytes). (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine,* 24th ed. Philadelphia: Saunders; 2012.

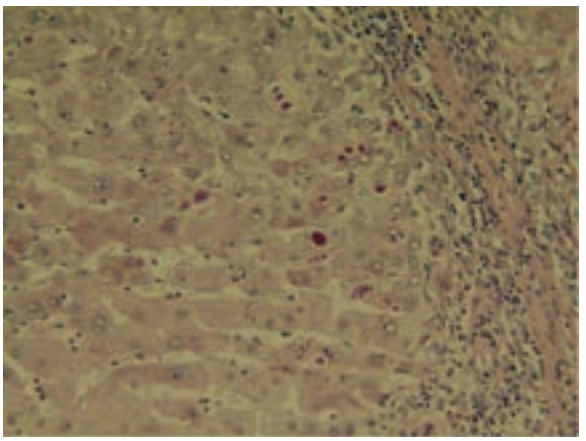

FIGURE 146-10. Liver biopsy in α_1-antitrypsin deficiency. On a periodic acid–Schiff, diastase-resistant stain, α_1-antitrypsin globules, with a characteristic magenta color, are found at the periphery of the lobule. (From Bacon BR. Inherited and metabolic disorders of the liver. In: Goldman L, Schafer AI, eds. *Goldman's Cecil Medicine*, 24th ed. Philadelphia: Saunders; 2012.)

with MM associated with normal circulating α_1-antitrypsin levels and the most common abnormal alleles, S and Z, associated with reduced levels. PiZZ homozygotes, who have the most severe α_1-antitrypsin deficiency, have only 15% of normal circulating levels and are prone to liver and lung disease. Liver disease has a bimodal distribution, with neonatal hepatitis and cholestatic jaundice manifesting in early life and cirrhosis in adulthood. Only approximately one third of adults with the PiZZ phenotype develop cirrhosis, thereby implying that other cofactors are involved in disease progression.[12] Other phenotypes with α_1-antitrypsin deficiency (e.g., PiMZ or PiSZ) increase the risk for liver disease, whereas null variants have lung but not liver disease. The condition may be suspected by a low α_1-1 globulin level on a routine protein electrophoresis, and the diagnosis can be confirmed by demonstration of a low serum α_1-antitrypsin level followed by Pi testing to determine the phenotype. Liver function tests are generally nonspecific, although the albumin level can be low and the INR prolonged if cirrhosis is present. Liver biopsy, which shows the extent of fibrosis, is characterized by periodic acid–Schiff (PAS)-positive, diastase-resistant globules in the periphery of the lobule (Fig. 146-10). No specific therapy is available for the liver disease, although weekly intravenous α_1-antitrypsin protein concentrate infusions, which are approved by the U.S. Food and Drug Administration, might prevent progression of lung disease by restoring serum and alveolar α_1-antitrypsin levels.

Wilson disease (Chapter 211) is excessive copper accumulation in liver and extrahepatic tissues owing to an inherited disorder in copper transport from hepatocytes to bile.[13] Hepatic manifestations include chronic hepatitis and cirrhosis, most typically appearing by the fourth decade of life, although they can manifest later. A characteristic finding in a fulminant manifestation of Wilson disease is hemolysis with an abnormally low alkaline phosphatase level, jaundice, and coagulopathy. More typically, patients have elevated aminotransferase levels without hemolysis at presentation. Diagnosis usually is based on an elevated 24-hour urinary copper level and low serum ceruloplasmin levels, but in unclear cases the quantification of increased hepatic copper content by biopsy is definitive. Copper chelation prevents disease progression.

Cystic fibrosis (Chapter 89) is usually dominated by pulmonary complications, but liver disease is an important cause of morbidity and mortality in adults.[14] In patients with elevated alkaline phosphatase and bilirubin levels, biliary cirrhosis (Chapter 155) can develop owing to abnormal bile viscosity. Ursodeoxycholic acid may improve biochemical test results but has no clear benefit on outcome. Liver transplantation (Chapter 154) may be necessary for decompensated cirrhosis.

REVIEW QUESTIONS

1. Fever is a frequent feature of which of the following?

A. Acute alcoholic hepatitis
B. Acute hepatitis C
C. Autoimmune hepatitis
D. Chronic hepatitis B
E. Chronic hepatitis C

Answer: A With the exception of the prodrome of acute hepatitis A, fever is not prominent in viral hepatitis nor in autoimmune hepatitis. It is a feature of acute alcoholic hepatitis even in the absence of infection.

2. Which of following suggests biliary obstruction as the cause of scleral icterus?

A. Dark urine and dark stool
B. Pale urine and pale stool
C. Dark urine and pale stool
D. Dark urine and alternating pale and dark stool
E. Pale urine and dark stool

Answer: C With jaundice from biliary obstruction, bilirubin is predominantly conjugated, water-soluble, and excreted in the urine, which is therefore dark. Because of biliary obstruction, bile salts cannot reach the intestine, so stools are pale. By comparison, the excess bilirubin from hemolysis is unconjugated and not water soluble, so it is not excreted in the urine.

3. Which of the following presentations suggests variceal hemorrhage?

A. Unexplained iron deficiency anemia
B. Dysphagia
C. Abdominal bloating
D. Abdominal pain
E. Hematemesis

Correct: E Variceal hemorrhage is typically profuse, painless, and not associated with esophageal symptoms such as dysphagia. Because bleeding is overt, unexplained iron deficiency is not usually due to bleeding varices.

4. Which of the following disorders has an autosomal dominant inheritance?

A. Wilson disease
B. Hemochromatosis
C. α_1-Antitrypsin deficiency
D. Adult polycystic disease
E. Hepatic adenoma

Correct: D Adult polycystic disease has an autosomal dominant inheritance, whereas the other conditions are sporadic, such as adenoma, or autosomal recessive, such as Wilson disease.

APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

PAUL D. BERK AND KEVIN M. KORENBLAT

JAUNDICE AND HYPERBILIRUBINEMIA

DEFINITION

Jaundice, from the French *jaune* ("yellow"), is the yellow-orange discoloration of the skin, conjunctivae, and mucous membranes that results from an elevated plasma bilirubin level. Mild hyperbilirubinemia may be clinically undetectable, but jaundice becomes evident at plasma bilirubin greater than 3 to 4 mg/dL, depending on the patient's normal skin pigmentation, the conditions of observation, and the bilirubin fraction that is elevated. Hyperbilirubinemia may result from hepatocellular dysfunction (pure hyperbilirubinemia) or from either increased bilirubin production or inherited or acquired defects in specific aspects of hepatic bilirubin disposition.

PATHOBIOLOGY

Bilirubin Metabolism

Bilirubin Production

Bilirubin is the degradation product of the heme moiety of hemoproteins, a class of proteins involved in the transport or metabolism of oxygen (Fig. 147-1). Normal adults produce approximately 4 mg of bilirubin per kilogram of body weight per day. Between 70 and 90% of bilirubin is derived from the hemoglobin of erythrocytes, which are sequestered and destroyed by the mononuclear phagocytic cells of the reticuloendothelial system, principally in the spleen, liver, and bone marrow. The remainder results primarily from the turnover of nonhemoglobin hemoproteins such as myoglobin, the P-450 cytochromes, catalase, and peroxidase, principally in the liver; a minor fraction reflects ineffective erythropoiesis, which is the premature destruction of newly formed erythrocytes within the bone marrow. Although bilirubin production occurs principally in the liver, bilirubin has proved to have antioxidant properties, and recent studies suggest that a limited, regulated production of bilirubin from heme may occur in many cell types and contribute to regulating the intracellular antioxidant environment.[1]

The two-step conversion of heme to bilirubin begins with the opening of the heme molecule at its α bridge carbon by the microsomal enzyme *heme oxygenase,* a process that results in the formation of equimolar quantities of carbon monoxide and the green tetrapyrrole biliverdin. This nontoxic, water-soluble pigment is the main excretory product of heme in birds, reptiles, and amphibians. However, biliverdin cannot cross the placenta. Accordingly, its reduction to bilirubin in mammals by a second enzyme, *biliverdin reductase,* allows its transplacental removal from the fetus into the maternal circulation. The unconjugated bilirubin produced in the periphery is transported to the liver in plasma. Because of its insolubility in aqueous media, it is kept in solution by tight but reversible binding to albumin. A number of compounds, including sulfonamides, furosemide, and radiographic contrast agents, can competitively displace bilirubin from its binding sites on albumin, a phenomenon that is of little clinical significance except in neonates, in whom the resulting increased concentration of unbound bilirubin raises the risk for kernicterus.

Disposition of Bilirubin by the Liver

Excretion of bilirubin from the body is a major function of the liver (see Fig. 147-1), where the specialized microanatomy enhances the extraction of tightly protein-bound compounds from the circulation. Hepatic translocation of bilirubin from blood to bile involves four distinct steps: (1) uptake of unconjugated bilirubin, principally by an incompletely characterized facilitated transport process and to a lesser extent by diffusion; (2) intracellular binding, mainly to various cytosolic proteins of the glutathione-*S*-transferase family; (3) conversion of unconjugated bilirubin to bilirubin monoglucuronides and diglucuronides by a specific uridine 5′-diphosphoglucuronosyltransferase (UDP-glucuronosyltransferase) isoform designated UGT1A1, encoded by the *UGT1* gene complex; and (4) transfer of bilirubin monoglucuronides and diglucuronides into bile by a canalicular membrane

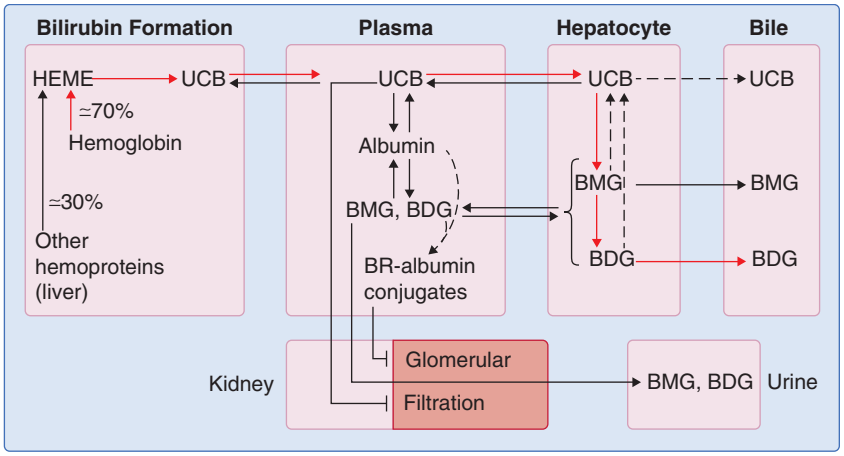

FIGURE 147-1. Overview of bilirubin metabolism. Unconjugated bilirubin (UCB) formed from the breakdown of heme from hemoglobin and other hemoproteins is transported in plasma reversibly bound to albumin and is converted in the liver to bilirubin monoglucuronide (BMG) and diglucuronide (BDG), the latter being the predominant form secreted in bile. BMG and BDG together normally account for less than 5% of normal serum bilirubin. In patients with hepatobiliary disease, BMG and BDG accumulate in plasma and appear in urine. Bilirubin glucuronides in plasma also react nonenzymatically with albumin and possibly other serum proteins to form protein conjugates, which do not appear in urine and have a plasma half-life similar to that of albumin. BR = bilirubin.

adenosine triphosphate (ATP)-dependent transporter designated multidrug resistance–associated protein 2 (MRP2) or canalicular multispecific organic anion transporter (cMOAT). MRP2/cMOAT is encoded by the gene *ABCC2*, a member of ATP-binding cassette (ABC) transporter superfamily of genes. ABC genes transport molecules across intracellular and extracellular membranes. The superfamily is divided into seven subfamilies. MRP2/cMOAT belongs to the MRP family, whose substrates include drug conjugates and unmodified anticancer drugs, which are pumped out of cells.

Conjugation of unconjugated bilirubin to bilirubin monoglucuronides and diglucuronides is a critical process that greatly increases the aqueous solubility of bilirubin, thereby enhancing its elimination from the body while simultaneously reducing its ability to diffuse across biologic membranes, including the blood-brain barrier. In newborn infants, a decreased capacity to conjugate bilirubin leads to unconjugated hyperbilirubinemia (physiologic jaundice of the newborn). If severe, this hyperbilirubinemia may lead to irreversible central nervous system toxicity. Phototherapy by exposure to blue light converts bilirubin to water-soluble photoisomers that are readily excreted in bile, thereby protecting the central nervous system from bilirubin toxicity. Gilbert syndrome and Crigler-Najjar syndrome types 1 and 2, which result from genetic defects in bilirubin conjugation, are characterized by unconjugated hyperbilirubinemia; by contrast, Dubin-Johnson syndrome, which results from inheritable defects in MRP2/cMOAT (see later), is characterized by conjugated or mixed hyperbilirubinemia. The recent discovery of the causative mutations in Rotor syndrome, which is also characterized by conjugated or mixed hyperbilirubinemia, has led to the finding of an additional step in bilirubin transport, characterized by the export of intracellular bilirubin conjugates across the sinusoidal membrane and their subsequent reuptake by transporters in downstream hepatocytes. The process, which is also involved in the disposition of drug metabolites, is believed to prevent the local saturation of upstream hepatocytes with bilirubin and drug conjugates.[2]

Enterohepatic Circulation and Excretion of Bilirubin

Normal human bile contains an average of less than 5% unconjugated bilirubin, 7% bilirubin monoconjugates, and 90% bilirubin diconjugates. Following canalicular secretion, conjugated bilirubin passes down the gastrointestinal tract without reabsorption by either the gallbladder or intestinal mucosa. Although some bilirubin reaches the feces, most is converted to urobilinogen and to related compounds by bacteria within the ileum and colon, where the urobilinogen is reabsorbed, returns to the liver through the portal circulation, and is re-excreted into bile in a process of enterohepatic recirculation. Any urobilinogen not taken up by the liver reaches the systemic circulation, from which it is cleared by the kidneys. Normal urine urobilinogen excretion is 4 mg/day or less. With hemolysis, which increases the load of bilirubin entering the gut and therefore the amount of urobilinogen formed and reabsorbed, or with liver disease, which decreases its hepatic extraction, plasma urobilinogen levels rise and more urobilinogen is excreted in the urine. Severe cholestasis, bile duct obstruction, or antibiotics that reduce or eliminate the bacterial conversion of bilirubin to urobilinogen markedly decrease the formation and urinary excretion of urobilinogen.

Unconjugated bilirubin ordinarily does not reach the gut except in neonates or, by ill-defined alternative pathways, in the presence of severe unconjugated hyperbilirubinemia (e.g., Crigler-Najjar type 1). In these circumstances, unconjugated bilirubin is reabsorbed from the gut, thereby amplifying the hyperbilirubinemia.

Measurement of Bilirubin in Plasma

The total plasma bilirubin concentration in normal adults is less than 1 to 1.5 mg/dL, depending on the measurement method. Modern analytic techniques show that normal plasma contains principally unconjugated bilirubin, with only a trace of conjugated bilirubin. Clinical laboratories typically quantify plasma bilirubin by a reaction in which bilirubin is cleaved by a diazo reagent, such as diazotized sulfanilic acid, to azodipyrroles that are readily quantitated spectrophotometrically. Bilirubin conjugates react rapidly ("prompt" or "direct"-reacting bilirubin). Unconjugated bilirubin reacts slowly because the site of attack by the diazo reagent is protected by internal hydrogen bonding. Accordingly, accurate measurement of the total plasma bilirubin concentration requires addition of an accelerator, such as ethanol or urea, to disrupt this internal hydrogen bonding and to ensure complete reaction of any unconjugated bilirubin.

The "indirect"-reacting bilirubin is calculated by subtracting the direct-reacting bilirubin from the total. Although physicians traditionally equate the direct-reacting fraction of bilirubin in plasma with conjugated bilirubin and the indirect fraction with unconjugated bilirubin, this approach is, at best, a rough approximation. The unqualified interpretation of direct and indirect fractions as reflecting conjugated and unconjugated bilirubin, respectively, may lead to diagnostic errors, particularly in the diagnosis of hereditary hyperbilirubinemias. In common practice, 10 to 20% of the bilirubin in normal plasma gives a prompt (direct) diazo reaction even though more than 95% of total bilirubin in normal plasma is unconjugated. Thus, at virtually any total bilirubin concentration, a direct-reacting fraction of less than 15% of the total bilirubin can be considered as essentially all unconjugated. When the direct-reacting fraction is greater than 15%, a simple dipstick test for bilirubinuria may clarify the situation. Unconjugated bilirubin is not excreted in urine regardless of the height of its plasma concentration because its binding to albumin is too tight for effective glomerular filtration and it is not secreted by the tubules. The canalicular transport mechanism for excretion of bilirubin conjugates is especially sensitive to injury. Accordingly, in parenchymal liver disease or mechanical bile duct obstruction, bilirubin conjugates within the hepatocyte or biliary tract may reflux into the blood stream, resulting in a mixed or, less often, a purely conjugated hyperbilirubinemia. Conjugated bilirubin, which is normally loosely bound to albumin, is readily filtered at the glomerulus; even modest degrees of conjugated hyperbilirubinemia result in bilirubinuria, which is *always* a pathologic finding. With prolonged conjugated hyperbilirubinemia, some of the conjugated bilirubin binds *covalently* to albumin and produces what is designated the δ-bilirubin fraction. Although δ-bilirubin gives a direct diazo reaction, it is not filterable by the glomerulus and does not appear in the urine; it disappears slowly from the plasma, with the 14- to 21-day half-life of the albumin to which it is

bound. δ-Bilirubin can account for the slow rate at which conjugated (direct) hyperbilirubinemia sometimes resolves as hepatitis improves or biliary obstruction is relieved. Although δ-bilirubin is not easily measured, its presence can be inferred when an elevated direct-reacting bilirubin persists after bilirubinuria resolves.

Transcutaneous bilirubinometry is an alternative method for measuring bilirubin in infants with neonatal jaundice. The method is based on the measurement of the light reflected from the percutaneous transmission of visible light and is conceptually analogous to pulse oximetry.[3]

Bilirubin Kinetics

The plasma unconjugated bilirubin concentration ([UCB]) is determined by a balance between the bilirubin production rate (BRP) and hepatic bilirubin clearance (C_{BR}) according to the relationship:

$$[UCB] \approx BRP/C_{BR}$$

C_{BR} is analogous to the creatinine clearance test of kidney function; it is a measure of the rate at which bilirubin is extracted from plasma, and it is a true quantitative test of liver function. Whereas BRP and C_{BR} are not easily quantified clinically, investigative measurements have yielded useful pathophysiologic insights. This equation indicates that [UCB] is directly proportional with increases in BRP and inversely proportional with CBR, thereby providing a basis for classifying unconjugated hyperbilirubinemias according to their pathogenesis.

Increased Bilirubin Production

An increased production of bilirubin and a resulting unconjugated hyperbilirubinemia can be caused by hemolysis, an accelerated destruction of transfused erythrocytes, resorption of hematomas, or ineffective erythropoiesis owing to lead poisoning, megaloblastic anemias related to deficiency of either folic acid or vitamin B_{12}, sideroblastic anemia, congenital erythropoietic porphyria, or myeloproliferative or myelodysplastic diseases. In these settings, other liver tests are typically normal and the hyperbilirubinemia is modest, rarely exceeding 4 mg/dL; higher values imply concomitant hepatic dysfunction. However, after brisk blood transfusion or resorption of massive hematomas caused by trauma, the increased bilirubin load may be transiently sufficient to lead to frank jaundice. The causes of hemolysis are numerous (Chapters 160 to 163). Besides specific blood disorders, mild hemolysis accompanies many acquired diseases. In the setting of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration. Prolonged hemolysis may lead to the formation of bilirubin gallstones, which may cause biliary tract disease (Chapter 155).

Decreased Hepatic Bilirubin Clearance

Decreased Bilirubin Uptake

Kinetic studies suggest that hepatocellular bilirubin uptake involves both facilitated and diffusive components. Several drugs (e.g., rifampin, novobiocin, and various cholecystographic contrast agents) competitively inhibit the hepatocellular uptake of bilirubin, thereby suggesting the existence of a component of facilitated uptake. Decreased hepatic bilirubin uptake is also believed to contribute to the unconjugated hyperbilirubinemia of Gilbert syndrome, although the principal molecular basis for that syndrome is a reduction in bilirubin conjugation. The identity of the bilirubin transporter remains controversial.

Impaired Bilirubin Conjugation

The most frequent cause of decreased bilirubin clearance is a decrease in bilirubin conjugating activity. Bilirubin conjugation with glucuronic acid is catalyzed principally by a specific UDP-glucuronosyltransferase, which is designated UGT1A1 and encoded by the *UGT1* gene complex. The *UGT1A1* gene is assembled by alternative splicing of a bilirubin-specific variant of exon 1, designated exon A_1, with four common exons (exons 2 to 5) that encode the shared carboxyl terminal end of all *UGT1*-encoded proteins. Its promoter region normally contains an $A(TA)_6TAA$ TATA box–like construct.

APPROACH TO THE PATIENT WITH HYPERBILIRUBINEMIA

Hyperbilirubinemia and jaundice (see Fig. 146-1) may result from isolated disorders of bilirubin metabolism, liver disease, or obstruction of the biliary tract. Jaundice represents the most visible sign of hepatobiliary disease of many causes (Table 147-1).

Genetic Disorders of Bilirubin Conjugation

The hereditary hyperbilirubinemias (Table 147-2) are a group of five syndromes in which hyperbilirubinemia occurs as an isolated biochemical abnormality, without evidence of either hepatocellular necrosis or cholestasis.[4]

CRIGLER-NAJJAR AND GILBERT SYNDROMES

Crigler-Najjar syndrome types 1 and 2 and Gilbert syndrome are hereditary forms of unconjugated hyperbilirubinemia that have been known for more than two decades to result principally from mutations in *UGT1A1*. In Crigler-Najjar type 1, essentially no functional enzyme activity is present, whereas patients with Crigler-Najjar type 2 have up to 10% of normal and patients with Gilbert syndrome have 10 to 33% of normal activity, leading to bilirubin concentrations of 18 to 45, 6 to 25, and 1.5 to 4 mg/dL, respectively (see Table 147-2). Because total UGT1A1 enzymatic activity must be reduced to less than 50% of normal to produce unconjugated hyperbilirubinemia, phenotypic expression of mutations in this enzyme requires either homozygosity or double heterozygosity, and each of these disorders is inherited as an autosomal recessive trait. Patients with Crigler-Najjar types 1 and 2 are either homozygotes or double heterozygotes for structural mutations within the coding region. In Western countries, patients with Gilbert syndrome are typically homozygous for an $A(TA)_7TAA$ promoter mutation; this polymorphism is designated *UGT1A1*28*. Structural mutations in exon 1 of UGT1A1 causing modest reductions in UGT1A1 enzymatic activity have been reported in some Japanese patients with Gilbert syndrome. To date, 130 different mutations in *UGT1A1* associated with hereditary hyperbilirubinemia have been identified, including 59 linked to Crigler-Najjar type 1 and 48 to Crigler-Najjar type 2.[5] Recent studies have identified mutations of multiple additional regions of *UGT1A* and also of the solute carrier protein SCLO1B1, both of which participate to varying degrees in the defective glucuronidation capacity of these three syndromes.[6] The resulting complex genotypes may pose a risk not only for hyperbilirubinemia but also for susceptibility to glucuronidation-associated drug toxicity and, perhaps, for subtle diverse benefits as well.[7]

Crigler-Najjar Syndrome Type 1

Crigler-Najjar type 1 is characterized by striking unconjugated hyperbilirubinemia that appears in the neonatal period, persists for life, and is unresponsive to phenobarbital. The majority of patients (type 1A) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin as the result of mutations in one of the common exons (2 to 5) of the *UGT1* complex. In a smaller subset (type 1B), a mutation in the bilirubin-specific exon A1 limits the defect to bilirubin conjugation. Fifty-nine structurally diverse *UGT1A1* mutations can cause Crigler-Najjar type 1; their common feature is they all encode proteins with absent or, at most, traces of enzymatic activity. Before the availability of phototherapy, most patients with Crigler-Najjar type 1 died of bilirubin encephalopathy (kernicterus) in infancy or early childhood.[8] Optimal treatment for a neurologically intact patient includes (1) approximately 12 hours/day of phototherapy from birth throughout childhood, perhaps supplemented by exchange transfusion in the neonatal period; (2) use of tin-protoporphyrin to blunt transient episodes of increased hyperbilirubinemia; and (3) early liver transplantation, before the onset of brain damage.[9] Plasmapheresis has been used to temporarily control abrupt increases in bilirubin[10] and transplantation with isolated allogeneic hepatocytes has been evaluated as an experimental therapeutic approach.

Crigler-Najjar Syndrome Type 2

Bilirubin concentrations are typically lower in Crigler-Najjar type 2, and plasma bilirubin levels can be reduced to 3 to 5 mg/dL by phenobarbital. At least 48 different mutations of *UGT1A1* have been associated with Crigler-Najjar type 2; all encode a bilirubin-UDP-glucuronosyltransferase with markedly reduced but detectable enzymatic activity. Although uncommon in Crigler-Najjar type 2, kernicterus has occurred at all ages, typically associated with factors that temporarily raise the plasma bilirubin concentration above baseline (e.g., fasting, intercurrent illness). For this reason, phenobarbital therapy is often recommended; a single bedtime dose usually maintains clinically safe plasma bilirubin concentrations.

Gilbert Syndrome

Gilbert syndrome is the most common form of the hereditary hyperbilirubinemias, with a genotypic prevalence of approximately 12% and a

TABLE 147-1 DIFFERENTIAL DIAGNOSIS OF HYPERBILIRUBINEMIA AND JAUNDICE

ISOLATED DISORDERS OF BILIRUBIN METABOLISM
Unconjugated Hyperbilirubinemia
Increased bilirubin production
Examples: Hemolysis, ineffective erythropoiesis, blood transfusion, resorption of hematomas
Decreased hepatocellular uptake
Examples: Drugs (e.g., rifampin)
Decreased conjugation
Examples: Gilbert and Crigler-Najjar syndromes, physiologic jaundice of the newborn, breast milk jaundice, HIV protease inhibitors
Conjugated or Mixed Hyperbilirubinemia
Decreased canalicular transport: Dubin-Johnson syndrome
Decreased reuptake of bilirubin conjugates: Rotor syndrome
LIVER DISEASE
Acute or Chronic Hepatocellular Dysfunction
Acute or subacute hepatocellular injury
Examples: Viral hepatitis A, B, C, E; hepatotoxins (e.g., ethanol, acetaminophen, mushroom *[Amanita phalloides]* poisoning); drugs (e.g., isoniazid, α-methyldopa), metabolic diseases (e.g., Wilson disease, Reye syndrome); pregnancy-related (e.g., acute fatty liver of pregnancy, HELLP); hepatic ischemia (e.g., hypotension, postoperative, hepatic artery thrombosis)
Chronic hepatocellular disease
Examples: Hepatitis B, B + D, C, and E; hepatotoxins (e.g., vinyl chloride, vitamin A), nonalcoholic and alcoholic fatty liver disease; autoimmune hepatitis; metabolic disease (Wilson disease, hemochromatosis, α_1-antitrypsin deficiency)
Hepatic Disorders with Prominent Cholestasis
Familial cholestatic disorders
Single gene disorders
Examples: Benign recurrent intrahepatic cholestasis types 1-3; progressive familial intrahepatic cholestasis types 1-3
Familial cholestatic disorders of unknown pathogenesis
Examples: Aagenaes syndrome, Navajo neurohepatopathy, North American Indian cholestasis
Diffuse infiltrative disorders
Examples: Granulomatous diseases (e.g., mycobacterial and fungal infections, sarcoidosis, lymphoma, drugs), amyloidosis, infiltrative malignancies
Inflammation of intrahepatic bile ductules and/or portal tracts
Examples: Primary biliary cirrhosis, liver allograft rejection, graft-versus-host disease, drugs (e.g., chlorpromazine, erythromycin)
Miscellaneous conditions
Examples: Uncommon presentations of viral or alcoholic hepatitis, intrahepatic cholestasis of pregnancy, contraceptive jaundice, estrogens, anabolic steroids, postoperative cholestasis, cholestasis of sepsis, total parenteral nutrition, bacterial infections, drugs
OBSTRUCTION OF THE BILE DUCTS
Choledocholithiasis
Examples: Cholesterol gallstones, pigment gallstones
Diseases of the Bile Ducts
Inflammation, infection
Examples: Primary sclerosing cholangitis, AIDS cholangiopathy, hepatic arterial chemotherapy, postsurgical strictures
Neoplasms (e.g., cholangiocarcinoma)
Extrinsic Compression of the Biliary Tree
Neoplasms
Examples: Pancreatic carcinoma, metastatic lymphadenopathy, hepatoma
Pancreatitis with or without pseudocyst formation
Vascular enlargement (e.g., aneurysm, cavernous transformation of portal vein)

AIDS = acquired immunodeficiency syndrome; HELLP = hemolysis, elevated liver enzymes, and low platelets; HIV = human immunodeficiency syndrome.

phenotypic prevalence of approximately 7% in whites. Its high prevalence may explain the frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients. Plasma bilirubin concentrations are most often less than 3 mg/dL, although both higher and lower values are frequent, with increases of two-fold to three-fold commonly occurring with fasting and intercurrent illness. The phenotypic distinction between mild Gilbert syndrome and a normal state is often blurred. Phenobarbital's ability to induce hepatic enzyme activity normalizes both the bilirubin concentration and C_{BR}. Oxidative drug metabolism and the disposition of many, but not all, xenobiotics that are metabolized by glucuronidation appear to be normal in Gilbert syndrome. A critical exception is the antitumor agent irinotecan (CPT-11), whose active metabolite (SN-38) is glucuronidated specifically by UGT1A1. In patients with Gilbert syndrome, CPT-11 can cause intractable diarrhea, myelosuppression, and other serious toxicities. Significant adverse events have not been described when individuals with Gilbert syndrome are prescribed many other agents that are metabolized by glucuronidation. Although Gilbert syndrome has no association with disease, occasional reports have demonstrated an association of the *UGT1A1*28* allele with decreased risk for cardiovascular and specific neoplastic diseases, an association that has been attributed to the vasodilatory and antioxidant effects of bilirubin and heme oxygenase.

UNCONJUGATED HYPERBILIRUBIN IN THE NEWBORN PERIOD

Most neonates develop mild unconjugated hyperbilirubinemia between days 2 and 5 after birth because of hepatic immaturity and low UGT1A1 levels. Peak bilirubin levels are typically less than 5 to 10 mg/dL, and levels return to normal within 2 weeks as mechanisms fostering bilirubin disposition mature. Prematurity, with hemolysis, is associated with higher bilirubin levels that may require phototherapy. The progestational steroid 3α,20β-pregnanediol and certain fatty acids that are found in breast milk (but not serum) of some mothers inhibit bilirubin conjugation and can cause excessive neonatal hyperbilirubinemia *(breast milk jaundice)*. By comparison, a UGT1A1 inhibitor, which is found in maternal serum, causes *transient familial neonatal hyperbilirubinemia* (Lucey-Driscoll syndrome).

CONJUGATED OR MIXED HYPERBILIRUBINEMIA

Two phenotypically similar but mechanistically distinct inherited disorders, Dubin-Johnson syndrome and Rotor syndrome, are characterized by conjugated or mixed hyperbilirubinemia with normal values for other standard liver tests (see Table 147-2). Dubin-Johnson syndrome results from any of several mutations in the gene encoding the ATP-dependent canalicular organic anion transporter MPR2/cMOAT (see Fig. 147-1). Individuals with Rotor syndrome exhibit the simultaneous disruption of two genes that code for the organic anion transporting polypeptides OATP1B1 and OATP1B3, which mediate the reuptake by downstream hepatocytes of conjugated bilirubin secreted into the sinusoid via the sinusoidal efflux transporter ABCC3 in more upstream hepatocytes.[11] Despite the conjugated hyperbilirubinemia, patients with Rotor syndrome are not cholestatic and can be distinguished noninvasively both from normal subjects and persons with Dubin-Johnson syndrome by their two-fold to five-fold increase in total copropophryin

TABLE 147-2 PRINCIPAL FEATURES OF THE HEREDITARY DISORDERS OF BILIRUBIN METABOLISM

FEATURE	CRIGLER-NAJJAR SYNDROME *Type I*	CRIGLER-NAJJAR SYNDROME *Type II*	GILBERT SYNDROME	DUBIN-JOHNSON SYNDROME	ROTOR SYNDROME
Incidence	Very rare	Uncommon	Up to 12% of population	Uncommon	Rare
Total serum bilirubin (mg/dL)	18-45 (usually >20), unconjugated	6-25 (usually ≤20), unconjugated	Typically ≤4 in absence of fasting or overt hemolysis; mostly unconjugated	Typically 2-5, less often ≤25; approximately 60% direct reacting	Usually 3-7, occasionally ≤20; approximately 60% direct reacting
Defect(s) in bilirubin metabolism*	Bilirubin UGT1A1 conjugating activity markedly reduced: trace to absent	Bilirubin UGT1A1 conjugating activity reduced: ≤10% of normal.	Complex haplotype Bilirubin UGT1A1 conjugating activity typically reduced to 10-33% of normal; reduced bilirubin uptake in some cases; mild hemolysis in up to 50% of patients	Impaired canalicular secretion of conjugated bilirubin owing to MRP2/cMOAT mutation	Impaired hepatic secretion or storage of conjugated bilirubin owing to impaired reuptake of bilirubin conjugates resulting from simultaneous OATP1B1 and OATP1B3 mutations.
Routine liver tests	Normal	Normal	Normal	Normal	Normal
Serum bile acids	Normal	Normal	Normal	Usually normal	Normal
Plasma sulfobromophthalein removal (% retention of 5 mg/kg dose at 45 min)†	Normal	Normal	Usually normal (<5%); mild 45-min (<15%) retention in some patients	Slow initial decline in plasma concentration (retention ≤20% at 45 min) with secondary rise at 90-120 min	Very slow initial decline in plasma concentration (45-min retention = 30-45%) without secondary rise
Oral cholecystography	Normal	Normal	Normal	Faint or non-visualization of gallbladder	Usually normal
Pharmacologic responses/special features	No response to phenobarbital	Phenobarbital reduces bilirubin by ≤75%	Phenobarbital reduces bilirubin, often to normal	Increased bilirubin concentration with estrogens; diagnostic urine coproporphyrin isomer pattern (total is normal, with isomer I increased to ≥80% of total)	Characteristic urine coproporphyrin excretion pattern (total is increased ≤2.5-fold in ~65% of cases but isomer I always <80% of total)
Major clinical features	Kernicterus in infancy if untreated; may occur later despite therapy	Rare late-onset kernicterus with fasting	None	Occasional hepatosplenomegaly	None
Hepatic morphology/histology	Normal	Normal	Normal; occasionally increased lipofucin pigment	Liver grossly black; coarse, dark centrilobular pigment	Normal
Bile bilirubin fractions‡	>90% unconjugated	Largest fraction (mean 57%) monoconjugates	Mainly diconjugates but monoconjugates are increased (mean 23%)	Mixed conjugates, reported increase in diconjugates	Increased conjugates
Inheritance (all autosomal)	Recessive	Recessive	Promoter mutation is recessive; missense mutation often dominant	Recessive; rare kindred appears dominant	Recessive
Diagnosis	Clinical and laboratory findings, lack of response to phenobarbital	Clinical and laboratory findings, response to phenobarbital	Clinical and laboratory findings; promoter genotyping; liver biopsy rarely necessary	Clinical and laboratory findings; liver biopsy unnecessary if coproporphyrin studies available; BSP disappearance	Clinical and laboratory findings; urine coproporphyrin analysis; BSP disappearance
Treatment	Phototherapy or tin protoporphyrin as short-term therapy; liver transplantation definitive	Consider phenobarbital if baseline bilirubin ≥8 mg/dL	None necessary	Avoid estrogens; no other therapy necessary	No treatment necessary

*UGT1A1 = bilirubin specific isoform of the UGT1 family of uridine diphosphate glucuronosyltransferases.
†Sulfobromophthalein (BSP) studies: Previously used to help distinguish Dubin-Johnson and Rotor syndromes if coproporphyrin isomer studies not available. However, BSP is no longer approved for clinical use in the United States.
‡Bilirubin in normal bile: <5% unconjugated bilirubin, with an average of 7% bilirubin monoconjugates and 90% bilirubin diconjugates.

excretion into the urine (see Table 147-2). Both syndromes carry a benign prognosis without specific therapy.

LIVER AND BILIARY TRACT DISEASE

Jaundice is a common sign of generalized hepatobiliary dysfunction, both acute and chronic. Icteric hepatobiliary disease is readily distinguished from the isolated disorders of bilirubin metabolism because the increase in plasma bilirubin concentration occurs in association with other markers of hepatobiliary disease (Fig. 147-2). Liver diseases can be categorized as those in which the primary injury results from inflammation and hepatocellular necrosis, inhibition of bile flow (cholestasis), or a combination of the two. The cholestatic disorders can be further subdivided into those resulting from mechanical obstruction of the bile duct flow and those from intrahepatic cholestasis, from a multitude of conditions that include several familial cholestatic syndromes; infiltrative disorders (Chapters 149 to 153), particularly those involving the intrahepatic biliary tree; certain other inflammatory or neoplastic conditions; and drug reactions (see Table 147-1 and Chapters 149 to 153).

Familial Cholestasis Syndromes

Bile secretion, which is essential both for the elimination of metabolic wastes and for the solubilization and subsequent absorption of specific nutrients, is a complex, energy-dependent process in which three ABC transporters (ATP8B1, ABCB11, and ABCB4) play critical roles. ATP8B1, also known as

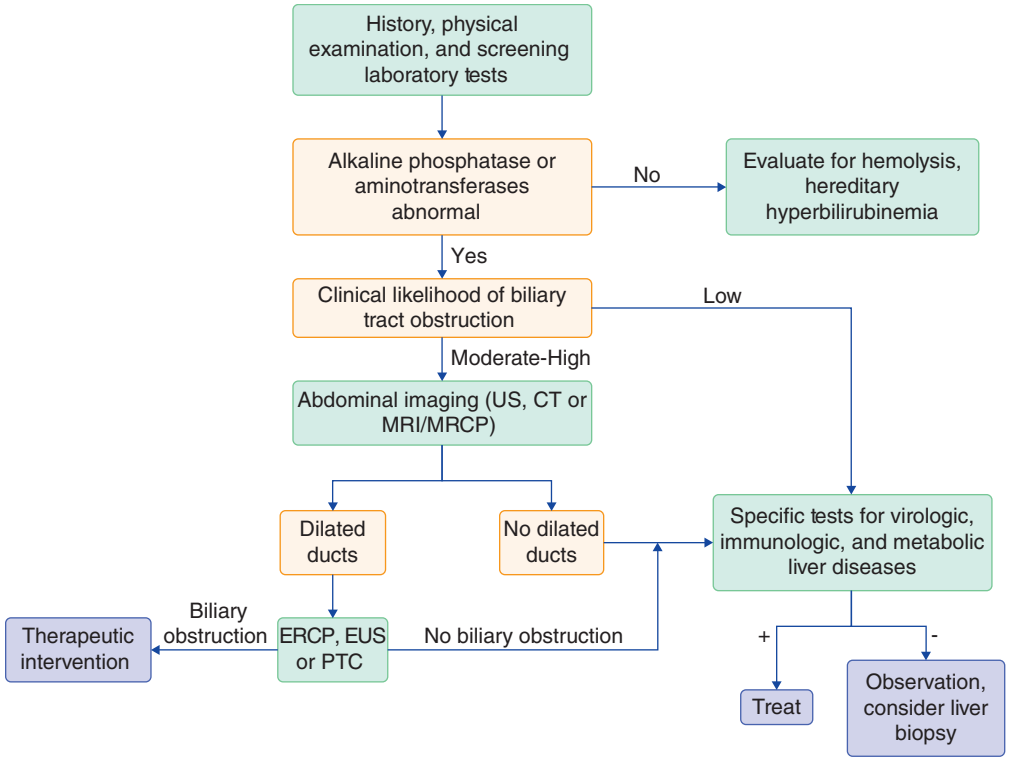

FIGURE 147-2. Diagnostic algorithm for the evaluation of hyperbilirubinemia and other liver test abnormalities and signs and symptoms suggestive of liver disease. CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; PTC = percutaneous transhepatic cholangiogram; US = ultrasound. (Modified from Lidofsky SD, Scharschmidt BF. Jaundice. In: Feldman M, Scharschmidt BF, Sleisenger MH, eds. *Gastrointestinal and Liver Disease.* 6th ed. Philadelphia: WB Saunders; 1998:227.)

familial intrahepatic cholestasis 1 (FIC1), is a phosphatidylserine flippase that translocates phosphatidylserine from the outer (canalicular) to the inner (cytoplasmic) leaflet of the canalicular plasma membrane; ABCB11, also known as the bile salt export pump (BSEP) or the sister of P glycoprotein (SPGP), translocates bile salts from the interior of the hepatocyte across the canalicular membrane into the bile. ABCB4 (multidrug resistance-associated protein 3 [MDR3]) is a phosphatidylcholine (lecithin) floppase translocating phosphatidylcholine outward from the cytoplasmic to the canalicular leaflet of the canalicular membrane.[12] A major function of ATP8B1 and ABCB4 is to maintain an appropriate physicochemical state of the canalicular membrane by regulating the balance of appropriate membrane phospholipids. Three different forms of severe pediatric cholestatic liver disease (designated progressive familial intrahepatic cholestasis types 1, 2, and 3) result from severe, homozygous mutations in these transporters. Less severe, nonprogressive cholestatic liver diseases (designated benign recurrent intrahepatic cholestasis [BRIC] types 1, 2, and 3) result from less severe mutations in these same genes.

Progressive familial intrahepatic cholestasis describes three phenotypically related syndromes of cholestasis during infancy and end-stage liver disease during childhood. All three disorders are inherited in an autosomal recessive pattern. In types 1 and 2, γ-glutamyl transpeptidase (GGT) levels are low despite elevations in alkaline phosphatase; by comparison, elevations in both GGT and alkaline phosphatase occur in type 3. In contrast to the selective bilirubin transport defect in Dubin-Johnson syndrome, the conjugated hyperbilirubinemia in these syndromes is caused by generalized bile secretory failure. Type 1 is the result of mutations in the *FIC1* gene that is also the cause of BRIC type 1. Types 2 and 3 are the result of mutations in genes *ABCB11* and *ABCB4,* respectively. *ABCB11* encodes a bile salt export pump, and *ABCB4* encodes the multidrug resistance protein 3 (MDR3), a protein responsible for the translocation of phosphatidylcholine.

Benign recurrent intrahepatic cholestasis is a rare, autosomal recessive disorder characterized by recurrent attacks of malaise, pruritus, and jaundice beginning in childhood or adulthood and varying in duration from weeks to months. Intervals between attacks may vary from months to years. This benign disorder does not progress to chronic liver disease or cirrhosis, and there is complete resolution between episodes. Treatment during the cholestatic episodes is symptomatic. Type 1 results from a mutation in the gene *familial intrahepatic cholestasis 1 (FIC1),* which is more severely mutated in progressive FIC1. It encodes the translocase protein ATP8B1 that transports aminophospholipids from the outer to the inner leaflet of various cell membranes. Phenotypically similar benign recurrent intrahepatic cholestasis type 2 and type 3 variants result from mutations in *ABCB11* and *ABCB4,* respectively.

Acquired Conjugation Defects

A modest reduction in bilirubin conjugating capacity occurs in advanced hepatitis or cirrhosis (Chapters 149 and 153). However, in these settings, conjugation is better preserved than other aspects of bilirubin disposition, such as canalicular excretion. Pharmacologic and metabolic perturbations may lead to acquired reductions in bilirubin conjugation. Unconjugated hyperbilirubinemia related to selective inhibition of UGT1A1 occurs with several human immunodeficiency virus (HIV) protease inhibitors (e.g., indinavir, atazanavir). Various other drugs (e.g., pregnanediol and the antibiotics novobiocin, chloramphenicol, gentamycin) also may cause unconjugated hyperbilirubinemia by inhibiting UGT1A1. In all settings in which UGT1A1 inhibitors cause unconjugated hyperbilirubinemia, the degree of hyperbilirubinemia is greater in patients with underlying Gilbert syndrome.

Jaundice in Pregnancy

Jaundice in pregnancy (Chapter 239) includes any liver disease that occurs during pregnancy. Conditions unique to pregnancy include a generally modest and self-limited elevation of the aminotransferase and bilirubin levels during the first trimester, often in patients with hyperemesis gravidarum. Intrahepatic cholestasis of pregnancy, which occurs during the second and third trimesters, is associated with intrauterine demise and resolves spontaneously after delivery. Mutations in genes encoding biliary transporters, especially *ABCB4,* have been reported in some but not all cases. Acute fatty liver or the HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome occurs in association with preeclampsia in the third trimester (Chapters 172 and 239). Acute fatty liver may resemble fulminant hepatic failure, with early delivery a prerequisite to maternal recovery.

Postoperative Jaundice

This multifactorial syndrome can be caused by increased bilirubin production (e.g., breakdown of transfused erythrocytes, resorption of hematomas), decreased hepatic bilirubin clearance (e.g., bacteremia, endotoxemia, parenteral nutrition, perioperative hypoxia), or both. Hyperbilirubinemia, which is the main biochemical feature, is often accompanied by a several-fold increase in alkaline phosphatase, GGT, or both levels. Aminotransferases are, at most, minimally elevated, and synthetic function is typically normal. The differential diagnosis includes biliary obstruction (Chapter 155) or hepatocellular injury related to shock, anesthetic injury (Chapter 150), or viral hepatitis (Chapter 148). Postoperative jaundice per se is not a threat to the patient, and it usually resolves in parallel with the patient's overall condition.

DIAGNOSIS

Accurate diagnosis and the distinction between acute and chronic disease often depend on appropriate selection and interpretation of a spectrum of laboratory and imaging studies. Tests used in initial evaluation of liver disease fall into two categories: tests that indicate injury, such as release of intracellular enzymes, and tests that measure, or at least reflect, actual function. Tests that reflect injury do not measure liver function and should not be called liver function tests. Liver tests must be chosen with care and interpreted within the overall clinical context. In specific situations, serial determinations are often helpful to assess the course of disease or the effects of therapy

Serum Enzyme Tests

The levels of hepatic enzymes found in plasma are a measure of hepatocyte turnover or injury. Enzymes released during normal hepatocyte turnover are believed to be the basis for normal circulating levels. Cell injury and cell death activate phospholipases that create holes in the plasma membrane, thereby increasing the release of intracellular contents.

Aminotransferases

The aminotransferases (formerly called transaminases) catalyze transfer of the α-amino group of aspartate (aspartate aminotransferase [AST]) or alanine (alanine aminotransferase [ALT]) to the α-keto group of α-ketoglutarate, with pyridoxal phosphate (vitamin B_6) as a cofactor. Laboratory methods that assay aminotransferase activity require supplementation with vitamin B_6 to avoid falsely decreased activity in subjects who are vitamin B_6 deficient.

Normal serum levels, which are established locally from samples obtained from normal populations, may vary appreciably in different populations but are typically 40 IU/L or less (see Appendix). Values can exceed 1000 IU/L in acute hepatocyte injury, for example, from viral infection (Chapter 148) or toxins (Chapter 150). ALT is a purely cytosolic enzyme. Distinct isoforms of AST are present in cytosol and mitochondria, and AST is also found on the plasma membrane. Expression of the mitochondrial isoform and its physiologic export from the hepatocyte are upregulated by ethanol. Circulating levels of AST and ALT are elevated in most hepatic diseases, and the degree of aminotransferase activity found in plasma roughly reflects the current activity of the disease process. There are, however, critical exceptions. In even the most severe cases of alcoholic hepatitis, aminotransferase levels greater than 200 to 300 IU/L are uncommon (Chapter 152). In nonalcoholic fatty liver disease, normal values for ALT may be found in an appreciable fraction of patients with active nonalcoholic steatohepatitis, fibrosis, or even cirrhosis. By contrast, aminotransferase activities of 1000 IU/L or greater are often present in even mild acute viral hepatitis (Chapter 148) or shortly after acute biliary obstruction, for example, during passage of a gallstone (Chapter 155). Conversely, aminotransferase levels may decline during the course of massive hepatic necrosis because liver injury is so extensive that little enzyme activity remains (Chapter 154). In rare circumstances, antibodies to AST result in an antibody-enzyme complex called a macroenzyme that has a delayed clearance from the circulation.

Aminotransferase levels are useful in several distinct ways. First, they provide a relatively specific screening test for hepatobiliary disease. Although AST levels may be increased with disease of other organs (notably myocardial and skeletal muscle), values 10 times the upper limit of normal or greater almost invariably indicate hepatobiliary pathology. Moreover, in the total clinical context, the source of increased aminotransferase activity is usually obvious. Aminotransferase levels are also used to monitor the activity of an acute or chronic parenchymal liver disease and its response to therapy. However, levels in a given patient may correlate poorly with the severity of the disease as assessed by liver biopsy, particularly in chronic hepatitis C (Chapter 149) and nonalcoholic fatty liver (Chapter 152).[13] Aminotransferases are also often normal despite advanced cirrhosis (Chapter 153), in which they are of limited prognostic value. Finally, aminotransferase levels may provide diagnostic clues. AST levels 15 or more times normal are unusual in chronic bile duct obstruction without cholangitis, and AST levels 6 or more times normal are uncommon in alcoholic liver disease in the absence of other causes. In most liver diseases, the ratio of AST to ALT is usually 1 or less; however, ratios are typically 2 or higher in alcoholic fatty liver and alcoholic hepatitis (Chapter 152), reflecting increased synthesis and secretion of mitochondrial AST into plasma and selective loss of ALT activity because of the pyridoxine deficiency commonly seen in alcoholism. An elevated AST/ALT ratio also occurs in fulminant hepatitis related to Wilson disease (Chapters 146 and 211).

Alkaline Phosphatase

Alkaline phosphatases are widely distributed enzymes (e.g., liver, bile ducts, intestine, bone, kidney, placenta, and leukocytes) that catalyze the release of orthophosphate from ester substrates at an alkaline pH. The normal activity level in adult serum is highly dependent on the measurement method, age, and sex. Two widely used current methods have upper limits of normal in adults of 85 and 110 IU/L (see Appendix). Higher levels are normal in children and in pregnancy. Results must always be compared with the appropriate normal range. In bone, alkaline phosphatase participates in the deposition of hydroxyapatite in osteoid. In other sites, including the liver, its phosphatase activity may facilitate movement of molecules across cell membranes. Serum alkaline phosphatase activity principally reflects the contribution of hepatic and bone isoforms; the intestinal form may account for 20 to 60% of the total after a fatty meal. There is a substantial placental contribution to the alkaline phosphatase level late in pregnancy; the Regan isozyme, a variant that appears identical to the placental form, is associated with hepatocellular cancer (Chapter 196), lung cancer (Chapter 191), and other tumors.

Elevations in the serum alkaline phosphatase activity in cholestatic hepatobiliary disease result from two distinct mechanisms: increased synthesis and secretion of the enzyme and solubilization from the apical (canalicular) surface of hepatocytes and the luminal surface of biliary epithelial cells by the increased local concentrations of bile acids that occur with cholestasis. Serum alkaline phosphatase activity also may be increased in bone disorders (e.g., Paget disease [Chapter 247], osteomalacia [Chapter 244], bone metastases [Chapter 202]), during rapid bone growth in children, in the later stages of pregnancy, with chronic renal failure (Chapter 130), and, occasionally, in the presence of malignancy not involving bones or liver. The source is often obvious, but when it is not, fractionation techniques can distinguish hepatobiliary alkaline phosphatase from other forms. A simpler alternative is to measure serum levels of GGT or 5′-nucleotidase (5′-NT), which tend to parallel levels of alkaline phosphatase in hepatobiliary disease but are usually not increased in bone disease. With a serum half-life of approximately 1 week, serum alkaline phosphatase levels may remain elevated for days to weeks after resolution of biliary obstruction. This delay may be especially misleading when it is accompanied by prolonged direct-reacting hyperbilirubinemia owing to delayed clearance of δ-bilirubin.

Modest increases in serum alkaline phosphatase activity (<3 times normal) occur in many hepatic parenchymal disorders, including hepatitis and cirrhosis. In the absence of bone disease, larger increases (3 to 10 times normal) usually indicate obstruction of bile flow. Although the highest levels usually reflect obstruction of the common bile duct, elevations also can occur with obstruction of intrahepatic bile ducts from infiltrative conditions that arise from granulomatous processes (sarcoidosis [Chapter 95], *Mycobacterium avium-intracellulare* infection [Chapter 325], mycobacteria tuberculosis [Chapter 324]), malignancy (lymphoma, cholangiocarcinoma, or metastatic cancer), or amyloidosis (Chapter 188).

Other Hepatic Enzymes

5′-NT is a plasma membrane enzyme that cleaves orthophosphate from the 5′ position on the pentose sugar of adenosine or inosine phosphate. Leucine aminopeptidase (LAP) is a ubiquitous cellular peptidase. The serum levels of both usually increase in cholestasis. Accordingly, their major use is to confirm whether an elevated serum alkaline phosphatase is of hepatobiliary origin. Both enzymes may be increased in the latter stages of a healthy pregnancy.

GGT is present in many tissues. Its serum activity increases in hepatobiliary disease but also after myocardial infarction; in neuromuscular diseases, pancreatic disease (even in the absence of biliary obstruction), pulmonary disease, and diabetes; and during the ingestion of ethanol and other inducers of microsomal enzymes. Nevertheless, because serum GGT levels are usually normal in bone disease, the enzyme may be helpful in confirming the hepatic origin of alkaline phosphatase. Measurement of GGT has been proposed as a sensitive screening test for hepatobiliary disease and for monitoring abstinence from ethanol. Because of its low specificity, many persons who test positive have no identifiable liver disease on further study. GGT offers no clear advantage over LAP or 5′-NT for identifying the source of increased serum alkaline phosphatase activity except in pregnancy. Serum GGT levels may be normal despite elevated hepatobiliary alkaline phosphatase levels in certain rare disorders, including benign recurrent intrahepatic cholestasis and progressive familial intrahepatic cholestasis types 1 and 2 (see earlier and Chapter 155).

Lactate dehydrogenase levels are often elevated in hepatic ischemia and other conditions that result in hepatic necrosis; otherwise the enzyme is too ubiquitous in other body tissues to be diagnostically useful.

Tests Based on Clearance of Metabolites and Drugs

A major function of the liver is to remove various metabolites and toxins from the blood (Chapter 150). In liver disease, clearance of such molecules may be impaired because of loss of parenchymal cells, diminished bile secretion, biliary obstruction, decreased cellular uptake or metabolism, or reduced or heterogeneous hepatic blood flow. When a metabolite is produced at a relatively constant rate (e.g., bilirubin), its serum level can be a sensitive indicator of liver function. The removal rate from plasma of certain exogenous drugs and dyes can be similarly interpreted. However, plasma removal rates of sulfobromophthalein (BSP) and indocyanine green, once widely used as tests of liver function, have essentially been abandoned.

Bilirubin

The differential diagnosis of hyperbilirubinemia (see earlier) includes generalized liver disease, inherited disorders of bilirubin metabolism (e.g., Gilbert, Crigler-Najjar, Dubin-Johnson, and Rotor syndromes) and nonhepatic conditions (e.g., hemolysis). Higher bilirubin levels correlate with a poorer prognosis in most forms of chronic liver disease.

Ammonia

Ammonia, a byproduct of amino acid metabolism, is removed from blood by the liver, converted to urea in the Krebs-Henseleit cycle, and excreted by the kidneys (Chapter 115). In the setting of portosystemic shunting or severe hepatic dysfunction (e.g., fulminant hepatic failure), ammonia levels rise. Measurements of blood ammonia are principally used to confirm a diagnosis of hepatic encephalopathy or response to treatment of the encephalopathy. However, serum ammonia levels do not strongly correlate with the severity of hepatic encephalopathy (Chapter 153). Correlations may be somewhat better if the measurement is made rapidly on an iced arterial blood sample. Elevated ammonia levels also occur when ammonia production is increased by intestinal flora (e.g., after a high-protein meal or gastrointestinal bleeding), by the kidney (in response to metabolic alkalosis or hypokalemia), or in rare genetic diseases that affect the pathway of urea synthesis (Chapter 205).

Drug Clearance

The rate of hepatic clearance of compounds such as lidocaine and aminopyrine from the circulation can be measured chemically or with radiolabeled tracers. Although such tests can quantify hepatic function, they are rarely used in clinical practice.

Tests Reflecting Hepatic Synthetic Function

Coagulation Tests

See also Chapters 38 and 171.

Prothrombin Time

The prothrombin time (PT) reflects the plasma concentrations of both extrinsic and common pathway factors, that is, factors VII, X, and V, prothrombin, and fibrinogen. A prolonged PT most often results from vitamin K deficiency, liver disease, or both. Vitamin K, a fat-soluble vitamin, is found in many foods and is also synthesized by gut bacteria (Chapter 174). Vitamin K deficiency can be caused by poor dietary intake and malabsorptive states, including the fat malabsorption that results from cholestasis, and it also occurs with antibiotic suppression of gut flora, particularly in patients who receive inadequate vitamin K replacement.

The half-lives of clotting factors are typically less than 1 day. Factor VII, which has the shortest half-life, is usually the earliest and most severely depressed during periods of defective hepatic synthesis. Because the PT is dependent on the level of factor VII, it responds rapidly with changes in hepatic synthetic function; it is useful for following the course of acute liver diseases, in which a significant or growing prolongation of the PT may indicate a poor prognosis (Chapter 148). An abnormal PT that is due solely to vitamin K deficiency usually becomes normal within 24 to 48 hours after parenteral repletion. However, if decreased synthesis of clotting factors reflects hepatocyte dysfunction, there may be little or no response to vitamin K.

Although the prolongation of PT with liver disease is generally accepted as indicative of defective clotting factor synthesis, the synthesis of both procoagulant and anticoagulant proteins is disturbed in liver disease.[14] The physiologic consequences of this rebalancing of coagulation may preserve the coagulation response. Prolongation of the PT may also reflect disseminated intravascular coagulation (Chapter 175), which should always be considered in the context of both acute liver failure and end-stage chronic liver disease.

Partial Thromboplastin Time

This test reflects both the intrinsic and common pathway factors, that is, all of the classical clotting factors except factor VII, and is, therefore, complementary to the PT. It is especially useful in detecting circulating anticoagulants (Chapter 175) but adds little to the PT in evaluating hepatic synthetic function.

Albumin

Albumin is produced solely by the liver. Its plasma concentration reflects a balance between its synthetic rate of approximately 100 to 200 mg/kg/day and its plasma half-life of approximately 21 days. The synthetic rate is affected by the patient's nutritional state, thyroid and glucocorticoid hormone levels, plasma colloid osmotic pressure, exposure to hepatotoxins (e.g., alcohol), and presence of systemic disorders, liver disease, or both. Many conditions increase albumin losses and shorten its plasma half-life, including nephrotic syndrome (Chapter 121), protein-losing enteropathy (Chapter 140), severe burns (Chapter 111), exfoliative dermatitis, and major gastrointestinal bleeding (Chapter 135). In cirrhosis with ascites (Chapters 153 and 154), hypoalbuminemia indicates diminished synthesis or redistribution into ascitic fluid. Thus, a reduced serum albumin concentration can be considered an indicator of decreased hepatic synthetic function only when these factors are not involved.

Hematologic Tests in Liver Disease

In moderate to severe acute liver diseases, varying degrees of cytopenias can be seen with all three cell lineages. The most common finding is thrombocytopenia from hypersplenism, which can be a surrogate marker of portal hypertension. Anemia may reflect low-grade hemolysis or marrow depression. Bone marrow suppression may be caused by ethanol or drugs, and aplastic anemia is an uncommon but well-recognized complication of acute viral hepatitis (Chapters 148 and 165). Zieve syndrome (hemolytic anemia and hypertriglyceridemia) is a rare but well-characterized complication of severe alcoholic liver disease (Chapters 152 and 153). Modest leukopenia, often with atypical lymphocytes, also may be present. Chronic liver disease, especially if cholestatic, may be accompanied by target cells in the peripheral blood smear. Target cells are erythrocytes with an expanded cell membrane that reflects abnormalities in serum lipids. Spur cells (acanthocytes), most often found in advanced alcoholic cirrhosis, reflect a still greater increase in membrane cholesterol.

Tests for Specific Liver Diseases

Patients who present with a picture of acute or chronic parenchymal liver disease are most likely to fall into one of three categories: viral or toxic hepatitis, including alcoholic liver disease; autoimmune liver disease; or an inherited or acquired metabolic disorder (Chapter 146). Specific tests for viral antigens, nucleic acids, and antibodies are available for the conventional hepatitis viruses, including A, B, C, D (delta), and E, chronic forms of which are being increasingly seen in immunosuppressed patients (Chapters 148 and 149), as well as Epstein-Barr virus (Chapter 377), cytomegalovirus (Chapter 376), and herpesviruses (Chapters 374 and 375), which are well-established but less common causes of liver disease. The major autoimmune diseases of the liver include primary biliary cirrhosis (Chapter 155), autoimmune hepatitis (Chapter 149), primary sclerosing cholangitis (Chapter 155), and various overlap syndromes. The starting point for establishing a specific diagnosis within this category is the search for specific autoantibodies in serum, including antimitochondrial antibodies against epitopes of the pyruvate dehydrogenase complex, which are virtually diagnostic of primary biliary cirrhosis (Chapter 155), and antinuclear, anti–smooth muscle, and anti–liver/kidney microsomal antibodies, which suggest a diagnosis of one of the subtypes of autoimmune hepatitis (Chapter 149). The most prevalent of the hereditary metabolic disorders affecting the liver include hemochromatosis, α_1-antitrypsin deficiency, and Wilson disease (Chapter 211). Nonalcoholic fatty liver disease is the most frequent acquired metabolic liver disease. The disorder is not associated with any known serologic markers, although nonspecific elevations in antinuclear antibody may be present (Chapter 152).

Liver Biopsy

Liver biopsy can be of great help in the diagnosis of diffuse or localized parenchymal diseases, including chronic hepatitis, cirrhosis, and primary or metastatic malignancy in the liver. The value of liver biopsy in acute hepatitis or acute cholestatic jaundice may be primarily prognostic because the histologic changes in these settings may be nonspecific. However, drug-induced liver injury due to certain specific agents (Chapter 150) may display diagnostic features. Liver biopsy for assessment of diffuse disease can be performed percutaneously after localization of the liver by physical examination or ultrasonographic visualization. When specific lesions, such as tumors, must be sampled, the biopsy can be guided by ultrasonographic or radiographic imaging or performed under direct visualization during laparoscopy. Relative or absolute contraindications include coagulopathy, high-grade biliary obstruction, biliary sepsis, ascites, and right pleural disease. Although liver biopsy remains the standard for assessment of hepatic histology in diffuse disease (Chapter 146), the procedure's invasiveness and concern for sampling error have generated interest in noninvasive measures of hepatic fibrosis. These noninvasive studies fall into two categories. One category uses magnetic resonance imaging or ultrasound to measure liver stiffness as a surrogate for fibrosis. The second category comprises panels of biomarkers accessible by blood testing to predict the severity of necroinflammation and fibrosis. These serologic panels typically include standard laboratory measures of hepatic injury (GGT, total bilirubin) and other serum markers (e.g. haptoglobin, hyaluronic acid, apolipoprotein A1). However, the ability of currently available noninvasive markers to assess the extent of hepatic fibrosis reliably across the clinically relevant histologic spectrum, especially in an individual patient, remains to be established.[15]

APPROACH TO THE PATIENT WITH JAUNDICE OR ABNORMAL LIVER TESTS

History, Physical Examination, and Initial Laboratory Studies

Patients with liver disease may present with jaundice or with other signs or symptoms, or the disease may be detected in the asymptomatic patient by the finding of abnormal liver tests during a routine evaluation. Regardless of how the patient comes to medical attention, the diagnostic approach (see Fig. 147-2) begins with a careful history and physical examination (Chapter 146) and screening laboratory studies (complete blood cell count, measurement of plasma bilirubin concentration, assay of ALT, AST, and alkaline phosphatase levels, and PT) to formulate an initial differential diagnosis.[16] The ability to distinguish expeditiously between liver disease and extrahepatic biliary tract obstruction is the major goal of the initial evaluation, in part because the latter may call for prompt surgical intervention. Appropriate selection of second-level laboratory tests and imaging studies leads to a definitive diagnosis in most patients. Care in selecting tests, particularly imaging studies, can both maximize the likelihood of making a correct diagnosis and protect the patient from unnecessary discomfort, risk, and expense.

If the patient is asymptomatic and hepatic tests other than bilirubin are normal, hemolysis or an isolated disorder of bilirubin metabolism should be considered. If signs, symptoms, or laboratory abnormalities indicate hepatobiliary disease, certain patterns of findings help to distinguish intrinsic liver disease from biliary obstruction (Table 147-3). Pain in the right upper quadrant accompanied by a predominant increase in serum alkaline phosphatase activity suggests biliary obstruction (Chapter 155), as does a history of biliary surgery, right upper quadrant scars, or an abdominal mass. Fever and rigors, indicative of cholangitis, strengthen this conclusion. The incidences of gallstone disease and malignant neoplasm increase with age, although risk factors such as obesity or recent extensive diet-induced weight loss increase the risk for gallstones. Other risk factors (e.g., hepatitis exposure, transfusions, intravenous drug use, alcohol use, certain medications, obesity, and family history of genetic diseases) and a predominant elevation in serum aminotransferase levels favor a diagnosis of parenchymal liver disease. Physical evidence of cirrhosis (e.g., spider angiomas, gynecomastia, ascites, splenomegaly) supports the diagnosis of chronic parenchymal disease.

Despite the general validity of these patterns, many exceptions exist. In particular, parenchymal disorders with prominent cholestasis may mimic biliary obstruction. Both alkaline phosphatase and GGT are usually elevated in patients with cholestasis; the combination of an elevated alkaline phosphatase and normal GGT suggests that the alkaline phosphatase is from bone. Conversely, an isolated elevation of GGT may result from certain drugs (e.g., diphenylhydantoin) or alcohol consumption even in the absence of liver disease. Because of the risk for life-threatening infection in the setting of unrelieved biliary tract obstruction, this possibility must always be considered and excluded if an alternative diagnosis is not definitely established.

TABLE 147-3 OBSTRUCTIVE JAUNDICE VERSUS CHOLESTATIC LIVER DISEASE

FEATURE	SUGGESTS OBSTRUCTIVE JAUNDICE	SUGGESTS PARENCHYMAL LIVER DISEASE
History	Abdominal pain Fever, rigors Prior biliary surgery Acholic stools	Anorexia, malaise, myalgias, suggestive of viral prodrome Known infectious exposure Use of injection drugs or intranasal cocaine Exposure to known hepatotoxin Family history of jaundice
Physical examination	High fever Abdominal tenderness Palpable abdominal mass Abdominal scar	Ascites Other stigmata of liver disease (e.g., prominent abdominal veins, gynecomastia, spider angiomata, asterixis, encephalopathy, Kayser-Fleischer rings)
Laboratory studies	Predominant elevation of serum bilirubin and alkaline phosphatase Prothrombin time that is normal or normalizes with vitamin K administration Elevated serum amylase	Predominant elevation of serum aminotransferases Prolonged prothrombin time that does not correct with vitamin K administration Blood tests indicative of specific liver disease

Imaging Studies

If extrahepatic obstruction is suspected, its site and nature can now be determined in virtually all patients (see Fig. 147-2). A reasonable initial step is the use of a noninvasive imaging study (Chapter 133) such as ultrasonography or magnetic resonance cholangiopancreatography to determine whether the intrahepatic, extrahepatic biliary system, or both are dilated, implying mechanical obstruction. Because of its lesser expense, portability, and convenience, ultrasound is often the procedure of choice, especially if gallstones are suspected. Magnetic resonance cholangiopancreatography may provide more precise resolution, including stricturing of intrahepatic ducts characteristic of primary sclerosing cholangitis. However, each of these techniques can fail to identify dilated ducts, particularly in patients with cirrhosis. Conversely, a modest degree of ductal dilatation is common in a patient with a previous cholecystectomy and does not necessarily signify current obstruction. If dilated ducts are found, the biliary tree should be examined by endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) (Chapter 134). ERCP involves positioning an endoscope in the duodenum, inserting a catheter through the ampulla of Vater, and injecting contrast medium into the distal common bile duct, pancreatic duct, or both. PTC involves percutaneous passage of a needle through the hepatic parenchyma into a peripheral bile duct, followed by injection of contrast medium into the biliary tree through the peripheral duct. The choice of procedure is based on the suspected site of obstruction (proximal vs. distal); the presence of coagulopathy; a history of abdominal surgery that might complicate PTC or ERCP; the likely need for a therapeutic procedure (e.g., stent placement or endoscopic sphincterotomy); and the skills of available staff. Endoscopic ultrasound (EUS) is a complementary approach that permits internal ultrasonographic analysis of the pancreas, extrahepatic bile ducts, and regional lymph nodes and blood vessels. EUS combined with fine needle aspiration permits tissue sampling of abnormalities in areas such as the bile ducts and pancreas that typically have been difficult to sample percutaneously.

Selection of Imaging Tests

Liver ultrasound is an ideal screening test to evaluate the liver architecture, assess for surface nodularity and parenchymal mass lesions, and exclude biliary obstruction. Ultrasound is relatively inexpensive in comparison to other imaging modalities, is widely available, and avoids ionizing radiation. The identification of mass lesions on ultrasound will commonly prompt further cross-sectional imaging with either computed tomography or magnetic resonance imaging. If there is evidence of biliary obstruction on imaging or, if obstruction is still considered likely despite imaging findings, direct

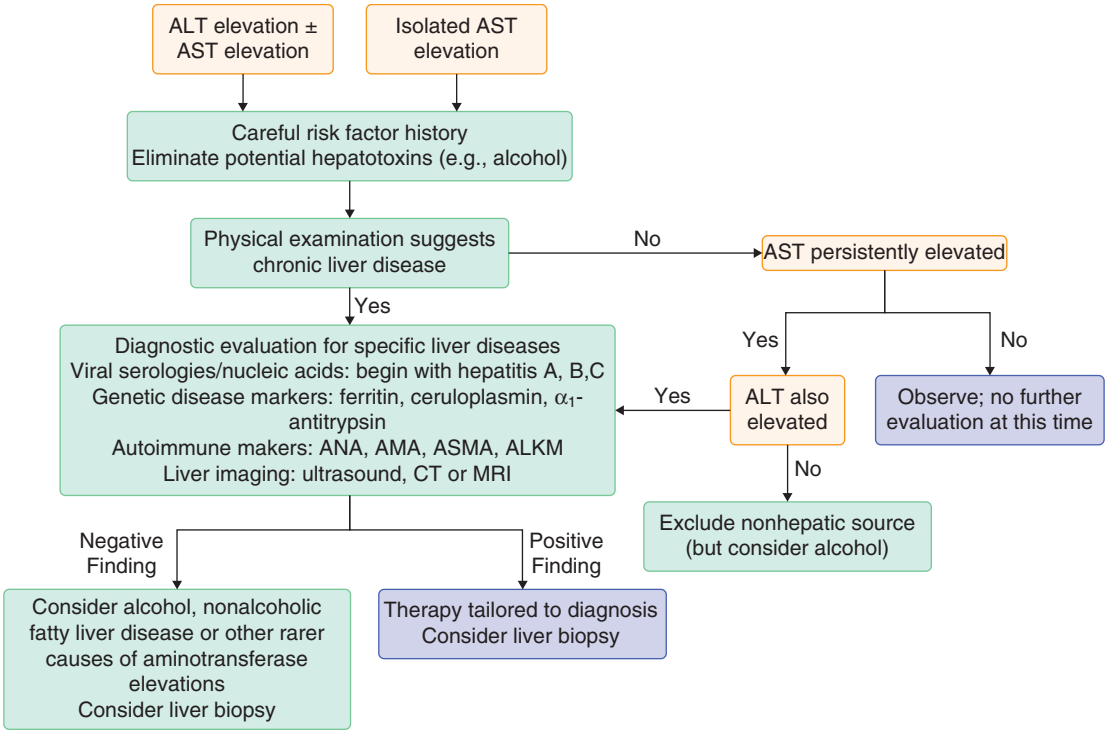

FIGURE 147-3. **Approach to the evaluation of isolated elevated levels of serum alanine aminotransferase (*ALT*), aspartate aminotransferase (*AST*), or both in the asymptomatic patient.** ANA = antinuclear antibody; AMA = antimitochondrial antibody; ASMA = anti–smooth muscle antibody; ALKM = anti–liver/kidney microsomal antibody; CT = computed tomography; MRI = magnetic resonance imaging.

cholangiography by ERCP or PTC, which offer therapeutic as well as diagnostic capabilities, may be an appropriate choice. If obstruction is considered possible but not highly likely, noninvasive imaging with MRCP is a reasonable study. Individual radiology suites have different levels of expertise for these procedures, and the local radiology staff may be quite helpful in recommending the best procedure for a given patient.

The apparently healthy patient with an isolated abnormality of the aminotransferase or alkaline phosphatase levels requires careful evaluation to identify any underlying disease while avoiding unneeded testing. Often, no significant disease is found despite extensive evaluation. Common causes of abnormal enzyme tests include alcohol consumption, hepatitis C infection, nonalcoholic fatty liver disease, bone disease, and muscle injury.

Asymptomatic Aminotransferase Elevation

Epidemiologic data suggest that up to 25% of asymptomatic adult Americans have a mild to moderate elevation of aminotransferase levels. The incidental discovery of such abnormalities is currently the most frequent means by which liver disease is first recognized. Whereas up to one third of such patients have no elevation on subsequent testing, many others prove to have steatohepatitis (Chapter 152) or chronic hepatitis C (Chapter 149). Further evaluation is generally indicated only in patients with persistent abnormalities (Fig. 147-3). Initial screening should include a careful history of exposure to hepatotoxins (alcohol, prescription drugs, over-the-counter medications, herbs, chemicals, and occupational exposures). If the abnormal test was an AST, a hepatic origin for the enzyme elevation should be confirmed with an ALT determination. If the ALT is normal, a muscle source is likely or the elevation may reflect the presence of a macroenzyme. If the ALT level is abnormal, the patient should be screened serologically for hepatitis B, C, and (at least in immunosuppressed patients) E; markers of autoimmune liver disease; and serologic markers of inherited metabolic disorders (Chapter 146). AST abnormalities caused by alcohol-induced injury should become normal with several weeks of abstinence. If the abnormalities persist for 6 to 12 months without an apparent cause, liver biopsy should be considered.

Asymptomatic Alkaline Phosphatase Elevation

Many patients with isolated elevation of the alkaline phosphatase level have nonhepatic causes, such as pregnancy or bone disease. The origin of an elevated alkaline phosphatase should be confirmed with a fasting sample because intestinal alkaline phosphatase may be elevated after a meal (Fig. 147-4).

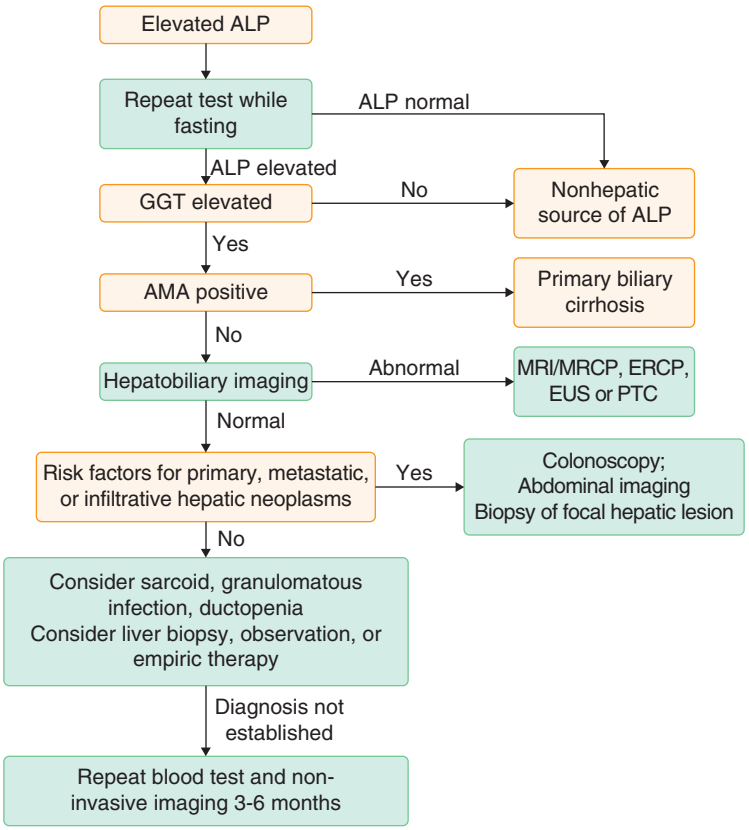

FIGURE 147-4. **Approach to the asymptomatic patient with isolated elevated levels of serum alkaline phosphatase (*ALP*).** In cases with a high index of suspicion of biliary tract disease (e.g., sclerosing cholangitis), cholangiography may be warranted even in the face of normal ultrasound imaging. AMA = antimitochondrial antibody; CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; GGT = γ-glutamyl transpeptidase; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; PTC = percutaneous transhepatic cholangiogram; US = ultrasonography.

A hepatic source is highly likely if the serum GGT is also abnormal. Serologic studies should include an antimitochondrial antibody test; a positive result suggests primary biliary cirrhosis (Chapter 155). A careful history identifies patients at risk for intrahepatic cholestasis related to drugs or toxins. Essentially all other patients with persistently abnormal alkaline phosphatase should receive a hepatobiliary sonogram or other noninvasive imaging test. Demonstration of dilated intrahepatic or extrahepatic bile ducts should prompt direct visualization of the biliary tract by ERCP or PTC (Chapters 134 and 155). Evidence of an intrahepatic mass should prompt thorough evaluation for possible malignancy (Chapters 155 and 196). Because colon cancer often metastasizes to liver, colonoscopy may be useful in appropriate cases (Chapter 193). Infiltrative diseases, including amyloidosis and granulomatous hepatitis (Chapter 151), should be considered. In the absence of evidence of biliary obstruction or a cause identifiable by noninvasive means, liver biopsy should be strongly considered to complete the evaluation of cholestatic liver test abnormalities.

REVIEW QUESTIONS

1. A 51-year-old man presents with 3 months of painless jaundice, pale stools, and dark urine, as well as spiking fevers. His Hgb is 10.2 g/dL; WBC 6500/μL with 64% PMNs; and platelets 145,000. Total bilirubin is 28 mg/dL; direct-reacting bilirubin 21 mg/dL; alkaline phosphatase 336, AST 94, ALT 116, albumin 3.1, PT INR 1.8. Urine urobilinogen is undetectable, and urine bilirubin is ++++. Abdominal ultrasound shows proximal dilatation of the intrahepatic bile ducts, and magnetic resonance cholangiopancreatography reveals a constricting mass in the common bile duct several centimeters distal to the junction of the right and left hepatic ducts. After being started on intravenous broad-spectrum antibiotics, the patient is taken to surgery, where the mass is resected and the common bile duct is anastomosed over a stent. Two weeks later his total bilirubin is 14 mg/dL, direct-reacting bilirubin 10 mg/dL, alkaline phosphatase 225, and urine urobilinogen still undetectable. Urine bilirubin is also undetectable. Because of the persistent direct-reacting hyperbilirubinemia and elevated alkaline phosphatase, the surgeon is considering taking the patient back to the operating room and re-exploring his biliary tract. Which of the following test results argues *against* that decision?

A. Total bilirubin
B. Direct-reacting bilirubin
C. Alkaline phosphatase
D. Urine urobilinogen
E. Urine bilirubin

Answer: E After successful relief of chronic bile duct obstruction, both the total bilirubin and the alkaline phosphatase may take several weeks to normalize. The combination of elevated direct-reacting bilirubin in plasma and an absence of bilirubin from the urine indicates that the direct-reacting fraction in plasma now consists of δ-bilirubin, a covalent complex of conjugated bilirubin with albumin, that is not cleared by the kidney. Although the absence of urobilinogen from the urine at the time of admission reflected complete bile duct obstruction, its persistence after 2 weeks of broad-spectrum antibiotic therapy no longer reflects biliary obstruction, but rather elimination by the antibiotics of the bacteria necessary to convert bilirubin in the gut to urobilinogen. In this case, use of a dipstick that detects bilirubinuria could save the patient from an unnecessary second surgical procedure.

2. A 24-year-old nurse presented to the employee health department of her hospital complaining of arthralgias, weakness, and fatigue for 2 weeks. She had previously been in good health and had a normal physical examination, CBC, and metabolic panel, including serum bilirubin determination, at her annual physical examination 2 months earlier. Her family history included relatives with rheumatoid arthritis and lupus erythematosus. On physical examination she was pale, with faintly icteric sclerae and a palpable spleen tip. Her Hgb was 7.6, Hct 23%, reticulocytes 14%, plasma total bilirubin 2.1 mg/dL, direct-reacting bilirubin 0.2 mg/dL, and indirect bilirubin 1.9 mg/dL. A lupus erythematosus preparation was negative, but because a direct Coombs test was strongly positive, the diagnosis of autoimmune hemolytic anemia was made. She consented to participate in a research study and was found to have a normal hepatic bilirubin clearance (C_{BR}) of 0.53 mL/min/kg (normal range: 0.65 ± 0.18 [SE]), a plasma bilirubin turnover of 14.4 mg/kg/day (normal: 3.9 ± 0.7), a circulating red blood cell mass of 15.3 mL/kg (normal: 25-35), and a calculated mean red blood cell lifespan of 16 days (normal in females: 94 ± 10 days). She was begun on prednisone, 60 mg/day. One week later her Hgb was 7.9 mg/dL, Hct 24%, reticulocytes 12.3%, and red blood cell mass 16.0 mL/kg. Her hepatic bilirubin clearance (C_{BR}) was 0.56 mL/min/kg, her plasma unconjugated bilirubin concentration was 0.5 mg/dL, and her calculated mean red blood cell lifespan was 62 days. There was a disagreement among the consultants on her case. Based on her persistent anemia and reticulocytosis, a rheumatologist argued that the current therapy was ineffective and urged increasing her prednisone dose to 80 mg/day. The hematologist said that she was essentially cured and urged continuation of the current treatment with follow-up in 2 weeks. When the patient returned in 2 weeks, her data fully confirmed the hematologist's prediction. Her Hgb was 12.0 g/dL, Hct 36%, reticulocytes 2.8%, and red blood cell mass 24.0 mL/kg. Plasma unconjugated bilirubin was 0.6 mg/dL. Which of the following test results led the hematologist to that correct conclusion?

A. The Hgb
B. The Hct
C. The reticulocyte count
D. The C_{BR}
E. The plasma unconjugated bilirubin concentration

Answer: E Hepatic bilirubin clearance (C_{BR}), plasma bilirubin turnover (BRT), and plasma unconjugated bilirubin concentration (BR) are related by the formula: $BR \approx BRT / C_{BR}$. In the present case, the plasma unconjugated bilirubin concentration fell by 76% during the first week of prednisone therapy, whereas C_{BR} was virtually unchanged. These data meant that the fall in plasma bilirubin concentration must have resulted from a decrease in plasma bilirubin turnover, which, in fact, also declined by 75%. Because the major source of bilirubin is the dying red blood cell, the conclusion is that RBC death must have declined by approximately the same 75%, precisely accounting for the nearly four-fold increase in calculated red blood cell lifespan. Thus, the fall in bilirubin concentration accurately reflected the beneficial effects of steroids on red blood cell survival in this patient with autoimmune hemolysis. By contrast, the continued reticulocytosis during the first week of prednisone treatment reflected the bone marrow's attempt to heal the ongoing anemia, not to the hemolytic process per se.

3. A 36-year-old man with a history of injection drug use is discovered to have hepatitis C and HIV coinfection during a medical screening examination. He has no signs or symptoms of chronic liver disease or portal hypertension, nor is there a history of AIDS-defining illnesses. Laboratory studies reveal albumin 4.2 mg/dL, AST 76 IU/mL, ALT 113 IU/mL, total bilirubin 0.6 mg/dL, and CD4 cells 450 cells/μL. Both HCV RNA and HIV RNA are detectable by PCR assays. Antiretroviral therapy is initiated with a combination of medications that include atazanavir. Evaluation following the start of antiretroviral therapy discloses mild scleral icterus. Laboratory results obtained following the start of treatment revealed albumin 4.0 mg/dL, AST 81 IU/mL, ALT 145 IU/mL, total bilirubin 2.4 mg/dL, direct bilirubin 0.3 mg/dL and haptoglobin 150 mg/dL. Which of the following is the most appropriate next step with regard to the jaundice?

A. Observation
B. Liver ultrasonography
C. Discontinuation of atazanavir
D. Liver biopsy
E. Magnetic resonance cholangiopacreatography

Answer: A Rates of HIV-HCV coinfection vary widely in populations but are highest in individuals with a history of injection drug use. The development of a mild indirect hyperbilirubinemia in the absence of evidence of hemolysis is strong evidence of Gilbert syndrome. Certain medications, including the antiretroviral protease inhibitor atazanavir, are inhibitors of UGT1A1 and also result in a mild, indirect hyperbilirubinemia similar to that seen in Gilbert syndrome. Atazanavir-associated hyperbilirubinemia may be more pronounced in individuals with Gilbert syndrome or with baseline hyperbilirubinemia from underlying liver disease. Although liver injury can occur with antiretroviral medications, there is no such factor in this case. Instead, the pattern is consistent with an acquired indirect hyperbilirubinemia related to atazanavir. No further diagnostic evaluation is warranted.

4. A 22-year-old woman is referred to your care for the evaluation of jaundice. She gives a history of episodic jaundice that is most pronounced around times of illness. On physical examination, she is well developed and healthy appearing. Scleral icterus is noted. The abdomen is soft, and there is neither shifting dullness nor organomegaly. Laboratory studies reveal hemoglobin 13 g/dL, platelets 225,000, alkaline phosphatase 95 IU/mL, AST 13 IU/mL, ALT 20 IU/mL, albumin 4.1 mg/dL, total bilirubin 2.4 mg/dL, direct bilirubin 1.5 mg/dL. Liver ultrasonography reveals cholelithiasis without gallbladder wall thickening. Which of the following is the next most appropriate diagnostic step?

A. Cholecystectomy with intraoperative cholangiography
B. Liver biopsy
C. Mutation analysis of the ABC transporter *ATP8B1*
D. Laboratory testing for antimitochondrial antibodies
E. Measurement of urinary coproporphyrin isomers

Answer: E Heritable disorders of bilirubin metabolism should be considered in the setting of a mixed or predominately direct hyperbilirubinemia in the absence of evidence of cholestasis. Dubin-Johnson syndrome is an autosomal recessive disorder arising from mutations in the ATP-dependent canalicular organic anion transporter MPR2/cMOAT. The diagnosis of Dubin-Johnson syndrome can be established by the measurement of urinary coproporphyrin isomers; the coproporphyrin isomer 1 is generally greater than 80% of total coproporphyrin concentration. Although liver biopsy is not required nor necessary for the diagnosis, the liver in Dubin-Johnson is described as containing a dark pigment comprising polymerized epinephrine metabolites.

5. A 34-year-old Hispanic woman presents for the preoperative evaluation for cholecystectomy. For the past 3 months, she has experienced episodic, colicky, right upper quadrant pain. On examination, she is obese (BMI 35 kg/m^2). She has no signs or symptoms of liver disease or portal hypertension. Laboratory evaluation reveals: ALT 44 IU/mL, AST 42 IU/mL, total bilirubin, alkaline phosphatase, and γ-glutamyl transpeptidase (GGT) are within the laboratory's reference range. Tests for chronic viral hepatitis, common genetic causes of chronic liver disease, and autoimmune liver disease are all negative. Her ferritin level is 400 ng/mL, and her transferrin saturation 27%. Liver ultrasonography reveals increased echogenicity of the liver and cholelithiasis without thickening of the gallbladder wall. In addition to cholecystectomy, which of the following options should be recommended?

A. *Hfe* genotype
B. Serologic studies for celiac disease
C. Nucleic acid testing for viral hepatitis
D. Intraoperative liver biopsy during cholecystectomy
E. Treatment with vitamin E (d-α) 800 IU daily.

Answer: D Liver diseases are commonly associated with aminotransferase elevations 2 or greater times the upper limits of the reference range. In some individuals, however, ALT levels at or within the upper limits of the reference range may be observed with nonalcoholic fatty liver disease (NAFLD). Thus, in patients at risk for NAFLD, it is imperative that aminotransferases be interpreted in the context of the patient's history, physical examination, and other laboratory findings. The presence of obesity and modest elevations in the ferritin level (without an increase in transferrin saturation) are commonly seen in subjects with NAFLD. Although the ferritin level is elevated, the transferrin saturation is not, so hereditary hemochromatosis is unlikely. Intraoperative liver biopsy is a safe and effective tool for diagnosing NAFLD and assessing the extent of fibrosis.

148 ACUTE VIRAL HEPATITIS

JEAN-MICHEL PAWLOTSKY

Infection with a hepatotropic virus causes an acute episode of liver inflammation, referred to as *acute hepatitis,* which can lead to either spontaneous clearance of the infectious agent or its persistence, which in turn leads to chronic infection for a subset of these viruses. Five hepatitis viruses are responsible for the vast majority of acute hepatitis cases (Table 148-1): hepatitis A virus (HAV); hepatitis B virus (HBV); hepatitis C virus (HCV); hepatitis D, or delta, virus (HDV), which is a defective viroid using the hepatitis B surface antigen (HBsAg) as its envelope; and hepatitis E virus (HEV).[1] Other viruses may cause acute inflammatory liver disease, including members of the Herpesviridae family such as human cytomegalovirus, Epstein-Barr virus, or herpes simplex virus. It is unclear to what extent other viruses, such as parvovirus B19 or human herpesvirus 6, can also cause acute hepatitis. Patients who present with an acute viral hepatitis syndrome but negative virologic tests are referred to as having non-A-to-E hepatitis, perhaps attributable to hepatotropic viruses that have yet to be identified. The worldwide incidence of acute viral hepatitis is decreasing because of global improvement in hygiene and the development and use of efficient vaccines against HAV and HBV, and perhaps in the future, HEV.

TABLE 148-1 VIRUSES RESPONSIBLE FOR ACUTE VIRAL HEPATITIS AND LIKELIHOOD OF CHRONIC EVOLUTION

VIRUS	EVOLUTION TO CHRONIC VIRAL HEPATITIS
Hepatitis A	Never
Hepatitis B	>90% (perinatal acquisition) to < 1% (adult infection)
Hepatitis C	50-80%
Hepatitis D or delta	2% (coinfection) to 90% (superinfection)
Hepatitis E	Occasionally in immunosuppressed patients
Other viruses Human cytomegalovirus Epstein-Barr Herpes simplex Human herpesvirus 6 Parvovirus B_{19}	May establish chronic infection, not associated with chronic hepatitis

GENERAL FEATURES OF ACUTE VIRAL HEPATITIS

PATHOBIOLOGY

Acute viral hepatitis is characterized by acute necroinflammation of the liver. Because none of the hepatotropic viruses is cytopathic, liver injury is mediated by a strong cytotoxic T cell–mediated reaction against infected hepatocytes that express viral antigens at their surface. Proinflammatory cytokines, natural killer cells, and antibody-dependent cellular cytotoxicity also appear to play a role in liver necroinflammation. Successful immune elimination may lead to viral clearance, which may or may not be associated with lifelong immunity, depending on the infecting agent. The immune reaction is sometimes so potent that the patient develops subfulminant or even fulminant hepatitis that requires liver transplantation (Chapter 154). In some patients—the proportion varies, according to the virus responsible for acute hepatitis—the immune response fails and chronic infection is established (Chapter 149).

CLINICAL MANIFESTATIONS

After infection, there is an incubation period of a few days to a few weeks, depending on the causative agent (Fig. 148-1). This incubation period is generally characterized by nonspecific symptoms, including fatigue, nausea, loss of appetite, flulike symptoms, and/or right upper quadrant pain (Table 148-2). The incubation period is often characterized by leukopenia and relative lymphocytosis. Immune-mediated symptoms, including rash, hives, arthralgias, angioneurotic edema, and fever, are observed in 10 to 20% of patients during the preicteric phase.

During the acute stage of the disease, symptoms may vary widely, from asymptomatic to subicteric, icteric or severe, and fulminant. The icteric form, which is not frequent, is characterized by fatigue, anorexia, nausea, dysgeusia, jaundice, dark urine, light-colored stool, and weight loss. Physical examination reveals jaundice and hepatic tenderness. Hepatomegaly and splenomegaly may be present. On laboratory testing, acute viral hepatitis is characterized by elevated total and direct serum bilirubin levels and aminotransferase levels that are often greater than 10 times the upper limit of normal. Cholestatic acute hepatitis is associated frequently with prolonged and fluctuating jaundice and pruritus. After 1 to 3 weeks, on average, both clinical and laboratory signs progressively improve and return to normal. Some patients, however, may experience a relapse before definitive resolution.

Signs of hepatic failure (Chapter 154), including changes in personality, aggressive behavior, sleeping disorders, and hepatic encephalopathy

TABLE 148-2 CLINICAL MANIFESTATIONS OF VIRAL HEPATITIS

PHASES OF INFECTION	DURATION*	MANIFESTATIONS*
Incubation	2-20 wk	Virus detectable in blood Aminotransferase and bilirubin levels normal No antibody detectable
Preicteric	3-10 days	Nonspecific symptoms: fatigue, anorexia, nausea, vague right upper quadrant pain Viral titers peak Aminotransferase levels begin to rise Serum sickness–like reaction (≈10-20% of cases) with rash, hives, arthralgias, fever
Icteric	1-3 wk	Jaundice appears; dark urine and light stools seen Nonspecific symptoms worsen Weight loss, dysgeusia, pruritus may occur Hepatosplenomegaly may develop Aminotransferase levels typically >10 times normal Antibodies appear Viral titers decline Rare extrahepatic manifestations (aseptic meningitis, encephalitis, seizures, ascending flaccid paralysis, nephrotic syndrome, seronegative arthritis)
Recovery	Up to 6 mo	Symptoms resolve gradually Antibody levels rise Aminotransferase and bilirubin levels normalize
Chronic	After 6 mo	See Chapter 149

*Varies by virus.

TABLE 148-3 LABORATORY TESTING FOR SUSPECTED ACUTE VIRAL HEPATITIS

GENERAL EVALUATION
Alanine aminotransferase Aspartate aminotransferase Alkaline phosphatase International normalized ratio (INR)
FIRST-LINE DIAGNOSTIC TESTS
Anti-HAV IgM HBsAg, anti-HBc IgM Anti-HCV antibodies HCV RNA
SECOND-LINE DIAGNOSTIC TESTS
Anti-HAV IgM present: none HBsAg present: HBeAg, anti-HBe antibodies, HBV DNA, HDV antigen, anti-HDV antibodies HCV RNA present with or without anti-HCV antibodies: none No virologic marker: See Fig. 147-3

HAV = hepatitis A virus; HBc = hepatitis B core; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HDV = hepatitis D virus; IgM = immunoglobulin M.

characterize fulminant forms of acute viral hepatitis. Coma can supervene rapidly, and widespread hemorrhage may develop.

DIAGNOSIS

The diagnosis of acute hepatitis is suspected based on elevated serum aminotransferase levels, which are generally more than 10 times the upper limit of normal (Table 148-3). Total and direct bilirubin levels are elevated if the acute hepatitis is subicteric or icteric. Alkaline phosphatase levels may be elevated in cases of cholestatic hepatitis.

Serologic and eventually molecular testing identifies the causal agent. Liver biopsy or a noninvasive assessment of liver inflammation and fibrosis are generally not required. All cases of acute hepatitis should be reported to the local, state, or national health department as soon as possible after diagnosis.

TREATMENT Rx

In addition to virus-specific therapy for HCV and hopefully in the future for HBV, patients with acute viral hepatitis should avoid alcohol consumption and acetaminophen. Sexual contact should be avoided if the partner is not protected. Patients with subfulminant or fulminant hepatitis should be evaluated for possible liver transplantation and supported in an intensive care unit setting (Chapter 154).

PROGNOSIS

Prognosis depends on the degree of prolongation of the prothrombin time, as well as the degree of elevation of the bilirubin and lactate levels. A factor V level less than 40% or any signs of encephalopathy are indications for hospitalization. Death is extremely rare and occurs only in fulminant cases. Other signs of poor prognosis are persistently worsening jaundice, ascites, and an acute decrease in the size of the liver. Serum aminotransferase levels and viral genome levels have no prognostic value.

HEPATITIS A

DEFINITION

The Pathogen

HAV is a member of the Picornaviridae family, genus *Hepatovirus*. The hepatitis A viral particle is a 27-nm nonenveloped icosahedral nucleocapsid that expresses the hepatitis A antigen and contains a positive-stranded RNA genome approximately 7.5 kb long. At least four different HAV genotypes have been described in humans (genotypes I, II, III, and VII), with genotype I predominating worldwide. Other genotypes have been isolated in nonhuman primates. It is currently unclear to what extent different genotypes are associated with distinct clinical courses of infection.

EPIDEMIOLOGY

HAV infection has a worldwide distribution, and infections can be sporadic or occur in epidemic outbreaks. The incidence of acute cases and the seroprevalence vary according to the hygiene, sanitation, housing, and socioeconomic standards of the region, with seroprevalences as low as approximately 13% in Sweden but up to 100% in many developing countries. In developing countries, infection generally occurs at a young age and most of the population has been exposed and is protected after age 10 years. In developed countries, however, infection can occur at any age, and the prevalence of exposed, immune subjects slowly increases with age. In the United States, according to the Centers for Disease Control and Prevention, the incidence of acute hepatitis A declined from 12.0 cases per 100,000 individuals in 1995 to 0.5 cases per 100,000 individuals by 2012.

HAV is generally transmitted via the oral-fecal route, most often directly from person to person or through the ingestion of fecally contaminated food or water. Transmission by blood transfusion has been reported, and isolated cases of apparent perinatal transmission have been described. High-risk groups for acute hepatitis A include travelers to developing countries, children in daycare centers and their parents, men who have sex with men, injection drug users, hemophiliacs who receive plasma products, and persons in institutions.

PATHOBIOLOGY

The genome serves as a messenger RNA and contains a single open reading frame that encodes both structural and nonstructural viral proteins. After attachment to a specific receptor at the surface of hepatocytes, the virus penetrates into cells and is uncoated. Subsequent events occurring exclusively in the cytoplasm include translation of the single open reading frame into a polyprotein that is later processed to generate the mature viral proteins; replication in a membrane-bound replication complex that generates new viral genomes, which are subsequently used for viral protein production and viral particle assembly; and packaging of newly formed genomes into new particles that are exported out of the cells. The virus is secreted into bile and, to a lesser extent, serum.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 15 to 45 days (see Table 148-2). In most cases, acute infection takes a mild and often unrecognized course. The incidence of symptomatic, icteric cases increases with the age at infection. Acute hepatitis A in adults may require hospitalization in up to 13% of cases[2]; prolonged courses of 6 to 9 months have been reported in 10% of adult patients with a diagnosis of acute hepatitis A. Hepatitis A is the most common cause of relapsing cholestatic hepatitis.

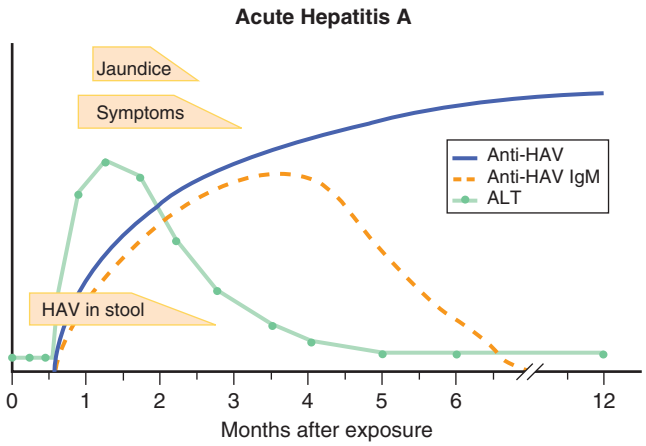

FIGURE 148-2. Serologic course of acute hepatitis A. ALT = alanine aminotransferase; HAV = hepatitis A virus; IgM = immunoglobulin M.

DIAGNOSIS

The diagnosis of acute hepatitis A is based on the detection of anti-HAV immunoglobulin M (IgM) in serum by enzyme immunoassay. IgM serum levels peak during the second month of infection (Fig. 148-2). HAV RNA can be transiently detected in stool and other body fluids by polymerase chain reaction (PCR) 3 to 10 days before the onset of illness and for 1 to 2 weeks thereafter; however, HAV RNA testing is generally not necessary. When the infection resolves, anti-HAV IgM disappears after 4 to 12 months, but anti-HAV IgG persists for life and confers definitive and durable protection against infection.

TREATMENT

Rx

Because HAV infection is self-limited, no specific antiviral treatment is required. In severe cases, patients may need to be hospitalized. If liver function is deteriorating, patients may need to be assessed for liver transplantation, which is the only therapeutic option for acute liver failure (Chapter 154).

PREVENTION

HAV vaccines (Chapter 18) consist of inactivated hepatitis A antigen purified from cell culture. Two doses of the vaccine are recommended at a 6- to 18-month interval. All vaccines are highly immunogenic, and virtually all healthy persons who are vaccinated develop protective anti-HAV antibodies. Patients with chronic liver disease also respond to vaccination but may display lower anti-HAV titers. An accelerated vaccine schedule, with vaccination on days 0, 7, and 21, is also effective and may be recommended for those planning to travel to endemic areas. HAV vaccines are well tolerated, and no serious adverse events have been linked with their administration; they can be safely administered with other vaccines or immunoglobulins without compromising the development of protective antibodies. A combination HAV and HBV vaccine is also available. Seroconversion rates are lower in patients with human immunodeficiency virus (HIV) infection and in other immunocompromised individuals.

HAV vaccination is recommended for nonimmune individuals who plan to travel to endemic countries, medical health professionals, men who have sex with men, persons who are in contact with hepatitis A patients, and individuals with chronic liver diseases. A childhood vaccination program leads to a significant decline in HAV infection, justifying its use as part of control efforts in endemic countries. Serologic testing for anti-HAV IgG can be performed before vaccination in adults born in endemic countries and in individuals older than 50 years born in industrialized areas; persons with detectable IgG are protected and should not be vaccinated. For post-exposure prophylaxis, both HAV vaccination and immunoglobulin are effective. Immunoglobulin confers a slightly lower rate of protection than vaccine,■ and HAV vaccine and immunoglobulin should be used together in this setting.

Long-term follow-up studies after complete HAV vaccination show that anti-HAV titers sharply decline during the first year after vaccination but remain detectable in almost all individuals for at least 10 years. Protective anti-HAV antibody titers persist for at least 27 years after the successful vaccination of children and young adults.

PROGNOSIS

Acute hepatitis A infection generally resolves without complications in 3 to 4 weeks and never evolves to chronic infection. Prolonged elevation of serum aminotransferase levels has been reported. Relapses a few weeks after the acute case also have been observed. Prolonged courses may occur in children and immunosuppressed individuals.

Cholestatic hepatitis A is unusual and has a good prognosis, with full recovery within a few weeks. Fulminant hepatitis A is rare, occurring in less than 0.1% of cases, but its incidence and mortality increase with the patient's age at acquisition. In the United States, 4% of all cases of fulminant hepatitis are caused by HAV infection. Overall, mortality of acute hepatitis A is 1.8% in patients older than 50 years. In patients with chronic hepatitis B, superinfection with HAV is associated with a 6- to 23-fold higher morbidity and mortality.

ACUTE HEPATITIS B

DEFINITION

The Pathogen

HBV is a member of the Hepadnaviridae family, genus *Hepadnavirus*. The infectious virion, the Dane particle, is 42 to 47 nm in diameter. It possesses an envelope and a capsid or core that contains the partially double-stranded, circular DNA genome. The HBV genome is the smallest known human virus genome, with approximately 3000 nucleotides.

EPIDEMIOLOGY

Two billion individuals worldwide have been in contact with HBV, and more than 350 million individuals have chronic infection. In the United States, approximately 0.5% of the population is chronically infected. HBV virions are produced and circulate in very high amounts in HBV-infected individuals, who are highly contagious. Four principal routes of transmission are responsible for acute HBV infections: (1) sexual transmission, which is the principal route in industrialized areas; (2) perinatal mother-to-infant transmission, which is associated with a very high (>90%) rate of chronic infection and is the principal cause of HBV transmission in Asia; (3) horizontal transmission through nonsexual interindividual contact, which is frequent at a young age in Africa and is associated with evolution to chronicity in approximately 15% of cases; and (4) percutaneous transmission by blood and blood products, unsafe medical or surgical materials, or injection drug use.

In industrialized countries, groups at high risk for HBV infection include individuals born in areas where HBV is endemic, including immigrants and adopted children; individuals who were not vaccinated as infants and whose parents were born in regions where HBV is endemic; household and sexual contacts of HBsAg-positive individuals; persons who have ever injected drugs; persons with multiple sexual partners or a history of sexually transmitted disease; men who have sex with men; inmates of correctional facilities; patients infected with HCV or HIV; patients undergoing renal dialysis; recipients of blood or blood products before 1987; and health care workers.

PATHOBIOLOGY

The HBV genome contains at least four overlapping open reading frames that encode a number of structural and nonstructural viral proteins. The pre-S/S gene encodes the three surface proteins—small (S), middle (M), and large (L)—that express HBsAg. The pre-C/C gene encodes the core protein that expresses the hepatitis B core (HBc) antigen and the hepatitis B e (HBe) protein, a nonstructural protein that plays a role in immune tolerance to HBV replication. The P gene encodes the HBV polymerase, whose two motifs—a reverse transcriptase motif and an RNAse H motif—code for two enzymes involved in HBV replication. Finally, the X gene encodes the X protein, which is a transactivator involved in HBV replication that bears oncogenic properties. The blood of infected patients contains not only infectious viruses but also a large excess of empty, noninfectious HBV envelopes.

The complex HBV life cycle involves multiple steps: fixation to an as yet unidentified receptor complex at the surface of hepatocytes; internalization; fusion and release of the nucleocapsid containing the HBV DNA genome and the associated HBV polymerase molecule in the cell cytoplasm; transport into the nucleus, where decapsidation occurs and the DNA genome molecule is released; transformation of the viral genome by the viral polymerase into a covalently closed circular DNA, which is the episomal form

responsible for persistence of the HBV genome in the nucleus of infected hepatocytes; generation of messenger RNAs and viral protein synthesis; generation of a pregenomic RNA, which serves as a template for reverse transcription that generates the long DNA strand; degradation of the pregenomic RNA by the RNAse H activity of the viral polymerase; DNA-dependent DNA polymerase activity of the reverse transcriptase motif, which synthesizes the short complementary DNA strand in newly formed nucleocapsids; and, finally, budding into the endoplasmic reticulum, maturation, and export of newly formed virions.

Nine HBV genotypes (A through I), which differ by approximately 8% of their genomic nucleotide sequence, have different geographic distributions and may be associated with different clinical outcomes. Genotype A predominates in Northern and Western Europe, whereas genotype D is the most frequent genotype in the Mediterranean area and in Eastern Europe. In non-Asian populations in the United States, genotype A predominates in men who have sex with men, whereas genotype D is the most frequent in intravenous drug users. In Asia and in Asian immigrants living in industrialized countries, genotypes B and C predominate. Genotype C has been associated with a higher incidence of severe liver disease and hepatocellular carcinoma compared with genotype B in Asia, perhaps because this genotype spread earlier than the others.

CLINICAL MANIFESTATIONS

Typically, the incubation period is 30 to 150 days. Jaundice has been reported in up to one third of adult patients with acute hepatitis B, but most cases are unrecognized.[3] Among symptomatic patients (see Table 148-2), the manifestations are similar to those of other causes of acute viral hepatitis.

DIAGNOSIS

Four markers should be sought for the diagnosis of acute hepatitis B: HBsAg, total anti-HBc antibodies, anti-HBc IgM, and anti-HBs antibodies (Table 148-4). Acute hepatitis B is characterized by the simultaneous presence of both HBsAg and anti-HBc IgM (Fig. 148-3). Total anti-HBc antibodies are also present, whereas anti-HBs antibodies are not. During the convalescence phase, patients lose HBsAg before the appearance of anti-HBs antibodies; they have isolated anti-HBc antibodies, and the diagnosis is based on the presence of anti-HBc IgM. Recovery is characterized by the appearance of anti-HBs antibodies. The presence of both total anti-HBc and anti-HBs antibodies characterizes recovery from acute hepatitis B. Anti-HBc IgG remains at high levels for the patient's lifetime, whereas anti-HBs antibody titers may fluctuate and sometimes become undetectable after several years. Quantitative HBsAg assessment may be useful during the course of acute hepatitis B because if the HBsAg level does not rapidly decrease, the patient is at risk for chronic evolution. Patients who remain positive for HBV DNA or HBeAg 6 weeks after the onset of symptoms are likely to develop chronic infection.

TABLE 148-4 SEROLOGIC PROFILES OBSERVED IN DIFFERENT PHASES OF ACUTE, SELF-RESOLVING HEPATITIS B

PHASE OF INFECTION	HBsAg	ANTI-HBc IgM	TOTAL ANTI-HBc ANTIBODIES	ANTI-HBs ANTIBODIES
Incubation	+	+/–	+/–	–
Acute hepatitis	+	+	+	–
Convalescence	–	+	+	–
Recovery	–	–	+	+

HBc = hepatitis B core; HBs = hepatitis B surface; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M.

TREATMENT

Rx

Acute HBV infection usually does not require antiviral therapy, and most patients spontaneously clear the infection. Antiviral therapy with lamivudine can decrease HBV DNA levels more rapidly but does not result in better clinical or biochemical improvement and may be associated with lower levels of protective anti-HBs at 1 year.[A] In a small randomized trial of patients with severe but nonfulminant acute hepatitis B, lamivudine (100 mg daily) led to more rapid viral clearance but no difference in clinical outcomes.[A] Nevertheless, nonrandomized data suggest that early antiviral therapy is safe and may reduce the need for liver transplantation in patients with fulminant hepatitis B. Although most of the experience has been with lamivudine (100 mg daily), more potent drugs with no risk for HBV resistance selection, such as tenofovir 300 mg daily or entecavir 0.5 mg daily, are recommended in this setting.[4]

PREVENTION

Because not everyone has been vaccinated, individuals who are aware that they are infected with HBV should take steps to avoid transmitting the infection to others. This is accomplished by ensuring that their sexual contacts and household members are vaccinated; using barrier protection during sexual intercourse; not sharing instruments such as toothbrushes, razors, and combs; cleaning blood spills with detergent or bleach; and not donating blood, organs, or sperm.

Prevention of HBV infection is based on vaccination. Universal infant vaccination programs have been initiated in many countries. High-risk individuals (e.g., health care workers, dialysis patients, family members and sexual partners of HBV carriers, pregnant women, and men who have sex with men) should be screened for HBV infection by HBsAg and anti-HBs antibody testing, and seronegative persons should be vaccinated.[5]

Vaccination consists of the administration of recombinant HBsAg in three injections at 0, 1, and 6 months in adults. A lower dose is given at the same time points in newborns, children, and adolescents. Adults on dialysis require four injections at months 0, 1, 2, and 6. HBV vaccination elicits a potent neutralizing response, characterized by the presence of anti-HBs antibodies at high titers. A titer greater than 10 U/L is considered protective. The seroconversion rate is higher than 90% in healthy individuals. HBV vaccines are well tolerated. Injection site reactions within 1 to 3 days, as well as mild general reactions, are common and transient. Postvaccination testing for anti-HBs antibodies to document seroconversion is not routinely recommended. However, persons who remain at risk for HBV infection, such as infants of HBsAg-positive mothers, health care workers, dialysis patients, and sexual partners of HBV carriers, should be tested to determine their response to vaccination.

Of vaccinated persons, 3 to 10% respond poorly or do not respond, especially smokers, obese patients, and elderly individuals. Nonresponders should receive another full course of vaccination, often with an increased dose. Other options include intradermal application and the coadministration of adjuvants and cytokines. One third to two thirds of vaccinated individuals lose their anti-HBs antibodies after 10 to 15 years. It is unclear whether these persons are still protected. Thus, persons at risk should receive booster immunization if anti-HBs antibodies have been lost.

When nonimmune persons or vaccinated individuals with an anti-HBs titer below 10 IU/L have contact with HBV-contaminated materials (e.g., needles) or have sexual intercourse with an HBV-infected person, active-passive immunization (i.e., infusion of hepatitis B immunoglobulin) plus active immunization (vaccination) is recommended within 48 hours after exposure. Vaccination alone is sufficient in persons with anti-HBs antibody titers between 10 and 100 IU/L, and no action is required if the anti-HBs titer is above 100 IU/L.

Infants born to HBsAg-positive mothers must receive hepatitis B immunoglobulin and be vaccinated within 12 hours of birth; this regimen reduces the rate of vertical HBV transmission from 95% to less than 5%. Mothers with

HBV DNA levels above 5×10^7 IU/mL should also be treated during pregnancy with a potent nucleoside/nucleotide analogue with no teratogenic risk; the safest and most potent drug in this setting is tenofovir. Cesarean section is not needed if active-passive immunization is to be performed. Mothers of vaccinated infants can breast-feed, unless oral antiviral medications are present in the breast milk.

PROGNOSIS

Fulminant hepatitis is more frequent in acute HBV infection than in other types of acute viral hepatitis, with an incidence of approximately 0.1%. Factors associated with adverse outcomes of acute hepatitis B include advanced age, female sex, and perhaps some strains of virus. Whether infection with a precore mutant strain is associated with more severe or fulminant disease is still debated.

Among patients infected at birth, the rate of spontaneous recovery after an acute HBV infection is less than 5%, whereas adult infections spontaneously resolve in 95 to 99% of cases. Spontaneous resolution confers lifelong immunity, which is usually characterized by the presence of anti-HBs antibodies. Anti-HBs antibodies may become undetectable several years after resolution, but patients rapidly produce protective antibodies if they are re-exposed to HBV.

ACUTE HEPATITIS C

DEFINITION

The Pathogen

HCV is a member of the Flaviviridae family, genus *Hepacivirus*. The genome is a single-stranded, positive, linear RNA molecule whose 5′ end contains an internal ribosome entry site involved in polyprotein translation; the genome also includes one single open reading frame and a short 3′ noncoding region involved in replication. The genome is contained in a protein capsid or core, which itself is surrounded by a lipid bilayer envelope into which two inserted viral glycoproteins mediate attachment of the viral particle to receptor molecules at the surface of target cells.

EPIDEMIOLOGY

HCV is present in all continents, and an estimated 170 million individuals are chronically infected. In industrialized countries, the incidence of HCV infection has declined considerably owing to blood screening and measures to prevent viral infections in intravenous drug users. However, approximately 17,000 new cases of acute hepatitis C still occur annually in the United States according to the Centers for Disease Control and Prevention. In France, approximately 2500 new infections occur each year. HCV incidence and prevalence are higher in developing areas of the world, where the main route of HCV infection is unsafe medical or surgical procedures; only approximately 50% of blood products are screened for anti-HCV antibodies in these countries, and approximately 40% of all injections are given with reused equipment. Egypt's estimated 9% prevalence is the highest worldwide, owing to unsafe injection campaigns for the treatment of schistosomiasis. Although the incidence of acute hepatitis C has declined in Egypt during the past 15 years, up to 10% of cases of acute hepatitis are still caused by HCV.

HCV is transmitted almost exclusively by infected blood. Preventive screening with highly sensitive enzyme immunoassays and, more recently, nucleic acid testing has virtually eliminated the risk for post-transfusional HCV infection (theoretical risk: 1 in 2 million donations in the United States, 1 in 8 million donations in France). As a result, the principal route for HCV transmission in industrialized countries is now intravenous drug use, which is responsible for 60 to 80% of new cases. The incidence of HCV infection in this high-risk group is as high as 39 per 100 person years. In this context, imprisonment is an important risk factor for acquiring HCV infection in industrialized countries.

Nosocomial transmission through the use of improperly decontaminated materials or the contaminated hands or gloves of health care workers is responsible for a substantial number of new infections worldwide. HCV also can be transmitted by tattooing, piercing, or acupuncture if standard precautions are not implemented. Although HCV can be acquired after accidental needlestick exposure, the risk for infection is low (<1%), and health care workers have only a slightly higher prevalence of HCV than the general population. HCV can be transmitted to household members who share instruments such as scissors, razors, and combs. Sexual transmission is unusual, but outbreaks of acute hepatitis have been reported in HIV-positive communities of men who have sex with men. The risk for mother-to-infant transmission of HCV is less than 5% and is generally related to exposure to the mother's blood in the perinatal period. Cesarean sections are not recommended, and breast-feeding is not contraindicated. The risk for perinatal transmission is higher when the mother is coinfected with HIV. Other factors possibly associated with high transmission rates include the level of HCV viremia and maternal intravenous drug abuse. In 10 to 30% of cases, no apparent risk factor for HCV infection is identifiable, suggesting other potential sources of community-acquired hepatitis C.

PATHOBIOLOGY

Entry of HCV into cells is followed by fusion. Decapsidation of viral nucleocapsids liberates free genomic RNAs into the cell cytoplasm, where they serve, together with newly synthesized RNAs, as messenger RNAs for synthesis of the HCV polyprotein. The post-translational processing of the HCV polyprotein results in the generation of at least 10 proteins, including 3 structural proteins (the core protein and the two envelope glycoproteins) and 7 nonstructural proteins. HCV replication takes place in the replication complex that associates viral proteins, cellular components, and nascent RNA strands. It is catalyzed by the RNA-dependent RNA polymerase. Viral particle formation is initiated by the interaction of the core protein with genomic RNA. Newly produced virus particles leave the host cell via constitutive secretory pathways.

Phylogenetic analyses of HCV strains isolated in various regions of the world have identified seven main HCV genotypes, designated 1 through 7. These HCV types comprise a large number of subtypes, identified by lowercase letters (1a, 1b, etc.). The genotypes' nucleotide sequences differ by 31 to 34%, and their amino acid sequences differ by approximately 30%; in contrast, the subtypes' nucleotide sequences differ by between 20 and 23%, with marked differences in particular genomic regions. The high prevalence and diversity of HCV genotype 3 and 6 strains in Asia and of genotype 1, 2, 4 and 5 strains in Africa suggest that these types and subtypes emerged and diversified in these regions. In industrialized countries, a small number of HCV genotypes, including 1a, 1b, 2a, 2b, 2c, 3a, and 4a, have been introduced and spread rapidly among exposed populations. Subtypes 1a and 1b predominate all over the world. The most common genotypes in the United States are 1a and 1b (~75%), 2a and 2b (~15%), and 3a (~7%). Genotype 3a is more prevalent in Western Europe, where it accounts for up to 35% of cases, especially among intravenous drug users. Genotype 4 is highly prevalent in the Middle East and Africa. Its incidence and prevalence are increasing in intravenous drug users in industrialized countries. Genotype 5 is rare outside South Africa, and genotype 6 is rare outside Southeast Asia. Infections with different genotypes do not differ in terms of the clinical manifestations, progression, or disease severity (although this is debated), but the HCV genotype is an important determinant of the response to interferon-α–based therapies.

CLINICAL MANIFESTATIONS

HCV RNA becomes detectable in the serum 3 to 7 days after exposure. HCV RNA levels rise rapidly during the first weeks, followed by serum aminotransferase levels 2 to 8 weeks after exposure. Anti-HCV antibodies arise late in the course of acute hepatitis C and may not be present at the onset of symptoms and serum aminotransferase elevation.

After an incubation period that ranges from 15 to 120 days, acute hepatitis C usually remains asymptomatic and is undiagnosed.[6] Nonspecific symptoms such as fatigue, low-grade fever, myalgias, nausea, vomiting, or itching may be present. Jaundice occurs in only 20 to 30% of patients, usually 2 to 12 weeks after infection. Serum aminotransferase levels commonly exceed 10 times the upper limit of normal in the acute stage, even in the absence of symptoms. Fulminant hepatitis C has been reported but appears to be exceptional in the absence of another chronic underlying liver disease.

DIAGNOSIS

When acute hepatitis C is suspected, patients should be tested for both anti-HCV antibodies by enzyme immunoassay and HCV RNA with a sensitive molecular biology technique (i.e., an HCV RNA assay with a lower limit of detection of ≤ 50 IU/mL). Four marker profiles can be observed, based on the presence or absence of either marker (Table 148-5). The presence of HCV RNA in the absence of anti-HCV antibodies is strongly indicative of acute HCV infection, which will be confirmed by seroconversion (i.e., the appearance of anti-HCV antibodies) a few days to weeks later. Acutely infected patients can have both HCV RNA and anti-HCV antibodies at the time of diagnosis; in this case, it is difficult to distinguish acute hepatitis C from an acute exacerbation of chronic hepatitis C or acute hepatitis of another cause in a patient with chronic hepatitis C.

TABLE 148-5 PATTERNS OF HEPATITIS C VIRUS (HCV) MARKERS AND THEIR SIGNIFICANCE DURING ACUTE HEPATITIS C

ANTI-HCV ANTIBODIES	HCV RNA	DIAGNOSIS
–	–	Not acute hepatitis C
–	+	Acute hepatitis C
+	–	Probably not acute hepatitis C (retest in a few weeks)
+	+	Difficult to differentiate acute from chronic hepatitis C

HCV = hepatitis C virus.

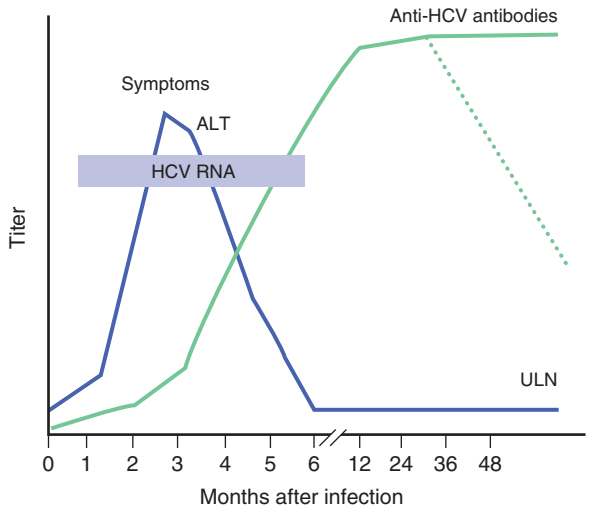

FIGURE 148-4. Kinetics of hepatitis C virus (HCV) markers during acute self-resolving hepatitis C. ALT = alanine aminotransferase; ULN = upper limit of normal.

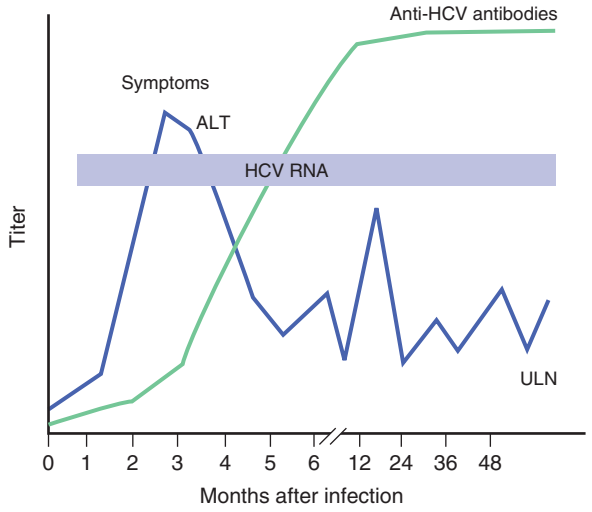

FIGURE 148-5. Kinetics of hepatitis C virus (HCV) markers during acute hepatitis C that evolves toward chronic infection. ALT = alanine aminotransferase; ULN = upper limit of normal.

Acute hepatitis C is very unlikely if both anti-HCV antibodies and HCV RNA are absent or if anti-HCV antibodies are present without HCV RNA (Fig. 148-4). Patients in the latter group should be retested in a few weeks, however, because HCV RNA may be temporarily undetectable owing to transient, partial control of viral replication before the infection becomes chronic (Fig. 148-5). Apart from such cases, the presence of anti-HCV antibodies in the absence of HCV RNA is generally seen in patients who have recovered from a past HCV infection. Nevertheless, this pattern cannot be differentiated from a false-positive enzyme immunoassay result, the exact prevalence of which is unknown.

TREATMENT

Rx

Treatment of acute hepatitis C should be considered not only because it prevents chronic HCV infection, which can lead to serious clinical sequelae, but also because HCV viremia, which is associated with a risk for transmitting HCV to other persons, may have social, legal, and economic consequences, especially for infected health care workers. Classically, treatment of acute hepatitis C is based on the use of pegylated interferon-α2a or interferon-α2b at doses of 180 µg/week or 1.5 µg/kg/week, respectively. Treatment is usually administered for 24 weeks, but 12 weeks is probably sufficient in most patients, especially patients with baseline parameters that predict a rapid viral clearance, such as symptomatic disease, high alanine aminotransferase levels, and low HCV RNA levels. Ribavirin should be added in patients who have a delayed or slow HCV RNA decrease with treatment, genotype 1 infection, low or normal baseline alanine aminotransferase levels, or a combination of these. With this treatment, 70% to more than 90% of patients have sustained viral clearance. Although delaying treatment can avoid the side effects of treatment in the 20 to 50% of patients who will spontaneously clear the virus, immediate treatment provides higher rates of viral clearance, mostly because asymptomatic patients tend to be less adherent with the close following needed to monitor patients for the institution of appropriately timed delayed therapy.

If treatment fails to clear the virus, patients can be re-treated with a combination of pegylated interferon-α2a (180 µg/week) or interferon-α2b (1.5 µg/kg/week) and ribavirin (0.8 g/day) for 48 weeks. No randomized data are available for new anti-HCV drugs. However, given its efficacy in patients with chronic hepatitis C, the oral combination of sofosbuvir 400 mg daily and ribavirin (1 or 1.2 g/day according to body weight less or more than 75 kg) for 24 weeks can be used to treat acute hepatitis C. More data will be generated soon with other antiviral drug combinations without ribavirin.

After accidental needlestick exposure, neither immunoglobulin nor preemptive therapy is recommended. Patients should be monitored with HCV RNA and aminotransferase level testing at baseline, week 2, and 4 and 6 months after exposure. Patients who have documented infection should be treated as described earlier.

PREVENTION

Prevention of HCV transmission is based on standard precautions such as screening of blood and blood products, application of standard medical and surgical hygiene procedures, and safe use of syringes and materials for drug preparation in drug users. Needle exchange programs and education regarding the risks of drug use (including intranasal cocaine) and the risk for transmission from shared injection equipment are important.

No prophylactic vaccine is or will soon be available against HCV.

PROGNOSIS

Approximately 50 to 80% of patients are unable to clear HCV spontaneously and develop chronic infection.[7] Spontaneous recovery is more frequent if infection is acquired at birth (~50%) and if acute hepatitis is symptomatic. It is unclear whether the genotype influences recovery rates. Other factors associated with better rates of spontaneous recovery include female sex, early decline of HCV RNA levels, and high aminotransferase or bilirubin levels. Patients who spontaneously recover may retain detectable anti-HCV antibodies for years to decades, but they are not protected against HCV reinfection.

ACUTE HEPATITIS D OR DELTA

DEFINITION

The Pathogen

HDV, which is a satellite of HBV, can be transmitted only to patients who are acutely or chronically infected with HBV. Its single, negative-strand, circular RNA genome of approximately 1700 nucleotides folds in native conditions into a nearly complementary rodlike structure that contains a ribozyme. The HDV genome encodes one single structural protein, the hepatitis D (HD) protein, which expresses HDAg. The 36-nm infectious HDV virion comprises the HD protein and the genome, both enclosed within an HBsAg coat derived from empty HBV envelopes.

EPIDEMIOLOGY

Five percent of chronic HBV carriers, or 15 million to 20 million individuals worldwide, are also infected with HDV. The prevalence of HDV infection in

HBV-infected patients varies according to the geographic area because it is transmitted primarily through parenteral exposure. As a result, its prevalence is relatively higher in HBsAg-positive intravenous drug users in Western countries, where approximately 8 to 12% of HBsAg-positive patients are infected with HDV. By comparison, the prevalence of HDV has decreased substantially in southern Europe, probably owing to universal HBV vaccination programs, improvement in hygiene and living conditions, and implementation of standard precautions to prevent HIV infection. The incidence of HDV is increasing in Russia, Eastern Europe, Japan, and India.

PATHOBIOLOGY

HDV uses host RNA polymerase II for its replication, following the rolling circle model. Within cells, HDV RNA is associated with multiple copies of the HD protein to form a ribonucleoprotein complex. This complex is exported by the HBV envelope, which contains the three HBV envelope proteins, into the Golgi apparatus before being secreted.

HDV has at least eight genotypes, which differ from one another by at least 15% of their nucleotide sequences. Genotype I is the most prevalent HDV worldwide. Additional genotypes have recently been identified in Africa.

CLINICAL MANIFESTATIONS

HDV can be acquired at the same time as HBV (coinfection) or by a chronic HBsAg carrier (superinfection).[8] Coinfection is characterized by one or two episodes of acute hepatitis, depending on the respective amounts of HBV and HDV present in the inoculum; acute hepatitis can range from mild to fulminant. In contrast, when chronic HBV carriers are superinfected by HDV, acute hepatitis D is generally severe, often fulminant, and generally becomes chronic.

DIAGNOSIS

Three markers of HDV infection are total anti-HD antibodies, anti-HD IgM, and HDV RNA; the latter can be detected and quantified by real-time PCR. All HBsAg-positive patients should be tested.

In patients with an HBV-HDV coinfection, HDV RNA is only transiently present and is often missed. Anti-HBc IgM indicates concomitant acute HBV infection.

In HDV superinfection of a chronic HBsAg carrier, no anti-HBc IgM is present. HDV RNA is found in serum or plasma before and during the acute episode, whereas both total anti-HD antibodies and anti-HD IgM are present during the acute phase. Both serologic markers remain at high levels if the disease becomes chronic.

TREATMENT Rx

No treatments are of proven benefit for acute hepatitis D.[9]

PREVENTION

The most effective means of preventing HDV infection is HBV vaccination, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and behavioral precautions should be practiced to avoid superinfection with HDV.

PROGNOSIS

In patients who are acutely coinfected with HBV and HDV, only approximately 2% become chronic HDV carriers. In contrast, when HDV infection is acquired by chronic HBV carriers, approximately 90% also become chronic carriers of HDV.

ACUTE HEPATITIS E

DEFINITION

The Pathogen

HEV is a member of the genus *Hepevirus* in the Hepeviridae family. HEV is a small, nonenveloped virus. Its genome is a positive sense, single-stranded RNA molecule. Five HEV genotypes have been described: genotypes 1 and 2 appear to be strictly human, whereas genotypes 3 and 4 appear to be of swine origin but can also infect humans.

PATHOBIOLOGY AND EPIDEMIOLOGY

HEV transmission is principally oral-fecal. HEV is endemic in most developing areas of the world, where acute infections are sporadic or occur during large epidemics related to the contamination of drinking water. Genotype 1 has been found principally in Asia and North Africa, whereas genotype 2 has been isolated in cases from Central America and Western Africa. No animal reservoir is known for these genotypes, and transmission appears to be linked to the contamination of food or drinking water. In industrialized countries, HEV genotypes 1 and 2 are not present. HEV genotypes 3 and 4 are endemic in swine, and zoonotic transmission appears to be the main route of transmission in Europe, the United States, and Asia. Diagnosed cases of acute hepatitis E have increased constantly in Western Europe and North America in recent years, and high HEV seroprevalences have been described in special at-risk populations, such as butchers or farmers. Transmission may be favored by the consumption of uncooked meat and direct contact with infected animals. It is now thought to be the most common cause of acute viral hepatitis worldwide.[10]

CLINICAL MANIFESTATIONS

The incubation period is 3 to 8 weeks. HEV infection causes only mild, nonspecific symptoms in the majority of cases, especially if the infection is acquired early in life. Immunocompetent individuals clear the virus spontaneously.[11] The peak of viremia occurs early during infection, whereas the peak of aminotransferase activity is reached approximately 6 weeks after infection. Severe disease is more frequent in pregnant women and in patients with underlying chronic liver disease, who may rarely progress to fulminant hepatic failure. In one European report, 5% of patients with Guillain-Barré syndrome (Chapter 420) had a preceding acute hepatitis E infection.[12]

DIAGNOSIS

Patients with otherwise unexplained acute hepatitis should be tested for hepatitis E. Diagnosis of acute hepatitis E is based on the detection of anti-HEV IgM antibodies, which appear within 6 weeks and persist for 3 to 12 months. Unfortunately, current assays lack sensitivity and specificity, and none are yet approved by the U.S. Food and Drug Administration. HEV RNA also can be detected in feces, serum, or plasma, where its presence is transient. Anti-HEV IgG generally persists for life after acute infection.

TREATMENT Rx

Treatment of acute hepatitis E is not recommended because the vast majority of patients recover spontaneously.[13] Severe and fulminant cases should be referred to specialized units, where ribavirin monotherapy can be successful.

PREVENTION

Improved public hygiene is the best defense against hepatitis E in developing countries. Travelers to areas of the world where HEV is endemic, particularly pregnant women, should be cautioned about drinking the water and eating uncooked food. An efficient prophylactic vaccine based on recombinant HEV proteins was 100% effective in a phase 3 trial and a hepatitis E vaccine is approved in China. However, the duration of protection is unclear, so the vaccine's efficacy in preventing the spread of HEV has yet to be determined.

PROGNOSIS

Acute cases can be severe in elderly patients, and fulminant cases are frequent among pregnant women who are infected during large-scale waterborne epidemics. Overall case fatality rates range from zero to 10%, and less than 1% of fatal cases of acute hepatitis in the United States are attributed to hepatitis E. HEV genotypes 3 and 4 are less virulent than genotypes 1 and 2. Sporadic cases in industrialized areas are generally benign. HEV does not commonly evolve into chronic infection, but immunosuppressed patients and HIV-positive individuals can become chronic carriers.

OTHER TYPES OF ACUTE VIRAL HEPATITIS

Infection by members of the Herpesviridae family, such as cytomegalovirus (Chapter 376), Epstein-Barr virus (Chapter 377), and herpes simplex virus

(Chapter 374), should be considered in the differential diagnosis of unclear episodes of elevated liver enzymes in the absence of markers of acute hepatitis virus infection, especially in immunocompromised individuals. For instance, cytomegalovirus infection can be associated with graft loss after liver transplantation (Chapter 154). Parvovirus B19 (Chapter 371) may persist in the liver and worsen liver disease in patients with chronic hepatitis B and perhaps in patients with chronic HCV infection. Human herpesvirus 6 variant A has been linked with syncytial giant-cell hepatitis.

Non-A-to-E Hepatitis

Rare patients develop acute hepatitis of presumed viral cause but have no markers of known hepatitis viruses. Some of these cases may be due to variants of known hepatitis viruses, in particular HBV, that are not detected by the usual serologic and molecular methods. However, the existence of other, unknown hepatotropic viruses cannot be excluded.

149

CHRONIC VIRAL AND AUTOIMMUNE HEPATITIS

JEAN-MICHEL PAWLOTSKY

DEFINITION

Chronic hepatitis is defined by chronic necroinflammation of the liver and may be due to various causes, including hepatotropic viruses, autoimmunity, alcohol (Chapter 152), and metabolic disorders (Chapter 146). Chronic infection by hepatitis viruses is by far the main cause of chronic hepatitis worldwide, with more than 500 million individuals chronically infected with hepatitis B virus (HBV) or hepatitis C virus (HCV). Chronic viral hepatitis B and C are the leading cause of cirrhosis (Chapter 153) and hepatocellular carcinoma (Chapter 196) worldwide and account for more than 1 million deaths per year. Chronic HBV infection can be associated with infection by hepatitis D virus (HDV). Hepatitis A virus does not cause chronic hepatitis. Hepatitis E virus (HEV) generally does not cause chronic hepatitis, except in immunosuppressed patients.

CLINICAL MANIFESTATIONS

The clinical symptoms of chronic viral and autoimmune hepatitis are typically nonspecific, and many patients have no symptoms. Fatigue, sleep disorders, and right upper quadrant pain may be present. Often the diagnosis is made when liver test abnormalities are identified by blood testing during a routine health evaluation or assessment for an unrelated problem or at the time of voluntary blood donation. More advanced symptoms include poor appetite, nausea, weight loss, muscle weakness, itching, dark urine, and jaundice. Patients can progress to full-blown cirrhosis (Chapter 153), with its typical clinical manifestations. If cirrhosis is present, weakness, weight loss, abdominal swelling, edema, bruisability, gastrointestinal bleeding, and hepatic encephalopathy with mental confusion may arise. Other findings may include spider angiomas, palmar erythema (see Fig. 146-2), ascites (see Fig. 146-4), edema, and skin excoriations.

TABLE 149-1 DIAGNOSIS OF CHRONIC HEPATITIS

DIAGNOSIS	SCREENING TESTS	CONFIRMATORY TESTS
Chronic hepatitis B	HBsAg	HBV DNA, HBeAg
Chronic hepatitis C	Anti-HCV antibodies	HCV RNA
Chronic hepatitis D	Anti-HDV antibodies	HDV RNA
Autoimmune hepatitis	ANA (anti-LKM1)	Exclusion of other causes and patterns of clinical disease
Drug-induced liver disease	History	Rechallenge, if necessary, if considered safe
Wilson disease	Ceruloplasmin	Urine copper concentration
Cryptogenic hepatitis	Exclusion of other causes	

ANA = antinuclear antibody; anti-LKM1 = anti–liver-kidney microsomal 1 antibody; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HDV = hepatitis D virus.

DIAGNOSIS

Levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are usually two to five times the upper limit of normal. The ALT level is generally higher than the AST level, but both can be normal in mild or inactive disease or 10 to 25 times the upper limit of normal during acute exacerbations. Biologic tests can establish the specific diagnosis (Table 149-1).

Alkaline phosphatase and γ-glutamyl transpeptidase levels are usually minimally elevated unless cirrhosis is present. Serum bilirubin and albumin levels and the prothrombin time are normal unless the disease is severe or advanced. Serum immunoglobulin levels are mildly elevated or normal in chronic viral hepatitis but may be very elevated in autoimmune hepatitis. Results that suggest the presence of advanced fibrosis are a platelet count below 160,000, AST levels higher than ALT levels, elevation in serum bilirubin, decrease in serum albumin, prolongation of the prothrombin time, elevation in α-fetoprotein levels, and presence of rheumatoid factor or high globulin levels.

Liver ultrasound can determine the texture and size of the liver and spleen, exclude hepatic masses, and assess the gallbladder, intrahepatic bile ducts, and portal venous flow. Computed tomography and magnetic resonance imaging of the liver are helpful if a mass or other abnormality is found by ultrasound. Hepatic transient elastography or acoustic radiation force impulse imaging can assess liver stiffness as a surrogate marker of fibrosis.

Liver biopsy is usually critical for diagnosis and to determine the severity of disease. Hepatocellular necrosis is typically eosinophilic degeneration or ballooning degeneration throughout the parenchyma, greater in the periportal area, spotty, or piecemeal. Fibrosis also typically begins in the periportal regions and can link adjacent portal areas or portal and central areas (bridging fibrosis), distort the hepatic architecture, and lead to cirrhosis and portal hypertension. The histologic grade of chronic hepatitis can be determined by combining scores for periportal necrosis and inflammation, lobular necrosis and inflammation, and portal inflammation. Recently, ultrasound-based methods or serologic markers have proved accurate for the assessment of mild disease and cirrhosis, but they are less accurate for identifying moderate to severe inflammation, except in patients with chronic hepatitis C. Patients with suspected chronic viral or autoimmune hepatitis should be evaluated carefully for fatty liver, alcohol-induced (Chapter 152) or drug-induced (Chapter 150) liver disease, and metabolic liver diseases (Chapter 146), each of which can coexist with hepatitis. Liver biopsy can exclude other diagnoses that mimic chronic hepatitis, including fatty liver, alcoholic liver disease, steatohepatitis (Chapter 152), drug-induced liver disease (Chapter 150), sclerosing cholangitis (Chapter 155), iron overload (Chapter 212), and veno-occlusive disease (Chapter 143).

TREATMENT AND PROGNOSIS

Rx

Chronic HBV infection is not curable, but it usually can be controlled by appropriate antiviral drugs. HCV infection is curable, and more than 80% of patients who have access to new therapies are cured. Autoimmune hepatitis responds to immunosuppression with corticosteroids and azathioprine.

CHRONIC HEPATITIS B

EPIDEMIOLOGY

More than 240 million individuals, or approximately 4% of the world's population, are chronic HBV carriers. Two billion individuals, or one human being in three, have been in contact with the virus. In North America, Western and Northern Europe, and Australia, less than 2% of the population is chronic hepatitis B surface antigen (HBsAg) carriers. In the United States, the prevalence is approximately 0.4%; that is, approximately 1.25 million Americans are infected. In Eastern Europe, South America, the Mediterranean basin, and the Indian subcontinent, the prevalence of chronic HBsAg carriage is between 2 and 8%. Highly endemic areas, with a rate of chronic HBsAg carriage exceeding 8%, include China, Southeast Asia, sub-Saharan Africa, and the native populations of the Far North of America.

HBV is the main cause of primary liver cancer (hepatocellular carcinoma, Chapter 196) worldwide, with approximately 350,000 new cases attributable to HBV every year. Hepatocellular carcinoma is more likely in the presence of underlying cirrhosis, but HBV has oncogenic properties of its own, and hepatocellular carcinoma can occur in noncirrhotic HBV patients.

PATHOBIOLOGY

HBV is not a cytopathic virus. Rather, liver injury in chronic hepatitis B is a consequence of the local immune response at the immune elimination phase. In particular, liver injury is related to cytotoxic T cells that recognize and kill infected hepatocytes that express HBV antigens at their surface and to the local production of cytokines. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. The hepatitis B X protein may also directly activate fibrogenesis. As a result, many patients with chronic hepatitis B have progressive fibrosis, which may evolve into cirrhosis.

The rate of chronicity after an acute HBV infection is more than 95% among patients infected at birth. This risk diminishes as the age at acquisition increases, and it is less than 5% in those infected as adults. Chronic HBV infection is defined by HBsAg carriage that persists for more than 6 months after the acute episode. Chronic HBsAg carriage typically evolves through three phases: immune tolerant, immune elimination, and inactive.

The immune tolerant phase is generally short if the infection occurred during adulthood, but it persists for years to decades in patients infected at birth or during early childhood. At the immune tolerant stage, the immune response of the host "tolerates" HBV infection and does not cause liver inflammation or hepatocyte destruction. The immune tolerant phase is characterized by the presence of hepatitis B e antigen (HBeAg), very high levels of HBV DNA in blood, normal serum or plasma aminotransferase levels, and no or minimal inflammatory activity on liver biopsy.

The immune elimination phase is characterized by an active immune response that causes necroinflammatory lesions and triggers hepatic fibrogenesis and progressive fibrosis. ALT and AST levels are increased, but HBV DNA levels are lower than during the immune tolerant phase and frequently fluctuate. The immune elimination phase has a variable duration, ranging from a few weeks to several decades. HBeAg, when present, defines HBeAg-positive chronic hepatitis B; HBeAg can be cleared and replaced by anti-HBe antibodies, defined as HBe seroconversion; or HBeAg can be absent while anti-HBe antibodies are present and define HBeAg-negative chronic hepatitis B. Patients with HBeAg-positive chronic hepatitis B are infected with a wild-type virus and are able to secrete the HBe protein. Patients with HBeAg-negative chronic hepatitis B are infected with so-called precore mutant viruses, which cannot produce the HBe protein because they have a stop codon in the pre-C gene, and/or with core promoter mutant viruses, which produce considerably lower amounts of HBe protein. Because of the prevalence of the HBV genotype D in Euro-Mediterranean and African countries, HBeAg-negative/anti-HBe-positive chronic hepatitis B is seven to nine times more frequent than HBeAg-positive disease in those locations.

The inactive HBsAg carriage phase is the result of successful immune elimination leading to HBe seroconversion. ALT and AST levels are normal, HBV DNA is undetectable or at very low levels, and patients without preexisting cirrhosis have normal liver histology.

CLINICAL MANIFESTATIONS

Chronic hepatitis B is usually asymptomatic. The most common symptom is fatigue, but sleep disorders, difficulty concentrating, and upper right quadrant pain are often observed. Chronic hepatitis B is characterized biologically by elevated aminotransferase levels, and ALT levels can fluctuate substantially during the immune elimination phase. Moderate cholestasis, with mildly elevated alkaline phosphatase and γ-glutamyl transpeptidase levels, also can be present, especially in patients with cirrhosis.

HBeAg-negative chronic hepatitis B is generally more severe than the HBeAg-positive variety. The incidence of spontaneous HBe seroconversion among HBeAg-positive patients is 8 to 12% per year when they are in the immune elimination phase; HBe seroconversion often follows a transient ALT flare. Some of these patients evolve toward inactive HBsAg carriage, whereas others switch into an HBeAg-negative form of chronic hepatitis B, with elevated ALT levels and an HBV DNA level greater than 2000 IU/mL.

The annual incidence of cirrhosis varies from 2 to 10% in patients with chronic HBV infection, with a cumulative incidence of approximately 20% at 5 years. The risk for cirrhosis is two- to four-fold higher in HBeAg-negative patients compared with HBeAg-positive ones, probably because they are older and have more severe disease at the time of diagnosis. The annual incidence of hepatocellular carcinoma in patients with chronic hepatitis B varies from 1% in patients without cirrhosis to 2 to 8% in cirrhotic patients, with the higher rates occurring in older patients. Patients with cirrhosis (Chapter 153), hepatocellular carcinoma (Chapter 196), or both have the typical signs associated with these conditions. Rarely, chronic HBV infection is associated with extrahepatic manifestations, including glomerulonephritis (Chapter 121), most often in children, and polyarteritis nodosa (Chapter 270), mostly in adults.

DIAGNOSIS

Serologic markers used to diagnose chronic hepatitis B (Table 149-2) include HBsAg, anti-HBs antibodies, total anti–hepatitis B core (HBc) antibodies and anti-HBc immunoglobulin M (IgM), HBeAg, and anti-HBe antibodies. Molecular markers include HBV DNA and HBV resistance substitutions; real-time polymerase chain reaction (PCR)–based assays are the best way to detect and quantify HBV DNA.

Chronic HBV infection is defined by the persistence of HBsAg in the serum for more than 6 months after the acute episode. The majority of subjects with isolated anti-HBc antibodies are not viremic. However, some individuals who test positive for anti-HBc antibodies, but not for HBsAg or anti-HBs antibodies, may be viremic; in these cases, the virus's amino acid substitutions in the HBsAg sequence make HBsAg undetectable with current enzyme immunoassays. Other individuals may have such low-level HBV replication in their livers that HBV DNA is not detectable in blood ("occult" hepatitis B). Screening is recommended only in high-risk individuals.[1]

Serum or plasma ALT and HBV DNA levels are important markers of severity and prognosis. For both HBV and HCV, the assessment of severity, including the grade of necroinflammation and the stage of fibrosis, is based on the liver biopsy (Fig. 149-1). Noninvasive assessment using serologic markers, transient elastography, or acoustic radiation force impulse imaging can discriminate cirrhosis from mild hepatitis and fibrosis; although they are not accurate enough for intermediate stages, these methods will likely replace liver biopsy in the pretreatment assessment of the severity of chronic hepatitis B in many patients in the future.

PREVENTION AND TREATMENT

Rx

Patients with chronic hepatitis B should be vaccinated against hepatitis A virus, abstain from alcohol, and avoid immunosuppressive therapies unless absolutely necessary. HBV-infected patients who require corticosteroids, rituximab, or other chemotherapy for other conditions should receive entecavir 0.5 mg/day or tenofovir 300 mg/day during therapy and for 12 months after its cessation as prophylaxis against reactivation of hepatitis B.

The goals of therapy are to suppress HBV replication, reduce the histologic activity of chronic hepatitis, and lessen the risk for cirrhosis and hepatocellular carcinoma. HBV infection cannot be completely eradicated because of the

persistence of covalently closed circular DNA in the nucleus of infected hepatocytes. As a result, therapy attempts to reduce HBV DNA levels as much as possible—ideally, below the limit of detection of real-time PCR assays (10 to 15 IU/mL)—to ensure a degree of viral suppression that will lead to biochemical remission, histologic improvement, and prevention of complications.

Two different types of drugs for the treatment of chronic hepatitis B are pegylated interferon-α (IFN-α) and nucleoside/nucleotide analogues. Pegylated IFN-α2a, administered subcutaneously at a dose of 180 μg/week for 48 weeks, improves various markers of HBV infection in both HBeAg-positive (Table 149-3) and HBeAg-negative (Table 149-4) patients. Pegylated IFN-α2b (1.5 μg/kg) is very similar to IFN-α2a and is used by many liver experts, although it is not currently approved for HBV. The most frequent side effects of IFN-α are flulike symptoms after the injections, fatigue, anorexia, weight loss, and alopecia. The most concerning side effects are neutropenia, thrombocytopenia, anxiety, irritability, depression, and suicidal ideation.

Nucleoside analogues (lamivudine, telbivudine, and entecavir) require triple phosphorylation to be active, whereas nucleotide analogues (adefovir and tenofovir) need only two phosphorylations to be active. These drugs are given orally (PO) once daily at the following dosages: 100 mg for lamivudine, 600 mg for telbivudine, 0.5 mg for entecavir, 10 mg for adefovir (administered as the pro-drug adefovir dipivoxil), and 300 mg for tenofovir (administered as the pro-drug tenofovir disoproxil fumarate). All have short-term benefits on various markers of HBV infection in HBeAg-positive (see Table 149-3) and HBeAg-negative (see Table 149-4) patients. Entecavir and tenofovir are two of the most potent inhibitors of HBV replication, and they are the least likely to select for resistant HBV variants. These drugs are generally well tolerated. However, adefovir is nephrotoxic at doses higher than those used for HBV therapy; renal impairment and decreases in mineral bone density are rarely seen with tenofovir; myopathy is a rare complication of telbivudine, and peripheral neuropathy has been observed when telbivudine is combined with pegylated IFN-α.

Patients should be considered for treatment when their HBV DNA levels are greater than 2000 IU/mL and/or their serum ALT levels are abnormal if the liver biopsy shows moderate to severe active necroinflammation, fibrosis, or both. Indications for treatment must also take into account the patient's age and health status and the availability of antiviral agents in individual countries. Patients in the immune tolerant phase and those with mild hepatitis on liver biopsy (or noninvasive markers) should not be treated, but follow-up ALT levels and HBV DNA assays are mandatory. Patients with compensated cirrhosis and detectable HBV DNA may be considered for treatment even if their ALT levels are normal, their HBV DNA levels are below 2000 IU/mL, or both. Patients with decompensated cirrhosis require urgent antiviral treatment.

Two treatment strategies can be considered: a 48-week course of pegylated IFN-α or long-term oral treatment with nucleoside/nucleotide analogues. Whether their combined use improves the rate of sustained virologic response after treatment is currently under study. Pegylated IFN-α can provide a sustained virologic response, defined as a sustained HBe seroconversion (clearance of HBeAg, which is replaced by anti-HBe antibodies) and an HBV DNA level that remains below 2000 IU/mL after a 48-week course of treatment; an ALT flare can be observed at the time of HBeAg loss in patients in whom treatment is successful. Pegylated IFN-α treatment should be reserved for patients with the best chance of a sustained virologic response off

treatment—HBeAg-positive patients with high baseline ALT levels (more than three times the upper limit of normal) and HBV DNA levels below 2.10^6 IU/mL. Pegylated IFN-α therapy is contraindicated in patients with advanced cirrhosis and in immunosuppressed patients. Patients infected with HBV genotypes A and B generally respond better to IFN-α therapy than do patients infected with genotypes C and D, but the predictive value of the HBV genotype for an individual patient is weak. Patients who fail to achieve a sustained virologic response after a single course of pegylated IFN-α are candidates for nucleoside/nucleotide analogue therapy.

Long-term treatment with nucleoside/nucleotide analogues is indicated in the majority of patients with chronic hepatitis B. Tenofovir or entecavir, which are the most potent drugs with an optimal resistance profile, are recommended as first-line monotherapies. HBV DNA should be suppressed to undetectable levels (<10 to 15 IU/mL) with a sensitive real-time PCR-based assay. If the HBV DNA level is reduced but still detectable in a compliant patient, the other agent may be added; however, the long-term safety of combined tenofovir and entecavir is unknown. When HBeAg-positive patients seroconvert to negative or HBeAg-negative patients lose their HBsAg, treatment should be continued for an additional 6 to 12 months at least. In all other cases, treatment should be continued for life and adherence is particularly important.

Virologic breakthroughs—defined by a subsequent increase of the HBV DNA level of 1 log or more above the nadir level—in adherent patients are due to HBV resistance to the administered antiviral drug or drugs. HBV DNA levels most often increase back to baseline levels, and the virologic breakthrough is generally followed a few weeks later by a biochemical breakthrough in which a previously normal ALT level rises above normal. The cumulative rates of resistance in newly treated patients are 70% at 5 years for lamivudine, 17% at 2 years for telbivudine, 1.2% at 6 years for entecavir, 29% at 5 years for adefovir, and 0% at 6 years for tenofovir. These figures illustrate the high genetic barrier against resistance of entecavir and tenofovir. In a patient who develops resistance to any of the available nucleoside/nucleotide analogues, adding a second drug without cross-resistance or switching to tenofovir are the only efficient strategies, although the long-term safety of some of these combinations is not known. In patients with lamivudine, telbivudine, or entecavir resistance, treatment should be switched to tenofovir or tenofovir should be added. Patients who have resistance to adefovir should be switched to tenofovir and eventually also given lamivudine, telbivudine, or entecavir. In patients with tenofovir resistance (never reported thus far), any of these three drugs should be added. The combination of tenofovir and emtricitabine, a nucleoside analogue similar to lamivudine, in a single tablet (approved for HIV but not for HBV therapy) is also a valid option in cases of resistance to any of these drugs.

In patients with cirrhosis, nucleoside/nucleotide analogue therapy is the only option because pegylated IFN-α is contraindicated if cirrhosis is decompensated. Because resistance in this population can be life-threatening, some experts recommend de novo treatment with two potent drugs without cross-resistance. In those with decompensated disease, efficient antiviral treatment most often stabilizes the patient's condition and can also delay or obviate the need for liver transplantation. If transplantation is needed, post-transplant administration of anti-HBV immunoglobulins in combination with a potent nucleoside/nucleotide analogue prevents recurrent HBV in the vast majority of cases. With the advent of potent drugs with a high barrier to resistance, such as tenofovir or entecavir, the utility of immune globulins is debated.

PROGNOSIS

Every year, approximately 0.5% of inactive HBsAg carriers spontaneously lose HBsAg, and most of them acquire anti-HBs antibodies. Reactivations are possible in inactive HBV carriers, especially if they become immunosuppressed, such as when they are treated for other conditions with corticosteroids, rituximab, or other chemotherapeutic agents. HBV reactivations often evolve into a subfulminant or fulminant form.

The risk of cirrhosis (Chapter 153) in chronic hepatitis B is 2 to 10% per year, and it is significantly associated with a higher HBV DNA level, older age, alcohol consumption, coinfection with other hepatotropic viruses, and coinfection with human immunodeficiency virus (HIV). The cumulative incidence of liver decompensation is about 15 to 20% at 5 years in patients with compensated cirrhosis. The complications of cirrhosis, including

hepatocellular carcinoma, are among the main causes of mortality in HBV-infected patients, and the annual incidence of death is about 3 to 4%.

The likelihood of developing hepatocellular carcinoma (Chapter 196) is approximately 1% per year in patients without cirrhosis and 2 to 8% per year in those with cirrhosis, and it is significantly associated with a higher HBV DNA level, male sex, old age, reversion from anti-HBe–positive to HBeAg-positive, and coinfection with other hepatotropic viruses. HBV carriers at risk for hepatocellular carcinoma should be screened every 6 to 12 months, with an ultrasound examination and an α-fetoprotein level.

CHRONIC HEPATITIS C

EPIDEMIOLOGY

HCV, which is present on all continents, is estimated to cause chronic infection in approximately 185 million individuals, or approximately 3% of the world's population. The prevalence of chronic HCV infection, which varies geographically, is estimated to be about 1.3% in the United States (affecting 2.7 million individuals),[2] 3.5% in Asia, 1.9% in the Americas overall, 5.2% in Africa, 1.7% in Europe, and 1.8% in Oceania. The highest prevalence is in Egypt (9% overall, but up to 40% in certain rural areas), where infection was initially spread by intramuscular injections for schistosomiasis during treatment campaigns several decades ago. By 2007, hepatitis C virus superseded HIV as a cause of death in the United States.

PATHOBIOLOGY

Acute HCV infection evolves into chronic infection in 50 to 80% of cases. Even patients who spontaneously recover and maintain detectable anti-HCV antibodies are not protected against reinfection. Persistence of infection is related to a qualitatively and quantitatively altered CD4+ T-helper cell and cytotoxic T lymphocyte response that fails to eradicate infection. The plasticity of the viral genomes is responsible for the coexistence of closely related but genetically different viral populations in equilibrium in the patient's replicative environment. This genetic diversity allows continuously generated variant viral populations to be selected by timely changes in the replicative environment.

Chronic HCV infection is responsible for necroinflammatory lesions of varying severity, sometimes associated with steatosis, which is the accumulation of triglycerides in hepatocytes. HCV is not a cytopathic virus. Liver injury in chronic hepatitis C is related to the action of immune effectors that recognize and kill infected hepatocytes that express HCV antigens at their surface. Chronic inflammation triggers fibrogenesis through the activation of hepatic stellate cells. Fibrosis progresses at nonlinear rates that are generally faster in older patients, in males, and in the presence of chronic alcohol intake, viral coinfections, or immunosuppression. The severity of chronic hepatitis is independent of the HCV RNA level and of the HCV genotype. This chronic inflammation and progression of fibrosis predispose patients to cirrhosis (Chapter 153) and hepatocellular carcinoma (Chapter 196).

CLINICAL MANIFESTATIONS

Acute hepatitis C (Chapter 148) is most often asymptomatic and therefore undiagnosed. The most common symptom associated with chronic HCV infection is fatigue, but it may remain inapparent for years. ALT levels are usually moderately elevated and fluctuate, but they can remain normal for weeks to months despite active hepatitis on liver biopsy. Moderate cholestasis can be present in patients with cirrhosis. Patients with cirrhosis (Chapter 153), hepatocellular carcinoma (Chapter 196), or both have the typical signs associated with these conditions.

HCV is the main cause of type II and type III mixed cryoglobulinemia (Chapter 187). Low levels of circulating cryoglobulins, which contain HCV RNA, anti-HCV antibodies, rheumatoid factor, and low levels of complement, can be found in 50 to 70% of cases, whereas elevated rheumatoid factor (Chapter 264) is found in 70% of cases. Fewer than 1% of HCV-infected patients develop symptoms of cryoglobulinemic vasculitis (Chapter 270), including fatigue, myalgias, arthralgias, rash (purpura, hives, leukocytoclastic vasculitis), neuropathy, and membranoproliferative glomerulonephritis. Cryoglobulinemia can be severe and lead to end-stage renal disease or severe neuropathies, and long-term cryoglobulinemia has been linked to non–Hodgkin B-cell lymphomas (Chapter 185).

Low titers of antinuclear and anti–smooth muscle antibodies can be found in HCV-infected patients, but they do not have any clinical significance. HCV has been reported to trigger the symptoms of porphyria cutanea tarda (Chapter 210), and an association with lichen planus (Chapter 438) has been suggested.

DIAGNOSIS

Chronic HCV infection is defined by the persistence of HCV RNA for more than 6 months. In patients with clinical, biologic, or both signs of chronic liver disease, chronic hepatitis C is diagnosed by the simultaneous presence of anti-HCV antibodies and HCV RNA. Detectable HCV replication in the absence of anti-HCV antibodies is observed almost exclusively in patients who are profoundly immunosuppressed, on hemodialysis, or agammaglobulinemic. In the United States, screening for HCV is recommended in high-risk individuals, and one-time screening is recommended in all persons born between 1945 and 1965 (Chapter 15).[3] The level of HCV replication does not correlate with the severity of liver disease or with the risk for progression to cirrhosis or hepatocellular carcinoma.

The HCV genotype, which has important therapeutic implications, should be determined. Anti-HCV IgM, which is found in approximately 50% of patients with chronic hepatitis, is of no significance. Laboratory testing often reveals high levels of monoclonal rheumatoid factor and cryoglobulins.

TREATMENT

Chronic HCV infection is curable. The goal of therapy is to achieve a sustained virologic response, defined by undetectable HCV RNA at 12 to 24 weeks after the end of therapy using a sensitive HCV RNA assay with a lower limit of detection of 10 to 20 IU/mL.[4]

The decision to treat chronic hepatitis C depends on a precise assessment of the severity of liver disease, the presence of absolute or relative contraindications to therapy, and the patient's willingness to be treated. Treatment typically requires a liver biopsy, but serologic markers of liver fibrosis, fibrogenesis, or both and transient elastography or acoustic radiation force impulse imaging have been validated in large series of patients with chronic hepatitis C. In patients with no indication for therapy or with contraindications to therapy, repeated assessments of aminotransferase levels are recommended on a yearly basis. Assessment of liver inflammation and fibrosis by liver biopsy or noninvasive serologic or ultrasound-based testing is indicated for patients with persistently or intermittently elevated aminotransferase levels.

Treatment strategies for chronic hepatitis C are evolving rapidly. Options vary in different countries based on the availability of newer medications.[5,6]

Historic Standard Therapy

For more than 15 years, the standard treatment for chronic hepatitis C has been the combination of ribavirin (0.8 to 1.4 g/day PO) with either pegylated IFN-α2a (180 μg subcutaneously [SC] once weekly) or pegylated IFN-α2b (1.5 μg/kg SC once weekly). This therapy yields sustained virologic response rates of the order of 50% in patients infected with HCV genotype 1 and 75-80% in those infected with HCV genotypes 2 or 3. Two inhibitors of the HCV protease, telaprevir (750 mg every 8 hours or 1250 mg every 12 hours PO) and boceprevir (800 mg every 8 hours PO), have been approved for use in combination with pegylated IFN-α and ribavirin exclusively in patients infected with HCV genotype 1, in whom this regimen yields sustained virologic response rates of the order of 65 to 75%. These regimens remain the only available treatments in many areas of the world where new therapies are not yet available.

The most common side effects of IFN-α are influenza-like symptoms (which can be prevented by acetaminophen), neutropenia, thrombocytopenia, irritability, difficulty concentrating, memory disturbances, thyroiditis, hair loss, sleep disorders, and weight loss. The principal side effect of ribavirin is hemolytic anemia. As a result of these side effects, dose modification is frequently required during therapy. Ribavirin should be decreased in 200-mg increments in patients with severe anemia. For IFN-induced side effects, the pegylated IFN-α dose should be decreased stepwise, from 180 to 135 to 90 μg/week for pegylated IFN-α2a, and from 1.5 to 1 to 0.5 μg/kg/week for pegylated IFN-α2b. In more than 50% of cases, telaprevir administration is associated with rash, which can be severe in approximately 5% of cases and can rarely manifest as *d*rug *r*eaction with *e*osinophilia and *s*ystemic *s*ymptoms (DRESS) syndrome or Stevens-Johnson syndrome. Boceprevir induces dysgeusia. Both telaprevir and boceprevir aggravate ribavirin-induced anemia.

The main contraindications to therapy with pegylated IFN-α and ribavirin are decompensated liver disease, renal failure, severe immunosuppression, solid organ transplantation, cytopenias, severe psychiatric disease, and active substance abuse. Ribavirin is also contraindicated in patients with anemia, significant coronary or cerebrovascular disease, or renal insufficiency. Because ribavirin is teratogenic, it is essential that adequate contraception be practiced during therapy and for at least 6 months thereafter in both men and women.

Newly Available Regimens

New treatment regimens (Chapter 360), which provide a sustained virologic response for 80 to 95% of patients, have changed the approach to hepatitis C in countries in which they are available.[7] Simeprevir (150 mg/day PO), which is an inhibitor of the HCV protease, has antiviral activity against genotypes 1 and 4 and a low barrier to resistance. Sofosbuvir (400 mg/day PO), which is a

nucleotide analogue inhibitor of the HCV RNA-dependent RNA polymerase, is active against all HCV genotypes with a high barrier to resistance. Both drugs are well tolerated. Adverse reactions in patients receiving simeprevir are rash (including photosensitivity), pruritus, and nausea, as well as mild, transient hyperbilirubinemia not accompanied by changes in other liver parameters. The only side effects reported with sofosbuvir are headache and fatigue.

In patients for whom therapy is deemed appropriate, treatment is guided by the patient's HCV genotype and eligibility for pegylated IFN-α administration. Patients infected with HCV genotype 1 should be treated with one of five regimens: daily sofosbuvir plus weight-based ribavirin plus weekly pegylated IFN-α for 12 weeks; daily sofosbuvir plus daily simeprevir with or without weight-based ribavirin for 12 weeks; daily simeprevir plus weight-based ribavirin plus weekly pegylated IFN-α for 12 weeks followed by 12 weeks of pegylated IFN-α and ribavirin in treatment-naïve patients and for 36 weeks in treatment-experienced patients; the combination of sofosbuvir with the NS5A inhibitor ledipasvir in one single pill with or without weight-based ribavirin for 12 weeks; or the combination of ritonavir-boosted paritaprevir, ombitasvir, and dasabuvir with or without weight-based ribavirin for 12 or 24 weeks. The combination of simeprevir, pegylated IFN-α, and ribavirin should not be used in patients who are infected with HCV subtype 1a with a detectable Q80K substitution in the HCV protease sequence before therapy and who should benefit from the other options.

Patients infected with HCV genotype 2 must be treated with daily sofosbuvir plus ribavirin for 12 weeks (eventually combined with pegylated IFN-α if the patient has failed prior therapy). Patients infected with HCV genotype 3 should be treated with either of two regimens: daily sofosbuvir plus weight-based ribavirin for 24 weeks or daily sofosbuvir plus weight-based ribavirin plus pegylated IFN-α for 12 weeks.

Patients infected with HCV genotype 4 should be treated with one of three regimens: daily sofosbuvir plus weight-based ribavirin plus weekly pegylated IFN-α for 12 weeks; daily sofosbuvir plus daily simeprevir with or without weight-based ribavirin for 12 weeks; or daily simeprevir plus weight-based ribavirin plus weekly pegylated IFN-α for 12 weeks followed by 12 weeks of pegylated IFN-α and ribavirin in treatment-naïve patients and 36 weeks in treatment-experienced patients. Patients infected with HCV genotypes 5 or 6 should be treated with daily sofosbuvir plus weight-based ribavirin plus weekly pegylated IFN-α for 12 weeks.[6]

Emerging Regimens

Numerous new anti-HCV drugs are in clinical development. They include protease inhibitors, nucleoside/nucleotide analogues, and non-nucleoside inhibitors of the HCV RNA-dependent RNA polymerase, inhibitors of the nonstructural 5A protein of HCV, and cyclophilin A inhibitors. Oral regimens with sustained virologic response rates greater than 90% are rapidly replacing IFN-based therapies.[6-8] Treatment regimens likely to become available soon include the combination of sofosbuvir with the NS5A inhibitor daclatasvir; and the triple combination of the protease inhibitor paritaprevir boosted by ritonavir, the NS5A inhibitor ombitasvir, and the non-nucleoside inhibitor of the HCV polymerase dasabuvir, with or without ribavirin.

End-Stage Disease

In patients with end-stage liver disease, liver transplantation (Chapter 154) is the only option. However, in the absence of treatment, the graft becomes infected in 100% of patients who are viremic at the time of transplantation. Treatment with daily sofosbuvir and ribavirin until liver transplantation (up to 48 weeks) efficiently prevents graft infection when HCV RNA has been undetectable for at least 30 days before transplantation.

PROGNOSIS

Spontaneous HCV clearance in patients with chronic hepatitis C is exceptional. The HCV RNA level has no prognostic value in chronic hepatitis C. An estimated 20% of patients with chronic hepatitis C develop cirrhosis (Chapter 153) after an average of 20 years of progression in the absence of therapy. Cirrhosis remains compensated for many years in the vast majority of patients, but decompensation occurs at an annual rate of 2 to 5% in cirrhotic patients. After a first decompensation, the mortality rate related to portal hypertension, hepatocellular insufficiency, and hepatocellular carcinoma is 10% per year, with a 50% survival rate at 5 years. The risk for death increases with advancing age, male gender, and the severity of cirrhosis.

Hepatocellular carcinoma (Chapter 196) is rare in patients with chronic hepatitis C without cirrhosis. In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2 to 4% per year, most often in patients with compensated cirrhosis. HCV has become the most common cause of hepatocellular carcinoma in most industrialized countries. However, hepatocellular carcinoma is less likely to develop in patients who have a sustained virologic response to treatment,[9] so this risk will hopefully decline now that better treatments are available.

Long-term follow-up shows that HCV does not recur in greater than 99% of patients who achieve a sustained virologic response, even in those who are immunosuppressed or receive chemotherapy. However, the liver disease may continue to evolve even after the infection has been eradicated. In addition, patients with chronic hepatitis C should abstain from alcohol and, unless there are other contraindications, should be vaccinated for hepatitis A and B (Chapter 18).

CHRONIC HEPATITIS D

EPIDEMIOLOGY

HDV infection occurs only in HBsAg carriers. Only approximately 2% of patients acutely coinfected with HDV and HBV develop chronic hepatitis D. In chronic HBV carriers superinfected by HDV, however, 90% of patients become chronic HDV carriers.

CLINICAL MANIFESTATIONS

Chronic hepatitis D is generally severe, with more than 80% of patients developing cirrhosis. Compared with patients who have chronic hepatitis B alone, patients with chronic infection with both HBV and HDV are three times as likely to develop hepatocellular carcinoma and twice as likely to die.

DIAGNOSIS

Markers of HDV infection should be sought at least once in every chronic HBsAg carrier. Both total anti-HD antibodies and anti-HD IgM remain at high levels in chronic HDV infection, and HDV RNA is present. Although all chronic HDV carriers also are chronic HBsAg carriers, chronic HDV carriers generally have low or undetectable HBV DNA levels because HDV inhibits HBV replication.

TREATMENT

Rx

High doses (9 million units three times/week for 1 year) of standard, nonpegylated IFN-α result in sustained normalization of ALT levels 24 weeks after the end of therapy in approximately 50% of cases, sometimes for as long as 20 years. Some patients clear HDV RNA and, eventually, HBsAg.

Pegylated IFN-α2b, 1.5 μg/kg once weekly for 12 months, provides a sustained virologic response in 20 to 40% of cases. Although there is no clear consensus, most experts now recommend 1 year of pegylated IFN-α as first-line treatment of chronic HDV infection.

PREVENTION

Chronic HDV infection is best prevented by preventing primary HBV infection, because individuals who are protected against HBV cannot be infected with HDV. In chronic HBsAg carriers, standard hygiene and behavioral precautions should be practiced to avoid superinfection with HDV. Once acute HDV infection occurs, no secondary prevention strategy is successful.

CHRONIC HEPATITIS E

HEV infection is usually an acute self-limiting disease, but in developed countries it causes chronic infection with rapidly progressive cirrhosis in organ transplant recipients, patients with hematologic malignancies that require chemotherapy, and immunosuppressed HIV-infected individuals, either from a latent virus reactivated by immunosuppression or from a virus transmitted at the time of transplantation. Almost all cases of chronic infection have been in immunosuppressed patients.[10,11]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Chronic hepatitis E occurs after transplantation. Diagnosis is based on the detection of anti-HEV IgM antibodies. HEV RNA also can be detected in blood or feces, where its presence is transient. Solid organ transplant recipients with chronic hepatitis E harbor repeatedly positive anti-HEV antibodies and HEV RNA in blood.

TREATMENT AND PREVENTION

Rx

There is no validated treatment of chronic HEV infection. Ribavirin (600 mg/day),[12] pegylated IFN, or a combination of the two has been used in small case series. Reducing the level of immunosuppression can result in viral clearance in approximately one third of patients. Whether candidates for transplantation or immunosuppressive therapies should be vaccinated to prevent chronic HEV infection remains to be determined.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis is a chronic inflammatory liver disorder characterized by the presence of autoantibodies in serum, high levels of serum immunoglobulins, and a frequent association with other autoimmune diseases.[13]

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoimmune hepatitis typically manifests between the ages of 15 and 25 years or between the ages of 45 and 60 years, and it is more common in women. The incidence rate is approximately 1.7 per 100,000 population per year.[14] Along with primary biliary cirrhosis (Chapter 155) and primary sclerosing cholangitis (Chapter 155), autoimmune hepatitis is one of the three major autoimmune liver diseases.

Autoimmune hepatitis is believed to be caused by autoimmune reactions against normal hepatocytes in genetically predisposed persons or persons exposed to unidentified triggers of an autoimmune process against liver antigens. Associations are seen with the human leukocyte antigen (HLA) class I B8 and class II DR3 and DR52a loci. In Asians, autoimmune hepatitis is associated with HLA DR4.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Autoimmune hepatitis tends to be more severe at its onset than chronic hepatitis B or C, and it progresses to end-stage liver disease if not treated with immunosuppression. Although it is occasionally detected by elevated serum aminotransferase levels on a routine health evaluation, most patients present with fatigue and jaundice. Elevations of bilirubin or alkaline phosphatase indicate more severe or advanced disease. Patients typically have marked elevations in serum γ-globulin, specifically immunoglobulin G, as well as autoantibodies directed at non–organ-specific cellular constituents.

Type 1 (classic) autoimmune hepatitis is characterized by the presence of titers of 1 : 80 or higher (>1 : 20 in children) of antinuclear, anti–smooth muscle, antiactin, and anti-asialoglycoprotein receptor antibodies. Type 2 autoimmune hepatitis is characterized by similar elevations of anti–liver-kidney microsomal 1 antibodies and anti–liver cytosol 1 antibodies, without antinuclear or anti–smooth muscle antibodies. Liver biopsy shows features that are typical of all chronic types of hepatitis, except plasma cell infiltrates.

TREATMENT

Rx

The clinical symptoms and liver test abnormalities of autoimmune hepatitis generally respond promptly to prednisone, usually at a dose of 20 to 30 mg/day, with a decrease in serum aminotransferase levels to the normal or near-normal range within 1 to 3 months; higher doses may be required in patients with more severe disease. Lack of a biochemical or clinical response should lead to reevaluation of the diagnosis. Azathioprine 50 to 100 mg can be combined with prednisone or added later to reduce long-term steroid side effects. Maintenance doses, which are typically required indefinitely, are often 5 to 10 mg/day of prednisone combined with 50 to 150 mg/day of azathioprine. Sometimes patients can be maintained on azathioprine (2 mg/kg/day) alone. After 3 years or more of remission, therapy can be carefully withdrawn, but severe and even fatal flares can occur weeks to months later.

PROGNOSIS

The prognosis is generally related to the histologic stage of the disease. Patients who initially respond to therapy may do well for many years. Patients who progress to end-stage liver disease require liver transplantation (Chapter 154).[15]

CRYPTOGENIC CHRONIC LIVER DISEASE

Cryptogenic chronic liver disease refers to chronic hepatitis or cirrhosis of unknown cause after excluding hepatitis B, C, D, and E; autoimmune hepatitis; steatohepatitis (Chapter 152); alcoholic liver disease (Chapter 152); drug-induced hepatitis (Chapter 150); and inherited and metabolic liver diseases (Chapter 146). Tests to exclude these conditions include serum levels of α_1-antitrypsin, iron, and ceruloplasmin and, if necessary, urine and liver copper concentrations. In its later stages, nonalcoholic steatohepatitis may be associated with little or no fat.

REVIEW QUESTIONS

1. Which of the following viruses can cause chronic hepatitis?

A. Only hepatitis A virus
B. Hepatitis B and C viruses
C. Hepatitis B, C, and D viruses
D. Hepatitis B, C, D, and E viruses
E. Hepatitis A, B, C, D, and E viruses

Answer: D Hepatitis A virus never causes chronic infection and related liver disease. HBV infection becomes chronic in 95% of infants at birth and in less than 1% of adults. HCV infection becomes chronic in approximately 80% of cases. HDV infection rarely becomes chronic in cases of coinfection but almost systematically becomes chronic in case of superinfection in a chronic HBV carrier. HEV infection can become chronic in immunosuppressed patients.

2. Which of the following viruses are the main causes of hepatocellular carcinoma (primary liver cancer) worldwide?

A. Only hepatitis A virus
B. Hepatitis A and B viruses
C. Hepatitis B and C viruses
D. Hepatitis A and C viruses
E. Hepatitis C and E viruses

Answer: C Because of the prevalence of their chronic infection, their carcinogenic properties, and their ability to induce cirrhosis after many years of infection, both HBV and HCV currently are the main causes of hepatocellular carcinoma, with a predominance of HBV in developing regions and HCV in industrialized regions.

3. Which of the following sentences about hepatitis E virus (HEV) is true?

A. HEV infections are always self-limiting.
B. Chronic HEV infection occurs exclusively in immunosuppressed patients.
C. HEV infection cannot be diagnosed biologically.
D. The treatment of chronic HEV infection is based on antiviral molecules active only against HEV.
E. HEV RNA is never detected in blood.

Answer: B HEV infection is generally self-limiting but may become chronic in immunosuppressed patients. It is diagnosed by the presence of anti-HEV antibodies, in particular anti-HEV IgM at the acute stage, although HEV RNA can be detected in feces and blood. Treatment is based on the use of pegylated IFN-α and/or ribavirin, nonspecific antiviral molecules that are also used in the treatment of chronic hepatitis B or C.

TOXIN- AND DRUG-INDUCED LIVER DISEASE

WILLIAM M. LEE

DEFINITION

Toxin-induced and drug-induced hepatotoxicity, defined as any degree of liver injury caused by a drug or a toxic substance, is a frequent cause of acute liver injury and accounts for more than 50% of all cases of acute liver failure with hepatic encephalopathy in the United States. Hepatotoxicity has been described with many drugs, although the number of cases is low, given the number of prescriptions written.[1]

EPIDEMIOLOGY

Few data are available on the epidemiology of toxin-induced and drug-induced liver disease. The precise number of drug-induced liver injuries in the United States is unknown, but European data on adverse drug reactions indicate approximately 20 cases of drug-induced liver disease per 1 million people per year.[2] In developing parts of the world, drug-induced liver disease is much less common and is related to fewer drugs. It is estimated that less than 10% of actual cases are reported, so the true incidence of toxin-induced and drug-induced liver disease may be difficult to determine except in relatively closed populations.

PATHOBIOLOGY

The liver is central to the metabolism of exogenous substances. Most drugs and xenobiotics cross the intestinal brush border because they are lipophilic.

Biotransformation is the process by which lipophilic therapeutic agents are rendered more hydrophilic by the liver, resulting in drug excretion in urine or bile. In most instances, biotransformation changes a nonpolar to a polar compound through several steps. Foremost are oxidative pathways (e.g., hydroxylation) mediated by the cytochromes (CYPs) P-450 (Chapter 29). The next step is typically esterification to form sulfates and glucuronides, a process that results in the addition of highly polar groups to the hydroxyl group. These two enzymatic steps are referred to as *phase I* (CYP oxidation) and *phase II* (esterification). Other important metabolic pathways involve glutathione-*S*-transferase, acetylating enzymes and alcohol dehydrogenase, but the principal metabolic pathways for most pharmacologic agents involve CYPs and subsequent esterification.

Pathogenesis

The exact details of the pathogenesis of liver injury are unclear for most drugs.[3] A single drug may cause toxic effects in several ways. One overarching approach suggests that high-energy unstable metabolites of the parent drug, the result of CYP activation, bind to cell proteins or DNA and disrupt cell function. Perhaps the best example is acetaminophen. Although used universally for non-narcotic pain relief, acetaminophen, when taken in large quantities, causes profound centrilobular necrosis. The metabolic pathway of acetaminophen involves phase I and phase II reactions, glutathione detoxification, and the formation of reactive intermediates (E-Fig. 150-1). The presence of alcohol, which competes for CYP P-450 2E1, not only inhibits the formation of *N*-aminoparaquinoneamine (NAPQI) but also induces the enzyme so that its half-life is slowed and more enzyme is present. After the cessation of alcohol ingestion, NAPQI formation is enhanced by the presence of the induced enzyme and the lack of competition from alcohol. Toxicity is a dynamic process and may be most pronounced in the 24 hours after the cessation of alcohol. Glucuronidation and sulfation occur as the initial detoxifying step because the parent compound contains a hydroxyl group. Glucuronidation and sulfation capacity greatly exceeds daily needs, so even patients with very advanced liver disease continue to have adequate glucuronidation capacity, which explains why no obvious enhancement of toxicity is observed when cirrhotic patients take acetaminophen.

TABLE 150-1 FACTORS THAT MAY INFLUENCE THE METABOLIC FATE OF DRUGS

AGE
The elderly seem to be affected more often; adults are more susceptible than children to some drugs (acetaminophen, halothane, isoniazid) and less susceptible to others (aspirin, valproic acid)
ALCOHOL: ACUTE AND CHRONIC INGESTION
Induction of CYP2E1 affects drugs metabolized by this pathway, including acetaminophen and isoniazid
GENDER
Females are affected more often, but the reason is unknown
PREGNANCY
Effects of drugs in pregnancy have been poorly studied
PREEXISTING LIVER DISEASE
Hepatic disease may *protect* against idiosyncratic reactions and may *enhance* the toxicity of dose-dependent hepatotoxins (e.g., acetaminophen)
RENAL DISEASE
Slowed disappearance of the parent compound yields higher concentrations and affects P-450 (e.g., enhancement of tetracycline toxicity in renal disease)
CERTAIN FOODS
Grapefruit has an unknown substance that interferes with the metabolism of some drugs
CONCOMITANT DRUGS
Drug-drug interactions are common causes of adverse effects (e.g., valproate and chlorpromazine together lead to enhanced cholestasis)
GENETIC FACTORS
Enzyme polymorphisms (e.g., enhanced phenytoin liver disease in patients with defective epoxide hydrolase activity), HLA phenotypes (e.g., nitrofurantoin susceptibility)

Genetics

Enzyme Polymorphism

Although acetaminophen is a dose-related toxin, the rarity of idiosyncratic drug toxicity (1 in 10,000 patients) suggests the importance of environmental and host factors (Table 150-1). Genetically variant CYP isoenzymes may partially explain the observed individual variation in response to drugs. An example is debrisoquine, an antihypertensive drug marketed in Europe that is hydroxylated by CYP2D6, an isoform that is totally absent in 5% of normal individuals. Lack of CYP2D6 greatly prolongs the half-life of the parent compound in affected individuals. Another example is the phenomenon of fast versus slow acetylation, which affects different ethnic groups and has been implicated in the differential metabolism of isoniazid. Most of the known genetic variants that occur relatively frequently, however, cannot explain the formation of a toxic intermediate in only a rare individual.

Most drugs are small organic compounds, unlikely to evoke an immune response. Although some toxic drug reactions are associated with an obvious allergic response, most are not. Nevertheless, immune mechanisms not associated with systemic allergic immunoglobulin E (IgE) reactions or skin hypersensitivity might be involved. Studies suggest that the products of CYP P-450 metabolism, the highly reactive intermediates formed within the microsomes, covalently bind to the enzyme itself to form a drug-hapten adduct that disables the enzyme and injures the cell. Haptenization then evokes an immune response directed against the newly formed antigen or neoantigen. P-450s have been shown to traffic to the plasma membrane, thereby allowing the drug–P-450 adduct to become the target of a subsequent cytolytic attack. It is unclear whether the targets are these adducts or the smaller peptides processed and presented by the major histocompatibility complex class I and class II schemes. The association among neoantigens, autoantibodies, and hepatotoxic drugs implicates an immunologic mechanism, as does latency, which is the delay between the first ingestion and evidence of toxicity.[4]

Regardless of whether an individual drug causes significant cell necrosis, the drug–P-450 adducts can evoke an immune response. Any subsequent drug–P-450 adduct present on the hepatocyte surface would evoke a further response. Responses may be antibody mediated or occur as a result of direct cytolytic attack by primed T cells. Specific genetically determined components of the immune response may be important. A specific human leukocyte antigen (HLA) haplotype has been associated with hepatitis induced by amoxicillin-clavulanate and other polymorphisms encoding for increased susceptibility have been identified. However, it is unlikely that a single polymorphism will be found for most hepatocellular reactions, even when the phenotype of injury is well-characterized, such as for isoniazid. For every patient with a severe injury caused by drugs, there are often many more individuals with asymptomatic aminotransferase elevations that subsided despite continuing the drug—sometimes referred to as an *adaptive response.*

Other Mechanisms

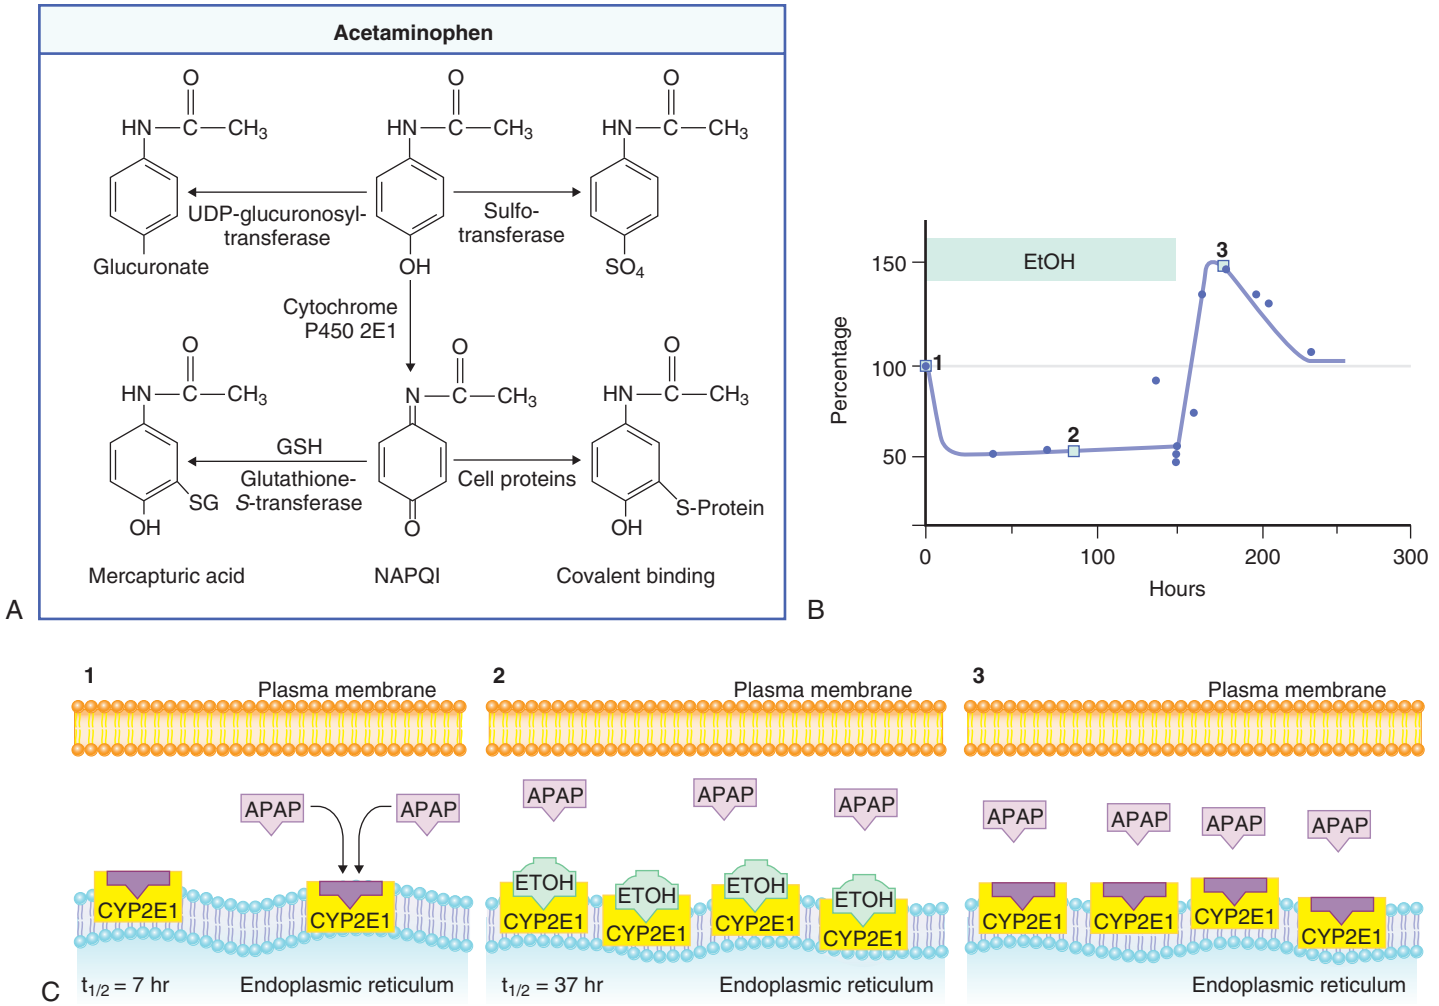
In drug-induced cholestasis, disruption of specific transport channels in hepatocytes or cholangiocytes may be the key event. Estrogen or androgenic steroids may cause multiple canalicular membrane transport changes that affect, among others, the canalicular bile salt pump. For a few drugs, a specific uncoupling of mitochondrial respiration may lead to microvesicular steatosis and lactic acidosis.

Hepatotoxic Agents

Although there are a few dose-related toxins, most drugs involved in liver disease cause idiosyncratic, unpredictable toxicity.[5] The use of herbal and dietary supplements and the toxicity resulting from them appears to be increasing in the United States. Most common are body building supplements containing androgenic steroids that lead to severe cholestasis; weight loss products may cause hepatocellular injury of varying severity, including occasional fatalities.[6]

Intrinsic (Dose-Dependent) Agents

Acetaminophen (see later) and a few other agents seem to have a clear dose-response effect, although idiosyncrasy usually plays a role as well (Table 150-2). Some toxins, such as α-amanitine produced by *Amanita* mushrooms, cause dose-related injury. *Amanita* poisoning may occur after ingestion of the mushrooms *Amanita phalloides* (death cap) or *Amanita virosa* (deadly agaric). The dose-dependent toxic effect on the liver is attributed to amatoxin, an ingredient of the mushrooms that enhances the toxic effect by its enterohepatic recirculation characteristics; the toxic effect is exerted on each cycle of the recirculation through the liver.



E-FIGURE 150-1. Acetaminophen metabolism. Although acetaminophen (*APAP*) is metabolized largely by sulfation or glucuronidation under normal conditions, exceeding the recommended dose increases the proportion metabolized by cytochrome P-450 2E1, which leads to the highly reactive intermediate *N*-aminoparaquinoneamine (*NAPQI*) (**A**). This compound leads to liver injury unless scavenging by glutathione yields the inert, water-soluble mercapturic acid. The presence of alcohol (*EtOH*), which competes for cytochrome P-450 2E1, not only inhibits NAPQI formation but also induces the enzyme so that its half-life is slowed and more enzyme is present (**B** and **C**). After cessation of alcohol, NAPQI formation is enhanced by the presence of the induced enzyme and the lack of competition from alcohol. Toxicity is a dynamic process and may be most pronounced in the 24 hours after cessation of alcohol. (Modified from Thummel KE, Slattery JT, Ro H, et al. Ethanol exposure and acetaminophen hepatotoxicity: inhibition and induction of hepatotoxic metabolite formation. *Clin Pharmacol Ther.* 2000;67:5991-5999.)

TABLE 150-2 DRUGS AND TOXINS IN WHICH A DOSE-RESPONSE EFFECT IS OBSERVED

DRUG OR TOXIN	RESPONSE
Acetaminophen	Total dose, single vs. multiple time points
Amiodarone	Total dose over time
Bromfenac	Toxicity occurs only after extended use
Cocaine	Dose-related vascular collapse
Cyclophosphamide	Dose related, worse with previous ALT elevations
Cyclosporine	Cholestasis with toxic blood levels, CYP3A phenotype
Methotrexate	Aminotransferase, fibrosis; single dose/total dose
Niacin	Large doses cause vascular collapse
Oral contraceptives	Prolonged use causes hepatic adenomas
Tetracycline	Total dose, renal dysfunction
Toxins (yellow phosphorus, carbon tetrachloride, *Amanita* toxin, bacterial toxins)	Total dose

ALT = alanine aminotransferase.

TABLE 150-3 TYPES OF TOXIN AND DRUG REACTIONS

REACTION TYPE	IMPLICATED DRUGS OR TOXINS
Autoimmune (attack on cell surface markers)	Lovastatin, methyldopa, nitrofurantoin
Cholestatic (attack on bile ducts)	Anabolic steroids, carbamazepine, chlorpromazine, estrogen, erythromycin
Fibrosis (activation of stellate cells leads to fibrosis)	Methotrexate, vitamin A excess
Granulomatous (macrophage stimulation)	Allopurinol, diltiazem, nitrofurantoin, quinidine, sulfa drugs
Hepatocellular (damage to smooth endoplasmic reticulum and immune cell surface)	Acetaminophen, *Amanita* poisoning, diclofenac, isoniazid, lovastatin, nefazodone, trazodone, venlafaxine
Immunoallergic (cytotoxic cell attack on surface determinants)	Halothane, phenytoin, sulfamethoxazole
Mixed (see earlier)	Amoxicillin-clavulanate, carbamazepine, cyclosporine, herbs, methimazole
Oncogenic (hepatic adenoma formation)	Oral contraceptives, androgenic agents
Steatohepatitis (mitochondrial dysfunction: β-oxidation and respiratory chain)	Amiodarone, perhexiline maleate, tamoxifen
Vascular collapse (ischemic damage)	Cocaine, ecstasy, nicotinic acid
Veno-occlusive disease (endotheliitis of sinusoidal endothelial cells)	Busulfan, cytoxan

Idiosyncratic Reactions

Drug reactions occur in 1 in 1000 to 1 in 200,000 patients. Characteristics of these idiosyncratic reactions include their infrequent occurrence, varying time intervals between the initial exposure and the reaction, and varying severity of reactions in affected individuals. There are also similarities such as "class effects" (similar drugs exhibit similar features; Table 150-3), a consistent pattern for each drug, and the fact that rechallenge with a responsible agent usually leads to a more severe reaction with a shorter latency than seen after the initial exposure.

Antibiotics, anticonvulsants, and nonsteroidal anti-inflammatory drugs are associated more frequently with drug-induced liver disease, whereas hormones, antihypertensive drugs, digoxin, and antiarrhythmic drugs are implicated rarely. In some cases, idiosyncratic reactions are so infrequent that a drug continues to be used if its effectiveness or uniqueness makes the risk acceptable. An example is isoniazid, which is among the few drugs implicated in drug-induced liver injury in developing countries. In individuals receiving isoniazid as a single agent for tuberculosis prophylaxis, increased aminotransferase levels may develop in 15 to 20%, but severe hepatic necrosis develops in only 0.1 to 1% (Chapter 324)—a rate that is high in comparison to idiosyncratic drug reactions, yet low enough for isoniazid, because of its effectiveness, to remain a key drug. Drugs that require relatively high dosing, more than 100 mg/day, and that have high lipophilicity are associated with most liver injury, not those at lower dose levels.[7]

CLINICAL MANIFESTATIONS

Patients may have few or nonspecific complaints despite very elevated aminotransferase levels. Clinical features include nausea, fatigue, occasional right upper quadrant pain, and nonspecific symptoms similar to those seen in other forms of acute hepatitis (Chapter 148). Fever or pharyngitis (typically seen in phenytoin reactions) may be present. No specific physical findings to raise suspicion of drug toxicity are noted, except possibly a rash. Any patient in whom jaundice develops is at risk for having a severe or fatal outcome, and patients who continue taking the drug despite jaundice are at highest risk.

DIAGNOSIS

Abnormal aminotransferase levels with the use of a new drug should raise the suspicion for a drug-induced reaction and prompt immediate discontinuation of the drug rather than awaiting diagnostic tests to confirm or exclude the diagnosis. Immediate discontinuation of medication at the first sign of liver disease can prevent most fatal liver injuries.

Evaluation of a patient with a suspected drug reaction is directed toward establishing the timeline for all drugs or herbs the patient may have taken. Responsible drugs have usually been started between 5 and 90 days before the onset of symptoms. Evidence of viral hepatitis (Chapters 148), gallstones (Chapter 155), alcoholic liver disease (Chapter 152), pregnancy (Chapter 239), severe right heart failure (Chapter 58), or a period of hypotension (Chapter 106) points to these specific causes. Less commonly, cytomegalovirus (Chapter 376), Epstein-Barr virus (Chapter 377), or herpesviruses (Chapters 374 and 375) can cause hepatic injury, primarily in immunosuppressed individuals. If all these causes can be excluded, the temporal relationship fits, and the patient begins to improve after withdrawal of the drug, the diagnosis is more secure. Liver biopsy is of limited value because the histologic picture in most cases of drug-induced liver injury is no different from that of viral hepatitis (Chapter 148). Nevertheless, an occasional liver biopsy specimen in an enigmatic case might reveal eosinophils or granulomas, consistent with a drug reaction.

Types of Drug Reactions

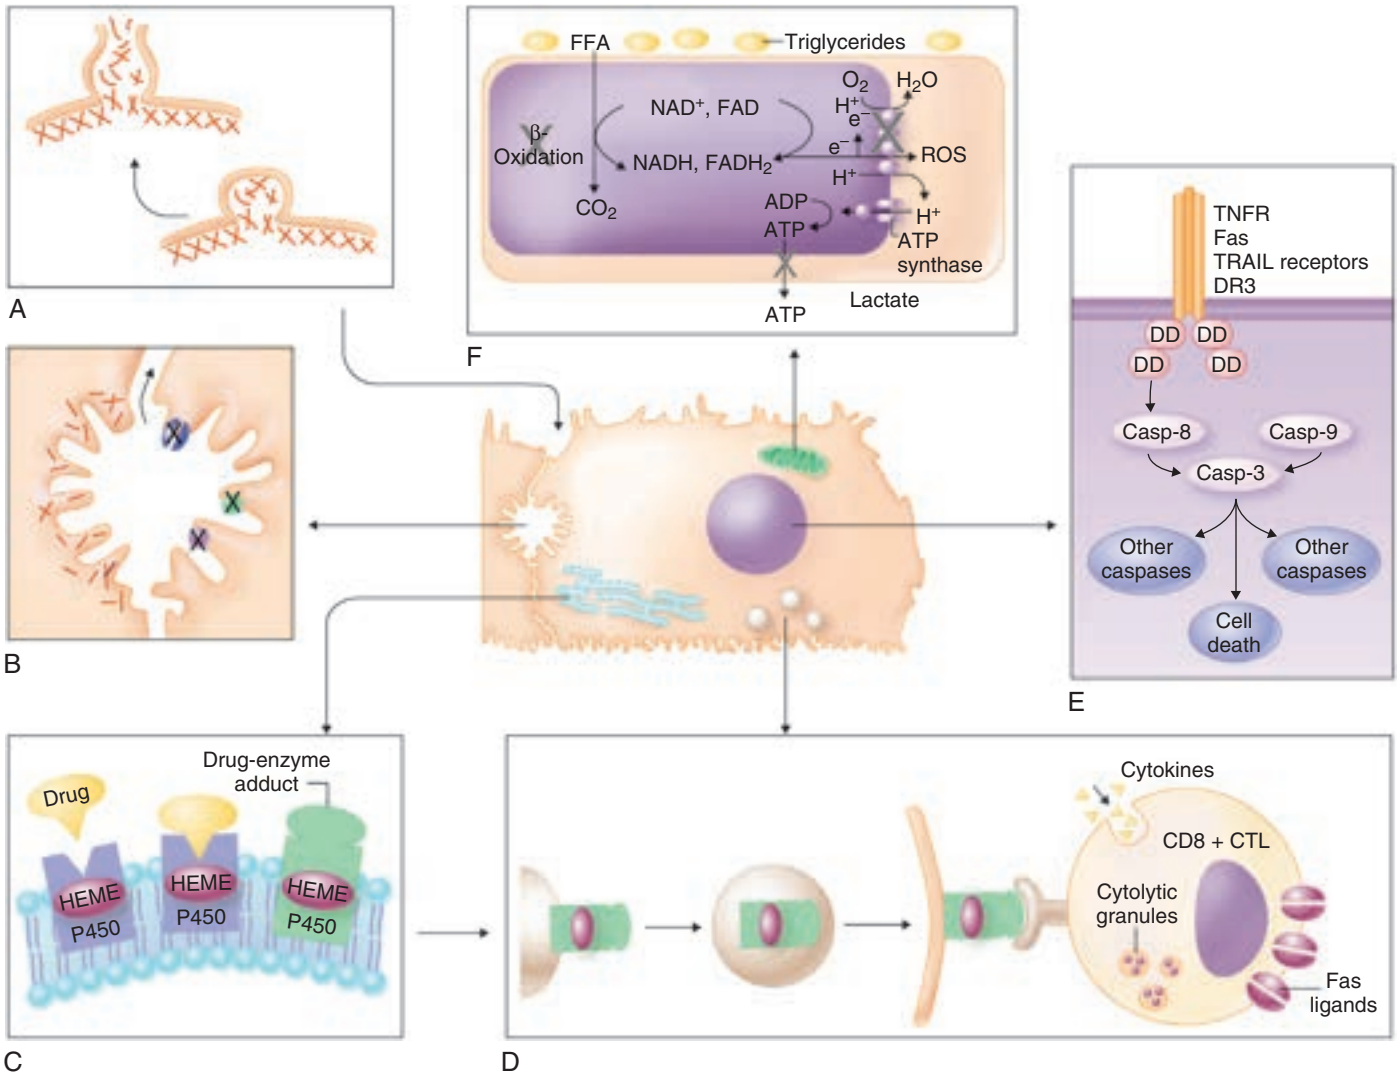
Although most liver injury involves direct hepatocyte necrosis or apoptosis (hepatocellular injury), some drugs injure primarily the bile ducts or canaliculi and cause cholestasis without significant damage to hepatocytes. Other drugs affect sinusoidal cells or present a particular pattern of liver injury affecting multiple cell types (mixed type). Another approach to drug reactions emphasizes the histologic changes involved and the cell type (see Table 150-3 and E-Fig. 150-2).

Hepatocellular Reactions

Hepatocellular reactions are the most common type of drug-induced liver disease and account for 90% of cases (Table 150-4). They are characterized by a pattern of serum liver test results that reflect hepatocellular injury. Usually, improvement is quick after discontinuation of the drug (1 to 2 months), and fulminant, acute liver failure with hepatic encephalopathy develops in only a few patients.

Histologic findings include necrosis and cellular infiltration. The necrosis may be zonal (e.g., induced by acetaminophen or carbon tetrachloride) or diffuse (e.g., induced by halothane), and the inflammatory response consists of lymphocytes or eosinophils. Massive necrosis may cause acute liver failure and death.

Acetaminophen toxicity is the most common form of acute liver failure in the United States and is the best understood example of direct hepatocyte toxicity. The incidence of acetaminophen poisoning varies widely throughout the world, but it is becoming more frequent and widespread. Liver injury occurs predictably after an intentional suicidal overdose (Chapter 110); it also occurs when acetaminophen is used in excessive doses or sometimes even in therapeutic doses for pain relief. Enhanced toxicity occurs when patients are fasting or are chronic alcohol users because of enzyme induction and depletion of glutathione by alcohol and fasting; by comparison, acute alcohol intake may protect against acetaminophen toxicity during the period of alcohol ingestion. Thereafter, a rebound increase in available CYP2E1 results in increased toxicity in the 12 hours after ingestion because of enzyme



E-FIGURE 150-2. Mechanisms of liver injury. Each form of liver injury targets specific organelles, although multiple organelles may be affected. The hepatocyte in the center may be affected in at least six ways. **A,** Disruption of intracellular calcium leads to actin fibril disassembly at the hepatocyte surface, which results in blebbing of the cell membrane and subsequent rupture and cell lysis. **B,** In cholestatic diseases, disruption of actin filaments may occur with the loss of villous processes. Interference with ion pumps limits the excretion of bilirubin and other organic compounds. **C,** Most hepatocellular reactions involve the cytochrome P-450 system. The high-energy reaction involved may lead to binding of drug to enzyme and create a new adduct. **D,** Enzyme-drug adducts may traffic to the cell surface and serve as target immunogens for cytolytic attack by T cells. **E,** Activation of apoptotic pathways results in cell death. **F,** Inhibition of β-oxidation or respiration in mitochondria results in microvesicular fat accumulation and lactic acidosis, a pattern characteristic of a variety of agents, including nucleoside analogues, tetracycline, and aspirin. ATP = adenosine triphosphate; FAD = flavin adenine dinucleotide; FFA = free fatty acid; NAD = nicotinamide adenine dinucleotide; ROS = reactive oxygen species; TNFR = tumor necrosis factor receptor. Modified from Danan G, Benichou C. Causality assessment of adverse reactions to drugs. I. A novel method based on the conclusions of international consensus meetings: application to drug-induced liver injuries. *J Clin Epidemiol.* 1993;46:1323-1330; and Benichou C, Danan G, Flahault A. Causality assessment of adverse reactions to drugs. II. An original model for validation of drug causality assessment methods: case reports with positive rechallenge. *J Clin Epidemiol.* 1993;46:1331-1336.
*Causality is highly probable (score >8), probable (score 6-8), possible (score 3-5), unlikely (score 1-2), or excluded (score ≤0).
†For cholestatic reactions, ≤ 30 days.
‡For cholestatic reactions, alcohol, or pregnancy.
§For cholestatic reactions, substitute alkaline phosphatase (or total bilirubin) for ALT.
ALT = alanine aminotransferase; AST = aspartate aminotransferase; CMV = cytomegalovirus; EBV = Epstein-Barr virus; HSV = herpes simplex virus; ULN = upper limit of normal.

induction (see E-Fig. 150-1). Patients with an unintentional acetaminophen overdose may fare worse than suicidal patients because the former seek treatment later in their course, even though suicidal patients take larger doses. The better outcome after an acute overdose may be explained by earlier medical attention and the use of *N*-acetylcysteine, an effective antidote. Nevertheless, one fifth of suicide attempts using acetaminophen are associated with severe liver injury and the potential for a fatal outcome.

The extremely elevated aminotransferase values (often > 6000 IU/L, and sometimes as high as 30,000 IU/L) observed in suicidal and unintentional acetaminophen ingestion help distinguish these cases from viral hepatitis or other drug injury. This signature of hyperacute injury (high aminotransferase levels, low bilirubin levels) are almost pathognomonic of acetaminophen injury, which can go unrecognized if a careful history is not elicited.[8] The availability of an antidote makes this diagnosis especially important. The antidote *N*-acetylcysteine (Chapter 110) may be given by nasogastric tube on admission and for the next 72 hours to provide glutathione substrate. The standard treatment is intravenous *N*-acetylcysteine beginning at a dose of 140 mg/kg in 300 mL of 5% dextrose given over 1 hour, followed by a dose of 70 mg/kg in 5% dextrose given over a 1-hour period every 4 hours for 48 hours. A loading dose of 140 mg/kg PO can be given, followed by 70 mg/kg every 4 hours for 17 doses (72 hours). Expected survival rates are greater than 80%, although liver transplantation is occasionally required.

Cholestatic Reactions

Cholestatic reactions have been described for many drugs. Cholestasis is best defined as failure of bile to reach the duodenum, and common symptoms are jaundice and pruritus. *Pure cholestasis,* with no signs of hepatocellular necrosis, is seen almost exclusively in patients taking oral contraceptives, anabolic steroids, or sex hormone antagonists such as tamoxifen. Acute *cholestatic hepatitis* is characterized histologically by cholestasis (dilated canaliculi, brown granules in the cytoplasm of hepatocytes), some degree of liver cell necrosis and bile duct injury, and inflammatory infiltration by polymorphonuclear leukocytes. Drugs that cause this type of reaction include carbamazepine, trimethoprim-sulfamethoxazole, captopril, and body building dietary supplements containing androgenic compounds

Generally, drug-induced cholestasis takes longer to resolve than drug-induced hepatotoxicity. In some cases, segments of the intrahepatic biliary tree may be destroyed progressively, the so-called vanishing bile duct syndrome that occurs after a protracted course (>6 months) of drug-induced cholestasis. The result is a state of chronic cholestasis that resembles primary biliary cirrhosis (Chapter 155). Approximately 30 drugs have been implicated in the vanishing bile duct syndrome, including levofloxacin and, occasionally, other antibiotics. A sclerosing cholangitis–like syndrome with jaundice caused by intrahepatic and extrahepatic strictures in the bile ducts is sometimes observed in patients receiving intra-arterial floxuridine chemotherapy for hepatic metastases of colorectal cancer.

Immunoallergic Reactions

Drugs also may be associated with definite allergic reactions. A combined toxic-immunologic mechanism is involved in liver injury caused by halothane, a fluorinated hydrocarbon anesthetic that causes severe, often fatal liver injury after multiple exposures (Chapter 432). Other fluorinated hydrocarbons, including isoflurane and desflurane, occasionally result in the same response. Although halothane has never been withdrawn, its use has been limited by the advent of safer agents. Hypersensitivity reactions, such as fever, eosinophilia, and rash, are common. Halothane may induce fever, eosinophilia, and antimitochondrial antibodies. Direct cytotoxicity and immune-mediated toxicity are observed, consistent with the clinical observation that severe halothane toxicity occurs with repeated exposure. Although evidence of injury can usually be identified within 1 week of the first exposure, the interval to toxicity is shortened and the damage is more severe with each successive exposure, as befits an immune reaction.

Phenytoin (Chapter 403) induces the simultaneous onset of fever, rash, lymphadenopathy, and eosinophilia. The mechanisms responsible for the combined allergic and hepatotoxic reaction are unknown, but the slow resolution of the illness suggests that the allergen remains on the surface of the hepatocyte for weeks or months. A concurrent mononucleosis-like picture is frequently confused with a viral illness or streptococcal pharyngitis. If phenytoin is not discontinued promptly despite signs of hepatitis, a severe Stevens-Johnson drug eruption (Chapters 439 and 440) and prolonged fever may result. As with any therapeutic agent, rapid recognition of the presence of a toxic drug reaction and immediate discontinuation of the compound are key to limiting hepatic damage. Systemic features of an allergic reaction may not be obvious, even when eosinophilia or granulomas are present on liver biopsy.

Steatohepatitis

Fatty liver disease (Chapter 152) related to the metabolic syndrome is increasingly evident in the United States and elsewhere. Differentiating this underlying condition from de novo fatty liver caused by a drug reaction can be difficult. In addition, certain agents such as statins may be associated with aminotransferase elevations independent of fatty liver disease. As a general rule, statins very rarely cause significant liver injury and should not be withheld from patients with hypercholesterolemia, even when fatty liver is present (Chapter 206). Steatosis in the liver (Chapter 152) can be present in a

microvesicular or macrovesicular pattern. Macrovesicular steatosis, the most common form, is characterized histologically by a single vacuole of fat filling up the hepatocyte and displacing the nucleus to the cell's periphery. Macrovesicular steatosis is typically caused by alcohol, diabetes, or obesity. Sometimes drugs such as corticosteroids or methotrexate may cause these hepatic changes. Amiodarone (Chapters 64 and 65) has been associated with a picture resembling alcoholic hepatitis, occasionally with progression to cirrhosis. The pathophysiology involves accumulation of phospholipids in the liver, eyes, thyroid, and skin. Treatment is primarily withdrawal of the drug and observation, although the half-life of amiodarone is prolonged. Tamoxifen, which has been used in long-term regimens for the prevention of recurrent breast cancer (Chapter 198), has also been associated with steatohepatitis evolving to cirrhosis.

In microvesicular steatosis, hepatocytes contain numerous small fat vesicles that do not displace the nucleus. Valproic acid, an anticonvulsant (Chapter 403), causes hepatotoxicity, either as a result of microvesicular fat deposition, resembling Reye syndrome, or in a more chronic, indolent fashion associated with macrovesicular fat accumulation. Toxicity is more severe and frequent in children. These lesions are associated with disruption of mitochondrial DNA, resulting in anaerobic metabolism that leads to lactic acidosis in the most severe cases. Macrovesicular and microvesicular lesions may be observed concomitantly in some patients, and microvesicular lesions are more often associated with a poor prognosis. Hepatocellular necrosis also may be present. Acute fatty liver of pregnancy (Chapters 147 and 239) and Reye syndrome are two examples of severe liver diseases caused by microvesicular steatosis.

Drugs involved in microvesicular steatosis include valproate, tetracycline, and fialuridine. Aspirin use in children has been associated with Reye syndrome, but the incidence of Reye syndrome has decreased dramatically since warnings were issued concerning aspirin use in children.

Effects of Sex Steroids

Anabolic steroids, such as methyltestosterone, may cause cholestasis. Androgens or estrogens may cause peliosis hepatis and benign or malignant tumors. Oral contraceptives (Chapter 238) may cause cholestasis, hepatic adenomas, or Budd-Chiari syndrome (hepatic vein thrombosis). Antiandrogens used to treat prostate cancer (Chapter 201), such as flutamide and nilutamide, and antipituitary drugs, such as cyproterone acetate, also have been associated with severe hepatocellular injury.

Other Drug Reactions

Other less severe drug reactions involving the liver include granulomatous reactions, fibrosis, ischemic injury, and chronic autoimmune liver injury (see Table 150-3). The type of reaction observed can be helpful in determining the probable agent because most drugs have a specific injury profile.

A pattern of veno-occlusive disease with obliteration of small intrahepatic veins, sinusoidal congestion, and necrosis is observed frequently in bone marrow transplant patients (Chapter 178) who receive chemotherapy with cyclophosphamide (Cytoxan) or busulfan. Symptoms, including rapidly accumulating ascites, painful hepatomegaly, and jaundice, develop soon after the chemotherapeutic regimen has begun. Oxiplatin can cause portal venular injury that leads to nodular regenerative hyperplasia and life-long portal hypertension. Rarely, herbal medicines (Chapter 39) such as pyrrolizidine alkaloids (*Crotalaria* and *Senecio* found in Jamaican bush tea) may cause veno-occlusive disease.

Toxins are associated with direct injury to hepatocytes in a dose-dependent fashion. Organic solvents such as carbon tetrachloride and trichloroethylene (Chapter 110) cause centrilobular injury. Yellow phosphorus, found in firecrackers and rat poisons, is a rare cause of liver injury from either accidental or intentional exposure. Symptoms of poisoning are similar to those of any other type of hepatitis.

Mushroom poisoning (Chapter 110), which follows the ingestion of *A. phalloides* and related species, typically occurs in amateur mushroom fanciers in a dose-related fashion. The associated muscarinic effects, including severe diarrhea, vomiting, and profuse sweating, predominate in the first hours after ingestion. Hepatic failure follows if antidotes (see later) are not given. The overall prognosis for spontaneous recovery is poor; liver transplantation may be life-saving.

Differential Diagnosis

The differential diagnosis of toxin-induced and drug-induced liver injury includes almost the entire spectrum of liver diseases. Some cases previously ascribed to drugs may now be linked to previously unsuspected hepatitis E (Chapters 148 and 149).[9] Because the clinical picture of drug-induced liver injury ranges from pure hepatocellular to pure cholestatic variants, a high index of suspicion must be maintained, even when toxin-induced or drug-induced liver injury is not obvious initially.

For dose-dependent hepatotoxins, the diagnosis may be easier to establish than for idiosyncratic drug reactions. Serum levels of acetaminophen, a thorough history, and characteristic biochemical abnormalities (high aminotransferase levels) usually reveal an acetaminophen overdose, whereas a diagnosis of *Amanita* poisoning depends on the history, symptoms of gastroenteritis (muscarinic reaction), and positive mushroom identification.

For idiosyncratic drug reactions, the diagnosis is sometimes more difficult to establish. A standardized reporting form called the Roussel-Uclaf Causality Assessment Method (RUCAM) (see Table 150-4), developed by an international panel, provides a worthwhile scoring system. These guidelines outline the steps an experienced clinician might use to assess the likelihood of a drug reaction. Causality assessment factors typically include the temporal relationship, course after cessation of the drug, risk factors, concomitant drugs, a search for nondrug causes (viral hepatitis), previous information concerning the drug, and response to rechallenge, which is typically not required. Recently, the Drug-Induced Liver Injury Network has used an expert opinion system that is helpful in defining phenotypes but is not readily applicable for day-to-day use.

TREATMENT

Rx

Prompt discontinuation of a suspected drug is mandatory. Available antidotes should be used for acetaminophen (*N*-acetylcysteine) and *Amanita* poisoning (penicillin 300,000 to 1 million U/kg/day intravenously (IV) and thioctic acid 5 to 100 mg every 6 hours IV have been recommended, but there are no controlled trials). General supportive therapy ranges from intravenous fluid replacement to intensive monitoring and treatment of patients with hepatic encephalopathy secondary to acute liver failure (Chapter 153). *N*-Acetylcysteine is the standard antidote for acetaminophen overdose, but it may improve outcomes in some cases of acute liver failure not associated with acetaminophen, such as severe alcoholic hepatitis.[10] Almost 10% of patients die or require liver transplantation within six months after serious drug-induced liver injury and about another 20% have persistent evidence of liver injury.[11] Liver transplantation (Chapter 154) is performed in more than 50% of patients with idiosyncratic drug-induced acute liver failure because the survival rate in this setting without transplantation is less than 20%.

FUTURE DIRECTIONS

Research in pharmacogenomics may allow the patient's own genetic information to guide individualized drug therapy and monitoring of idiosyncratic drug reactions. The genetic information would probably concentrate initially on enzymes with variant alleles associated with poor metabolism, such as CYP1A2 or CYP2C19 for isoniazid, CYP2C9 for piroxicam, or CYP2D6 for nortriptyline. Better postmarketing surveillance of all drugs to identify those with previously unappreciated hepatotoxicity should be a high priority.

PREVENTION

It is reasonable to consider a drug reaction whenever an episode of apparent hepatitis is unexplained, particularly if a new agent has been introduced in the previous 3 months. It is prudent to defer embracing new drugs during their first year of introduction, particularly if they show no unique advantages over accepted formulations. Physicians must strive to instill in their patients a healthy level of alertness with regard to drug-induced liver injury, particularly for agents with known hepatotoxicity. Monitoring of aminotransferase levels on a monthly basis is suggested for known hepatotoxins such as isoniazid or diclofenac, but it is unlikely to be cost-effective when adverse reactions occur less frequently, such as in only 1 in 50,000 patients. Because many drug reactions develop within days, monitoring provides no guarantee. Most fatal drug reactions could have been prevented if the offending agent were withdrawn immediately, at the first sign of illness.

REVIEW QUESTIONS

1. A 24-year-old woman is brought to the emergency department by her family because of altered mental status. She is rousable but drowsy, with normal vital signs except for tachycardia. Initial testing shows AST 10,200 IU/L, ALT 8,100 IU/L, INR 3.2, T bilirubin 3.7 mg/dL. The most plausible explanation for this scenario is:

A. Alprazolam (Xanax) overdose.
B. Alcohol binge drinking.
C. Aspirin overdose.
D. Acetaminophen overdose.
E. Methyl alcohol ingestion.

Answer: D Although drowsiness would follow alprazolam and possibly an alcoholic binge, only acetaminophen is associated with very high aminotransferases. Approximately 75% of acetaminophen overdoses occur in women.

2. The proper course of treatment for this patient would be:

A. Gastric lavage.
B. Normal saline at 250 mL/hour.
C. Syrup of ipecac.
D. Narcan by injection.
E. Intravenous *N*-acetylcysteine.

Answer: E *N*-Acetylcysteine is a sulfhydryl donor that repletes glutathione and is effective in preventing liver injury when given early in acetaminophen overdose. Even after severe liver damage has occurred, it is still likely to be of some benefit.

3. A college student who is trying out for the wrestling team is seen for new-onset itching and jaundice. The most likely cause would be:

A. Hepatitis A.
B. Hepatitis D.
C. Anabolic steroid use.
D. Hepatitis E.
E. Hepatitis C.

Answer: C Body-building supplements contain androgenic compounds highly associated with cholestatic liver disease, which is usually self-limited but very slow to resolve.

4. A 49-year-old truck driver with a body mass index of 42 is evaluated for life insurance. His cholesterol level is 285 mg/dL. He complains of right upper quadrant pain, and his abdominal ultrasound reveals a fatty liver. His AST is 42 IU/L, ALT is 34 IU/L. He should be considered for which of the following treatments?

A. Phen-phen for weight reduction
B. Herbal weight loss product
C. Lovastatin 40 mg/day
D. Daily aspirin 81 mg
E. Support stockings

Answer: C Lovastatin will deal with his hypercholesterolemia. He also needs exercise and dietary programs to help lose weight.

5. A 42-year-old woman is found incidentally to have multiple masses in her liver, but she is totally asymptomatic. Biopsy of one of the masses discloses an hepatic adenoma. Which of her medications should be discontinued at this time?

A. Oral contraceptive
B. Metformin
C. Lisinopril
D. Hydrochlorthiazide
E. Alprazolam

Answer: A Oral contraceptives, particularly after prolonged use, can be associated with hepatic adenomas. These adenomas regress but must be watched closely over time.

151 BACTERIAL, PARASITIC, FUNGAL, AND GRANULOMATOUS LIVER DISEASES

K. RAJENDER REDDY

INFECTIONS OF THE LIVER

Infections of the liver can be due to a variety of pathogens, including bacteria, fungi, amebae, protozoa, helminths, spirochetes, and rickettsiae. The manifestations of these infections are protean; some are generic to all infections, whereas others are specific to particular infections. The epidemiology can vary and depend on the geographic region of the world. In endemic areas, *Entamoeba histolytica* is a key consideration in the differential diagnosis of a liver abscess (Table 151-1).

Bacterial Infections

PYOGENIC LIVER ABSCESS

DEFINITION

Pyogenic liver abscess is a focal collection of purulent bacterial material and necroinflammatory debris. It can be solitary or multiple and can be caused by one or more aerobic and anaerobic bacteria (Fig. 151-1).

EPIDEMIOLOGY

Pyogenic liver abscess has an estimated global incidence of approximately 1.1 to 2.3 per 100,000 person-years, whereas in the United States, the incidence is approximately 3.6 per 100,000 and has been rising.[1] Biliary obstruction, caused by either a malignant or benign disease, accounts for 50 to 60% of pyogenic liver abscesses, whereas portal pyemia, due to appendicitis or other intra-abdominal infections, accounts for about 20% of cases. Recently, a number of studies from Asia, where *Klebsiella pneumoniae* is the primary etiologic source of pyogenic liver abscess, have proposed a correlation with underlying colorectal neoplasms,[2] some of which were evident at the time of diagnosis but also with a 5- to 8-fold higher risk of newly diagnosed colorectal cancers in the 3 years after diagnosis.[3] However, it is yet to be determined whether these findings can be extrapolated to other regions of the world.

PATHOBIOLOGY

Bacteria can enter the liver through the portal system from infections in areas drained by the mesenteric system into the portal system, such as appendicitis (Chapter 142). Other mechanisms for pyogenic liver abscess include bacterial cholangitis due to benign or malignant obstruction and infection of the liver from a systemic bacteremia, such as an infection of the oral cavity. Pyogenic liver abscess can also be caused by blunt or penetrating trauma, including such unusual causes as the ingestion of a toothpick or fish bone that can cause an intestinal perforation, fistula to the liver, and subsequent abscess formation. Liver abscesses can occur in a transplanted graft owing to vascular compromise caused by hepatic artery thrombosis and ischemic bile duct strictures.

Multiple organisms can cause pyogenic liver abscess. The most common organism, *Klebsiella pneumoniae*,[4] often is associated with biliary tract

TABLE 151-1 FEATURES OF BACTERIAL AND AMEBIC ABSCESSES

	DEMOGRAPHICS	RISK FACTORS	SYMPTOMS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Bacterial liver abscess	50-70 years old Male = female	Recent bacterial infection, biliary obstruction, diabetes mellitus	Fevers, chills, malaise, anorexia, diarrhea, cough, pleuritic chest pain, RUQ pain	Leukocytosis, anemia, elevated alkaline phosphatase and bilirubin, low albumin, positive blood cultures (50%)	Multifocal (50%), usually right lobe, irregular margins	Aspirate (70-80% positive)	Percutaneous drainage and antibiotics
Amebic liver abscess	18-50 years old Male > female	Alcohol intake, HLA-DR3, oral and anal sex, contaminated enema apparatus, travel to or living in an endemic area	Fever, RUQ pain, hepatic tenderness, anorexia, weight loss, uncommon to have colitis	Leukocytosis, no eosinophilia, mild anemia, elevated alkaline phosphatase, elevated ESR, positive serology	Single abscess (80%), usually right lobe, wall enhancement seen on CT scan with IV contrast	Aspirate (trophozoites rarely seen) can rule out superimposed bacterial infection, positive serology and risk factors	Metronidazole and iodoquinol

RUQ = right upper quadrant; ESR = erythrocyte sedimentation rate; CT = computed tomography; IV = intravenous.

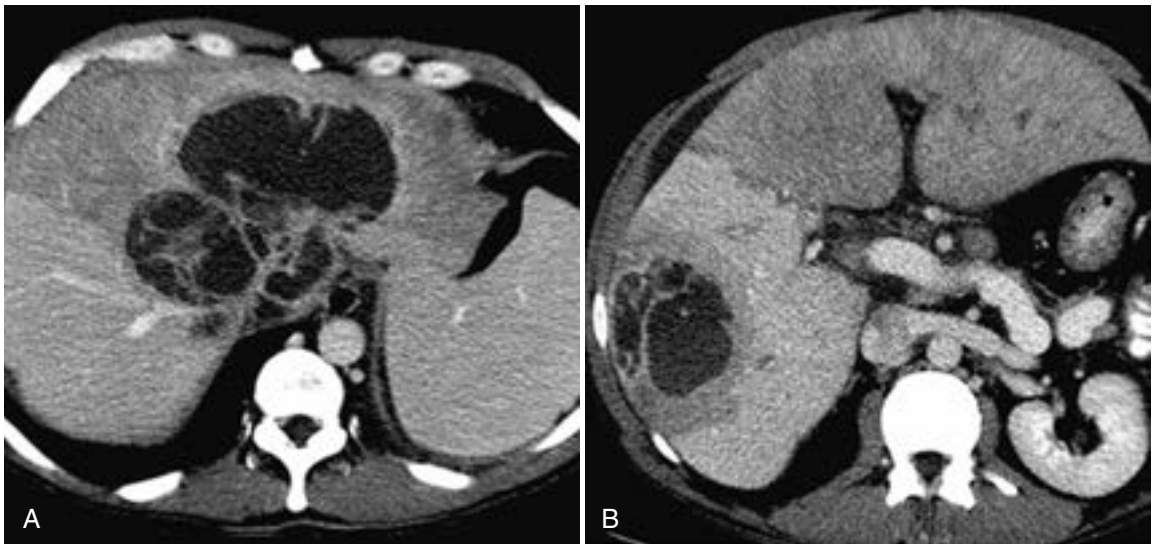

FIGURE 151-1. A and B, Computed tomographic scans of pyogenic liver abscess lesions. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

disease. Other aerobes include *Escherichia coli*, group D streptococci, β-hemolytic streptococci, and *Staphylococcus aureus*. Anaerobic infection is often seen with colonic disease. Less common causes of liver abscesses include *Actinomyces*, *Nocardia asteroides*, *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*, *Listeria monocytogenes*, *Campylobacter jejuni*, *Legionella pneumophila*, *Mycobacterium tuberculosis*, *Salmonella typhi* or *Salmonella paratyphi*, *Candida albicans*, and *Bartonella henselae*. Most often, the organism recovered from an abscess cavity is single, but multiple organisms can be isolated in as many as a third of patients. Bacteria may not be isolated from the abscess because of prior antibiotic therapy or the failure to perform proper anaerobic cultures.

CLINICAL MANIFESTATIONS

The signs and symptoms associated with a liver abscess typically include fever, right upper quadrant abdominal pain, chills, nausea, vomiting, weight loss, and jaundice. The presentation can be acute or indolent. An associated bacteremia is seen in approximately 50% of the patients, but frank sepsis is rare. About 10% of patients develop metastatic infection to other sites.[5]

DIAGNOSIS

Appropriate diagnosis requires a high degree of clinical suspicion, and diagnosis is sometimes delayed. Usually, however, the diagnosis is made promptly with the wide availability of the various radiologic modalities. The two common types of liver abscesses are pyogenic and amebic abscesses, and it is important to make a distinction because the prognosis and management differ. Amebic abscesses can become secondarily infected with other bacteria.

The diagnosis of an abscess is based on a constellation of clinical, bacteriologic, and radiologic features. Ultrasonography and computed tomography (CT) scanning are the most common radiologic modalities to diagnose an abscess cavity reliably, either as single or multiple lesions (see Fig. 151-1). CT is the preferred diagnostic indicator of an abscess, with sensitivity of more than 90%. Any concurrent biliary obstruction also can be diagnosed by these imaging modalities. Approximately 50% of patients have multiple abscesses. On CT, the lesion is seen as a fluid collection with irregular borders and wall edema. One drawback to this imaging modality is that no specific features differentiate a pyogenic abscess from other infectious causes (i.e., amebic or fungal). Another drawback is that a very early stage abscess may not be well formed and may have characteristics more suggestive of a solid mass. It is critical to distinguish an abscess from a tumor (Chapter 196) or a simple cyst, a process that can be complicated on noninvasive imaging by various events, such as bleeding into a cyst, calcification, necrosis, or bleeding into a tumor. A finding of smaller (<2 cm) peripheral lesions that surround a central abscess (the cluster sign) can help exclude a hepatic neoplasm. Calcification suggests bleeding into a tumor, but it also can be seen in the wall of an echinococcal cyst. Nonspecific radiologic features, including elevation of the right hemidiaphragm, right lower lung lobe atelectasis, and right pleural effusion, are seen in up to 30% of patients with pyogenic liver abscesses. Magnetic resonance imaging and tagged white blood cell scans add little to the diagnosis of a liver abscess.

Microbial cultures are essential. In addition to blood cultures, the abscess cavity should be aspirated percutaneously, with either ultrasound or CT guidance, and the aspirate should be cultured for aerobic and anaerobic organisms as well as for amebae if there is any suspicion of an amebic abscess. Blood cultures are positive in only approximately 50% of cases. In approximately 15 to 20% of cases, multiple organisms are identified in the abscess cavity, but 20 to 50% of cases may have negative cultures despite appropriate culture techniques.[6]

TREATMENT

Rx

Immediate broad-spectrum antibiotic coverage and the prompt identification and treatment of the source of the infection are essential for successful outcomes. Any underlying biliary source must be resolved, and any biliary obstruction must be relieved.

As soon as the causative bacterium is identified, the antibiotic regimen can be tailored appropriately. Recommendations should be guided by the culture and by prevailing bacterial resistance patterns. Monotherapy with a β-lactam or β-lactamase inhibitor such as ampicillin-sulbactam (3 g IV every 6 hours) or piperacillin-tazobactam (4.5 g IV every 6 hours) or ticarcillin-clavulanate (3.1 g IV every 4 hours) can be used, or a third-generation cephalosporin such as ceftriaxone (1 g IV daily) *plus* metronidazole (500 mg IV every 8 hours) can be considered. Other regimens for consideration include a fluoroquinolone (such as ciprofloxacin 400 mg IV every 12 hours or levofloxacin 500 or 750 mg IV daily) *plus* metronidazole (500 mg IV every 8 hours) and monotherapy with a carbapenem such as imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g IV every 8 hours), or ertapenem (1 g IV daily).

The duration of therapy is partly based on the response to therapy. An average of 4 to 6 weeks of antibiotic therapy is reasonable, and the last 2 to 4 weeks of the antibiotic regimen can be administered orally. Abscesses that are difficult to drain or slow to demonstrate radiographic resolution require longer courses of therapy. Importantly, radiologic abnormalities resolve more slowly than clinical and biochemical features do, so the latter should be used as an indicator for tailoring of the therapeutic regimen.

Antibiotics alone can sometimes successfully resolve small, multiple pyogenic abscesses, but most patients will require drainage of the abscesses. The standard approach is placement of a drain for about 7 days. Alternatively, needle aspiration, repeated as needed when the abscess is large enough to be drained percutaneously, provides equivalent results.[■■] Surgical drainage seldom is the first option except in patients who also have a surgically correctable precipitating lesion, such as appendicitis or biliary obstruction.[7] More often, biliary obstruction is treated with endoscopic retrograde cholangiopancreatography or transhepatic cholangiography with accompanying biliary drainage. For pyogenic abscesses in transplanted livers, management and proper biliary drainage may be difficult to achieve because of the diffuse nature of the biliary strictures.

PROGNOSIS

Abscesses smaller than10 cm can take up to 16 weeks to resolve, whereas abscesses larger than10 cm may take, on average, an additional 6 weeks to resolve. Mortality from pyogenic liver abscess is associated with older age and with comorbidities such as cirrhosis, diabetes, chronic renal failure, and malignant disease. Jaundice is an ominous sign. In developed countries, the mortality rate ranges from 2 to 12%.[8]

NON-ABSCESS HEPATIC BACTERIAL INFECTIONS

Bacterial infections of the liver can also cause more diffuse infections without frank abscess formation. Implicated organisms include *Listeria monocytogenes* (Chapter 293), *Yersinia enterocolitica* (Chapter 312), *Salmonella typhi* and *Salmonella paratyphi* (Chapter 308), *Legionella* (Chapter 314), *Ehrlichia* (Chapter 327), and gonococci (Chapter 299). There are no specific features associated with these infections, and these organisms do not necessarily cause abscesses. Patients with chronic liver disease are especially at risk for *Listeria* infection. Patients with active enteric *Yersinia* infection can have secondary liver involvement with or without liver abscesses. Disseminated gonococcal infections (Chapter 299) can cause a perihepatitis (Fitz-Hugh–Curtis syndrome), which can be manifested with right upper quadrant pain and tenderness.

Systemic bacteremia can cause a variety of hepatobiliary abnormalities, which may range from elevated aminotransferase and alkaline phosphatase levels (Chapter 147) to the cholestasis of sepsis with the development of jaundice. Several organisms can disrupt normal liver function after entering the blood stream, the most common of which are *E. coli*, *Klebsiella* spp, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Typically, in patients suffering from jaundice, sources of bacteremia include pneumonia, urinary tract infection, and soft tissue infection, although organisms may originate from a range of other sites. The hepatic biochemical abnormalities associated with bacteremia may be related to factors such as hemodynamic instability and liver hypoperfusion as well as to the infection. Associated renal failure, a blood transfusion–derived bilirubin load, and drugs may complicate the picture. The course of cholestasis may be prolonged for several days to a few weeks, but it typically resolves with resolution of the systemic infection. There is no specific treatment for the cholestasis related to a systemic infection, but it is important to rule out drug-induced cholestasis that may evolve as a consequence of one or more of the antibiotics.

Fungal Diseases of the Liver

Except for hepatosplenic candidiasis, clinically significant fungal diseases of the liver are unusual. Typically, other fungal infections will also be manifested as liver granulomas but will not show the high, swinging pyrexia that is characteristic of hepatosplenic candidiasis. Tissue cultures are required to confirm a diagnosis.

HEPATOSPLENIC CANDIDIASIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Hepatosplenic candidiasis typically is caused by *Candida albicans*, but other species, including *C. tropicalis*, *C. parapsilosis*, *C. glabrata*, and *C. krusei*, have occasionally been reported. It occurs as part of disseminated candidiasis

(Chapter 338), almost exclusively in patients with acute leukemia but rarely in patients with lymphoma, aplastic anemia, and sarcoma. With the current widespread use of prophylactic antifungal agents early in the course of disease in patients with acute leukemia, hepatosplenic candidiasis develops in only 1 to 2% of patients, more commonly with acute lymphoblastic leukemia than with acute myeloid leukemia. Hepatosplenic candidiasis presumably results from translocation of *Candida* species from the gastrointestinal tract into the blood stream as a result of prolonged neutropenia and a breach in mucosal integrity.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatosplenic candidiasis is manifested with persistent and high spiking fevers in a patient who was previously neutropenic and has now returned to a normal neutrophil count. Right upper quadrant pain, nausea, vomiting, and anorexia may accompany fever.

Patients typically have elevated levels of alkaline phosphatase and, less frequently, of aminotransferases, bilirubin, and leukocytes. CT, which is the imaging modality of choice, classically shows multiple lucencies representing microabscesses in the liver, spleen, and kidneys. If the CT scan is nondiagnostic but clinical suspicion remains high, magnetic resonance imaging should be performed. A definitive diagnosis is usually made on a liver biopsy specimen that shows multiple granulomas and may show yeast and hyphal forms with special stains. However, biopsy often will not show evidence of infection, especially in cases in which antifungal therapy has been used. Although biopsy is the only means to establish a definitive diagnosis, it often is not required because the clinical, laboratory, and radiographic manifestations of the disease are almost always sufficient to establish a specific diagnosis.

TREATMENT AND PROGNOSIS

Rx

The mainstay of therapy is antifungal therapy. In clinically stable patients, oral fluconazole (400 mg, orally daily) can be used. In acutely ill patients, a lipid formulation of amphotericin B (3 to 5 mg/kg IV daily) is recommended. If the lipid formulation of amphotericin B is not used, other options are caspofungin (loading dose of 70 mg, then 50 mg IV daily), anidulafungin (loading dose of 200 mg, then 100 mg IV daily), and micafungin (100 mg IV daily). After 1 to 2 weeks, oral fluconazole at 400 mg daily should be started. Treatment should continue until the lesions resolve on follow-up CT scans, typically within 6 months of treatment. Patients receiving chemotherapy or stem cell transplants are at a higher risk for development of hepatosplenic candidiasis; if these treatments are indicated in patients who have a history of hepatosplenic candidiasis, fluconazole (400 mg orally, daily) should be used prophylactically to prevent relapse.

PROGNOSIS

With prolonged treatment with antifungal agents, there has been good success at treating hepatosplenic candidiasis.

OTHER FUNGAL DISEASES

Several additional fungal infections affect the liver, although rarely. *Coccidioides immitis* (Chapter 333) is often asymptomatic but may lead to fungal hepatitis characterized by increased alkaline phosphatase and the development of hepatic granulomas. Hepatic *Cryptococcus neoformans* (Chapter 336) infection is rare but has a higher prevalence in patients with AIDS, in whom it typically causes hepatomegaly. In the non–HIV-infected patient, disseminated cryptococcosis less frequently can result in focal granulomatous hepatitis, which may clinically mimic viral hepatitis, or can be manifested as obstructive jaundice secondary to sclerosing cholangitis. *Histoplasma capsulatum* (Chapter 332) infects individuals who inhale the fungus, but most cases are subclinical. In symptomatic hepatic histoplasmosis, two thirds of patients will present with hepatomegaly, with some showing splenic enlargement as well. On histologic examination, histoplasmosis can cause multiple granulomas diffusely distributed throughout the liver, although a more common finding is portal lymphohistiocytic infiltrate. *Paracoccidioides brasiliensis* (Chapter 335) most commonly infects adult men, and autopsy series have shown hepatic involvement in up to 50% of patients who die of this infection. Some individuals may present with hepatomegaly or jaundice, although jaundice is found in less than 6% of patients. Aminotransferase levels are often elevated in the early stages of the disease; changes in alkaline phosphatase or bilirubin levels tend to occur in the later stages. Biopsy may reveal lesions ranging from small granulomas to diffuse infiltration of yeast forms and fibrosis, often with bile duct involvement. In all of these examples, fungal cultures are necessary to establish a definitive diagnosis.

Parasitic, Protozoal, and Helminthic Infections of the Liver

AMEBIC LIVER ABSCESS

EPIDEMIOLOGY

Entamoeba histolytica (Chapter 352) is found throughout the world where the barriers between human feces and food and water are inadequate. After malaria, it is the second leading cause of death from parasitic diseases worldwide, accounting for an estimated 40,000 to 100,000 deaths annually. In the United States, most cases of amebiasis arise in immigrants from endemic areas and people living in states that border Mexico. Travelers to endemic areas are also at risk; ingestion of amebic cysts and colonization of the gastrointestinal tract can occur years before the development of a liver abscess. Amebic liver abscesses mainly affect men between the ages of 18 and 50 years but are also more common in postmenopausal women, thereby suggesting a hormonal protective effect. Other risk factors include alcohol intake, HLA-DR3, oral and anal sex, and contaminated enema apparatuses.[9]

PATHOBIOLOGY

E. histolytica has a simple life cycle consisting of the cyst (infectious form) and trophozoite (the motile stage associated with disease); it infects only humans and some nonhuman primates. Cysts are ingested and mature into trophozoites in the intestinal lumen. The development of amebic colitis is not essential for liver abscess formation. *E. histolytica* trophozoites penetrate through the mucosa and submucosal tissues and enter the portal circulation. *E. histolytica* blocks intrahepatic portal venules. When the trophozoites reach the liver, they create their unique abscesses, which are well-circumscribed regions of dead hepatocytes, liquefied cells, and cellular debris that are surrounded by a rim of connective tissue, a few inflammatory cells, and amebic trophozoites. The adjacent liver parenchyma is unaffected. Given the small numbers of amebae relative to the size of the abscess, it is suggested that *E. histolytica* can cause hepatocyte death without direct contact.

CLINICAL MANIFESTATIONS

Patients can present with amebic liver abscesses months to years after traveling to an endemic area, so a detailed travel history is essential for the diagnosis.[10] The disease should be suspected in patients with an appropriate travel history, fever, right upper quadrant pain, and substantial hepatic tenderness.[11] Jaundice is extremely uncommon. Symptoms are usually acute (<10 days in duration) but can be chronic, with anorexia and weight loss. Patients with acute disease tend to have multifocal disease, whereas patients with a more indolent course tend to have a solitary lesion. Laboratory data tend to demonstrate a leukocytosis without eosinophilia, mild anemia, elevated alkaline phosphatase level, and high erythrocyte sedimentation rate.

DIAGNOSIS

Although some individuals with amebic liver abscesses have concurrent amebic colitis, the majority of patients have no bowel symptoms; hence, the results of stool microscopy for *E. histolytica* trophozoites and cysts are usually negative. The diagnosis relies on identification of space-occupying lesions in the liver and a positive amebic serology. Both ultrasound and CT scan are sensitive (Fig. 151-2), but neither provides absolute specificity for amebic liver abscesses. Serologic testing of the blood is highly sensitive (>94%) and specific (>95%). False-negative test results can be obtained within the first 7 to 10 days of infection, but results on repeated testing will usually be positive. Polymerase chain reaction testing of the abscess aspirate has proved valuable for making the diagnosis in returning travelers. Aspiration of the lesion may be necessary to exclude a primary or secondary bacterial infection.

TREATMENT AND PROGNOSIS

Rx

Metronidazole (500 to 750 mg orally three times daily or a loading dose of 15 mg/kg followed by 7.5 mg/kg every 6 hours intravenously) will usually provide evidence of clinical improvement within 72 to 96 hours but should be continued for 5 to 10 days. Nitroimidazole tinidazole at 2 g daily for 5 days is also effective. Drainage is not necessary, except in patients who have abscesses larger than 10 cm or do not respond within 5 days.[12] The abscess usually will shrink by about 50% within a week, but the mean time to complete radiologic resolution is 3 to 9 months. Repeated imaging in a clinically improving patient may lead to unwarranted concern and unnecessary treatment.

Treatment must also address the removal of all of the cysts from the intestinal lumen in patients with evidence of intraluminal infection (Chapter 352). A recommended treatment is diiodohydroxyquinoline (650 mg orally three

times a day for 20 days) to prevent continued colonization and possible recurrence of the liver abscess. With prompt diagnosis and adequate medical treatment, the mortality rate from amebic abscess is 1 to 3%.

OTHER PROTOZOAN LIVER DISEASES

In addition to *Entamoeba histolytica*, other protozoan diseases that affect the liver include *Cryptosporidium*, *Toxoplasma gondii*, *Leishmania*, *Plasmodium*, and *Babesia microti* (Table 151-2).

HELMINTH INFECTIONS

Echinococcosis and Hydatid Cyst Disease

EPIDEMIOLOGY AND PATHOBIOLOGY

Human cystic echinococcosis is a zoonosis caused by the larval cestode *Echinococcus granulosus*. It is often referred to as hydatid cyst disease because of the watery cysts that characterize the infection.

FIGURE 151-2. Computed tomographic scan of an amebic liver abscess. (Courtesy Dr. Chalermrat Bunchorntavakul, Bangkok, Thailand.)

The disease remains endemic in sheep-raising areas of the world, including Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand. Dogs are the definitive hosts for *E. granulosus*, and sheep are the major intermediate hosts, although yaks, goats, and camels are other relevant intermediate hosts. Humans are only accidental hosts when they ingest food or water that is fecally contaminated with eggs. Human contact with sheepdogs that are in frequent contact with livestock is a major risk for infection.

The disease cycle begins when an adult tapeworm infects the intestinal tract of the definitive host (dogs usually). The adult tapeworm then produces eggs, which are expelled in the host's feces. Intermediate hosts become infected through the ingestion of parasitic eggs in fecally contaminated food. Inside the intermediate host, the eggs hatch and release tiny hooked embryos (called oncospheres), which travel in the blood stream and eventually lodge in the liver, lungs, or kidneys, where they develop into hydatid cysts. Inside these cysts grow thousands of tapeworm larvae, the next stage in the life cycle of the parasite.

CLINICAL MANIFESTATIONS

The initial infection is asymptomatic, but an enlarging hydatid liver cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass.[13] Patients may describe symptoms of mild upper right quadrant pain, urticarial rash, and episodes of pruritus. If the cyst ruptures, serious complications can develop. Cysts that perforate into the peritoneum can lead to the development of extrahepatic cysts and may induce an allergic reaction leading to an increase of eosinophils in the blood, pruritic urticaria, and systemic anaphylaxis. In most cases, however, cysts rupture into bile ducts, which can result in cholestatic jaundice, cholangitis, or biliary pain.

DIAGNOSIS

On ultrasound or CT scans (Fig. 151-3), the hydatid cysts are often large with a flaky appearance that is referred to as hydatid sand. CT imaging also may show multiple daughter cysts or a fluid density cyst with peripheral focal areas of calcification. Fluid is of variable density, depending on the amount of proteinaceous debris.

Hydatid cysts of the liver can be diagnosed by a serologic assay, the Weinberg reaction, but it can be falsely negative in up to 38% of cases. An enzyme-linked immunosorbent assay may be more sensitive. Eosinophilia is not a feature unless the cyst ruptures; in fact, there are usually no changes in blood chemistries.

TABLE 151-2 PARASITIC INFECTIONS INVOLVING THE LIVER

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS	MAJOR HEPATIC MANIFESTATIONS
MAJOR PROTOZOA				
Entamoeba histolytica	Ingested cysts develop into invasive trophozoites that colonize the colon and occasionally spread to the liver by the portal blood	Mexico, regions of Central and South America, India, and regions of Africa	Male gender, alcohol intake, HLA-DR3, oral and anal sex, and contaminated enema apparatuses	Amebic liver abscesses develop as a tissue response to trophozoite invasion with acute and chronic manifestations (see text)
OTHER PROTOZOA				
Cryptosporidium sp and microsporidia	Ingested cysts develop into trophozoites in intestinal mucosa	Worldwide distribution	AIDS	Biliary tract infection with obstruction and cholangitis
Toxoplasma gondii	Ingestion of oocysts in contaminated soil or water or in infected meat; systemic spread of tachyzoites in the circulation	Worldwide distribution	Consumption of undercooked meat, contact with soil, and travel outside the United States, Europe, or Canada	Immunocompetent: asymptomatic or hepatomegaly and mild LFT elevations Immunocompromised: occasional overt hepatitis
Leishmania sp	Sand fly bite transmits promastigotes; proliferation in the reticuloendothelial system	Worldwide distribution	Children younger than 10 years and immunocompromised adults Contact with sand flies	Hepatosplenomegaly months to years after infection
Plasmodium sp	Mosquito (*Anopheles*) bite transmits sporozoites	Multiple regions throughout the world	Exposure to anopheline mosquito bites	Proliferation in hepatocytes causes hepatomegaly, enzyme elevations, and jaundice
Babesia microti	Tick bite transmits the agent, which parasitizes erythrocytes	Europe	Asplenia is a risk for fatal hepatic failure, especially bovine babesiosis	Mild liver enzyme elevations

TREATMENT AND PROGNOSIS

Rx

Drug therapy includes albendazole 400 mg twice a day for three- to six-month cycles, but treatment with albendazole alone is not effective, so drainage is essential to the effective treatment of hydatid cysts. In a randomized trial, percutaneous drainage consisting of puncture, aspiration, injection, and reaspiration of scolicidal solutions resulted in a rate of cyst disappearance similar to that of open surgical drainage, but with fewer side effects, provided patients received preprocedure and postprocedure albendazole therapy.[■] Chlorhexidine, hydrogen peroxide, 80% alcohol, and 0.5% cetrimide are preferred scolicidal agents rather than hypertonic saline or formalin. If the cyst communicates with the biliary tree, however, injection of scolicidal agents carries an almost universal risk of secondary sclerosing cholangitis, and so it is contraindicated. In such cases, the cyst must be treated surgically, by either cystectomy or hepatic resection.

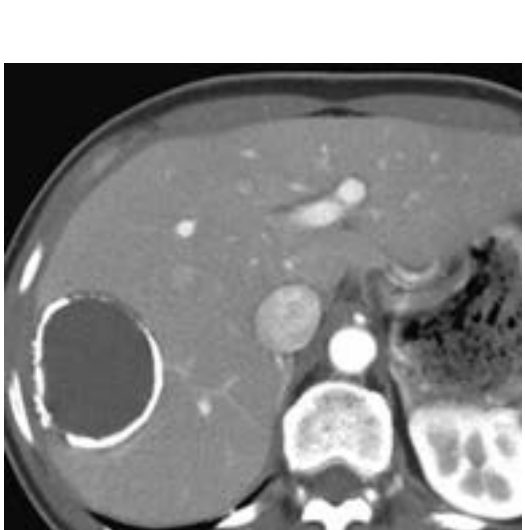

FIGURE 151-3. Computed tomographic scan of a hepatic echinococcal cyst.

The prognosis is generally good, with complete cure expected after successful percutaneous or surgical treatment. However, spillage occurs in 2 to 25% of cases, depending on the location of the cyst and the surgeon's experience; the operative mortality rate varies from 0.5 to 4% for the same reasons.

Schistosomiasis

EPIDEMIOLOGY AND PATHOBIOLOGY

Schistosomiasis is an infection of trematodes. *Schistosoma* (Chapter 355) causes periportal fibrosis and liver cirrhosis by deposition of eggs in the small portal venules. *S. mansoni* and *S. japonicum* lead to liver disease. Infection with *S. mansoni* is found in parts of South America, Africa, and the Middle East. Infection with *S. japonicum* is found in the Far East, mostly China and the Philippines. Although primary infection does not occur in the United States, 5% of the world's population (200 million people) may be infected, thereby making it a major international health concern and highly prevalent in immigrants.

Humans become infected after contact with water that contains the infective stage (cercaria) of schistosomes. After penetration of the skin, the larvae migrate to the lungs and then to the venules of the mesentery, urinary bladder, or ureters. They release eggs in the venules of the mesentery, and the eggs enter the liver through the portal vein, where they become lodged in the terminal branches of the portal venules. The lodged eggs cause a granulomatous inflammation, and the lesions heal by periportal fibrosis. *S. japonicum* is more virulent than *S. mansoni* because its infections produce 10 times more eggs.

CLINICAL MANIFESTATIONS

Initial infection is manifested as itching that is caused by skin penetration by larvae.[14] Several weeks later, patients may complain of fever, diarrhea, chills, headaches, or hives. At this time, patients will have eosinophilia. During the next 5 to 15 years, periportal liver fibrosis develops and leads to presinusoidal portal hypertension, splenomegaly (Chapter 168), and gastroesophageal varices (Chapter 138). With *S. japonicum*, however, the progression can be much more rapid, with little interval between the acute and chronic disease. Hepatic function is generally well preserved, and patients usually present with hematemesis from ruptured gastroesophageal varices.

SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Fever, RUQ pain, and substantial hepatic tenderness	Leukocytosis without eosinophilia, mild anemia, elevated serum AP, and high ESR	US, CT, and MRI can detect abscess but cannot always differentiate amebic from pyogenic. On CT or MRI, amebic abscess sometimes appears "cold" with bright rim.	Imaging, serology, stool antigen test (microscopic evaluation of stool has a poor yield)	Metronidazole, 500-750 mg PO tid × 5-10 days, or tinidazole, 2 g daily × 3 days Iodoquinol, 650 mg tid × 20 days, also needed to eradicate intestinal colonization

TABLE 151-2 PARASITIC INFECTIONS INVOLVING THE LIVER—cont'd

	CHARACTERISTICS	ENDEMIC AREAS	RISK FACTORS	MAJOR HEPATIC MANIFESTATIONS
MAJOR HELMINTHS				
Schistosoma sp	Cercaria in fresh water penetrate the skin, travel by the circulation to portal vein radicals	*S. mansoni* found in South America, Africa, and Middle East *S. japonicum* found in Far East (mostly China and Philippines)	Contact with fresh water containing cercaria of schistosomes	Progressive presinusoidal blood flow obstruction, periportal fibrosis, portal hypertension, varices, ascites, splenomegaly
Echinococcus granulosus	Eggs of small (3-7 mm) tapeworms in stool of canid hosts; ingested eggs produce larval oncospheres that migrate to the liver and form cysts in sheep, humans, and other intermediate hosts	Worldwide distribution, found especially in sheep-raising areas (Africa, the Mediterranean region of Europe, the Middle East, Asia, South America, Australia, and New Zealand)	Ingestion of food or water fecally contaminated with eggs and human contact with sheepdogs	Initial infection asymptomatic Liver cysts increase in diameter by 1-5 cm yearly and cause variable abdominal pain, hepatomegaly, and variable eosinophilia Occasional cyst rupture, secondary bacterial infection
Echinococcus multilocularis	Eggs of small tapeworms in stool of foxes; ingested eggs produce oncospheres in the liver of rodents, humans, and other intermediate hosts	Endemic in Northern Hemisphere	Human exposure increasing with growing fox populations	Metacestodes colonize the liver as a tumor-like mass of small vesicles
Fasciola sp	Leaf-shaped flukes up to 13 × 30 mm derived from ingested cysts; the fluke excysts in the duodenum, migrates directly across the bowel wall into the peritoneal cavity, and burrows directly into the liver (or occasionally out to the skin)	Worldwide distribution	Consumption of freshwater or aquatic plants contaminated by colonized livestock	Adult flukes live in the common and hepatic bile ducts, causing obstruction that leads to thickening of the ducts, dilation, and fibrosis of the proximal biliary tree
Opisthorchis sp and *Clonorchis sinensis*	Flukes of 8-25 mm derived from ingested cysts; the fluke excysts in the duodenum and migrates into the bile ducts	*Opisthorchis* sp: Southeast Asia, central and eastern Europe (particularly Siberia) *C. sinensis*: China, Japan, Vietnam, Korea	Consumption of raw, pickled, dried, smoked, or salted freshwater fish or crayfish originating from East Asia or, in the case of *Opisthorchis felineus*, Russia and eastern Europe	Acute: typically asymptomatic Chronic: abdominal pain, fever, anorexia, tender hepatomegaly, sometimes eosinophilia Late sequelae: intermittent biliary obstruction, cholelithiasis, cholecystitis, cholangitis, secondary bacterial abscesses, cholangiocarcinoma
Toxocara sp	Nematode infection disseminates to cause visceral larva migrans after ingestion of soil contaminated with dog or cat feces	Highest prevalence in southeastern United States	Consumption of food contaminated with soil containing eggs; distributed throughout the United States	Often an asymptomatic cause of eosinophilia (exclude *Trichinella*, *Strongyloides*, filaria, hookworm, schistosomiasis) Hepatomegaly is common, but nonhepatic manifestations dominate the clinical picture
OTHER HELMINTHS				
Ascaris lumbricoides	Ingested eggs develop into larvae that migrate to the lungs and are coughed and swallowed; develop into roundworms 15-30 mm long in the small intestine	Global distribution with higher prevalence in Africa, South America, India, and the Far East; 20% of the world's population is colonized	Consumption of fecally contaminated food or water, particularly in young children	Colonization is typically asymptomatic with eosinophilia Biliary migration of worms can cause symptomatic biliary obstruction, cholangitis, cholecystitis, and secondary bacterial liver abscess
Capillaria hepatica	Ingested eggs develop into larvae in the intestinal mucosa; larvae migrate to the liver by portal blood flow and develop into short-lived roundworms	Human infection is rare	Consumption of food contaminated with rodent feces	Fever, eosinophilia, and hepatomegaly; subsequent foci of liver fibrosis, granulomas, and calcification in involved areas
Strongyloides stercoralis	Ingested eggs develop into 1.5- to 2.5-mm nematodes that invade the hepatic vasculature, lymphatics, and biliary tract	Tropical and subtropical areas including southeast United States and southern and eastern Europe	Consumption of food contaminated with soil containing eggs, infection with HTLV-1, and immunocompromised individuals	Hepatic disease in the setting of immunosuppression: jaundice, abdominal pain; eosinophilia is uncommon

RUQ = right upper quadrant; AP = alkaline phosphatase; ESR = erythrocyte sedimentation rate; US = ultrasonography; CT = computed tomography; MRI = magnetic resonance imaging; ELISA = enzyme-linked immunosorbent assay; ERCP = endoscopic retrograde cholangiopancreatography; HTLV = human T-cell lymphotrophic virus.
Modified from Neuschwander-Tetri BA. Bacterial, parasitic, fungal, and granulomatous liver disease. In: Goldman L, Ausiello D, eds. *Cecil Textbook of Medicine.* 23rd ed. Philadelphia: WB Saunders; 2007.

SYMPTOMS AND SIGNS	LABORATORY FINDINGS	RADIOGRAPHIC FEATURES	DIAGNOSIS	TREATMENT
Initial infection presents as itching; later presentations include fever, diarrhea, chills, headaches, or hives Hematemesis from ruptured gastroesophageal varices	Eosinophilia and splenomegaly Seroconversion occurs within 4-6 weeks	Extensive calcification with typical "turtle-back" appearance along portal tracts	Rectal biopsy, liver biopsy, microscopic examination of stool	Praziquantel (single dose 40 mg/kg) with a second dose 6-12 weeks later if necessary
Enlarged hydatid cyst can cause abdominal pain, nausea, hepatomegaly, or a palpable mass Mild RUQ pain, urticaria, and episodes of pruritus	Positive Weinberg reaction (false-negative reaction in 38% of cases) or ELISA analysis Eosinophilia seen in ruptured cysts	On US or CT, cysts appear flaky, sometimes showing daughter cysts or peripheral focal calcification; fluid is of variable density	Imaging, Weinberg reaction, or ELISA	Albendazole (400 mg) 2× daily for 3-6 monthly cycles with 10- to 14-day intervals Drainage of the cyst is essential Surgical resection if the cyst communicates with the biliary tree
See Chapter 354	See Chapter 354	See Chapter 354	See Chapter 354	See Chapter 354
Acute: fever, abdominal pain, eosinophilia Chronic: symptomatic biliary obstruction, variable eosinophilia	Serologic tests include hemagglutination, complement fixation, ELISA, and counterimmunoelectrophoresis Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia are often seen	CT is most useful: liver shows hypodense nodules or tortuous tracks; thickening of the liver capsule, subcapsular hematoma, and parenchymal calcification may also be seen	Serology, stool examination	Triclabendazole, 10 mg/kg once or twice
Chronic infection presents as dyspepsia, abdominal pain, diarrhea, nausea, vomiting, anorexia, weight loss, fevers, hepatomegaly, and urticaria Acute presentation includes serum sickness, intrahepatic pigment stones, and facial edema Other rare complications are cholangitis, pancreatitis, and obstructive jaundice	Anemia, leukocytosis, eosinophilia, elevated AP, and hypergammaglobulinemia	US may detect flukes in biliary tree CT shows small hypodense nodules	Serology and stool examination	Praziquantel, 25 mg/kg q8h × 3 doses
See Chapter 358	See Chapter 358	See Chapter 358	See Chapter 358	See Chapter 358
Sensitized patients during pulmonary phase present with asthma-like symptoms, hemoptysis, chest pain, and cyanosis Urticaria and other allergic reactions sometimes seen Patients in intestinal phase show cognitive and nutritional impairment with abdominal pain, hepatomegaly, cholangitis, and obstructive jaundice	Leukocytosis with eosinophilia Hyperbilirubinemia occasionally seen	Movement of the worms within the biliary tree can sometimes be observed A "bull's-eye" appearance can be seen on cross-sectional imaging	Stool examination, imaging, and ERCP	Albendazole, 400 mg once
Persistent fever, eosinophilia, and hepatomegaly most common Splenomegaly, anorexia, nausea, vomiting, night sweats, and altered bowel habits also seen	Anemia, eosinophilia, moderately elevated liver enzymes, increased ESR, and hypergammaglobulinemia	US shows nonspecific hyperechoic areas in the portal spaces	Stool and liver biopsy	Mebendazole, 200 mg bid × 20 days
Recurrent urticaria, abdominal pain, diarrhea, and cough; mild jaundice and hepatomegaly in the absence of splenomegaly	Eosinophilia and hypoalbuminemia Patients may have elevated liver enzymes	Imaging studies not used in diagnosis	Serology and stool examination	Ivermectin, 200 µg/kg/day × 2 days, or albendazole, 400 mg/day × 7 days

DIAGNOSIS

Schistosomal eggs typically have lateral or terminal spines and are easy to detect on microscopic examination of feces or on a rectal biopsy specimen. Seroconversion occurs within 4 to 8 weeks of infection but cannot distinguish active infection from a history of exposure. Newer, more sensitive and specific molecular and immunodiagnostic techniques (including polymerase chain reaction–enzyme-linked immunosorbent assay systems) for detection of schistosome DNA in feces or serum and plasma have the potential to diagnose schistosomiasis in all stages of clinical disease, not only when the adult worms are producing eggs.[15] Imaging may show extensive calcification with the typical "turtle-back" appearance along the portal tracts reflecting the clustered, calcified eggs along the portal triads. Liver biopsy may demonstrate an egg of *S. mansoni* along with intense granulomatous change in the portal tract (Fig. 151-4).

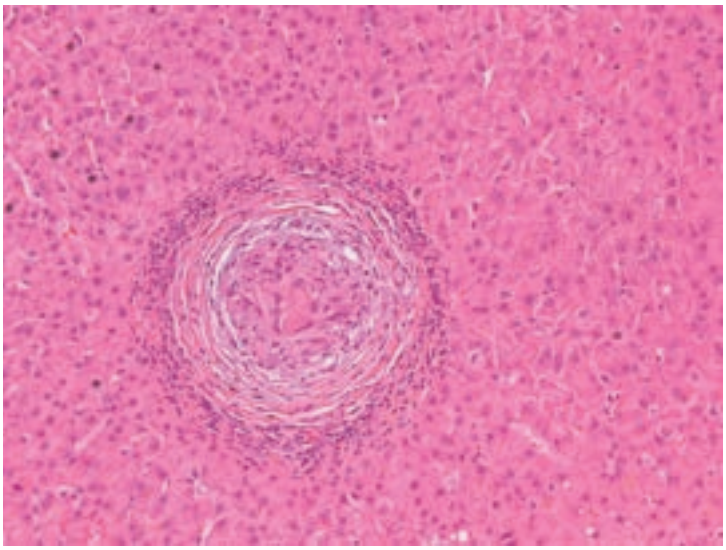

FIGURE 151-4. Liver biopsy specimen demonstrating an egg of *Schistosoma mansoni* and intense granulomatous change in the portal tract. (Courtesy Alberto Q. Farias, MD, São Paulo, Brazil.)

TREATMENT AND PROGNOSIS

Praziquantel (a single or two divided doses of 40 mg/kg for *S. mansoni* infections, and two divided doses of 60 mg/kg for *S. japonicum*), which is the preferred treatment, is effective in 70 to 100% of cases, but a second dose can be given 6 to 12 weeks later, particularly in patients with eosinophilia, high antibody titers, or persistent symptoms. Treatment of portal hypertension (Chapter 153) may be necessary. The mortality is 0.05% with heavy *S. mansoni* infection and 1.8% for severe *S. japonicum* infection. Bleeding from esophageal varices is the most serious complication. Chronic infection can lead to hepatocellular carcinoma.

GRANULOMATOUS DISEASES OF THE LIVER

Granulomas, which are found in up to 15% of liver biopsy specimens, can be an incidental finding or may represent a wide array of liver diseases (Table 151-3). A granuloma is an accumulation of epithelioid cells, including transformed macrophages, mononuclear cells, and other inflammatory cells. Granulomas may have associated necrosis (caseating), as in tuberculosis (Chapter 324), or may be non-necrotizing (noncaseating), as in sarcoidosis (Chapter 95). In addition, fibrin-ring granulomas are characterized by a vacuole encircled by a ring of fibrinoid necrosis and surrounded by lymphocytes and histiocytes, as seen in Q fever (Chapter 327).

An incidental granuloma requires minimal further evaluation. Tuberculosis should be excluded (Chapter 324). Sarcoidosis should also be considered as it is the most common cause of granulomas in the United States. An antimitochondrial antibody should be ordered to rule out primary biliary cirrhosis. The use of potentially causative drugs should be stopped (see Table 151-3).

Sarcoidosis

Sarcoidosis (Chapter 95), which is the most frequently identified cause of hepatic granuloma in the United States, affects all racial and ethnic groups and occurs at all ages. In patients with sarcoidosis, the liver is the third most commonly involved organ, after the lymph nodes and lungs; about 50 to 80% of patients with sarcoidosis will have granulomas in their livers. The classic granuloma is found mainly in the portal triads, with a cluster of large epithelioid cells and often with multinucleated giant cells.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatic involvement of sarcoidosis is often subclinical, and only a minority of patients will present with pruritus, fever, abdominal pain, hepatomegaly,

TABLE 151-3 CAUSES OF GRANULOMATOUS LIVER DISEASE

DIAGNOSIS	SPECIAL AND UNIQUE FEATURES
Sarcoidosis	Evidence of pulmonary sarcoidosis, granulomas found on biopsy of other organs, elevated ACE level
Bacterial infections	
Mycobacterium tuberculosis	Caseating granulomas on biopsy, positive PPD response or interferon-gamma release assay, active pulmonary tuberculosis
Other mycobacteria (*M. avium-intracellulare, M. leprae, M. mucogenicum, M. bovis*)	HIV, exposure history
Other bacteria (brucellosis, listeriosis, melioidosis, tularemia, yersiniosis, bartonellosis, Q fever, syphilis, psittacosis)	Fever, exposure history
Viral infections (cytomegalovirus, Epstein-Barr virus, hepatitis C, hepatitis B, hepatitis A)	Serology for acute or recent exposure
Fungal infections (histoplasmosis, coccidioidomycosis, blastomycosis, nocardiosis, candidiasis)	Fever, immunocompromised
Parasitic infections (schistosomiasis, *Ascaris lumbricoides*, toxoplasmosis, visceral leishmaniasis)	Travel to endemic regions, positive serologic testing
Primary biliary cirrhosis	Female sex, positive AMA, elevated IgM
Malignant diseases (Hodgkin disease, non-Hodgkin lymphoma, renal cell carcinoma)	Evidence of malignant disease in kidney or bone marrow
Drug reactions (allopurinol, chlorpropamide, phenylbutazone, sulfonamides, carbamazepine, glyburide, quinidine, quinine, diltiazem, hydralazine, rosiglitazone, phenytoin, methyldopa, procainamide, amoxicillin–clavulanic acid, mebendazole, mesalamine, acetaminophen, pyrazinamide, halothane, isoniazid, norfloxacin)	Exposure history
Toxins (beryllium, copper sulfate, Thorotrast)	Previous exposure history
Miscellaneous (talc, Crohn disease, granulomatosis with polyangiitis, post–jejunoileal bypass, mineral oil lipogranulomas, hepatic allograft rejection, chronic granulomatous disease)	History of IV drug use, history of liver transplantation, diarrhea

ACE = angiotensin-converting enzyme; PPD = purified protein derivative; HIV = human immunodeficiency virus; AMA = antimitochondrial antibody; IV = intravenous.

cholestatic jaundice, or portal hypertension. In some patients, the granulomatous injury and destruction of the interlobular bile ducts eventually cause ductopenia and a histologic picture similar to primary biliary cirrhosis (Chapter 155). In other patients, damage to the large bile ducts may lead to a syndrome that mimics primary sclerosing cholangitis (Chapter 155). Other patients may present with focal liver lesions suggestive of malignant neoplasm.

Patients typically have markedly elevated serum alkaline phosphatase levels. Angiotensin-converting enzyme levels also are characteristically elevated but may not be helpful in differentiating sarcoidosis from other chronic liver diseases, such as primary biliary cirrhosis, in which it also may be elevated. The presence of noncaseating granulomas in a patient with clinically suspected sarcoidosis generally establishes the diagnosis. However, granulomas do not correlate with liver function test results or duration of disease.

TREATMENT AND PROGNOSIS

Rx

In general, hepatic sarcoidosis does not need to be treated except in patients with other indications for treatment (Chapter 95). Corticosteroids improve liver function test results but do not alleviate portal hypertension, and serial biopsies often show little improvement. Sarcoidosis that leads to portal hypertension and fibrosis may ultimately require liver transplantation (Chapter 154), although sarcoidosis may recur in the new organ.

Other Granulomatous Liver Diseases

In addition to sarcoidosis, another major cause of granulomatous liver disease is tuberculosis (Chapter 324). Military tuberculosis, caused by *Mycobacterium tuberculosis*, commonly results in hepatic granulomas, and patients present with hepatomegaly, abnormal liver function test results, or both. A biopsy revealing caseating granulomas along with a positive PPD (purified protein derivative) response and active pulmonary tuberculosis can help in establishing a diagnosis. Other mycobacteria are also known to cause granulomatous liver disease, including *M. avium-intracellulare*, *M. genavense*, and *M. scrofulaceum* (Chapter 325).

Other causes of granulomatous liver disease include zoonotic infections such as cat-scratch disease (Chapter 315), Q fever (Chapter 327), and brucellosis (Chapter 310). Cat-scratch disease, which primarily affects children, is caused by *Bartonella henselae*, with cats serving as the main reservoir for the organism. Patients typically present with lymphadenopathy associated with persistent pyrexia of unknown origin, abdominal pain, and weight loss. *B. henselae* can be identified by a Warthin-Starry stain, or an imaging study may demonstrate scattered defects in the liver. Q fever is caused by the intracellular gram-negative rickettsial organism *Coxiella burnetii*. Most infections are asymptomatic but may have self-limited influenza-like symptoms, pneumonia, and hepatitis. A liver biopsy specimen may demonstrate fibrin-ring granulomas (doughnut shaped) in the background of nonspecific reactive hepatitis and steatosis. Brucellosis, which is not common in the United States, is caused by at least four species of *Brucella*: *B. abortus*, *B. suis*, *B. melitensis*, and *B. canis*. The disease is manifested as recurrent high fevers, drenching sweats, malaise, arthralgia, fatigue, abdominal pain, anorexia, and headaches. Patients often have hepatomegaly and elevated serum levels of aminotransferases and alkaline phosphatase. The granulomas formed by this infection are typically smaller than those caused by sarcoidosis or tuberculosis, and a definitive diagnosis can be established through serologic testing.

It is important to keep in mind that hepatic granulomas are formed naturally as a consequence of the immune response, so they may be seen in infections with hepatic involvement. Many of the diseases noted can be manifested as granulomatous liver disease (see Table 151-3): listeriosis, yersiniosis, candidiasis, histoplasmosis, coccidioidomycosis, and schistosomiasis. Viral infections (e.g., cytomegalovirus, hepatitis A, hepatitis B, and hepatitis C), primary biliary cirrhosis, malignant diseases, and certain drug reactions have been etiologically linked to granulomatous liver disease. Table 151-3 categorically lists the major causes of hepatic granulomas and the means by which a differential diagnosis can be established.

152 ALCOHOLIC AND NONALCOHOLIC STEATOHEPATITIS

NAGA P. CHALASANI

Alcoholic liver disease and nonalcoholic fatty liver disease (NAFLD), which represent two of the most common forms of liver disease, can lead to cirrhosis, liver failure, and death. Although these two conditions have different risk factors and natural histories, in both conditions (Table 152-1) the hepatocytes are characterized by macrovesicular steatosis, which is the accumulation of triglycerides as one large cytoplasmic globule that displaces the nucleus. In microvesicular steatosis, cytoplasmic accumulation of fat occurs as multiple small globules with a central nucleus.

ALCOHOLIC LIVER DISEASE

DEFINITION

Excessive alcohol consumption (Chapter 33) causes alcoholic liver disease and can significantly worsen other liver disorders, such as viral hepatitis (Chapter 149) and hemochromatosis (Chapter 212). Although most individuals who consume alcohol do not consume it excessively and do not develop any physical or social consequences, some alcoholics consume sufficient alcohol and, presumably because of other predisposing factors, develop alcoholic liver disease. Alcoholic liver disease is a spectrum of chronic liver diseases ranging from alcoholic fatty liver to alcoholic hepatitis and cirrhosis.

Alcoholic fatty liver disease will develop in nearly 90% of individuals who consume alcohol heavily (on average, >6 drinks per day), but only some individuals develop the more severe conditions of alcoholic hepatitis and alcoholic cirrhosis. Genetic predisposition is likely to play a role in the pathogenesis of acute alcoholic hepatitis and alcoholic cirrhosis, but these genetic factors have not been well defined.[1] Nearly 50% of the patients with alcoholic

TABLE 152-1 COMMON CAUSES OF MACROVESICULAR AND MICROVESICULAR STEATOSIS

MACROVESICULAR STEATOSIS	MICROVESICULAR STEATOSIS
Obesity, type 2 diabetes, metabolic syndrome, and dyslipidemia (nonalcoholic fatty liver disease)	Reye syndrome
Excessive alcohol consumption	Medications (valproate, antiretroviral medicines, intravenous tetracycline)
Hepatitis C (genotype 3)	Heat stroke
Wilson disease	Acute fatty liver of pregnancy
Lipodystrophy starvation	HELLP syndrome
Jejunoileal bypass	Inborn errors of metabolism (lecithin–cholesterol acyltransferase deficiency, cholesterol ester storage disease, Wolman disease)
Parenteral nutrition	
Medications (amiodarone, methotrexate, tamoxifen, corticosteroids, antipsychotics)	

HELLP = *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets.

hepatitis have preexisting cirrhosis (Chapter 153), and individuals who do not yet have cirrhosis are at high risk for its development, especially if they continue to consume alcohol.

EPIDEMIOLOGY

The true prevalence of alcoholic liver disease is not known, but nearly 1% of North American adults are believed to have alcoholic liver disease. Even this figure is considered an underestimation because milder forms of alcoholic liver disease are asymptomatic and often unrecognized. It has been estimated that alcoholic liver disease accounts for 40% of deaths from cirrhosis and 28% of all deaths from liver disease. It is the second most common indication for liver transplantation in the United States once abstinence from alcohol has been established.

PATHOBIOLOGY

The mechanisms underlying alcoholic liver injury can be broadly categorized into those caused by the effects of alcohol directly on hepatocytes and those caused by the effects mediated by Kupffer cells.[2] The hepatocyte mechanisms include the altered redox state induced by alcohol and aldehyde dehydrogenase reactions; the oxidative stress and lipid peroxidation caused by the induction of CYP2E1 enzymes and the mitochondrial electron transfer system; and the effects of alcohol on the nuclear transcription factors AMP kinase and SREBP-1c, protein adduct formation, and altered methionine and folate metabolism with resulting endoplasmic reticulum stress. Chronic alcohol consumption increases gut permeability, and the resulting portal endotoxemia activates Kupffer cells. Activated Kupffer cells release a number of proinflammatory mediators. These include tumor necrosis factor-α (TNF-α); transforming growth factor-β1; interleukins 1, 6, 8, and 10; and platelet-derived growth factor. TNF-α has plethora of biologic effects and causes hepatocyte apoptosis, whereas transforming growth factor-β1 and platelet-derived growth factor play important roles in stellate cell activation, collagen production, and hepatic fibrosis.

Among the known risk factors for development of alcoholic liver disease (Table 152-2), the amount of alcohol consumed is the single most important. For unclear reasons, only 30 to 35% of individuals with heavy and long-term drinking develop alcoholic hepatitis, and less than 20% develop cirrhosis. Women are at higher risk; for example, the risk of alcoholic cirrhosis increases after 10 years of alcohol consumption at quantities of more than 60 to 80 g/day in men, whereas in women, it can develop at quantities of only more than 20 g/day. Moreover, the peak incidence of alcoholic liver disease in women is approximately a decade earlier than in men. The type of alcoholic beverage consumed may not be as critical, but "spirits" and beer may be more hepatotoxic than wine. African American and Hispanic ethnic groups may be predisposed to more significant alcoholic liver injury. Both obesity and protein-calorie malnutrition, in which micronutrients and antioxidant capacity are diminished, also are important predispositions.

Polymorphisms in genes associated with alcohol metabolism (alcohol and aldehyde dehydrogenases and cytochrome P-450 enzymes) and dysregulated cytokine production (e.g., TNF-α) may also influence genetic susceptibility. In patients with other forms of chronic liver disease (e.g., viral hepatitis B or C), concomitant alcohol consumption significantly aggravates liver injury.

CLINICAL MANIFESTATIONS

Patients with alcoholic liver disease may have signs and symptoms from underlying alcoholism as well as those caused by liver disease. Stigmata of chronic alcoholism include palmar erythema (see Fig. 146-2), spider nevi, bilateral gynecomastia, testicular atrophy, bilateral parotid enlargement, and Dupuytren contractures (Fig. 152-1). The clinical features of liver disease will depend on the stage of alcoholic liver disease, that is, whether a patient has alcoholic fatty liver or more advanced liver disease, such as alcoholic hepatitis and cirrhosis.

Patients with alcoholic fatty liver disease are generally asymptomatic, but some patients may have anorexia, fatigue, right upper quadrant discomfort, and tender hepatomegaly. These patients may also have biochemical evidence of alcoholism and alcoholic liver disease with macrocytosis as well as elevated levels of aspartate aminotransferase (AST) and γ-glutamyl transpeptidase. Patients with alcoholic fatty liver typically do not have jaundice, ascites, or splenomegaly.

Patients with alcoholic hepatitis may have a more dramatic presentation with severe malaise, fatigue, anorexia, fever, evidence of protein-calorie malnutrition, and features of decompensated liver disease, including jaundice, coagulopathy, ascites, and encephalopathy. However, these classic features of acute alcoholic hepatitis are not universally present. Physical examination invariably shows at least some features of chronic alcoholism, and jaundice (see Fig. 146-1), ascites (see Fig. 146-4), and splenomegaly are common. The laboratory examination findings are typically abnormal. Common hematologic abnormalities include leukocytosis with neutrophil predominance, macrocytic anemia (Chapter 164), thrombocytopenia (Chapter 172), and prolonged prothrombin time. Liver biochemistries (Chapter 147) are abnormal with an elevated AST and ratio of AST to alanine aminotransferase (ALT), alkaline phosphatase, γ-glutamyl transpeptidase, and total bilirubin but decreased levels of serum albumin. The AST rarely exceeds 300 IU/L. Serum electrolyte abnormalities including hypokalemia (Chapter 117), hypomagnesemia (Chapter 119), hypocalcemia (Chapter 245), and hypophosphatemia (Chapter 119) are frequent. Patients with alcoholic cirrhosis have the same clinical features that are common to other types of cirrhosis (Chapter 153) but also with striking features of underlying chronic alcoholism.

DIAGNOSIS

The diagnosis of alcoholic liver disease strongly depends on the history of excessive alcohol consumption and the presence of liver disease. Although laboratory abnormalities are not specific for alcoholic liver disease, they can be suggestive in the context of excessive alcohol consumption. An AST/ALT ratio of more than 2 is typical in alcoholic liver disease, and ALT values greater than 150 to 200 IU/L are very rare in alcoholic liver disease. Serology testing for coexisting chronic viral hepatitis (Chapter 149) is critical. Diagnostic dilemmas arise when a patient denies excessive alcohol consumption in the face of clinical features that are suggestive of alcoholic liver disease. Interviewing family members about specific alcohol consumption may be helpful in the accurate ascertainment of alcohol consumption. Elevated blood levels of carbohydrate-deficient transferrin, which is a form of transferrin with fewer than the four sialic acid chains present in normal transferrin, can identify recent heavy alcohol consumption. Hepatic imaging by ultrasound, computed tomography, or magnetic resonance imaging will show changes consistent with hepatic steatosis or more advanced forms of liver disease, such as cirrhosis and portal hypertension. Imaging is also important to exclude other forms of liver disease, including malignant disease and

TABLE 152-2 RISK FACTORS FOR ALCOHOLIC LIVER DISEASE AND NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)

ALCOHOLIC LIVER DISEASE	NAFLD

biliary obstruction. Imaging findings specific for alcoholic liver disease include an enlarged caudate lobe, greater visualization of the right posterior hepatic notch, and focal fat sparing or geographic fat distribution.

Because specific treatment for alcoholic hepatitis may be harmful in patients with other liver diseases, it is important to exclude other predominant or coexisting liver diseases, including chronic viral hepatitis (Chapter 149) and drug-induced liver injury, especially from acetaminophen (Chapter 150), by history, blood tests, and biopsy if needed. Hyperferritinemia generally reflects an acute phase reactant, rather than an iron overload disorder, so it usually will return to normal when the acute liver injury resolves.

Liver biopsy is the key to precisely characterizing the nature of alcoholic liver disease and determining whether a patient has fatty liver or more advanced alcoholic hepatitis. Histologic features of alcoholic fatty liver include macrovesicular steatosis that is predominantly centrilobular (zone 3) in nature. In alcoholic hepatitis, the biopsy is more striking and reveals macrovesicular steatosis, lobular neutrophilic infiltration, Mallory hyaline, balloon degeneration of the hepatocytes, and perivenular fibrosis. In general, patients with alcoholic hepatitis also have histologic evidence of chronic liver injury in the form of more advanced fibrosis (periportal or bridging fibrosis or cirrhosis).

TREATMENT

Rx

Total abstinence, which is the most important treatment measure, is mandatory for the improvement of the clinical and histologic features of alcoholic liver disease. Its benefits are unequivocal, even in patients with severe decompensation. However, long-term abstinence is difficult to achieve, so a multidisciplinary approach with counseling and medications that promote abstinence should be considered. Disulfiram is not commonly used because of its poor tolerability and hepatotoxicity. Opioid antagonists, such as naltrexone (50 mg/day for up to 6 months or even longer), nalmefene (20 mg/day as maintenance), and acamprosate (333-mg tablets, 2 tablets three times each day for 1 year), can help promote abstinence when they are used as part of a multidisciplinary approach (Chapter 33).

Alcoholic fatty liver disease requires no specific treatment other than abstinence. Patients with alcoholic hepatitis, however, have increased short- and long-term mortality and should be considered for therapeutic interventions in addition to mandatory abstinence.[3] If a patient's liver biopsy findings are consistent with alcoholic hepatitis and there is no evidence of other inflammatory liver diseases, such as hepatitis C (Chapter 149), prednisolone (40 mg/day for 4 weeks) should be given to carefully selected patients with severe alcoholic hepatitis who have a score higher than 32 on Maddrey's discriminant function (4.6 × [patient's prothrombin time − control prothrombin time] + total bilirubin level) and encephalopathy but do not have gastrointestinal bleeding or systemic infection. Studies have suggested that a Model for End-Stage Liver Disease (MELD) score (see Table 153-2) higher than 21 can substitute for Maddrey's score to guide the use of prednisolone. Adding intravenous *N*-acetylcysteine (on day 1 at a dose of 150, 50, and 100 mg per kilogram of body weight in 250, 500, and 1000 mL of 5% glucose solution during a period of 30 minutes, 4 hours, and 16 hours, respectively; and on days 2 through 5, 100 mg per kilogram per day in 1000 mL of 5% glucose solution) to prednisolone appears to be superior to prednisolone alone in terms of a significantly lower mortality at 1 month (8% vs. 24%) and a somewhat but not significantly lower mortality at 6 months (22% vs. 34%; $P = .06$). Although randomized trials also have shown a benefit of pentoxifylline (400 mg three times daily for 28 days) for severe alcoholic hepatitis, prednisolone is more effective than pentoxifylline and the combination of pentoxifylline with prednisolone is no better than prednisolone alone.

The anti–TNF-α agents infliximab and etanercept are not effective and have significant side effects. All patients with alcoholic hepatitis and alcoholic cirrhosis should be assessed and treated for protein-calorie malnutrition and micronutrient deficiency. Hospitalized patients with severe decompensation should be considered for enteral nutrition (Chapter 216).

Complications such as ascites, spontaneous bacterial peritonitis, encephalopathy, variceal bleeding, hepatorenal syndrome, osteoporosis, and hepatopulmonary syndrome may occur in patients with decompensated alcoholic cirrhosis and must be managed carefully (Chapter 153). Liver transplantation is a reasonable option in patients with decompensated alcoholic cirrhosis, and observational data suggest that early liver transplantation can improve survival in patients with severe, medically refractory alcoholic hepatitis.[4] In general, however, 6 months of abstinence and strong social support are required for eligibility (Chapter 154). Patients with alcoholic cirrhosis are at risk for hepatocellular carcinoma (Chapter 196) and should be screened with semiannual liver imaging and serum α-fetoprotein levels. They are also at risk for extrahepatic malignant disease, notably head and neck, lung, and esophageal cancer. For Dupuytren contracture, injection of collagenase clostridium histolyticum can reduce the severity and improve the range of motion significantly.

PROGNOSIS

Alcoholic fatty liver is generally reversible with total abstinence for a few months. Alcoholic hepatitis carries high mortality, with nearly 40% of patients dying within 6 months after its presentation. Predictors of poor outcome include the severity of disease as quantified by approaches such as the MELD score[5] (Chapters 153 and 154) and the severity of fibrosis and the neutrophilic infiltration on liver biopsy.[6]

NONALCOHOLIC FATTY LIVER DISEASE

DEFINITIONS

On histologic examination, NAFLD resembles alcoholic liver disease, but it occurs in individuals without significant alcohol consumption. Average alcohol consumption of more than two drinks per day in men and more than one drink per day in women generally is not consistent with a diagnosis of NAFLD. In addition, the definition of NAFLD excludes patients with a history of exposure to steatogenic medications, such as amiodarone, methotrexate, and tamoxifen.

NAFLD encompasses a spectrum of abnormal liver histologic features, ranging from simple steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis. In simple steatosis, liver histology reveals macrovesicular steatosis without ballooning degeneration of hepatocytes or liver fibrosis. NASH, which is a more advanced form of NAFLD, is histologically characterized by macrovesicular steatosis, ballooning degeneration of the hepatocytes, and sinusoidal fibrosis.

EPIDEMIOLOGY

NAFLD is one of the most common causes of elevated liver enzymes and chronic liver disease in the Western world. Its incidence in adults and children is rising rapidly because of the ongoing epidemics of obesity (Chapter 220), type 2 diabetes mellitus (Chapter 229), and metabolic syndrome. Its prevalence is high in certain populations of patients; for example, nearly 80% of type 2 diabetic patients and 90% of morbidly obese individuals have imaging evidence of NAFLD. Nearly one third of adults in westernized countries are estimated to have NAFLD, and about 5% of adults may have NASH.[7] These percentages compare reasonably well with other data suggesting that the prevalence of cirrhosis from NAFLD is about 2%. Hispanics and whites are at higher risk for NAFLD, whereas its prevalence is intriguingly low in African Americans.

PATHOBIOLOGY

The major risk factors for NAFLD include obesity, type 2 diabetes mellitus (Chapter 229), metabolic syndrome, and dyslipidemia (see Table 152-2). Other comorbidities associated with NAFLD include polycystic ovary syndrome (Chapter 235), hypothyroidism (Chapter 226), hypopituitarism (Chapter 224), hypogonadism (Chapter 234), and sleep apnea (Chapter 100).

Two fundamental defects in NAFLD are insulin resistance/hyperinsulinemia and excessive levels of nonesterified fatty acids within the hepatocytes. An excessive influx of nonesterified fatty acids into the hepatocytes results in macrovesicular steatosis, which is predominantly centrilobular in location.

In addition, patients with NAFLD have increased de novo intrahepatic lipogenesis. Although patients with NAFLD robustly esterify free fatty acids into neutral triglycerides, free fatty acids within the hepatocytes are considered the primary mediators of cell injury (lipotoxicity). In the background of hepatic steatosis, factors that promote cell injury, inflammation, and fibrosis include oxidative stress, endoplasmic reticulum stress, apoptosis, adipocytokines, and stellate cell activation. The sources of oxidative stress include mitochondria and microsomes. Adipocytokines that play an important role in the pathogenesis of NAFLD include adiponectin and TNF-α. It is unclear why some patients with NAFLD exhibit NASH, whereas other patients with a comparable risk factor profile have only simple steatosis. There is a consistent and significant relationship of *PNPLA3* genetic polymorphisms with the severity of steatosis and other histologic features of NAFLD. However, the genetic factors that play a role in NASH and NAFLD have not been fully elucidated.

CLINICAL MANIFESTATIONS

NAFLD is often asymptomatic but may rarely cause fatigue and right upper quadrant pain. Physical examination may reveal hepatomegaly, palmar erythema (see Fig. 146-2), and spider nevi. If liver disease is advanced,

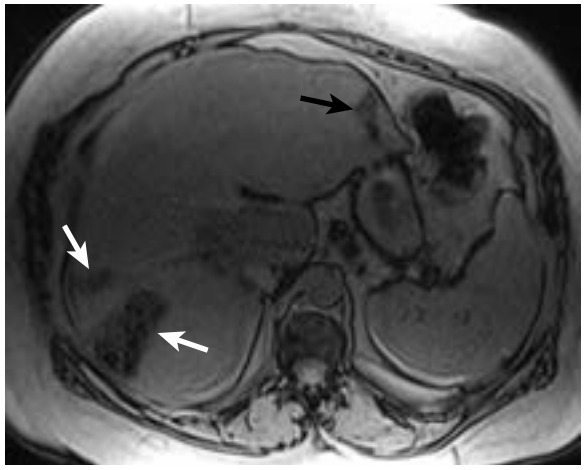

FIGURE 152-2. Magnetic resonance image of chronic liver disease due to nonalcoholic fatty liver disease. Out-of-phase T1-weighted images show focal fat infiltration of varying shapes in right lobe (*white arrows*) and left lobe (*black arrow*). (Courtesy Professor Kumar Sandrasegaran, Indiana University School of Medicine, Indianapolis, Ind.)

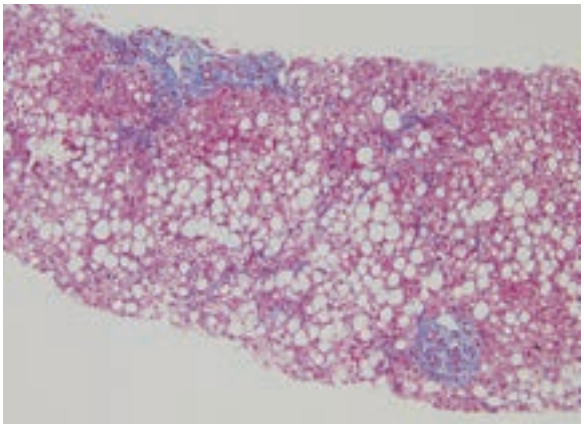

FIGURE 152-3. Liver biopsy specimen showing nonalcoholic steatohepatitis, with increased fat and with early cirrhosis. (Courtesy the NASH Clinical Research Network.)

the features of liver failure, such as ascites, encephalopathy, and abdominal collateral vessels, are present. Simple steatosis is benign with a minimal risk of cirrhosis, whereas NASH is progressive and can lead to cirrhosis (Chapter 153) and liver failure (Chapter 154). In up to 20% of patients with NASH, liver histologic features will worsen and cirrhosis will develop during a 10- to 15-year period. Severe obesity, advancing age, and diabetes are believed to be risk factors for disease progression. Disease progression during the early phase can be identified only with a repeated liver biopsy, but in later stages, the signs and symptoms of portal hypertension (e.g., abdominal collateral vessels and low platelet count) indicate the development of cirrhosis. Patients with NASH-induced cirrhosis are at risk for development of hepatocellular carcinoma (Chapter 196). Patients with NAFLD have several metabolic risks that predispose them to atherosclerosis, and coronary artery disease is the single most common cause of death in patients with NAFLD.

DIAGNOSIS

NAFLD is generally suspected when aminotransferase levels are asymptomatically elevated in an individual with metabolic risk factors (obesity, diabetes, or the metabolic syndrome) or when liver imaging (ultrasound, computed tomography, or magnetic resonance imaging) obtained for another reason shows fatty infiltration (Fig. 152-2). The diagnosis of NAFLD requires that there is no history of previous or ongoing significant alcohol consumption, no exposure to steatogenic medications, and no evidence of other causes of liver disease, such as viral hepatitis B or C.[8] Elevated levels of aminotransferases, although common, are not required for the diagnosis of NAFLD. In contrast to alcoholic liver disease, ALT levels are higher than AST levels, but they rarely exceed 250 IU/L. In general, AST and ALT levels do not have diagnostic or prognostic significance. Mild hyperferritinemia is common and should not be confused with hereditary hemochromatosis (Chapter 212). Similarly, low-grade autoantibody (antinuclear antibody, anti–smooth muscle antibody) positivity is not uncommon and should not be confused with autoimmune liver disease (Chapter 149). Because steatosis is common in patients with Wilson disease (Chapter 211), serum ceruloplasmin levels should be obtained as part of the diagnostic evaluation.

Fatty liver on ultrasonography has a positive predictive value of only 77% and a negative predictive value of only 67% compared with liver biopsy. Abdominal magnetic resonance imaging is more accurate, but its high cost limits its usefulness in routine practice. Because neither of these imaging tests can differentiate simple steatosis from NASH or identify cirrhosis until hepatic fibrosis has caused nodular liver or overt portal hypertension, liver biopsy is required to establish the presence of NASH or cirrhosis. Common indications for a percutaneous liver biopsy in patients with NAFLD include persistently high aminotransferase levels, inability to exclude a competing or a coexisting cause (e.g., iron overload or autoimmune liver disease), and clinical suspicion of NASH and advanced fibrosis. In patients with NASH, liver histology shows steatosis, inflammation, ballooning, and fibrosis (Fig. 152-3). However, liver histology alone cannot reliably distinguish NASH from alcoholic hepatitis because these two entities have remarkably similar microscopic features.

TREATMENT

Rx

Lifestyle modification with dietary restriction and regular exercise is the first choice of treatment for NAFLD. Weight reduction and increased physical activity consistently reduce liver fat, improve glucose control and insulin sensitivity, and may improve histopathologic features.[9] It is generally recommended that patients with NAFLD lose 10% of their body weight in a gradual fashion, but this goal is difficult to achieve. If resources are available, a multidisciplinary approach with behavioral therapy, dietary advice, and monitoring by a professional nutritionist and an exercise expert is more successful than a prescriptive approach.[10]

Statins (e.g., atorvastatin 20 mg daily) with or without vitamins C and E can improve liver test results and reduce subsequent NAFLD. In one large trial, 800 IU of vitamin E administered daily for 2 years significantly improved liver histologic findings in adults, but other trials did not show such convincing benefits in children. Thiazolidinedione insulin sensitizers (pioglitazone and rosiglitazone) improve steatosis, inflammation, and ballooning, and perhaps fibrosis, but with the side effect of an average gain of nearly 10 pounds. Unfortunately, the weight gain that is common with thiazolidinediones may offset the histologic benefits that they offer. Treatment with pentoxifylline (400 mg three times daily) can also improve liver enzymes and liver histologic findings in individuals with NASH.

Patients with NAFLD often have dyslipidemia that puts them at excessive risk for coronary artery disease; their dyslipidemia (Chapter 206) should be treated aggressively with statins and other lipid-lowering agents, which can be safely administered to patients with NAFLD and NASH. In morbidly obese individuals with NASH and other significant metabolic comorbidities, foregut bariatric surgery can lead to significant improvement in hepatic histologic features, but the physician must exclude the presence of portal hypertension before offering this type of surgery.[11] Carefully selected patients with decompensated cirrhosis due to NASH can be treated with liver transplantation (Chapter 154), but recurrence during the post-transplantation period is common.

PREVENTION

The measures to prevent NAFLD include maintaining optimal body weight, exercising regularly, and treating any associated metabolic comorbidities such as diabetes and dyslipidemia. Avoidance of saturated fat, high fructose intake, and alcohol consumption may reduce the development of NAFLD.

PROGNOSIS

Steatosis alone is generally benign, whereas steatohepatitis is often progressive. One third of NAFLD patients may have remission within 7 years, mostly depending on modest weight reduction. Otherwise, however, data are sparse regarding the risk and risk factors for the progression of NAFLD and NASH to cirrhosis and liver failure.

Because NAFLD often coexists with one or more components of the metabolic syndrome, its presence reflects guarded long-term overall prognosis. The long-term complications in patients with simple steatosis generally result from cardiovascular disease and atherosclerosis, not from liver failure.

Patients with NASH also are at risk for liver failure and liver cancer (Chapter 196), in addition to their significantly increased risk of cardiovascular disease. For example, among patients with NASH on their initial biopsy,

one third or more develop progressive fibrosis during a mean follow-up interval of about 5 years. Older age, diabetes, and ballooning and fibrosis on liver biopsy are important predictors of progression.

REVIEW QUESTIONS

1. A 17-year-old adolescent boy presents with right upper quadrant discomfort of 3 to 4 months in duration. This pain is constant and is dull in nature. He consumes no alcohol. He has a long-standing history of type 1 diabetes, for which he takes subcutaneous insulin twice daily. Physical examination reveals a relatively thin individual with tender hepatomegaly. His blood test results were positive for elevated alanine aminotransferase (82 U/L; normal, <45 U/L), blood glucose (181 mg/dL; normal, <125 mg/dL), and hemoglobin A_{1c} (9%; normal, <7%). A liver ultrasound examination revealed increased echogenicity. Which is the likely diagnosis for this patient's abdominal discomfort, elevated alanine aminotransferase level, and tender hepatomegaly?

A. Nonalcoholic fatty liver disease
B. Glycogen hepatopathy
C. Wilson disease
D. Hemochromatosis
E. Glycogen storage disorder

Answer: B Tender hepatomegaly, elevated alanine aminotransferase level, and echogenic liver by ultrasound evaluation are suggestive of some form of infiltrative liver disorder. In type 1 diabetics, especially those with poorly controlled blood glucose levels, there is risk of glycogen hepatopathy, which may be manifested with abdominal discomfort, hepatomegaly, and elevated liver test results. Glycogen accumulation also enhances echogenicity on ultrasound examination and may mimic fatty liver. One must keep in mind that type 1 diabetes is rarely if ever associated with nonalcoholic fatty liver disease. It is believed that hyperinsulinemia is needed for development of nonalcoholic fatty liver disease.

2. A 46-year-old woman presents with 3 weeks' duration of fatigue, anorexia, low-grade fever, and jaundice. She is a heavy drinker and has been consuming more than 7 drinks of vodka each night for the previous 5 years. She is otherwise healthy and is not taking any medications. Physical examination reveals an emaciated woman with deep scleral icterus, peripheral muscle wasting, tender hepatomegaly, and pedal edema. Laboratory test results show macrocytic anemia, mild leukocytosis, elevated aminotransferase levels, and direct bilirubinemia. Which of the following treatments is not a suitable treatment option for this individual?

A. Alcohol abstinence
B. Prednisolone
C. *N*-Acetylcysteine
D. Liver transplantation
E. Enteral nutrition

Answer: D On the basis of the clinical picture, the most likely diagnosis for this individual's condition is acute alcoholic hepatitis. Liver transplantation is not a suitable treatment option for acute alcoholic hepatitis in individuals who are actively consuming alcohol. Most transplant centers require up to 6 months of total abstinence and some form of behavioral therapy for underlying alcoholism. In eligible patients, 28 days of oral prednisolone improves short-term survival in individuals with acute alcoholic hepatitis. Similarly, some previous clinical investigations have shown promising results for *N*-acetylcysteine and enteral nutrition.

3. A 37-year-old morbidly obese man is noted to have an echogenic liver incidentally when he had an abdominal ultrasound examination performed for his hematuria. He has no right upper quadrant pain. He rarely consumes alcohol and takes no medications. His physical examination is essentially unremarkable except for morbid obesity with a body mass index of 42 kg/m^2. Blood test results show mildly elevated aminotransferase levels but otherwise are within normal range. Your likely diagnosis is nonalcoholic fatty liver disease (NAFLD), and you recommend weight loss. Which of the following best represents his liver condition?

A. NAFLD is a rare condition, and its incidence has remained relatively steady during the last decade.
B. Type 2 diabetes, obesity, dyslipidemia, and metabolic syndrome are the major risk factors for NAFLD.
C. Hyperthyroidism is a common cause of NAFLD.
D. Sleep disturbance is rare in NAFLD.
E. This condition can be ignored because it is rarely of any clinical significance.

Answer: B Hypothyroidism, hypopituitarism, hypogonadism, polycystic ovary syndrome, and obstructive sleep disorders are emerging risk factors for NAFLD. Although hyperthyroidism is associated with liver test abnormalities, it is not known to be associated with fatty liver disease. In fact, thyroid hormone analogues may improve hepatic steatosis, although they may carry significant adverse events and are not a recommended treatment. Clearly, the incidence of NAFLD is increasing because of the increasing prevalence of obesity and related comorbid conditions, and it is now one of the most common causes of cirrhosis, liver failure, and liver cancer. Therefore, it cannot be ignored as clinically insignificant.

4. A 46-year-old woman presents with chronically elevated liver enzymes and mild hepatomegaly. She has type 2 diabetes, which is diet controlled, and has dyslipidemia, which is managed with a low-dose statin. She denies significant alcohol consumption. Her liver biopsy showed 30% hepatic steatosis with ballooned hepatocytes and mild sinusoidal fibrosis. Your clinical and histologic diagnosis is nonalcoholic steatohepatitis. Which of the following treatments is not a suitable option for her?

A. Weight loss
B. Pioglitazone
C. Vitamin E
D. Ursodeoxycholic acid
E. Pentoxifylline

Answer: D Weight loss is the first-line treatment option for both NAFLD and NASH. Loss of 3 to 5% of body weight will improve hepatic steatosis, whereas a loss of 7 to 10% is needed to see an improvement in steatohepatitis. Calorie restriction and physical exercise are advised to achieve the desired weight loss in individuals with NAFLD and NASH. When such measures are not achieved, therapy with agents such as pioglitazone, vitamin E, and pentoxifylline can be considered. In clinical studies, these compounds have shown therapeutic efficacy in various subgroups of patients. Ursodeoxycholic acid, a medication used to treat primary biliary cirrhosis, has been tested in individuals with NASH but has not proved to be effective. Metformin is not effective for improving liver histology findings in NASH and therefore should not be used for this purpose.

CIRRHOSIS AND ITS SEQUELAE

GUADALUPE GARCIA-TSAO

DEFINITION

Cirrhosis, which can be the final stage of any chronic liver disease, is a diffuse process characterized by fibrosis and conversion of normal architecture to structurally abnormal nodules (Fig. 153-1). These "regenerative" nodules lack normal lobular organization and are surrounded by fibrous tissue. The process involves the whole liver and generally is considered irreversible. Although cirrhosis is histologically an "all-or-nothing" diagnosis, clinically it can be classified by its status as compensated or decompensated. Decompensated cirrhosis is defined by the presence of ascites, variceal bleeding, encephalopathy, or jaundice, which are complications that result from the main consequences of cirrhosis: portal hypertension and liver insufficiency.

EPIDEMIOLOGY

Because many patients with cirrhosis are asymptomatic until decompensation occurs, it is difficult to assess the real prevalence and incidence of cirrhosis in the general population. The prevalence of chronic liver disease or cirrhosis worldwide is estimated to be 100 (range, 25 to 400) per 100,000 subjects, but it varies widely by country and by geographic region.

Cirrhosis is an important cause of morbidity and mortality worldwide and in the United States. According to the World Health Organization, about 800,000 people die of cirrhosis annually. In the United States, cirrhosis accounts for about 32,000 deaths each year, or a death rate of 10.3 per 100,000, thereby making it the 12th leading cause of death overall. Importantly, chronic liver disease and cirrhosis are the sixth leading cause of death in the United States in individuals between 25 and 44 years of age and fifth in individuals between 45 and 64 years of age. As chronic liver disease affects people in their most productive years of life, it has a significant impact on the economy as a result of premature death, illness, and disability.

Any chronic liver disease can lead to cirrhosis (Table 153-1). Chronic viral hepatitis C and alcoholic liver disease are the most common causes of cirrhosis, followed by nonalcoholic fatty liver disease (in particular, nonalcoholic steatohepatitis) and chronic hepatitis B (Chapters 149 and 152). However, other causes of cirrhosis include cholestatic and autoimmune liver diseases, such as primary biliary cirrhosis, primary sclerosing cholangitis (Chapter 155), and autoimmune hepatitis (Chapter 149), and metabolic diseases, such as hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency (Chapter 146). When all potential causes have been investigated and excluded, cirrhosis is considered "cryptogenic." Many cases of cryptogenic cirrhosis are now thought to be due to nonalcoholic fatty liver disease (Chapter 152).

Although the entity termed primary biliary cirrhosis assumes the presence of cirrhosis, this term is actually misleading. Primary biliary cirrhosis (Chapter 155) is an immune-mediated cholestatic chronic liver disease that is characterized by progressive destruction of intrahepatic bile ducts and progresses over time from an initial stage in which fibrosis is minimal (stage 1) to a final stage in which there is well-established cirrhosis (stage 4).

PATHOBIOLOGY

Liver Fibrosis and Cirrhosis

The key pathogenic feature underlying liver fibrosis and cirrhosis is activation of hepatic stellate cells. Hepatic stellate cells, which are known as *Ito cells* or *perisinusoidal cells*, are located in the space of Disse between hepatocytes and sinusoidal endothelial cells. Normally, hepatic stellate cells are quiescent and serve as the main storage site for retinoids (vitamin A). In response to injury, hepatic stellate cells become activated, as a result of which they lose their vitamin A deposits, proliferate, develop a prominent rough endoplasmic reticulum, and secrete extracellular matrix (collagen types I and III, sulfated proteoglycans, and glycoproteins). In addition, they become contractile hepatic myofibroblasts.[1]

Unlike other capillaries, normal hepatic sinusoids lack a basement membrane. The sinusoidal endothelial cells themselves contain large fenestrae (100 to 200 nm in diameter) that permit the passage of large molecules with molecular masses up to 250,000 daltons. Collagen deposition in the space of Disse, as occurs in cirrhosis, leads to defenestration of the sinusoidal endothelial cells ("capillarization" of the sinusoids), thereby altering exchange between plasma and hepatocytes and resulting in a decreased sinusoidal diameter that is further exacerbated by the contraction of stellate cells.

Complications of Cirrhosis

The two main consequences of cirrhosis are portal hypertension, with the accompanying hyperdynamic circulatory state, and liver insufficiency (Fig. 153-2). The development of varices and ascites is a direct consequence of portal hypertension and the hyperdynamic circulatory state, whereas jaundice occurs as a result of an inability of the liver to excrete bilirubin (i.e., liver insufficiency). Encephalopathy is the result of both portal hypertension and liver insufficiency. Ascites, in turn, can become complicated by infection, which is called *spontaneous bacterial peritonitis*, and by functional renal failure, which is called *hepatorenal syndrome.*

Portal Hypertension and the Hyperdynamic Circulatory State

In cirrhosis, portal hypertension results from both an increase in resistance to portal flow and an increase in portal venous inflow. The initial mechanism is increased sinusoidal vascular resistance (Fig. 153-3) secondary to (1) deposition of fibrous tissue and subsequent compression by regenerative nodules (fixed component), which could theoretically be amenable to antifibrotic agents and could be ameliorated by resolving the underlying etiologic process, and (2) active vasoconstriction (functional component), which is amenable to the action of vasodilators such as nitroprusside and is caused by a deficiency in intrahepatic nitric oxide (NO) as well as enhanced activity of vasoconstrictors.

Early in the portal hypertensive process, the spleen grows and sequesters platelets and other formed blood cells, thereby leading to hypersplenism. In addition, vessels that normally drain into the portal system, such as the coronary vein, reverse their flow and shunt blood away from the portal system to the systemic circulation. These portosystemic collaterals are insufficient to decompress the portal venous system and offer additional resistance to portal

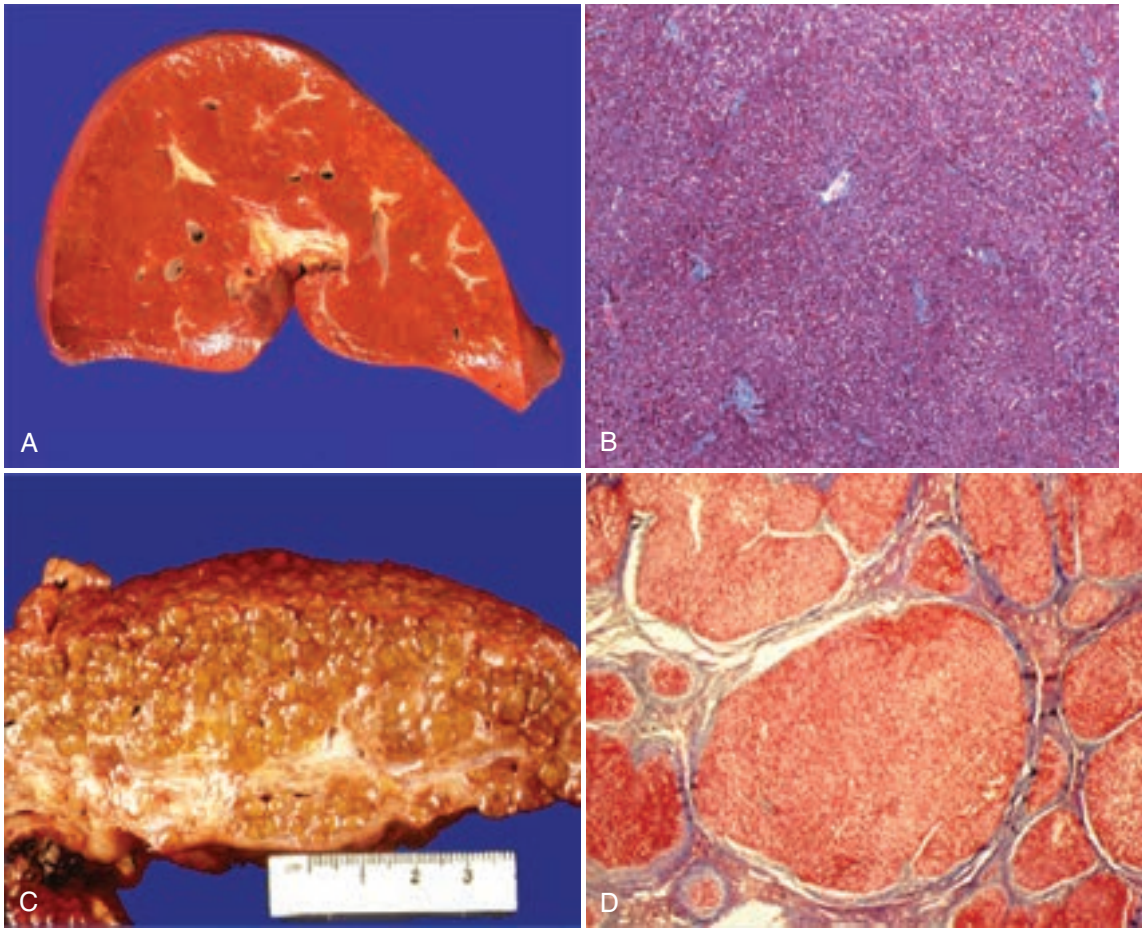

FIGURE 153-1. Gross and microscopic images of a normal and cirrhotic liver. A, Gross image of a normal liver with a smooth surface and homogeneous texture. **B,** On microscopic examination, liver sinusoids are organized, and vascular structures are normally distributed. **C,** Gross image of a cirrhotic liver. The liver has an orange-tawny color with an irregular surface and a nodular texture. **D,** On microscopic examination, the architecture is disorganized, and there are regenerative nodules surrounded by fibrous tissue.

TABLE 153-1 CAUSES OF CIRRHOSIS

MAIN FACTORS CAUSING CIRRHOSIS
Chronic hepatitis C
Alcoholic liver disease
Nonalcoholic fatty liver disease
Chronic hepatitis B
OTHER CAUSES OF CIRRHOSIS (<2% OF ALL CASES)
Cholestatic and autoimmune liver diseases
Primary biliary cirrhosis
Primary sclerosing cholangitis
Autoimmune hepatitis
Intrahepatic or extrahepatic biliary obstruction
Mechanical obstruction
Biliary atresia
Cystic fibrosis
Metabolic disorders
Hemochromatosis
Wilson disease
α_1-Antitrypsin deficiency
Glycogen storage diseases
Abetalipoproteinemia
Porphyria
Hepatic venous outflow obstruction
Budd-Chiari syndrome
Veno-occlusive disease
Right-sided heart failure
Drugs and toxins
Intestinal bypass
Indian childhood cirrhosis

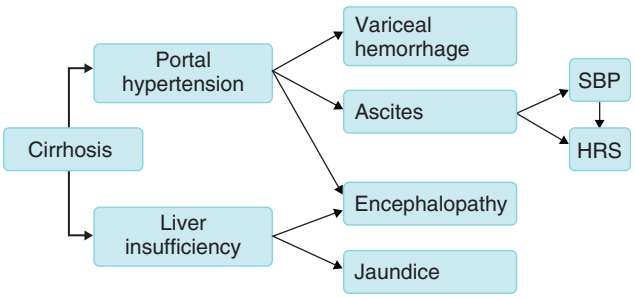

FIGURE 153-2. Complications of cirrhosis result from portal hypertension or liver insufficiency. Varices and variceal hemorrhage are a direct consequence of portal hypertension. Ascites results from sinusoidal portal hypertension and can be complicated by infection (spontaneous bacterial peritonitis [SBP]) or renal dysfunction (hepatorenal syndrome [HRS]). Hepatic encephalopathy results from portosystemic shunting (i.e., portal hypertension) and liver insufficiency. Jaundice results solely from liver insufficiency.

flow. As collaterals develop, an increase in portal blood inflow, which results from splanchnic vasodilation, maintains the portal hypertensive state. Splanchnic arteriolar vasodilation is, in turn, secondary to increased production of NO. Thus, the paradox in portal hypertension is that a deficiency of NO in the intrahepatic vasculature leads to vasoconstriction and increased resistance, whereas overproduction of NO in the extrahepatic circulation leads to vasodilation and increased portal flow.

In addition to splanchnic vasodilation, there is systemic vasodilation, which by causing a decreased *effective* arterial blood volume leads to activation of neurohumoral systems (renin-angiotensin-aldosterone system),

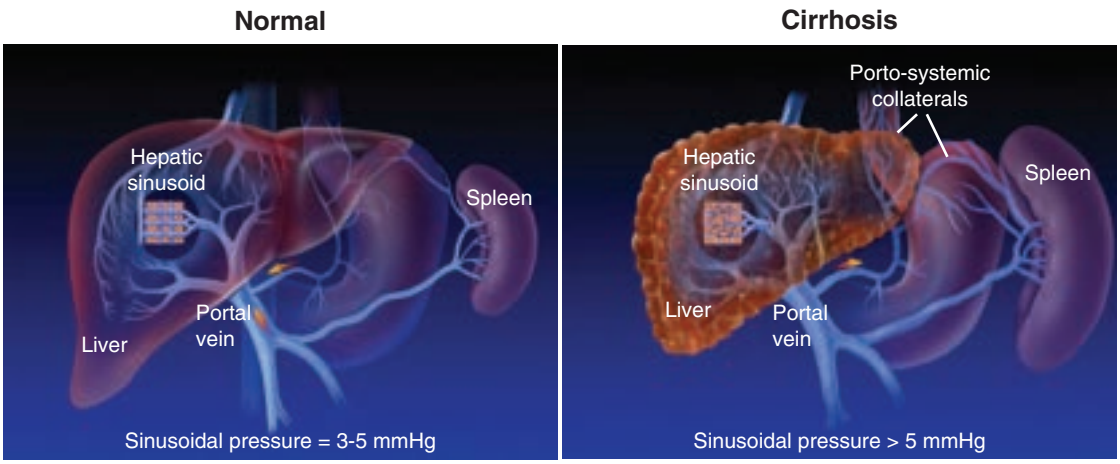

FIGURE 153-3. Hepatic sinusoidal pressure is increased in cirrhosis. In the normal liver (*left*), the intrahepatic vasculature is compliant, and the hepatic venous pressure gradient, which is a measure of sinusoidal pressure, is 5 mm Hg or lower. In the cirrhotic liver (*right*), the sinusoidal architecture is distorted by regenerative nodules and fibrosis that lead to increased intrahepatic resistance, portal hypertension, splenomegaly, and portosystemic collaterals; the hepatic venous pressure gradient is above 5 mm Hg. Complications of cirrhosis develop when the gradient increases above 10 to 12 mm Hg.

retention of sodium, expansion of plasma volume, and development of a hyperdynamic circulatory state. This hyperdynamic circulatory state maintains portal hypertension, thereby leading to the formation and growth of varices, and plays an important role in the development of all other complications of cirrhosis.

Varices and Variceal Hemorrhage

The complication of cirrhosis that results most directly from portal hypertension is the development of portal-systemic collaterals, the most relevant of which are those that form through dilation of the coronary and gastric veins and constitute gastroesophageal varices. The initial formation of esophageal collaterals depends on a threshold portal pressure, clinically established by a hepatic venous pressure gradient of 10 to 12 mm Hg, below which varices do not develop.

Development of a hyperdynamic circulatory state leads to further dilation and growth of varices and eventually to their rupture and variceal hemorrhage, one of the most dreaded complications of portal hypertension. Tension in a varix determines variceal rupture and is directly proportional to variceal diameter and intravariceal pressure and inversely proportional to variceal wall thickness.

Ascites and Hepatorenal Syndrome

Ascites, which is the accumulation of intraperitoneal fluid, in cirrhosis is secondary to sinusoidal hypertension and retention of sodium. Cirrhosis leads to sinusoidal hypertension by blocking hepatic venous outflow both anatomically by fibrosis and regenerative nodules and functionally by increased postsinusoidal vascular tone. Similar to the formation of esophageal varices, a threshold hepatic venous pressure gradient of 12 mm Hg is needed for the formation of ascites. In addition, retention of sodium replenishes the intravascular volume and allows the continuous formation of ascites. Retention of sodium results from vasodilation that is mostly due to an increase in NO production because NO inhibition in experimental animals increases urinary sodium excretion, lowers plasma aldosterone levels, and reduces ascites. With progression of cirrhosis and portal hypertension, vasodilation is more pronounced, thereby leading to further activation of the renin-angiotensin-aldosterone and sympathetic nervous systems and resulting in further sodium retention (refractory ascites), water retention (hyponatremia), and renal vasoconstriction (hepatorenal syndrome).

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis, an infection of ascitic fluid, occurs in the absence of perforation of a hollow viscus or an intra-abdominal inflammatory focus, such as an abscess, acute pancreatitis, or cholecystitis. Bacterial translocation, or the migration of bacteria from the intestinal lumen to mesenteric lymph nodes and other extraintestinal sites, is the main mechanism implicated in spontaneous bacterial peritonitis. Impaired local and systemic immune defenses are a major element in promoting bacterial translocation and, together with shunting of blood away from the hepatic Kupffer cells through portosystemic collaterals, allow a transient bacteremia to become more prolonged, thereby colonizing ascitic fluid. Spontaneous bacterial peritonitis occurs in patients with reduced ascites defense mechanisms, such as a low complement level in ascitic fluid. Another factor that promotes bacterial translocation in cirrhosis is bacterial overgrowth attributed to a decrease in small bowel motility and intestinal transit time. Infections, particularly from gram-negative bacteria, can precipitate renal dysfunction through worsening of the hyperdynamic circulatory state.

Encephalopathy

Hepatic encephalopathy is brain dysfunction caused by liver insufficiency, portosystemic shunting, or both.[2,3] Ammonia, a toxin normally removed by the liver, plays a key role in its pathogenesis. In cirrhosis, ammonia accumulates in the systemic circulation because of shunting of blood through portosystemic collaterals and decreased liver metabolism (i.e., liver insufficiency). The presence of large amounts of ammonia in the brain damages supporting brain cells or astrocytes and leads to structural changes characteristic of hepatic encephalopathy (Alzheimer type II astrocytosis). Ammonia results in upregulation of astrocytic peripheral-type benzodiazepine receptors, the most potent stimulants of neurosteroid production. Neurosteroids are the major modulators of γ-aminobutyric acid, which results in cortical depression and hepatic encephalopathy. Other toxins, such as manganese, also accumulate in the brain, particularly the globus pallidus, where they lead to impaired motor function. Other yet-to-be-elucidated toxins may also be involved in the pathogenesis of encephalopathy.

Jaundice

Jaundice (Chapter 147) in cirrhosis is a reflection of the inability of the liver to excrete bilirubin and is therefore the result of liver insufficiency. However, in cholestatic diseases leading to cirrhosis (e.g., primary biliary cirrhosis, primary sclerosing cholangitis, vanishing bile duct syndrome), jaundice is more likely due to biliary damage than to liver insufficiency. Other indicators of liver insufficiency, such as the presence of encephalopathy or prolongation of the international normalized ratio, help determine the most likely contributor to hyperbilirubinemia (Chapter 147).

Cardiopulmonary Complications

The hyperdynamic circulatory state eventually results in high-output heart failure with decreased peripheral utilization of oxygen, a complication that has been referred to as *cirrhotic cardiomyopathy.* Vasodilation at the level of the pulmonary circulation leads to arterial hypoxemia, the hallmark of hepatopulmonary syndrome. Normal pulmonary capillaries are 8 μm in diameter, and red blood cells (slightly less than 8 μm) pass through them one cell at a time, thereby facilitating oxygenation. In *hepatopulmonary syndrome,* the pulmonary capillaries are dilated up to 500 μm, so passage of red cells through the pulmonary capillaries may be many cells thick. As a result, a large number of red cells are not oxygenated, which causes the equivalent of a right-to-left shunt.

Conversely, *portopulmonary hypertension* occurs when the pulmonary bed is exposed to vasoconstrictive substances that may be produced in the splanchnic circulation and bypass metabolism by the liver; the initial result

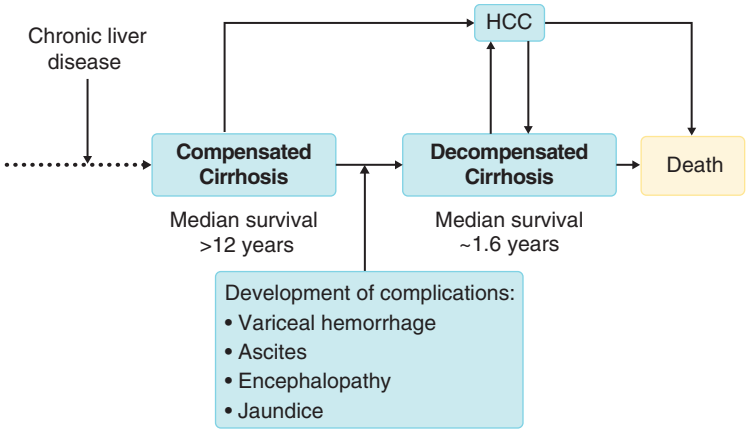

FIGURE 153-4. Natural history of cirrhosis. Any chronic liver disease will lead to cirrhosis. Initially, cirrhosis will be compensated (median survival, >12 years), but once complications (ascites, variceal hemorrhage, encephalopathy, jaundice) develop, it becomes decompensated (median survival, 1.6 years). Hepatocellular carcinoma (HCC) can develop at any stage and precipitate decompensation and death.

is reversible pulmonary hypertension. However, because these factors result in endothelial proliferation, vasoconstriction, in situ thrombosis, and obliteration of vessels, irreversible pulmonary hypertension ensues.

CLINICAL MANIFESTATIONS

The clinical manifestations of cirrhosis range widely, depending on the stage of cirrhosis, from an asymptomatic patient with no signs of chronic liver disease to a patient who is confused and jaundiced with severe muscle wasting and ascites. The natural history of cirrhosis is characterized by an initial phase, termed *compensated* cirrhosis, followed by a rapidly progressive phase marked by the development of complications of portal hypertension or liver dysfunction (or both), termed *decompensated* cirrhosis (Fig. 153-4).[4] In the compensated phase, liver synthetic function is mostly normal, and portal pressure, although increased, is below the threshold level required for the development of varices or ascites. As the disease progresses, portal pressure increases and liver function worsens, thereby resulting in the development of ascites, portal hypertensive gastrointestinal bleeding, encephalopathy, and jaundice. The development of any of these clinically detectable complications marks the transition from a compensated to a decompensated phase. Progression to death may be accelerated by the development of other complications, such as recurrent gastrointestinal bleeding, renal impairment (refractory ascites, hepatorenal syndrome), hepatopulmonary syndrome, and sepsis (spontaneous bacterial peritonitis). The development of hepatocellular carcinoma (Chapter 196) may accelerate the course of the disease at any stage (see Fig. 153-4). Transition from a compensated to a decompensated stage occurs at a rate of approximately 5 to 7% per year. The median time to decompensation, or the time at which half the patients with compensated cirrhosis will become decompensated, is about 6 years.

Compensated Cirrhosis

In this stage, cirrhosis is mostly asymptomatic and is diagnosed either during the evaluation of chronic liver disease or fortuitously during routine physical examination, biochemical testing, imaging for other reasons, endoscopy showing gastroesophageal varices, or abdominal surgery in which a nodular liver is detected. Nonspecific fatigue, decreased libido, or sleep disturbances may be the only complaints. About 40% of patients with compensated cirrhosis have esophageal varices. Nonbleeding gastroesophageal varices are asymptomatic, and their presence (without bleeding) does not denote decompensation.

Decompensated Cirrhosis

At this stage, there are signs of decompensation: ascites, variceal hemorrhage, jaundice, hepatic encephalopathy, or any combination of these findings. Ascites, which is the most frequent sign of decompensation, is present in 80% of patients with decompensated cirrhosis.

Variceal Hemorrhage

Gastroesophageal varices are present in approximately 50% of patients with newly diagnosed cirrhosis. The prevalence of varices correlates with the severity of liver disease and ranges from 40% in Child A cirrhotic patients (Table 153-2) to 85% in Child C cirrhotic patients.

TABLE 153-2 THE TWO MOST COMMONLY USED SCORING SYSTEMS IN CIRRHOSIS

1. CHILD-TURCOTTE-PUGH (CTP) SCORE (RANGE, 5-15)

	POINTS ASCRIBED		
Parameters	**1**	**2**	**3**
Ascites	None	Grade 1-2 (or easy to treat)	Grade 3-4 (or refractory)
Hepatic encephalopathy	None	Grade 1-2 (or induced by a precipitant)	Grade 3-4 (or spontaneous)
Bilirubin (mg/dL)	<2	2-3	>3
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds > control) or INR	<4 <1.7	4-6 1.7-2.3	>6 >2.3

CTP classification: Child A: score of 5-6; Child B: score of 7-9; Child C: score of 10-15

2. MODEL OF END-STAGE LIVER DISEASE (MELD) SCORE (RANGE, 6-40)

$[0.957 \times \text{LN (creatinine in mg/dL)} + 0.378 \times \text{LN (bilirubin in mg/dL)} + 1.12 \times \text{LN (INR)} + 0.643] \times 10$

INR = international normalized ratio; LN = natural logarithm.

Both the development of varices and the growth of small varices occur at a rate of 7 to 8% per year. The incidence of a first variceal hemorrhage in patients with small varices is about 5% per year, whereas medium and large varices bleed at a rate of approximately 15% per year. Large varices, severe liver disease, and red wale markings on varices are independent predictors of variceal hemorrhage. Bleeding from gastroesophageal varices can be manifested as overt hematemesis, melena, or both (Chapter 135).

Ascites and Hyponatremia

Ascites is the most common cause of decompensation in cirrhosis and occurs at a rate of 7 to 10% per year. The most frequent symptoms associated with ascites are increased abdominal girth, which is often described by the patient as tightness of the belt or garments around the waist, and recent weight gain. When it is present in small to moderate amounts, ascites can be identified on examination by bulging flanks, flank dullness, and shifting dullness (Chapter 146).

Hyponatremia, which is defined as a serum sodium concentration below 130 mEq/L (Chapter 116), is present in about 25% of patients with cirrhosis and ascites. However, patients with cirrhosis do not usually have significant neurologic manifestations or hyponatremia, presumably because it typically develops gradually. Nevertheless, hyponatremia is a marker of the severity of cirrhosis and is associated with poorer quality of life and the development of hepatic encephalopathy.[5]

Hepatorenal syndrome is a type of prerenal kidney injury that occurs in patients with cirrhosis and ascites.[6] It represents the extreme of the spectrum of abnormalities that lead to cirrhotic ascites and is the result of maximal peripheral vasodilation as well as maximal activation of hormones that cause the retention of sodium and water and intense vasoconstriction of the renal arteries. Hepatorenal syndrome is divided into two types based on clinical characteristics and prognosis. Type 1 hepatorenal syndrome is rapidly progressive *acute* kidney injury in which the rise in serum creatinine concentration occurs within a 2-week period. Type 2 hepatorenal syndrome is more slowly progressive and associated with ascites that is refractory to diuretics. Patients with hepatorenal syndrome usually have tense ascites that responds poorly to diuretics, but no specific symptoms or signs typify this entity.

Spontaneous Bacterial Peritonitis

About one third of cirrhotic patients are admitted for bacterial infection or acquire a bacterial infection during hospitalization, the most common being spontaneous bacterial peritonitis. The two most important predictors of the development of bacterial infection are the severity of liver disease and admission for gastrointestinal hemorrhage. The most frequent clinical manifestations of spontaneous bacterial peritonitis are fever, jaundice, and abdominal pain. On physical examination, there is typically abdominal tenderness, with or without rebound tenderness, or ileus (or both). However, up to one third of patients with spontaneous bacterial peritonitis initially may have no abdominal symptoms or symptoms of infection[7] and may present instead with encephalopathy, acute kidney injury, or evidence of shock.

Hepatic Encephalopathy

Hepatic encephalopathy, which is the neuropsychiatric manifestation of cirrhosis, occurs at a rate of approximately 2 to 3% per year. Hepatic encephalopathy associated with cirrhosis is of gradual onset and rarely fatal. It is manifested as a wide spectrum of neurologic and psychiatric abnormalities ranging from subclinical alterations to coma. Clinically, it is characterized by alterations in consciousness and behavior ranging from inversion of the sleep-wake pattern and forgetfulness (grade 1); to confusion, bizarre behavior, and disorientation (grade 2); to lethargy and profound disorientation (grade 3); to coma (grade 4). On physical examination, early stages may demonstrate only a distal tremor, but the hallmark of overt hepatic encephalopathy is the presence of asterixis (Chapter 154). In addition, patients with hepatic encephalopathy may have sweet-smelling breath, a characteristic termed *fetor hepaticus*.

Pulmonary Complications

Hepatopulmonary syndrome is associated with exertional dyspnea, which can lead to extreme debilitation. Clubbing of the fingers, cyanosis, and vascular spiders may be seen on physical examination. Hepatopulmonary syndrome is present in approximately 5 to 10% of patients awaiting liver transplantation.

Portopulmonary hypertension is manifested as exertional dyspnea, syncope, and chest pain. On examination, an accentuated second sound and right ventricular heave are prominent (Chapter 68).

DIAGNOSIS

The diagnosis of cirrhosis should be considered in any patient with chronic liver disease.[8] In asymptomatic patients with *compensated cirrhosis*, typical signs of cirrhosis may not be present, and the physical examination and laboratory test findings may be entirely normal. The diagnosis may often require histologic confirmation by liver biopsy, which is the "gold standard" for the diagnosis of cirrhosis. However, liver biopsy is an invasive procedure subject to sampling error, and the presence of cirrhosis can often be confirmed noninvasively by a combination of serum biomarkers, imaging techniques, and measurements of liver stiffness.

Physical Examination

On physical examination, stigmata of cirrhosis consist of muscle atrophy, mainly involving the bitemporal muscle regions and the thenar and hypothenar eminences; spider angiomas, mostly on the trunk, face, and upper limbs; and palmar erythema involving the thenar and the hypothenar eminences and the tips of the fingers. Although muscle atrophy is a marker of liver insufficiency, spider angiomas and palmar erythema are markers of vasodilation and a hyperdynamic circulation. Men may have hair loss on the chest and abdomen, gynecomastia, and testicular atrophy. Petechiae and ecchymoses may be present as a result of thrombocytopenia or a prolonged prothrombin time. Dupuytren contracture, which is a thickening of the palmar fascia, occurs mostly in alcoholic cirrhosis. A pathognomonic feature of cirrhosis is the finding on abdominal examination of a small right liver lobe, with a span of less than 7 cm on percussion, and a palpable left lobe that is nodular with increased consistency. Splenomegaly may also be present and is indicative of portal hypertension. Collateral circulation on the abdominal wall (caput medusae) may also develop as a consequence of portal hypertension. Absence of any of these physical findings does not exclude cirrhosis.

Laboratory Tests

Laboratory test results suggestive of cirrhosis include even subtle abnormalities in serum levels of albumin or bilirubin or elevation of the international normalized ratio. The most sensitive and specific laboratory finding suggestive of cirrhosis in the setting of chronic liver disease is a low platelet count (<150,000/μL), which occurs as a result of portal hypertension and hypersplenism. Other serum markers that are often abnormal include levels of aspartate aminotransferase, γ-glutamyl transpeptidase, hyaluronic acid, α_2-macroglobulin, haptoglobin, tissue metalloproteinase inhibitor 1, and apolipoprotein A. Combinations of these tests have been used to predict the presence of cirrhosis, but they are not as accurate as imaging studies.[9]

Imaging Studies

Confirmatory imaging tests include computed tomography, ultrasound, and magnetic resonance imaging. Findings consistent with cirrhosis include a nodular contour of the liver, a small liver with or without hypertrophy of the left or caudate lobe, splenomegaly, and, in particular, identification of intra-abdominal collateral vessels indicative of portal hypertension (Fig. 153-5). With increasing fibrosis, the liver becomes stiff, and this stiffness can be measured by ultrasound (transient elastography, acoustic radiation force impulse imaging) or magnetic resonance imaging. Measurement of liver stiffness, a new noninvasive technique, appears to be useful in the diagnosis of cirrhosis and in excluding its presence.[10] These tests are becoming more widely available, and typical findings on any of these imaging studies, together with a compatible clinical picture, are indicative of the presence of cirrhosis. A liver biopsy then would not be required unless the degree of inflammation or other features require investigation.

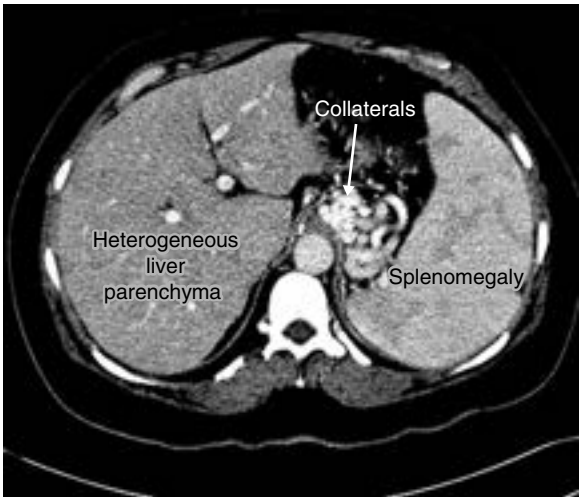

FIGURE 153-5. **Computed tomography in a patient with compensated cirrhosis. The liver parenchyma is heterogeneous, there is splenomegaly, and, importantly, there are portosystemic collaterals.**

In *decompensated cirrhosis*, detection of ascites, variceal bleeding, or encephalopathy in the setting of chronic liver disease essentially establishes the diagnosis of cirrhosis, so a liver biopsy is not necessary to establish the diagnosis. Patients with decompensated cirrhosis often exhibit malnutrition, more severe muscle wasting, more numerous vascular spiders, and hypotension and tachycardia as a result of the hyperdynamic circulatory state.

Portal Pressure Measurements

Direct measurements of portal pressure involve catheterization of the portal vein, are cumbersome, and may be associated with complications. Hepatic vein catheterization with measurement of wedged and free pressure is the simplest, safest, most reproducible, and most widely used method to indirectly measure portal pressure. Portal pressure measurements are expressed as the hepatic venous pressure gradient: the gradient between wedged hepatic venous pressure, which is a measure of sinusoidal pressure, and free hepatic or inferior vena cava pressure, which is used as an internal zero reference point. In a patient with clinical evidence of portal hypertension (e.g., varices), the hepatic venous pressure gradient is useful in the differential diagnosis of the cause of portal hypertension: it will be normal (3 to 5 mm Hg) in prehepatic causes of portal hypertension, such as portal vein thrombosis (Chapter 143), and in intrahepatic but presinusoidal causes, such as schistosomiasis (Chapter 355); but it will be abnormal (≥6 mm Hg) in sinusoidal causes of portal hypertension, such as cirrhosis, and in postsinusoidal causes, such as veno-occlusive disease. In patients with viral or alcoholic cirrhosis, a hepatic venous pressure gradient of 10 mm Hg or greater ("clinically significant" portal hypertension) predicts the development of complications of portal hypertension, and its reduction with pharmacologic therapy predicts a favorable outcome in patients with cirrhosis. In patients with variceal hemorrhage, a hepatic venous pressure gradient of more than 20 mm Hg predicts recurrent variceal hemorrhage and may portend death.

Complications of Cirrhosis

Varices and Variceal Hemorrhage

Upper gastrointestinal endoscopy (Chapter 134) remains the main method for diagnosis of varices and variceal hemorrhage. Varices are classified as small (straight, minimally elevated veins above the esophageal mucosal surface), medium (tortuous veins occupying less than one third of the esophageal

lumen), or large (occupying more than one third of the esophageal lumen). The diagnosis of variceal hemorrhage is made when diagnostic esophagogastroduodenoscopy shows one of the following: active bleeding from a varix, a "white nipple" overlying a varix, clots overlying a varix, or varices with no other potential source of bleeding.

Ascites

The most common cause of ascites is cirrhosis, which accounts for 80% of cases. Peritoneal malignant disease (e.g., peritoneal metastases from gastrointestinal tumors or ovarian cancer), heart failure (Chapter 58), and peritoneal tuberculosis (Chapter 324) together account for another 15% of cases. The initial, most cost-effective, and least invasive method to confirm the presence of ascites is abdominal ultrasonography.

Diagnostic paracentesis is a safe procedure that should be performed in every patient with new-onset ascites, even in those with coagulopathy. Ultrasound guidance should be used in patients in whom percussion cannot locate the ascites or in whom a first paracentesis attempt does not yield fluid. The fluid in a patient with new-onset ascites should always be evaluated for albumin (with simultaneous estimation of serum albumin), total protein, and polymorphonuclear (PMN) blood cell count, and bacteriologic cultures and cytology should be performed. The PMN cell count and bacteriologic culture are useful to exclude infection (either spontaneous or secondary bacterial peritonitis), and cytologic evaluation is needed if peritoneal carcinomatosis is suspected. Depending on the clinical setting, additional tests can be performed on the fluid: glucose and lactate dehydrogenase levels (if secondary bacterial peritonitis is suspected), smear and culture for acid-fast bacilli (if peritoneal tuberculosis is suspected), and amylase level (if pancreatic ascites is suspected).

The serum-ascites albumin gradient and ascites protein levels are useful in the differential diagnosis of ascites (Table 153-3). The serum-ascites albumin gradient correlates with sinusoidal pressure and will therefore be elevated (>1.1 g/dL) in patients in whom the source of ascites is the hepatic sinusoid (e.g., cirrhosis or cardiac ascites). Protein levels in ascitic fluid are an indirect marker of the integrity of the hepatic sinusoids: normal sinusoids are permeable structures that "leak" protein, whereas sinusoids in cirrhosis are "capillarized" and do not leak as much protein. The three main causes of ascites—cirrhosis, peritoneal malignant disease or tuberculosis, and heart failure—can easily be distinguished by combining the results of both the serum-ascites albumin gradient and ascites total protein content. Cirrhotic ascites typically has a high serum-ascites albumin gradient and low protein, cardiac ascites has a high serum-ascites albumin gradient and high protein, and ascites secondary to peritoneal malignant disease typically has a low serum-ascites albumin gradient and high protein. A high serum B-type natriuretic peptide has a high diagnostic accuracy in the diagnosis of ascites due to heart failure.

Hepatorenal Syndrome

Hepatorenal syndrome, which is a diagnosis of exclusion, should be diagnosed only after diuretics have been discontinued, any condition that leads to worsening of the hemodynamic status of the cirrhotic patient has been excluded or treated, and intravascular volume has been expanded with albumin. Ascites unresponsive to diuretics is universal, and dilutional hyponatremia is almost always present. The differential diagnosis includes conditions that worsen vasodilation, such as sepsis, the use of vasodilators, and large-volume paracentesis not accompanied by albumin infusion; conditions that decrease effective arterial blood volume, such as gastrointestinal hemorrhage, overdiuresis, or diarrhea (often induced by overdoses of lactulose); conditions that induce renal vasoconstriction, such as nonsteroidal anti-inflammatory drugs; and nephrotoxic insults, such as from aminoglycosides.

TABLE 153-3 USING THE SERUM-ASCITES ALBUMIN GRADIENT AND THE ASCITES TOTAL PROTEIN LEVEL TO DIAGNOSE THE CAUSE OF ASCITES

CONDITION	SERUM-ASCITES ALBUMIN GRADIENT*	ASCITES TOTAL PROTEIN LEVEL†
Cirrhosis	High	Low
Malignant ascites	Low	High
Cardiac ascites	High	High

*High is more than 1.1 g/dL; low is less than 1.1 g/dL.
†High is more than 2.5 g/dL; low is less than 2.5 g/dL.

Spontaneous Bacterial Peritonitis

A high index of suspicion and early diagnosis are key in the management of spontaneous bacterial peritonitis. Diagnostic paracentesis should be performed in any patient with symptoms or signs of spontaneous bacterial peritonitis, including unexplained encephalopathy and renal dysfunction. Because spontaneous bacterial peritonitis is often asymptomatic and frequently community acquired, diagnostic paracentesis should be performed when any cirrhotic patient is admitted to the hospital, regardless of the cause for admission.

The diagnosis of spontaneous bacterial peritonitis is established by an ascitic fluid PMN count greater than 250/μL. Bacteria can be isolated from ascitic fluid in only 40 to 50% of cases, even with sensitive methods such as inoculation directly into a blood culture bottle. Spontaneous bacterial peritonitis is mostly a monobacterial infection, usually with gram-negative enteric organisms. However, the widespread use of antibiotic prophylaxis in cirrhosis has led to an increased prevalence of infections with multidrug-resistant organisms. Anaerobes and fungi very rarely cause spontaneous bacterial peritonitis; their presence, as well as a polymicrobial infection, should raise suspicion of secondary bacterial peritonitis.

Hepatic Encephalopathy

The diagnosis of overt hepatic encephalopathy is mainly clinical and based on a history and physical examination that shows alterations in consciousness and behavior as well as the presence of asterixis. Ammonia levels are unreliable, and there is poor correlation between the grade of hepatic encephalopathy and ammonia blood levels. High levels (>150 μmol/L) are, however, indicative of hepatic encephalopathy and can be useful in the evaluation of a patient with neurocognitive disturbances of unknown origin. Psychometric tests and an electroencephalogram, which typically shows generalized slow waves and the presence of triphasic waves, are commonly used in research but are not generally used for clinical diagnosis. Minimal or subclinical hepatic encephalopathy, which is present in up to 80% of patients with cirrhosis, is diagnosed solely on the basis of abnormal results of psychometric and neuropsychological tests of attention (e.g., number connection test, digit symbol test) and psychomotor function (e.g., grooved pegboard). Screening of cirrhotic patients for minimal hepatic encephalopathy is not widely recommended because diagnostic tests are not standardized and the benefits of treatment are uncertain.

Hepatopulmonary Syndrome and Portopulmonary Hypertension

The diagnostic criteria for hepatopulmonary syndrome are arterial hypoxemia with a Pao_2 of less than 80 mm Hg or an alveolar arterial oxygen gradient of greater than 15 mm Hg, along with evidence of pulmonary vascular shunting on contrast echocardiography (Chapter 55) or a ^{99m}Tc-labeled macroaggregated albumin scan demonstrating abnormal shunting of radioactivity to the brain.[11] Portopulmonary hypertension is diagnosed by the presence of mean pulmonary arterial pressure higher than 25 mm Hg on right-sided heart catheterization, provided pulmonary capillary wedge pressure is less than 15 mm Hg.

TREATMENT

Rx

Treatment of cirrhosis should ideally be aimed at interruption or reversal of fibrosis. Although antifibrotic drugs have not been shown to reverse fibrosis consistently or to improve outcomes in cirrhotic patients, eradication of the hepatitis C or the hepatitis B virus has been associated with reversal of fibrosis. Treatment of compensated cirrhosis is currently directed at preventing the development of decompensation by (1) treating the underlying liver disease (e.g., antiviral therapy for hepatitis C or B) to reduce fibrosis and to prevent decompensation; (2) avoiding factors that could worsen liver disease, such as alcohol, hepatotoxic drugs, and superimposed viral infections; and (3) screening for varices (to prevent variceal hemorrhage) and for hepatocellular carcinoma (to treat it at an early stage) (Fig. 153-6). Treatment of decompensated cirrhosis focuses on specific decompensating events and the option of liver transplantation. Increasingly, data reveal that different therapies for the same complication may be applicable to patients with different risk profiles, mainly based on severity of the disease (see Table 153-2).

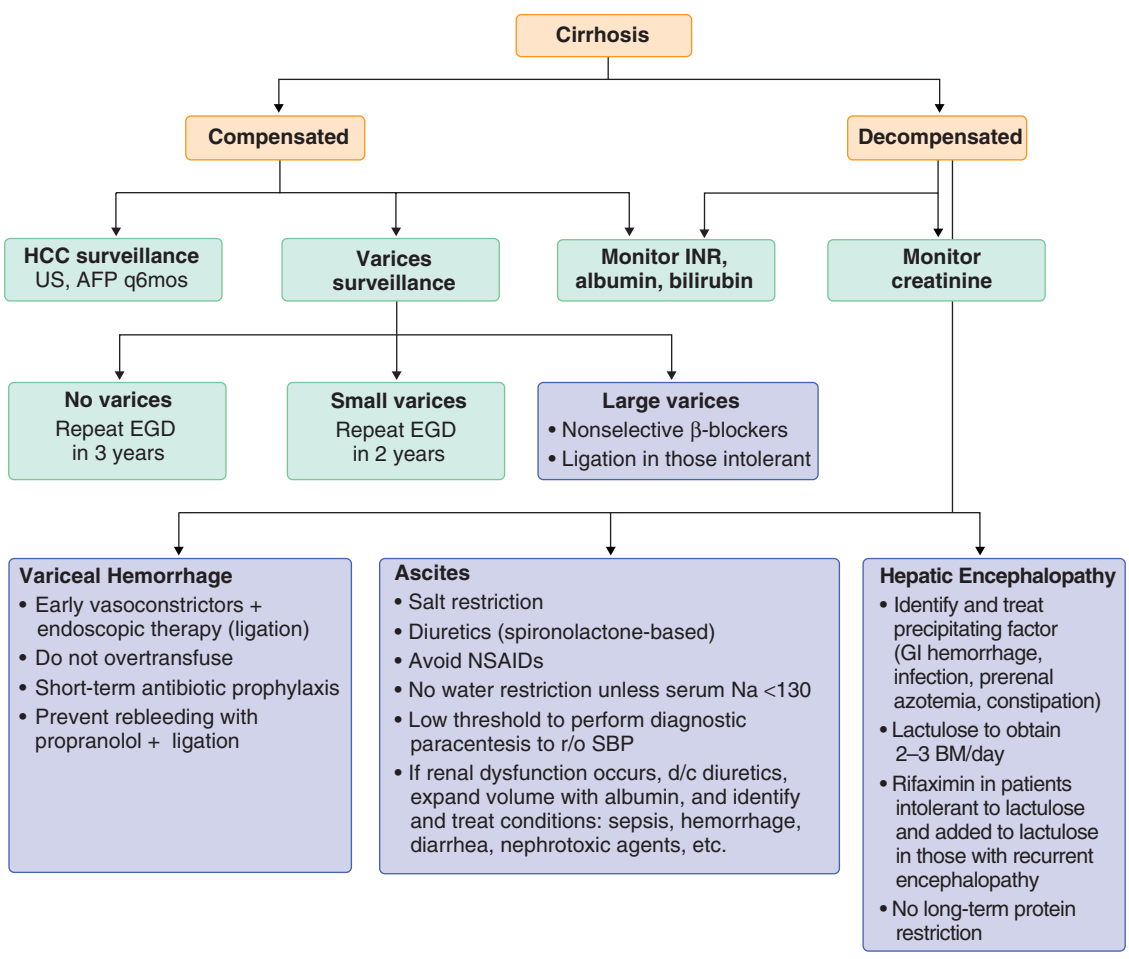

FIGURE 153-6. Summary of the management of compensated and decompensated cirrhosis. AFP = α-fetoprotein; BM = bowel movement; d/c = discontinue; EGD = esophagogastroduodenoscopy; GI = gastrointestinal; HCC = hepatocellular carcinoma; INR = international normalized ratio; Na = sodium; NSAIDs = nonsteroidal anti-inflammatory drugs; r/o = rule out; SBP = spontaneous bacterial peritonitis; US = ultrasound.

Varices and Variceal Bleeding

Reducing portal pressure decreases the risk for the development of varices and variceal hemorrhage as well as the risk for ascites and death. Nonselective β-adrenergic blockers (propranolol, nadolol) reduce portal pressure by producing splanchnic vasoconstriction and decreasing portal venous inflow. In patients with cirrhosis and medium or large varices that have never bled, nonselective β-blockers significantly reduce the risk for first variceal hemorrhage. Treatment options have included propranolol (initiated at a dose of 20 mg orally twice a day) and nadolol (initiated at a dose of 20 mg orally every day), with the dose titrated to produce a resting heart rate of about 50 to 55 beats per minute.[12] β-Adrenergic blockers also reduce portal pressure and lower the risk for development of ascites. Endoscopic variceal ligation (see Fig. 134-3), a therapy that aims to obliterate varices by placing rubber rings on variceal columns, is at least as useful as traditional nonselective β-blockers to prevent a first variceal hemorrhage.[■] Ligation has no effect on portal pressure and can lead to hemorrhage from ligation-induced ulcers. Carvedilol (a nonselective β-blocker with vasodilating properties at a dose of 12.5 mg/day) has been shown to be superior to ligation[■] and to lower portal pressure in patients who do not respond to propranolol[■]; however, its use in patients with ascites may not be advisable because of its vasodilating effect. A rational approach is to start therapy with propranolol or nadolol and to use ligation in patients who cannot tolerate or have contraindications to β-blockers. In the compensated patient, carvedilol could be used in patients who cannot tolerate propranolol or nadolol.

In patients with no varices, nonselective β-blockers do not prevent the development of varices and are associated with more side effects. In patients with small varices, data are insufficient to recommend therapy with nonselective β-blockers. Endoscopy should be repeated every 2 to 3 years in patients with no varices, every 1 to 2 years in patients with small varices, and sooner in patients with decompensated disease so that effective therapy can be instituted before the varices grow in size and bleed.[13]

Patients with cirrhosis and variceal hemorrhage require resuscitation in an intensive care unit. However, overtransfusion should be avoided because it can precipitate rebleeding.[■] Hemoglobin values should be maintained at about 8 g/dL. Prophylactic antibiotics should be used in this setting not only to prevent bacterial infections but also to decrease rebleeding and death.[■] The recommended antibiotic is oral norfloxacin at a dose of 400 mg twice daily for 5 to 7 days, although intravenous ceftriaxone at a dose of 1 g/day for 5 to 7 days is preferable in patients with advanced liver disease (malnutrition, ascites, encephalopathy, and jaundice) or in those already receiving norfloxacin prophylaxis.[■]

The most effective specific therapy for the control of active variceal hemorrhage is the combination of a vasoconstrictor with endoscopic therapy. Safe vasoconstrictors include terlipressin, somatostatin, and the somatostatin analogues octreotide and vapreotide[■]; they can be initiated at admission to the hospital and continued for 2 to 5 days. The vasoconstrictor currently available in the United States is octreotide, which is used as a 50-μg intravenous bolus followed by an infusion at 50 μg/hour. The transjugular intrahepatic portosystemic shunt (TIPS) is generally recommended for patients who fail to respond to standard therapy (Fig. 153-7). In patients at high risk of failure, Child C (score 10-13) patients and Child B patients who have actively bleeding varices at endoscopy, preemptive TIPS placement (24 to 48 hours after admission) is associated with a reduced failure rate and a significant improvement in survival.[■] Therefore, preemptive "early" TIPS should be considered in this high-risk subpopulation of patients with variceal hemorrhage. Even though patients with cirrhosis and coagulopathy (prolonged international normalized ratio or decreased platelet count) have a higher risk of not responding to hemostasis for variceal hemorrhage or bleeding from procedures (ligation, paracentesis, TIPS, surgery), neither recombinant factor VII nor eltrombopag has proved beneficial in randomized trials, and neither is recommended.

After control of hemorrhage, the 1-year recurrence of hemorrhage without treatment is high at about 60%. Therefore, therapy to prevent rebleeding should be instituted before the patient is discharged. The recommended therapy is combination of nonselective β-blockers (propranolol or nadolol), with or without isosorbide mononitrate, and endoscopic variceal ligation.[■] The dose of β-blockers should be the maximal dose tolerated, and endoscopic variceal ligation should be repeated every 2 to 4 weeks until the varices are obliterated. Patients who had TIPS placed during the episode of acute variceal hemorrhage do not require β-blockers or ligation but do require periodic Doppler examination of the shunt to assess its patency.

Shunt therapy, either surgical or through radiologic placement of a TIPS, should be used in patients whose variceal bleeding has persisted

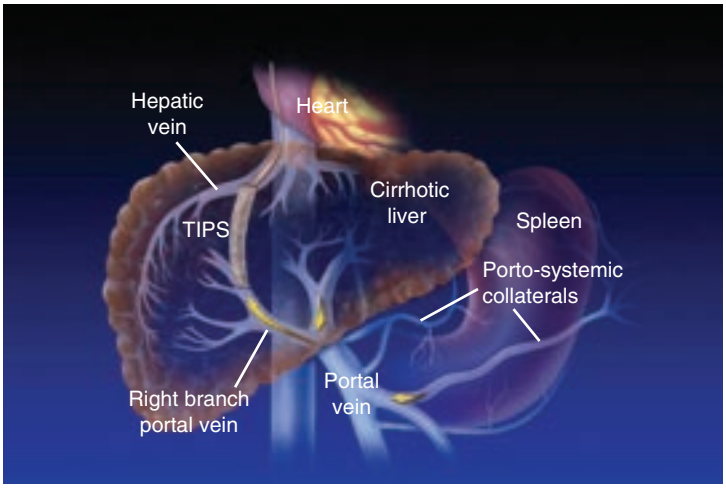

FIGURE 153-7. Transjugular intrahepatic portosystemic shunt (TIPS). This shunt is performed by interventional radiologists and consists of an expandable metal stent (most often coated with polytetrafluoroethylene) that connects a branch of the portal vein (high-pressure vein) to a branch of the hepatic vein (low-pressure vein). The shunt decompresses the portal system and portosystemic collaterals, and therefore it is used in the treatment of selected patients with cirrhosis and variceal hemorrhage. The shunt also decompresses the hepatic sinusoids and therefore is also used in the treatment of refractory ascites.

or recurred despite combined pharmacologic and endoscopic therapy. Both types of shunts are equally effective,[NEW] and the choice will depend on local expertise. Although the uncovered TIPS frequently occludes, newer polytetrafluoroethylene-covered stents are associated with lower occlusion rates and lower rates of hepatic encephalopathy.

Ascites

Salt restriction and diuretics constitute the mainstay of management of ascites. Dietary sodium intake should be restricted to 2 g/day. A more restrictive diet is not recommended and may compromise nutritional status.

Spironolactone, which is more effective than loop diuretics, should be started at a dose of 100 mg/day (once a day in the morning). The dose should be adjusted every 3 to 4 days to a maximal effective dose of 400 mg/day. Furosemide, at an escalated dose from 40 to 160 mg/day, can be started concurrently with spironolactone if ascites is tense or added subsequently if weight loss is inadequate or if hyperkalemia develops with spironolactone alone. The goal is weight loss of 1 kg in the first week and 2 kg/week subsequently. However, diuretics should be reduced if the rate of weight loss is more than 0.5 kg/day in patients without peripheral edema or more than 1 kg/day in patients with peripheral edema. Side effects of diuretic therapy include hypovolemic hyponatremia, hyperkalemia, renal dysfunction, encephalopathy, and, with spironolactone, painful gynecomastia.

In the 10 to 20% of patients with ascites who are refractory to diuretics, large-volume paracentesis, aimed at removal of all or most of the fluid, plus albumin at a dose of 6 to 8 g intravenously per liter of ascites removed, particularly when more than 5 L is removed at once, is a reasonable approach. The frequency of large-volume paracentesis is dictated by the rapidity at which the ascites reaccumulates. TIPS with uncovered stents is more effective than large-volume paracentesis plus albumin in preventing recurrent ascites but is associated with a higher rate of encephalopathy.[NEW] In patients requiring frequent large-volume paracentesis (more than twice per month), a polytetrafluoroethylene-covered TIPS should be considered. A peritoneovenous shunt, with use of a subcutaneously placed silicone tube that transfers ascites from the peritoneal cavity to the systemic circulation, can be used in patients who are not candidates for TIPS or liver transplantation. Automated flow pumps to move ascitic fluid to the bladder are under investigation.

Hyponatremia

Fluid restriction to 1.5 liters daily is recommended for severe hyponatremia (serum sodium concentration <130 mEq/L), but adherence with this recommendation is poor. Although V2-receptor antagonists such as tolvaptan are effective at increasing free water excretion and raising the serum sodium level in hyponatremic cirrhotic patients,[NEW] they have no overall effect on survival and are not approved for this use because of their hepatotoxicity. Because hyponatremia is a marker of neurologic dysfunction and increased mortality, short-term use of tolvaptan (15 mg/day, increased to 30 to 60 mg/day if needed) may be indicated only as a bridge to liver transplantation in patients in whom transplantation is imminent (Chapter 154).

Hepatorenal Syndrome

Because hepatorenal syndrome is a functional kidney injury that results from hemodynamic abnormalities secondary to end-stage liver disease and severe portal hypertension and is associated with a high mortality despite specific therapy, documented hepatorenal syndrome in the absence of prerenal azotemia or acute tubular necrosis is an indication for transplantation (Chapter 154). Specific therapies for hepatorenal syndrome that have been used to "bridge" a patient to transplantation include vasoconstrictors (terlipressin, norepinephrine, octreotide plus midodrine) plus albumin, TIPS, and extracorporeal albumin dialysis, which is an experimental hemofiltration dialysis method that uses an albumin dialysate. The largest experience is with the use of terlipressin, which at a dose 0.5 to 2.0 mg intravenously every 4 to 6 hours leads to a higher reversal rate of hepatorenal syndrome compared with placebo.[NEW] Because terlipressin is not yet available in the United States, the combination most used is octreotide (100 to 200 µg subcutaneously three times a day) plus midodrine (7.5 to 12.5 mg orally three times a day), with the dose adjusted to obtain an increase of at least 15 mm Hg in mean arterial pressure. Improvements may become clinically noticeable at day 7.

Spontaneous Bacterial Peritonitis

Empirical antibiotic therapy with an intravenous third-generation cephalosporin (e.g., cefotaxime, 2 g intravenously every 12 hours, or ceftriaxone, 2 g intravenously every 24 hours) should be initiated as soon as the diagnosis is established and before culture results are available; the minimal duration of therapy should be 5 days. Response to recommended empirical antibiotics is significantly lower in patients with health care–associated infections (i.e., infections that occur in patients who have been in a health care facility within the prior 3 months) and particularly low in nosocomial infections (i.e., infections that occur >48 hours after hospitalization)[14] because more infections are caused by multidrug-resistant organisms. In these settings, broader spectrum antibiotics (e.g., vancomycin-tazobactam, imipenem, ertapenem [Chapter 108]) should be given initially and then modified after culture results and antibiotic sensitivities are obtained. Aminoglycosides should be avoided because of the high incidence of renal toxicity in cirrhotic patients.

Repeated diagnostic paracentesis should be performed 2 days after antibiotics are started, by which time the number of PMN neutrophils in ascitic fluid should have decreased by more than 25% from baseline. Lack of response should prompt further investigations to exclude secondary peritonitis. The renal dysfunction associated with spontaneous bacterial peritonitis can be prevented by the intravenous administration of albumin, particularly in patients who have any evidence of renal dysfunction (blood urea nitrogen >30 mg/dL or creatinine >1 mg/dL, or both) or serum bilirubin concentration higher than 4 mg/dL at the time of diagnosis. Albumin has been used at a dose of 1.5 g per kilogram of body weight at diagnosis, repeated on the third day at an intravenous dose of 1 g per kilogram of body weight. However, this dosing is empirical and should not exceed 100 g per dose.

The administration of nonabsorbable (or poorly absorbable) antibiotics can prevent the development of spontaneous bacterial peritonitis and other infections in cirrhosis by selectively eliminating gram-negative organisms in the gut. However, the widespread use of prophylactic norfloxacin is associated with a higher rate of infections by antibiotic-resistant organisms. Long-term antibiotic prophylaxis with oral norfloxacin at a dose of 400 mg/day may be justified only in two groups: patients who have recovered from a previous episode of spontaneous bacterial peritonitis and patients who have an ascites protein level of less than 1 g/L with advanced liver and circulatory dysfunction as evidenced by the presence of jaundice, hyponatremia, or renal dysfunction.

Hepatic Encephalopathy

Treatment of overt hepatic encephalopathy starts by exclusion of alternative causes of altered mental status. Once the diagnosis of hepatic encephalopathy has been made, treatment involves identifying and treating the precipitating factor and reducing the ammonia level.[15] Precipitating factors include infections, overdiuresis, gastrointestinal bleeding, high oral protein load, and constipation. Narcotics and sedatives contribute to hepatic encephalopathy by directly depressing brain function. TIPS is a common precipitant of hepatic encephalopathy, and shunt reduction or occlusion may be required. Among agents aimed at decreasing ammonia production in the gut, lactulose (15 to 30 mL orally twice daily adjusted to obtain two or three soft bowel movements per day) has been the first choice for the treatment of episodic overt encephalopathy. Polyethylene glycol 3350-electrolyte solution (4 L orally or by nasogastric tube over 4 hours), however, may lead to a more rapid clinical response.[NEW] Other agents include orally administered nonabsorbable antibiotics, such as rifaximin (550 mg two times per day), neomycin (500 mg to 1 g three times per day), and metronidazole (250 mg two to four times per day). Drugs that may increase ammonia fixation in the liver, such as L-ornithine-L-aspartate, benzoate, and glycerol phenylbutyrate, are being studied.

Once an episode of overt encephalopathy has resolved, secondary prophylaxis with lactulose is recommended. If a precipitating factor has been identified and is well controlled or when liver function or nutritional status has improved, prophylactic therapy may be discontinued. In patients with recurrent encephalopathy, rifaximin together with lactulose is useful in preventing further recurrence.[NEW] Switching dietary protein from an animal source to a vegetable source may be beneficial in recurrent or persistent

encephalopathy, but protein restriction is not necessary and should not be used long term.[16]

Pulmonary Complications

Hepatopulmonary syndrome rarely resolves spontaneously, and medical therapy is disappointing. TIPS is not generally recommended. The only viable treatment is liver transplantation (Chapter 154).

By comparison, liver transplantation is indicated only in a subset of patients with portopulmonary hypertension. In fact, a mean pulmonary arterial pressure higher than 45 mm Hg is an absolute contraindication to liver transplantation. The use of vasodilators should be considered in these patients (Chapter 68).

Surgical Therapy

Liver Transplantation

Orthotopic liver transplantation (Chapter 154), which is the definitive therapy for cirrhosis, is indicated when the risk for dying of liver disease is greater than the risk for dying of transplantation, as determined by a Child-Pugh score of 7 or higher (see Table 153-2) or a Model for End-Stage Liver Disease (MELD) score of 15 or higher. MELD (see Table 153-2), which is a mathematical model that estimates the risk for 3-month mortality, is used to determine the priority for liver transplantation (see E-Table 154-1). The number of available deceased donor organs is lower than the number of patients awaiting liver transplantation; as a result, 15 to 20% of patients awaiting liver transplantation in the United States die before an organ becomes available.

PRIMARY PREVENTION

Treatment of the underlying liver disease, before the development of cirrhosis, is a primary prevention strategy. Because the major causes of cirrhosis are related to lifestyle choices such as injection drug use (Chapter 34), alcohol consumption (Chapter 33), obesity, and unprotected sex, primary prevention programs that focus on encouraging alcohol abstinence, reducing high-risk behavior for hepatitis virus infection, weight reduction, and vaccination for hepatitis B are even better prevention strategies.

PROGNOSIS

The outcome of cirrhosis depends on the patient's stage. Patients with compensated cirrhosis die of liver disease only after transition to a decompensated stage. The 10-year survival rate of patients who remain in a compensated stage is approximately 90%, whereas their likelihood of decompensation is 50% at 10 years. Inception cohort studies of patients with compensated cirrhosis show a median survival of all patients, including those in whom decompensation develops over time, of about 10 years, whereas the median survival after decompensation is about 2 years. Survival is even lower in patients with refractory ascites, hyponatremia, or recurrent variceal hemorrhage and is lowest in patients who are hospitalized with an acute decompensating event, in whom 28-day mortality is about 30% and correlates with the number of organ failures present.[17] Hepatocellular carcinoma develops at a fairly constant rate of 3% per year and is associated with a worse outcome at whatever stage it develops.

Predictors of survival are different in compensated and decompensated patients. Parameters of portal hypertension (varices, splenomegaly, platelet count, γ-globulin) assume greater importance in compensated patients, whereas renal dysfunction, hemorrhage, and hepatocellular carcinoma are important predictive factors in patients with decompensated cirrhosis. In clinical practice, the Child-Pugh score is applicable to all cirrhotic patients, and the MELD score is used in decompensated patients to determine priority for liver transplantation.

REVIEW QUESTIONS

1. A 55-year-old man with chronic hepatitis C complains of fatigue. On physical examination, he has vascular spiders, palmar erythema, and a palpable left lobe of his liver. He has no ascites or asterixis. Laboratory analysis demonstrates aspartate aminotransferase 100, alanine aminotransferase 67, alkaline phosphatase 145, and platelet count of 120,000. Abdominal computed tomography (CT) scan shows a nodular liver contour, portosystemic collaterals, but no masses. Which of the following would you recommend as the next step?

A. Liver biopsy
B. Upper endoscopy
C. Start nonselective β-blockers
D. Start spironolactone
E. Magnetic resonance imaging of the liver

Answer: B Although the "gold standard" in the diagnosis of cirrhosis is liver biopsy, this procedure is not necessary when clinical, laboratory, and imaging results are sufficient to establish the diagnosis. In the setting of chronic liver disease, a palpable left lobe of the liver is almost diagnostic of cirrhosis. The most sensitive and specific laboratory finding suggestive of cirrhosis in the setting of chronic liver disease is a low platelet count (<150,000/μL) due to portal hypertension and hypersplenism.[1] Confirmatory imaging tests include ultrasound, CT, and magnetic resonance imaging. Findings consistent with cirrhosis include a nodular liver surface, a small liver with or without left or caudate lobe hypertrophy, splenomegaly, and especially the identification of intra-abdominal collaterals, which are indicative of portal hypertension. A liver biopsy is not required if these findings are present. Any patient with newly diagnosed cirrhosis should undergo upper endoscopy to investigate the presence and size of gastroesophageal varices.[2] β-Blockers should be initiated in patients with medium or large varices or in patients with high-risk small varices (i.e., those present in a Child class C patient or with red wale marks). β-Blockers are not useful in patients without varices and are associated with significant adverse events.[3] Studies have not shown diuretics to be useful in patients with compensated cirrhosis. In the absence of masses on CT scan or ultrasound, performing a magnetic resonance imaging study is unnecessary.

3. Groszmann RJ, Garcia-Tsao G, Bosch J, et al. Beta-blockers to prevent gastroesophageal varices in patients with cirrhosis. *N Engl J Med.* 2005;353:2254-2261.

2. A 69-year-old obese, diabetic man with biopsy-proven compensated cirrhosis and without a prior history of variceal hemorrhage has large esophageal varices on a screening endoscopy study. Which of the following medications would you recommend at this point?

A. No specific medication
B. Metoprolol
C. Nadolol
D. Spironolactone
E. Pantoprazole

Answer: C Nonselective β-blockers are the treatment of choice for the primary prevention of variceal bleeding.[1] In patients with large varices, the 2-year rate of first variceal hemorrhage is significantly lower in patients receiving nonselective β-blockers (15%) compared with those receiving no specific medication. β_1-Specific blockers (atenolol, metoprolol) are not as effective as nonselective (β_1 and β_2) β-blockers (nadolol or propranolol) or a nonselective β-blocker with vasodilating properties (carvedilol)[2,3] because the most important portal pressure–reducing effect results from β_2-blockade. Spironolactone is a diuretic that may reduce portal pressure but has not been shown to prevent first variceal hemorrhage. Although there appears to be a benefit in blocking gastric acid with proton pump inhibitors for the reduction of post-ligation ulcers and bleeding, there is no benefit in preventing a first variceal bleed.

3. A 64-year-old obese man presents for evaluation of new ascites and peripheral edema. He is a heavy smoker and typically drinks two to four alcoholic beverages daily, but he has no history of liver disease. Physical examination reveals decreased breath sounds, moderate ascites, and peripheral edema but no other abnormalities. Laboratory tests reveal a total bilirubin 1.2 mg/dL, aspartate aminotransferase 37 IU/mL, alanine aminotransferase 35 IU/mL, albumin 3.7 g/dL, and international normalized ratio of 1.4. Paracentesis discloses clear yellow fluid with the following characteristics: total protein 3.5 g/dL, albumin 1.7 g/dL, white blood cells 640/μL (12% neutrophils). Which one of the following is the most appropriate action?

A. Begin intravenous cefotaxime and await ascites culture results
B. Perform a liver biopsy
C. Obtain serum B-type natriuretic peptide and perform cardiac echocardiography
D. Perform an abdominal CT scan to investigate peritoneal malignant disease
E. Begin therapy for tuberculosis

Answer: C This patient without documented chronic liver disease has ascites with a high serum-ascites albumin gradient (>1.1 g/dL), indicating ascites that is secondary to hepatic sinusoidal hypertension.[1] The fluid also has a high protein content (>2.5 g/dL) indicative of normal "leaky" sinusoids, so the problem is unlikely to be in the liver. A liver biopsy would not be the most indicated test. In this clinical setting, the most likely possibility is right-sided heart failure, which should be evaluated, initially with an echocardiogram. A high serum B-type natriuretic peptide has a high diagnostic accuracy in the diagnosis of ascites due to heart failure.[2] Although the ascites total white blood cell count is somewhat elevated, the fluid contains only 77 neutrophils (640 × 0.12), and therefore it is not consistent with bacterial peritonitis, which is based on more than 250 neutrophils/μL.[3] In peritoneal causes of ascites (carcinomatosis, tuberculosis), the ascites protein is high and the serum-to-ascites albumin gradient is low (<1/1 g/dL) because fluid formation does not result from sinusoidal hypertension.

3. Rimola A, Garcia-Tsao G, Navasa M, et al. Diagnosis, treatment and prophylaxis of spontaneous bacterial peritonitis: a consensus document. International Ascites Club. *J Hepatol.* 2000;32:142-153.

4. A 53-year-old woman with cirrhosis secondary to primary biliary cirrhosis presents with 2 weeks of weight gain and an increase in abdominal girth. On physical examination, she has gained 8 pounds, and she has a modestly distended abdomen with flank dullness and shifting dullness. She does not have asterixis. Her laboratory tests include creatinine 0.8, blood urea nitrogen 24, Na 136, K 3.5. Analysis of her ascitic fluid is compatible with cirrhotic ascites, without any evidence of spontaneous bacterial peritonitis. An ultrasound examination shows no hepatic masses. Appropriate management at this point should be

A. Large-volume paracentesis
B. Salt and water restriction alone
C. Transjugular intrahepatic portosystemic shunt (TIPS)
D. Spironolactone
E. Intravenous furosemide

Answer: D The patient has the new onset of uncomplicated, nontense ascites. The mainstay of therapy is sodium restriction and diuretics. Water restriction is not indicated unless her serum sodium concentration is below 125 mEq/L.[1] The most effective diuretic is spironolactone, which should be initiated alone at a dose of 100 mg once daily in the morning, particularly in patients with modest ascites. Furosemide is not as effective as spironolactone[2] because sodium that is not reabsorbed in the loop of Henle is taken up at the distal and collecting tubules as a result of the hyperaldosteronism that is present in most patients with cirrhosis and ascites. Therefore, furosemide should not be used as the sole agent in the treatment of cirrhotic ascites and should not be used intravenously. Large-volume paracentesis is indicated to decrease discomfort in patients with tense ascites and is first-line therapy for patients with refractory ascites. TIPS placement is second-line therapy for patients with refractory ascites.[1]

5. A 48-year-old man with chronic hepatitis C virus infection, cirrhosis, and ascites presents with 2 days of confusion. He denies fever, chills, hematemesis, or melena. On physical examination, his temperature is 35.5° C, blood pressure 90/60, heart rate 100 beats per minute, respiratory rate 30/minute. He is confused and agitated, and asterixis is present. His abdomen has tense ascites but is nontender, and his stool is negative for blood. His laboratory tests include white blood cell 8.6, creatinine 2.1 (previously 0.8), and bilirubin 7.7 (previously 2.3). He is making only small amounts of urine, but his urinalysis is normal. Which of the following is the most appropriate test?

A. Diagnostic paracentesis and blood cultures
B. Large-volume paracentesis
C. Upper endoscopy
D. Brain CT
E. Renal ultrasound

Answer: A The presence of unexplained encephalopathy or deterioration in renal function in a patient with ascites should always raise the suspicion of spontaneous bacterial peritonitis (SBP), so therefore a diagnostic paracentesis should always be performed in this setting.[1] The ascites culture is negative in about 40% of patients with SBP, so ascites and blood cultures should be performed whenever SBP is suspected. In this patient, blood cultures are particularly important because he presents with evidence of systemic inflammatory response system (hypothermia, tachycardia, and tachypnea) and jaundice and therefore may be septic. Large-volume paracentesis in this setting could theoretically lead to further deterioration in renal function and should be avoided. There is no evidence of gastrointestinal bleeding, so endoscopy is not indicated. Brain scan is not an initial test in a cirrhotic patient with encephalopathy unless there is a history of trauma or other causes of encephalopathy are suspected. A renal ultrasound study is a low-yield test because obstruction is an unlikely cause of his decompensation.

154

HEPATIC FAILURE AND LIVER TRANSPLANTATION

GREGORY T. EVERSON

In the United States, 130 programs perform about 6000 transplants per year, and about 17,000 patients are on waiting lists because recipients needing liver transplantation exceed the donor liver supply. The mortality rate while waiting on a list is 116 deaths per 1000 patient-years.

Since 1982, patient survival after liver transplantation has steadily increased by 20 to 30%, whether it is measured at 3 months, 1 year, 5 years, or 10 years, largely because of improvements within the first year after transplantation (Fig. 154-1). The positive shift in survival during the first 3 months after transplantation is related to improvements in surgical techniques and immediate postoperative care. By comparison, lack of further improvement beyond 3 months is because of long-term complications, such as recurrent hepatitis C (Chapter 149), recurrent autoimmune disease (Chapters 149 and 155), chronic allograft rejection, renal dysfunction (Chapter 130), hypertension (Chapter 67), and diabetes mellitus (Chapter 229). Further improvement in long-term survival after liver transplantation will require better management of these chronic complications.

GENERAL SELECTION CRITERIA

By far, the most common indication for liver transplantation is noncholestatic cirrhosis (Table 154-1). Livers may be donated from deceased donors (94%) or living donors (6%). Regardless of the type of transplantation, three fundamental questions must be addressed at the time of evaluation.[1]

1. Is liver transplantation indicated? The patient should have liver failure, complications of liver disease, or a metabolic condition that is best treated by liver transplantation and for which there are no alternative treatments.
2. Are there contraindications to transplantation (Table 154-2)? Comorbid conditions that could severely compromise graft or patient outcome must be identified.
3. Will the patient be able to tolerate and comply with immunosuppression and post-transplantation management? Inability to comply with the rigors of post-transplantation care and management could lead to graft loss and recipient death.

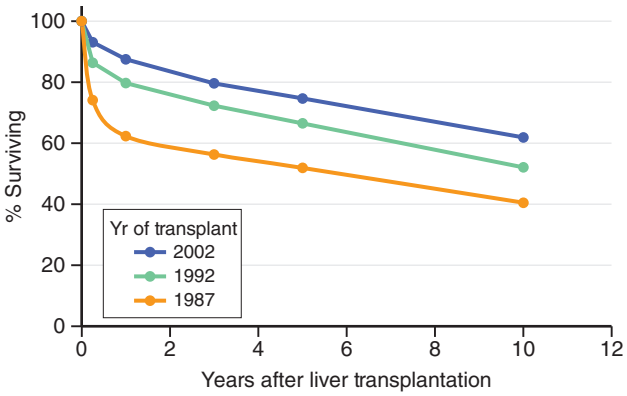

FIGURE 154-1. Survival of patients for three different years of transplantation, 1987, 1992, and 2002, by years after transplantation. The curves diverge early within the first year and then are nearly parallel, thereby suggesting that most of the improvement in survival is attributed to improvements in surgical techniques, intensive care unit management, and early post-transplantation care. Annual mortality rates between years 1 and 10 were 2.4% for the 1987 cohort, 3.1% for the 1992 cohort, and 2.8% for the 2002 cohort. (From Organ Procurement and Transplantation Network and Scientific Registry of Transplant Recipients. *OPTN/SRTR 2011 Annual Data Report*. Rockville, MD: Department of Health and Human Services, Health Resources and Services Administration, Healthcare Systems Bureau, Division of Transplantation; 2012).

TABLE 154-1 INDICATIONS FOR LIVER TRANSPLANTATION

CATEGORY	PERCENTAGE OF LISTED PATIENTS (TOTAL N = 15,748)	
Cirrhosis, non-cholestatic		72%
Hepatitis C	(27%)	
Alcoholic	(18%)	
Hepatitis C plus alcohol	(5%)	
Nonalcoholic steatohepatitis	(9%)	
Cryptogenic	(5%)	
Autoimmune	(4%)	
Hepatitis B	(3%)	
Other	(1%)	
Cholestatic liver disease		9%
Primary sclerosing cholangitis	(5%)	
Primary biliary cirrhosis	(3%)	
Other	(1%)	
Malignant neoplasms (primarily hepatocellular carcinoma)		7%
Acute liver failure		2%
Metabolic diseases		2%
Biliary atresia		1%
Other (e.g., Budd-Chiari syndrome) or unknown		8%

Based on Organ Procurement and Transplantation Network data as of May 30, 2014. http://optn.transplant.hrsa.gov/latestData/rptData.asp.

TABLE 154-2 CONTRAINDICATIONS TO LIVER TRANSPLANTATION

- Active substance abuse and inability to comply with rehabilitation
- Inadequate social support, extreme psychosocial dysfunction, active psychosis, or other underlying psychosocial disease that makes it impossible for the patient to comply with peri-transplantation care and postoperative management
- Unstable, active cardiopulmonary disease
  - Symptomatic ischemic coronary disease not amenable to revascularization
  - Severe pulmonary hypertension (mean PAP >45 mm Hg despite pharmacologic interventions)
- Active, incurable extrahepatic malignant disease
  - Metastatic nonhepatic malignant disease
  - Hepatoma with macrovascular invasion, extrahepatic metastases, or exceeding Milan or UCSF criteria and not able to be downstaged
  - Cholangiocarcinoma with percutaneous transperitoneal biopsy (likely seeding from the biopsy), tumor diameter >3 cm, or extrahepatic spread
- Active, uncontrolled, and untreatable sepsis or other serious infectious disease
- Active HIV infection with AIDS-defining illness, high-titer HIV RNA, very low CD4 count, or unresponsive to HAART
- Anatomic anomaly or extensive vascular thromboses precluding hepatic transplantation

PAP = pulmonary artery pressure; UCSF = University of California, San Francisco; HIV = human immunodeficiency virus; AIDS = acquired immunodeficiency syndrome; HAART = highly active antiretroviral therapy.

Medical Assessment

Certain components of the medical evaluation apply to all potential recipients. Viral serologies characterize the status of ongoing infection, prior exposure, or vaccination related to the hepatitis viruses (Chapters 148 and 149), Epstein-Barr virus (Chapter 377), cytomegalovirus (Chapter 376), and human immunodeficiency virus (HIV; Chapter 388). Colonoscopy is recommended for all patients older than 50 years to exclude colon cancer or polyps (Chapter 193) and in all patients with primary sclerosing cholangitis (Chapter 155) to detect inflammatory bowel disease (Chapter 141). Cardiopulmonary assessment (Chapters 51, 71, and 85) is performed in patients older than 50 years and in any patient with risk factors for coronary artery disease, such as hypertension, hypercholesterolemia, a significant family history, cigarette smoking, or diabetes. Cardiac catheterization (Chapter 57) is performed in patients with positive cardiac stress test results to confirm and to delineate the extent of coronary disease. Ultrasonography, computed tomography, and magnetic resonance imaging are useful to examine the biliary tract (Chapter 146), to exclude hepatocellular cancer (Chapter 196) or cholangiocarcinoma (Chapter 196), and to determine the patency of major vascular structures, such as the hepatic artery, celiac axis, splenic artery, portal vein, and superior mesenteric vein (Chapter 143).

The primary principle for consideration of liver transplantation is that a patient's predicted survival with transplantation must exceed expected survival without transplantation. For deceased donor liver transplantation, this principle is fulfilled by a Model for End-Stage Liver Disease (MELD) score of approximately 12 to 15 (see Table 153-2). In addition, certain complications of cirrhosis (Chapter 153), such as ascites, spontaneous bacterial peritonitis, encephalopathy, uncontrolled variceal hemorrhage, nutritional wasting, failure to thrive, and development of hepatoma (Chapter 196), shorten survival. Immediate evaluation and listing for transplantation are indicated for any patient with a MELD score of 15 or more or any of these complications.

Other complications that are not considered life-threatening may also be indications for consideration of liver transplantation. Examples include metabolic bone disease resulting in osteopenia and bone fractures (Chapters 243 and 244), inadequate nutrition, muscle wasting, severe fatigue, poor concentrating ability, and intractable pruritus.

Because the supply of donor livers is limited, transplant centers must select patients who have the greatest chance for a successful outcome. Elderly, obese, and deconditioned patients as well as patients with underlying vascular disease or long-standing diabetes mellitus are poor candidates for liver transplantation.

Surgical Assessment

The three phases of surgery are native liver dissection, the anhepatic phase, and revascularization of the graft. Native liver dissection, which is characterized by meticulous dissection and prompt control of bleeding vessels, can be complicated by morbid obesity, significant portal hypertension, portal thromboses, prior portosystemic shunt surgery, or prior abdominal surgery. The length of this phase is usually 1 to 2 hours, with blood losses ranging from 0 to 5 units of blood.

During the anhepatic phase, which usually lasts 1.5 to 3 hours and is associated with blood loss ranging from 0 to 5 units of blood, the vascular supply of the liver is completely interrupted, and the native liver is excised. Toward the end of the anhepatic phase, vessels are anastomosed, with the donor hepatic veins typically grafted to the recipient vena cava with only one caval anastomosis. Recipients with severe coagulopathy, cachexia, and nutritional deficiencies may be prone to excessive bleeding and metabolic complications.

When the venous clamps are removed, patients are at risk for primary fibrinolysis or consumptive coagulopathy. The arterial anastomosis is typically performed after unclamping to shorten the warm ischemia period.

Psychosocial Assessment

A patient referred for liver transplantation may have a history of alcohol, drug, or substance abuse. Psychosocial evaluation is important to help determine

the risk of recidivism after transplantation. Today, nearly all transplant centers require a minimum 6-month period of documented abstinence and enrollment in education or rehabilitation programs. Social workers and psychiatrists may require the patient to undergo alcohol or drug treatment, counseling, and unannounced random screens for alcohol and drugs. Other key aspects of the psychosocial assessment include (1) evaluating the patient for any underlying psychiatric illness (Chapter 397), its severity, and how it should be managed; (2) defining and establishing social and psychological support for the potential recipient, including family, friends, and significant others; and (3) in living donor liver transplantation, evaluating the potential living donors.

Assigning Priority: Model for End-Stage Liver Disease

The prioritization of U.S. liver transplantation candidates and the allocation of deceased donor livers are based on the MELD score (see Table 153-2), which ranges from 6 (best prognosis) to 40 (worst prognosis). The 3-month mortality rate increases from 10% with a MELD score of 20 to 60% at a MELD score of 35, and essentially to 100% with a MELD score above 40. A patient's survival is not improved by deceased donor liver transplantation if the MELD score is below about 15. As a result, deceased donor livers must be made available more broadly if no local patient has a MELD score of 15 or higher and must be made available to local or regional patients with scores of 35 or higher. Patients with acute liver failure or post-transplantation patients with graft failure due to hepatic artery thrombosis have a MELD score of 40 and top priority status. This allocation system (E-Table 154-1) has improved transplantation rates and has not altered waiting list or post-transplantation mortality.

In patients with cirrhosis (Chapter 153), hyponatremia (Chapter 116) is associated with hepatorenal syndrome, ascites, and death from liver disease. Hyponatremia is an independent predictor of mortality up to a MELD score of 30. As a result, the MELD score is now adjusted for serum sodium concentration in allocating deceased donor livers.

The most common exception to liver allocation by MELD score is for hepatocellular carcinoma (Chapter 196) with a tumor diameter of more than 2 cm. Other exceptions can include patients with the hepatorenal syndrome (Chapter 153), the portopulmonary syndrome (Chapter 153), cholangiocarcinoma (Chapter 155), cystic fibrosis (Chapters 89 and 146), familial amyloid polyneuropathy (Chapter 188), and primary hyperoxaluria (Chapter 205) (E-Table 154-2).

DISEASE-SPECIFIC INDICATIONS FOR TRANSPLANTATION

Acute Liver Failure

Acute liver failure is defined as hepatic injury of fewer than 26 weeks in duration, an international normalized ratio of 1.5 or greater, and altered mental status in the absence of chronic liver disease except for Wilson disease (Chapter 211), vertically acquired hepatitis B, or autoimmune hepatitis (Chapter 149).[2] The main causes of acute liver failure in the United States are acetaminophen toxicity (Chapter 110), drug-induced liver injury (Chapter 150), viral hepatitis (Chapters 148 and 149), autoimmune hepatitis (Chapter 149), Wilson disease, mushroom poisoning (Chapters 110 and 150), acute hepatic ischemia (Chapter 143), Budd-Chiari syndrome, acute fatty liver of pregnancy (sometimes associated with the HELLP syndrome—hemolysis, elevated liver enzymes, low platelets; Chapters 160 and 239), and malignant infiltration of the liver (Chapter 196).

TREATMENT

Rx

Patients with acute liver failure criteria should be transferred to the intensive care unit for enhanced monitoring, and a liver transplant center should be contacted for potential transfer of the patient. Specific treatments include *N*-acetylcysteine for acetaminophen hepatotoxicity (Chapters 110 and 150), *N*-acetylcysteine plus either silibinin or penicillin G for mushroom poisoning (Chapters 110 and 150), *N*-acetylcysteine and removal of the offending drug for drug-induced liver injury (Chapter 150), nucleos(t)ide analogues for hepatitis B (Chapters 148 and 149), acyclovir for herpes or varicella-zoster hepatitis (Chapters 374 and 375), dialysis and copper chelation for Wilson disease (Chapter 211), corticosteroids for autoimmune hepatitis (Chapter 149), delivery of the infant for acute fatty liver of pregnancy, and transjugular intrahepatic portosystemic shunting for the Budd-Chiari syndrome (Chapter 143). In addition, all causes of acute liver failure can cause a range of systemic complications.

A key issue in the general management of patients with acute liver failure is monitoring and treatment of encephalopathy. Progressive encephalopathy in acute liver failure is characteristically associated with cerebral edema and an elevated intracranial pressure (ICP). Elevated ICP is rare in patients with grade I (mild confusion) or grade II (agitated state) encephalopathy but occurs in 25 to 35% of patients with grade III encephalopathy (stuporous) and 65 to 75% of patients with grade IV (coma, but responsive to deep pain) encephalopathy. Irreversible brain injury is likely when the ICP is above 50 mm Hg and the cerebral perfusion pressure (mean arterial pressure minus ICP) is below 40 mm Hg for more than 2 hours. Liver transplantation may be contraindicated under these circumstances.

Because ammonia may play a role in the pathogenesis of cerebral edema, lactulose (20 g every 4 to 6 hours), rifaximin (550 mg twice daily), or both are recommended, especially for lower grades of encephalopathy. Patients with grade III/IV encephalopathy require intubation, mechanical ventilation, elevation of the head of the bed, sedation (e.g., propofol, initial dose of 0.005 mg/kg/minute IV, maintenance dose of 0.005 to 0.05 mg/kg/minute IV, which can be increased in increments of 0.005 mg/kg/minute every 5 minutes), and paralysis (cisatracurium, initial dose of 0.1 to 0.2 mg/kg IV, maintenance dose of 1 to 3 µg/kg/minute IV). Seizures (Chapter 403) should be treated with phenytoin (initial dose of 15 mg/kg IV, maintenance dose of 3 mg/kg every 12 hours IV), propofol (1 mg/kg IV loading dose, 3 to 7 mg/kg/hour IV maintenance), pentobarbital (13 mg/kg IV loading dose, 2 to 3 mg/kg/hour IV maintenance), or midazolam (0.2 mg/kg IV loading dose, 0.1 to 0.25 mg/kg/hour IV maintenance). Levetiracetam (500 [up to 1500] mg every 12 hours IV) may be used if renal function is preserved. Placement of an intracranial transducer for monitoring of ICP is desirable, but severe underlying coagulopathy may prohibit its placement. Elevated ICP may require treatment with mannitol (0.5 to 1.0 mg/kg every 4 to 6 hours IV), hypertonic saline (boluses every 2 to 4 hours of either 30 mL of 23.4% saline or 2 mL/kg of 7.5% saline), hyperventilation (target pH 7.45), pentobarbital (dose described before), and hypothermia (32° C to 34° C). The goal for these interventions is to maintain ICP below 20 mm Hg. Corticosteroids do not improve cerebral edema or lower ICP in acute liver failure,[3] and their use is not recommended.

Patients with acute liver failure are at increased risk for bacterial and fungal infections. Common infections include line sepsis, pneumonia (Chapter 97), and urinary tract infections (Chapter 284). Prolonged ventilation, dialysis, invasive procedures, and use of multiple antibiotics increase the risk for fungal infection (Chapter 282). Surveillance cultures of blood, urine, and sputum and periodic chest radiography are required every 2 days. Prophylactic antibiotic or antifungal therapy is not currently recommended.

In addition to an elevated international normalized ratio, many patients develop thrombocytopenia because of consumptive coagulopathy (Chapter 175). However, prophylactic use of transfusion of clotting factors or platelets should be restricted to the treatment of hemorrhage or in preparation for invasive procedures.

Patients with acute liver failure have a low systemic vascular resistance and a low mean arterial pressure. In patients with elevated ICP, the decrease in mean arterial pressure may further compromise cerebral perfusion pressure and blood flow. A goal of vasopressor therapy is to maintain cerebral perfusion pressure from 60 to 80 mm Hg. Treatment of hypotension to maintain a mean arterial pressure above 75 mm Hg may include dextrose-containing crystalloid, albumin, norepinephrine, and vasopressin (Chapter 106). Careful monitoring of volume status is critical, and care should be taken to avoid volume overload, which may worsen cerebral edema.

Acute renal failure (Chapter 120) is common in patients with acute liver failure, particularly when it is caused by acetaminophen, mushroom poisoning, or Wilson disease. Renal replacement therapy, when required, should be administered as continuous venovenous dialysis (Chapter 131). Intermittent modes of hemodialysis should be avoided because of their adverse hemodynamic effects.

In acute liver failure, hypoglycemia is a common complication that should be avoided and managed by continuous glucose infusions. Supplementation with phosphate, magnesium, and potassium (Chapter 117) may be required. Enteral feedings (Chapter 216) should be initiated early, and parenteral nutrition (Chapter 217) should be started if enteral feedings are contraindicated.

Selecting for Liver Transplantation

Clinical variables associated with reduced likelihood for spontaneous recovery include severe encephalopathy, advanced age, certain causes (hepatitis B, drug-induced hepatitis, sporadic non-A/non-B/non-C hepatitis, Wilson disease), long duration of jaundice, massive necrosis on liver biopsy, and markedly diminished liver volume on radiologic imaging. Transplant-free survival in patients with acute liver failure is approximately 50% for acetaminophen toxicity, hepatitis A, shock liver, and acute fatty liver of pregnancy/HELLP but less than 25% for all other causes.[4] Indications for listing for transplantation are based on the severity of disease but vary somewhat among countries (Table 154-3).[5]

MELD = Model for End-Stage Liver Disease (see Table 153-2).

E-TABLE 154-2 LIVER CANDIDATES WITH EXCEPTIONAL CASES NOT REQUIRING REVIEW BY THE REGIONAL REVIEW BOARD IN THE U.S.

Hepatopulmonary syndrome. The patient must have evidence of intrapulmonary shunt and Pao_2 below 60 mm Hg on room air. These patients are listed with MELD 22 with 10% increase every 3 months if the Pao_2 remains under 60 mm Hg.

Cholangiocarcinoma. The liver center requesting the MELD exception must have a written United Network for Organ Sharing–approved protocol that includes neoadjuvant chemoradiation and pretransplantation operative staging to exclude metastatic disease. MELD 22 with 10% increase every 3 months as long as tumor is controlled by the treatment protocol and there is no evidence of metastases.

Cystic fibrosis. The patient must have FEV_1 below 40% of normal range. MELD 22 with 10% increase every 3 months.

Familial amyloid polyneuropathy. The patient must lack significant cardiac involvement with echocardiogram showing ejection fraction greater than 40% and have ambulatory status, appropriate *TTR* gene mutation, and biopsy-proven amyloid. MELD 22 with 10% increase every 3 months.

Primary hyperoxaluria (type I). The patient must have renal failure due to oxalate stone disease and alanine:glyoxylate aminotransferase deficiency proven by liver biopsy (sample analysis with measurement of alanine:glyoxylate aminotransferase enzyme activity and/or genetic analysis of the alanine:glyoxylate aminotransferase gene). MELD 28 with 10% increase every 3 months.

Portopulmonary syndrome. The patient must have pulmonary hypertension diagnosed by appropriate measurements of mean pulmonary artery pressure (MPAP), pulmonary vascular resistance (PVR), and transpulmonary gradient. With treatment, the MPAP should be less than 35 mm Hg and PVR should be less than 400 dynes/sec/cm^{-5}. MELD 22 with 10% increase every 3 months.

MELD = Model for End-Stage Liver Disease.

TABLE 154-3 CRITERIA FOR SELECTION OF PATIENTS WITH ACUTE LIVER FAILURE FOR LIVER TRANSPLANTATION

KING'S COLLEGE, LONDON, UNITED KINGDOM
Acetaminophen toxicity
Acidosis (pH <7.3), or
INR >6.5 plus creatinine >3.4 mg/dL
Other causes of acute liver failure
INR >6.5, or
Any three of the following:
Age <10 years or >40 years
Non-A, non-B hepatitis or drug-induced disease
Duration of jaundice before encephalopathy >7 days
INR >3.5
Bilirubin >17.5 mg/dL
HÔPITAL PAUL-BROUSSE, VILLEJUIF, FRANCE
For all causes of acute liver failure:
Hepatic encephalopathy, and
Factor V <20% of normal in patient younger than 30 years or
Factor V <30% of normal in patient 30 years of age or older

INR = international normalized ratio.

Transplantation for acute liver failure accounts for less than 5% of all liver transplants. About 45% of patients with acute liver failure are listed for transplantation; about 10% die on the waiting list, about 5% improve without transplantation, and about 30% undergo liver transplantation. Overall 1- and 5-year survival rates after liver transplantation are 79% and 71%, respectively, but post-transplantation survival is better for patients with acute acetaminophen overdose and worse for patients with severe encephalopathy before transplantation. Living donor and auxiliary liver transplantation may be considered, but their use is controversial.

Chronic Liver Failure

Cirrhosis (Chapter 153) due to the hepatitis C virus (Chapter 149) is the most common indication for liver transplantation in the United States. Hepatitis C universally recurs in the liver allograft of recipients who are viremic at the time of liver transplantation and is associated with early graft loss and death of the patient. Pretransplantation treatment (Chapter 149) with an interferon-free, pangenotypic regimen of sofosbuvir (400 mg daily) plus weight-based ribavirin (1.0 to 1.2 g/day) for 48 weeks eliminates detectable hepatitis C virus RNA in nearly all patients within 4 weeks, and patients with undetectable hepatitis C virus RNA for 30 days or more before transplantation have only about a 4% risk of becoming viremic after transplantation.[6] A similar regimen given for 24 weeks after transplantation can achieve a sustained virologic response in about 70% of recipients with hepatitis C virus genotype I infection.[7] The combination of ledipasvir, sofosbuvir, and ribavirin yields sustained virologic response rates of approximately 90% in patients with decompensated cirrhosis and in transplant recipients with recurrent hepatitis C and advanced fibrosis or cirrhosis.

Alcoholic cirrhosis (Chapter 152) is a major albeit controversial indication for liver transplantation because many patients who totally abstain from alcohol may recover to the point that transplantation is no longer indicated.[8] Candidates for transplantation must typically adhere to at least 6 months of rehabilitation and document abstinence from alcohol by testing of urine or blood. Risk factors for noncompliance and return to alcohol use include polysubstance abuse, poor social support, joblessness, and underlying psychiatric illness. However, properly selected and compliant patients have excellent post-transplantation outcomes, even though 8 to 33% return to some degree of drinking. The 1-, 3-, and 5-year patient survival rates range from 81 to 92%, 78 to 86%, and 73 to 86%, respectively.

Transplantation for alcoholic hepatitis is even more controversial. One nonrandomized study from seven French liver transplant units suggested that carefully selected patients with severe alcoholic hepatitis could substantially benefit from liver transplantation, with a 2-year survival of 77% with transplantation compared with 23% without it.[9] It is not known whether this experience can be duplicated in other centers or countries, and alcoholic hepatitis currently is considered a relative contraindication to liver transplantation in most U.S. centers.

Patients with hepatocellular carcinoma (Chapter 196) are candidates for liver transplantation unless they have large tumors, multicentric tumors, macrovascular invasion, or extrahepatic spread. The Milan criteria recommend transplantation for a single hepatocellular carcinoma less than 5 cm in diameter or up to three hepatocellular carcinomas with no single lesion more than 3 cm in diameter. The post-transplantation survival of patients satisfying these Milan criteria is similar to that of patients transplanted for other indications. The University of California, San Francisco (UCSF) criteria recommend transplantation for a single tumor less than 6.5 cm in diameter or up to five tumors with total cumulative diameter of less than 8.5 cm. Patients who are "downstaged" by transarterial chemoembolization or other locoregional treatments from UCSF to Milan criteria have a post-transplantation outcome similar to that of patients who initially met Milan criteria.

The rare fibrolamellar variant of hepatocellular carcinoma constitutes only 0.85% of all cases of primary liver cancer. Compared with patients with typical hepatocellular carcinoma, patients with fibrolamellar carcinoma are younger (mean age, 39 years vs. 65 years) and more likely to be female (52% vs. 26%) and white (85% vs. 57%). Fibrolamellar carcinoma is characterized by broad bands of fibrosis, no association with cirrhosis, slow growth, and easier resection. Although post-transplantation recurrence rates of fibrolamellar carcinoma are similar to those for standard hepatocellular carcinoma, 5-year survival is higher in patients with fibrolamellar carcinoma.

Cholangiocarcinoma (Chapter 196), in the absence of underlying liver or biliary disease, typically is manifested in elderly patients with significant comorbidities and is not an indication for liver transplantation. By contrast, cholangiocarcinoma arising in younger patients with underlying biliary disease, such as primary sclerosing cholangitis (Chapter 155), may be considered for transplantation if staging is negative for vascular, lymphatic, or neural invasion. The 2- and 5-year post-transplantation survivals of patients with cholangiocarcinoma limited to the perihilar region of the liver and treated with adjuvant chemoradiation are 78% and 65%, respectively.[10] Factors associated with early recurrence and diminished survival are tumor diameter of more than 3 cm, performance of a percutaneous transperitoneal biopsy of the tumor, metastatic disease at time of surgery, and history of a prior malignant neoplasm.

Rare Primary Hepatic Malignant Neoplasms

Other primary hepatic malignant neoplasms—epithelioid hemangioendotheliomas, hemangiosarcomas, and hepatoblastomas—represent less than 10% of all tumors undergoing transplantation. Epithelioid hemangioendothelioma is generally thought to be indolent in nature, and reported post-transplantation survivals have been favorable. By contrast, hemangiosarcoma universally recurs, so transplantation is contraindicated.

In patients with liver metastases from primary endocrine tumors, such as carcinoid tumor (Chapter 232), gastrinoma, insulinoma, glucagonoma, and VIPoma (Chapters 195 and 230), liver transplantation is best restricted to those with metastases that are confined to the liver and are unresponsive to chemotherapy, local ablative therapies, surgical resection, and hormonal therapy.[11] Even in highly selected patients, tumor recurrence is the rule, with a 5-year post-transplantation patient survival of 52% but a disease-free 5-year survival of only 30%.

With the advent of effective antiviral regimens, the post-transplantation outcomes for patients transplanted for hepatitis B (Chapter 149) are now among the best for any indication,[12] with a 3-year survival of 87%. In the United States, potential recipients are treated before transplantation with either tenofovir or entecavir monotherapy, which is continued indefinitely in the post-transplantation period.

Nonalcoholic steatohepatitis (Chapter 152) has become an increasing indication for liver transplantation.[13] The likelihood of 1-, 3-, and 5-year survival is similar to that of other recipients because their higher risk for post-transplantation cardiovascular death is offset by a lower risk of graft failure.

For primary biliary cirrhosis (Chapter 153), the mean survival for patients with a serum bilirubin level above 10 mg/dL is only 1.4 years. By comparison, actuarial survival for patients undergoing liver transplantation is 83%, 78%, and 67% at 1 year, 5 years, and 10 years, respectively.[14] Although primary biliary cirrhosis may recur in the allograft, recurrence rarely leads to graft failure, retransplantation, or the patient's death.

Among patients with primary sclerosing cholangitis (Chapter 155), the 1-, 2-, 5-, and 10-year actuarial survival rates after liver transplantation are 94%, 92%, 86%, and 70%, respectively. Primary sclerosing cholangitis recurs after transplantation at a rate of approximately 4% per year, and recurrent primary sclerosing cholangitis occasionally may progress and require retransplantation.

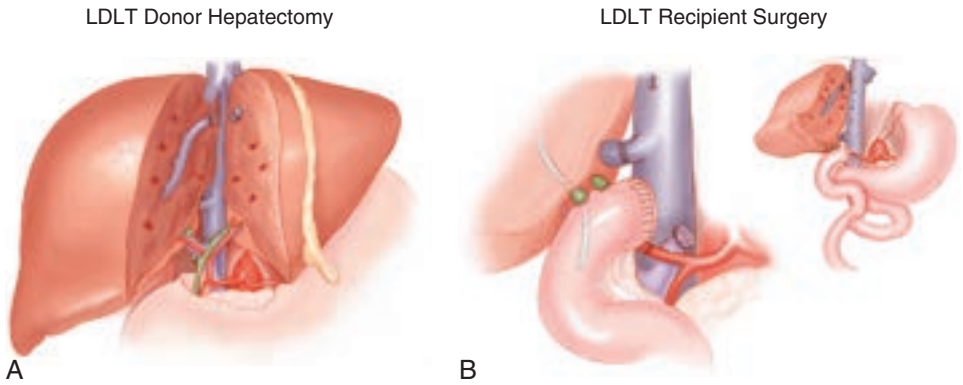

FIGURE 154-2. Living related donor hepatectomy (A) and orthotopic implantation of the right lobe graft (B). LDLT = living donor liver transplantation.

Up to 30% of patients with primary sclerosing cholangitis will develop cholangiocarcinoma, which diffusely infiltrates bile ducts, liver parenchyma, neural elements, lymphatic vessels, and surrounding tissues. Cholangiocarcinoma complicating primary sclerosing cholangitis, either before or after transplantation, reduces survival,[15] although the outcome is excellent if the cholangiocarcinoma is detected during surveillance imaging, treated with adjuvant chemoradiation, and then removed with the explant during transplantation.

In patients with autoimmune hepatitis (Chapter 149), 1-year patient survival rates after liver transplantation range from 83 to 92%, with an estimated 10-year survival of 75%. Recurrence is observed in 17% of patients after 4.6 ± 1 years, and an occasional patient with recurrent autoimmune hepatitis will require retransplantation.

For hemochromatosis (Chapter 212), liver transplantation now yields 1-, 3-, and 5-year survival rates similar to the survivals of all other transplant recipients. Patients with hemochromatosis who are considered for liver transplantation should undergo screening for hepatocellular carcinoma and also have a complete cardiologic evaluation. It is uncertain whether pretransplantation phlebotomy improves survival.

Patients with either the ZZ (n = 50) or SZ (n = 23) α_1-antitrypsin deficiency (Chapter 146) have excellent outcomes after liver transplantation.[16] Pulmonary evaluation is critical because one third of adults transplanted for α_1-antitrypsin deficiency will have significant underlying obstructive respiratory disease, which typically stabilizes and then improves after liver transplantation but sometimes may progress despite it.

In patients with polycystic liver disease, liver transplantation is rarely indicated but is highly successful in relieving symptoms of abdominal fullness, early satiety, and related complaints. The post-transplantation outcome is better for patients with isolated polycystic liver disease compared with polycystic liver in the setting of polycystic kidney disease (Chapter 127),[17] thereby highlighting the higher morbidity and mortality associated with cystic renal disease.

In patients with primary hyperoxaluria,[18] which is inherited as an autosomal dominant trait, liver transplantation is required to remove the source for the overproduction of oxalate and to halt the progression of renal disease. For patients with familial amyloid polyneuropathy, which is an inherited and fatal systemic amyloidosis that is caused by a point mutation in the transthyretin gene, liver transplantation halts the production of the amyloidogenic variant transthyretin, halts the progression of the disease, and significantly improves survival.[19]

An increasing number of HIV-infected patients are being considered for liver transplantation, primarily because of coinfection with hepatitis C virus.[20] Selection criteria include the absence of AIDS or AIDS-defining illness, adequate CD4 counts, low HIV levels, and lack of resistance to highly active antiretroviral therapies. The overall patient survival at 3 years after transplantation is 60% for HIV/hepatitis C virus coinfection, compared with 79% for hepatitis C virus monoinfection.

RISK FACTORS FOR POOR OUTCOME AFTER LIVER TRANSPLANTATION

Patients older than 60 years have about a 10% lower survival because of infection, cardiac complications, neurologic disease, and malignant disease. Survival is also lower in patients with ischemic heart disease, diabetes, persistent smoking, or chronic obstructive pulmonary disease, although patients who undergo liver transplantation for α_1-antitrypsin deficiency may show improvement in their pulmonary function test results.

LIVING DONOR LIVER TRANSPLANTATION IN ADULTS

Living donor liver transplantation is an option to expedite transplantation for adult patients with end-stage liver disease. Living donor liver transplantation already is the most common form of liver transplantation in Asia, where cultural barriers have limited liver donation from deceased donors, but it represents only 5% of all adult liver transplants in the United States. In adults, either the left or right lobe may be used, but most U.S. experts prefer the right hepatic lobe. In this procedure, the entire native liver of the recipient is removed and replaced with the right lobe of the liver from a living donor (Fig. 154-2).

The major clinical advantage of living donor liver transplantation is a reduction in recipient mortality, largely related to a reduction in pretransplantation mortality among patients who otherwise would languish on a waiting list. By comparison, both short-term and long-term survival after transplantation is nearly identical with living donor liver transplantation and deceased donor liver transplantation.[21]

The major disadvantage of living donor liver transplantation is donor safety. Most donors undergo successful right hepatectomy uneventfully, but significant complications, such as bile leakage and infection, occur in 10 to 20% of patients, and the death rate among living donors is 0.2%.[22] In the majority of donors, the quality of life returns to baseline by 6 months, although mild abdominal complaints and pain are common. More than 90% of donor-recipient pairs report that they have returned to their original predonation relationships at 1 year.

RECIPIENT OUTCOMES AFTER LIVER TRANSPLANTATION

Recipients of either deceased donor liver transplantation or living donor liver transplantation may encounter a number of complications that occur at different times after transplantation (Fig. 154-3).[23] Graft injury within the first 3 days is most often due to either primary nonfunction or hepatic artery thrombosis. Less common causes of graft dysfunction during this period include hyperacute rejection, portal vein thrombosis, and obstruction of the inferior vena cava. Between 3 and 14 days, graft dysfunction is most commonly related to acute cellular rejection, recurrent hepatitis C infection, hepatic artery thrombosis, or biliary leak or cholangitis. Infrequent causes of dysfunction during this period are portal vein thrombosis, drug hepatotoxicity, and functional cholestasis. From 14 days to 3 months, the most common causes of graft dysfunction include allograft rejection, recurrent hepatitis C infection, biliary complications, cytomegalovirus hepatitis, and drug hepatotoxicity. Vascular thromboses rarely are manifested after the first 3 months, and hepatitis B recurrence (in untreated patients) is typically delayed beyond 1 month.

The most severe form of early graft dysfunction is primary nonfunction, which is characterized by acute liver failure (encephalopathy, ascites, coagulopathy, unstable hemodynamics), elevated liver enzymes, and development of multiorgan failure (renal failure and pulmonary complications). Primary nonfunction is encountered in only 1% of recipients after living donor liver transplantation, because the graft is implanted quickly after it has been removed from the donor, but in 7 to 8.5% of recipients after deceased donor liver transplantation. Anywhere from 20 to 45% of recipients experience

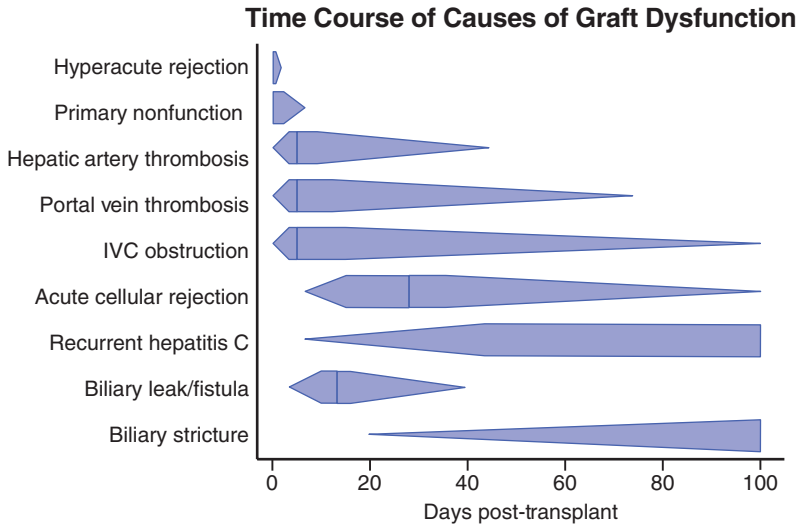

FIGURE 154-3. The time course of graft dysfunction varies by etiology. Hyperacute rejection is rare (ABO incompatibility) but occurs within the first few hours to days. Primary nonfunction, vascular thrombosis, and biliary leaks are early events, and acute rejection episodes begin after the first 7 days. Recurrent hepatitis C may begin early but typically is manifested after the first 2 or 3 weeks after transplantation. Biliary strictures evolve more slowly and tend to be later events. IVC = inferior vena cava.

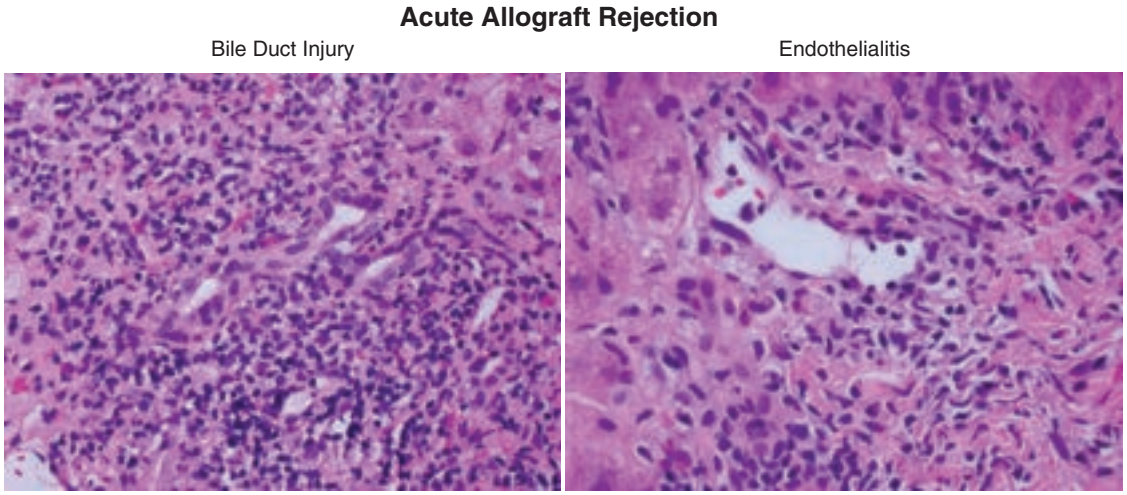

FIGURE 154-4. Liver histology of acute allograft rejection (hematoxylin and eosin stain). The immune inflammatory response is centered around the portal triad, and the typical features include a mixed cellular infiltrate (eosinophils, neutrophils, plasma cells, lymphocytes), lymphocytic cholangitis, and endothelialitis.

postoperative bleeding, including 5 to 15% who will need reoperation for bleeding. Hemorrhage is second only to infection as a cause of death.

Hepatic artery thrombosis, which complicates 3 to 10% of adult liver transplants, is one of the leading causes of graft failure in the immediate postoperative period. It is manifested as fever, bacteremia from a biliary source, and sudden elevations in liver enzymes. The preferred initial investigation of the hepatic artery is Doppler ultrasonography, followed by angiography if positive. In general, emergent revascularization is required for graft survival.

Portal Vein Thrombosis

Portal venous thrombosis, which is less common than hepatic arterial thrombosis, is manifested as hepatic failure and portal hypertension. Portal hypertension may be treated by radiologic thrombectomy, lytic therapy, stenting of underlying portal vein stenosis, or decompressive shunt surgery, but patients with significant hepatic dysfunction should be considered for revascularization or retransplantation.

Hepatic venous outflow obstruction may be manifested clinically by hepatic dysfunction, coagulopathy, and jaundice or even by hepatomegaly and ascites. Chronic outflow obstruction with preservation of graft function may be managed conservatively with diuretic therapy, radiologic evaluation of venous anastomoses, and angioplasty or stenting of outflow stenosis, but acute outflow obstruction can be a graft- and life-threatening condition that may require emergent revision of the outflow anastomosis.

Biliary tract complications, leaks, and strictures occur after approximately 5 to 30% of all liver transplants, usually within the first 3 months. Biliary scintigraphy can be diagnostic for large bile leaks, but cholangiography may be required for small, contained leaks. Anastomotic biliary strictures are focal and localized to the choledochocholedochostomy or choledochoenterostomy, whereas ischemic strictures are multiple and diffuse. Patients may present with jaundice, cholangitis, or asymptomatic elevations in liver test results. Choledocholithiasis may complicate strictures. Cholangiography is the "gold standard" for the diagnosis of biliary strictures as well as for their management with dilation and stenting. Surgical revision is reserved for patients in whom these procedures are unsuccessful, but diffuse ischemia strictures may necessitate retransplantation.

Rejection, which occurs in about 15 to 30% of liver transplants, usually is initially seen as an acute rejection within the first 30 days. Any acute rejection occurring beyond 30 days should raise the suspicion of subtherapeutic levels of immunosuppressive medications, drug interactions affecting immunosuppressant levels, or noncompliance of the patient with the medical regimen. Most patients are asymptomatic, although fever, malaise, abdominal pain, and worsening of portal hypertension with associated clinical manifestations can occur. Liver biopsy is essential for diagnosis. The classic findings are a mixed inflammatory infiltrate of lymphocytes, plasma cells, eosinophils, and neutrophils and nonsuppurative destructive cholangitis and endothelialitis (Fig. 154-4). Treatment consists of pulse doses of methylprednisolone (1 g IV daily for 1 to 3 days) and a taper of oral prednisone. Patients who fail to respond to corticosteroid treatment may be rescued by anti–T-cell therapy, such as thymoglobulin. In some cases in which the acute rejection may be mediated by B cells, plasmapheresis and anti–B-cell treatment (e.g., rituximab, 100 to 375 mg/m^2 weekly for two or three doses) may be required. Graft loss due to acute rejection is rare.

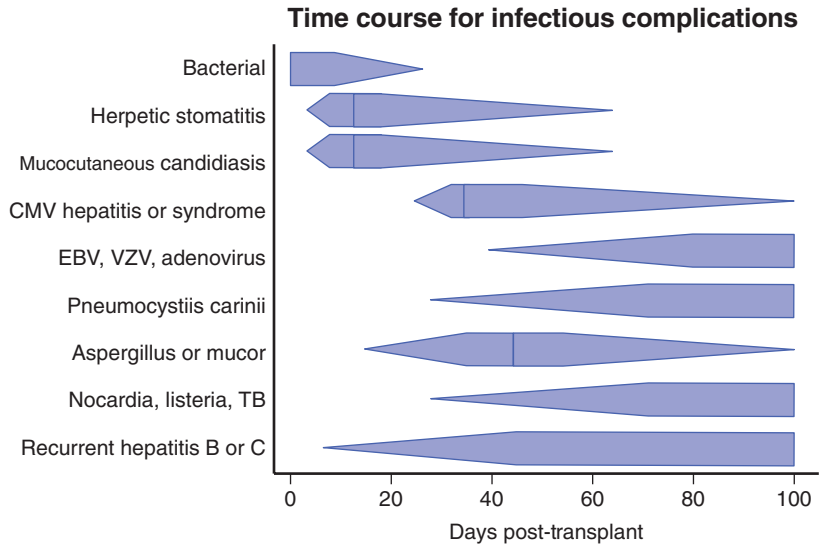

FIGURE 154-5. The time course of infectious complications varies by type of infection. Bacterial and mucocutaneous viral or candidal infections occur early, and most of the others occur after the first 2 or 3 weeks after transplantation. CMV = cytomegalovirus; EBV = Epstein-Barr virus; VZV = varicella-zoster virus; TB = tuberculosis.

Chronic allograft rejection occurs in 2 to 3% of liver transplants. Patients may be asymptomatic early in the course or present with jaundice or pruritus later in the course. Laboratory test results reveal elevated cholestatic liver enzymes, such as alkaline phosphatase or γ-glutamyltransferase, and bilirubin. Liver biopsy reveals paucity of inflammation, portal fibrosis, and loss of intralobular and interlobular bile ducts. Chronic rejection is poorly responsive to immunosuppressive therapy and often progresses to graft loss, need for retransplantation, and ultimately death.

Infections

Most infectious complications of liver transplantation occur within the first 3 months of transplantation (Fig. 154-5).[24] Bacterial and mucocutaneous herpetic (Chapter 374) or candidal (Chapter 338) infections dominate the immediate post-transplantation period. Other viral infections (such as cytomegalovirus [Chapter 376], Epstein-Barr virus [Chapter 377], varicella-zoster [Chapter 375], and adenovirus [Chapter 365]), *Pneumocystis jiroveci* infection (Chapter 341), or fungal infections tend to occur or to activate after the first 30 days. Hepatitis C replication begins immediately after transplantation in patients who are viremic at the time of transplantation, and recurrent hepatitis can occur as early as 7 days but more typically occurs after 30 days. Current strategies with nucleos(t)ides and hepatitis B immune globulin (Chapters 148 and 149) have essentially eliminated recurrent hepatitis B.

Approximately 80 to 90% of adults undergoing liver transplantation have serologic evidence of prior exposure to cytomegalovirus. Recipients who have positive cytomegalovirus serology or who receive a liver from a cytomegalovirus-positive donor are at risk for either cytomegalovirus syndrome (influenza-like illness) or cytomegalovirus hepatitis. Cytomegalovirus hepatitis requires liver biopsy for diagnosis (E-Fig. 154-1). The greatest risk is in a cytomegalovirus-negative recipient who receives a liver from a cytomegalovirus-positive donor (~60% risk for cytomegalovirus disease). Prophylaxis with oral valganciclovir (900 mg orally daily) during the first 90 days after transplantation effectively reduces risk for cytomegalovirus disease.

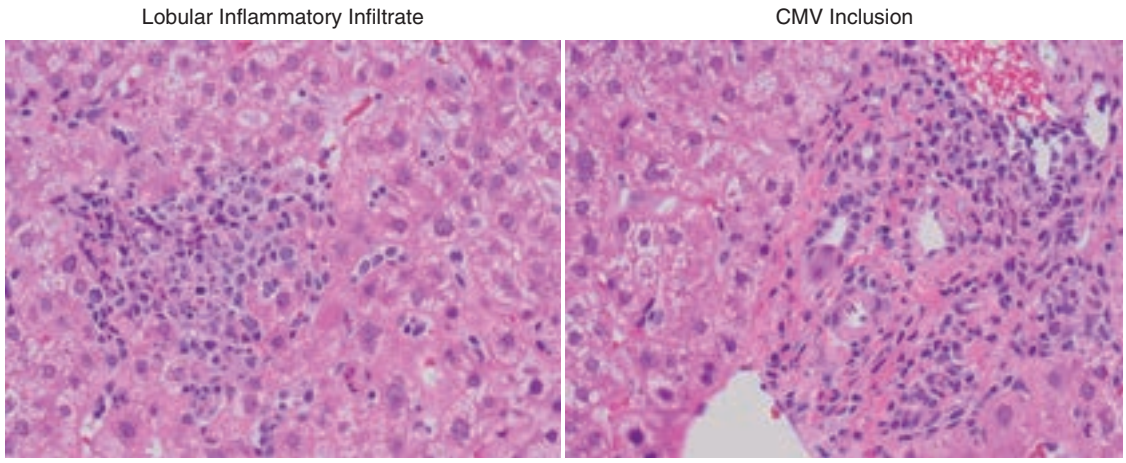
Immunosuppressive Medications

Immunosuppressive medications are managed by experts at the patient's liver transplant center. The primary care provider, however, should be aware of the typical maintenance immunosuppressive drugs, how they are monitored, and some of the common toxicities (Table 154-4). The backbone of most maintenance immunosuppressive regimens is an inhibitor of either calcineurin (cyclosporine and tacrolimus) or mTOR (sirolimus and everolimus). These immunosuppressants are metabolized through the hepatic enzyme CYP3A4, which is a pathway for the metabolism of about 60% of commonly prescribed medications. Coadministration of potent inhibitors of CYP3A4 (e.g., ritonavir, erythromycin, telaprevir, and boceprevir) with cyclosporine, tacrolimus, sirolimus, or everolimus will increase the plasma concentrations of the latter

TABLE 154-4 IMMUNOSUPPRESSIVE MEDICATIONS: MONITORING AND ADVERSE SIDE EFFECTS

TYPE	DOSE	MONITORING	ADVERSE EFFECTS
Cyclosporine[a]	100-200 mg bid	Blood level[b]	Nephrotoxicity[c] Neurotoxicity[d] Hypertension
Tacrolimus[e]	1-2 mg bid	Blood level[b]	Nephrotoxicity Neurotoxicity Diabetes mellitus[f]
Prednisone	5-20 mg qd	Clinical	Hypertension Diabetes mellitus[f] Neurotoxicity Fluid retention
Azathioprine	50-200 mg qd	CBC	Neutropenia Thrombocytopenia Anemia
Mycophenolate[g]	500-1500 mg bid	CBC	Neutropenia Dose-related increase in risk of HSV, CMV[h] Gastrointestinal symptoms
Sirolimus[i]	1-3 mg qd	Blood level	Neutropenia Thrombocytopenia Hyperlipidemia Vascular thrombosis
Everolimus[i]	1-2 mg bid	Blood level	Neutropenia Thrombocytopenia Hyperlipidemia

[a]Several different forms of cyclosporine are available. Additional adverse effects of long-term use of cyclosporine include hirsutism, gingival hyperplasia, and dyslipidemia.
[b]Dosages of cyclosporine and tacrolimus are adjusted primarily from trough plasma levels. There are different methods for measuring cyclosporine and tacrolimus levels. The therapeutic range will differ by the method used and whether whole blood or plasma is assayed.
[c]Nephrotoxicity is related to doses and plasma concentrations of cyclosporine or tacrolimus.
[d]Neurotoxicity includes paresthesias, neuropathy, and seizures. Neurotoxicity may be more common with tacrolimus than with cyclosporine.
[e]Several different forms of tacrolimus are available. Additional adverse effects of long-term use of tacrolimus include hirsutism, gingival hyperplasia, and dyslipidemia.
[f]Diabetes mellitus incidence is reduced by steroid withdrawal. Monotherapy with tacrolimus is more often associated with diabetes than is monotherapy with cyclosporine.
[g]Mycophenolate mofetil and mycophenolic acid are inhibitors of inosine 5′-monophosphate dehydrogenase and used as steroid-sparing or calcineurin inhibitor–sparing agents.
[h]Risk of CMV infection under mycophenolate immunosuppression is dose related, with greatest risk at doses of 3 g/day or more.
[i]Sirolimus and everolimus are inhibitors of mTOR, the mammalian target of rapamycin.
CBC = complete blood count; HSV = herpes simplex virus; CMV = cytomegalovirus.



E-FIGURE 154-1. Liver histology of cytomegalovirus (CMV) hepatitis (hematoxylin and eosin stain). The characteristic lobular inflammatory infiltrate (*left*) and magenta-colored CMV inclusion body in a biliary epithelial cell (*right*) are shown. (Courtesy Kalpana M. Devaraj, MD, MHS, Department of Surgical Pathology, Gastrointestinal, Liver, and Heart Transplant Pathology, University of Colorado, Denver.)

drugs and increase the risk for toxicity. Potent enhancers of CYP3A4 (e.g., rifampin, phenobarbital, St. John's wort, and ketoconazole) will decrease plasma concentrations and increase the risk for rejection.

General Management Issues

The liver recipient requires ongoing monitoring and management to promote overall health and wellness. Special attention must be focused on cardiovascular risk factors (hypertension, diabetes, obesity, dyslipidemia, cigarette smoking), monitoring of renal function, adjustment of immunosuppressant medications, attention to drug-drug interactions, monitoring of bone health with bone densitometry every 2 years, and screening or surveillance for cancer. Patients receiving immunosuppressive medications are at long-term risk for infection, and fever should be carefully evaluated for viral, bacterial, atypical bacterial (e.g., tuberculosis), and fungal infections.

Epstein-Barr virus–associated post-transplantation lymphoproliferative disease is an uncommon but serious complication, with an incidence of 0.9 to 2.9% (Chapters 185 and 377). Fever and lymphadenopathy are the usual presenting findings. Initial treatment is reduction of immunosuppressive drugs, but other therapies including rituximab or chemotherapy may be required (Chapter 185).

REVIEW QUESTIONS

1. A 50-year-old male liver transplant recipient comes to your office with community-acquired pneumonia, for which he had been prescribed erythromycin 7 days ago by an emergency department physician. His maintenance immunosuppression is tacrolimus and mycophenolate mofetil. He is now confused, and his laboratory tests reveal Na 135, K 6.2, HCO_3 15, Cl 108, blood urea nitrogen 45, creatinine 4.1. The results of his complete blood count and the rest of the chemistry profile are normal. A computed tomography scan of the brain is unremarkable. The most likely cause of this patient's clinical presentation is

A. Viral meningitis
B. Urinary tract infection
C. Tacrolimus toxicity
D. Mycophenolate mofetil toxicity
E. Erythromycin toxicity

Answer: C A key to appropriate management of the liver transplant recipient is an understanding of potential drug-drug interactions. Calcineurin and mTOR inhibitors are cornerstones of maintenance immunosuppression in most liver recipients. These drugs are processed by P-glycoprotein and metabolized by CYP3A4, both of which are key drug disposition pathways located in intestinal epithelial cells, hepatocytes, and renal tubular cells. Erythromycin inhibits CYP3A4, thereby blocking the metabolism of tacrolimus and leading to high tacrolimus levels and tacrolimus renal and neurologic toxicity. Physicians must check for any drug-drug interactions before prescribing medications to liver transplant recipients who are taking immunosuppressive medications.

2. A 62-year-old woman who received a liver transplant 5 years ago comes for a routine physical examination. She has a body mass index of 32 kg/m^2, blood pressure (BP) 165/105, total cholesterol 285 mg/dL (low-density lipoprotein 205 mg/dL), triglycerides 305 mg/dL, and fasting blood glucose of 165 mg/dL. Her current immunosuppression regimen is cyclosporine and prednisone. You notify her transplant center, and they switch her immunosuppression to low-dose tacrolimus and mycophenolate mofetil. The expected outcomes of the change in immunosuppression are

A. Weight loss, lower BP, improved lipids, improved insulin sensitivity
B. Weight gain, lower BP, improved lipids, improved insulin sensitivity
C. Weight loss, higher BP, improved lipids, improved insulin sensitivity
D. Weight loss, lower BP, higher lipids, improved insulin sensitivity
E. Weight loss, lower BP, improved lipids, worsened insulin resistance

Answer: A Each immunosuppressive medication has a characteristic pattern of side effects. Most are manageable by dose reduction or changing the immunosuppressive prescription. In this case, both cyclosporine and prednisone contributed to the constellation of obesity, hypertension, dyslipidemia, and glucose intolerance. Mycophenolate mofetil does not have these side effects, and low-dose tacrolimus is less likely than cyclosporine to cause obesity, dyslipidemia, or glucose intolerance.

3. A 47-year-old woman underwent liver transplantation for autoimmune hepatitis 5 years ago. After transplantation, she experienced steroid-refractory rejection, which was treated with antilymphocyte globulin, and cytomegalovirus hepatitis, which was treated with intravenous ganciclovir. She now presents with fever, leukopenia, anemia, and lymphadenopathy. Viral, bacterial, and fungal cultures are negative. Epstein-Barr virus serology indicates past exposure, but Epstein-Barr virus DNA is negative. Lymph node biopsy is likely to demonstrate

A. Mycobacteria
B. Epstein-Barr Virus
C. Cytomegalovirus
D. Fungi
E. CD20-positive lymphocytes

Answer: E Risk factors for post-transplantation lymphoproliferative disease (PTLD) include primary Epstein-Barr virus infection, cytomegalovirus disease, cytomegalovirus donor-recipient mismatch, and augmented immunosuppression, especially antilymphocyte globulin. The association of PTLD and Epstein-Barr virus is variable in adult liver transplant recipients; later onset PTLD is less likely to be associated with Epstein-Barr virus activation or infection. Fever, cytopenias, and lymphadenopathy are the key clinical features. Initial treatment is a reduction in immunosuppression. Monoclonal anti-CD20 antibodies and chemoradiation treatments may be required. Antiviral therapy is ineffective.

DISEASES OF THE GALLBLADDER AND BILE DUCTS

EVAN L. FOGEL AND STUART SHERMAN

GALLBLADDER

Gallstones

EPIDEMIOLOGY

Gallstone disease is one of the most common and costly digestive diseases, with an estimated annual direct cost of $15 billion in the United States. Newly diagnosed gallstone disease occurs in more than one million people annually in the United States, and more than 750,000 cholecystectomies are now performed annually. The prevalence of gallstones is about 10 to 15% in American and European adults, with women affected about twice as often as men. Cholesterol gallstones are uncommon in individuals younger than 20 years, but a sharp increase is noted with each decade up to approximately the age of 70 years, particularly in women. About 20% of women and 10% of men have gallstones by 60 years of age. Together, approximately 12% of Americans or 36 million men and women harbor gallstones.

In the United States, the prevalence of stones is highest in Mexican American women (26%), followed by white women (17%) and African American women (14%). The prevalence of gallstones is extremely high in Native Americans, especially in women. In Chileans and Bolivians of Indian ancestry, gallstones are also common, and gallstone-associated cancer is the most common gastrointestinal cancer in these countries.

Environmental factors and genetic predisposition are likely to play an interactive role for gallstone formation. Pregnancy may contribute to the predominance of cholesterol stones in younger women as it is associated with progesterone-induced impaired gallbladder emptying and estrogen-mediated increased cholesterol saturation of bile. The prevalence of gallbladder stones in nulliparous women is approximately one tenth of that noted in multiparous women (1.3% vs. 13%). Exogenous estrogen administration in the form of hormone replacement therapy and oral contraceptives is also associated with stone formation. Other medications, including somatostatin analogues, ceftriaxone, and clofibrate, have been associated also with an increased incidence of gallbladder stones.

Obesity is a major risk factor for development of cholesterol stones. Obese individuals have an increase in biliary cholesterol secretion relative to bile acid and lecithin secretion, thereby resulting in bile supersaturation. However, rapid weight loss is also associated with an increased risk of gallstones. Diminished ileal absorption of bile acids, due to surgical resection or bypass or to active inflammation (e.g., Crohn disease), may also lead to an increased likelihood of gallstones.

PATHOBIOLOGY

Gallstone Formation

Gallstones represent a failure to maintain certain biliary solutes, primarily cholesterol and calcium salts, in a solubilized state. Gallstones are classified by their cholesterol content as either cholesterol or pigment stones. Pigment stones are further classified as either black or brown. Most cholesterol stones contain calcium salts in their core, and pure cholesterol gallstones are uncommon (10%). In most American populations, 70 to 80% of gallstones are cholesterol, and black pigment stones account for most of the remaining 20 to 30%.

In normal bile, cholesterol is soluble in the form of mixed micelles with optimal concentration of bile salts and phospholipids. With disproportionate concentrations, bile becomes supersaturated, and the excess cholesterol precipitates as monohydrate crystals. These crystals become embedded in gallbladder mucin gel with bilirubinate to form biliary sludge, which may eventually aggregate into a gallbladder stone.

Black pigment stones make up a small proportion of gallstones. These stones consist of polymerized calcium bilirubinate, precipitated as a result of exceeding the solubility of calcium and unconjugated bilirubin. In addition to increasing age, the formation of black pigment stones is more common in individuals who have conditions that create an excessive amount of unconjugated bilirubin (e.g., chronic hemolysis in hemoglobinopathies, cirrhosis, ineffective erythropoiesis), who are being fed by total parenteral nutrition (Chapter 217), or who have ileal diseases. Black pigment stones are typically tarry, are usually not associated with infected bile, and are located almost exclusively in the gallbladder.

By contrast, brown pigment stones are coarse in texture and are primarily formed in the bile duct as a result of bacterial infection that releases β-glucuronidase to hydrolyze glucuronic acid from bilirubin. Phospholipid hydrolysis also increases, thereby leading to precipitation of calcium, bilirubin, and free fatty acids and also resulting in the formation of brown pigment stones. Brown pigment stones account for 30 to 90% of gallstones in Asian populations, may also occur throughout the entire biliary tree, and are frequently associated with pyogenic cholangiohepatitis.

Gallbladder contractility is impaired in some patients with gallstones. Although gallbladder dysfunction can be the consequence of gallstone disease or of excessive cholesterol infiltration into the gallbladder's smooth muscle, evidence suggests that gallbladder stasis itself can lead to gallbladder stone formation. A normal gallbladder ejects 10 to 20% of its contents into the duodenum in response to enteric nervous stimulation. The presence of postprandial intestinal fat further increases gallbladder contractility, which is mediated by the enteric nervous system and cholecystokinin. Gallbladder stasis is frequently evident in patients with risk factors for forming gallstones, including obesity, pregnancy, rapid weight loss, and prolonged fasting (Table 155-1). Furthermore, gallbladder dysmotility is an independent risk factor for recurrent gallstones in patients who have been treated with extracorporeal shock wave lithotripsy.

Acute Calculous Cholecystitis

The most common complication of gallstone disease is acute cholecystitis, which occurs in 15 to 20% of symptomatic patients. Acute cholecystitis results when a stone becomes lodged at the gallbladder–cystic duct junction, where it impairs gallbladder outflow and drainage. The extent of inflammation and the progression of acute cholecystitis are related to the duration and degree of obstruction. In the most severe cases, this process can lead to ischemia and necrosis of the gallbladder wall. More often, the stone spontaneously dislodges, and the inflammation gradually resolves. Acute cholecystitis is primarily an inflammatory rather than an infectious process, but about 50%

TABLE 155-1 RISK FACTORS ASSOCIATED WITH GALLSTONE FORMATION

NONMODIFIABLE FACTORS	MODIFIABLE FACTORS
Increasing age	Pregnancy and parity
Female gender	Obesity
Ethnicity	Low-fiber, high-calorie diet
Genetics, family history	Prolonged fasting
	Medications: clofibrate, estrogens, octreotide
	Low-level physical activity
	Rapid weight loss
	Hypertriglyceridemia, low high-density lipoprotein
	Metabolic syndrome
	Gallbladder stasis
	Terminal ileal disease or resection
	Total parenteral nutrition, fasting state

of patients with acute cholecystitis have secondary bacteriobilia, most commonly with *Escherichia coli*.

CLINICAL MANIFESTATIONS

The clinical spectrum of cholelithiasis ranges from the asymptomatic state to fatal complications. Among patients with asymptomatic gallstones, approximate annual risks are 1% for biliary pain, 0.3% for acute cholecystitis, 0.2% for symptomatic choledocholithiasis, and 0.04 to 1.5% for gallstone pancreatitis. However, these low individual percentages represent a huge population-wide number of symptomatic patients, given the frequency of gallstones. Overall, about 1 to 2% of asymptomatic individuals with gallstones develop serious symptoms or complications each year related to their gallstones.

The majority of gallstones are asymptomatic and are discovered on imaging studies performed for other indications. In such individuals, the gallbladder fills and empties normally, and the gallstones remain in the gallbladder and do not obstruct the cystic duct. Over time, however, asymptomatic gallstones can become symptomatic and be manifested as biliary colic due to impaction of a gallstone at the neck of the gallbladder or cystic duct. Although the pain is commonly termed biliary colic, the majority of patients actually note constant pain due to obstruction of the cystic duct and a progressive increase in gallbladder wall tension, rather than the paroxysmal pain of typical colic. The pain usually is located in the right upper quadrant or epigastrium and frequently radiates to the back and right scapula. Although biliary colic classically occurs after fatty meals, an association with meals is present in only 50% of patients, and the pain often develops more than 1 hour after eating. The duration of pain is typically 1 to 5 hours, but it may persist up to 24 hours. Pain persisting beyond 24 hours suggests that acute inflammation or cholecystitis is present. Episodes of biliary colic are usually less frequent than one episode per week. Other symptoms, such as nausea and vomiting, accompany each episode in 60 to 70% of cases. Bloating and belching are also present in 50% of patients. Fever and jaundice occur much less frequently with simple biliary colic. Although some patients with gallstones have continuous pain, predominantly in the back or the left upper quadrant, rather than episodic pain, alternative causes should be considered in such patients.

Acute Calculous Cholecystitis

Patients with acute cholecystitis typically present with right upper quadrant pain similar to biliary colic. In acute cholecystitis, however, the pain is usually unremitting, may last several days, and is often associated with nausea, emesis, anorexia, and fever. On physical examination, patients usually have a low-grade fever, with localized right upper quadrant tenderness and guarding. The presence of Murphy sign, an inspiratory arrest during deep palpation of the right upper quadrant, is the classic physical finding of acute cholecystitis. A palpable right upper quadrant mass is appreciated in one third of patients and usually represents omentum that has migrated to the area around the gallbladder in response to the inflammation. Mild jaundice (bilirubin level < 6 mg/dL) may be present. Significant jaundice is rare with acute cholecystitis but when present suggests the presence of common bile duct stones, cholangitis, or obstruction of the common hepatic duct by severe pericholecystic inflammation because of the impaction of a large stone in Hartmann pouch, which mechanically obstructs the bile duct. High fever suggests ascending cholangitis, often with bacterial infection (Fig. 155-1). Acute cholecystitis may coexist with choledocholithiasis or its complications of acute cholangitis and gallstone pancreatitis.

FIGURE 155-1. Endoscopic image of pus exiting the biliary orifice in this patient who presented with ascending cholangitis secondary to choledocholithiasis (note several small stones in duodenum).

FIGURE 155-2. Ultrasound showing a gallstone. (From Afdhal N. Diseases of the gallbladder and bile ducts. In: Goldman L, Schafer A, eds. *Goldman's Cecil Medicine.* 24th ed. Philadelphia: Elsevier Saunders; 2012:1017.)

DIAGNOSIS

Transabdominal ultrasound is the radiologic procedure of choice to identify gallstones (Fig. 155-2).[1] Because the ultrasound waves cannot penetrate the stones, acoustic shadowing is seen posterior to the stones, thereby facilitating diagnosis. Free-floating gallbladder stones will also move to a dependent position when the patient is repositioned during scanning. If both of these features are present, the positive predictive value of ultrasound approaches 100%. Nonshadowing echoes alone, however, may be caused by gallbladder polyps. Gallstones may be missed because of a lack of contrasting bile around the stones, as may occur with an impacted cystic duct stone or when the

gallbladder is filled with stones. Small gallstones may not cast an acoustic shadow. An ileus with increased abdominal gas, as can occur with acute cholecystitis or pancreatitis (Chapter 144), may limit visualization of the gallbladder. Overall, the false-negative rate of ultrasound for detection of gallstones is less than 5% but may increase to 15% with acute cholecystitis. Ultrasound may also demonstrate dilation of the intrahepatic and extrahepatic bile ducts. Dilated ducts may signify obstruction due to stones in the common bile duct, distal strictures, or malignant obstruction (Chapters 194 and 196).

Ultrasound has a sensitivity and specificity of 85% and 95%, respectively, for diagnosis of acute cholecystitis. In addition to the presence of gallstones, findings suggestive of acute cholecystitis include thickening of the gallbladder wall (>4 mm) and the presence of pericholecystic fluid. Focal tenderness directly over the gallbladder (sonographic Murphy sign) also is suggestive of acute cholecystitis.

Cholescintigraphy provides a noninvasive, anatomic, and functional evaluation of the liver, gallbladder, bile duct, and duodenum, although it has generally been superseded by ultrasound for this purpose, except in certain situations, such as identification of a suspected bile leak after cholecystectomy or a functional gallbladder disorder (see later). In this procedure, technetium Tc 99m–labeled iminodiacetic acid derivatives are injected intravenously, taken up by the liver, and excreted into the bile. These hepatobiliary iminodiacetic acid (HIDA) scans provide functional information about the liver's ability to excrete radiolabeled substances into a nonobstructed biliary tree. The tracer should be taken up by the liver, gallbladder, common bile duct, and duodenum within 1 hour. Nonvisualization of the gallbladder 1 hour after the injection of the radioisotope with filling of the bile duct and duodenum indicates an obstructed cystic duct and in the acute clinical setting is highly sensitive (95%) and specific (95%) for acute cholecystitis, although false-positive results are often seen in the setting of gallbladder stasis (e.g., critically ill patients, total parenteral nutrition). Slow uptake of the tracer by the liver suggests hepatic parenchymal disease. Filling of the gallbladder and bile duct with delayed or absent filling of the intestine may suggest an obstruction at the level of the major papilla.

Abdominal computed tomography (CT) is less sensitive than ultrasound for diagnosis of gallstones and is primarily indicated for the diagnosis of complications of gallstone disease, such as acute cholecystitis, choledocholithiasis, pancreatitis, and gallbladder cancer. By comparison, *plain abdominal radiographs* are of little value in the evaluation of gallbladder disease because only 15% of gallstones contain sufficient calcium to appear radiopaque. Plain films can be useful, however, for diagnosis of other causes of acute abdominal pain (e.g., perforated viscus, bowel obstruction). Rarely, abdominal films may show a calcified gallbladder wall (Fig. 155-3) in chronic cholecystitis or findings such as pneumobilia or gallstone-associated ileus in acute cholecystitis.

A CT scan also is frequently performed to evaluate an acutely ill patient with abdominal pain. The CT scan can detect gallstones, gallbladder wall thickening, pericholecystic fluid and edema, and air in the gallbladder or gallbladder wall (emphysematous cholecystitis), but it is generally less sensitive than ultrasonography for finding these conditions.

Magnetic resonance imaging is highly sensitive for diagnosis of both gallstones and common duct stones, but stones smaller than 3 mm may be missed. Endoscopic ultrasound provides excellent imaging of the gallbladder and biliary tree but is rarely the primary imaging modality for detection of a gallbladder stone. Endoscopic collection of bile for crystal analysis may serve as a surrogate for microlithiasis not seen on transabdominal ultrasound.

With cholecystitis, laboratory evaluation can show a mild leukocytosis, with a white blood cell count of 12,000 to 15,000 cells/μL. However, many patients have a normal white blood cell count. Leukocytosis greater than 20,000 cells/μL should suggest further complications of cholecystitis, such as gangrene, perforation, or cholangitis. Mild elevations in serum bilirubin, alkaline phosphatase, aminotransferase, and amylase levels may also be seen with acute cholecystitis.

FIGURE 155-3. Plain abdominal radiograph illustrating a porcelain gallbladder. Note the calcified gallbladder wall.

TREATMENT

Silent Gallstones

The longer that stones remain silent, the less likely they are to cause symptoms. Furthermore, almost all patients will develop symptomatic disease before developing one of the serious complications of gallstones. Therefore, prophylactic cholecystectomy is not generally indicated in patients with asymptomatic gallstones.

In select groups of patients, however, prophylactic cholecystectomy should be considered, even when gallbladder stones are absent. A porcelain gallbladder with a calcified gallbladder wall is associated with a 5% or higher risk of malignant transformation, high enough to justify cholecystectomy. Patients with a long common channel between the bile and pancreatic ducts (i.e., anomalous pancreaticobiliary duct junction; see later) also are at significant risk for gallbladder cancer and should undergo prophylactic cholecystectomy. Acute cholecystitis is a potentially life-threatening condition in immunosuppressed patients, so prophylactic cholecystectomy is generally recommended before or at the time of major organ transplantation. Data also support cholecystectomy in patients undergoing bariatric weight loss surgery even in the absence of gallstones because of their nearly 30% risk for developing gallstones and requiring cholecystectomy during rapid weight loss in the first year after surgery. Prophylactic cholecystectomy adds minimal morbidity and mortality risks to most bariatric operations and is clearly indicated in patients with gallstones. Some patients with silent gallbladder stones may also benefit from prophylactic cholecystectomy. In patients with sickle cell disease (Chapter 163), for example, cholecystitis can precipitate a crisis with substantial operative risks. Large gallstones (>3 cm) are more frequently associated with acute cholecystitis and gallbladder carcinoma, so prophylactic cholecystectomy may also be indicated in these patients.

Symptomatic Gallstones

The operative management of gallstones has been the standard of care for more than a century. Early surgery within 24 hours is generally preferred for patients with biliary colic,[■] and day surgery is as safe and effective as an overnight stay.[■] More than 90% of these cholecystectomies are performed laparoscopically, with about 3% of elective procedures converted to an open procedure in the operating room. Contraindications to laparoscopic surgery include significant bleeding and Child's class C cirrhosis (Chapter 153). Some patients with severe chronic obstructive pulmonary disease or heart failure may not tolerate the pneumoperitoneum required for laparoscopic surgery, and the prior upper abdominal surgery may increase the difficulty of or preclude laparoscopic cholecystectomy. Serious complications of laparoscopic cholecystectomy are rare, with a reported incidence of 0.6 to 1.5% for any bile duct leaks and 0.3 to 0.6% for a major bile duct injury. Although these risks are higher than for open surgery, the overall mortality rate (<0.3%) is lower for laparoscopic surgery, and the postoperative recovery is much easier.

Nonsurgical options for the treatment of gallstone disease are rarely used today because of their limited efficacy and the widespread application of laparoscopic cholecystectomy. Oral dissolution therapy (e.g., ursodeoxycholic acid, 15 mg/kg/day) may be considered in symptomatic but not in asymptomatic patients who have cholesterol gallstones in a functioning gallbladder, but it completely dissolves stones in only 40% of patients, and stones recur in up to 50% of patients within 5 years after therapy is stopped. Lifelong therapy, therefore, may be necessary. The direct infusion of organic solvents (methyl *tert*-butyl ether, continuously infused and aspirated manually four to six times

per minute, for an average of 5 hours/day, for 1 to 3 days) into the gallbladder also is efficacious only for cholesterol gallstones, and the recurrence rate is similar to that of oral dissolution therapy. Extracorporeal shock wave lithotripsy can be considered for a single stone of any type (i.e., cholesterol or calcium bilirubinate) 0.5 to 2 cm in diameter, but only a small percentage of symptomatic patients fit these criteria. As a result, this therapy is limited to a very select group of patients.

Acute Calculous Cholecystitis

After medical stabilization of the patient with intravenous fluids as needed, broad-spectrum antibiotics (e.g., piperacillin-tazobactam, 3.375 g every 6 hours; or ceftriaxone, 1 to 2 g once daily, plus metronidazole, 500 mg every 6 hours; or levofloxacin, 500 mg once daily, plus metronidazole), and parenteral analgesics as necessary (see Table 30-5), the treatment of choice for acute cholecystitis is cholecystectomy. When antibiotic therapy is initiated, the duration is tailored to clinical improvement. Laparoscopic cholecystectomy significantly reduces morbidity, length of hospital stay, and time to return to work, favoring patients compared with open surgery. However, the conversion rate to an open procedure is up to 25% compared with about 3% for elective laparoscopic surgery.

Prospective randomized trials have shown that early laparoscopic cholecystectomy (within 3 days of symptom onset) can be accomplished with a morbidity and mortality rate similar to that of delayed cholecystectomy,■ with no differences in the conversion rate to open cholecystectomy. Length of hospital stay, and therefore costs, are significantly reduced in patients undergoing early surgery. Because about 20% of patients fail to stabilize with initial medical therapy and require operation during the initial admission or before the end of the planned cooling-off period, the current recommendation is to proceed with early laparoscopic cholecystectomy for acute cholecystitis unless there are contraindications to it. If the bilirubin level is <4 mg/dL and the patient has no evidence of cholangitis, common duct exploration is probably not required.■

In high-risk patients whose medical conditions preclude cholecystectomy, a percutaneous cholecystostomy can allow prompt gallbladder drainage. If such drainage and appropriate antibiotics do not lead to clear improvement within 24 hours, however, laparotomy is indicated because failure to improve after percutaneous drainage is usually caused by gangrene of the gallbladder or perforation. If cholecystostomy is successful and the acute episode resolves, the patient can electively undergo either cholecystectomy or percutaneous stone extraction and removal of the cholecystostomy tube. Alternatively, an endoscopic retrograde cholangiopancreatography (ERCP)–guided stent can be placed to drain the gallbladder if the cystic duct is patent.

PREVENTION

Moderate physical activity and dietary management (high fiber intake, avoidance of saturated fatty acids) may lower the risk of gallstone disease. Daily administration of cholecystokinin (3.5 μg) in patients receiving prolonged total parenteral nutrition may prevent formation of gallbladder sludge. Oral ursodeoxycholic acid (15 mg/kg/day) has been clearly demonstrated to be beneficial in prevention of gallstone disease during rapid weight loss■ and in patients who need long-term somatostatin therapy. For secondary prevention (i.e., in patients with gallstones already present), there are insufficient data to support the use of any medical therapy.

Complications of Acute Calculous Cholecystitis

Several complications of acute cholecystitis include empyema of the gallbladder, emphysematous cholecystitis, and gangrene leading to gallbladder perforation. Each of these complications can be associated with significant morbidity and mortality and therefore requires prompt surgical intervention. In 1 to 2% of patients with acute cholecystitis, the gallbladder will perforate into an adjacent hollow viscus, thereby creating a cholecystenteric fistula; the duodenum (79%) and the hepatic flexure of the colon (17%) are the most common sites. The episode of acute cholecystitis generally resolves as the gallbladder spontaneously decompresses after the fistula forms. If a large gallstone passes from the gallbladder into the small intestine, a mechanical bowel obstruction, termed gallstone ileus, may result. Gallstone ileus occurs in 10 to 15% of patients with a cholecystenteric fistula. Patients with gallstone ileus present with signs and symptoms of intestinal obstruction—nausea, vomiting, and abdominal pain. Abdominal films will demonstrate small bowel distention and air-fluid levels and may give additional clues to the source of the obstruction (pneumobilia or a calcified gallstone distant from the gallbladder). The initial management of gallstone ileus includes relieving the obstruction. Most frequently, this goal can be achieved by removing the gallstone through an enterotomy, although endoscopic retrieval of the offending stone can be done, depending on where the stone is located.

Acute Acalculous Cholecystitis

Acute acalculous cholecystitis, which accounts for 5 to 10% of all cases of acute cholecystitis, usually occurs in critically ill patients after trauma, burns, long-term parenteral nutrition, and major nonbiliary operations (e.g., abdominal aneurysm repair, cardiopulmonary bypass). The cause of acute acalculous cholecystitis remains unclear, although gallbladder stasis with increased bacterial colonization and ischemia have been implicated.

The symptoms and signs of acute acalculous cholecystitis are similar to those of acute calculous cholecystitis, with right upper quadrant pain and tenderness, fever, and leukocytosis. The disease often has a more fulminant course than acute calculous cholecystitis and more frequently progresses to gangrene, empyema, or perforation. Except for the absence of gallstones, ultrasound and CT findings are similar to those of calculous cholecystitis, including gallbladder wall thickening and pericholecystic fluid. On cholescintigraphy, the gallbladder does not fill; however, the false-positive rate (absent gallbladder filling without acute acalculous cholecystitis) may be as high as 40%.

Emergency cholecystectomy is recommended if the diagnosis is established or even if clinical suspicion is high because the risk of gangrene, perforation, or empyema exceeds 50%. Cholecystectomy rather than cholecystostomy is usually required, but percutaneous cholecystostomy or endoscopic gallbladder stenting is recommended in patients unable to undergo surgery. The mortality rate for acute acalculous cholecystitis can be as high as 40%, mostly because of the concomitant illnesses in patients who develop this disease.

Functional Gallbladder Disorder

Some patients present with typical symptoms of biliary colic but do not have any evidence of gallstones on ultrasound examination. If further investigations such as liver chemistries, amylase and lipase levels, CT scan, and even upper gastrointestinal endoscopy are unremarkable, the diagnosis of a functional gallbladder disorder should be considered.[2] The pathobiology is poorly understood, but one possibility is that the obesity epidemic has increased the population-wide accumulation of fat in the gallbladder wall—cholecystosteatosis—thereby decreasing the gallbladder's ability to empty. Some patients may have intermittent gallbladder outlet obstruction due to cystic duct spasm, poor coordination between the contraction of the gallbladder and the sphincter of Oddi, or dysmotility of the gallbladder. In a cholecystokinin-stimulated ^{99m}Tc-HIDA scan, cholecystokinin is infused intravenously after the gallbladder has filled with the ^{99m}Tc-labeled radionuclide, and a gallbladder ejection fraction is calculated 20 minutes later. An ejection fraction of less than 35% at 20 minutes is considered abnormal, and most of these patients have histopathologic evidence of chronic cholecystitis, although a low gallbladder ejection fraction is not specific for a functional gallbladder disorder (Table 155-2). The efficacy of laparoscopic cholecystectomy is controversial in this setting, but the Society of American Gastrointestinal and Endoscopic Surgeons recommends it. The percentage of patients undergoing cholecystectomy for functional gallbladder disorder in the United States during the past 15 years has increased from less than 5% to more than 20% of patients having the gallbladder removed.

Tumors of the Gallbladder

Benign

Cholesterol polyps are not true neoplasms but rather are cholesterol-filled projections of gallbladder mucosa that protrude into the lumen. These polyps account for approximately 50% of all polypoid gallbladder lesions, are usually

TABLE 155-2 SETTINGS IN WHICH A LOW GALLBLADDER EJECTION FRACTION MAY BE IDENTIFIED

Cirrhosis
Obesity
Celiac disease
Medications (narcotic analgesics, calcium-channel antagonists, oral contraceptive agents, benzodiazepines, histamine H_2-receptor antagonists)

smaller than 1 cm, are typically found incidentally on imaging studies as nonmobile filling defects, are usually asymptomatic unless associated with gallstones, and do not have malignant potential.

Adenomyosis consists of a hypertrophic gallbladder muscle layer with mucosal diverticula called Rokitansky-Aschoff sinuses. This condition may affect the gallbladder locally, particularly in the fundus, where it appears as a hemispheric lesion with a central dimple; segmentally, as an annular stricture; or diffusely, when it involves the entire gallbladder wall. The cause is not entirely clear but may be secondary to a gallbladder motility disorder. Isolated adenomyosis can cause biliary-type symptoms and can progress to gallbladder cancer, so prophylactic cholecystectomy is recommended.

Gallbladder adenomas are benign epithelial tumors with malignant potential. Adenomas usually are manifested as solitary, nonmobile filling defects on ultrasound. Polyps smaller than 0.5 cm, regardless of total polyp number, can be observed with serial imaging studies every 3 to 6 months. Larger polyps, however, may harbor a carcinoma in situ, and cholecystectomy is recommended for polyps larger than 1 cm and for any patients with biliary symptoms.

Malignant

Gallbladder cancer is the most common biliary tract malignant neoplasm and fifth most common gastrointestinal cancer overall, with approximately 7000 new cases diagnosed annually in the United States (2.5 cases/100,000 population). The usual age at onset is the sixth or seventh decade, with a female-to-male ratio of 3:1. Gallbladder cancer is more common in Native Americans, Mexicans, Alaskans, and American Hispanics as well as in residents of Israel, Chile, and northern Japan.

Perhaps because of chronic inflammation, gallbladder cancer is strongly associated with gallstones, which are identified in more than 90% of patients with gallbladder carcinoma. Conversely, only 1% of patients with gallstones develop gallbladder carcinoma. Choledochal cysts are associated with an increased risk of malignant neoplasms throughout the biliary tree, including the gallbladder, perhaps because of increased stasis, chronic inflammation, and infection. In patients with choledochal cysts, excision of extrahepatic cysts is recommended to avoid biliary tract cancer. By comparison, biliary sphincterotomy alone may be adequate for a type III extrahepatic cyst.

About 90% of gallbladder cancers are adenocarcinomas (90% scirrhous, 5% papillary, 5% colloid). The remaining tumors are anaplastic or squamous cell cancers. Gallbladder cancers spread by local extension and direct invasion of adjacent structures, including the common hepatic duct, liver, duodenum, and colon. Lymphatic drainage is to adjacent lymph nodes, and disseminated disease is to the liver and the peritoneal surface.

Most patients (80%) present with abdominal pain of less than 1 month in duration, which may be difficult to distinguish from symptoms of biliary colic or acute cholecystitis. Nausea and vomiting (50%) and weight loss (40%) are often present, and jaundice (30%) is a poor prognostic sign that typically signifies porta hepatis involvement with tumor. Up to 20% of gallbladder cancers are found at cholecystectomy performed for gallstones, whereas incidental cancers are found at 1% of cholecystectomies.

Diagnosis may be difficult preoperatively because laboratory test results may be normal or nonspecific even when advanced disease is manifested by hypoalbuminemia and anemia. There is no reliable tumor marker. Liver test results are abnormal when the tumor or periportal lymphadenopathy is associated with biliary obstruction. Ultrasonography has a sensitivity of 75 to 80% for detection of gallbladder cancer, with findings ranging from a complex luminal mass to gallbladder wall thickening, polypoid mass, or gallstones. CT or magnetic resonance cross-sectional imaging can assess the extent of disease, including regional and distant metastases. Endoscopic ultrasound may aid in determining the extent of local invasion and nodal involvement, but it rarely is necessary in the preoperative evaluation. ERCP is indicated only in patients who have clinical evidence of biliary obstruction and are being considered for stent placement to palliate their jaundice.

PREVENTION AND TREATMENT

Rx

Patients with gallstones larger than 3 cm have a 10-fold increased risk for development of gallbladder cancer, so prophylactic cholecystectomy should be considered even in an asymptomatic patient. A porcelain gallbladder, with diffuse calcification of the gallbladder wall, is an indication for cholecystectomy in the asymptomatic patient because of the increased risk of cancer. Cholecystectomy also is indicated for any gallbladder polyp larger than 1 cm, in patients with choledochal cysts other than type III, in anomalous pancreaticobiliary union, and in adenomyosis of the gallbladder.

The resectability rates for gallbladder cancer range from 15 to 30%. When the tumor does not extend beyond the muscle layer of the gallbladder wall (T_1), simple cholecystectomy alone may be curative, with a 5-year survival rate approaching 100%. Tumors that extend through the gallbladder wall (stage II/III) require a more extensive resection (cholecystectomy, partial hepatectomy, lymph node dissection). Stage II tumors (no invasion beyond the gallbladder serosa) may have up to a 60 to 80% 5-year survival rate, whereas stage III tumors have a 25% 5-year survival rate. Median survival with unresectable (stage IV) disease is only 2 to 3 months. Radiation therapy has not been shown to be effective, whereas chemotherapy regimens in unresectable disease (typically similar to regimens for pancreatic cancer [Chapter 194]) are associated with response rates of approximately 20%. Because of the late presentation of this disease and spread of tumor at diagnosis, the overall 5-year survival is less than 10%.

BILE DUCTS

Bile Duct Stones

PATHOBIOLOGY

Bile duct stones, or choledocholithiasis, can be classified as either primary or secondary. Primary duct stones develop de novo within the bile ducts, whereas secondary stones develop in the gallbladder and subsequently pass into the bile duct. In the Western world, more than 85% of all bile duct stones are secondary. Primary duct stones typically occur in conditions associated with bile stasis (e.g., benign biliary strictures, sclerosing cholangitis, choledochal cysts, periampullary diverticula), which promotes bacterial overgrowth with subsequent bilirubin deconjugation and the breakdown of biliary lipids, thereby resulting in the formation of brown pigment stones.

CLINICAL MANIFESTATIONS

Bile duct stones are discovered incidentally in 5 to 12% of patients during the evaluation of gallbladder stones and suspected cholecystitis. It is difficult to determine whether the existing bile duct stones are asymptomatic in patients who present with biliary pain alone because pain can originate from either the gallbladder stones or bile duct stones. More than 50% of patients with retained bile duct stones experience recurrent symptoms during a follow-up period of 6 months to 13 years, and 25% of cases develop serious complications.

Common clinical symptoms and signs of bile duct stones include epigastric or right upper quadrant pain, fever, and jaundice (referred to as Charcot triad). Pain can be mild or severe, and severe episodes must be differentiated from other potentially life-threatening events. Occasional patients may present with painless jaundice and weight loss mimicking pancreaticobiliary malignant disease (Chapter 194).

DIAGNOSIS

Patients with cholangitis, with or without associated pancreatitis (Chapter 144), typically have elevated serum aminotransferase levels. The serum bilirubin level usually is less than 15 mg/dL with choledocholithiasis because most bile duct stones cause intermittent, incomplete biliary obstruction. In unusual cases, the serum aminotransferase levels can be profoundly elevated (up to 2000 IU/L), mimicking acute viral hepatitis.

Although ultrasound is the most common initial test for patients with suspected gallbladder stones, it has a low sensitivity rate (25 to 60%) for detection of bile duct stones, in part because the bile duct may not be dilated in acute obstruction. CT scan may demonstrate calcified bile duct stones (Fig. 155-4), but its sensitivity for this purpose is generally little better. CT is useful, however, for identifying other potential causes of biliary obstruction (e.g., mass lesion) and local complications, such as a liver abscess (Chapter 151). Magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasound can detect bile duct stones with an accuracy comparable to that of ERCP (Fig. 155-5). Because of potential procedure-related risks, ERCP is now reserved for patients with confirmed or a high suspicion of biliary disease who are likely to require therapeutic intervention.

TREATMENT

Rx

Given the potential serious complications of bile duct stones (i.e., cholangitis, pancreatitis), specific therapy is generally required regardless of symptoms.

About 85 to 90% of bile duct stones can be removed at ERCP by standard balloon dilation and basket extraction after biliary endoscopic sphincterotomy, with a complication rate, including pancreatitis, bleeding, cholangitis, cholecystitis, and perforation, of less than 10%. Endoscopic biliary orifice dilation without sphincterotomy may reduce some acute complications but increases the risk of pancreatitis and may lead to more subsequent procedures.

The 10 to 15% of bile duct stones that cannot be removed by standard ERCP are generally larger than 1.5 cm, impacted, or located above a stricture. Alternative therapies include the use of large-diameter dilation balloons (12 to 18 mm) and fragmentation by mechanical or electrohydraulic lithotripsy. Whenever stones cannot be completely removed endoscopically, biliary stents should be placed to ensure adequate biliary drainage and to prevent recurrent symptoms while awaiting further therapy. Long-term biliary stenting can also be used in patients with severe comorbid medical conditions that preclude surgery or repeated endoscopic interventions.

Ideally, patients with concomitant gallbladder and bile duct stones would be best treated with a single laparoscopic cholecystectomy and bile duct exploration, which is preferable to ERCP followed by cholecystectomy.[■] However, only a minority of surgeons can successfully perform laparoscopic bile duct exploration, so open common bile duct exploration is generally performed if endoscopic and laparoscopic approaches are unsuccessful.

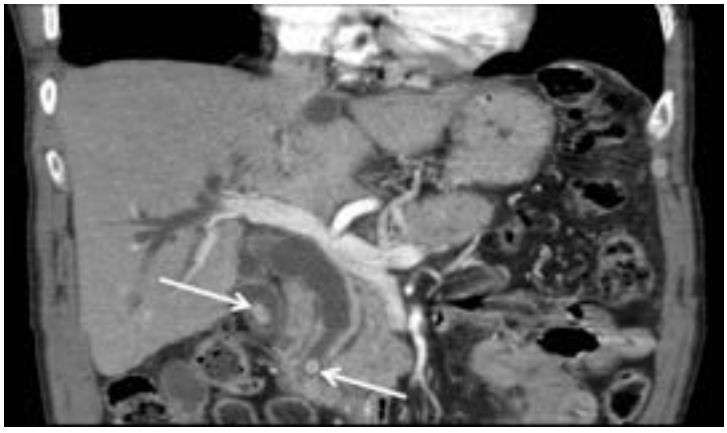

FIGURE 155-4. **Computed tomography scan demonstrating calcified gallstones and a distal bile duct stone.**

Complications of Bile Duct Stones

Cholangitis is a potentially life-threatening disease that results from bacterial infection of obstructed bile. Systemic toxicity occurs when intraductal pressure is sufficiently elevated to cause reflux of bacteria or endotoxin into the blood. About 80 to 90% of acute cholangitis is caused by choledocholithiasis, with the remaining cases caused by a benign biliary stricture (e.g., primary sclerosing cholangitis, chronic pancreatitis, postoperative bile duct injury, or narrowing at an anastomosis) or by malignant biliary obstruction, typically after previous endoscopic instrumentation and stent placement. In certain parts of the world, parasitic biliary obstruction (e.g., *Ascaris*; Chapter 357) may be manifested with cholangitis. The most common bacteria are gram-negative bacilli and *Streptococcus* spp, but *Enterococcus* spp are frequently seen in patients with occluded biliary stents. Prompt antibiotic therapy (e.g., intravenous ceftriaxone, 1 to 2 g once daily; ampicillin-sulbactam, 1.5 to 3 g every 6 hours; piperacillin-tazobactam, 3.375 g every 6 hours; ciprofloxacin, 400 mg twice daily; or levofloxacin, 500 mg orally once daily) is critical and usually can permit conservative management with endoscopic biliary decompression within 24 to 48 hours.[■] However, urgent decompression is indicated if improvement is not seen within a few hours. The advantages of ERCP are that it can delineate the cause of obstruction, obtain bile for culture, and rapidly decompress the biliary tree definitively by removing the stone or temporarily by placing a stent without removing the stone. Routine stenting is not indicated after successful stone removal,[■] unless the adequacy of biliary drainage is uncertain.

Acute gallstone pancreatitis accounts for up to 50% of cases of acute pancreatitis in Western countries (Chapter 144). Most patients quickly respond to conservative therapy, but some develop severe pancreatitis. Although early ERCP with biliary sphincterotomy and stone removal (Fig. 155-6) would appear

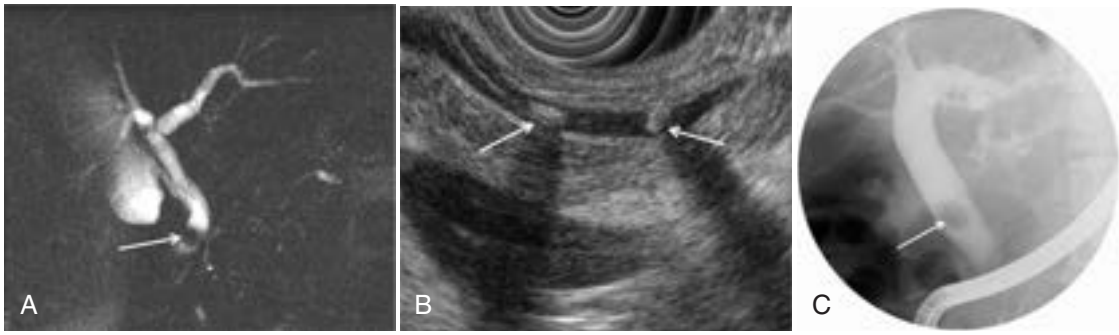

FIGURE 155-5. **Common bile duct stones seen at magnetic resonance cholangiopancreatography (A), endoscopic ultrasound (B), and endoscopic retrograde cholangiopancreatography (C).**

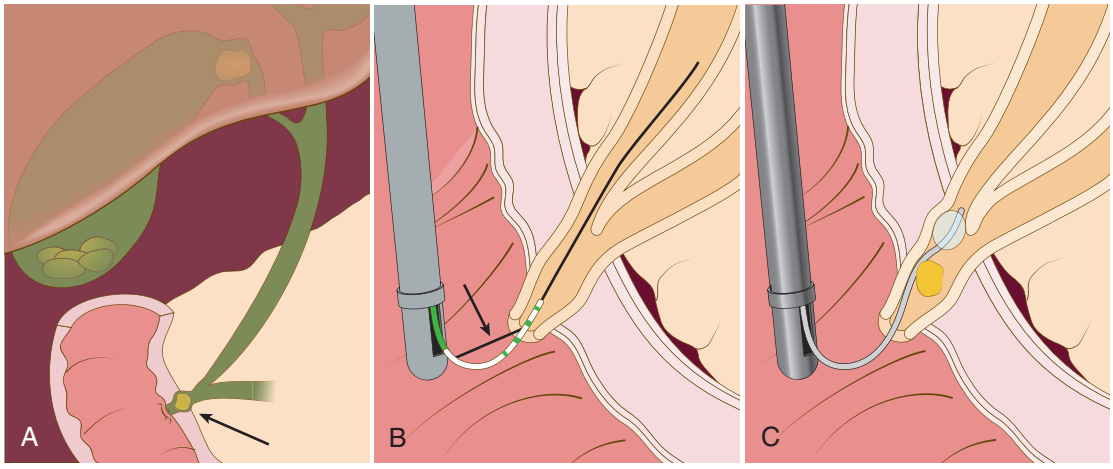

FIGURE 155-6. **A, A stone that is impacted in the distal bile duct is causing biliary pancreatitis, with gallbladder stones also seen. B, Performance of biliary sphincterotomy. C, Subsequent stone removal by balloon sweep.**

to be an attractive therapeutic option, early ERCP does not reduce mortality or complications except in patients with biliary obstruction or cholangitis.[3] After recovery from an episode of biliary pancreatitis, laparoscopic cholecystectomy with intraoperative cholangiography is recommended to prevent further episodes, preferably during the same hospital admission. If a common bile duct stone is found at intraoperative cholangiography, laparoscopic or open common bile duct exploration and stone removal can be accomplished with high success rates in experienced hands, or postoperative ERCP can remove any retained stones.

PREVENTION

Up to 25% of patients may have recurrent bile duct stones, with or without a gallbladder, but it remains uncertain what proportion of these recurrent stones are in fact overlooked residual stones from a prior event. A dilated extrahepatic bile duct (≥13 mm) and periampullary diverticula are risk factors for recurrent stones, perhaps by increasing biliary stasis. Identification and treatment of biliary strictures, papillary stenosis, and gallstones in patients with gallbladder in situ are essential for preventing recurrent stones. Unfortunately, no preventive therapy has been proved effective, although ursodeoxycholic acid (15 mg/kg/day) appears to reduce the risk of gallstones during weight loss.

Benign Biliary Strictures

Postoperative extrahepatic bile duct strictures occur after 0.25 to 1% of cholecystectomies. Most such lesions are manifested as abnormal liver test results, obstructive jaundice, and cholangitis within 2 to 3 months postoperatively, although the presentation can be delayed. The cholangiogram commonly shows a short, smooth narrowing near the cystic duct stump with proximal duct dilation (Fig. 155-7). Strictures typically must be redilated, and stents are exchanged at 3- to 4-month intervals for 8 to 12 months until the stricture is nearly as open as the downstream bile duct. About 80% of patients will have a good result,[4] although some patients will ultimately require a bilioenteric bypass. Strictures more than 2 cm in length, strictures with clips placed securely across the duct, or strictures associated with resected segments of duct require surgical intervention. Biliary strictures complicating liver transplantation (Chapter 154) are usually treated similarly with good results.

Intrapancreatic common bile duct strictures, which may occur in 3 to 46% of patients with chronic pancreatitis, can lead to secondary biliary cirrhosis or recurrent cholangitis. With the complication of cholangitis or jaundice, intervention is clearly indicated, typically with ERCP and stent placement. In the absence of cholangitis or jaundice, either surgical repair or endoscopic biliary decompression with multiple plastic stents (Fig. 155-8) is generally recommended when the alkaline phosphatase level is consistently more than twice the upper limit of normal during a 6-month period of observation.

ORIENTAL CHOLANGIOHEPATITIS

Recurrent cholangitis with hepatolithiasis has a prevalence of more than 10% in parts of East Asia, especially in Taiwan, owing to infection with *Ascaris lumbricoides* (Chapter 357) and *Clonorchis sinensis* (Chapter 356). This condition results in local strictures and dilation of the intrahepatic biliary tree. Biliary stasis and subsequent bacterial infection cause brown stones to form. Most patients have recurrent cholangitis, but cholangiocarcinoma can also

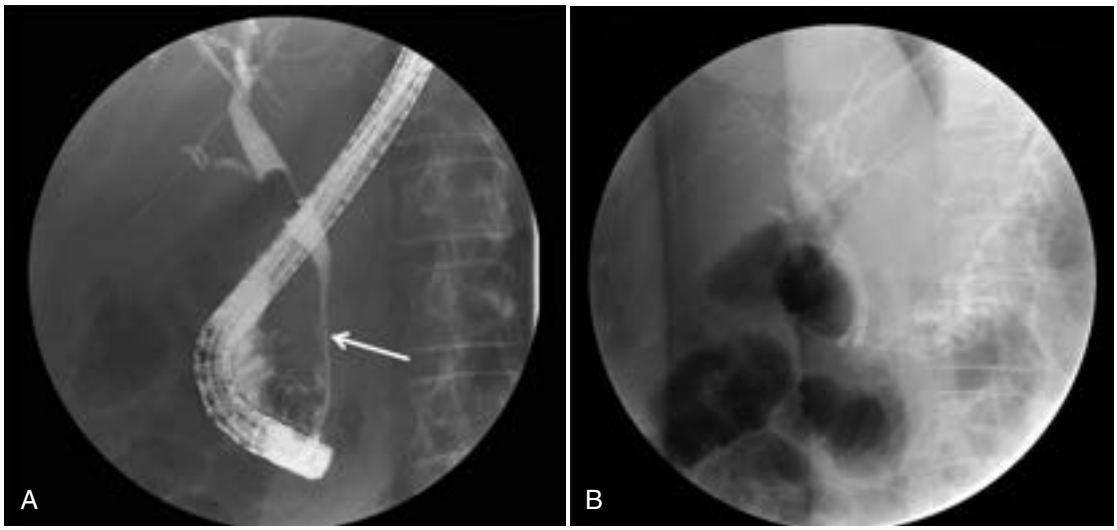

FIGURE 155-8. Endoscopic retrograde cholangiopancreatography images obtained from a patient with a history of alcohol abuse who presented with pruritus and was found to have markedly elevated alkaline phosphatase. A, A smooth distal bile duct stricture is seen *(arrow)*. **B,** Four stents have been placed through the stricture.

ensue. Ultrasound or CT can establish the diagnosis. Treatment includes intravenous fluids and antibiotics. Endoscopic stone removal is usually the preferred treatment, but localized surgical resection targeted to the cultured organisms may be necessary.

PRIMARY SCLEROSING CHOLANGITIS

DEFINITION

Primary sclerosing cholangitis is a chronic cholestatic disease characterized by fibrosing inflammation of segments of the intrahepatic and extrahepatic bile ducts.[5] It results in progressive narrowing of the duct lumen and ultimately may be manifested with recurrent episodes of ascending cholangitis or, alternatively, may progress to secondary biliary cirrhosis and its associated complications. Cholangiocarcinoma (Chapter 196) is a dreaded complication with a reported incidence of 25 to 40% at autopsy or liver transplantation.

EPIDEMIOLOGY

The true prevalence of primary sclerosing cholangitis is unknown, but current estimates are 0.2 to 8.5 per 100,000 in the U.S. population. Its prevalence is much higher in populations in which inflammatory bowel disease (Chapter 141) is more common. Affected men outnumber women in a 2 : 1 ratio, with the mean age at diagnosis of 32 to 40 years. However, primary sclerosing cholangitis has been reported in infants, children, and the elderly.

PATHOBIOLOGY

The cause of primary sclerosing cholangitis and the mechanisms responsible for its progression are unknown.[6] However, autoimmune and genetic causes are supported by its frequent association with inflammatory bowel disease and the increased prevalence of the HLA B8, DR3 haplotype. About two thirds of patients with primary sclerosing cholangitis have ulcerative colitis or Crohn colitis, and it is rarely associated with Crohn disease that is limited to the small bowel. However, only 1 to 13% of patients with colitis are diagnosed with primary sclerosing cholangitis during their lifetime. First-degree relatives of patients with primary sclerosing cholangitis have a 9- to 39-fold increased risk for development of the disease.

On pathologic examination, involved segments of bile ducts in strictured areas show diffuse thickening with a mononuclear inflammatory cell infiltrate. The most characteristic biopsy features are bile duct proliferation, periductal fibrosis, periductal inflammation, and loss of bile ducts. Obliterative cholangitis with a chronic inflammatory cell infiltrate and periductular "onion ring" fibrosis is strongly associated with primary sclerosing cholangitis but is infrequently observed in biopsy specimens. Given the patchy nature of the disease and possible lack of significant intrahepatic involvement, however, the histologic appearance of primary sclerosing cholangitis is variable and may resemble extrahepatic biliary obstruction, chronic active hepatitis, or, rarely, primary biliary cirrhosis.

CLINICAL MANIFESTATIONS

Most patients with primary sclerosing cholangitis are asymptomatic at presentation and are identified after investigation of an elevated alkaline phosphatase level (Chapter 147). Overall, about 90% of patients have an elevated alkaline phosphatase level, with or without mildly elevated serum aminotransferase levels. Fatigue, anorexia, malaise, and weight loss are common but may erroneously be attributed to a patient's inflammatory bowel disease. Patients may exhibit signs or symptoms of cholestatic liver disease, including pruritus, upper abdominal pain, and fever. The serum bilirubin concentration is elevated in only about 40% of patients at presentation. Some patients have anemia, hypoalbuminemia, or hypergammaglobulinemia, and a prolonged international normalized ratio suggests biliary obstruction or synthetic dysfunction. Nearly 90% of patients will have a positive perinuclear antineutrophilic cytoplasmic antibody, but this antibody is also nonspecific and may be found in both ulcerative colitis (Chapter 141) and autoimmune hepatitis (Chapter 149). Antinuclear or anti–smooth muscle antibodies are found in 25% of patients but are not specific, and a positive antimitochondrial antibody suggests primary biliary cirrhosis as the diagnosis.

DIAGNOSIS

Cholangiography is necessary to establish the diagnosis of primary sclerosing cholangitis (Fig. 155-9).[7] MRCP generally is the test of choice,[8] but ERCP may be indicated if MRCP is inconclusive, particularly when the disease is confined to small intrahepatic ducts. The role of biopsy remains uncertain owing to the segmental nature of the disease and the overlap of the histologic features with other disease states. Diffuse multifocal strictures are usually short, with intervening normal or dilated segments that give a beaded appearance. Other frequent findings on cholangiography include pseudodiverticula, mural irregularities, and biliary stones and sludge. Secondary causes of sclerosing cholangitis include obstruction (postoperative, autoimmune cholangiopathy, choledocholithiasis, and recurrent pyogenic cholangitis), ischemic (hepatic artery instillation of the chemotherapeutic agent 5-fluorouracil, radiation, and paroxysmal nocturnal hemoglobinuria), and neoplastic (cholangiocarcinoma, hepatocellular carcinoma, lymphoma, and metastasis).

TREATMENT

Rx

The chronic cholestasis of primary sclerosing cholangitis can be treated with cholestyramine (4 to 8 g/day), ursodeoxycholic acid (15 mg/kg/day), rifampicin (300 to 600 mg/day), or phenobarbital (30 to 120 mg/day) with modest success. Fat-soluble vitamin deficiencies (Chapter 218) must be corrected. The prevalence of osteoporosis (Chapter 243) in primary sclerosing cholangitis is between 4 and 10%, so bone densitometry should be performed at diagnosis and every 2 to 3 years thereafter. Supplementation with oral vitamin D and calcium seems prudent, even in the absence of symptomatic deficiency. Treatment with bisphosphonates (Chapter 243) is reserved for

FIGURE 155-9. Magnetic resonance cholangiopancreatography demonstrating the typical cholangiographic features of primary sclerosing cholangitis. Note the narrowed segment of the common bile duct *(arrow)* as well as the diffuse strictures and dilated segments of several intrahepatic bile ducts, giving the classic "beaded" appearance.

patients with confirmed osteoporosis. Unfortunately, no medical treatment slows disease progression; ursodeoxycholic acid, D-penicillamine, corticosteroids, cyclosporine, methotrexate, and colchicine have all been shown to be ineffective for improving survival or delaying the time to liver transplantation. Whether repeated endoscopic treatment to maintain bile duct patency can improve outcomes is unknown.

Liver transplantation (Chapter 154) is the only potentially curative therapy. The 1-year and 5-year survival rates typically are in the 90% and 80% range, respectively. Primary sclerosing cholangitis may recur in the transplanted organ in 15 to 20% of patients.

PROGNOSIS

The natural history of primary sclerosing cholangitis is variable and incompletely understood. Asymptomatic patients have a much better prognosis than symptomatic patients, with 10-year actuarial survival rates of 80% and 50%, respectively. In symptomatic patients, the median time of survival until death or liver transplantation is 9 years, compared with 12 to 18 years for all patients with primary sclerosing cholangitis, regardless of symptoms. An elevated serum bilirubin level and hepatomegaly appear to correlate with a poor prognosis, whereas cholangiographic appearance, the presence or absence of inflammatory bowel disease, and the patient's age do not. Cholangiocarcinoma (Chapter 196) is a dreaded complication of primary sclerosing cholangitis, and the risk appears to be greatest in patients with long-standing ulcerative colitis and cirrhosis.

Choledochal Cysts and Anomalous Pancreaticobiliary Duct Junction

Choledochal cysts are uncommon anomalies of the biliary tree that are manifested as cystic dilation of the intrahepatic or extrahepatic ducts (or both). The incidence is 1 in 100,000 to 150,000 births in Western populations and 1 in 1000 in Asian populations. There is a 3 : 1 to 4 : 1 female-to-male preponderance. These cysts (E-Fig. 155-1) usually involve only the extrahepatic biliary tree, but they can present as extrapancreatic bile duct diverticula, involve only the intraduodenal part of the common bile duct, or present as multiple intrahepatic and extrahepatic cysts (Table 155-3). An anomalous pancreaticobiliary duct junction (E-Fig. 155-2) is frequently associated with choledochal cysts but may be found in isolation, especially in Asian populations.

TABLE 155-3 CLASSIFICATION OF CHOLEDOCHAL CYSTS

TYPES	DESCRIPTION	PROPORTION OF CHOLEDOCHAL CYSTS
I	Segmental or diffuse fusiform dilation of the bile duct	50-80%
II	Choledochal diverticulum	2%
III	Dilation of the intraduodenal portion of the bile duct	1.4-5%
IVa	Multiple intrahepatic and extrahepatic cysts	15-35%
IVb	Multiple extrahepatic cysts	
V (Caroli disease)	Single or multiple dilations of the intrahepatic ducts	20%

Patients with choledochoceles commonly have biliary colic, cholangitis, jaundice, or unexplained pancreatitis. Bile reflux may also result in acute pancreatitis or predispose to biliary cancers.

Cholangiography, preferably by ERCP, is the diagnostic "gold standard," although MRCP can also delineate the anatomy noninvasively. Because of the increased risk for development of biliary tract cancers, cyst resection (including cholecystectomy) is the generally recommended treatment, although it does not eliminate the risk entirely.[9]

Biliary Fistula

A biliary fistula represents an injury to the bile duct, most commonly seen as a complication of cholecystectomy, common bile duct exploration, or inadvertent operative injury of the bile duct or as a consequence of a local infection. Rarely, biliary fistulas result from long-standing untreated biliary tract disease. With more widespread use of laparoscopic cholecystectomy, the incidence of bile duct injury, including biliary fistula, has increased.

Postoperative bile duct leaks are usually manifested within a week after surgery, with patients presenting with abdominal pain (90%), tenderness (80%), fever (75%), nausea and vomiting (50%), and jaundice (40%). Clinically detectable ascites is rare. Biochemical testing is usually nonspecific, with variable elevations in serum liver test values and the white blood cell count.

Patients with suspected biliary fistulas often undergo abdominal ultrasonography or CT to look for evidence of a biloma as well as a hepatobiliary scan to diagnose the leak. However, ERCP is the most sensitive test to detect a biliary fistula. Treatment options for biliary leaks include percutaneously or endoscopically placed biliary drains or stents and surgical drainage and repair of the leak.

Vanishing Bile Duct Syndromes

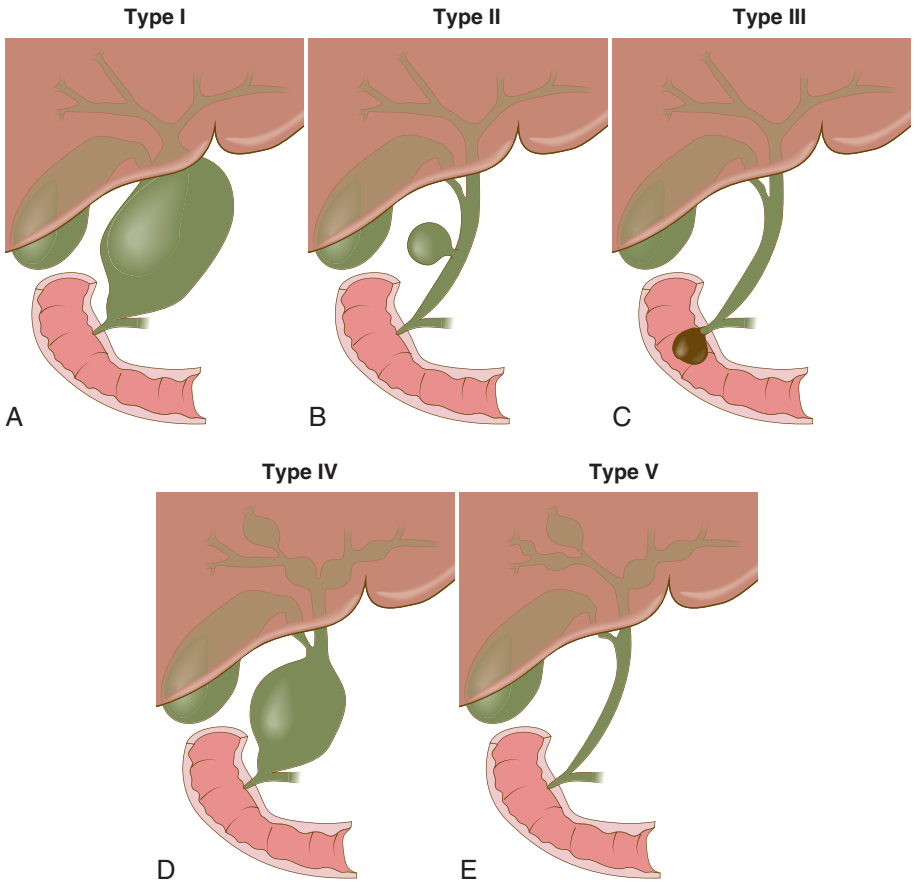
The vanishing bile duct syndrome is characterized by a paucity of intrahepatic bile ducts, an elevated alkaline phosphatase level, and cholestasis. Causes include primary biliary cirrhosis, primary sclerosing cholangitis, autoimmune hepatitis (Chapter 149), graft-versus-host disease, chronic liver transplant rejection (Chapter 154), ischemia, intrahepatic chemotherapy, drug toxicity (e.g., ampicillin, amoxicillin, flucloxacillin, erythromycin, tetracycline, doxycycline, cotrimoxazole), human immunodeficiency virus (HIV) infection (Chapter 390), sarcoidosis (Chapter 95), and histiocytosis. Ursodeoxycholic acid (15 mg/kg) can increase bile flow, but the condition inexorably progresses to biliary cirrhosis, which ultimately requires liver transplantation.

PRIMARY BILIARY CIRRHOSIS

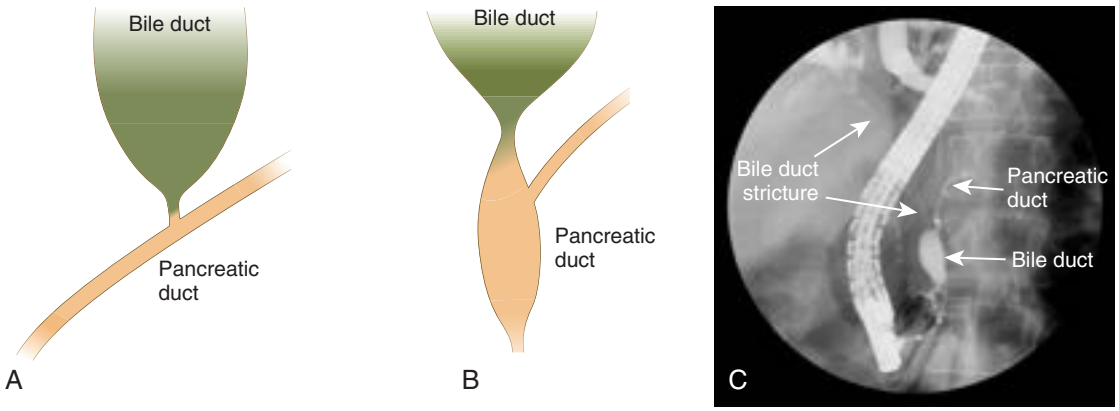
Primary biliary cirrhosis is an obliterative autoimmune cholangiopathy that involves the small and medium-sized bile ducts and that slowly progresses during a decade or so. As the ducts are obliterated, patients develop cholestasis, fibrosis, and, ultimately, liver failure.[10]

EPIDEMIOLOGY

About 95% of patients with primary biliary cirrhosis are women, and the peak age at onset is between 20 and 60 years. The incidence of the disease may be increasing. In the United States, the estimated annual incidence is about 4.5 per 100,000 per year for women and 0.7 for men. Because of the limited life



E-FIGURE 155-1. **Schematic diagram of choledochal cysts.**



E-FIGURE 155-2. **A,** Schematic diagram of anomalous pancreaticobiliary duct junction, with the terminal bile duct draining directly into the pancreatic duct (B-P type). **B,** Schematic diagram of P-B type of anomalous pancreaticobiliary duct junction. **C,** ERCP image illustrating the P-B type of anomalous pancreaticobiliary duct junction, with a bile duct stricture due to gallbladder cancer.

expectancy of affected patients, the age- and gender-adjusted prevalence of primary biliary cirrhosis is about 65 per 100,000 in women and about 12 per 100,000 in men.

PATHOBIOLOGY

Although the mechanism of progressive destruction of the small interlobular ducts is unknown, primary biliary cirrhosis is considered to be an autoimmune disorder. Genome-wide studies show an association with HLA, interleukin-12A, and interleukin-12RB2 variants, suggesting that interleukin-12 signaling might be important. The disease progresses slowly and can eventually lead to biliary cirrhosis, portal hypertension, and liver failure. The classic histologic finding is noncaseating granulomas and paucity of bile ducts in the portal tracts.

CLINICAL MANIFESTATIONS

The most common symptoms are fatigue (50%), which can be debilitating and is unrelated to the degree of underlying liver disease, and pruritus (30%), but about 50% of patients are asymptomatic at the time of diagnosis. Many patients are initially seen by dermatologists for pruritus, which may be first noticed in pregnancy but persists after delivery.

Autoimmune syndromes associated with primary biliary cirrhosis include autoimmune thyroid dysfunction (Chapter 226), Sjögren syndrome (Chapter 268), Raynaud phenomenon (Chapter 267), and celiac disease (Chapter 140). Vitamin D malabsorption can also lead to metabolic bone disease (Chapters 243 and 244).

DIAGNOSIS

The first clue to primary biliary cirrhosis is an elevated serum alkaline phosphatase level, which should be confirmed by an elevated γ-glutamyl transpeptidase level (Chapter 147). The antimitochondrial antibody level has a sensitivity and specificity of more than 95% when the titer is higher than 1 : 40, and it may be positive even before there is any clinical or biochemical evidence of the disease. By comparison, the bilirubin level often is not elevated until later in the course of the disease, with most of the elevation typically due to an elevation in conjugated bilirubin. Total immunoglobulins are generally normal, but IgM levels can be elevated.

An ultrasound examination of the biliary tree is critical to confirm the absence of extrahepatic disease. A liver biopsy is occasionally needed to confirm the diagnosis, particularly in antimitochondrial antibody–negative patients, and to stage the disease.

TREATMENT

Rx

Ursodeoxycholic acid therapy (12 to 15 mg/kg) improves serum bilirubin, alkaline phosphatase, and cholesterol levels and has a variable effect on pruritus. Unfortunately, it does not relieve fatigue, reduce mortality, or delay the need for liver transplantation. Bezafibrate therapy also generally improves liver chemistry test results but not pruritus, liver-related mortality, or overall mortality.

There is no definite benefit from steroids, colchicine, azathioprine, or methotrexate. Bisphosphonates (Chapter 243) are commonly prescribed for the accompanying metabolic bone disease, but their benefit is uncertain. Liver transplantation (Chapter 154) is indicated for refractory disease. The posttransplantation prognosis is excellent, with 2-year and 5-year survival rates of 80% and 70%, respectively. However, studies suggest an 8 to 40% recurrence in the transplanted liver.

PROGNOSIS

Up to two thirds of asymptomatic patients become symptomatic within 2 to 4 years. Significant bridging fibrosis or cirrhosis on biopsy carries a worse prognosis. Prognosis is also influenced by the serum bilirubin and albumin levels, the international normalized ratio, older age, and the presence of peripheral edema. Liver failure develops in about 25% of patients within 10 years after diagnosis, and median survival after diagnosis is 12 to 15 years.

Bile Duct Tumors

BENIGN

Benign bile duct tumors are exceedingly rare compared with malignant tumors and are much less common than benign gallbladder tumors. They can be divided into three histologic types (papillomas, adenomas, cystadenomas), may be solitary or multiple, and often are found incidentally during the evaluation of bile duct dilation or intraductal filling defects. Patients may be asymptomatic or have symptoms of biliary obstruction. Treatment typically consists of surgical bile duct resection with hepaticojejunostomy reconstruction. Even benign tumors tend to recur after excision, and some undergo malignant change.

CHOLANGIOCARCINOMA

Cholangiocarcinoma is discussed in Chapter 196.

Ampullary Tumors

Benign ampullary lesions seen on endoscopic or radiologic studies include heterotopic gastric mucosa, a lipoma, or an impacted common bile duct stone. Primary tumors of the ampulla of Vater can be premalignant or malignant, but the overwhelming majority (>95%) are either adenomas or adenocarcinomas. The prevalence of ampullary adenomas has been estimated to be 0.04 to 0.12% in autopsy series, but the prevalence is higher in patients with hereditary polyposis syndromes (Chapter 193), in which ampullary adenomas occur in up to 80% of individuals and progress to malignancy in 4%.

Malignant ampullary lesions are most commonly adenocarcinomas, although metastatic breast cancer, renal cell cancers, and melanomas also have been identified. Carcinoid tumors (Chapter 232) and other neuroendocrine tumors are rare. Ampullary adenomas probably follow an adenoma to carcinoma sequence similar to colorectal adenocarcinoma (Chapter 193), with a 25 to 85% risk of transformation to carcinoma.

Patients with ampullary lesions may present with biliary colic, obstructive jaundice, pancreatitis, or nonspecific upper abdominal pain, with or without fluctuating serum liver test results, malaise, and anorexia. However, ampullary lesions are often found incidentally on cross-sectional imaging or during upper endoscopy performed for a different indication.[11]

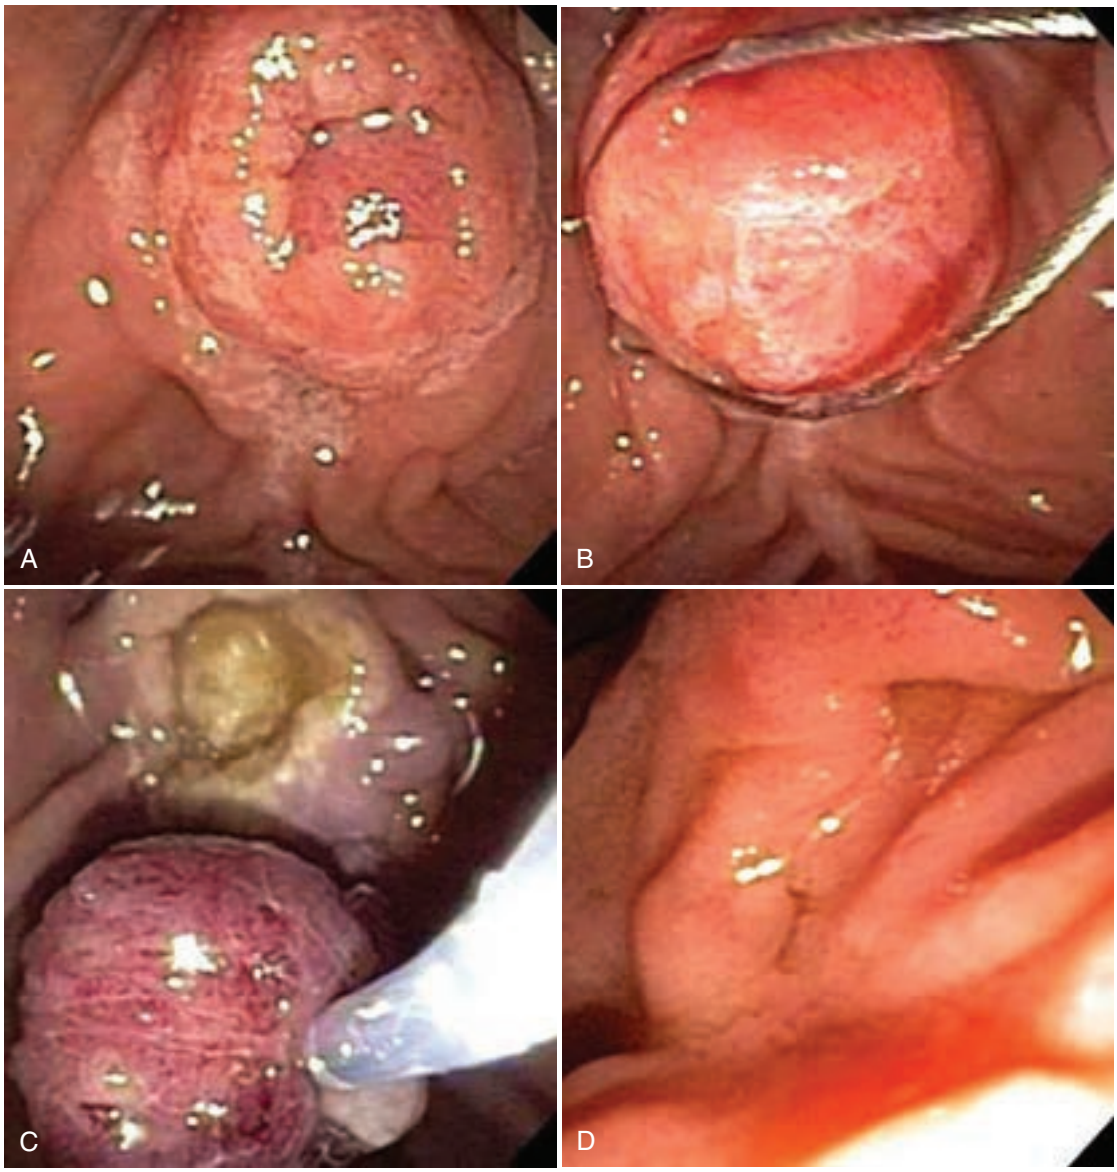
For ampullary adenomas, options include observation with surveillance biopsies and attempts to resect the lesion completely through endoscopy or surgery. Surveillance of an ampullary adenoma in the setting of familial adenomatous polyposis is reasonable if the lesion is small (<1 cm) and asymptomatic, but resection is preferred if advanced histology (e.g., villous features, dysplasia) is identified. Surgical resection has been the standard for ampullary tumors. Treatment modalities include pancreatoduodenectomy, which has a high rate of morbid and even fatal complications, and transduodenal excision, which is associated with high recurrence rates. The 5-year survival rates after pancreaticoduodenectomy range from 64 to 80% for patients with node-negative disease and from 17 to 50% for node-positive disease. Limited data exist regarding adjuvant therapy, the benefits of which are uncertain. A common practice is to treat these patients in a manner similar to patients with resected pancreatic adenocarcinomas (Chapter 194). Patients who present with unresectable disease tend to receive combination gemcitabine (1000 mg/m^2) plus cisplatin (25 mg/m^2) chemotherapy, each administered on days 1 and 8, every 3 weeks for eight cycles. Palliative biliary stenting can be performed in individuals who have a short life expectancy.

In patients with small, localized, and clearly benign ampullary adenomas, endoscopic resection represents an alternative to surgical therapy in appropriately selected patients (E-Fig. 155-3). Whether endoscopic resection is effective for larger or higher risk adenomas is uncertain. Furthermore, recurrence rates after endoscopic papillectomy approach 20%, thereby emphasizing the need for careful follow-up endoscopic surveillance.

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction is a benign, noncalculous obstruction to flow of bile or pancreatic juice through the pancreaticobiliary junction. It may be manifested clinically by pain, pancreatitis (Chapter 144), abnormal liver test results, or abnormal pancreatic enzymes. Post-cholecystectomy pain resembling the patient's preoperative biliary colic occurs in at least 10 to 20% of patients.

Evaluation of patients with suspected sphincter of Oddi dysfunction includes standard serum liver chemistries, serum amylase and lipase levels, and an abdominal ultrasound examination or CT scan. The specimens for serum enzyme studies should be drawn during bouts of pain, if possible. Mild elevations (less than two times the upper limits of normal) are frequent in sphincter of Oddi dysfunction, whereas greater abnormalities are more suggestive of stones, tumors, and parenchymal liver disease. The findings on CT and abdominal ultrasound studies are usually normal, but abnormal liver or pancreatic enyzmes or a dilated bile duct or pancreatic duct may occasionally be found. ERCP and sphincter of Oddi manometry may be considered in patients who have objective evidence of pancreatic or biliary disease



E-FIGURE 155-3. A 58-year-old man was found to have a prominent major papilla during upper endoscopy performed for evaluation of dysphagia. Duodenoscopy confirmed these findings (**A**), and biopsies revealed this to be a tubulovillous adenoma. This was grasped with a polypectomy snare (**B**), removed in one piece by electrocautery, and retrieved for pathologic analysis (**C**). A temporary pancreatic duct stent was placed (not shown), and rectal indomethacin was given to minimize the risk of postprocedure pancreatitis. No residual adenoma was seen on surveillance endoscopy 1 year later (**D**).

(abnormal liver or pancreatic enzymes or a dilated bile or pancreatic duct) or clinically significant or disabling symptoms and in whom definitive sphincter ablation is planned if abnormal sphincter function is found. In patients without objective evidence of pancreatic or biliary disease, ERCP and manometry are no longer recommended.

Medical therapy with nonspecific antispasmodics (e.g., dicyclomine, 10 to 20 mg every 6 hours; hyoscyamine, 0.375 mg every 12 hours) or smooth muscle relaxants (e.g., nifedipine, 60 mg daily) for a 1-month trial should be considered in patients with pancreaticobiliary-type pain (with or without abnormal liver enzyme, amylase, or lipase levels) or a dilated bile or pancreatic duct. If patients do not respond satisfactorily, ERCP and endoscopic sphincterotomy can improve pain in 55 to 95% of patients with abnormal findings on laboratory testing or abdominal imaging. Alternatively, only about 25% of patients without objective evidence of pancreatic or biliary disease improve after sphincterotomy.

REVIEW QUESTIONS

1. A 55-year-old woman is found to have several large calcifications in the right upper quadrant on plain radiographs of her spine, performed as part of her routine chiropractic examination. She denies abdominal pain and has normal serum liver test results. She has diabetes mellitus but no other significant comorbidities. Subsequent abdominal ultrasound reveals a 3.8-cm gallbladder stone, three smaller stones each less than 10 mm in diameter, a normal gallbladder wall, and a nondilated bile duct. The *most appropriate* next step in the management of this patient is

A. Magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/MRCP) for further evaluation of her biliary tree
B. Oral dissolution therapy with ursodeoxycholic acid
C. Surgical consultation for elective laparoscopic cholecystectomy
D. Extracorporeal shock wave lithotripsy
E. Continue a conservative watch-and-wait approach, with surveillance ultrasound in 12 months

Answer: C As discussed for asymptomatic gallstones, gallbladder stones larger than 3 cm are associated with an increased incidence of acute cholecystitis, and there is a 10-fold increased risk of gallbladder cancer. Prophylactic cholecystectomy is recommended in this scenario. MRI/MRCP may be considered, but it is unlikely to add additional information in this patient because significant bile duct disease is less likely in the setting of a nondilated bile duct on ultrasound, with normal liver test results. The nonoperative methods listed (ursodeoxycholic acid, extracorporeal shock wave lithotripsy) are not options in patients with gallbladder stones of this size. A conservative watch-and-wait approach may be advocated by some in this asymptomatic patient, but given the increased cancer risk and her lack of significant comorbidities, surgery is the better option here. Furthermore, there is no evidence to support surveillance ultrasound in 12 months.

2. A 44-year-old woman with a history of recurrent urinary tract infections undergoes abdominal/renal ultrasound for further evaluation. She previously underwent laparoscopic cholecystectomy for gallbladder stones 20 years ago. Ultrasound reveals normal kidneys without hydronephrosis, but an incidental single 8-mm shadow suggesting a common bile duct stone is seen. The bile duct is 11 mm in diameter. She denies upper abdominal pain but has noted nausea and dark urine recently, which she has attributed to a recurrent urinary tract infection. She also notes diffuse pruritus. Her serum liver test results are as follows: aspartate transaminase 78 IU/L (normal, <40 IU/L), alanine transaminase 95 IU/L (<45 IU/L), alkaline phosphatase 235 IU/L (<125 IU/L), bilirubin 3.2 mg/dL (<1.0 mg/dL). Which of the following statements is the *most correct*?

A. Magnetic resonance cholangiopancreatography (MRCP) should be performed to confirm the finding of a bile duct stone, given the poor specificity of transabdominal ultrasound for detection of choledocholithiasis.
B. The bile duct stone is most likely to be a cholesterol stone.
C. In the absence of abdominal pain, a watch-and-wait approach is justified in this scenario.
D. Proceed directly to endoscopic retrograde cholangiopancreatography (ERCP) for attempted bile duct stone removal.
E. Perform a surgical exploration.

Answer: D Although transabdominal ultrasound has a low sensitivity for detection of common bile duct stones, its specificity is more than 90% in most series. MRCP is unnecessary in this case because the patient also has elevated liver test values and biliary dilation. Choledocholithiasis occurring 20 years after cholecystectomy probably represents a primary bile duct stone, which is likely to be a brown pigment stone rather than a cholesterol stone. Given the potential for severe, even life-threatening complications of bile duct stones (cholangitis, pancreatitis), a watch-and-wait approach is not recommended. Proceeding with ERCP and stone removal is the most appropriate next step in this scenario.

3. Regarding primary sclerosing cholangitis (PSC), which of the following statements is *true*?

A. Women outnumber men in a 2 : 1 ratio.
B. A liver biopsy demonstrating characteristic findings is necessary to establish the diagnosis of PSC in all affected patients.
C. Ursodeoxycholic acid is the only medical therapy that has been shown to slow the progression of PSC.
D. The risk for development of cholangiocarcinoma increases with the duration of the disease.
E. Current guidelines suggest that bone densitometry be performed in all PSC patients at diagnosis and every 2 to 3 years thereafter.

Answer: E Affected PSC patients are at risk for hepatic osteodystrophy, a metabolic bone disease that may be seen in chronic liver disease. The American Association for the Study of Liver Diseases (AASLD) has suggested that bone densitometry be performed to screen for this disorder. PSC is seen more commonly in men than in women in a 2 : 1 ratio. Cholangiography is necessary to establish the diagnosis of PSC because liver biopsy findings are nonspecific. Only in patients with "small-duct PSC," in which cholangiography is normal, may the liver biopsy suggest the diagnosis in association with other associated features (e.g., presence of inflammatory bowel disease, elevated alkaline phosphatase). No medical therapy has been shown to slow the progression of PSC, and recent AASLD guidelines do not support the routine use of ursodeoxycholic acid in these patients. Interestingly, there is an inverse relationship between incidence of cholangiocarcinoma and duration of PSC; PSC patients who have had the disease for a shorter time appear to be at increased risk for the development of this complication.

4. A 35-year-old woman presents to you for evaluation of a 6-month history of episodic, postprandial right upper quadrant pain. Her pain is identical to pain that previously responded to cholecystectomy 4 years ago for a functional gallbladder disorder. No gallbladder stones were identified at surgery. Aspartate transaminase and alanine transaminase were both found to be two to three times elevated during two recent emergency department visits but are normal on days when she is pain free. Alkaline phosphatase, bilirubin, amylase, and lipase levels are repeatedly normal. You obtain MRI/MRCP, which reveals a normal pancreas and biliary tree without intraductal filling defects or duct dilation. Findings on upper endoscopy and endoscopic ultrasound are normal. She continues to work full-time, without days missed from work, need for hospitalization, or use of narcotics. Which of the following statements is *correct*?

A. A common bile duct stone is the most likely diagnosis.
B. A liver biopsy is recommended as the next investigation.
C. She may have type III sphincter of Oddi dysfunction.
D. A trial of nifedipine or other antispasmodic is suggested before proceeding with ERCP.
E. This patient is at low-risk for the development of post-ERCP pancreatitis.

Answer: D Bile duct stones can occur after cholecystectomy but are rarely found in a patient who did not have gallbladder stones at cholecystectomy, especially in the absence of factors that increase the likelihood of bile stasis (see Bile Duct Stones, Pathobiology). Furthermore, normal findings on MRCP and endoscopic ultrasound make this diagnosis much less likely. Given the elevated liver test values associated with abdominal pain, but not during normal pain-free intervals, a biliary etiology is more likely than hepatocellular disease. Liver biopsy, therefore, is less likely to be helpful in the diagnostic evaluation of this patient. Biliary-type pain associated with elevated liver test values during attacks of pain and a nondilated bile duct on abdominal imaging defines type II sphincter of Oddi dysfunction. Medical trials with nonspecific antispasmodics or smooth muscle relaxants (e.g., calcium-channel blockers) should be considered in less severely symptomatic patients before proceeding with ERCP and sphincter of Oddi manometry as patients with suspected sphincter of Oddi dysfunction are at high risk for post-ERCP pancreatitis.

5. A 44-year-old woman with a remote history of alcohol abuse is brought to her local emergency department for evaluation after her family noted that her eyes and skin were yellow. She has been abstinent from alcohol for 15 years. She notes mild pruritus but is otherwise asymptomatic and has lost no weight. She previously had complained of episodic abdominal pain and was found to have a decreased gallbladder ejection fraction, leading to laparoscopic cholecystectomy 6 months earlier. Ultrasound did not reveal gallbladder stones. Her pain completely resolved postoperatively. Laboratory tests in the emergency department reveal a normal complete blood count, serum bilirubin 6.0 mg/dL (normal, <1 mg/dL), alkaline phosphatase 722 IU/L (<125 IU/L), aspartate transaminase 93 IU/L (<45 IU/L), alanine transaminase101 IU/L (<40 IU/L), amylase 64 IU/L (<125 IU/L), and CA19-9 367 U/mL (<37 U/mL). A computed tomography scan with intravenous administration of contrast material reveals dilated intrahepatic bile ducts proximal to the mid–hepatic duct, adjacent to the cholecystectomy clips, as well as a normal distal bile duct and pancreas, without stones or mass identified. Her pancreatic duct is normal. Which of the following statements is *true*?

A. Choledocholithiasis is the most likely diagnosis.
B. The elevated CA19-9 suggests that the most likely diagnosis is cholangiocarcinoma.
C. MRI/MRCP would be expected to identify a type I choledochal cyst in this scenario.
D. The presentation 6 months after cholecystectomy is consistent with a postoperative bile duct injury.
E. Your most likely diagnosis is a benign biliary stricture from chronic pancreatitis.

Answer: D Bile duct injuries after laparoscopic cholecystectomy may be manifested in the immediate postoperative period (e.g., bile duct transection or when a surgical clip is placed over the common bile duct) or delayed, when thermal or ischemic injury may result in a biliary stricture. Ischemic injuries most commonly occur within a few months of surgery but may be manifested longer than 1 year postoperatively. Although primary bile duct stones may occur after cholecystectomy, they are very unlikely when gallbladder stones are not identified before surgery, as in this case. An elevated CA19-9 may be seen in any tumor that causes biliary obstruction (not specific to cholangiocarcinoma) as well as in benign obstructing lesions (bile duct stones, primary sclerosing cholangitis). The computed tomography findings of biliary dilation adjacent to the surgical clips and a nondilated distal bile duct suggest an obstructing lesion in the proximal bile duct (e.g., stricture, stone), not a type I choledochal cyst. A patient with a history of alcohol abuse might present with cholestatic liver test results and painless jaundice from a biliary stricture secondary to chronic pancreatitis, but such a complication would be less likely in a patient who has been abstinent for 15 years. Furthermore, cross-sectional imaging or cholangiography would be expected to reveal a distal biliary stricture within the head of the pancreas or perhaps with a dilated bile duct proximally, not the imaging findings described in this case.

156 HEMATOPOIESIS AND HEMATOPOIETIC GROWTH FACTORS

KENNETH KAUSHANSKY

Hematopoiesis is the process by which bone marrow stem cells develop into all of the cell types present in the blood (erythrocytes, neutrophils, eosinophils, basophils, monocytes, platelets, T lymphocytes, B lymphocytes, natural killer cells) (Fig. 156-1). The regulation of the numbers of each cell type is carefully controlled by paracrine and endocrine hematopoietic growth factors, which exert antiapoptotic, proliferative, and differentiative effects on hematopoietic stem, progenitor, and maturing blood cells. Many of these glycoproteins are produced by recombinant DNA technology and have been among the most successful therapeutics in modern medicine.

HEMATOPOIETIC STEM AND PROGENITOR CELLS

Hematopoietic stem cells comprise one in 10^5 to 10^6 marrow cells and are not morphologically distinguishable from other progenitors or small lymphocytes but can be purified to homogeneity using physical characteristics and combinations of monoclonal antibodies (including $CD34^+$) to cell surface proteins.[1] The two critical characteristics of a hematopoietic stem cell are its ability to differentiate into all blood cell types and to self-renew. The decision to self-renew or differentiate is a stochastic process, at the stem cell stage and at the subsequent multipotent or unipotent stages of differentiation, that can be influenced by a number of cell extrinsic (growth factors and stromal proteins) and cell intrinsic (transcription factors) molecules. Hematopoietic stems cells reside in specialized microenvironments (niches) within the bone marrow. The complex and diverse stromal cell populations that comprise the stem cell niche provide signals that support critical stem cell properties such as maintenance, self-renewal capacity, and long-term multilineage repopulation ability.[2]

HEMATOPOIETIC CELL EXPANSION: HEMATOPOIETIC GROWTH FACTORS

A large number of transcription factors regulate stem cell number and differentiation state. Several molecular switches have been identified that determine hematopoietic cell fate.

Equally important to hematopoiesis is a group of hematopoietic growth factors that share structural homology and bind to nonredundant type I transmembrane proteins belonging to the cytokine receptor family. Many of these proteins are the physiological regulators of a specific lineage of blood cells (e.g., erythropoietin, granulocyte colony-stimulating factor, thrombopoietin); others appear to represent redundant hematopoietic growth-promoting activities of molecules essential for other biologic functions (e.g., interleukin-3 [IL-3], interleukin-11 [IL-11], granulocyte-macrophage colony-stimulating factor).

Erythropoietin is produced predominantly by the kidneys and to a lesser extent in the liver and acts on marrow erythroid progenitors to enhance their survival, proliferation, and differentiation. Levels of erythropoietin are inversely related to hemoglobin concentrations in the blood, as reflected in renal oxygen tension. In the presence of tissue (renal) hypoxia, the transcription factor hypoxia-induced factor (HIF) 1α is stabilized against proteasome-mediated destruction and drives erythropoietin transcription by binding to a critical hypoxia responsive element located in the 3′ untranslated region of the gene. Genetic elimination of erythropoietin or its receptor results in embryonic lethality, establishing that although other cytokines can influence erythropoiesis, red blood cell production is absolutely dependent on the hormone.

Granulocyte colony-stimulating factor stimulates the production of neutrophils from their marrow progenitors (Fig. 156-2). Levels of the hormone are also inversely related to neutrophil numbers but are regulated primarily by inflammatory stimuli, including tumor necrosis factor-α (TNF-α) and IL-1α acting on endothelial cells, fibroblasts, and macrophages. Similar to the action of erythropoietin on erythroid progenitors, granulocyte colony-stimulating factor acts to enhance the survival, proliferation, and differentiation of neutrophil progenitors. In addition, the cytokine acts to functionally activate the mature cells it helps to produce. Genetic elimination of granulocyte colony-stimulating factor or its receptor in mice reduces neutrophil levels to 25% of normal, the only hormone known to exert this great an impact on granulopoiesis.

Thrombopoietin, the primary regulator of platelet production, is produced in the liver and kidney and by marrow stromal cells and is regulated by both platelet receptor–mediated uptake and destruction and by transcriptional feedback inhibition of the thrombopoietin gene in marrow stromal cells by platelet granule proteins.[3] The plasma levels of free thrombopoietin are normally inversely related to bone marrow megakaryocyte (MK) and platelet mass. In a hypoproliferative thrombocytopenia, therefore, the resultant increase in plasma free thrombopoietin that is not bound to its MK and platelet receptors will drive a compensatory increase in thrombopoiesis. Similar to granulocyte colony-stimulating factor, thrombopoietin stimulates the survival, proliferation, and differentiation of its corresponding lineage, MKs and their precursors, and primes mature platelets to respond to platelet activation agonists. Genetic elimination of thrombopoietin or its receptor in mice or congenital nonsense or missense mutations in the gene for the thrombopoietin receptor in humans result in platelet levels approximately 10% of normal. Elimination of the thrombopoietin receptor in children leads to aplastic anemia by 1 to 2 years of age.

Other cytokine–receptor systems related to erythropoietin, granulocyte colony-stimulating factor, and thrombopoietin essential for one or more aspects of hematopoiesis include IL-7, critical for all types of lymphocyte production; IL-5, the primary regulator of eosinophil production; IL-4, responsible for immunoglobulin class switching in B lymphocytes; IL-15, essential for normal natural killer cell differentiation; and IL-2, a lymphocyte activation cytokine. They display modest effects on blood cell growth, but their genetic elimination fails to affect basal or stimulated production of those cells.

A second class of cytokines and receptors that influences hematopoiesis is exemplified by the c-kit receptor, a member of the receptor tyrosine kinase family of surface proteins, and its cognate ligand, stem cell factor (also termed steel factor or kit-ligand). Although the c-kit receptor is structurally distinct from members of the hematopoietic cytokine receptor family, possessing an intrinsic tyrosine kinase motif in its cytoplasmic domain, stem cell factor is structurally related to the cytokines that bind to members of the hematopoietic growth factor family. Genetic deletion of stem cell factor or the c-kit receptor results in the near complete elimination of hematopoietic stem cells, erythroid precursors and basophils, and mast cells. Two other hematopoietic members of this family of cytokines and receptors are Flt3 ligand and its receptor Flt-3 and monocyte colony-stimulating factor and its receptor, c-Fms. Similar to stem cell factor, both Flt3 ligand and monocyte colony-stimulating factor play nonredundant roles in hematopoiesis, inducing the formation of dendritic cells and monocytes, respectively.

The molecular mechanisms by which the hematopoietic growth factors affect blood cell survival, proliferation, and differentiation are becoming increasingly well understood. Binding of cognate ligand to each of the hematopoietic cytokine receptors results in activation of one or more tyrosine kinases, either tethered cytoplasmic kinases of the Janus (JAK) family for the hematopoietic cytokine receptor family or the intrinsic kinase of the cytokines that use the receptor tyrosine kinase class of receptors (stem cell factor, Flt3 ligand, and monocyte colony-stimulating factor). After activation, these kinases phosphorylate tyrosine residues within the cytoplasmic domains of each receptor, providing docking sites for cytoplasmic signaling intermediates possessing Src homology (SH)2 domains. Among the best characterized SH2 domain containing proteins that bind to hematopoietic receptors are nascent transcription factors, such as the signal transducers and activators of transcription (STAT) proteins; adapter proteins, including Grb2, Gab1, tensin2, and SHC; phosphatases, for example, SHP1 and SHP2; and the regulatory subunit (p85) of phosphoinositol-3-kinase (PI3K). When bound to one or more of the newly induced phosphotyrosine residues of the cytokine receptor or receptor tyrosine kinase, these secondary molecules are phosphorylated, either by JAK or other kinases, making them competent to bind additional molecules (e.g., the adapters that ultimately activate Ras, and p85 PI3K that binds its kinase [p110] subunit) or are activated as transcription factors (e.g., STATs). The downstream effector molecules then activated include a number kinases, transporter molecules, and transcription factors, ultimately leading to hematopoietic cell survival, proliferation, and differentiation.

CLINICAL USES OF HEMATOPOIETIC CELLS AND GROWTH FACTORS

The clinical development of erythropoietin, granulocyte colony-stimulating factor, and thrombopoietin mimetics represent some of the very best

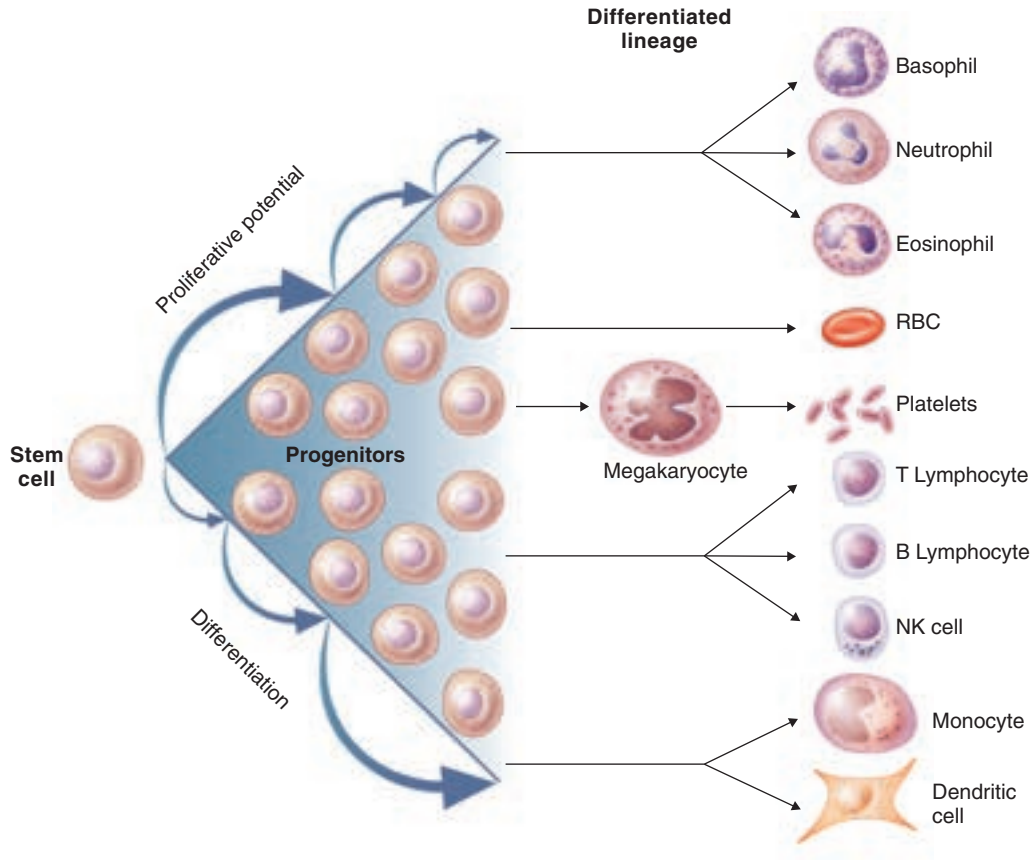

FIGURE 156-1. Hierarchical model of lymphohematopoiesis. NK = natural killer; RBC = red blood cell.

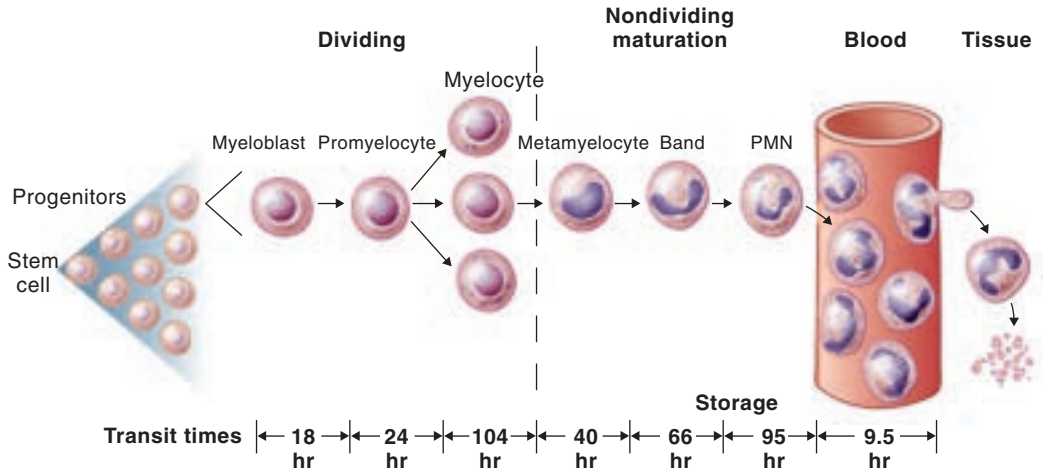

FIGURE 156-2. Neutrophil production system. PMN = polymorphonuclear leukocyte.

examples of harnessing recombinant DNA technology for therapeutic benefit. Patients with renal failure, widespread inflammation, or bone marrow replacement and those undergoing chemotherapy for cancer all experience variable degrees of anemia that are often very debilitating. Administration of erythropoietic stimulating agents almost invariably results in a rapid reticulocyte response and correction of the anemia. Most patients undergo an enhanced sense of well being as the blood hemoglobin concentration rises to 10 g/dL. Clinical trials have demonstrated the efficacy of these agents in patients with renal failure and with cancer, although recent analyses call into question the safety of these agents in some settings.[■■] For example, patients receiving higher levels of the drug for anemia secondary to kidney failure progressed to requiring dialysis more frequently and experienced increased cardiovascular events, such as myocardial infarction and stroke, than patients on low levels of the hormone sufficient to maintain their blood Hgb at 10 g/dL or lower.[■] And patients receiving erythropoietin for cancer also experienced increased relapses of their tumors than individuals not receiving the hormone. The only patients who regularly demonstrate a poor response are individuals with severe inflammation (Chapter 158). Overall, erythropoietic stimulating agents are safe and effective drugs for patients with anemia caused by a wide range of conditions, but their use and dose must be carefully considered.

Many patients undergoing cytotoxic therapy for cancer experience severe neutropenia and are thus at substantial risk for life-threatening infection. Clinical trials of recombinant granulocyte colony-stimulating factor in patients undergoing aggressive chemotherapy for leukemia and solid tumors resulted in the Food and Drug Administration (FDA) approval of the drug for use in patients undergoing chemotherapy of intensity sufficient to produce severe neutropenia (Chapter 167). The use of the drug is associated with the more rapid return of neutrophils to safe levels if administered soon after the inciting chemotherapy is completed but not at the nadir of neutrophil production and results in lower risk of severe infections. However, the use of granulocyte colony-stimulating factor has not enhanced survival in patients

with any tumor type. And similar to the use of erythropoietin in patients with cancer, the administration of granulocyte colony-stimulating factor to some patients receiving cytotoxic chemotherapy for cancer, (e.g., breast cancer) has been associated with a statistically significant increase in cancer recurrence, although this finding is controversial.

Thrombopoietin was cloned and characterized in 1994 and was quickly advanced to clinical trials following the model of granulocyte colony-stimulating factor use in patients undergoing cancer chemotherapy. Initial results with the intact hormone and a truncated version that included only the receptor-binding domain were mixed, and use of the truncated form of the drug, administration to healthy volunteer donors to improve platelet apheresis yields, resulted in a significant number of subjects developing anti-drug antibodies that cross-reacted with their native thrombopoietin, resulting in severe thrombocytopenia. This experience caused both manufacturers of thrombopoietin to cease clinical trials. Instead, a series of small molecule mimics have been developed that bind to the thrombopoietin receptor and stimulate thrombopoiesis. Two such drugs are approved by the FDA for use in patients with severe immune thrombocytopenia—one a peptibody that contains four copies of a thrombopoietin receptor binding peptide grafted onto an immunoglobulin scaffold and the other a small organic molecule that is orally bioavailable and binds to a spatially distinct site on the thrombopoietin receptor. The use of each drug results in a high rate of platelet responses into the normal range in patients with severe immune thrombocytopenia (Chapter 172) who were refractory to conventional therapies. However, because thrombopoietin mimics do not affect the underlying immune destruction of platelets and MKs in patients with this disease, discontinuation of each drug results in rapid relapse of thrombocytopenia. Current clinical trials in other settings of transient myelosuppression have led to improved platelet recovery, but such indications are not yet approved by the FDA.

THE PERIPHERAL BLOOD SMEAR

BARBARA J. BAIN

With the development of sophisticated automated instruments to count and characterize blood cells, Romanowsky (Wright-Giemsa or May-Grünwald-Giemsa)–stained peripheral blood smears are now performed on only a minority of blood specimens received in a hematology laboratory. Nevertheless, the blood smear remains important for a number of reasons: it can (1) verify the result of an automated instrument, (2) provide an immediate specific diagnosis, or (3) indicate a narrow range of diagnostic possibilities, permitting a focused rather than indiscriminate investigation.[1-3] A blood film can provide a rapid diagnosis in cases in which speed is crucial, such as in acute promyelocytic leukemia, thrombotic thrombocytopenic purpura, Burkitt lymphoma, and certain infections.[4,5] Sometimes a smear provides unexpected information that is of value in patient management.

Usually, blood smears are initially interpreted by a laboratory scientist. In some countries, it is customary for clinicians to examine the blood smears of their own patients because the clinician has the final responsibility for integrating all information and making a diagnosis. However, the interpretation of a blood smear can be difficult, and a trained laboratory hematologist or hematopathologist has a major role in interpreting smears that may have been initially examined by a laboratory scientist. It is crucial that, when requesting a blood count, the clinician provides all the essential information needed to interpret the count and any associated smear. Regardless of whether the clinician examines the blood film, he or she must be able to interpret the written report issued by the laboratory. To do so, the clinician must be familiar with the terms generally used by laboratory staff and the possible significance of the abnormalities described. The most important of these terms are illustrated in Figures 157-1 through 157-20.

REASONS FOR PERFORMING A BLOOD SMEAR

A blood smear may be requested by a clinician or initiated by a laboratory scientist or a laboratory hematologist. Clinical findings that should lead a clinician to request a blood smear are summarized in Table 157-1.

Laboratory scientists and physicians may initiate a blood smear that has not been requested by the clinician if the clinical details indicate the possibility of a significant hematologic abnormality. However, they are also likely to evaluate a blood smear in response to abnormalities revealed by an automated instrument. These abnormalities may be quantitative or qualitative. Quantitative abnormalities that require evaluation include anemia, polycythemia, macrocytosis, microcytosis, neutrophilia, lymphocytosis, eosinophilia, thrombocytopenia, and thrombocytosis.

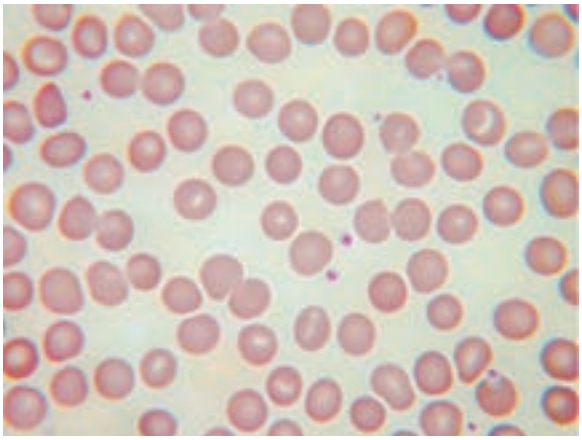

FIGURE 157-1. Normal peripheral blood smear. These normal red cells are described as *normocytic* (i.e., of normal size) and *normochromic* (i.e., their staining characteristics are normal). Normal erythrocytes are biconcave discs, causing them to have an area of central pallor that does not exceed one third the diameter of the cell. There are also scattered normal platelets (×1000).

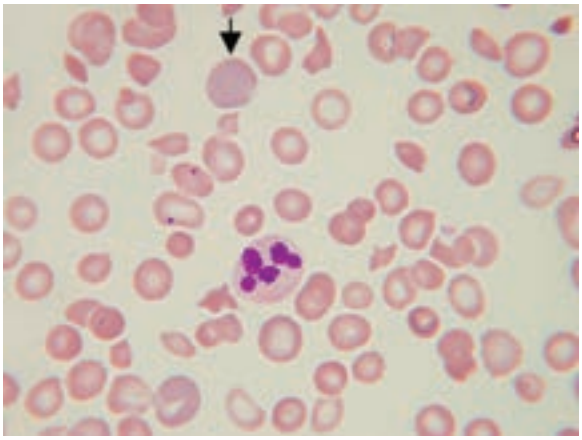

FIGURE 157-2. Smear showing multiple abnormalities. There is *anisocytosis,* defined as an increased variation in cell size; *poikilocytosis,* defined as an increased variation in cell shape; and *polychromasia,* defined as the presence of erythrocytes with a blue tinge to their cytoplasm—indicating a young cell recently released from the bone marrow in which the polychromasia is due to the presence of RNA. *Polychromatic cells* are erythrocytes with a blue tinge; because polychromatic cells are larger than normal mature erythrocytes, they are known as *polychromatic macrocytes (arrow)*. The film also shows two cells containing bluish purple *Howell-Jolly bodies*; these inclusions are nuclear remnants (×1000).

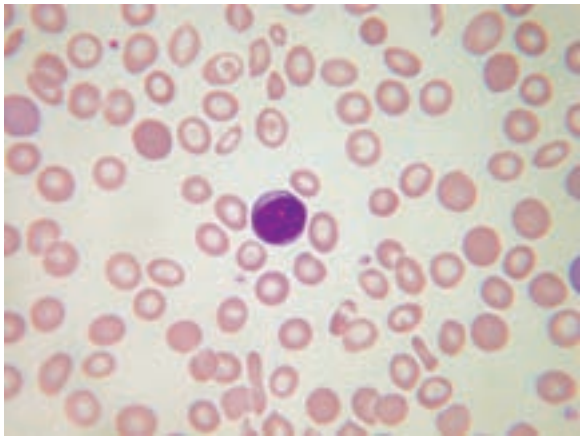

FIGURE 157-3. Microcytic red cells from a case of thalassemia minor. In a blood smear, a *microcyte* can be defined as a cell with a diameter less than that of the nucleus of a normal small lymphocyte. There are also some cells showing *hypochromia*, an area of central pallor that is larger than one third of the diameter of the red cell. In addition, there are two *target cells*, with a hemoglobinized area in the center of the area of pallor (×1000).

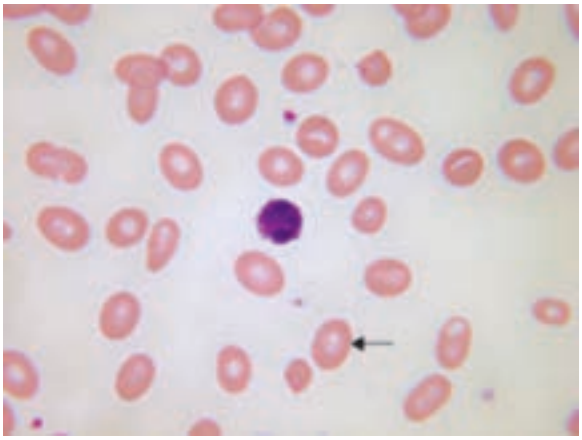

FIGURE 157-4. Macrocytic anemia. A *macrocyte* is recognized on a blood film as a cell with a diameter that is considerably greater than that of the nucleus of a small lymphocyte. In addition, this smear shows *oval macrocytes* (also known as *macro-ovalocytes*), defined as cells that are larger than normal and oval in shape *(arrow)*. They are of considerable diagnostic importance, being characteristic of megaloblastic anemia; they can also be seen in dyserythropoiesis (×1000).

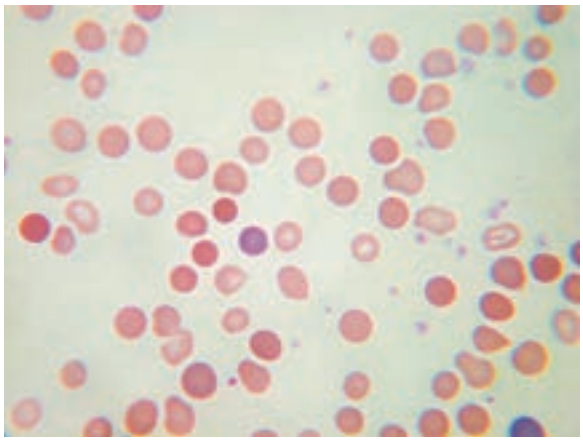

FIGURE 157-5. Hereditary spherocytosis. A *spherocyte* is a red cell that lacks central pallor because of its spherical shape. In hereditary spherocytosis, there are usually cells in which the central pallor is reduced rather than absent, and they are intermediate in shape between a spherocyte and a *discocyte,* which is an erythrocyte with the normal shape of a biconcave disc (×1000).

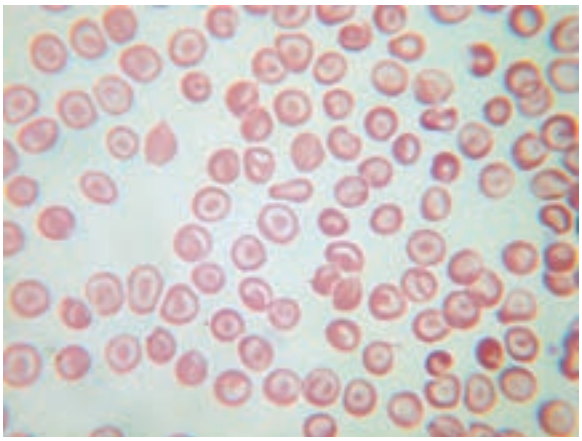

FIGURE 157-6. Target cells. A *target cell* is an erythrocyte with a hemoglobinized area in the middle of the normal area of central pallor (×1000).

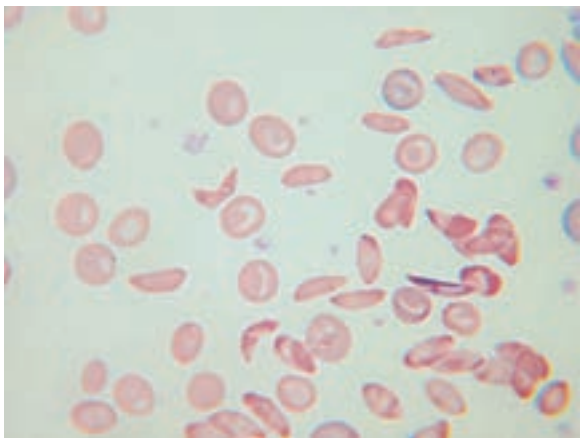

FIGURE 157-7. Sickle cells. A *sickle cell* is a cell with a sickle or crescent shape resulting from the polymerization of hemoglobin S. These cells are seen not only in sickle cell anemia (homozygosity for hemoglobin S) but also in compound heterozygous states such as sickle cell/hemoglobin C disease and sickle cell/β-thalassemia, which also lead to sickle cell disease. This smear also shows target cells and boat-shaped cells with a lesser degree of polymerization of hemoglobin S than in a classic sickle cell (×1000).

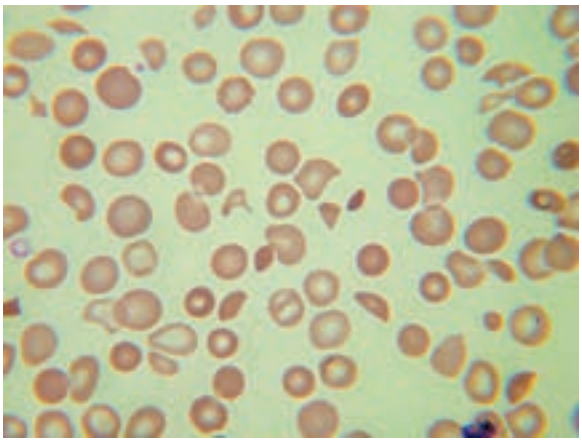

FIGURE 157-8. Red cell fragmentation. *Red cell fragments* or *schistocytes* are defined as fragments of erythrocytes. In addition to small angular fragments, there may be *microspherocytes,* cells of reduced size and spherical in form (also known as *spheroschistocytes*), and *keratocytes,* cells with two horn-like projections. Keratocytes can result from removal of a Heinz body, as well as from red cell fragmentation. Some schistocytes are referred to as *helmet cells* because of their typical shape. Schistocytes are seen in microangiopathic hemolytic anemias and in mechanical hemolysis (×1000).

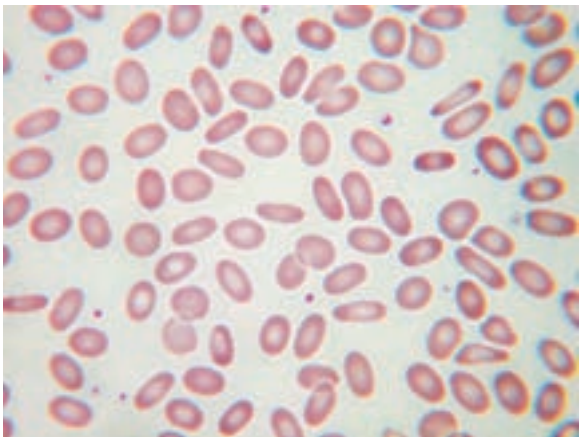

FIGURE 157-9. Hereditary elliptocytosis. An *elliptocyte* is an elliptical red cell. When seen in the numbers present in this smear, they are indicative of hereditary elliptocytosis; smaller numbers are seen in other conditions such as iron deficiency anemia, in which they are sometimes referred to as *pencil cells* (×1000).

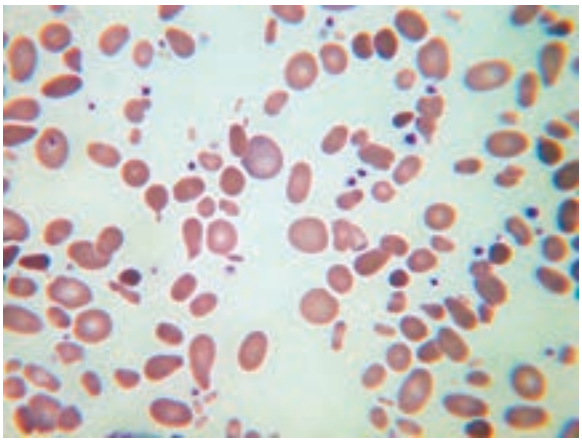

FIGURE 157-10. Hereditary pyropoikilocytosis. This smear shows striking poikilocytosis, including elliptocytes, microspherocytes and other fragments, and teardrop cells. This congenital condition, which is related to hereditary elliptocytosis, usually results from the inheritance of two different mutated genes from the two parents and is characterized by a severe hemolytic anemia (×1000).

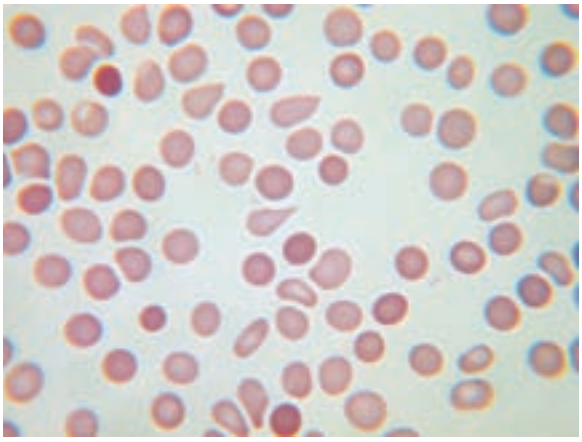

FIGURE 157-11. Teardrop poikilocytes. *Teardrop poikilocytes,* or *dacrocytes,* are teardrop-shaped red cells; they are characteristic of primary myelofibrosis but are also seen in megaloblastic anemia (×1000).

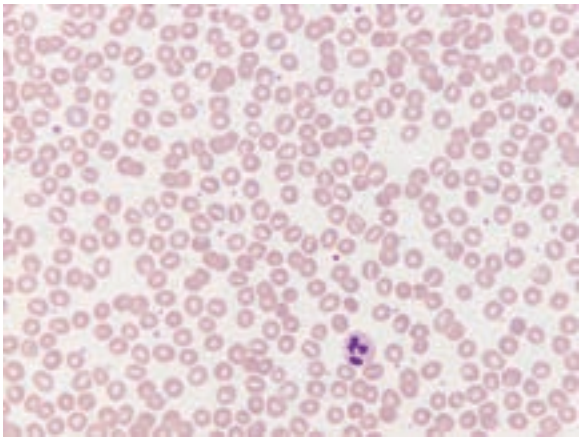

FIGURE 157-12. Stomatocytosis. A *stomatocyte* is a cell that appears to have a central mouth-shaped or slit-like stoma. Among the less common causes is hereditary stomatocytosis. Alcohol and hydroxycarbamide therapy are more common causes (×400).

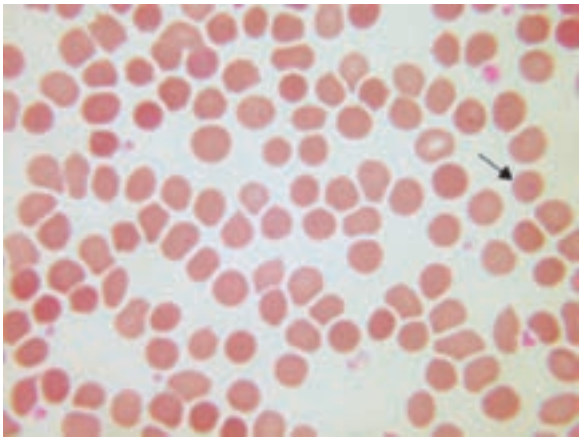

FIGURE 157-13. Numerous Pappenheimer bodies. A *Pappenheimer body* is an iron-containing red cell inclusion *(arrow)*. It is smaller and more angular than a Howell-Jolly body and stains navy blue rather than purple. Pappenheimer bodies are seen following splenectomy and in sideroblastic anemias (×1000).

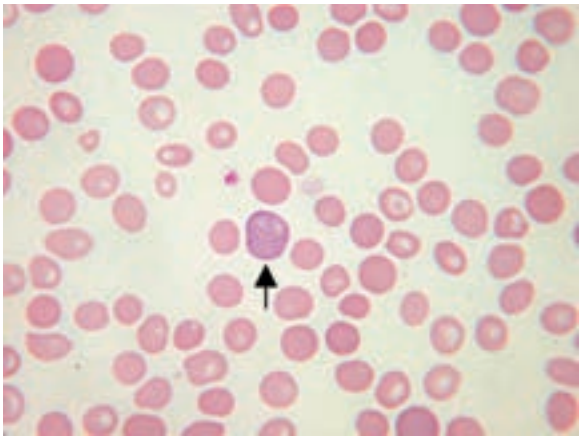

FIGURE 157-14. Basophilic stippling. *Basophilic stippling* means that there are fine (as in this case) or coarse purplish blue dots dispersed through the red cell *(arrow)*. They are a very nonspecific feature occurring in thalassemia trait, lead poisoning, pyrimidine 5′-nucleotidase deficiency, and dyserythropoiesis in general (×1000).

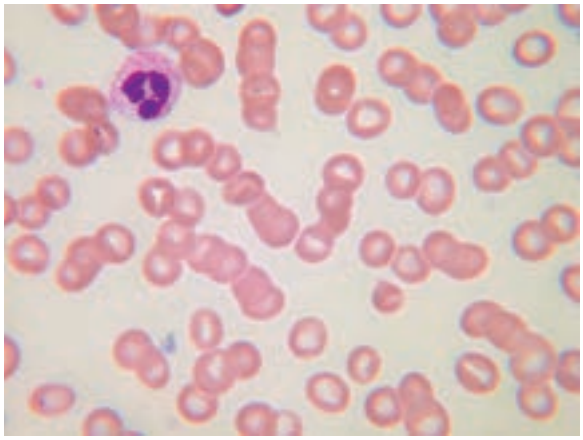

FIGURE 157-15. Rouleaux formation. *Rouleaux* are stacks of red cells, often compared to stacks of coins. They result from an increase of high-molecular-weight globulins in the plasma, either as a reactive change or as a result of secretion of a paraprotein in a plasma cell neoplasm (×1000).

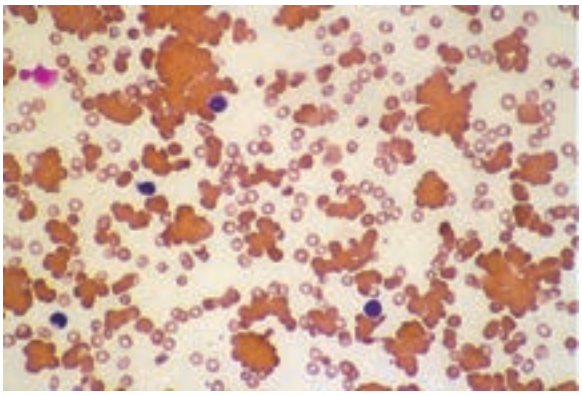

FIGURE 157-16. Red cell agglutination. *Red cell agglutinates* are irregular aggregates of red cells, as seen in *Mycoplasma pneumoniae* infection. They are also seen in other infections, such as infectious mononucleosis, and in chronic cold hemagglutinin disease (×100). (Courtesy of Jean Schafer.)

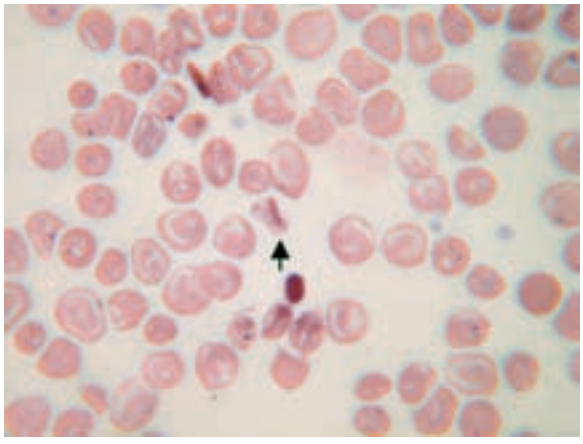

FIGURE 157-17. Homozygous hemoglobin C. Three *hemoglobin C crystals* are present, one indicated by an *arrow.* Hemoglobin C crystals are usually six-sided, with a long axis having parallel edges (×1000).

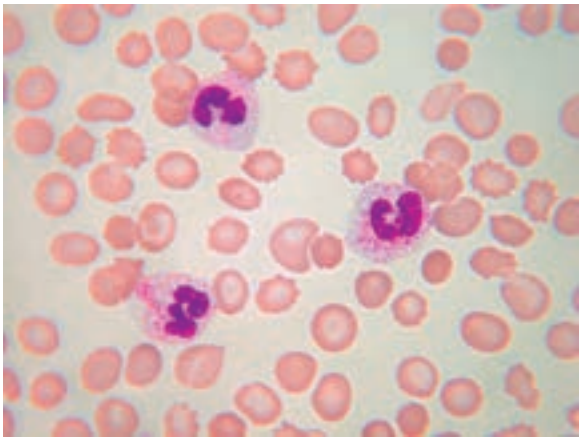

FIGURE 157-18. Toxic granulation. *Toxic granulation* refers to heavy staining of azurophilic granules of neutrophils. When accompanied by neutrophil vacuolation, it is often indicative of infection, but it can also result from inflammation, tissue damage, and normal pregnancy (×1000).

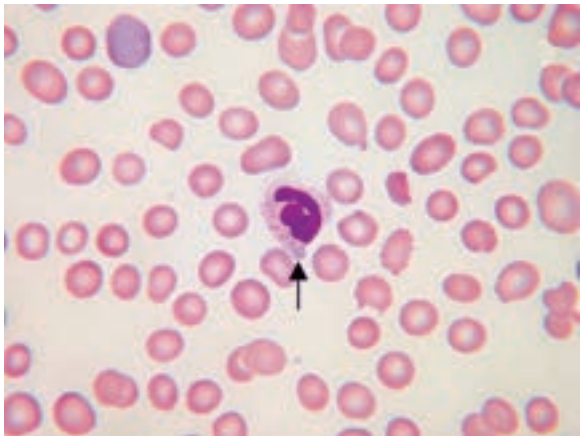

FIGURE 157-19. Döhle body. A *Döhle body (arrow)* is a pale blue-gray amorphous inclusion near the cell membrane of a neutrophil. Döhle bodies can result from infection and inflammation. Similar but different inclusions (larger and more angular) are seen in the May-Hegglin anomaly (×1000).

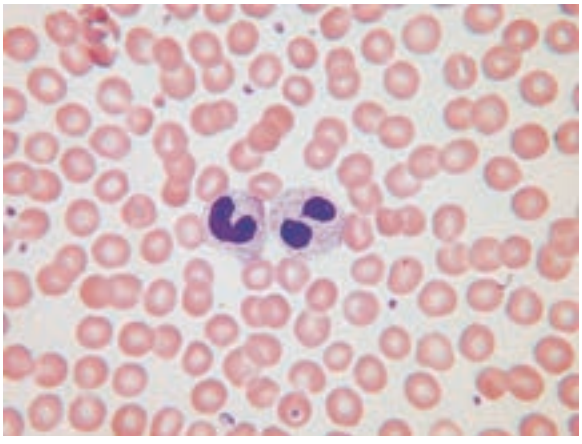

FIGURE 157-20. Pelger-Huët anomaly. A *Pelger-Huët anomaly* is a cytologic abnormality of neutrophils in which there is hypolobulation of nuclei and increased chromatin clumping. Nuclei may have a shape resembling a peanut or a pince-nez, as in the examples shown. The Pelger-Huët anomaly is inherited, but similar Pelger neutrophils are seen in myelodysplastic syndromes, in which the neutrophils may also be hypogranular (×1000). They can also be seen as an acquired reversible phenomenon in response to specific drugs, including tacrolimus and mycophenolate mofetil.

TABLE 157-1 CLINICAL FEATURES SUGGESTING THE NEED FOR A BLOOD SMEAR

CLINICAL FEATURE	REASON TO PERFORM A BLOOD SMEAR
Lymphadenopathy or splenomegaly	May be indicative of infectious mononucleosis or another reactive condition, or of leukemia or lymphoma
Clinically evident anemia	Helps in the differential diagnosis
Bruising or bleeding tendency, including unexplained retinal hemorrhages	May confirm thrombocytopenia or show morphologically abnormal platelets (which may have defective function); sometimes shows acute leukemia or other condition causing bone marrow failure
Acute renal failure	Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura should be confirmed or excluded
Jaundice and hypertension in a pregnant woman	May show schistocytes, supporting a diagnosis of HELLP syndrome
Bone pain	May indicate multiple myeloma, bone marrow infiltration, or sickle cell disease
Unexplained chest or abdominal pain or acute splenic enlargement in a child	Possible sickle cell disease
Unexplained hyperbilirubinemia	Assessment of possible hemolysis

HELLP = hemolysis, elevated liver enzymes, low platelets.

Modern automated instruments are able to "flag" the presence of qualitative abnormalities that require a blood film to be examined for confirmation of the abnormality or for further elucidation. "Flags" are generated in response to the electrical impedance or the light scattering characteristics of individual cells. Some instruments are dependent on cytochemical reactions of cells or on the cells' ability to polarize light. Most instruments can indicate the possibility of the presence of blast cells, reactive or other atypical lymphocytes, granulocyte precursors, or nucleated red blood cells. Some instruments can enumerate nucleated red blood cells. Instruments using a cytochemical reaction for peroxidase to help identify neutrophils, eosinophils, and monocytes may flag the appearance of large, unstained (i.e., peroxidase-negative) cells; such cells may indicate a harmless inherited peroxidase deficiency, but sometimes such cells are lymphoma cells, reactive lymphocytes, or leukemic blast cells. Instruments often flag the possibility of an erroneous platelet count, such as when there is an overlap in size between platelets and red cells or when light-scattering characteristics suggest the presence of platelet aggregates (a potential cause of pseudothrombocytopenia). A reported increase in basophil count should generally also be regarded as a flag because it often represents a pseudobasophilia, resulting from the presence of leukemia or lymphoma cells. Some instruments alert the instrument operator to the possible presence of malaria parasites.

International consensus guidelines indicate which automated instrument results require blood smear review. Whether a review is needed is determined in part by whether that specimen is the first one obtained from that patient and whether there has been a significant change from a previously validated result (referred to as a *delta check*). Laboratory computers can be programmed to indicate when a result meets the criteria for smear review.

Automated red cell measurements can, to some extent, replace examination of the blood film.[6] An increased red cell distribution width indicates the presence of anisocytosis. A decreased mean cell volume is usually a reliable indicator of microcytosis. A reduction in the mean cell hemoglobin concentration indicates hypochromia (for most instruments, however, this measurement is less sensitive than the human eye in the detection of hypochromia). An increased mean cell volume usually indicates macrocytosis, but examination of a smear is necessary both to confirm that the result is not artifactual and to elucidate the cause. Some instruments can measure the hemoglobin concentration in individual cells and thus flag the presence of hyperdense cells; however, a blood film is still necessary to distinguish spherocytes from irregularly contracted cells, sickle cells, and other cells that have an increased hemoglobin concentration. Most instruments produce a histogram of the size distribution of red cells, and some do the same for the distribution of hemoglobin concentration; either of these graphic representations may show dimorphic red cells (i.e., two populations of cells).

TABLE 157-2 USEFUL FEATURES FOR DETERMINING THE CAUSE OF MACROCYTIC ANEMIA

CAUSE	SMEAR FEATURES
Megaloblastic anemia (vitamin B_{12} or folic acid deficiency)	Oval macrocytes, teardrop poikilocytes, hypersegmented neutrophils; when severe, marked anisocytosis and poikilocytosis, which may include red cell fragments
Ethanol excess	Target cells and stomatocytes; anisocytosis and poikilocytosis less than in megaloblastic anemia
Liver disease	Target cells, stomatocytes
Myelodysplastic syndromes, including sideroblastic anemias	Other dysplastic features such as hypogranular and hypolobulated neutrophils; if erythropoiesis is sideroblastic, a population of hypochromic microcytic cells and Pappenheimer bodies
Chronic hemolytic anemia	Polychromasia; characteristic poikilocytes sometimes present (e.g., irregularly contracted cells if there is an unstable hemoglobin)

THE BLOOD SMEAR IN THE DIFFERENTIAL DIAGNOSIS OF ANEMIA

Microcytic Anemias

In microcytic anemias (Chapter 159), the automated count is of considerable importance and may permit a distinction between iron deficiency and thalassemia heterozygosity. In iron deficiency, there is initially a normocytic normochromic anemia; only when the deficiency becomes more severe is there microcytosis. Conversely, in β-thalassemia heterozygosity, there is usually a normal or near-normal hemoglobin concentration, but the red blood cell count is increased, and there is marked microcytosis (low mean cell volume) together with a parallel reduction in mean cell hemoglobin. The blood film provides supplementary information that can favor one diagnosis or the other. Iron deficiency is more likely to be associated with hypochromia and elliptocytes ("pencil cells"), whereas in β-thalassemia heterozygosity, there is microcytosis, hypochromia is less marked, and there are more likely to be target cells and basophilic stippling. Individuals with α-thalassemia involving the deletion of two α genes (–α/–α) or (– –/α α) have red cell indices similar to those of β-thalassemia heterozygosity; in this case, the blood film usually does not provide any additional diagnostically useful information, although individuals with nondeletional α-thalassemia due to hemoglobin Constant Spring have prominent basophilic stippling. When there is deletion of a single α gene, the blood count is either less abnormal or normal, and the blood smear does not provide any extra diagnostically useful information. The blood smear is, however, a useful supplement to the blood count in suggesting a diagnosis of hemoglobin H disease (Chapter 162). The count shows anemia, marked microcytosis (low mean cell volume and mean cell hemoglobin), and usually a reduction in the mean cell hemoglobin concentration. The smear usually shows marked poikilocytosis in addition to microcytosis, and there may be polychromasia, correlating with an elevated reticulocyte count. Iron deficiency anemia also needs to be distinguished from anemia of chronic disease. The blood counts may be quite similar, but in anemia of chronic disease, the smear often shows features of inflammation, such as increased rouleaux formation, background staining (as a result of increased plasma proteins), and sometimes neutrophilia. Other rare microcytic anemias that must be distinguished from iron deficiency include congenital sideroblastic anemia (Chapter 159) and lead poisoning. In congenital sideroblastic anemia, the film is dimorphic, with one population of hypochromic microcytes and another of normochromic normocytic cells. In lead poisoning, the presence of basophilic stippling and polychromasia in a patient with microcytosis can suggest the diagnosis.

Macrocytic Anemias

A blood film can be important in distinguishing true macrocytosis from factitious macrocytosis as a result of the presence of red cell agglutinates (see Fig. 157-16). Diagnostic features that can suggest the cause of macrocytosis are shown in Table 157-2.

A smear is particularly important in evaluating the possibility of a megaloblastic anemia (Chapter 164) (Figs. 157-4 and 157-21). Sometimes assays of

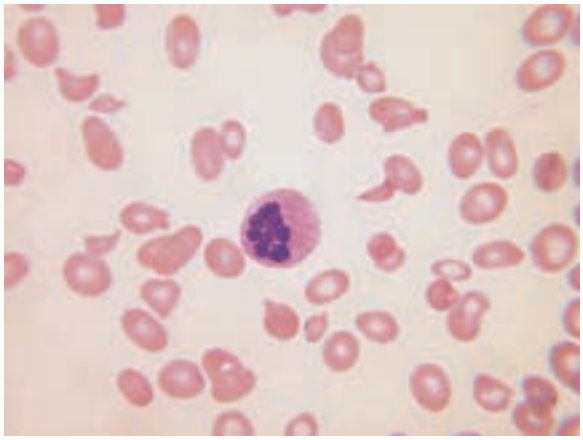

FIGURE 157-21. Hypersegmented neutrophils. A *hypersegmented neutrophil* is a neutrophil with more than five nuclear segments or lobes, as in this example from a patient with megaloblastic anemia. Neutrophil hypersegmentation is also said to be present if there are increased numbers of neutrophils with five lobes or if the median lobe count is increased (×1000).

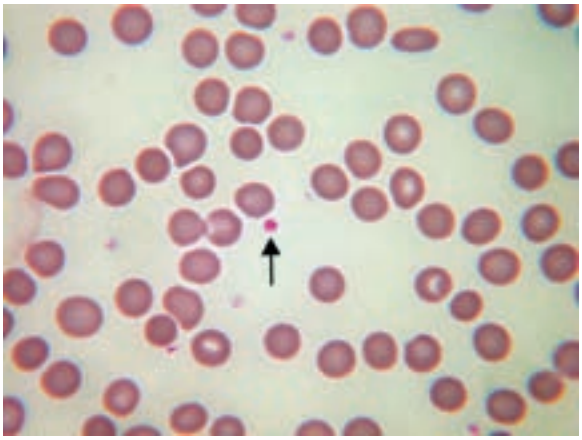

FIGURE 157-22. Normal-sized platelet *(arrow).* Platelets have central granules, although this is not apparent in this photomicrograph (×1000).

TABLE 157-3 BLOOD SMEAR FEATURES SUGGESTING A SPECIFIC CAUSE OF INHERITED OR ACQUIRED HEMOLYTIC ANEMIA

BLOOD SMEAR FEATURES	CONDITIONS SUGGESTED
Spherocytes	Hereditary spherocytosis, autoimmune hemolytic anemia, alloimmune hemolytic anemia (e.g., hemolytic disease of the newborn, delayed hemolytic transfusion reaction), drug-induced immune hemolytic anemia, *Clostridium perfringens* sepsis
Elliptocytes	Hereditary elliptocytosis
Oval macrocytes plus stomatocytes	South-East Asian ovalocytosis
Irregularly contracted cells	Glucose-6-phosphate dehydrogenase deficiency, oxidant damage from chemicals or drugs in individuals with normal red cell enzymes (e.g., dapsone administration), liver failure due to Wilson disease (release of copper from liver), unstable hemoglobin, hemoglobin C homozygosity
Sickle cells and boat-shaped cells	Sickle cell disease (e.g., sickle cell anemia or compound heterozygous states such as S/C, S/D-Punjab, S/O-Arab, S/β-thalassemia)
Target cells	Hemoglobin C homozygosity, other hemoglobinopathies, hereditary xerocytosis
Stomatocytes	Hereditary stomatocytosis
Acanthocytes	Liver failure (spur cell hemolytic anemia)
Basophilic stippling	Lead poisoning, pyrimidine 5′-nucleotidase deficiency
Red cell fragments (schistocytes)	Microangiopathic hemolytic anemia (including hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, HELLP syndrome, and sometimes hemolysis associated with disseminated intravascular coagulation), mechanical hemolytic anemia (e.g., defective cardiac prosthetic valve, march hemoglobinuria)

HELLP = hemolysis, elevated liver enzymes, low platelets.

vitamin B_{12} and folate are normal despite a deficiency, and only the blood film features suggest the true diagnosis and indicate the need for further investigation.

Normocytic Normochromic Anemia

A blood smear is only occasionally useful in determining the cause of a normocytic normochromic anemia. Signs of inflammation may be present in anemia of chronic disease. Increased rouleaux formation and background staining can also indicate multiple myeloma. Polychromasia suggests the possibility of young red cells as a result of recent blood loss or hemolysis. Small numbers of acanthocytes may indicate hypothyroidism or anorexia nervosa. Dysplastic features, such as hypogranular or pseudo-Pelger neutrophils, suggest a myelodysplastic syndrome.

Hemolytic Anemias

The possibility of hemolysis is suggested by the presence of polychromasia and macrocytosis. Specific causes of hemolysis are suggested by the presence of various poikilocytes, as shown in Table 157-3.

The distinction between spherocytes and irregularly contracted cells is important; both are dense cells with absent central pallor, but the differential diagnosis is quite different. Recognition of the features of oxidant damage is important in diagnosing glucose-6-phosphate dehydrogenase (G6PD) deficiency because sometimes an assay for G6PD performed during an acute hemolytic episode is normal (Chapter 161). In addition to irregularly contracted cells, there may be ghost cells, hemi-ghost cells ("blister cells"), and even Heinz bodies protruding from the red cells and confirmed on a Heinz body preparation. The observation of these features is an indication to repeat the assay when the acute hemolytic episode is over.

ASSESSMENT OF THROMBOCYTOPENIA, THROMBOCYTOSIS, AND PLATELET MORPHOLOGY

A blood smear is essential to validate the cell count whenever an automated count shows thrombocytopenia (e.g., a count $<60 \times 10^9$/L) (Chapter 172). This should be done quickly before patient management is altered, such as by postponing surgery or initiating further diagnostic workup. A platelet transfusion should never be given for an unexpected thrombocytopenia without microscopic confirmation of the count. A factitiously low platelet count is often the result of in vitro platelet aggregation (Chapter 171) and is occasionally the result of platelet satellitism, possibly also with platelet phagocytosis. To detect aggregates reliably, the edges and the tail of the smear should be examined. The presence of fibrin strands also suggests the activation of coagulation and an erroneous platelet count.

If a low platelet count is confirmed, the film may give clues to the cause (Chapter 172). Giant platelets (Figs. 157-22 and 157-23) occur in a number of inherited thrombocytopenias, including Bernard-Soulier syndrome and MYH9-related disorders (the May-Hegglin anomaly and related conditions). Small platelets are less common but are a feature of Wiskott-Aldrich syndrome and familial platelet disorder with propensity to myeloid malignancy. Agranular platelets occur in the gray platelet syndrome[7] and platelets with a reduced number of larger than normal granules are seen in Jacobsen/Paris-Trousseau syndrome. The presence of May-Hegglin inclusions (Döhle-like bodies; see Fig. 157-19) in neutrophils indicates that the cause of the thrombocytopenia is a mutation in *MYH9*. In acquired thrombocytopenias, increased platelet turnover is often accompanied by the presence of large platelets, whereas bone marrow failure is associated with platelets of normal size. It is important to look for red cell fragments to confirm or exclude a diagnosis of thrombotic thrombocytopenic purpura and atypical hemolytic-uremic syndrome in any patient with the apparent recent onset of

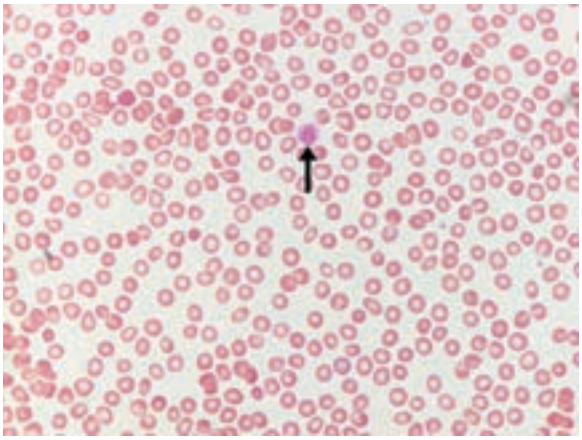

FIGURE 157-23. Giant platelet *(arrow).* Giant platelets are as large as or larger than normal red cells. Giant platelets can indicate increased platelet turnover or an inherited or acquired defect in thrombopoiesis (×1000).

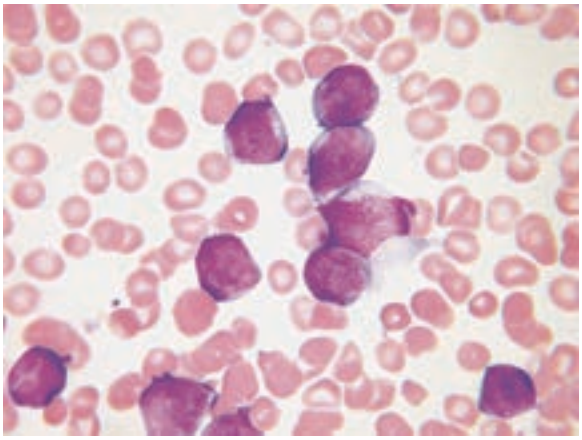

FIGURE 157-24. Acute lymphoblastic leukemia. Numerous agranular blast cells with a high nuclear-to-cytoplasmic ratio are present. Platelets are decreased in number (×1000).

thrombocytopenia; because platelet transfusions are usually contraindicated in these conditions, the smear should be examined before platelet transfusion is contemplated. The smear of any patient with the apparent recent onset of severe thrombocytopenia should be examined carefully for evidence of acute promyelocytic leukemia; the leukemic cells may be infrequent in the circulating blood. Hemorrhagic manifestations and a low platelet count can also be indicative of meningococcal septicemia; in some patients, organisms are seen in the blood smear and the diagnosis is confirmed; in other patients, only marked toxic changes in neutrophils are detected.

Thrombocytosis should also be confirmed on a smear. Factitiously elevated counts may be the result of the presence of red cell fragments (in microangiopathic or mechanical hemolytic anemia, burns, or accidental in vitro heating of the blood sample), white cell fragments (in acute leukemia and, less often, in lymphoma), cryoglobulin precipitates, or microorganisms (particularly *Candida* species). If the count is confirmed, the blood smear may be useful to indicate a likely cause (e.g., features of hyposplenism or the presence of basophilia in a myeloproliferative disorder).

It is sometimes necessary to examine a smear to confirm that an apparently normal platelet count is valid. This should always be done in patients with acute leukemia and an elevated white cell count; the presence of white cell fragments of a similar size to platelets can suggest that the platelet count is at a safe level when it is in fact dangerously low. Counting the ratio of platelets to other particles of similar size permits the count to be corrected. Any unexpectedly normal count should be confirmed; for example, the sudden rise of the automated platelet count in a patient being treated for a hematologic neoplasm may be the result of fungi that have colonized an indwelling intravenous line and are being shed into the blood stream.

LEUKOCYTOSIS AND LEUKOPENIA

The finding of leukocytosis is not necessarily an indication for a blood smear (Chapter 170). For example, this finding would be expected in a patient with infection or following surgery or trauma, in which case smear confirmation is not required. However, unexpected leukocytosis requires a smear. Artifactual elevation is unusual but can occur as a result of cryoglobulinemia, hyperlipidemia, or the presence of *Candida* species. Distinguishing reactive changes from leukemia on the basis of morphology is usually straightforward for myelocytosis but more difficult for lymphocytosis.[8] In reactive leukocytosis, there is usually toxic granulation, and Döhle bodies may be present (see Figs. 157-18 and 157-19). Vacuolation is particularly characteristic of bacterial infection, and there may be some degranulation of neutrophils. The hematologist should be aware of the changes induced by granulocyte colony-stimulating factor so that they are not confused with a response to infection; this cytokine can cause toxic granulation, Döhle bodies, vacuolation, and the presence of macropolycytes (giant neutrophils) and circulating neutrophil precursors. The changes typical of leukemia are discussed later.

Leukopenia (Chapter 167) usually requires a film for confirmation and elucidation. The exception is when it is expected in a given clinical context, such as when a patient has had recent chemotherapy. Rarely, an apparent leukopenia is artifactual, owing to the aggregation of neutrophils mediated by an autoantibody or resulting from infection-induced changes in adhesion molecules of the leukocyte surface membrane.

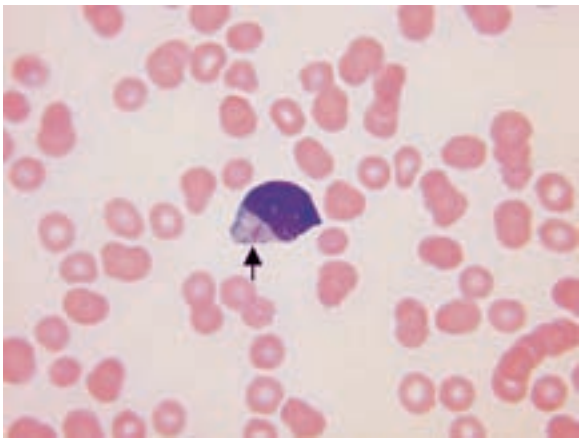

FIGURE 157-25. Auer rod. An Auer rod *(arrow)* is a rod-shaped inclusion in the cytoplasm of cells of myeloid lineage formed by the crystallization of azurophilic granule constituents. Auer rods are seen only in acute myeloid leukemia and high-grade myelodysplastic syndromes. They are usually seen in blast cells but are occasionally found in maturing cells (×1000).

With some automated instruments, it is necessary to confirm that neutropenia is real. If the automated count is based on peroxidase cytochemistry, the presence of an inherited deficiency will lead to an apparent neutropenia associated with an increase of large, unstained (i.e., peroxidase-negative) cells. The scatter plot is characteristic, but because the same features could be due to acute leukemia with neutropenia and circulating blast cells, a smear is needed for confirmation.

LEUKEMIAS AND LYMPHOMAS

The blood smear is critical in the diagnosis of leukemias and lymphomas. The lymphoblasts of acute lymphoblastic leukemia are usually medium-sized agranular cells with relatively scanty cytoplasm (Fig. 157-24), whereas in acute myeloid leukemia, blast cells are generally larger, with more plentiful cytoplasm that may contain granules or Auer rods (Fig. 157-25). Myeloid blast cells vary in appearance according to whether they are myeloblasts or monoblasts. Myeloblasts are usually medium sized and may have plentiful granules, scanty granules, or no visible granules; they may contain Auer rods. Monoblasts are much larger cells with plentiful cytoplasm containing few granules and, very rarely, Auer rods. Megakaryoblasts are present in some patients and are sometimes cytologically distinctive because of their tendency to form cytoplasmic blebs or develop platelet-type granules.

Chronic myelogenous leukemia has a very characteristic blood smear (Fig. 157-26) in which the most numerous cells are myelocytes and mature neutrophils. Eosinophils and basophils are also present. Dysplastic features are generally absent. In atypical Philadelphia chromosome–negative chronic myeloid leukemia, monocytosis is more frequent and dysplastic features are present. Chronic myelomonocytic leukemia is characterized by increased

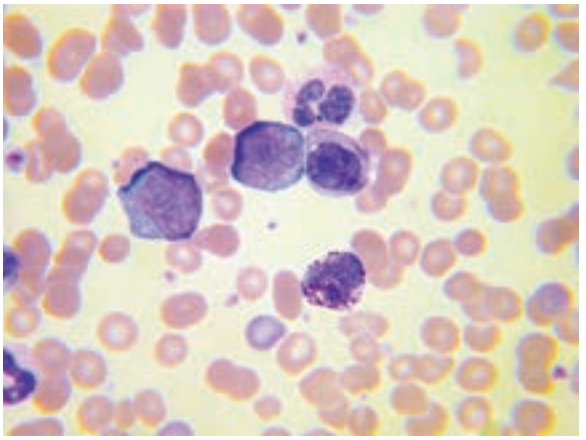

FIGURE 157-26. Chronic myelogenous leukemia. In this view there are myeloblasts, a myelocyte, a basophil, and a segmented neutrophil (×1000).

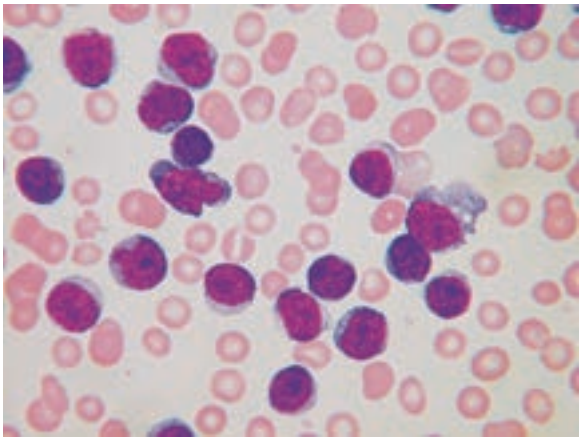

FIGURE 157-27. Chronic lymphocytic leukemia. There are large numbers of rather monotonous, mature small lymphocytes with chromatin clumping. Smear cells, reflecting the mechanical fragility of the cells, are characteristic but are not seen in this photomicrograph (×1000).

monocytes, some of them immature, with inconspicuous dysplastic features and infrequent granulocyte precursors.

Chronic lymphocytic leukemia also has a very characteristic blood film, with an increase of small, mature lymphocytes of rather uniform appearance. The chromatin is often irregularly clumped, creating a mosaic effect (Fig. 157-27). Smear cells are almost always increased in number but are not pathognomonic.

Lymphoma in leukemic phase often has cytologic features that aid in the diagnosis. Follicular lymphoma, Burkitt lymphoma, and splenic marginal zone lymphoma can all be distinctive.

THE INCIDENTAL DETECTION OF CLINICALLY SIGNIFICANT ABNORMALITIES

Sometimes the examination of a blood film reveals unexpected but clinically significant information. Examples are given in Table 157-4. Detection of microorganisms is particularly likely in patients with acquired immunodeficiency syndrome (AIDS), hyposplenic patients,[9] and patients with overwhelming sepsis, but sometimes they are detected in immunologically normal patients with only trivial symptoms. It should be noted that microorganisms in blood smears sometimes represent contaminants, particularly if specimens have been obtained by skin prick or from the umbilical cord and if there has been a delay in making the film.

CONCLUSION

Despite major advances in other diagnostic methods, the blood smear remains very useful in hematologic diagnosis. Sometimes it is critical either because it yields a diagnosis very quickly or because it provides information that is not available in any other way.

TABLE 157-4 INCIDENTAL BUT CLINICALLY RELEVANT BLOOD SMEAR OBSERVATIONS

OBSERVATION	POSSIBLE SIGNIFICANCE
Acanthocytes	Abetalipoproteinemia, neuroacanthocytosis (includes choreoacanthocytosis, McLeod phenotype, Huntington-like disease 2 and pantothenate-kinase associated neurodegeneration)
Howell-Jolly bodies, target cells, and acanthocytes	Hyposplenism (congenital, previous splenectomy, celiac disease, amyloidosis)
Cryoglobulin	Hepatitis C, multiple myeloma, Waldenström macroglobulinemia
Vacuolated lymphocytes	Inherited metabolic disorders
Parasites (e.g., malaria parasites, *Babesia*, microfilaria, trypanosomes, *Leishmania*)	Parasitic infection
Fungi (*Candida* spp, *Histoplasma capsulatum*, *Penicillium marneffei*, *Cryptococcus neoformans*, *Malassezia furfur*)	Disseminated fungal infection or, in the case of *Candida*, colonization of an indwelling intravenous line
Bacteria (e.g., pneumococcus, meningococcus, *Capnocytophaga canimorsus*, *Borrelia*, *Ehrlichia*, *Anaplasma*, *Yersinia pestis*)	Bacterial infection
Leukoerythroblastic blood film	Bone marrow infiltration (e.g., metastatic malignancy)

REVIEW QUESTIONS

1. A 72-year-old woman presents with gradual onset of digital paresthesia and difficulty with fine movement of the hands. More recently, she has noticed an electrical sensation running down her trunk and into her limbs when she bends her head forward. She is found to have a hemoglobin concentration of 9.8 g/dL and a mean cell volume of 107 fL. A blood film shows macrocytes, oval macrocytes, and hypersegmented neutrophils. Which of the following is the most likely diagnosis?

A. Neuroacanthocytosis
B. Vitamin B_{12} deficiency
C. Folic acid deficiency
D. Alcoholic liver disease
E. Copper deficiency

Answer: B The patient has described the features of peripheral neuropathy and Lhermitte syndrome. These neurologic features in a patient with macrocytic anemia and hypersegmented neutrophils are indicative of vitamin B_{12} deficiency causing megaloblastic anemia, peripheral neuropathy, and subacute combined degeneration of the spinal cord (Chapter 164). (Larkman N, Hulson O, Gilhooly M. Picture quiz: a man with tingling fingers. *BMJ.* 2013;346:37-38.)

2. A 67-year-old man presents with right heart failure and extensive bruising. The cardiac silhouette is normal on chest radiography. Electrocardiography shows reduced voltage of QRS complexes. Coagulation screen shows prolongation of the prothrombin time and activated partial thromboplastin time. A full blood count is normal apart from a slight increase of the platelet count to 487×10^9/L. A blood film shows Howell-Jolly bodies, target cells, occasional acanthocytes, and platelet anisocytosis. There is no relevant previous medical history. Which of the following is the most likely diagnosis?

A. Essential thrombocythemia
B. Hypothyroidism
C. AL (light-chain associated) amyloidosis
D. Acquired hemophilia
E. Disseminated intravascular coagulation

Answer: C The blood film features are those of hyposplenism, which also provides an explanation for the slight increase in the platelet count. The hyposplenism is the result of extensive amyloid deposition in the spleen. AL amyloidosis causes a variety of coagulation abnormalities, including acquired factor X deficiency, which could explain the prolonged prothrombin and activated partial thromboplastin times (Chapter 188). Acquired hemophilia would not explain the hyposplenism. (Gatt ME, Palladini G. Light chain amyloidosis 2012: a new era. *Br J Haematol.* 2013;160:582-598; and Gillmore JD, Wechalekar A, Bird J, et al. Guidelines on the diagnosis and investigation of AL amyloidosis. *Br J Haematol.* 2015;168:207-218.)

3. A young Greek woman presents to the emergency department because of the sudden onset of jaundice and fatigue. She has just returned from a brief trip to Greece for a family wedding. She is taking no medications. She is noted to be pale and has tachycardia. Her hemoglobin concentration is 8.7 g/dL and mean corpuscular volume is 109 fL. Reticulocyte count is increased to 280×10^9/L. Bilirubin is elevated and is found to be mainly unconjugated. Her blood film confirms marked anemia and shows polychromatic macrocytes, irregularly contracted cells, hemighosts (blister cells), and a few ghost cells. An assay for glucose-6-phosphate dehydrogenase is normal. Which of the following is the most likely diagnosis?

A. Acute liver failure
B. Autoimmune hemolytic anemia
C. Glucose-6-phosphate dehydrogenase deficiency
D. Hereditary spherocytosis
E. Pyruvate kinase deficiency

Answer: C Unconjugated hyperbilirubinemia does not suggest acute liver failure. The blood film features are those of oxidant-induced hemolysis, and a diagnosis of glucose-6-phosphate dehydrogenase (G6PD) deficiency must therefore be considered. The blood film features are not consistent with the other types of hemolytic anemia listed. Most patients with acute hemolysis due to G6PD deficiency are men because this is an X-linked condition. However, hemolysis can occur in women because a proportion of red cells will be deficient. If there is marked lyonization, hemolysis may be severe. The G6PD assay is likely to be normal because the remaining red cells are not deficient and the G6PD concentration will be increased by the presence of reticulocytes. In this circumstance, the blood film is very important in suggesting the right diagnosis. A dietary history should be taken. It is possible that the patient has recently eaten broad beans (Chapter 161). (Bain BJ. Sudden onset of jaundice in a Sardinian man. *Am J Hematol.* 2008;83:810; Bain BJ. A ghostly presence. *Am J Hematol.* 2010;85:271.)

4. A 35-year-old pregnant woman complains of severe fatigue and swollen ankles. Her blood count shows the following: red blood cells, 4.22×10^{12}/L; hemoglobin concentration, 7 g/dL; hematocrit, 0.29 L/L; mean corpuscular volume, 67 fL; mean corpuscular hemoglobin, 16.6 pg; mean corpuscular hemoglobin concentration, 24.5 g/dL. Her blood film shows hypochromia, microcytosis, and poikilocytosis including elliptocytes (pencil cells), target cells, and acanthocytes. Some Howell-Jolly bodies are present. Which of the following is the most likely diagnosis?

A. β-Thalassemia heterozygosity
B. Chronic blood loss
C. Celiac disease
D. Congenital sideroblastic anemia
E. Dietary iron deficiency

Answer: C The blood count is suggestive of iron deficiency, not β-thalassemia heterozygosity (in which moderately severe anemia would not be expected). The blood film shows the features of iron deficiency (hypochromia, microcytosis, and pencil cells) and of hyposplenism (acanthocytes, target cells, and Howell-Jolly bodies). The combination of hyposplenism and iron deficiency suggests a diagnosis of celiac disease with splenic atrophy (Chapter 159). (Croese J, Harris O, Bain BJ. Coeliac disease. Haematological features and delay in diagnosis. *Med J Aust.* 1979;ii:335-338.)

5. A 24-year-old woman who was hypertensive during pregnancy has an epileptiform convulsion 24 hours postpartum. She has jaundice, edema, and proteinuria. An urgent blood count shows leukocytosis, neutrophilia, anemia, and thrombocytopenia. Her blood film confirms the thrombocytopenia and in addition shows left shift, toxic granulation, and red cell fragments (schistocytes). Which of the following is the most appropriate diagnosis?

A. Disseminated intravascular coagulation
B. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
C. Hemolytic-uremic syndrome
D. Preeclampsia
E. Thrombotic thrombocytopenic purpura

Answer: B This syndrome is a severe form of preeclampsia/eclampsia, occurring during pregnancy or within 48 hours of delivery. The hemolytic anemia is microangiopathic in nature, and the detection of schistocytes is diagnostically useful. (Bain BJ, Riches J. Help with HELLP. *Am J Hematol.* 2010;85:70; Zini G, d'Onofrio G, Briggs C, et al; International Council for Standardization in Haematology [ICSH]. ICSH recommendations for identification, diagnostic value, and quantitation of schistocytes. *Int J Lab Hematol.* 2012;34:107-116.)

158

APPROACH TO THE ANEMIAS

H. FRANKLIN BUNN

Anemia is defined as a significant reduction in the mass of circulating red blood cells. As a result, the oxygen binding capacity of the blood is diminished. Because blood volume is normally maintained at a nearly constant level, anemic patients have a decrease in the concentration of red cells or hemoglobin in peripheral blood. As shown in Table 158-1, hemoglobin and hematocrit levels vary with the age of the individual and, in adults, with gender. The values in women of childbearing age are 10% lower than those in men. At altitude, higher values are found, roughly in proportion to the elevation above sea level. Anemic patients' values are more than 1 standard deviation below the mean values for their gender. However, because of the wide range in normal hemoglobin and hematocrit levels, it is often difficult to document mild anemia. Anemia affects one fourth of the world's population, with a higher prevalence in low socioeconomic groups.[1]

Sometimes the diagnosis of anemia is confounded by a concomitant change in the plasma volume. For example, if a patient with a low red cell mass sustains a loss of plasma volume from dehydration, diarrhea, vomiting, or severe burns, the blood hemoglobin and hematocrit levels will be increased and may even be in the normal range. Another important example, discussed in detail later in this chapter, is acute hemorrhage, in which the loss of both red blood cells and plasma results in a false elevation of hemoglobin and hematocrit. In contrast, hemoglobin and hematocrit values may be falsely low in patients with an expanded plasma volume, such as in pregnancy or congestive heart failure.

PATHOBIOLOGY

Impact of Anemia on Oxygen Transport

In any organ or region of the body, the transport of oxygen is a product of three independent variables expressed in the Fick equation (Fig. 158-1). The middle variable—the oxygen carrying capacity of the blood—is, by definition, low in anemic patients. The two other variables in the Fick equation undergo compensatory changes that, as explained later, greatly enhance oxygen transport.[2]

TABLE 158-1 NORMAL VALUES FOR RED BLOOD CELL MEASUREMENTS

MEASUREMENT	UNIT	NORMAL RANGE (APPROXIMATE)*
Hemoglobin	g/dL	Males: 13.5-17.5 Females: 12-16
Hematocrit	%	Males: 40-52 Females: 36-48
Red blood cell (RBC) count	$\times 10^6$/μL of blood	Males: 4.5-6.0 Females: 4.0-5.4
Mean cell volume (MCV)	fL	81-99
Mean cell hemoglobin (MCH)	pg	30-34
Mean cell hemoglobin concentration (MCHC)	g/dL	30-36
RBC size distribution width RDW-CV† RDW-SD†	 % fL	 12-15 37-47
Reticulocyte count (absolute number)	No./μL of blood	20,000-100,000
Reticulocyte percentage	% of RBCs	0.5-1.5

*Actual normal ranges for many of these values may vary slightly, depending on factors such as the location and type of laboratory instruments used, altitude above sea level, and patient age.
†Depending on analyzer instrument used, the RDW (red cell distribution width) can be reported as coefficient of variation (CV) and/or standard deviation (SD), RDW-CV and/or RDW-SD, respectively.

O_2 Delivery = Blood Flow × Hb Concentration × (Asat – Vsat)

In anemia: ↑ Cardiac output, Altered flow distribution | ↑↑ Plasma Erythropoietin | ↑RBC 2,3-DPG, ↓RBC O_2 affinity

FIGURE 158-1. The Fick equation expresses the three independent variables that determine the transport of oxygen to a given organ or tissue. The impact of anemia on each of these variables is shown beneath the equation. Asat = oxygen saturation of arterial blood (oxyhemoglobin/oxyhemoglobin + deoxyhemoglobin); 2,3-DPG = 2,3-diphosphoglycerate (2,3-bisphosphoglycerate); Hb = hemoglobin; RBC = red blood cell; Vsat = oxygen saturation of venous blood.

Blood Flow

Anemia has a marked impact on blood flow, the left-hand variable in the Fick equation. In all anemic individuals, there is enhanced flow to vital organs, including the heart, brain, liver, and kidneys, at the expense of nonvital organs. Anemic patients are pale because blood is diverted away from the skin and mucous membranes to preserve oxygen supply to the critical organs. Resting cardiac output is normal in patients with mild or moderate anemia, but with exercise, it increases more than that of a normal individual. In severe anemia, resting cardiac output is increased, putting patients at risk for developing high-output cardiac failure, particularly those with coronary artery insufficiency or other types of preexisting cardiac disease.

Oxygen Binding to Hemoglobin

The variable on the right side of the Fick equation is the difference in fractional oxygenation between the arterial and venous blood. This difference in oxygen saturation is determined by the hemoglobin oxygen-binding curve. A comparison between a normal individual and an anemic patient is shown in Figure 158-2. As shown in part A, the curve is shifted to the right in an anemic patient. At any given oxygen tension (P_{O_2}), the oxygen saturation of hemoglobin is lower. Thus, red cells of anemic patients have decreased oxygen affinity. This change is due entirely to elevated levels of red cell 2,3-diphosphoglycerate (2,3-DPG) in red cells. This glycolytic intermediate is the principal determinant of oxygen affinity in human red cells. The P_{O_2} in arterial blood is normally approximately 95 mm Hg, resulting in nearly 100% oxygen saturation. During the transit of red cells from an artery through its capillary bed to its vein, oxygen is released to respiring cells. In normal individuals, at a normal venous P_{O_2} of about 40 mm Hg, the oxygen saturation is approximately 80%. Thus, as shown in Figure 158-2A, 20% of the oxygen in the blood is unloaded. In contrast, in patients with anemia and elevated red cell 2,3-DPG levels, the lower oxygen affinity of their red cells enables a much higher fraction of the oxygen (as much as 35%) to be unloaded. In Figure 158-2B, the oxygen-binding curves are depicted with the volume fraction of oxygen plotted on the *y*-axis. One gram of hemoglobin binds up to 1.34 mL of oxygen under standard conditions of temperature and pressure. Thus, in a normal individual having a hemoglobin of 15 g/dL, the oxygen-carrying capacity of the blood is 15 × 1.34, or 20 mL O_2/dL. As mentioned earlier, 20% of this oxygen will be unloaded, that is, 4 mL O_2/100 mL blood during arterial-venous transit. In contrast, an anemic patient with a hemoglobin of 7.5 g/dL has an oxygen-binding capacity that is half normal, or 10 mL O_2/dL. If this patient had red cells with normal oxygen affinity, 20%, or only 2 mL of oxygen, would be unloaded per 100 mL of blood. However, because the patient's red cells have a lower affinity for oxygen, 3.5 mL is unloaded, nearly as much as normal. Thus, the decrease in oxygen affinity is an important mechanism by which anemic patients compensate for the deficit in red cell mass.

Methemoglobinemia

In order for hemoglobin to reversibly bind oxygen, the iron atom in the heme must be in the reduced (Fe^{2+}) valence state. As red cells circulate, the heme iron slowly auto-oxidizes to Fe^{3+}, forming methemoglobin, which is incapable

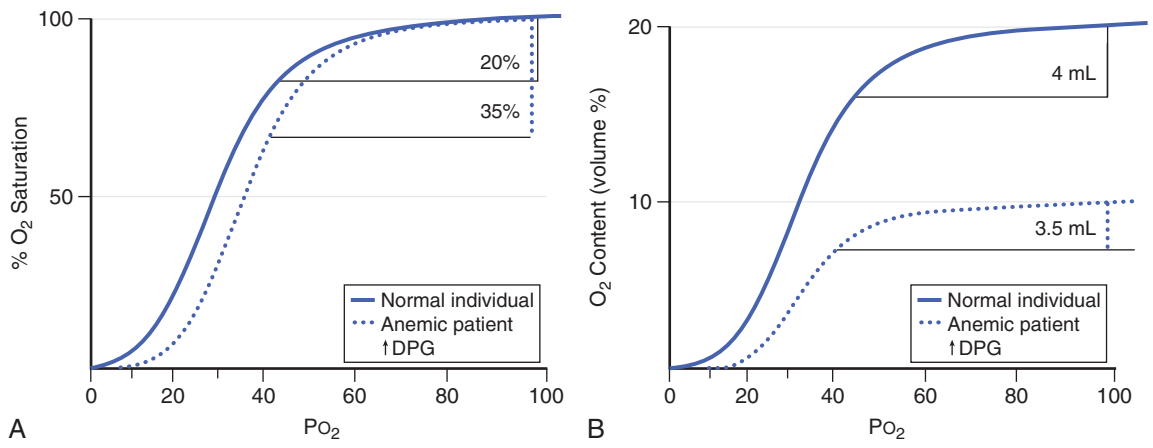

FIGURE 158-2. Oxygen-binding curves for hemoglobin of a normal individual and a patient with anemia. A, Conventional plot of percent of oxygen (O_2) saturation versus oxygen tension (P_{O_2}). **B,** The *y*-axis shows the volume of oxygen in milliliters per 100 mL of blood. DPG = diphosphoglycerate.

of binding oxygen. Normal red cells are endowed with a very efficient enzymatic pathway composed of cytochrome b_5, cytochrome b_5 reductase, and NADH that rapidly reduces the iron in methemoglobin back to its functional Fe^{2+} form. Thus, normal red cells contain less than 0.5% methemoglobin. However, either an inherited deficiency in cytochrome b_5 reductase or exposure to an oxidant drug or toxin can result in methemoglobinemia.[3] Laboratory samples of blood containing methemoglobin are dark brown, whereas patients with greater than 10% methemoglobinemia have cyanosis, a blue discoloration of the skin indistinguishable from that commonly seen in patients having normal hemoglobin but low oxygen saturation owing to pulmonary or cardiac disease. In many hospitals and large clinical laboratories, the instrument that measures oxygen saturation in blood samples also provides an accurate determination of methemoglobin.

Patients with congenital methemoglobinemia inherit an autosomal recessive deficiency in cytochrome b_5 reductase. Heterozygote relatives have low or undetectable methemoglobin levels, whereas affected individuals (homozygotes and compound heterozygotes) generally have 10 to 35% methemoglobin. These individuals are usually asymptomatic because the methemoglobin is distributed primarily in the older population of red cells. Nevertheless, many affected individuals have cosmetic concerns. Treatment with oral ascorbic acid or riboflavin is effective in lowering the level of methemoglobin below the threshold of detectable cyanosis.

A variety of drugs can cause methemoglobinemia, including acetaminophen (Tylenol), dapsone, nitroprusside, amyl nitrate, procaine congeners used for local anesthesia[4], and recreational drugs (volatile nitrites called "poppers" and cocaine). It is not clear why only a very small fraction of those using these drugs develop this complication, but some affected individuals have been shown to be heterozygous for cytochrome b_5 reductase deficiency. When these drugs are taken in prescribed doses, methemoglobinemia seldom reaches levels high enough to cause clinical concern.

In contrast, individuals exposed to industrial toxins such as nitrite, nitrate, or aniline may develop life-threatening levels of methemoglobin. The threshold at which symptoms occur is highly variable. Acute induction of 20% methemoglobin may cause fatigue; at 30%, individuals often develop tachycardia. When methemoglobin exceeds 50%, patients experience weakness, breathlessness, and confusion. At 70 to 80%, coma and death may occur. The toxicity of methemoglobinemia is not just because of the inability of oxidized hemes to bind oxygen; the remaining functional (Fe^{2+}) hemes in the hemoglobin tetramer have increased oxygen affinity and therefore, as suggested in Figure 158-2, are much less effective in releasing oxygen to tissues. Patients with toxic methemoglobinemia can be effectively treated with intravenous infusion of methylene blue (1 to 2 mg/kg).

Regulation of Erythropoiesis by Erythropoietin

Anemia also affects the middle component of the Fick equation (see Fig. 158-1). As mentioned earlier, hemoglobin levels are, by definition, low in anemic patients. The resultant decrease in the oxygen-carrying capacity of the blood causes cellular hypoxia. In all cells of the body, a molecular sensor detects even modest degrees of low oxygen tension and induces a hypoxia-inducible transcription factor called HIF. HIF upregulates expression of the hormone erythropoietin in the kidney and, to a lesser extent, in the liver. Erythropoietin (Chapter 156) binds to a specific receptor abundantly expressed on erythroid progenitor cells in the bone marrow and salvages these cells from apoptosis, thereby enhancing red blood cell production. Normal individuals maintain nearly constant levels of circulating red cells by finely tuned regulation of erythropoietin production. In anemic patients, the hypoxic signal in the kidneys and, to a lesser extent, in the liver results in a robust induction of erythropoietin expression. As the hematocrit falls, the plasma erythropoietin level rises markedly; in severely anemic patients, it may be 1000-fold higher than normal (Fig. 158-3). In patients with anemia due to impaired red cell production, the erythroid progenitors are unresponsive to such high levels of plasma erythropoietin. In contrast, in patients whose anemia is due to hemolysis or blood loss, elevated erythropoietin levels maximize red cell production.

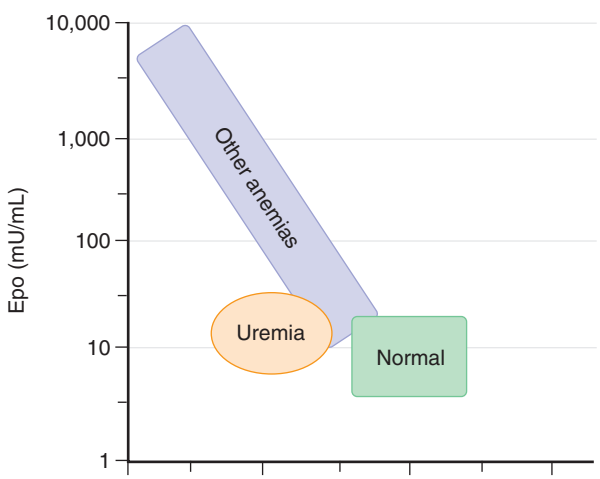

FIGURE 158-3. Plasma erythropoietin (Epo) levels in patients with different degrees of anemia. The subset of anemia patients with chronic renal disease (labeled "Uremia") have much lower plasma erythropoietin levels than those with other types of anemia. Values for normal individuals are also shown.

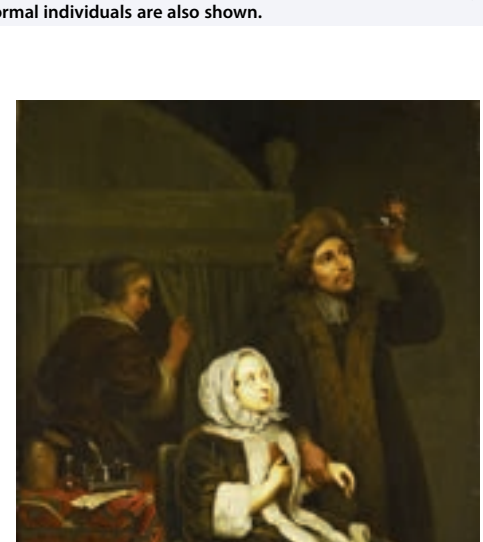

FIGURE 158-4. "The Sick Lady," a 17th-century painting attributed to Caspar Netscher, from the Royal Collection, Buckingham Palace.

CLINICAL MANIFESTATIONS

Figure 158-4 is a 17th-century painting of a pale young woman clutching her chest, apparently complaining of palpitations. Her physician is feeling her pulse, documenting her rapid, forceful heartbeat. These signs and symptoms, common in patients with very low hemoglobin levels, can be readily explained by the cardiovascular adjustments discussed in the preceding section. These clinical findings pertain to anemia per se, irrespective of cause, and are dependent on its severity and chronicity. The history and physical examination may reveal additional findings peculiar to specific causes of anemia or to other comorbid conditions. The degree to which symptoms occur in an anemic patient depends on several contributing factors. If the anemia has developed rapidly, there may not have been adequate time for compensatory adjustments to take place, and the patient may have more marked symptoms than if an anemia of equivalent severity had developed insidiously. Furthermore, the patient's complaints may depend on the presence of local vascular disease. For example, symptoms owing to ischemia in patients with angina pectoris, intermittent claudication, or transient cerebral episodes may be triggered by the development of anemia.

Symptoms

Many individuals with mild anemia have no complaints and are unaware that they have "tired blood." Others may complain of fatigue as well as dyspnea and palpitations, particularly following exercise. Patients with severe anemia are often symptomatic at rest and are unable to tolerate significant exertion. If the hemoglobin concentration falls below 7.5 g/dL, resting cardiac output is likely to rise, with an increase in both stroke volume and heart rate. The patient may be aware of this hyperdynamic state and complain of a rapid,

pounding sensation in the precordium. Patients with compromised myocardial reserve may develop complaints due to cardiac failure.

The symptoms of severe anemia often extend beyond the cardiac or circulatory system. Patients sometimes experience dizziness and headache and, less often, syncope, tinnitus, or vertigo. Many are irritable and have difficulty sleeping or concentrating. Because blood flow is shunted away from the skin, patients may complain of increased sensitivity to cold. In like manner, gastrointestinal symptoms such as indigestion, anorexia, or even nausea are attributable to the shunting of blood away from the splanchnic bed. Females commonly develop abnormal menstruation, either amenorrhea or increased bleeding. Males may experience impotence or loss of libido.

Physical Findings

Pallor is the most commonly encountered physical finding in patients with anemia. As mentioned earlier, this sign is due to the shunting of blood away from the skin and other peripheral tissues, permitting enhanced blood flow to vital organs. The usefulness of pallor as a physical finding is limited by other factors that affect the appearance of the skin. Blood flow to the skin may undergo wide fluctuations. Moreover, the skin's thickness and texture vary widely among individuals. Those with a fair complexion may appear pale even though they are not anemic, whereas pallor is difficult to detect in deeply pigmented individuals. The amount of melanin in the epidermis is an important determinant of skin color. Pallor may be difficult to detect in patients who have increased melanin pigmentation due to Addison disease or hemochromatosis. Nevertheless, even in blacks, the presence of anemia may be suspected by the color of the palms or of noncutaneous tissues such as oral mucous membranes, nail beds, and palpebral conjunctivas. When the creases of the palm are as pale as the surrounding skin, the patient usually has a hemoglobin of less than 7 g/dL.

In addition to tachycardia, wide pulse pressure, and hyperdynamic precordium, a systolic ejection murmur is often heard over the precordium, particularly at the pulmonic area. In addition, a venous hum may be detected over the neck vessels. These findings disappear when the anemia is corrected.

DIAGNOSIS

Laboratory Evaluation of the Patient with Anemia

In the clinical assessment of the anemic patient, it is important to proceed in a systematic way so that the diagnosis can be established with a minimum of laboratory tests and procedures. A thorough history and careful physical examination are critical in the initial evaluation of the anemic patient. For example, a family history that reveals a dominant inheritance pattern would reinforce the tentative diagnosis of hereditary spherocytosis. The presence of fever, a new heart murmur, and splenomegaly is an anemic patient suggests subacute bacterial endocarditis.

In evaluating the anemic patient, the clinician must first ask whether the anemia is caused by decreased production of red cells or by loss of blood cells as a result of hemorrhage or hemolysis (Table 158-2). Blood loss may be either the sole cause of the anemia or a significant contributor. Therefore, examination of the stool for occult blood is an indispensable part of the evaluation of all anemic patients.

The laboratory work-up of anemia includes a complete blood count, red cell indices, reticulocyte count, and microscopic examination of the blood smear. In addition, in many cases a bone marrow examination is a critical component of the initial laboratory assessment.

TABLE 158-2 INITIAL ASSESSMENT OF ANEMIA

Decreased red cell production
Usually acquired
Onset is insidious
Reticulocyte count is inappropriately low
Red cell indices (MCV, MCHC) are informative
Bone marrow examination is often required for diagnosis
Increased red cell destruction (hemolysis)
Often inherited
Onset may be abrupt or insidious
Reticulocyte count is increased
Red cell morphology on peripheral blood smear is usually informative
Bone marrow examination is usually not indicated
Blood loss—must be ruled out in any patient with anemia

MCHC = mean cell hemoglobin concentration; MCV = mean cell volume.

Complete Blood Count

Most hospitals and clinical laboratories use equipment that provides high-throughput analyses of red cell, platelet, and white cell counts and white cell differential, along with measurements of cell size. The mean red cell volume (MCV) is normally 81 to 99 fL. These instruments also provide accurate determinations of hemoglobin concentration. The hematocrit, or fraction of packed red cells over total blood volume, is determined indirectly from the red cell count and the MCV. The mean concentration of hemoglobin within the red cell population (MCHC) is the quotient of hemoglobin divided by hematocrit. The MCV is particularly useful in classifying the anemias caused by decreased red cell production. Microcytic anemias have low MCV values and often low MCHC. Microscopic examination reveals small and often pale red cells. The MCV in the macrocytic anemias is increased, and large, oval cells (macro-ovalocytes) are seen. In contrast to the anemias of underproduction, the hemolytic anemias are either normocytic or slightly macrocytic owing to the preponderance of young red cells that are relatively large. Severe forms of thalassemia (Chapter 162) are an exception; there, microcytic red cells may be accompanied by brisk hemolysis.

Reticulocyte Count

This simple and cost-effective test is extremely useful for distinguishing anemias secondary to decreased red cell production from those caused by hemolysis. With the application of an appropriate supravital stain, the 1- to 2-day-old red cells in the peripheral blood reveal a network of purple strands, which are aggregates of ribosomes. The reticulocyte count in normal individuals is about 1%, consistent with a red cell lifespan of approximately 120 days. An elevated reticulocyte count reflects the release of an increased number of young cells from the bone marrow. The rate of red cell production can be assessed more quantitatively by determining the absolute reticulocyte count, the product of the percentage of reticulocytes and the red cell count. Thus, normal blood contains about 50,000 reticulocytes/mm^3. In interpreting this test, one should consider the distribution of reticulocytes between the bone marrow and the peripheral blood. When erythropoiesis is robust, marrow reticulocytes enter the circulation prematurely. These "shift reticulocytes" appear larger than average on a routine (Wright-stained) blood smear and have a lavender hue, called polychromatophilia. Because the circulation of shift reticulocytes in the peripheral blood is prolonged, the reticulocyte count should be divided by two. This correction should always be made if normoblasts are encountered in the peripheral blood because this finding indicates the premature release of newborn red cells into the circulation.

A failure to produce red cells is reflected in an inappropriately low reticulocyte count. In contrast, a significant elevation of reticulocytes is suggestive of hemolysis. Exceptions include the following:

- The brisk reticulocyte response seen in patients with hemorrhage
- Reticulocytosis encountered in patients recovering from impaired erythropoiesis (e.g., an individual with pernicious anemia who received an injection of cobalamin 1 week earlier)
- Mild to moderate elevations in reticulocytes (3 to 7%) encountered in myelophthisic anemia (Chapter 157), in which the orderly release of cells is affected by alterations of the marrow stroma owing to tumor, fibrosis, or granuloma

These exceptions are generally appreciated in the initial evaluation of the patient.

A number of ancillary laboratory tests described later under Hemolytic Anemias are useful in determining both the cause and extent of hemolysis.

Examination of the Blood Smear

In the evaluation of any patient with unexplained anemia, the physician should take the time to examine a well-stained peripheral blood film (Chapter 157). Many subtleties escape the attention of the technologist, whose primary aim is to confirm or refine the white cell differential count provided by automated cell counters. The clinician approaches the specimen with a prepared mind and can scrutinize it for specific abnormalities. Examination of the blood film can confirm the size and color of red cells estimated by red blood cell indices. In contrast to the mean statistical values provided by automated cell counters, microscopic examination can reveal variations in red cell size (anisocytosis) or shape (poikilocytosis), abnormalities that are helpful in diagnosing specific anemias. Examination of the blood smear is particularly important in a patient with hemolysis. Many types of hemolytic anemia have characteristic abnormalities in red cell morphology. The presence of

abnormal white cells may be the first clue to a lymphoproliferative or primary bone marrow disorder.

Bone Marrow Examination

A microscopic examination of the bone marrow (aspirate with or without a core biopsy) is often useful and may be critical in the work-up of any *unexplained* anemia. Study of the bone marrow is informative in the diagnosis of anemias of underproduction, particularly those accompanied by abnormalities in white cells and/or platelets, suggesting disordered hematopoiesis. The more severe the anemia, the more likely it is that the procedure will be informative. An assessment of the quantity and quality of red cell precursors may identify a defect in cell production due to either hypoplasia or ineffective erythropoiesis. A marrow biopsy is required for estimating overall cellularity. The ratio of myeloid (M) to erythroid (E) precursors is normally about 2 : 1, but it may be artifactually increased by the inclusion of circulating leukocytes. The ratio is increased in patients with infection, a leukemoid reaction, or neoplastic proliferation of myeloid cells. Rarely, a high M/E ratio is due to selective aplasia of the red cell precursors. A decreased M/E ratio indicates erythroid hyperplasia. Erythroid maturation is normal in hemolysis and hemorrhage, but it is disordered when erythropoiesis is ineffective, such as in megaloblastic and sideroblastic anemias and in β-thalassemia major or intermedia. The bone marrow examination is also important in demonstrating the presence of cellular infiltrates such as those found in leukemia, lymphoma, or multiple myeloma. The demonstration of tumor, fibrosis, or granuloma usually requires a bone marrow biopsy, which provides information not available from bone marrow aspiration. A portion of the marrow specimen should be stained with Prussian blue. In addition to providing an assessment of iron stores, this iron stain is required for the identification of erythroid sideroblasts.

ANEMIA DUE TO BLOOD LOSS

The clinical presentation of anemia resulting from blood loss varies considerably, depending on the site, severity, and rapidity of the hemorrhage. At opposite extremes are acute fulminant bleeding producing hypovolemic shock and chronic occult blood loss leading to iron deficiency anemia.

Acute Blood Loss

Patients who have had a sudden hemorrhage present with clinical findings secondary to hypovolemia and hypoxia. Symptoms and signs depend on the severity of the process. The patient may experience weakness, fatigue, lightheadedness, or stupor and may appear pale, diaphoretic, and irritable. The vital signs reflect cardiovascular compensation for the acute blood loss. The degree of hypotension and tachycardia depends on the extent of the hemorrhage. Elicitation of postural signs is useful in the initial evaluation of a patient with acute blood loss. When a patient is lifted from a supine to a sitting position, an increase in the pulse of 25% or more or a fall in the systolic blood pressure of 20 mm Hg or more signifies significant hypovolemia (blood loss >1000 mL). Acute blood loss in excess of 1500 mL usually leads to cardiovascular collapse.

Following acute hemorrhage, the red cell mass and plasma volume are contracted in parallel; accordingly, there is often not a significant decrease in the hemoglobin or hematocrit level initially. This stress induces a moderate leukocytosis and a "shift to the left" in the white cell differential count. In both acute and chronic blood loss, the platelet count is often increased, particularly if the patient is already iron deficient. During the first few days after acute blood loss, there is usually an increase in reticulocytes. Severe hypoxia may trigger the release of nucleated red cells from the bone marrow into the peripheral blood. Because young red cells are larger than old ones, the MCV generally rises slightly. If significant blood loss continues, reticulocytosis will persist until iron stores have been exhausted. Internal bleeding is often accompanied by an increase in unconjugated bilirubin, reflecting an increase in the catabolism of heme from extravasated red cells. Patients with acute gastrointestinal blood loss sometimes have an elevation of blood urea nitrogen owing to impaired renal blood flow and perhaps to the absorption of digested blood protein.

These patients must be assessed promptly, and treatment must be initiated without delay. Patients with severe acute blood loss require transfusion of packed red cells, with central monitoring of the appropriate amount of volume replacement. The site or sites of bleeding should be emergently identified and controlled. In addition, an emergency coagulation profile should be obtained. The approach to the patient with shock is discussed in detail in Chapter 106.

Chronic Blood Loss

Chronic blood loss is usually due to lesions in the gastrointestinal tract or the uterus. Testing of stool specimens for occult blood is an essential but frequently overlooked part of the evaluation of anemia. It is sometimes necessary to examine serial specimens over a prolonged period because gastrointestinal bleeding may be intermittent. The hematologic manifestations of chronic blood loss are those of iron deficiency anemia, discussed in detail in Chapter 159.

ANEMIAS DUE TO DECREASED RED CELL PRODUCTION

As shown in Table 158-3, anemias caused by the underproduction of red cells can be conveniently classified according to red cell size: microcytic, macrocytic, and normocytic.

Microcytic Anemias

The presence of small red cells (MCV <77 fL) indicates a defect in the production of hemoglobin.[5] As shown in Figure 158-5, hemoglobin is composed of globin subunits into which heme is inserted. Heme is produced by the insertion of an iron atom into porphyrin (protoporphyrin IX). A defect in any of these three key components can cause microcytic anemia. Most individuals with microcytosis have either iron deficiency anemia (Chapter 159) or thalassemia (Chapter 162). A congenital or, more often, acquired impairment in porphyrin synthesis can lead to a buildup of excess iron in erythroid cells, resulting in the morphologic entity of ringed sideroblasts, which are identified in red cell precursors in the bone marrow (Chapter 159). Most patients with acquired sideroblastic anemia actually have a normal or somewhat elevated MCV but a broad distribution of red cell size, including a population of microcytes (because of this ambiguity, sideroblastic anemia appears in parentheses in Table 158-3). Iron deficiency anemia, the thalassemias, and sideroblastic anemia all involve some degree of ineffective erythropoiesis.

The anemias of chronic inflammation and malignancy, described in detail later, may be slightly microcytic owing to a defect in the availability of iron. However, these disorders are more often normocytic. Measurement of serum

iron and iron-binding capacity (Fig. 158-6A) and serum ferritin (Fig. 158-6B) particularly useful in distinguishing between iron deficiency and the anemia of chronic inflammation.

Macrocytic Anemias

A modest increase in red cell size is encountered in a variety of conditions, including liver disease, hypothyroidism, acute blood loss, hemolytic anemia, aplastic anemia, and alcoholism. Macrocytosis is so commonly seen in alcoholism that the MCV has been used as a clinical screen for abstinence from alcohol. Even in nonalcoholics, alcohol use can elevate the MCV. The macrocytes in liver disease and hypothyroidism may be related to an increased deposition of lipid in the red cell membrane. If the MCV exceeds approximately 105 fL, the patient is likely to be deficient in either cobalamin (vitamin B_{12}) or folic acid. The bone marrow reveals megaloblastic morphology, reflecting impaired replication of DNA. Because nuclear maturation lags behind cytoplasmic development, large red cells tend to be produced in the bone marrow. Megaloblastic anemias are discussed in detail in Chapter 164. Like the microcytic anemias, these disorders are maturation defects associated with ineffective erythropoiesis.

Normocytic Anemias

The normocytic anemias of underproduction are a diverse group of disorders. They can be conveniently divided into two categories: those due to intrinsic pathology within the bone marrow, and those secondary to some other underlying disease.

PRIMARY BONE MARROW DISORDERS

The primary disorders of the bone marrow, such as the leukemias (Chapters 183 and 184), myelodysplasia (Chapter 182), aplastic anemia (Chapter 165), and myelophthisis, are best approached by microscopic examination of a marrow aspirate and biopsy. This group of anemias is often accompanied by leukopenia and thrombocytopenia. A lesser degree of pancytopenia can also occur in hypersplenism and in the megaloblastic anemias.

ANEMIAS OF CHRONIC DISEASE

Among the most common anemias and the ones most prevalent in patients hospitalized on a medical service are those secondary to an underlying chronic disease. The diagnosis is usually quite straightforward. However, in some patients the predisposing illness may not be apparent. Thus, the presence of an unexplained normocytic anemia should prompt the search for the disorders listed in Table 158-4. Even if the presence of an underlying illness is established, the physician should investigate whether other factors such as blood loss or a nutritional deficiency are also contributing to the patient's anemia. Generally, the anemias due to chronic inflammation, an endocrinopathy, or liver disease are of only moderate severity. In contrast, the anemia of uremia is often severe.

ANEMIA OF CHRONIC INFLAMMATION

If a systemic inflammatory disorder persists for more than a few weeks, it is nearly always accompanied by anemia. As shown in Table 158-4, the most common causes of chronic inflammation are infection, tumor, or a connective tissue disorder. Many chronic infections can be responsible, including tuberculosis, lung abscess, subacute bacterial endocarditis, pyelonephritis, and osteomyelitis. The pathogenesis is more complex in some types of chronic infections. For example, in AIDS (Chapter 393), the human immunodeficiency virus can directly attack hematopoietic cells and suppress erythropoiesis. In malaria and babesiosis, the parasite enters circulating red cells and triggers their destruction.

There is considerable variability in tumors' ability to evoke an inflammatory response. Many tumors express inflammatory cytokines as part of their profile of abnormal gene expression. In some cases, impaired supply of oxygen or nutrients to the interior of the tumor mass can lead to necrosis and an inflammatory response. Red cell production may be further compromised by encroachment of the bone marrow with leukemia, lymphoma, or metastatic tumor.

Anemia is also a feature of a broad range of inflammatory conditions that are not associated with either infection or cancer. In some of these disorders, the autoimmune attack on the patient's cells and tissues is met with a robust inflammatory response. Rheumatoid arthritis (Chapter 264) is the most commonly encountered connective tissue disorder and gives rise to the prototypical anemia of chronic inflammation. Even more intense inflammation

and, accordingly, more severe anemia are seen in polymyalgia rheumatica and temporal arteritis (Chapter 271). In patients with systemic lupus erythematosus (Chapter 266), the anemia of chronic inflammation is often compounded by either immune hemolysis (Chapter 160) or renal insufficiency (discussed later).

PATHOBIOLOGY

Recently, the mechanism underlying the anemia of chronic inflammation has been elucidated by the discovery that plasma hepcidin levels are markedly increased as a result of induction by inflammatory cytokines. As shown in Figure 158-7, hepcidin blocks both iron absorption from the gut and the exit of iron from macrophages, thus explaining both reduced levels of serum iron and increased iron stores.

DIAGNOSIS

The anemia of chronic inflammation is associated with disordered iron homeostasis. Increased storage of iron in macrophages within the bone marrow, liver, and spleen results in elevated levels of serum ferritin (Fig. 158-6B). However, because of a block in the transfer of this excess iron into the plasma, serum iron is low (see Fig. 158-6A). The level of total transferrin in the serum is also low for unclear reasons. With the recent development of a reliable assay for hepcidin, elevated serum levels of this "master regulator" of iron homeostasis should become useful in the diagnosis of the anemia of chronic inflammation. Because of the impairment in iron availability, erythropoiesis is somewhat "iron deficient." The amount of cytoplasmic iron is decreased in erythroid precursors in the bone marrow, and the red cells that enter the circulation are slightly microcytic. This suppression of red cell production is earmarked by a low reticulocyte index. Because this block in iron utilization is subtle, the degree of anemia is seldom severe in patients with inflammatory disorders. If the hemoglobin is less than 8 g/dL, it is necessary to look for additional contributors such as hemolysis or bleeding.

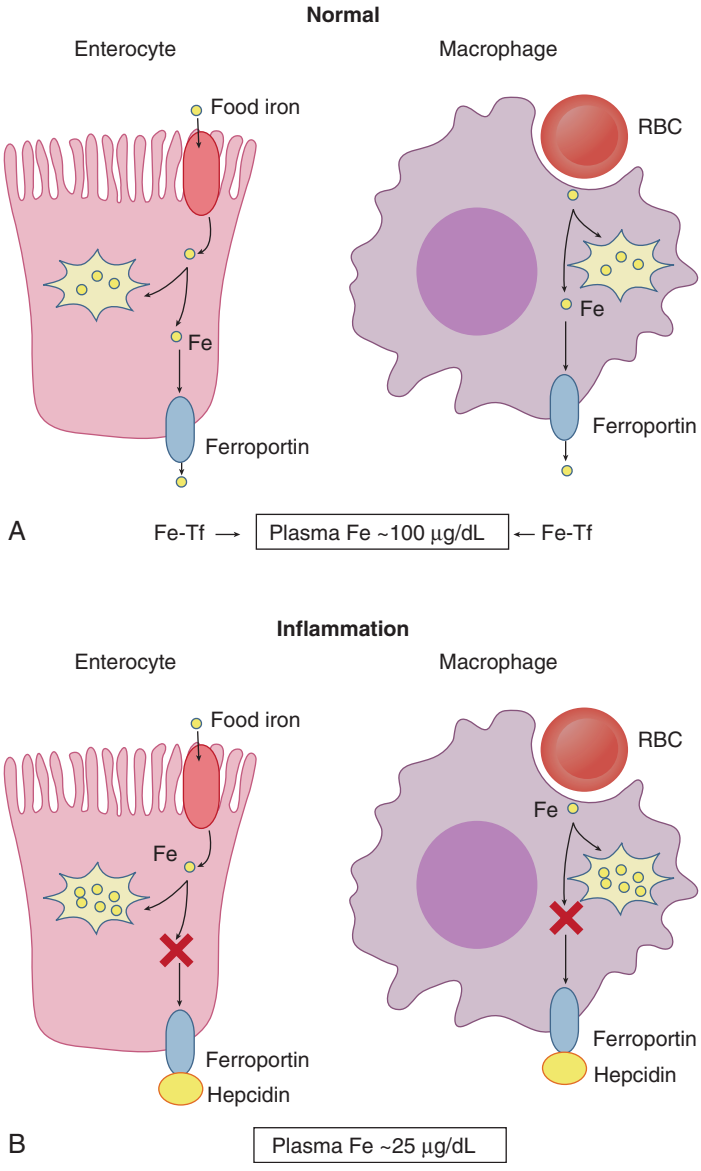

FIGURE 158-7. Pathogenesis of the block in iron availability in the anemia of chronic inflammation. The primary sources of iron in the plasma are from the breakdown of senescent red blood cells (RBCs) within macrophages and from duodenal absorption. **A,** In the presence of physiologically low levels of hepcidin in the plasma, there is efficient release of iron from the duodenal enterocyte and from macrophages through ferroportin. **B,** In patients with inflammation, the induction of plasma hepcidin by interleukin-6 and other cytokines results in the inactivation of ferroportin and the loss of iron egress from the duodenal enterocyte and from the macrophage.

TREATMENT

Rx

Because the anemia of chronic inflammation is not severe, patients seldom require red cell transfusions. Some patients may benefit from recombinant erythropoietin therapy. However, the anemia is not fully corrected unless the underlying disease is effectively treated.

ANEMIA OF RENAL INSUFFICIENCY

A normocytic anemia almost always accompanies uremia (Chapter 130). Although the hemoglobin level is highly variable, the severity of the anemia is roughly proportional to the degree of impaired renal function. The cause of the kidney failure usually has little bearing on the extent of anemia. However, for any level of serum creatinine, patients with polycystic disease tend to be less anemic than those with other types of renal disease. In contrast to the anemias associated with other chronic disorders, the anemia of uremia can be very severe, with hemoglobin levels as low as 4 g/dL.

Examination of the bone marrow seldom reveals any abnormalities. Red cell morphology is usually normal. In a minority of patients, the peripheral blood smear reveals so-called burr cells characterized by an evenly scalloped border. Neither the degree of anemia nor the red blood cell lifespan is influenced by the presence of burr cells. In most patients, the corrected reticulocyte count is low, and the red blood cell survival is only modestly decreased. Thus, the low red blood cell mass is due to decreased red blood cell production.

PATHOBIOLOGY

The primary basis for the anemia is the diseased kidneys' inability to secrete adequate amounts of erythropoietin. Plasma erythropoietin levels are lower than those of nonuremic patients with a comparable degree of anemia (see Fig. 158-3). Erythropoiesis is further impaired but not abolished in patients who have undergone bilateral nephrectomy. In addition, red blood cell production may be suppressed by the accumulation of substances that are normally cleared by the kidneys.

Other factors may aggravate the anemia of renal disease. Uremic patients have a propensity to hemorrhage, owing to a qualitative defect in platelet function. As in other patients, chronic gastrointestinal blood loss leads to iron deficiency. Folic acid deficiency may also occur, owing to the poor nutrition of many patients or to the loss of this vitamin during dialysis. Patients whose renal failure is due to thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome (Chapter 172) have a severe form of microangiopathic hemolytic anemia, with characteristic abnormalities of red blood cell morphology (Chapter 157).

TREATMENT

Rx

Treatment of the anemia of uremia first focuses on reversing the renal failure. A prompt and dramatic correction of the anemia follows successful renal transplantation. Occasionally, polycythemia may be encountered after renal engraftment and may be a harbinger of impending rejection.

In patients who are not candidates for renal transplantation, the treatment of anemia of uremia has been revolutionized by the administration of recombinant human erythropoietin (rHuEPO). The rapid and complete responses that occur underscore the importance of erythropoietin in the pathogenesis of anemia. Figure 158-8 shows the hematologic response of one of the first patients treated with rHuEPO. Within a few days of initiating rHuEPO therapy, the hematocrit approached normal, necessitating a reduction in dose. Before rHuEPO treatment, this patient was overloaded with iron, as documented by increased serum ferritin and nearly full saturation of serum transferrin. As the

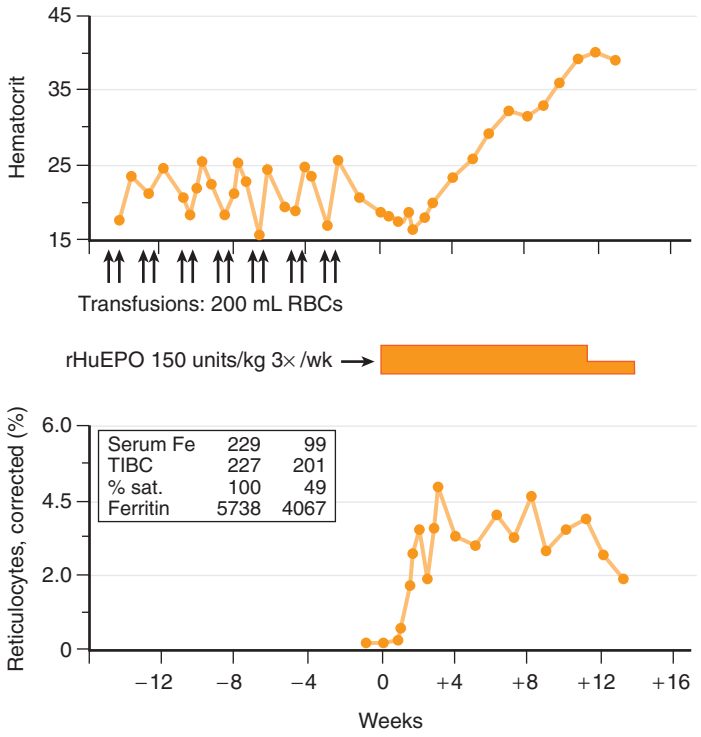

FIGURE 158-8. Response of a uremic patient to recombinant human erythropoietin (rHuEPO) therapy. Before therapy, the patient was severely anemic and transfusion dependent. Treatment with rHuEPO resulted in a reticulocytosis, followed by a progressive increase in hemoglobin. The dose of rHuEPO had to be lowered to prevent the hemoglobin from rising too high. Before rHuEPO therapy, the patient was severely iron overloaded. The marked increase in red cell mass following therapy was accompanied by a significant reduction in iron stores. RBC = red blood cell; TIBC = total iron-binding capacity. (From Eschbach JW, Egrie JC, Downing MR, et al. Correction of the anemia of end-stage renal disease with recombinant human erythropoietin: results of a combined phase I and II clinical trial. *N Engl J Med.* 1987;316:73-78.)

red cell mass increased rapidly following treatment, the robust utilization of iron stores resulted in a decline in serum ferritin and transferrin saturation. In contrast to this patient with iron overload, many uremic patients on dialysis therapy have normal or low iron stores before rHuEPO therapy and need the concomitant administration of iron to maximize the erythropoietic response. (See Erythropoietin Therapy in section on Approach to the Treatment of Anemia.)

ANEMIA OF ENDOCRINE HYPOFUNCTION

The in vitro proliferation of erythroid cells is stimulated by a number of hormones, including thyroxine, glucocorticoids, testosterone, and growth hormone. Therefore, it is not surprising that a mild to moderate normocytic anemia generally accompanies endocrine deficiency states, including hypothyroidism, Addison disease, hypogonadism, and panhypopituitarism.

In the anemia of hypothyroidism, erythropoiesis is suppressed, and the red blood cell lifespan is normal. A minority of patients have macrocytic red blood cells, sometimes owing to cobalamin deficiency. Patients with hypothyroidism have an increased incidence of pernicious anemia. Some patients, particularly females with menorrhagia, develop iron deficiency and a microcytic anemia. The anemia of hypothyroidism may be masked because of a reduction in plasma volume. Because the signs and symptoms of hypothyroidism are sometimes elusive (Chapter 226), this diagnosis should be considered in any patient with unexplained anemia.

The anemia of adrenal insufficiency, including Addison disease, may also be masked by a decrease in plasma volume. Untreated patients have an average hemoglobin level of about 13 g/dL. Upon hormone replacement, the plasma volume is rapidly reconstituted, and the hemoglobin level falls to 80% of its pretreatment value. With continued therapy, the red blood cell mass returns to normal.

Testosterone influences erythropoiesis in a physiologic manner. In males, the mean hemoglobin level increases from 13 to 15 g/dL during the transition from puberty to adulthood. Eunuchoid males usually have a mild anemia (hemoglobin ≈ 13 g/dL). Pituitary dysfunction or ablation is also associated with a mild anemia.

The anemias secondary to endocrine failure are all readily corrected when adequate hormone replacement is given.

ANEMIA OF CHRONIC LIVER DISEASE

Chronic liver disease, regardless of cause (Chapter 146), is usually accompanied by mild or moderate anemia that is normocytic or slightly macrocytic. An increased plasma volume may artificially lower the hematocrit, making the anemia seem worse than it is. Red cell morphology is normal, except for the presence of target cells (see Fig. 157-6) and occasional stomatocytes that have a slitlike rather than a circular area of central pallor. These morphologic features reflect an increased red cell membrane surface area due to increased deposits of cholesterol and phospholipid. The bone marrow is usually normal. Erythropoiesis fails to compensate for a modest shortening of the red cell lifespan. The mechanism underlying the anemia of chronic liver disease is not understood. The anemia is usually corrected if the patient regains normal hepatic function.

In patients with alcoholic liver disease (Chapters 152 and 153), the situation is much more complex. Many factors can contribute to the development of anemia. Alcohol in high doses suppresses not only erythropoiesis but also neutrophil and platelet production. In alcoholics who continue to drink up to the time of clinical evaluation, the bone marrow often reveals vacuoles in the cytoplasm of red and white blood cell precursors. In addition, ringed sideroblasts may be observed, especially if there is concurrent malnutrition. Folic acid deficiency is common in alcoholics because of both a suboptimal diet and an impairment of folate utilization. Moreover, the anemia in alcoholics is often compounded by gastrointestinal hemorrhage as a result of gastric erosions, duodenal ulcers, or esophageal varices. The risk for blood loss is further increased by the presence of thrombocytopenia and/or deficiencies in soluble clotting factors. Although alcoholics usually have increased iron stores, they may become iron deficient after prolonged gastrointestinal bleeding. Rarely, patients with alcoholic cirrhosis develop a severe hemolytic anemia accompanied by the appearance of rigid blood cells with irregular borders called acanthocytes or "spur" cells.

ANEMIA OF THE ELDERLY

As individuals age there is a slight and gradual fall in hemoglobin and hematocrit levels. Elderly individuals whose values fall below 2 standard deviations of normal have significantly enhanced morbidity and mortality. As people age, there is also an increased incidence of cancer, myelodysplasia, renal insufficiency, and chronic inflammatory disorders, all of which can suppress red cell production. Because of the high likelihood of comorbid conditions among the elderly,[6] it is not possible to affirm with any certainty whether aging per se is a cause of anemia. Nevertheless, a fall in hemoglobin in any patient, old or young, should prompt an investigation into the possible presence of one of these underlying disorders. Further studies will be needed to elucidate the molecular pathogenesis of anemia of elderly people, as well as to determine the appropriate hemoglobin concentrations for older adults in light of age, gender, race, and comorbidities.

HEMOLYTIC ANEMIAS

With the exception of sickle cell disease (Chapter 163), hemolytic anemias are encountered much less frequently than those caused by decreased red cell production. Although they are a diverse group, the hemolytic anemias share a number of clinical and laboratory features. Patients with moderate or severe hemolysis may have icterus owing to an elevation in nonconjugated (indirect) bilirubin. In addition, individuals with various types of hemolytic anemia often have splenomegaly, signifying the primary site of enhanced red cell destruction.

PATHOBIOLOGY

The presence of hemolysis is established by the laboratory tests outlined in Table 158-5. Further evaluation is required to establish the specific diagnosis. The clinician saves both time and money by using the available tests in a rational and orderly manner. Diagnosis of hemolytic anemias is greatly facilitated by the use of a logical and pathophysiologically based classification scheme. Table 158-6 groups these disorders going from the outside of the red cell into the cytoplasm, as well as by whether the defect is inherited or acquired. Hemolytic anemias due to environmental factors such as immune destruction or traumatic rupture (Chapter 160) are acquired. Abnormalities of red cell membrane proteins can also cause hemolysis. Mutations in

G6PD = glucose-6-phosphate dehydrogenase; HUS = hemolytic-uremic syndrome; TTP = thrombotic thrombocytopenic purpura.

proteins of the red cell cytoskeleton may cause hemolysis of varying severity. The most commonly encountered is hereditary spherocytosis (Chapter 161). Acquired red cell membrane defects are rare. Paroxysmal nocturnal hemoglobinuria is discussed in Chapter 160, and spur cell anemia was mentioned earlier in the section on anemias secondary to chronic liver disease. The proteins in the cytosol of the red cell include hemoglobin and enzymes. Mutations in these proteins can result in inherited hemolytic anemias. Sickle cell disease (Chapter 163) and the thalassemias (Chapter 162) are the most commonly encountered hemoglobinopathies. Homozygous SS disease and the compound heterozygous states SC disease and S/β-thalassemia are pure hemolytic anemias. In contrast, anemia in the clinically significant forms of β-thalassemia is primarily due to ineffective erythropoiesis. By far the most common red cell enzyme defect is glucose-6-phosphate dehydrogenase deficiency (Chapter 161).

DIAGNOSIS

A number of laboratory tests are used to establish the presence of accelerated breakdown of red cells (see Table 158-5). As mentioned in the section Laboratory Evaluation of the Patient with Anemia, the reticulocyte count is the simplest and most cost-effective way to distinguish between hemolytic anemias and those due to decreased red cell production. In this test, a supervital stain or a probe for RNA reveals strands of polyribosomes that are present for only 24 to 48 hours after red cells exit the bone marrow. On a routine Wright or Romanowsky stain, these cells often appear relatively large, with a blue-gray hue (so-called polychromasia). The reticulocyte count is nearly always elevated in patients with hemolysis (unless there is concomitant marrow suppression, such as by folic acid or iron deficiency). This test is a reliable index of red cell production. Thus, in patients with hemolytic anemia, the bone marrow nearly always exhibits erythroid hyperplasia. Because this result is predictable, a bone marrow examination is seldom helpful in patients with hemolytic anemia, unless there is suspicion that the hemolysis is due to an underlying lymphoma.

A number of serum and urine tests are available to confirm the presence of hemolysis and assess its magnitude. As mentioned earlier, serum nonconjugated bilirubin is elevated in proportion to the severity of the hemolysis. Lactate dehydrogenase (LDH) isoforms type 1 through 3 are released from red cells during hemolysis, resulting in increased serum LDH. Most kinds of hemolytic anemia are extravascular, with red cell destruction mediated by macrophages in the spleen, liver, and bone marrow. In these patients, a relatively small amount of hemoglobin is released from engulfed red cells into the plasma, where it binds specifically to haptoglobin. The hemoglobin-haptoglobin complex is rapidly cleared from the circulation. Measurement of serum haptoglobin is a useful test of hemolysis. Most patients with clinically significant hemolysis have very low or absent levels. Less often, patients have intravascular hemolysis with much higher levels of free hemoglobin in the plasma, sufficient to traverse renal glomeruli and exceed the tubular reabsorption capacity. These patients have red or brown urine that, after centrifugation, tests positive with a "dipstick" that detects heme protein. Hemoglobinuria can be readily distinguished from myoglobinuria. In the former, both the plasma and the urine are pigmented. In the latter, the plasma remains colorless because the smaller myoglobin molecule rapidly traverses the glomeruli. Hemoglobinuria is often transient. For a week or so after the episode has abated, the urine sediment will contain hemosiderin, which can be readily detected with the Prussian blue iron stain.

After these general laboratory tests confirm the presence of hemolysis, an array of specific tests is available to establish the specific cause (Chapters 160 through 163).

APPROACH TO THE TREATMENT OF ANEMIA

As in other disorders, the effective treatment of anemia is based on a thorough diagnostic evaluation. Hematinics such as iron, cobalamin, or folic acid should not be administered unless a specific deficiency has been demonstrated or is anticipated. Although indiscriminate treatment with cobalamin is not harmful per se, it lulls both the patient and the physician into a false sense of security in the absence of a firm diagnosis. In contrast, the inappropriate use of iron preparations over a prolonged period can be directly harmful, leading to a state of iron overload in some incorrectly diagnosed patients.

Many kinds of anemias can be corrected if a precipitating cause can be uncovered and reversed. If a drug or toxin is responsible, its withdrawal may allow full recovery. Correction of anemia secondary to a chronic disease usually depends on whether the underlying condition can be reversed. One of the most dramatic dividends of successful renal transplantation is the rapid correction of the anemia of uremia.

Erythropoietin Therapy

The administration of erythropoiesis-stimulating agents (ESA) (epoetin alfa and darbepoetin alfa) is remarkably effective in certain circumstances. In addition to those with the anemia of chronic renal failure, selected patients with other types of anemia may benefit from ESAs. Treatment can lower transfusion requirements in patients with cancer or HIV infection in whom anemia has been aggravated by chemotherapy. In comparison with patients with renal failure, higher doses are required for those with cancer or AIDS to achieve the same increase in red cell mass. Treatment with ESAs has also been effective in some patients with primary bone marrow disorders, particularly myelodysplasia (Chapter 182). Transfusion requirements in surgical patients, both perioperatively and postoperatively, may be reduced by prior short-term administration of ESAs. Treatment may also benefit rare patients who are unable to receive blood transfusions because of either antigen incompatibility or religious convictions.

A note of caution has emerged from a number of large studies suggesting that high doses of ESAs that drive the hemoglobin level above 12 g/dL are associated with a slight but significant increase in the risk for thrombosis and cardiovascular mortality. Systematic reviews and meta-analyses of treatment with ESAs in patients with chronic kidney disease that target higher hemoglobin levels increase the risk for vascular access thrombosis and cardiovascular complications (Chapters 130 and 131),[■■] and likewise for thromboembolic events in patients with cancer.[■]

Primary bone marrow disorders pose a formidable therapeutic challenge. Aplastic anemia (Chapter 165) can be cured by both immunosuppressive therapy and stem cell transplantation. Long-lasting remissions can be achieved in an increasing fraction of patients with acute leukemias by chemotherapy, often coupled with stem cell transplantation (Chapter 178). Other primary bone marrow disorders that are unresponsive to these interventions are treated with supportive measures such as transfusions of red cells and platelets.

Red Cell Transfusion

The decision whether to transfuse an anemic patient is often challenging. The risks and complications of the administration of blood products are discussed in Chapter 177. Patients with chronic or long-standing anemia are able to compensate in several ways, discussed earlier in this chapter. A considerable reduction in red cell mass can be surprisingly well tolerated, especially if the patient is young or sedentary. Transfusion is seldom indicated in a patient with chronic anemia whose hemoglobin is 9 g/dL or greater. Those who are expected to respond to the administration of a specific agent such as iron, folic acid, or vitamin B_{12} can usually be spared transfusions.

Current evidence does not support the benefit of liberal transfusions in patients with asymptomatic anemia and heart disease. Indeed the American College of Physicians Guidelines on Treatment for Anemia in Patients with Heart Disease warns against both red cell transfusion and the use of ESAs in patients with cardiovascular disease who have mild to moderate anemia.[7] However, if the anemia is severe and accompanied by myocardial or cerebral ischemia or by congestive heart failure, prompt but slow administration of packed red cells is indicated. Whole blood should be given only if the patient is hypovolemic.

Splenectomy

Splenectomy is indicated in the treatment of certain hemolytic anemias. The efficacy of splenectomy correlates with the degree to which the abnormal or defective red cells are destroyed or sequestered in the spleen. Splenectomy is curative in nearly all patients with hereditary spherocytosis (Chapter 161). The operation may be also beneficial in selected patients with immunohemolytic anemia, congestive splenomegaly, spur cell anemia, and certain hemoglobinopathies and enzymopathies. The operative morbidity and mortality from elective splenectomy are very low. The procedure can often be done by laparoscopy. Occasional patients develop postoperative left subphrenic abscess. Following splenectomy, young children are at risk for developing overwhelming septicemia. This complication can be partially prevented by vaccination against pneumococcus and meningococcus. Post-splenectomy sepsis occurs rarely in adults. The risk for sepsis can be circumvented by partial splenectomy. Thrombocytosis generally develops promptly following splenectomy. However, in most cases it is transient. In patients with continued hemolysis or with a myeloproliferative disorder (Chapter 166), the thrombocytosis usually persists and may occasionally be associated with thromboembolic complications.

REVIEW QUESTIONS

1. Which of the following laboratory tests would be *least* informative for establishing the presence of ineffective erythropoiesis in a patient with anemia?

A. Serum lactate dehydrogenase (LDH)
B. Serum bilirubin
C. Reticulocyte count
D. Serum erythropoietin level
E. Bone marrow examination

Answer: D In patients with ineffective erythropoiesis, there is erythroid hyperplasia in the bone marrow. Therefore, the bone marrow examination (answer E) is informative. Moreover, these patients have markedly enhanced destruction of these erythroid precursors and, as a direct consequence, elevations of serum (nonconjugated) bilirubin (answer B) and LDH (answer A). Unlike patients with hemolytic anemia, the reticulocyte count (answer C) is low in ineffective erythropoiesis. In contrast to these informative tests, serum erythropoietin (answer D) is not helpful because it will be elevated in nearly all patients with anemia irrespective of pathogenesis.

2. What physiologic mechanism determines the regulation of erythropoietin levels in the plasma?

A. Sensing of arterial oxygen tension in the carotid body
B. Sensing of intracellular oxygen tension in the carotid body
C. Sensing of arterial oxygen tension in the kidney
D. Sensing of intracellular oxygen tension in the kidney
E. Sensing of blood viscosity in the kidney

Answer: C The kidney is the primary site of erythropoietin production in humans and other mammals. The transcriptional regulation of the erythropoietin gene depends on the sensing of oxygen tension within a subset of renal interstitial cells at the boundary of the cortex and medulla. Note that sensing of arterial oxygen tension in the kidney (answer D) would not benefit the patient with anemia because arterial Po_2 would likely be normal. The sensing of oxygen tension in the carotid body (answers A and B) regulates the rate of respiration. Regulation of the red cell mass by sensing blood viscosity would be maladaptive (answer E).

3. Which of the following causes of anemia is best explained by inadequate production of erythropoietin?

A. Uremia
B. Chronic liver disease
C. Iron deficiency
D. Renal cell carcinoma
E. Aplastic anemia

Answer: A In most patients with chronic renal failure (answer A), there is damage to cells at the medullary-cortical boundary that produce erythropoietin. Therefore, serum erythropoietin levels in these patients are inappropriately low. The liver (answer B) produces much less erythropoietin than the kidney, and therefore liver disease does not significantly affect erythropoietin production. Renal cell carcinoma (answer D) sometimes causes elevated levels of serum erythropoietin but never decreased levels. Serum erythropoietin is markedly elevated in patients with aplastic anemia.

4. Which of the following best characterizes the impact of hepcidin on iron homeostasis?

A. Decreased release of iron from the duodenal enterocyte and decreased release of iron from the macrophage
B. Increased release of iron from the duodenal enterocyte and decreased release of iron from the macrophage
C. Decreased release of iron from the duodenal enterocyte and increased uptake of iron into the bone marrow
D. Increased release of iron from the duodenal enterocyte and decreased uptake of iron into the bone marrow
E. Increased release of iron from the duodenal enterocyte and increased uptake of iron into the bone marrow

Answer: A Hepcidin binds to and inactivates ferroportin, the transmembrane protein responsible for the export of iron from mucosal epithelial cells in the duodenum as well as macrophages in the bone marrow and liver. As a result, there is impairment of iron absorption from the gut and release of iron from macrophages.

5. What is the most effective way a patient compensates for anemia due to impaired red cell production?

A. Increased heart rate and stroke volume
B. Increased red cell oxygen affinity
C. Decreased red cell oxygen affinity
D. Decreased peripheral vascular resistance
E. Increased production of erythropoietin

Answer: C By far the most effective way in which the anemic patient compensates for a reduction in red cell mass and oxygen carrying capacity is by elevation of red cell 2,3-DPG, which shifts the oxygen binding curve to the right and lowers oxygen affinity, thereby enhancing oxygen unloading to tissues. Erythropoietin production (answer E) is markedly enhanced in nearly all patients with moderate or severe anemia (except those with chronic renal failure), but the high levels of plasma erythropoietin are ineffective in boosting hemoglobin levels in those with impairment of red cell production. Increased resting heart rate and stroke volume (answer A) occur only in patients with severe anemia, and neither these cardiac changes nor decreased peripheral vascular resistance (answer D) are efficient modes of compensation.

MICROCYTIC AND HYPOCHROMIC ANEMIAS

GORDON D. GINDER

The oxygen-carrying hemoglobin molecule executes the principal function of the mature erythrocyte. The hemoglobin content of erythrocytes is determined by the coordinated production of globin protein, the heme porphyrin ring, and the availability of iron. A deficiency in any of these three critical components of hemoglobin results in hypochromic and/or microcytic anemia (see Fig. 158-5).[1] Microcytic anemia is typically reported initially by automated red blood cell (RBC) indices. Hypochromic microcytic anemia can be confirmed on the peripheral blood smear (Fig. 159-1). Disorders of globin protein production typically produce microcytosis but not hypochromia and are discussed elsewhere (Chapter 162).

IRON DEFICIENCY ANEMIA

EPIDEMIOLOGY

Iron deficiency is by far the most common cause of anemia worldwide and is among the most frequently encountered medical problems seen by primary care physicians in the United States. More than 1.6 billion people, almost one fourth of the world's population, are anemic, and iron deficiency accounts for about half of the world's anemia burden.[2] It is estimated that between 2 and 5% of adolescent girls in the United States have iron deficiency sufficient to cause anemia. Elsewhere, the prevalence of iron deficiency–induced anemia is much higher, with estimates that up to 10% of the world population, or more than 500 million people, are affected. The prevalence rates are especially high in developing countries where dietary insufficiency and intestinal parasites are prevalent.

PATHOBIOLOGY

Most of the approximately 4 g of iron in the adult human body is incorporated into hemoglobin (approximately 2100 mg) in erythrocytes or myoglobin (approximately 300 mg) in muscle. The remainder is chiefly present as storage iron in the liver (1000 mg) and in the reticuloendothelial macrophages of the bone marrow and spleen (600 mg) (Fig. 159-2). Only a small

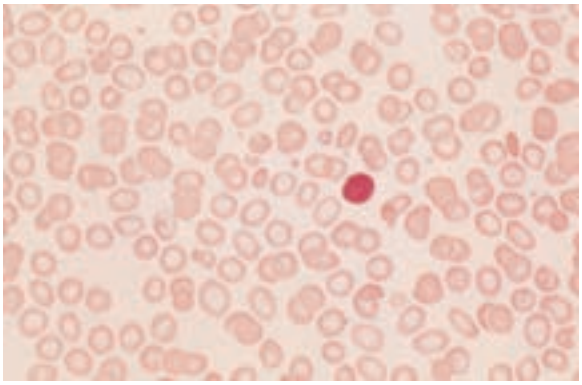

FIGURE 159-1. Iron deficiency anemia. Many of these red blood cells are microcytic (smaller than the nucleus of the normal lymphocyte near the center of the field) and hypochromic (with central areas of pallor that exceed half the diameter of the cells).

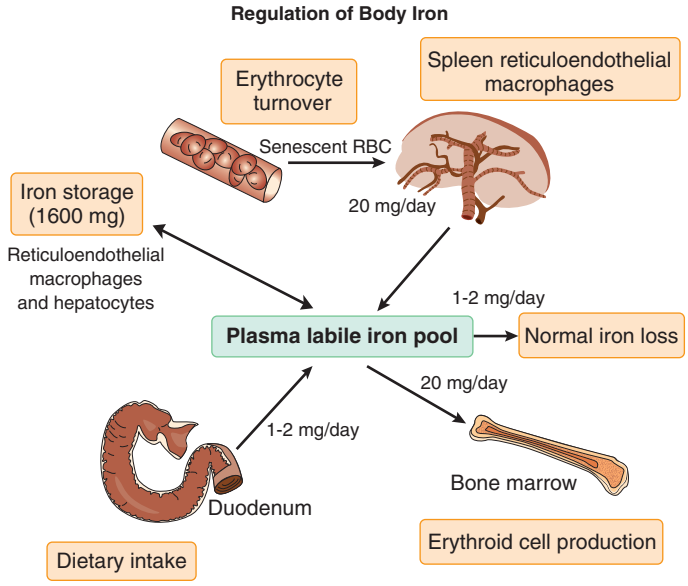

FIGURE 159-2. Iron homeostasis in normal humans. RBC = red blood cell.

amount of iron (3 to 7 mg) is freely circulating in plasma bound to transferrin, but this pool is kinetically very active, turning over every 3 to 4 hours. Because of the potent conservation mechanisms of iron recycling through the reticuloendothelial macrophage system, only an average of about 1 to 2 mg of iron is normally lost per day, largely through mucosal sloughing, desquamation, and, in females of reproductive age, menstruation.

The ability of iron to donate or accept electrons readily through conversion between the ferrous (Fe^{2+}) and ferric (Fe^{3+}) states makes it a critical component of the hemoglobin and myoglobin porphyrin rings that transport oxygen as well as cytochromes and various other vital enzymes. Free iron is extremely toxic owing to its capacity to catalyze the formation of free radicals, which lead to cellular damage. Therefore, the majority of body iron that is not stably incorporated into porphyrin rings is associated with proteins. Transferrin is the major protein associated with circulating plasma iron, and ferritin is the major protein associated with stored intracellular iron both in the cytoplasm and in mitochondria. Because the normal rate of iron loss is low, only about 1 to 2 mg/day of dietary iron is needed to maintain homeostasis. The average Western diet contains about 20 mg/day, and the efficiency of iron absorption in the duodenum is usually sufficient to maintain the amount of iron required for homeostatic balance.

Control of iron absorption by the duodenal crypt cells is critical because of the lack of any regulated physiologic mechanism for iron excretion. As a result, excessive iron intake can lead to deleterious iron overload, with concomitant organ damage (Chapter 212). Nonheme dietary iron is dissolved in part by the low pH of the stomach effluent. After reduction to the ferrous state by ferroreductase, iron is transferred across the apical crypt cell membrane by divalent metal transporter-1 (DMT-1). Several levels of regulation are involved in iron absorption by the intestine. One of these is modulated by dietary intake; thus, after a large influx of dietary iron, the duodenal absorptive capacity is diminished. A second regulatory mechanism modulates the iron absorption capacity based on total body iron stores. Finally, the so-called erythropoietic regulator modulates the capacity for enterocyte absorption based on the iron needed for erythropoiesis. A paradoxical increase in iron absorption through this mechanism occurs in certain types of anemia characterized by predominantly intramedullary destruction of erythroid cells (causing ineffective erythropoiesis): sideroblastic anemia, the thalassemias (Chapter 162), and congenital dyserythropoietic anemias.

Once inside the intestinal absorbing cell, iron is stored in complex with ferritin. Circulating plasma iron is complexed with the iron transport protein transferrin. The transferrin-iron complex is then taken up by erythroid precursors through the transferrin receptor. The high density of transferrin receptors on erythroid precursors ensures the preferential uptake of iron by these cells and explains why erythropoiesis proceeds normally until a critical deficiency of transferrin-bound iron, reflecting a depletion of total body iron, is present. The levels of transferrin, transferrin receptor, ferritin, and other proteins important in iron metabolism are regulated by the iron regulatory proteins IRP-1 and IRP-2.

Hepcidin, a 25-amino acid peptide, is the central regulator of iron homeostasis through its effects on intestinal absorption, macrophage recycling of iron from senescent RBCs, and iron mobilization from hepatic stores.[3] Thus, hepcidin affects all major sites of iron uptake and storage. Hepcidin is produced in the liver and acts as a negative regulator of iron absorption by the intestine and of iron release from storage in the macrophages and hepatocytes (see Fig. 158-7). It is believed that hepcidin binds to ferroportin, the major iron transporter in the membranes of the enterocyte, macrophage, and hepatocyte, causing the internalization and degradation of ferroportin. This process blocks the transport of iron across the membrane of the basolateral crypt cell, preventing its incorporation into transferrin-bound plasma iron. Likewise, loss of ferroportin function blocks the major export pathway of iron stores from macrophages and hepatocytes. Hepcidin production is upregulated by iron and downregulated by hypoxia, consistent with its homeostatic role. Because hepcidin is also upregulated by inflammatory cytokines, it is believed to play an important role in the paradoxical lack of transferrin-bound iron available for erythropoiesis in the face of adequate or even excess iron stores found in the anemia of chronic inflammation (see later and Chapter 158).

Blood Loss

Iron deficiency anemia results from an imbalance between available body iron for hemoglobin production and the minimal amount needed to sustain normal hemoglobin production during erythropoiesis (see Fig. 159-2). Because of the combined effectiveness of dietary absorption and retention of iron under normal circumstances, this mismatch is most often due to blood loss, with the gastrointestinal (GI) tract being the most common site (Chapter 135) in men and nonmenstruating women. In developed countries, the blood loss is usually secondary to benign or neoplastic lesions of the GI tract (Chapters 192 and 193) or chronic ingestion of drugs that cause GI mucosal damage (Chapter 139). The most common offending agents are alcohol and salicylates or other nonsteroidal anti-inflammatory agents. In developing countries, helminthic infections, including hookworm (Chapter 357) and schistosomiasis (Chapter 355), are among the most common causes of GI blood loss.

Genitourinary tract blood loss resulting in iron deficiency is most common in menstruating women. Less common are urinary tract malignancies (Chapter 197) and hemoglobinuria due to intravascular hemolysis (Chapter 160). Respiratory tract blood loss is far less common as a cause of iron deficiency.

Reproduction and Growth

In most cases, an increased iron requirement is due to blood loss; other causes include rapid growth in infancy and adolescence and pregnancy and lactation in adulthood. It is estimated that failure to satisfy the increased iron requirements during pregnancy with supplemental iron may result in a deficiency equivalent to a cumulative blood loss of up to 1500 mL.

Inadequate Iron Intake

The other major cause of iron deficiency is inadequate iron intake. Only diets that lack 1 to 2 mg/day fail to provide adequate iron. The average Western meal contains about 6 mg of iron, so dietary insufficiency is not a common cause of iron deficiency. Certain diets that lack iron or contain large quantities of phytates from cereals or tannate from tea, both of which inhibit intestinal iron absorption, may result in iron deficiency. Although iron is usually readily absorbed, primarily in the duodenum, pathologic states that can impair the process include generalized intestinal malabsorption (Chapter 140), atrophic gastritis (Chapter 139) with achlorhydria, and extensive gastric surgery. In contrast, chronic use of histamine-2 (H_2) receptor blockers or proton pump inhibitors does not appear to cause iron deficiency. In the United States, celiac disease (Chapter 140) is an increasingly common cause of iron deficiency, with resulting anemia.

CLINICAL MANIFESTATIONS

Because of compensatory physiologic mechanisms, patients with mild iron deficiency anemia may be asymptomatic. Iron deficiency in these patients may be recognized during the evaluation of an underlying disease process or as part of routine laboratory studies. The findings of microcytosis and hypochromia occur only after the hematocrit has fallen to approximately 30%, so neither finding may be present in early stages.

The anemia of iron deficiency, like other anemias, manifests with nonspecific symptoms such as weakness, pallor, dizziness, decreased exercise tolerance, or irritability. Because iron is a critical component of the porphyrin complex in muscle as well as many essential metabolic enzymes, its deficiency affects other organ systems besides the erythron, often resulting in a degree of fatigue, exercise intolerance, and weakness out of proportion to the hemoglobin level. Repletion of iron in iron-deficient individuals may improve cognitive and exercise performance. In addition, intravenous iron treatment in patients with heart failure and coexisting iron deficiency (to which heart failure patients are prone) can improve symptoms, functional capacity, and quality of life, irrespective of the presence or absence of anemia.

Rare patients, most frequently elderly women, may have dysphagia due to an esophageal stricture or web (Plummer-Vinson syndrome). A clinical manifestation unique to iron deficiency is pica, which is an unusual craving for certain non-nutritional substances. Pica may manifest as a craving for ice (pagophagia) or, less commonly, for clay (geophagia) or starch (amylophagia); pagophagia is believed to be the most specific for iron deficiency.

Physical findings that may be associated with the iron-deficient state include glossitis and angular stomatitis. Other less common but highly specific findings are spooning of the fingernails (koilonychia) and blue-tinged sclerae.

DIAGNOSIS

The diagnosis of iron deficiency anemia is made by laboratory testing. Because microcytic hypochromic RBCs are a sine qua non of this type of anemia, initial screening consists of a determination of hemoglobin levels, mean corpuscular volume, erythrocyte hemoglobin content, and reticulocyte

TABLE 159-1 LABORATORY FINDINGS FOR IRON STUDIES IN MICROCYTIC AND HYPOCHROMIC ANEMIAS

ANEMIA	SERUM IRON	TIBC	TRANSFERRIN SATURATION (%)	SERUM FERRITIN	SERUM TRANSFERRIN RECEPTOR	MARROW RE IRON	MARROW RINGED SIDEROBLASTS
Iron deficiency anemia	Low	High	0-15	Low (<30 μg/L)	High	Absent	Absent
Anemia of chronic disease	Low	Normal or low	5-15	Normal or high	Normal	Normal or high	Absent
Sideroblastic anemia	High	Normal	60-90	High	Normal or high	High	Present

RE = reticuloendothelial; TIBC = total iron-binding capacity.

count. In experienced hands, the peripheral blood smear (Chapter 157) is an excellent indicator of iron deficiency anemia. In iron deficiency anemia, most erythrocytes are smaller in diameter than the nucleus of a typical lymphocyte, and the area of central pallor is greater than 50% of the total diameter of the erythrocyte (see Fig. 159-1). Variability of erythrocyte size distinguishes iron deficiency anemia from other conditions that give rise to microcytosis; the calculated variability in RBC volume (the so-called RBC volume distribution width, or RDW) is elevated early in iron deficiency anemia.

The definitive diagnosis of iron deficiency anemia is made by tests that measure total body iron stores: the absence of iron stores that can be mobilized is unique to this microcytic hypochromic anemia. Transferrin and transferrin-bound iron levels may not be reliable indicators of iron deficiency because they are also abnormal in the anemia of chronic disease, despite adequate total body iron stores (see Fig. 158-6).

The serum ferritin level is the most reliable, noninvasive, and cost-effective indicator that is routinely available in most clinical laboratories (Table 159-1). In a large study of 259 anemic patients, a serum ferritin level less than 18 μg/L was diagnostic of iron deficiency with greater than 95% specificity and a 55% sensitivity. At a serum ferritin level of 45 μg/L, the sensitivity rose to approximately 70%, and a level higher than 100 μg/L in populations with a less than 40% prevalence of iron deficiency excluded a diagnosis of iron deficiency with more than 90% sensitivity. Although some recent studies have questioned the accuracy of the routine determination of stainable marrow iron, this test is still generally considered to be the "gold standard" for tests of iron deficiency. However, determination of total bone marrow iron stores is rarely necessary to diagnose iron deficiency anemia, except when there is some other complicating process.

One setting in which serum ferritin levels can be spuriously elevated is chronic inflammation or chronic disease. A meta-analysis involving 8796 subjects suggested that measurement of C-reactive protein (CRP) and α_1-acid glycoprotein (ACP) to assess for the level of inflammation can improve the accuracy of ferritin level as an indicator of iron deficiency.[4] The soluble serum transferrin receptor (sTfR) level is an excellent measure of total erythroid precursor mass. The sTfR is aberrantly elevated in the presence of iron deficiency, so it is considered a useful test for this condition. A number of studies have demonstrated the utility of the sTfR/ferritin ratio in distinguishing iron deficiency from the anemia of chronic disease. However, the lack of reliable standards and a meta-analysis of efficacy of the test indicating that additional data are needed to define the diagnostic accuracy of the sTfR[5] have prevented this assay from becoming routinely available in clinical practice.

TREATMENT

Rx

The treatment of iron deficiency anemia is replenishment of body iron stores. However, the underlying cause should always be investigated before treatment is begun because in many cases it is a correctable and potentially fatal GI lesion (Chapter 135).

Oral Administration

The preferred route of iron administration is oral. Oral iron is most readily absorbed in the absence of food, especially in the setting of decreased stomach acid production owing to atrophic gastritis, gastric surgery, or chronic suppression of gastric acid with an H_2 antagonist or proton pump inhibitor. The major obstacle to oral iron replacement is unacceptable side effects, chiefly epigastric discomfort or nausea; diarrhea or constipation also occurs in some patients. Reducing the dose often eliminates nausea and epigastric discomfort. Despite the development of a number of orally effective iron-containing compounds, the original salt, ferrous sulfate (325 mg three times daily), remains the most useful. Although some newer oral iron preparations, such as ferrous gluconate (300 mg two or three times daily) or ferrous fumarate (325 mg two or three times daily), may induce fewer GI side effects per milligram of iron, they are also less well absorbed, so there is no net advantage to these costlier formulations except for patients who cannot tolerate ferrous sulfate. Given both the low toxicity and the low cost of oral iron replacement, a therapeutic trial is an alternative means of confirming a diagnosis of iron deficiency anemia.

Parenteral Administration

In situations in which primary blood loss is uncontrollable, iron cannot be absorbed owing to severe malabsorption, or oral iron is not tolerated despite concerted efforts to minimize side effects, parenteral iron is an effective alternative treatment. Intramuscular dosing is limited to 100 mg/injection, so intravenous administration is recommended. Sodium ferric gluconate (given intravenously at a dose of 125 mg over 10 minutes) is the preferred form of parenteral iron owing to the low incidence of adverse reactions. A multiinstitutional, double-blind, randomized, placebo-controlled trial of more than 2500 patients showed similar adverse events in patients receiving sodium ferric gluconate versus those receiving placebo, and only one life-threatening complication occurred; in comparison, there were 23 such events among 3768 patients treated with iron dextran in a historical control arm. One limitation of sodium ferric gluconate is that the maximum dose deliverable in a single injection is approximately 125 mg, and a total dose of 500 to 2000 mg is usually required for adequate repletion. Although large doses of iron dextran can be delivered in a single intravenous injection, this is currently reserved for situations in which rapid iron replacement is required because of the life-threatening anaphylactic and delayed adverse reactions that occur in 0.6 and 2.5% of cases, respectively. If iron dextran is to be given intravenously, premedication with diphenhydramine and a slow test-dose injection of 30 to 40 mg diluted in normal saline are recommended.

Newer iron preparations for intravenous use include ferric carboxymaltose, iron isomaltoside 1000, and ferumoxytol. These preparations allow the administration of much higher doses of intravenous iron in a shorter time and can be used safely to replenish iron stores, sometimes even in a single treatment session.

The response to iron repletion therapy is usually quite rapid, with elimination of symptoms within a few days. Increased reticulocytosis usually begins within 4 to 5 days, and the hemoglobin level often rises within 1 week and reaches a normal level after 6 weeks of therapy if adequate iron replacement is achieved. The goal of therapy, which is to reach a serum ferritin level of greater than 50 mg/L, usually takes 4 to 6 months. Therapy must be continued after adequate replacement is achieved if the underlying cause of iron deficiency is not reversible. Because of the avidity of transferrin receptor–rich erythroid precursors for transferrin-bound iron, the serum ferritin level usually does not rise until hemoglobin levels reach normal.

Failure to Respond to Iron Therapy

An incomplete or lack of response to oral iron therapy, as determined by failure to normalize the hemoglobin level, usually means either that iron replacement has not been adequate (most commonly due to noncompliance with oral iron because of its side effects) or that iron deficiency is not the primary cause of the anemia (e.g., coexisting anemia of chronic disease). Less common causes of failure to respond to oral iron include iron malabsorption (e.g., celiac disease, atrophic gastritis) or blood loss in excess of iron replacement. Refractoriness to oral iron due to celiac disease can be screened by testing for anti-tissue transglutaminase (TTG) antibodies; autoimmune atrophic gastritis by serum gastrin, parietal cell, or intrinsic factor antibodies; and *Helicobacter pylori* infection and gastritis by antibody screening or fecal antigen and urease breath test.

TMPRSS6, also called matriptase-2, is a type II transmembrane serine protease that suppresses hepcidin production. Several types of mutations in *TMPRSS6* that are either sporadic or familial (usually autosomal recessive) have recently been described as causes of iron-refractory iron deficiency anemia (IRIDA). Associated with inappropriately increased levels of urinary hepcidin, the defect causes impaired iron absorption and recycling, leading to IRIDA. Characteristically, these patients exhibit no hematologic improvement in response to oral iron intake and are only partially responsive to parenteral iron because of abnormal iron utilization.[6,7]

PROGNOSIS

In most cases, iron deficiency anemia can be corrected rapidly by either oral or parenteral replacement, but the long-term prognosis ultimately depends on the clinical course of the underlying cause. It is critical that the patient undergo a full evaluation to determine the underlying cause of the iron deficiency, especially because an occult gastrointestinal lesion, often malignant, may be present, particularly in patients older than 50 years (Chapters 192 and 193).

ANEMIA OF CHRONIC DISEASE AND INFLAMMATION

DEFINITION

Anemia of chronic disease (or *anemia of chronic inflammation*) refers to anemia that occurs in the setting of a chronic disease state, usually one associated with elevated levels of inflammatory cytokines. Although anemia of chronic inflammation usually manifests as a normochromic normocytic process (Chapter 158), between 20 and 50% of cases are associated with microcytic RBC indices. The anemia is usually mild to moderate, and it may not be symptomatic.

EPIDEMIOLOGY

Anemia of chronic inflammation is believed to be the second most common cause of anemia, after iron deficiency. It is the most common type of anemia encountered among hospitalized patients. The wide spectrum of underlying diseases includes acute and chronic infections, inflammatory and autoimmune diseases, cancers, and chronic kidney diseases.

PATHOBIOLOGY

There are three major mechanisms of anemia of chronic inflammation, and all are believed to result from the effects of abnormal levels of inflammatory cytokines. The first is dysregulated iron homeostasis, manifested by low serum iron (hypoferremia) in the presence of normal or elevated serum ferritin levels and abundant reticuloendothelial macrophage iron stores. The functional consequence is a limited availability of iron for erythroid progenitor cells and resultant restriction of erythropoiesis. Pro-inflammatory stimuli, including lipopolysaccharides, interferon-γ, and tumor necrosis factor-α (TNF-α), upregulate DMT-1, which increases iron uptake by the reticuloendothelial cells. At the same time, these stimuli cause the downregulation of ferroportin expression; ferroportin is the protein required for the release of ferrous iron from storage cells and for the transport of dietary iron from duodenal enterocytes into the circulation.

Because hepcidin is an iron-regulated, acute phase reactant peptide that blocks both iron uptake in the gut and iron release from hepatocytes and macrophage stores, its upregulation by lipopolysaccharides, interleukin (IL)-6, and possibly IL-1 (indirectly, through induction of IL-6) results in another mechanism of anemia. Also, patients with hepatic adenomas that secrete high levels of hepcidin have iron-refractory anemia in the presence of normal or elevated ferritin and macrophage iron stores, despite the absence of elevated inflammatory cytokine levels. Elevated urinary hepcidin concentrations correlate with ferritin levels in patients with anemia of inflammation, iron overload, and iron deficiency.[8] These relationships are depicted in Figure 158-7.

A third pathophysiologic feature of anemia of chronic inflammation is the inhibition of erythroid progenitor expansion. Interferon-γ is the most potent inhibitory factor of erythropoiesis, but similar inhibition is believed to be mediated by IL-1, TNF-α, and interferon-β. These mediators of inflammation act to increase erythroid progenitor apoptosis, downregulate erythropoietin receptors, and antagonize pro-hematopoietic factors. The action of erythropoietin appears to be directly antagonized by these pro-inflammatory cytokines, which would explain why responsiveness to erythropoietin seems to be inversely related to the severity of the underlying chronic inflammation and the levels of interferon-γ and TNF-α. Finally, increased erythrophagocytosis in the presence of inflammation results in a modest shortening of RBC half-life.

CLINICAL MANIFESTATIONS

The clinical manifestations in patients with anemia of chronic inflammation are usually dominated by the underlying disease process. The anemia in this condition is usually mild, with hemoglobin levels in the range of 8 to 10 g/dL. However, supervening blood loss, absolute iron deficiency, or other aggravating factors can produce life-threatening anemia. Even mild to moderate anemia contributes to the debilitating effects of the underlying disease, adversely affecting performance status and quality of life. Moreover, the presence of anemia is associated with a poorer overall prognosis in many of the underlying chronic diseases, although correction of anemia has not been directly demonstrated to improve survival.

DIAGNOSIS

The clinical diagnosis of anemia of chronic disease presenting with microcytic hypochromic RBC indices is one of exclusion, based on low serum iron in the presence of normal or increased total body iron stores (see Table 159-1). Serum ferritin is the best single laboratory marker for assessing iron storage, and it is almost invariably normal or elevated in anemia of chronic disease. If both the serum iron and the transferrin saturation are reduced, reflecting dysregulation of iron homeostasis, the diagnosis of anemia of chronic disease can be made in the appropriate clinical setting after the exclusion of other causes of anemia, such as coexistent blood loss, thalassemia (Chapter 162), and drug-induced suppression of erythropoiesis. In the presence of inflammation, however, up to 30% of patients with true iron deficiency have serum ferritin levels greater than 100 μg/L, potentially obscuring the diagnosis of iron deficiency. Assays for sTfR are useful to diagnose iron deficiency in the presence of the inflammation associated with anemia of chronic disease, but problems with standardization have limited this test's availability in clinical practice. Examination of the bone marrow for reticuloendothelial macrophage iron stores (hemosiderin) and erythroblasts containing iron granules (sideroblasts) can provide definitive evidence of absent iron stores in the setting of anemia of chronic inflammation. A low serum erythropoietin level is also useful in supporting a diagnosis of anemia of chronic inflammation, but only when the hemoglobin level is less than 10 g/dL.

TREATMENT

Rx

Treatment of the Underlying Disease

The most effective treatment for anemia of chronic disease is successful treatment of the underlying inflammatory disease process, whether it is an acute or chronic infection, treatable cancer, renal failure, or rheumatoid arthritis. Even if definitive treatment is not possible, quality of life and perhaps prognosis can improve if symptomatic anemia is treated directly. Unfortunately, anemia of chronic inflammation remains undertreated, even in developed countries.

Blood Transfusion

Blood transfusion (Chapter 177) offers the immediate resolution of anemia, but it is indicated chiefly when the anemia is life threatening or seriously limits the patient's functioning. These situations almost always involve supervening blood loss or some other acute process that compounds the anemia of chronic disease. Transfusion is not recommended for the long-term treatment of mild or moderate anemia of chronic inflammation because of the secondary risks, which include transfusional iron overload, human leukocyte antigen (HLA) sensitization in the case of potential renal transplantation, and other side effects of transfusion.

Intravenous Iron and Erythropoietin Therapy

If iron replacement is needed for anemia of chronic inflammation, parenteral iron administration is usually required to replenish stores because of the block in intestinal absorption (see Parenteral Administration under Iron Deficiency Anemia). In hemodialysis patients receiving erythropoietin therapy, intravenous iron therapy improves anemia and increases both ferritin and transferrin saturation levels more than oral iron replacement; however, when intravenous iron replacement raises the transferrin saturation to greater than 20%, there appears to be an increased risk for developing bacteremia, underscoring the complex relationship between iron homeostasis and immunity.

Erythropoietin therapy is currently approved for use in patients with chronic kidney disease[9] or HIV infection, and in cancer patients who are undergoing myelosuppressive treatment. In patients with chronic kidney disease, the hemoglobin concentration goal should be 10-12 g/dL in chronic kidney disease[A2] (Chapter 130) and >9 g/dL but not >11 g/dL in end-stage renal disease patients on dialysis[A2] (Chapter 131).

Patients with demonstrated iron deficiency should receive supplemental iron with intravenous iron gluconate (see the earlier discussion) while being treated with erythropoietin. There is increasing evidence that addition of iron in this setting reduces the need for higher dose erythropoietin with its attendant risks.

In patients undergoing chemotherapy for cancer whose hemoglobin is less than 10 g/dL, erythropoietin therapy improves quality of life and performance status[A] but increases the risk of thromboembolic complications and death.[A] Current recommendations are for cautious use during chemotherapy and against routine use in inpatients not receiving chemotherapy.

PROGNOSIS

The overall prognosis of anemia of chronic inflammation is determined almost exclusively by the course of the underlying disease. It is well established that the degree of anemia correlates well with the severity of the underlying disease process and therefore with levels of inflammatory cytokines. In the absence of a supervening process, anemia of chronic inflammation is not life threatening, and treatment of the anemia per se has not been proved to affect overall survival.

SIDEROBLASTIC ANEMIAS

DEFINITION

This heterogeneous group of anemias is distinguished by the characteristic finding of excessive mitochondrial iron in erythroblasts, as manifested by iron-laden, ringed sideroblasts in the bone marrow in the presence of moderate to severe anemia. These disorders result from mitochondrial defects either in the biosynthesis of the heme porphyrin ring or in the metabolism of iron. Both hereditary and acquired types of sideroblastic anemia have been described. Although often characterized by microcytic and sometimes hypochromic anemia, these disorders can manifest with normochromic normocytic RBCs; if the anemia is associated with myelodysplasia (Chapter 182), macrocytic RBC indices may be present.

EPIDEMIOLOGY

Although acquired sideroblastic anemias are relatively rare, they are much more prevalent than hereditary forms. The true incidence of acquired sideroblastic anemia is not well established, in part owing to the heterogeneity of causes and clinical presentations. Hereditary X-linked sideroblastic anemias usually manifest in childhood or early adulthood.

PATHOBIOLOGY

Genetics

The pathophysiologic mechanisms of hereditary sideroblastic anemias are much better understood than those of the more common idiopathic, acquired variety associated with myelodysplasia.[10,11] Two main forms of X-linked hereditary sideroblastic anemia have been characterized, and both result from defects in the heme synthesis pathway (Fig. 159-3). The first type is caused by mutations in the gene coding for erythroid-specific δ-aminolevulinic acid synthase, known as *ALAS-2*, on the X chromosome. These mutations may affect the affinity of the enzyme for pyridoxal phosphate or its structural stability, catalytic site, or susceptibility to mitochondrial proteases. In those cases in which the affinity of ALAS-2 for pyridoxal phosphate is altered, pyridoxine supplementation can ameliorate the associated anemia. The other major group of X-linked sideroblastic anemias results from defects in the adenosine triphosphate binding cassette (ABC) protein known as hABC7. The hABC7 protein is believed to be involved in iron-sulfur [FeS] cluster formation. Because [FeS] cluster–associated proteins include ferrochelatase and the cytosolic IRP-1, defects in hABC7 are believed to result in defective iron metabolism or inadequate incorporation of iron into the heme porphyrin ring by ferrochelatase. This type of X-linked sideroblastic anemia is associated with ataxia.

In addition to the two X-linked causes, both autosomal dominant and recessive forms of hereditary sideroblastic anemia have been described. However, the exact mechanisms involved in these disorders are not known.

Other types of hereditary sideroblastic anemia are believed to result from mutations in the mitochondrial genome rather than in nuclear genes. The inheritance of these disorders is complex, owing to the exclusively maternal inheritance pattern of mitochondria; the ovum is the only source of embryonic mitochondria.

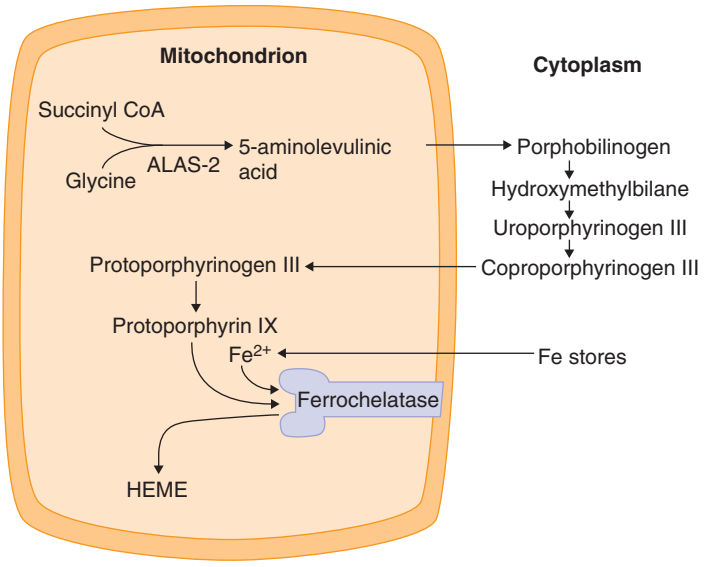

FIGURE 159-3. **The heme synthesis pathway.** ALAS-2 = δ-aminolevulinic acid synthase; CoA = coenzyme A.

Exposure to Drugs or Toxins

The most common form of acquired sideroblastic anemia results from nutritional deficiency or exposure to exogenous drugs or toxins, especially alcohol. Although sideroblastic anemia is not a common finding in alcoholism, the high incidence of alcohol abuse in Western cultures accounts for its frequency as a cause. Alcohol directly inhibits erythropoiesis, but sideroblastic anemia is usually seen only in the setting of concurrent alcoholism and nutritional deficiencies. Other well-documented drug exposures associated with sideroblastic anemia include isoniazid, chloramphenicol, and cycloserine. Sideroblastic anemia has also been attributed to lead exposure (Chapter 22), but there are limited primary data to support this association. Deficiency of pyridoxine causes sideroblastic anemia in animals and may also occur in the setting of alcoholism in humans, although ethanol is believed to be an antagonist of the interaction of pyridoxal phosphate with 5-aminolevulinic acid as a cofactor in the first step of heme biosynthesis. Copper deficiency, though rare, has also been associated with sideroblastic anemia, usually in the setting of an overdose of bivalent cation chelators such as penicillamine or trientine, used to treat the copper overloading found in Wilson disease (Chapter 211).

Idiopathic Forms

The major cause of acquired sideroblastic anemia is idiopathic, in association with myelodysplastic syndromes (Chapter 182). Refractory anemia with ringed sideroblasts is characterized by abnormalities in all three hematopoietic cell lineages, in addition to the presence of ringed sideroblasts.[12]

A second form, known as pure sideroblastic anemia, is less frequently associated with cytogenetic abnormalities, is characterized by dysplasia only in erythroid progenitors, and lacks cytopenias other than anemia. The prognosis in this type of acquired idiopathic sideroblastic anemia is much better than that in refractory anemia with ringed sideroblasts, in part because of a very low incidence (about 10%) of evolution to acute leukemia.

Because of the important differences in prognosis, it is imperative to evaluate cytogenetics and marrow morphology at the time of diagnosis. Recent evidence suggests that mitochondrial DNA mutations and attendant mitochondrial cytopathies account for many, if not all, cases.

CLINICAL MANIFESTATIONS

Because of the heterogeneous nature of the sideroblastic anemias, many of the clinical manifestations vary according to the underlying pathophysiologic cause. The anemia is usually moderate to severe, with hemoglobin levels in the range of 4 to 10 g/dL. The peripheral blood smear frequently reveals hypochromia, often with basophilic stippling. Microcytosis is often seen in hereditary forms, but normochromic, normocytic, or even macrocytic RBCs may be seen, especially in the setting of myelodysplasia or in a rare X-linked hereditary form known as Pearson syndrome.

DIAGNOSIS

The most useful diagnostic laboratory test for sideroblastic anemia is bone marrow morphology with Prussian blue iron staining, which reveals abnormally large and numerous bluish green siderosomes within at least 15% of erythroblasts, giving the characteristic appearance of ringed sideroblasts (Fig. 159-4). These ringed sideroblasts distinguish this disorder from iron deficiency anemia and anemia of chronic inflammation. Bone marrow findings in idiopathic acquired sideroblastic anemias include dyspoietic features of erythroid and/or myeloid and megakaryotic cell lineages.

Iron studies usually reveal normal iron stores or evidence of iron overload, which is caused by the ineffective erythropoiesis found in sideroblastic anemia as well as by the transfusion therapy often required for its treatment. Iron deficiency can occur coincident with sideroblastic anemia, complicating

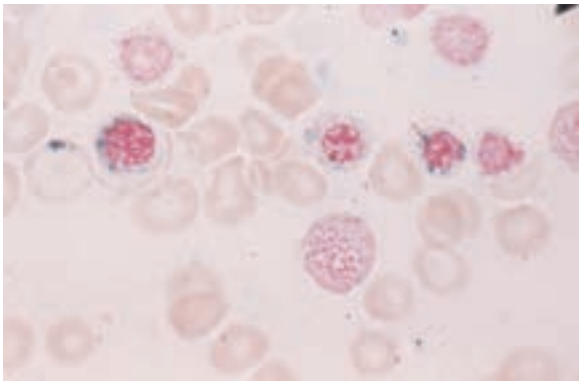

FIGURE 159-4. Sideroblastic anemia. Prussian blue iron stain of the bone marrow shows ringed sideroblasts, which are nucleated red blood cell precursors with perinuclear rings of iron-laden mitochondria.

the diagnosis owing to the lack of characteristic ringed sideroblasts, particularly in myelodysplastic syndromes in which thrombocytopenia leads to GI blood loss. If coexisting iron deficiency is suspected, a repeat bone marrow examination after iron repletion has failed to correct the anemia reveals the diagnostic ringed sideroblasts.

TREATMENT

Rx

Treatment of Underlying Disease

Most forms of sideroblastic anemia lack a specific therapy aimed at the underlying mechanism. Exceptions are those types caused by alcohol or drugs, for which removal of the offending agent usually results in resolution, or at least improvement, of the anemia. Abstinence from alcohol usually reverses the abnormalities in heme biosynthesis in 1 to 2 weeks, as evidenced by the disappearance of ringed sideroblasts in the marrow.

Pyridoxine markedly improves the relatively rare cases of nutritional deficiency, which are usually associated with alcoholism, and some forms of X-linked hereditary sideroblastic anemias in which the binding of pyridoxine by ALAS-2 is defective. Because of its low toxicity in moderate doses, a trial of pyridoxine, 100 to 200 mg/day orally for up to 3 months, is worthwhile in all patients. In responsive cases, reticulocytosis occurs within 2 to 3 weeks, and the hemoglobin level improves over several months. High-dose pyridoxine has been shown to overcome the defect in ALAS-2 activity in some patients with X-linked sideroblastic anemia, but prolonged high-dose therapy can be associated with peripheral neuropathy.

Transfusion

The mainstay of therapy for most severe sideroblastic anemias remains RBC transfusions. Because of the risks of long-term transfusion therapy, treatment should be aimed at achieving a normal performance status rather than a specific target hemoglobin level. Iron stores should be monitored regularly, and iron chelation therapy should be used in the setting of iron overload.

Erythropoietin

Therapy with erythropoietin, with or without granulocyte colony-stimulating factor (G-CSF), benefits a small percentage of patients with acquired sideroblastic anemia due to myelodysplasia. A meta-analysis of 17 studies in which 205 patients were treated with erythropoietin showed an overall response rate of only 16%. However, patients with a diagnosis other than refractory anemia with ringed sideroblasts who were not transfusion dependent had response rates greater than 50%, whereas none of the patients who had refractory anemia with ringed sideroblasts and a serum erythropoietin level greater than 200 U/L responded. Studies using a combination of erythropoietin and G-CSF showed somewhat higher response rates, although none of these studies was large or randomized. Allogeneic bone marrow transplantation (Chapter 178) benefits eligible patients whose myelodysplasia (Chapter 182) has a high risk for evolving into acute leukemia.

PROGNOSIS

As with the underlying pathophysiology, the prognosis in sideroblastic anemias is highly variable. Secondary acquired forms of the disease due to alcohol or toxins respond well to withdrawal of the offending agent, with rapid and often complete normalization of erythropoiesis. The pure sideroblastic anemia variant of myelodysplasia-associated sideroblastic anemia can usually be managed well for many years with transfusions and, if necessary, concordant iron chelation therapy. Other myelodysplasia-related sideroblastic anemias generally have a poor prognosis because of the frequent coexistence of pancytopenia and the relatively high incidence of progression to acute leukemia.

REVIEW QUESTIONS

1. A 60-year-old woman with a history of chronic arthritis that is currently under good control presents with symptoms of increased fatigue. She is noted to have a decreased hemoglobin of 8 g/dL and microcytic indices on her complete blood count. There is no evidence of blood loss by history or laboratory testing. The patient has a normal erythrocyte sedimentation rate (ESR) and a normal C-reactive protein (CRP) level. Which of the following routine laboratory tests is most likely to indicate whether this patient will respond to oral iron replacement with improvement in her hemoglobin level?

A. Transferrin saturation level
B. Serum ferritin level
C. Serum iron level
D. Vitamin B_{12} level
E. Reticulocyte count

Answer: B The ferritin level is generally the best clinically available indicator of available iron for erythropoiesis. Although inflammation associated with arthritis could falsely elevate the estimation of iron stores associated with ferritin, this patient's arthritis is not highly active, as shown by the normal ESR and CRP level. Elevated CRP and ESR are indicative of even subclinical inflammation. Because these are normal, a ferritin level in this individual would likely indicate whether there is iron deficiency. Moreover, there are criteria for correcting ferritin levels in the presence of low or moderate inflammation.

The use of soluble transferrin receptor (sTfR) assay and sTfR/ferritin ratio may provide a more accurate test for iron deficiency than ferritin level in the setting of inflammatory disease. However, this test is not routinely available, and a recent meta-analysis suggests that further data are needed to define its overall diagnostic usefulness. (See Diagnosis under Iron Deficiency Anemia.) (Thurnham DI, McCabe LD, Haldar S, et al. Adjusting plasma ferritin concentrations to remove the effects of subclinical inflammation in the assessment of iron deficiency: a meta-analysis. *Am J Clin Nutr.* 2010;92:546-555; Infusino I, Braga F, Dolci A, et al. Soluble transferrin receptor (sTfR) and sTfR/log ferritin index for the diagnosis of iron-deficiency anemia: a meta-analysis. *Am J Clin Pathol.* 2012;138:642-649.)

2. A 55-year-old man with metastatic colon cancer presents 6 months after completing chemotherapy with complaints of fatigue. His complete blood count shows a hemoglobin level of 10 g/dL with microcytic, normochromic indices, and his serum ferritin level is in the high-normal range. He has no history or physical findings of cardiovascular disease. He requests some kind of treatment for his anemia. Which of the following is the most appropriate recommendation?

A. Erythropoietin injections to increase his hemoglobin level
B. Begin red cell transfusions to maintain a hemoglobin of 12g/dL or higher
C. Advise that his fatigue may be somewhat affected by his hemoglobin level but that treatment to increase his hemoglobin level alone is unlikely to improve his symptoms and carries significant risks
D. Oral folate replacement
E. Oral pyridoxine therapy

Answer: C Although erythropoietin injections have been documented to improve quality of life and performance status in patients with cancer and a hemoglobin of less than 10 g/dL who are undergoing chemotherapy, strong data supporting this therapy in patients with a hemoglobin of 10 g/dL or higher is lacking. The same is true for red cell transfusions, in the absence of symptomatic cardiovascular disease. In cancer patients not on chemotherapy, large meta-analyses of randomized trials have shown increased mortality and cancer progression in those treated with erythropoietin for anemia. In the absence of documented folate deficiency or sideroblastic anemia, there is no clear evidence that either folic acid replacement or pyridoxine therapy is of benefit in this setting. (See Treatment under Anemia of Chronic Disease and Inflammation.) (Ludwig H, Crawford J, Osterborg A, et al. Pooled analysis of individual patient-level data from all randomized, double-blind, placebo-controlled trials of darbepoetin alfa in the treatment of patients with chemotherapy-induced anemia. *J Clin Oncol.* 2009;27:2838-2847; Bohlius J, Schmidlin K, Brillant C, et al. Recombinant human erythropoiesis-stimulating agents and mortality in patients with cancer: a meta-analysis of randomised trials. *Lancet.* 2009;373:1532-1542.)

3. An otherwise healthy 20-year-old woman with a history of excessive menstrual bleeding and increased fatigue was found to have a hemoglobin of 7 g/dL with microcytic, hypochromic indices, a low ferritin level, a low serum iron level, and reticulocyte count of 1.2%. Her menstrual bleeding pattern was normalized by hormone therapy, and she was begun on oral iron replacement with ferrous sulfate 350 mg three times daily. After 2 months, her hemoglobin was 8 g/dL, and there was no change in her other hematologic test results. After a full course of 2 g of intravenous iron gluconate, her hemoglobin, red cell indices, and iron level were partially corrected, but she remained somewhat anemic with a hemoglobin of 10 g/dL. A C-reactive protein (CRP) level and an ??$_1$-acid glycoprotein (ACP) level were both normal. Which of the following laboratory tests would be most helpful to potentially explain her lack of complete response to iron therapy?

A. Reticulocyte count
B. Serum vitamin B_{12} level
C. Bone marrow biopsy
D. Genetic analysis for mutation in the *TMPRSS6* gene
E. RDW on automated complete blood count

Answer: D This patient presents with classic routine laboratory findings of iron deficiency anemia. The failure to respond to oral iron replacement therapy suggests some reason for refractoriness to iron absorption. The patient is otherwise healthy, with no findings suggestive of malabsorption or inflammation or other reason to have high hepcidin levels that could account for this. However, the fact that intravenous iron supplementation only partially corrects the patient's anemia and iron deficiency suggests the presence of an excessive hepcidin level. Because the CRP and ACP levels were normal, demonstrating no evidence of inflammation to account for an elevated hepcidin level, it could be caused by a mutation in the *TMPRSS6* gene, which encodes the matriptase-2 protein that acts to suppress excess hepcidin production. Mutations in *TMPRSS6* can be either sporadic or familial. (See Failure to Respond to Iron Therapy under Iron Deficiency Anemia.) (Guillem F, Lawson S, Kannengiesser C, et al. Two nonsense mutations in the TMPRSS6 gene in a patient with microcytic anemia and iron deficiency. *Blood.* 2008;112:2089-2097; Finberg KE. Iron-refractory iron deficiency anemia. *Semin Hematol.* 2009;46:378-386.)

4. A healthy 25-year-old man who was in a minor auto crash was found to have a microcytic, hypochromic anemia (hemoglobin 10 g/dL), unrelated to the accident, because there was no blood loss. The remainder of the complete blood count was normal. The patient was noted to be mildly ataxic but had no alcohol or drugs detectable on screening, and there was no head trauma. Serum iron level was normal, and serum ferritin level was in the high normal range. Workup for evidence of tumor or subclinical inflammation was negative, as was any history of prior drug or toxin exposure. A bone marrow showed normal hematopoiesis but demonstrated ringed sideroblasts. Which of the following tests or procedures is most likely to be useful for determining the underlying cause of this patient's anemia?

A. Upper gastrointestinal endoscopy
B. Genetic testing for mutations of the *TMPRSS6* gene
C. Serum transferrin receptor level assay
D. Genetic testing for gene mutations of the genes coding for the adenosine triphosphate–binding cassette gene *(ABC-7)* and the *ALAS-2* gene
E. Serum folate level assay

Answer: D This patient has a moderate anemia that is not symptomatic, so it could have existed for many years undetected. Despite hypochromic and microcytic red cell features, there is no evidence of occult blood loss, and specific laboratory tests for diagnosing iron deficiency and inflammatory conditions were negative. The presence of ringed sideroblasts in an otherwise healthy young male with no history of drug or toxin exposure suggests that this may be a congenital X-linked sideroblastic anemia. The two major X-linked hereditary types of sideroblastic anemia result from mutations in either the erythroid-specific δ-aminolevulinic acid synthase gene, also known as *ALAS-2*, or the adenosine triphosphate–binding cassette gene *(ABC-7)*. X-linked sideroblastic anemias are often mild with minimal or no symptoms and therefore may go undetected until a supervening process results in symptomatic anemia or they are detected incidentally, such as in this case. The presence of mild ataxia in this young male would be most consistent with a subgroup of patients with *ABC-7* gene mutations who have associated ataxia.

(See Genetics under Sideroblastic Anemias.) (Camaschella C. Hereditary sideroblastic anemias: pathophysiology, diagnosis and treatment. *Semin Hematol.* 2009;46:371-377; Harigae H, Furuyama K. Hereditary sideroblastic anemia: pathophysiology and gene mutations. *Int J Hematol.* 2010;92: 425-431.)

5. A 60-year old man with chronic renal failure who is on hemodialysis has a falling hemoglobin level despite having been on erythropoietin (epo) therapy for a documented low serum epo level. His peripheral blood smear shows microcytic hypochromic red blood cells, and serum iron levels are low, but the serum ferritin level is 120 μg/dL. A bone marrow biopsy shows absent sideroblasts, and workup for occult blood loss is negative. Which of the following therapeutic interventions is likely to be the safest and most effective for increasing the patient's hemoglobin level?

A. Oral iron supplement with ferrous sulfate
B. Intravenous iron gluconate injections
C. Doubling the dose of erythropoietin
D. Intravenous iron dextran injections
E. Oral iron supplementation with ferrous fumarate.

Answer: B The clinical setting and laboratory findings in this patient are all consistent with coexistent anemia of chronic disease and iron deficiency. The normal ferritin level is most likely due to the chronic inflammation seen in patients with renal failure on hemodialysis. Increasing the dosage of erythropoietin in this setting in the absence of increasing available iron for erythropoiesis is unlikely to be beneficial and may introduce increased risk for thrombosis. Oral iron supplementation is usually ineffective in the setting of chronic inflammation due to elevated hepcidin levels that block iron uptake by the gastrointestinal mucosa. Intravenous iron therapy has been demonstrated to be effective in increasing the response to erythropoietin in patients with chronic renal failure. Although both iron dextran and iron gluconate are effective in this setting, iron gluconate has been shown to be safer. (See Parenteral Administration under Iron Deficiency Anemia.) (Michael B, Coyne DW, Fishbane S, et al; Ferrlecit Publication Committee. Sodium ferric gluconate complex in hemodialysis patients: adverse reactions compared to placebo and iron dextran. *Kidney Int.* 2002;61:1830-1839; Goodnough LT, Nemeth E, Ganz T. Detection, evaluation, and management of iron-restricted erythropoiesis. *Blood.* 2010;116:4754-4761; Albaramki J, Hodson EM, Craig JC, et al. Parenteral versus oral iron therapy for adults and children with chronic kidney disease. *Cochrane Database Syst Rev.* 2012;1:CD007857.)

160

AUTOIMMUNE AND INTRAVASCULAR HEMOLYTIC ANEMIAS

MARC MICHEL

DEFINITION

Hemolytic anemia (HA) is defined as anemia caused by a shortened lifespan of mature red blood cells (RBCs) in the peripheral circulation. Hemolysis and accelerated destruction of RBCs can take place within the vasculature (i.e., intravascular hemolysis) or mainly in the liver and the spleen (i.e., extravascular hemolysis). HA can be the consequence of an intrinsic and often genetically determined defect of the RBC membrane (discussed in Chapter 161) or an RBC constituent (hemoglobin [Hb] structure [Chapters 162 and 163] or enzyme machinery [Chapter 161]), or HA can result from an extrinsic and usually acquired disorder of the RBC membrane (immune, infectious, toxic) (Table 160-1).

Autoimmune hemolytic anemia (AIHA) is an acquired autoimmune disease in which autoantibodies directed against autologous RBC membrane antigens lead to their accelerated destruction. The diagnosis of AIHA is thus based on the presence of a positive result on the direct antiglobulin test (DAT), also known as the direct Coombs test, and on the absence of any other hereditary of acquired cause of hemolysis. In AIHA, hemolysis is mainly extravascular, but some features of concomitant intravascular hemolysis may also be present at onset. Beyond AIHA, other causes of immune-mediated HAs that do not involve autoantibodies may occur, as with certain drug-induced HAs or in a posttransfusional hemolytic reaction because of the presence of alloantibodies or other more complex mechanisms (Chapter 177). *Paroxysmal nocturnal hemoglobinuria (PNH)* is a rare and potentially life-threatening acquired clonal blood disorder with protean manifestations in which RBC membranes are highly vulnerable to damage by activated complement. The resulting chronic intravascular hemolysis is the hallmark of the classical hemolytic form of the disease, and the release of free Hb contributes to most of its clinical manifestations.

AUTOIMMUNE HEMOLYTIC ANEMIA

EPIDEMIOLOGY

Autoimmune hemolytic anemia can affect both children (mainly before the age 5 years) and adults and is estimated to have an overall (not age-adjusted) annual incidence of approximately one to three per 100,000 individuals. Whereas boys tend to be more frequently affected than girls, the female-to-male sex ratio is 1.5 to 2 in adults. Among adults, most patients are older than 40 years of age, and the peak incidence occurs around the seventh decade of

TABLE 160-1 PRINCIPAL CAUSES OF HEMOLYTIC ANEMIAS

INTRACORPUSCULAR	EXTRACORPUSCULAR
DISORDERS OF THE RBC MEMBRANE	**IMMUNOLOGIC**
Inherited	• Autoimmune HA
• Hereditary spherocytosis	• Alloimmunization
• Elliptocytosis	• Drug-induced HA
• Hereditary stomatocytosis	**MECHANICAL**
Acquired	• Thrombotic thrombocytopenic purpura
• Paroxysmal nocturnal hemoglobinuria	• Hemolytic-uremic syndrome
HEMOGLOBINOPATHY	• Other microangiopathies
Qualitative defect in hemoglobin	• HELLP syndrome
• Sickle cell disease	• Prosthetic heart valve dysfunction
• Unstable hemoglobins	• Acanthocytosis
Quantitative defect in hemoglobin	**INFECTIOUS**

• α-Thalassemia	• Babesiosis; *Clostridium perfringens*; gram-positive bacteria
RBC ENZYME ABNORMALITY	**TOXIC**
• G6PD deficiency	• **Exogenous:** thermal burns; industrial copper, arsine, lead poisoning, spider bite, snake bite, mushroom ingestion.
• Pyruvate kinase deficiency	• **Endogenous:** Wilson disease
• Others: pyrimidine 5′ nucleotidase deficiency	• **Drug related**

HA = hemolytic anemia; HELLP = hemolysis, elevated liver function tests, low platelets; RBC = red blood cell.

life. This age distribution may be related to the increased frequency of underlying lymphoproliferative malignancies in elderly adults, resulting in an age-related increase in secondary AIHA caused by lymphoma. Most cases of AIHAs develop sporadically; familial cases are very uncommon. AIHA usually occurs as an isolated immune "cytopenia" but can sometimes be associated simultaneously or sequentially with immune thrombocytopenia (ITP) as *Evans syndrome* or autoimmune neutropenia. Among AIHAs, the so-called warm AIHA (wAIHA; see Diagnosis and Classification section) accounts for 70% to 80% of all cases in adults and almost 90% of the cases in children. Whereas *paroxysmal cold hemoglobinuria (PCH)* is a very uncommon AIHA subtype seen almost exclusively in children, *cold agglutinin disease (CAD)* occurs almost exclusively in adults older than 50 years of age. AIHA can be primary (or idiopathic), or it can occur in association with or disclose an underlying disease (secondary AIHA).

PATHOBIOLOGY

The pathogenesis of AIHA is a complex multistep process involving not only the autoantibodies but also various effectors of the immune system, including the complement system, macrophages, and B and T lymphocytes. Whereas the mechanisms leading to hemolysis have been partially elucidated (antibody-dependent, cell-mediated cytotoxicity, and complement-dependent cytotoxicity being primarily involved), the mechanisms leading to the breakdown of self-tolerance are far from fully understood.

Red Blood Cell Antibodies

IgG anti–RBC autoantibodies mediate the destruction of RBCs mainly by the process of extravascular hemolysis. In contrast, when lytic components of the complement system participate in the process, the destruction of RBCs usually occurs directly within the circulation (intravascular hemolysis). The participation of lytic complement components in IgG-mediated AIHA is rare.

In warm (or warm-reactive) AIHA, the autoantibody targeting RBCs is mainly of the IgG1 isotype. It is able to bind macrophages via its Fc-γ receptors, thereby causing extravascular hemolysis to take place mainly in the spleen. The autoantigens on RBC membranes targeted by the autoantibody are, in decreasing frequency, the following: (1) peptides from the Rhesus system (~one third of the cases); (2) band 3 protein; and (3) glycophorin A, an RBC membrane glycoprotein. In other cases, the antibodies have specificity for antigens in the Kell or Duffy blood group system (very rarely the ABO antigens), and in less than 10% of cases of wAIHA, no specificity can be found. Cold agglutinins are IgM antibodies that react with polysaccharides on the RBC surface, mainly with the I/i antigens or less commonly with the Pr glycoprotein and sialylated polysaccharides. Whereas cold agglutinins associated with *Mycoplasma pneumoniae* infection have an anti-I specificity, those related to infectious mononucleosis have anti-i specificity. In CAD, the cold autoantibodies are almost always anti-I monoclonal IgM antibodies with a VH4-34 heavy chain, a heavy-chain shape of the antigen-binding surface that favors attachment to polysaccharides.

Mechanism of Antibody-Mediated Red Blood Cell Destruction

IgG anti–RBC autoantibodies are opsonins; when bound to autoantigens on RBC membranes, they instigate phagocytosis of the cells by macrophages. Using its Fcγ receptors, the macrophage can ingest an entire IgG-coated erythrocyte or transform it into a spherocyte (microspherocyte) by nibbling away its surface. Antibody-coated spherocytes are more vulnerable to osmotic forces than normal, unsensitized RBCs and ultimately surrender to macrophages, especially in the splenic sinusoids, where blood flows sluggishly. The rate of hemolysis in AIHA depends on the amount of autoantibody on the RBC surface, the affinity and avidity of autoantibodies for the RBC autoantigen, and the number of macrophages in the environment of the antibody-coated erythrocyte. Populations of autoantibodies with high avidity cause a higher rate of RBC destruction than populations with low avidity. Free (monomeric) IgG competes with antibody-coated RBCs for interaction with the Fc receptors of macrophages, but the IgG normally present in plasma has only a minor influence on the hemolytic rate. The importance of the subclasses of IgG is unclear, but IgG3 antibodies seem more potent than IgG1 antibodies in promoting phagocytosis.

The basis of RBC destruction in CAD is the ability of IgM antibodies to fix complement, with each IgM molecule having two binding sites for C1q. When blood cools sufficiently in the extremities, it allows the cold agglutinins to bind RBC. The adherent IgM attracts C1q, which initiates the generation of C3b and C4b on the RBC's surface. On entering the warmer visceral circulation, the RBC releases the cold agglutinin, but the C3 fragments remain engaged to the CR1 of macrophages, thereby enabling phagocytosis of the RBC.

The efficiency of this process depends on the amount of cold agglutinin on the RBC surface and the thermal amplitude of the cold agglutinin. These factors account for the great variability of severity in CAD. The abnormal production of autoantibody directed toward RBC antigens could be the consequence of different and nonmutually exclusive mechanisms: an immune response toward some cryptic antigens or molecular mimicry with cross reactivity between external antigens and autoantigens. Polyclonal activation of both B and T cells is likely to play a role in wAIHA. A positive DAT result is more frequently observed in patients with chronic infections with hypergammaglobulinemia such as HIV (Chapter 393) or leishmaniasis (Chapter 348). In other noninfectious settings with hypergammaglobulinemia and immune dysregulation such as in the *autoimmune lymphoproliferative syndrome (ALPS)* or in *angioimmunoblastic T-cell lymphoma*, a significant proportion of patients have a positive DAT result with or without active hemolysis. Regarding T-cell activation, there is a disequilibrium of the CD4+ T helper 1(Th1)/Th2 balance in patients with active AIHA compared with healthy control participants, with an increase of Th2 cells subsets and an increased expression of both interleukin-4 (IL-4) and IL-10 and a reduced expression of interferon-γ and IL-12. This "Th2 pattern" promotes the induction and proliferation of autoreactive B cell clones. More recently, it has been shown that the production of the effector cytokine IL-17 is strongly associated with AIHA compared with healthy donors and correlates with the severity of the disease. This observation suggests some future therapeutic potential for the use of anti-IL17 monoclonal antibodies in AIHA.

The role of a regulatory T cells (Tregs) defect in the loss of tolerance in wAIHA has been mainly suggested through the study of animal models (e.g., New Zealand Black mice). In humans, few data on the potential role of Tregs in AIHA is available. Some Tregs specific for autoantigens from the Rhesus system are able to inhibit the Th1 effector immune response in vitro through an IL-10–dependent mechanism. Indirect evidence suggesting that a decrease in the number or function of Tregs is likely to play a role in AIHA in humans comes from the **immune dysregulation polyendocrinopathy enteropathy X-linked** (IPEX) syndrome (Chapter 250). IPEX syndrome is a rare inherited disease linked to the dysfunction of the transcription factor FOXP3, widely considered to be the master regulator of the regulatory T-cell lineage. Patients diagnosed with an IPEX syndrome have a high risk of developing a number of autoimmune manifestations (enteropathy; endocrinopathies, including diabetes), including in a lesser extent AIHA.

CLINICAL MANIFESTATIONS

Clinical symptoms of AIHA are those of anemia (unusual fatigue, exertional dyspnea, tachycardia) or those attributable to active hemolysis (jaundice with or without dark urine). Moreover, specifically in patients with high-affinity cold agglutinins, exposure to cold can precipitate episodes of acrocyanosis by inducing massive agglutination of RBCs in the capillary circulation of the hands, feet, or both. Mild splenomegaly may be present, especially in wAIHA; splenomegaly is uncommon in CAD unless there is an underlying B-cell lymphoma. AIHA is associated with an increased risk of venous thromboembolism.[3]

The usual clinical and biologic features of AIHA are shown in Table 160-2. Elevated serum levels of indirect bilirubin and lactate dehydrogenase (LDH) and a reduced serum haptoglobin concentration are the usual albeit nonspecific signs of HA. Laboratory signs of intravascular destruction of RBCs (hemoglobinemia, hemoglobinuria, and hemosiderinuria) are unusual in the setting of AIHA. After HA has been recognized, the diagnosis of AIHA is usually rather easy. It is based first on the identification of anti-RBC autoantibody by means of the DAT, also known as the Coombs test, and then on the exclusion of other causes of HA. To rule out other causes of hereditary or acquired hemolysis, ethnicity must be taken into account, and the history should also focus on previous personal episodes of unexplained anemia with or without jaundice and any familial history of HA or splenectomy. Moreover, a careful analysis of the peripheral blood smear is essential, keeping in mind that an increase in the number of spherocytes can be observed in approximately 30% to 40% of AIHAs.

DIAGNOSIS

The Direct Antiglobulin (Coombs) Test

The DAT that reveals antibody-coated RBCs is central to the diagnosis of autoimmune HA. The indirect antiglobulin (Coombs) test was devised to test for the presence of incomplete antibodies in the patient's serum, not on RBC surfaces. As presently used, the standard antiglobulin reagent contains antibodies against all four classes of IgG and components of complement (usually C3 and C4).

A positive DAT result requires cautious interpretation when there are no other features of AIHA. False-positive test results are not unusual. The reported incidence of positive DATs in normal blood donors and general populations of hospitalized patients varies widely, from one in 100 to one in 15,000. Differences in the technique used to perform the test account for this variation. The usual reason for a false-positive DAT result is nonspecific, low-avidity adherence of IgG to RBCs. In rare cases, however, the result is not a false-positive result but a harbinger of the development of AIHA. False-negative DAT results in true AIHA are very rare and are usually due to low-affinity autoantibodies that spontaneously elute from the RBC in vitro or to amounts of erythrocyte-coating antibodies that are below the limit of detection by the antiglobulin test. Before considering the diagnosis of DAT-negative AIHA[4] as a possibility, every other potential cause of HA has to be excluded. The distinction between a true-positive and a false-positive DAT result can be made by eluting the antibody from the RBCs and testing its ability to bind to normal RBCs. In a false-positive reaction, the eluted antibody does not bind to normal RBCs, but binding does occur in a true-positive test.

Classification of Aiha: Warm versus Cold Autoimmune Hemolytic Anemia (see Table 160-2)

After the diagnosis of AIHA is made, the classification of the AIHA type is essential.

According to the DAT pattern and the optimal temperature at which the autoantibody reacts with human RBCs, AIHAs are typically subdivided in four major subtypes: (1) wAIHA, (2) cold AIHA (including the chronic CAD), (3) mixed-type AIHA, and (4) the exceptional PCH. The great majority of cold-reactive autoantibody are so-called "cold agglutinins," cold hemolysins being indeed much less common. A small proportion (~5%) of patients may exhibit both cold-reactive and warm-reactive autoantibodies defining mixed AIHA. The distinction between cold and wAIHA is very important because the mechanisms of RBC injury, the primary site of hemolysis, and especially the therapeutic approaches are significantly different. Table 160-2 summarizes the main features of the different types of AIHA.

In wAIHAs, which represent 70 to 80% of all AIHAs in adults, the DAT pattern is either solely IgG positive or IgG and C3 positive, autoantibodies are of IgG isotype (mainly IgG_1), and they bind and react optimally with RBCs at a temperature of 37° C (range, 35 to 40° C). In wAIHA, the hemolysis is mainly extravascular and occurs predominantly in the spleen. On the other hand, in AIHAs caused by cold autoantibodies, which account for 15% to 20% of AIHAs, the usual DAT pattern is IgG negative and C3 positive, and circulating cold agglutinins are detectable in the serum at a significant titer (i.e., >1/64). Cold autoantibodies that are also cold agglutinins are almost exclusively of IgM isotype. However, the RBC antigen-reactive IgM immunoglobulins themselves that are able to activate the classical complement pathway on RBC membranes in vivo are seldom found fixed on the RBCs membrane on laboratory testing because they are rapidly eluted ex vivo. Cold antibodies typically react with RBCs at temperatures below 30° C (optimum, 4° C) and lead to various degree of extravascular hemolysis, predominantly in the liver. In rare cases of AIHAs (~10%) known as mixed-type AIHAs, autoantibodies (mostly of IgM isotype) can react with RBCs within a wide

TABLE 160-2 MAIN CHARACTERISTICS OF VARIOUS TYPES OF AIHA

AIHA TYPE	EPIDEMIOLOGY/ TYPE OF HEMOLYSIS	SECONDARY FORMS	AUTOANTIBODY ISOTYPE	OPTIMAL TEMPERATURE	DAT PATTERN	ELUATE	AUTOANTIBODY SPECIFICITY (TARGETED RBC ANTIGENS)
Warm AIHA	~70%-80% of all AIHA; adults > children (mean age, 3 yr); EV hemolysis; subacute onset (rarely abrupt with associated IV hemolysis)	~50% of cases (see Table 160-3)	IgG ≫ IgA, IgM	37° C	IgG ± C3d	IgG	Antigens of the Rh system, band 3, glycophorin, A
Cold agglutinin syndrome	~20%-30% of all AIHA cases in adults; age >50 yr; EV hemolysis	CAD associated with monoclonal IgM κ gammopathy in 90% of cases ± features of definite clonal B-cell lymphoproliferative disorder	IgM ⋙ IgA or IgG; cold agglutinin titer >1/500	4° C	C3	Negative	I antigen > i ≫ Pr
Cold transient AIHA	Children, young adults; IV hemolysis	Infections (*Mycoplasma pneumoniae*, EBV, other viruses)	Polyclonal IgM; cold agglutinin titer ≥1/64	4° C	C3	Negative	I > i antigens
Paroxysmal cold hemoglobinuria	Children (rare); exceptional in adults; acute IV hemolysis	Infections (*M. pneumoniae,* virus)	IgG (Donath-Landsteiner hemolysin)	>30° C	C3	Negative	P + c antigens (biphasic hemolysins)
Mixed-type AIHA	Adult; mainly EV hemolysis	Mainly B-cell lymphoma	IgG, IgM	Wide range (4°-37° C)	IgG ± C3	IgG	Polyreactivity

AIHA = autoimmune hemolytic anemia; CAD = cold agglutinin disease; DAT = direct antiglobulin test; EBV = Epstein-Barr virus; EV = extravascular, Ig = immunoglobulin; IV = intravascular

range of temperatures (thermal amplitude from 4° to 37° C). Last, PCH is a very uncommon AIHA subtype that is seen almost exclusively in children. It is caused by an IgG hemolysin that reacts with autologous RBCs only at low temperatures (2° to 10° C) and can be detected only by means of the Donath Landsteiner test, a test available only in few referral laboratories. Besides these four distinct subtypes of AIHAs, drug-induced HAs must be regarded as a distinct entity.

In addition to the distinction between warm and cold AIHA, which is an essential step in diagnosis because it does influence the therapeutic strategy, AIHAs are also classified as (1) primary (or idiopathic) or (2) secondary, depending on the presence or absence of an underlying disease or condition promoting immune dysregulation. On average, 50% to 60% of wAIHAs are secondary (see Table 160-3 for associated conditions); therefore, a minimal workup must be performed at time of diagnosis in every patient to search for an underlying disease or condition (Table 160-4). It is important to emphasize that a presumably primary form of wAIHA can precede by many years the occurrence of a non-Hodgkin lymphoma, and therefore patients with wAIHA must be followed even after a remission of AIHA has been obtained.

Regarding AIHAs due to cold autoantibodies, in children and young adults they are mainly secondary to either bacterial (*M. pneumoniae* infection) or viral (Epstein-Barr virus [EBV] or cytomegalovirus) infection. In adults older than 50 years of age, although rare, chronic CAD is by far the most common cause of AIHA caused by cold autoantibodies.[5] Although chronic CAD in an older adult has long been considered as a primary (i.e., idiopathic) form of AIHA, it is now recognized that in about 90% of cases, it is associated with a monoclonal IgM κ and with other features of a clonal B-cell lymphoproliferative disorder in approximately 75% of cases. Thus, chronic CAD should be viewed more as a true lymphoproliferative disease characterized by clonal expansion of B cells with most often features of lymphoplasmacytic lymphoma in the bone marrow. HA is seldom very severe in the setting of chronic CAD, and it is classically exacerbated by exposure to cold or infections.

TABLE 160-3 MAIN DISORDERS OR CONDITIONS ASSOCIATED WITH SECONDARY WARM-REACTIVE AUTOIMMUNE HEMOLYTIC ANEMIAS

Hematologic disorders and lymphoproliferative diseases
- Chronic lymphocytic leukemia,* acute lymphoblastic leukemia,† LGL leukemia
- B-cell lymphoma,* Hodgkin lymphoma
- Angioimmunoblastic T-cell lymphoma
- Castleman disease
- Myelodysplasias, myelofibrosis

Solid tumors
- Thymoma
- Ovarian dermoid cyst
- Carcinomas

Autoimmune and inflammatory diseases
- Systemic lupus erythematosus, antiphospholipid syndrome
- Rheumatoid arthritis
- Inflammatory bowel disease
- Pernicious anemia, thyroiditis
- Myasthenia gravis
- Autoimmune hepatitis, giant cell hepatitis*
- Sarcoidosis
- Eosinophilic fasciitis

Infections
- Viruses: EBV,* hepatitis C, CMV
- Bacteria: tuberculosis, brucellosis, syphilis

Drugs

Primary immunodeficiencies
- Common variable immunodeficiency
- Hyper-IgM syndrome,† ALPS†
- IPEX syndrome,† APECED syndrome†

Others
- Pregnancy
- After allogeneic bone marrow transplantation or liver or small bowel transplant*
- Rosai-Dorfman disease

*Diseases that can also be associated with cold autoimmune hemolytic anemia and cold agglutinins.
†Seen almost exclusively in childhood.
ALPS = autoimmune lymphoproliferative syndrome; APECED = autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy; CMV = cytomegalovirus; EBV = Epstein-Barr virus; IPEX = immune dysregulation, polyendocrinopathy, enteropathy X-linked.
LGL = large granular lymphocytes.

TREATMENT

Rx

The management of AIHA is, regardless the subtype, mainly empirical or based on retrospective uncontrolled studies. Very few prospective studies have been reported (mainly in CAD), and only two randomized controlled studies have been performed in wAIHA to date.

Supportive Care and Transfusion

Regardless the type of AIHA, folic acid supplementation (5-10 mg/day) is warranted in patients with active AIHA to prevent further depletion of folate stores (caused by increased erythropoiesis), which may be misinterpreted as a treatment failure. RBC transfusions are also indicated in patients with disabling symptoms of anemia or a poor underlying cardiovascular condition (i.e., coronary artery disease or heart failure). Although younger patients may tolerate a stable Hb level as low as 6 g/dL, in patients with comorbidities, maintaining an Hb level of at least 8 g/dL is usually recommended. It is important for the managing physician to understand that no patient with symptomatic AIHA should be denied blood transfusions because of an "incompatible crossmatch." The blood bank should be informed of the patient's status. Indeed, the patient's positive DAT result almost always interferes with compatibility testing, so the role of the blood bank is to provide packed RBCs that are the "least incompatible" ones in regard to the specificity of the patient's autoantibody. It is possible that DNA-based methods might become clinically feasible to replace hemagglutination assays in these situations in the future.[6] Close communication and cooperation between the clinician and the specialist in transfusion medicine is therefore essential for reducing the risks associated with transfusion in patients with AIHA. Because transfused RBCs can be destroyed by the patient's autoantibodies, rapid transfusion of large volumes of RBCs must be avoided because they can have serious consequences. This risk is increased if the patient also has alloantibodies induced by previous transfusions or pregnancy. Packed RBCs units should therefore not be administered at a rate that exceeds 1 mL/kg/hour. There is no strong evidence supporting the efficacy of plasma exchange in enhancing the response to blood transfusions.

Although this is not supported by strong evidence-based data, in cold AIHA, it is usually recommended to transfuse prewarmed (at a temperature close to 37° C) packed RBCs by means of a specific warming device to minimize the risk of hemolysis.

Treatment of Acute Cold Autoimmune Hemolytic Anemias

In cases of transient cold AIHAs induced by an infection, the onset is usually abrupt, and the degree of anemia may be profound and sometimes life threatening, requiring transfusions of prewarmed packed RBCs, which must not be postponed. Besides supportive care, the use of antibiotics is justified in case of pneumonia caused by infection with *M. pneumoniae*. A short course of corticosteroids can sometimes be considered in case of severe cold AIHA secondary to a viral infection (EBV) to reduce the duration of anemia, but this approach is not evidence based and not uniformly recommended.

Treatment of Chronic Cold Agglutinin Disease

The treatment of CAD has long been only supportive and symptomatic. Avoidance of cold is still the mainstay in the management of CAD, especially to avoid cold-induced circulatory symptoms, but this measure is often not sufficient to avoid episodes of hemolysis. With cold exposure, in cases of infections and acute phase reactions, the level of both C_3 and C_4 increase because of enhanced production, resulting in exacerbation of complement-dependent

TABLE 160-4 RECOMMENDED WORKUP IN WARM-REACTIVE AUTOIMMUNE HEMOLYTIC ANEMIA

1. Antinuclear antibodies (± anti-DNA Abs if ANA positive)
2. Anticardiolipin antibodies and lupus anticoagulant*
3. Serum protein electrophoresis and immunoelectrophoresis
4. Immunophenotyping of peripheral lymphocytes
5. CT scan of the thorax, abdomen, and pelvis (in the absence of obvious SLE or APS)
6. Bone marrow biopsy: recommended only in the presence of hypogammaglobulinemia, or monoclonal gammopathy, or abnormal lymphadenopathy on the CT scan

*Especially in case of previous episode of venous and/or arterial thrombosis or in case of recurrent miscarriage in women, and systematically before splenectomy.
Abs = antibodies; ANA = antinuclear antibodies; APS = antiphospholipid syndrome; CT = computed tomography; SLE = systemic lupus erythematosus.

cytotoxicity caused by autoantibody directed toward autologous RBCs, leading to increased hemolysis as well as agglutination. Consequently, prompt treatment of febrile infections or illnesses as well as prevention of infection by means of influenza with or without pneumococcal vaccines is strongly recommended in patients with CAD. In case of exacerbation of hemolysis and severe anemia, transfusion of prewarmed packed RBCs must be considered because patients with CAD are often elderly with comorbid conditions. Whereas CAD is usually considered a rather indolent and slowly progressive lymphoproliferative disease with a relatively good prognosis, transfusion dependency may be observed in some patients with recurrent episodes of active hemolysis.

In patients with CAD who have active hemolysis and need to be treated, a number of single-agent therapies have shown little or no efficacy, and their use should therefore be avoided because they all have a significant toxicity. These include corticosteroids, alkylating agents, interferon-α, immunosuppressives, and cladribine. Oral cyclophosphamide and chlorambucil have shown favorable responses in a minority of patients with CAD. Because hemolysis takes place mainly in the liver in CAD, splenectomy should be avoided in these individuals because it is notoriously ineffective. In transfusion-dependent patients with normal or slightly elevated reticulocyte counts, the transient use of an erythropoiesis-stimulating agent off label may be useful as a transfusion-sparing strategy. Plasma exchanges can be temporarily helpful in cases of severe hemolysis or in preparation for surgery requiring cold exposure, such as lung–heart surgery. For patients with active or relapsing symptomatic episodes of HA, rituximab given either alone or in combination with fludarabine can be an option, especially in patients with an underlying B-cell lymphoma. An algorithm for the management of cold AIHAs is proposed in Figure 160-1. Last, because the hemolytic activity of cold agglutinins is complement dependent, the efficacy of eculizumab, an anti C5 humanized monoclonal antibody licensed in PNH (see later section Paroxysmal Nocturnal Hemoglobinuria), seems theoretically promising. Because only very few case reports have shown the efficacy of eculizumab, this approach should be only considered as a last-resort option in case of life-threatening exacerbation of HA not controlled by RBC transfusions.

Treatment of Primary Warm Autoimmune Hemolytic Anemias

First-line Treatment: Corticosteroids

Primary wAIHAs usually have a chronic course and, except for the very few patients who are unusual for having a mild compensated hemolysis with a normal or almost normal Hb level, treatment is needed in the large majority of the cases to improve RBC survival and significantly and durably increase the Hb level (Fig. 160-2). Corticosteroids are the cornerstone of therapy in wAIHAs, and they must be given as first-line treatment. As noted later under the discussion of rituximab, a recently reported randomized trial showed that rituximab and prednisolone combined, compared with prednisolone alone, increased the rate and duration of response as first-line treatment of warm antibody-reactive AIHA. Intravenous immunoglobulin (IgIV) has only little efficacy in wAIHAs, and because of their cost, they should be considered (at a total dose of 2 g/kg over 2 days) only in patients with severe, transfusion-dependent AIHA and in the absence of response to corticosteroids. The corticosteroid regimen is usually based on oral prednisone or prednisolone at the initial daily dose of 1 to 2 mg/kg. By analogy with other autoimmune diseases, the use of intravenous methylprednisolone at a dose of 250 to 1000 mg/day for 1 to 3 days may be considered in patients with profound anemia, although no clinical trials supporting their higher efficacy are available. The starting dose of oral prednisone is usually maintained for 3 to 4 weeks and then tapered progressively in case of at least partial initial response. There is no agreement on the total duration of treatment, but because the likelihood of early relapse is high when the treatment is prematurely stopped, corticosteroids should be maintained for at least 3 months after a complete response (defined by an increase of the Hb level back to normal and no active hemolysis) is achieved. Except for children, the use of alternate-day prednisone before stopping the treatment is not recommended. The effect of corticosteroids can take few days to 2 weeks, and one or several blood transfusions may be necessary at AIHA onset, especially in case of severe anemia in young children or elderly adults for maintaining a "safe" Hb level. After 2 to 3 weeks of treatment with corticosteroids, a clinically significant response is observed in 80% to 85% of the cases. Except for the few patients who are truly refractory to corticosteroids, the major issue that clinicians have to deal with when treating patients with wAIHA is that approximately 50% to 60% of them turn out to be dependant to corticosteroids. Thus, flares of relapses or wAIHA may occur either within weeks after withdrawal of corticosteroids or even while on treatment when the dose of daily prednisone is decreased below a threshold, which is usually between 10 to 15 mg, a dose that is associated with several adverse events in the long term. Overall, only one third of the patients can be considered to be in complete remission off treatment 1 year after disease onset.

Second-line Treatment

Danazol

In patients dependent on corticosteroids, the use of danazol, an attenuated androgen analog, at 400 to 800 mg/day can be helpful as a corticosteroid-sparing strategy in adults requiring a dose of daily prednisone greater than 15 mg to maintain a remission. However, because of its common masculinizing side effects, its use is usually rather limited in females, and its potential liver toxicity makes its long-term use also problematic in men.

Rituximab

The efficacy of rituximab, the well-known chimeric monoclonal antibody that targets CD20 antigen on B lymphocytes, was first shown in refractory wAIHA in children with a response rate reaching up to 100% in some studies. In adults, rituximab has also shown (both through retrospective but also a few prospective studies, including a randomized controlled trial) to be highly effective in primary wAIHAs, with an 80% to almost 100% response rate at 1 year. Rituximab can be effective in patients who have failed to respond to splenectomy (see later discussion),[7] and, conversely, patients who do not respond to rituximab are able to achieve a response after splenectomy. The

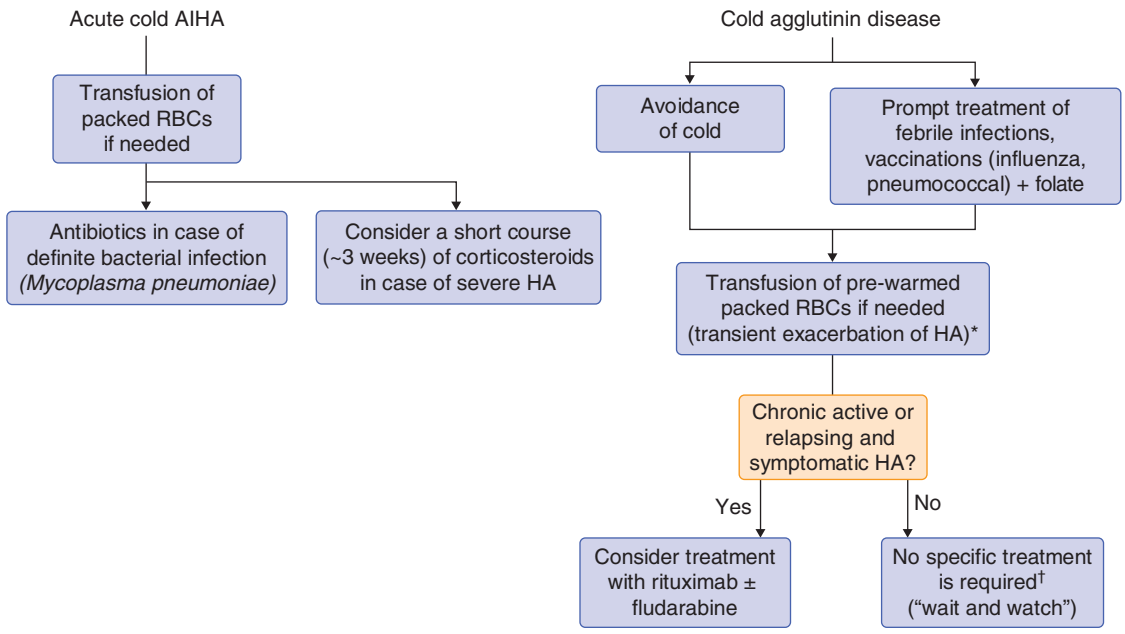

FIGURE 160-1. Proposed algorithm for the management of cold-reactive autoimmune hemolytic anemias (AIHAs). HA = hemolytic anemia; RBC = red blood cell. *The short-term use of an erythropoiesis stimulating agent can be considered off-label; †Unless the underlying B cell-clonal lymphoproliferative disorder requires any specific management.

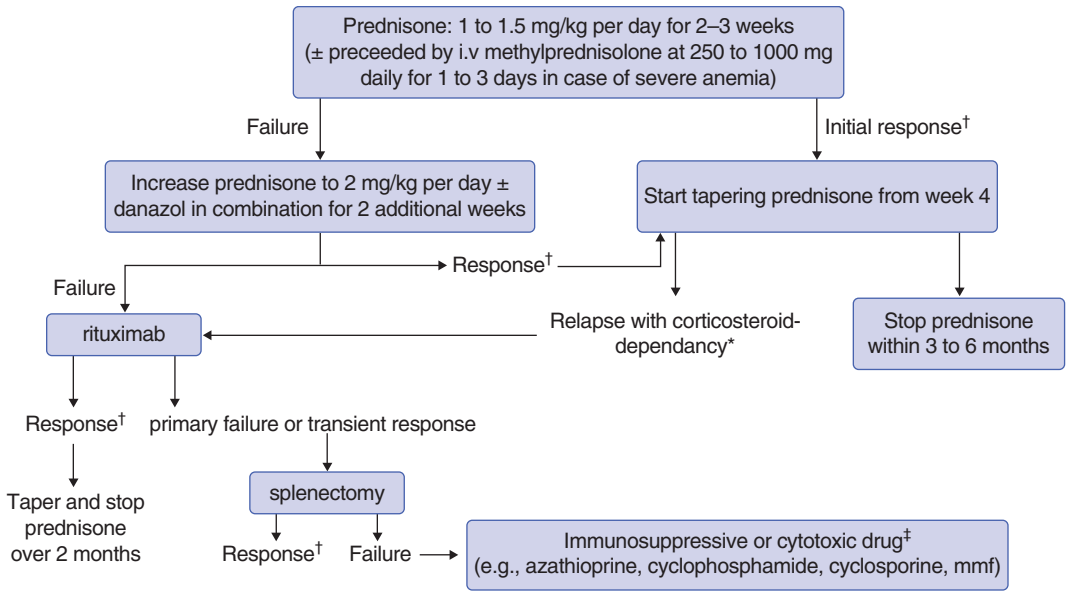

FIGURE 160-2. Proposed algorithm for the treatment of primary warm-reactive autoimmune hemolytic anemia (AIHA) in adults. IV = intravenous; mmf = mycophenolate mofetil. *Dose of prednisone ≥10 mg/day needed to maintain at least a partial response (i.e., Hb level >10g/dL with at least a 2 g increase from baseline without recent transfusion). †Partial response defined as a hemoglobilin level >10g/dL with at least a 2 g increase from baseline and complete response defined as a normal hemoglobin level withouth hemolysis. ‡In alphabetical order (no evidence for preferring any one of these drugs).

usual dose of rituximab is 375 mg/m^2 by intravenous infusion once a week for 4 weeks, but other regimens can be used. The safety profile is usually acceptable, although late-onset neutropenia and opportunistic infections, such as *Pneumocystis jiroveci* pneumonia, may rarely occur. Therefore, the systematic use of primary antibiotic prophylaxis should be considered in patients with AIHA treated with rituximab. Taken together the data from the literature clearly support, whenever possible, the use of rituximab (off-label use) in patients with chronic active or relapsing wAIHA who need to pursue a daily dose of prednisone (or prednisolone) of 15 mg or greater to maintain at least a partial remission. If rituximab is administered before splenectomy, vaccination against *Streptococcus pneumoniae* with or without *Haemophilus influenzae* type B or *Neisseria meningitides* must be systematically administered whenever possible 2 weeks before rituximab because splenectomy may be required thereafter.

Splenectomy

Splenectomy has long been the main and preferred second-line option for the treatment of primary wAIHAs. The rate of sustained response after splenectomy is approximately 60% to 70% according to the most recent data from the literature, but predicting factors of response are still lacking. The perioperative risk of laparoscopic splenectomy is low and acceptable with a mortality rate of less than 1%. The most feared complication remains the rare but unpredictable risk of overwhelming sepsis. Laparoscopy does not reduce the risk of postoperative thromboembolic complications, especially in the portal vein system. A systematic perioperative course of low-molecular-weight heparin is therefore recommended in patients with wAIHA who undergo splenectomy and especially in those who have positive antiphospholipid antibodies. The best time for splenectomy is controversial now that alternatives such as rituximab are available at least in some countries. In children younger than 5 to 7 years of age, this procedure should be avoided and delayed as long as possible. In adults, it must be considered early in the course of the disease in patients who fail to respond to corticosteroids (or need high and unacceptable doses to maintain at least a partial remission) and rituximab.

Other Treatment Lines

Immunosuppressive and Cytotoxic Agents

In patients with refractory wAIHA who have failed splenectomy and rituximab, the management is mainly based on the experience of the individual hematologist and on the few retrospective data available in the literature as opposed to prospective studies. The efficacy of azathioprine, cyclophosphamide, and to a lesser extent cyclosporine and mycophenolate mofetil has been reported in small cases series. The choice depend on the efficacy-to-safety ratio for each patient, and these drugs should be reserved for patients who have failed to respond to rituximab and to splenectomy or who, because of comorbidities, are not suitable candidates for splenectomy.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

There are several mechanisms by which a drug can induce HA, and true drug-induced AIHAs are rare.[8] Many drugs or drug metabolites have the potential to elicit antidrug antibodies. Drugs that form covalent bonds with proteins in the RBC membrane can bind antidrug antibodies to the RBC surface, causing a positive DAT result and, in some cases, initiating antibody-mediated destruction of RBCs. Other drugs, such as the cephalosporins, can bind to RBC membranes and take up IgG nonspecifically from plasma. In these cases, there is no antidrug antibody. The diagnosis of drug-induced immune-mediated HA should be considered if the patient has a history of taking a suspected medication, there is acute complement-mediated hemolysis, only complement components are detectable on the RBC surface, or the patient's serum reacts with RBCs in the presence of the suspected drug. Some drugs can induce true autoantibodies against RBCs. Fludarabine, a purine nucleoside analogue used in the treatment of chronic lymphocytic leukemia, and monoclonal antibodies against tumor necrosis factor-α (infliximab and adalimumab), T cells (alemtuzumab), α4 integrin (natalizumab), and IL-2 receptor (daclizumab) also have this property, the cause of which is unknown. Notably, there is no definitive way of distinguishing drug-induced AIHA from primary AIHA.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

DEFINITION

Paroxysmal nocturnal hemoglobinuria is a rare and potentially life-threatening clonal blood disorder with protean manifestations caused by an acquired somatic mutation in the phosphatidylinositol glycan *(PIG)-A* gene. In pluripotent hematopoietic stem cells, the mutation in *PIG-A* leads to a deficiency of glycosylphosphatidylinositol (GPI)-anchors and GPI-anchored membrane proteins, including the complement regulatory proteins CD55 and CD59 that are normally expressed on the surfaces of RBCs (and other blood cells). PNH RBCs are therefore highly vulnerable to the activation of complement (especially at times of fever, acidosis or hypoxia) and the unregulated formation of the membrane attack complex (MAC). The resulting chronic intravascular hemolysis is the hallmark of the classic hemolytic form of the disease and the release of free Hb contributes to most of its clinical manifestations (fatigue, dysphagia, recurrent abdominal pain, erectile dysfunction).

EPIDEMIOLOGY

Paroxysmal nocturnal hemoglobinuria can present at any age but most commonly between 10 and 50 years. The mean age at diagnosis is about 34 years

(median age is about 40 years), and the female-to-male ratio is close to 1. The median survival time after diagnosis is approximately 20 years. It is a rare disorder with an estimated prevalence in the population of one in 10^5 to one in 10^6. A family history of PNH is unusual.

PATHOBIOLOGY

Genetics

Paroxysmal nocturnal hemoglobinuria is caused by a somatic mutation that causes a defect in the RBC membrane.[9] The disease begins in a single hematopoietic stem cell in which the *PIGA* gene on the short arm of the active X chromosome acquires a somatic mutation. The *PIGA* gene encodes PIG-A, an enzyme that is essential for the synthesis of glycosylphosphatidylinositol (GPI). The lipid GPI forms a peptide link with the C-terminal amino acid of numerous proteins, normally anchoring them to the RBC membrane. The somatic mutation in a hematopoietic stem cell affects *PIG-A* in blood cells of all lineages. Almost 150 different mutations of *PIG-A* have been identified. Most of them inactivate *PIG-A* and cause total loss of the GPI anchor in the descendants of the affected hematopoietic stem cell. RBCs with complete deficiency of GPI are termed *PNH III erythrocytes*, and those with partial deficiency are called *PNH II erythrocytes*. The coexistence of PNH III and PNH II RBCs in the same patient indicates the presence of two mutant clones. A small number of hematopoietic stem cells in normal people bear the *PIG-A* mutation; they have no proliferative advantage and persist in small numbers. In normal blood, the frequency of PIG-A–deficient cells is about one in 50,000 RBCs. In contrast to those with PNH, however, the deficient cells in normal subjects arise from committed hematopoietic cells. The presence of PIG-A–deficient cells in normal subjects suggests that PNH involves not only the *PIG-A* mutation but also a second step, perhaps another mutation, that allows competitive expansion of the mutated clone.

Functional Consequences of Deficiency of GPI

The membrane inhibitor of reactive hemolysis (CD59, or protectin) and CD55, an inhibitor of C3 convertase, are two of the many proteins that GPI anchors to the RBC under normal circumstances. They prevent polymerization of C9, the final step in assembly of the MAC that begins with cleavage of C5 to C5b. Deficiencies of CD59 and CD55 on PNH RBC membranes thereby allow unimpeded assembly of the MAC on the erythrocyte surface (and the surfaces of other blood cells derived from the mutated hematopoietic stem cell clone), thereby initiating intravascular hemolysis. A variety of nonspecific factors, such as a reduction in the pH of blood, can activate complement. The morning hemoglobinuria of PNH is probably the result of subtle acidification of blood during sleep.

CLINICAL MANIFESTATIONS

Classically, a patient with PNH arises in the morning and passes dark urine. The typical but actually rarely described paroxysms of hemoglobinuria occur on a background of chronic, low-grade intravascular hemolysis that causes constant hemosiderinuria in PNH. About one third of cases evolve into aplastic anemia (Chapter 165). Transformation to acute myelogenous leukemia is a rare event. Abdominal pain, dysphagia, and erectile dysfunction are additional clinical features. The basis of these symptoms is probably the scavenging by free plasma Hb of nitric oxide, a vasodilatory regulator of vasomotor and smooth muscle tone. In about one third of cases, venous thrombosis occurs in unusual sites and can cause Budd-Chiari syndrome by obstructing the hepatic veins, portal vein thrombosis or less frequently cerebral vein thrombosis (Chapter 143). Splenomegaly is uncommon; hepatomegaly and ascites suggest the complication of hepatic vein thrombosis and the resultant portal hypertension. Hemosiderinuria is the result of chronic intravascular hemolysis. Subtle or overt signs of bone marrow damage (coexisting leukopenia and thrombocytopenia) are frequent. The extent of RBC destruction in PNH depends on the number of PNH (versus normal) RBCs in blood, the level of GPI on the RBC membrane (PNH III cells are devoid of GPI), and the degree of activation of complement at the cell surfaces. The anemia is often aggravated by iron deficiency caused by chronic urinary iron loss in the form of hemosiderinuria. Long-term, repeated episodes of hemoglobinuria may lead to iron deficiency. Therefore, a DAT-negative HA associated with iron deficiency should raise suspicion of PNH. The basis of the tendency to develop venous thrombosis[10] is unclear. Hypercoagulability caused by the release of prothrombotic materials from RBC and platelet membranes (the latter being also abnormal in PNH) and impaired fibrinolysis has been implicated. Nitric oxide scavenging by free plasma Hb may also cause vasoconstriction and endothelial cell dysfunction, leading to the activation and aggregation of platelets.

DIAGNOSIS

Often, the clinical picture is virtually diagnostic. The diagnosis can be established by demonstrating, by flow cytometry, a deficiency of CD59 on erythrocytes. Another reagent with utility in flow cytometry is Aerolysin, a bacterial protein that binds to the GPI anchor. The fluorescinated Aerolysin variant (FLAER) is also a very good and reliable reagent to study GPI-linked antigens on leukocytes, helpful for diagnosing PNH. Flow cytometry can also measure the proportions of PNH III and PNH II RBCs in blood, providing information about the severity of the disease. The usual cut-off being the presence more than 5% GPI-AP–deficient polymorphonuclear cells in the peripheral blood, the clone size is usually correlated with the degree of intravascular hemolysis.

TREATMENT

Rx

Eculizumab, a humanized monoclonal antibody against C5 that is essential for formation of the MAC, can reduce the signs of intravascular hemolysis, the requirement for transfusions, and the tendency to thrombosis. In a randomized trial,[A2,A3] the dose of the antibody was 600 mg every week for 4 weeks followed 1 week later by a 900-mg dose and then by 900 mg every other week for a total treatment period of 52 weeks. A thrombotic event is a strong indication for eculizumab treatment. A molecular basis for poor response to eculizumab was recently elucidated in a small population of Japanese patients who were found to have a missense mutation in the gene encoding C5 that made the complement factor incapable of binding to eculizumab and being blocked by it.[11] Peptide inhibitors of C3 activation have been shown to prevent hemolysis and C3 opsonization of PNH RBCs and are potential therapeutic candidates.[12]

Warfarin can also be used in patients with a history of a thrombosis. Oral iron can correct the iron deficiency; treatment with iron does not exacerbate the hemolysis. Transfusions are helpful in supportive care. Aplastic anemia (Chapter 165) has been treated successfully with immunosuppressive agents (antithymocyte globulin, usually at a dose of 1.5 mg/kg/day for 7-14 days) with or without cyclosporine (3-5 mg/kg for at least 3 months). Allogeneic bone marrow transplantation (Chapter 178) is risky but can be curative.

OTHER EXTRACORPUSCULAR HEMOLYTIC ANEMIAS

Hemolytic Transfusion Reactions

The cause of hemolytic transfusion reactions (Chapter 177) is intravascular lysis of the donor's RBCs by antibodies (alloantibodies or isoantibodies) in the recipient that bind to one or more blood group antigens on the transfused cells. The recipient's isoantibodies can be natural anti-A or anti-B antibodies, or they can be induced by previous transfusions or pregnancy. Whether IgM or IgG, the isoantibodies trigger the assembly of lytic complement components on the surface of the donor's RBC. The rapid formation of large amounts of C3a and C5a fragments causes hypotension and bronchial and smooth muscle spasm. Renal failure is a consequence of severe, prolonged hypotension; the main renal lesion is renal cortical ischemia secondary to shunting of blood away from the kidneys. Hb itself is not nephrotoxic. The signs and symptoms of a hemolytic transfusion reaction are nonspecific and include fever, back pain, urticaria, dyspnea, hypotension, and evidence of disseminated intravascular coagulation. These nonspecific signs appear and worsen during administration of the transfusion. Immediate steps must be taken to stop the transfusion, submit the transfused blood and a sample of the patient's blood to the blood bank, and order tests of plasma and urine for free Hb. Management is further discussed in Chapter 177.

Other Causes of Intravascular Hemolysis

Conditions in which vascular abnormalities, toxins, infections, or drugs damage RBCs and cause them to lose pieces of membrane and ultimately fragment into Hb-containing bits should be considered in the differential diagnosis of intravascular hemolysis (see Table 160-3). Most of these conditions are readily apparent from the history and physical examination. Treatment focuses on the underlying cause of the hemolysis.

REVIEW QUESTIONS

1. A 68-year-old man is admitted to the intensive care unit because of acute respiratory failure secondary to clinically diagnosed community-acquired pneumonia. His temperature on admission is 41.2° C. Chest radiograph shows diffuse bilateral infiltrates. He is intubated and placed on a respirator, cultured, promptly started on broad-spectrum antibiotics, and placed on a cooling blanket. Intravenous hydration is begun. On the second day, the patient's condition deteriorates. Acrocyanosis develops in his fingertips and toes, the sclerae are noted to be icteric, and the urine from his Foley catheter has turned red (testing 4+ positive for heme but with only a small number of red blood cells). The admission hemoglobin of 14.2 has dropped to 7.8. What is the most likely cause of the acute anemia?

A. Gross hematuria possibly secondary to ureteral trauma or a previously undiagnosed genitourinary malignancy
B. Fulminant alveolar hemorrhage
C. Warm antibody-mediated autoimmune hemolytic anemia most likely secondary to previously undiagnosed, widely metastatic lung cancer
D. Drug-induced autoimmune hemolytic anemia, possibly caused by one of the antibiotics started on admission, with intravascular hemolysis
E. Acute cold antibody-mediated autoimmune hemolytic anemia and agglutination secondary to *Mycoplasma pneumoniae* infection

Answer: E Although unusual, community-acquired *M. pneumoniae* infection can present with bilateral pulmonary infiltrates and acute respiratory failure. *M. pneumoniae* infection (as well as certain viral infections) are associated with cold-reactive autoantibody-mediated cold agglutinin and simultaneously hemolytic disease. This patient's abrupt onset of massive intravascular hemolysis could have been triggered by artificially cooling his body temperature. The patient's intravascular cold autoimmune hemolytic anemia (AIHA) is manifested by hemoglobinuria and his acute intravascular cold agglutinin disease by the development of acrocyanosis. The patient does not have gross hematuria; he has gross hemoglobinuria, so genitourinary tract disease cannot be the cause. Fulminant alveolar hemorrhage could cause a precipitous decline in hemoglobin but is very unlikely in the absence of bloody airway secretions via his endotracheal tube. Warm antibody-mediated AIHA secondary to cancer would not be expected to begin suddenly on hospitalization and would not explain the acrocyanosis. It would be too early for drug-induced hemolysis to begin in this way on the second day of admission.

2. Which of the following statements about chronic cold agglutinin disease is incorrect?

A. It occurs mainly in young women, sometimes with other autoimmune disorders.
B. It is mediated by IgM autoantibody.
C. The direct antiglobulin (Coombs) test result is positive for only complement on the red blood cell surface.
D. It is associated with neoplastic B-cell lymphoproliferative disorders in most cases.
E. Splenectomy not effective in its treatment.

Answer: A Chronic cold agglutinin disease occurs in the great majority of cases in adults older than the age of 50 years. It is generally mediated by a complement-fixing monoclonal IgM autoantibody directed at the red blood cell (RBC) I antigen. However, when a direct antiglobulin test (DAT) is performed, the result is typically positive only for complement that remains fixed to the RBC membrane, and the associated IgM is readily eluted at room temperature before it can be detected in vitro. The great majority of patients with chronic cold agglutinin disease are now recognized to have an underlying B-cell lymphoproliferative neoplasm, such as non-Hodgkin lymphoma or chronic lymphocytic leukemia. The liver, not the spleen, is the major site of extravascular hemolysis in this disease, so splenectomy is not effective treatment.

3. A 45-year-old woman who has been treated in the past for presently clinically inactive systemic lupus erythematosus (SLE) presents with a recent onset of fatigue, lightheadedness, and yellowness of her eyes. Her hemoglobin is found to be 6.3 g/dL (with a baseline of about 12.5-13.0), reticulocytes are 15%, indirect bilirubin is 2.8 IU/L, and LDH is 840 mg/dL. A peripheral blood smear shows a large number of polychromatic red cells and spherocytes. Her direct antiglobulin test (Coombs test) result is positive for IgG. Her treatment at this time should include

A. plasmapheresis.
B. rituximab plus danazol.
C. intravenous methylprednisolone.
D. urgent splenectomy.
E. restarting her previous SLE treatment with azathioprine.

Answer: C This patient has severe warm antibody-mediated autoimmune hemolytic anemia (AIHA), which is probably related to her history of SLE. It appears to be sufficiently acute and severe to require transfusions of packed red blood cells, although the blood bank will likely have difficulty with typing and crossmatching. (The latter problem should not deter giving transfusions in a case like this in consultation with the transfusion medicine specialist on call, often having to resort to transfusing with not completely matched but the "best-matched" units of blood available.) High-dose corticosteroids are the mainstay of initial therapy. Rituximab, danazol, and splenectomy are all second-line treatment options. Plasmapheresis is usually ineffective because at least 50% of an individual's IgG (in this case, IgG autoantibody) is distributed into the extravascular space at any given time. Although azathioprine may have been effective in controlling this patient's other manifestations of SLE in the past, it is not good initial therapy for AIHA.

161 HEMOLYTIC ANEMIAS: RED BLOOD CELL MEMBRANE AND METABOLIC DEFECTS

PATRICK G. GALLAGHER

The mature erythrocyte differs from all other cells in the body. Lacking a nucleus, DNA, RNA, and ribosomes, it cannot synthesize RNA, DNA, or protein. It does not divide, it has no mitochondria, it cannot perform the Krebs cycle, and it lacks an electron transport system for oxidative phosphorylation. After enucleation, the reticulocyte, the precursor of the mature erythrocyte, leaves the marrow and enters the circulation equipped with a full complement of enzymes, transporters, signaling molecules, and all other proteins necessary to perform the essential functions of the red blood cell (RBC) during its lifespan.

The erythrocyte membrane accounts for only about 1% of the total weight of an RBC, yet it plays a critical role in the maintenance of normal RBC homeostasis through a number of mechanisms. These include retention of vital compounds and removal of metabolic waste, regulation of erythrocyte metabolism and pH, and import of iron required for hemoglobin (Hb) synthesis during erythropoiesis. The membrane maintains a slippery exterior so that erythrocytes do not aggregate or adhere to endothelial cells. The membrane skeleton, a network of proteins on the inner surface of the RBC, provides the strength and flexibility needed to maintain the normal shape and deformability of the erythrocyte.

The principal functions of erythrocyte metabolism in the mature erythrocyte include maintenance of adequate supplies of adenosine triphosphate (ATP), production of reducing substances to act as antioxidants, and control of oxygen affinity of Hb by production of adequate amounts of 2,3-diphosphoglycerate (2,3-DPG). Because the mature erythrocyte has lost its ability to perform oxidative phosphorylation, its energy is supplied by anaerobic glycolysis though the Embden-Meyerhof pathway, by oxidative glycolysis through the hexose monophosphate (HMP) shunt, and through nucleotide salvage pathways.

THE ERYTHROCYTE MEMBRANE

Composed of a lipid bilayer and an underlying cortical membrane skeleton (Fig. 161-1), the membrane provides the erythrocyte the deformability and stability required to withstand its travels through the circulation. In one circulatory cycle throughout the body, an erythrocyte is subjected to high sheer stress in the arterial system, dramatic size and shape changes in the microcirculation with capillary diameters as small as 7.5 μm and marked fluctuations in tonicity, pH, and Po_2.

Membrane Lipids

Red blood cell membrane lipids are asymmetrically distributed across the bilayer membrane, reflecting a steady state involving a constant exchange of phospholipids between the two bilayer hemileaflets. Glycolipids and cholesterol are intercalated between the phospholipids in the bilayer with their long axes perpendicular to the bilayer plane. Glycolipids, located in the external half of the bilayer with their carbohydrate moieties extending into the aqueous phase, carry several important RBC antigens and serve other important functions. Phospholipids are asymmetrically organized, with the choline phospholipids, phosphatidylcholine and sphingomyelin, primarily in the outer half of the bilayer, and the amino phospholipids, phosphatidylethanolamine and phosphatidylserine (PS), in the inner half of the bilayer. In pathologic states, such as thalassemia, sickle cell disease, and diabetes, loss of phospholipid asymmetry with externalization of PS leads to activation of blood clotting through conversion of prothrombin to thrombin and facilitates macrophage attachment to erythrocytes, marking them for destruction. Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol de novo and depend on lipid exchange and fatty acid acylation as mechanisms for phospholipid repair and renewal.

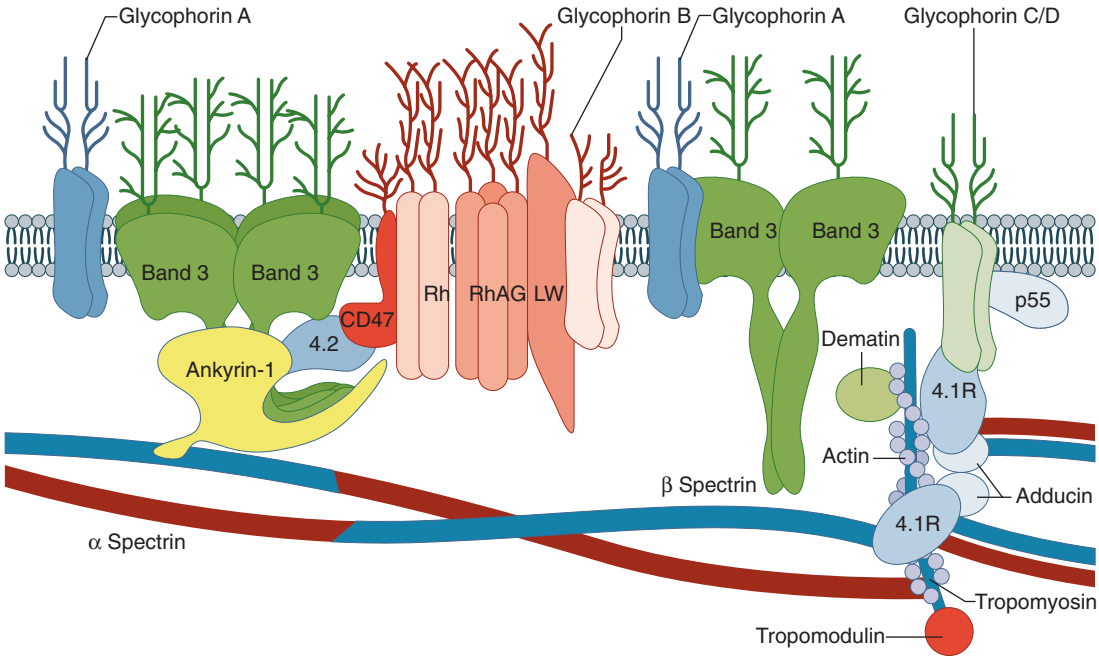

FIGURE 161-1. The erythrocyte membrane. A model of the major proteins of the erythrocyte membrane is shown: α and β spectrin, ankyrin, band 3 (the anion exchanger), 4.1 (protein 4.1) and 4.2 (protein 4.2), actin, and glycophorin. (From Perrotta S, Gallagher PG, Mohandas N. Hereditary spherocytosis. *Lancet.* 2008;372:1411-1426.)

Membrane Proteins

Membrane proteins are classified as *integral*, penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or *peripheral*, interacting with integral proteins or lipids at the membrane surface but not penetrating into the bilayer core. Integral membrane proteins include the glycophorins, the Rh proteins, Kell and Duffy antigens, and transport proteins such as band 3 (AE1, anion exchanger 1, SLC4A1), Na^+,K^+-ATPase, Ca^{2+}-ATPase, and Mg^{2+}-ATPase. Numerous membrane receptors and antigens are present on integral membrane proteins. Peripheral membrane proteins are on the cytoplasmic membrane face and include enzymes such as glyceraldehyde-3-phosphate dehydrogenase and the structural proteins of the spectrin-actin–based membrane skeleton.

Integral Membrane Proteins

Band 3, the major integral protein of the RBC, has two primary functions, ion transport and maintenance of protein–protein interactions. Band 3 mediates chloride–bicarbonate exchange and provides a binding site for glycolytic enzymes, Hb, and the skeletal proteins ankyrin, protein 4.1, and protein 4.2. A single *N*-glycan chain attached to an Asn in the membrane spanning domain of band 3 is composed of *N*-acetyl-D-lactosamine units arranged in an unbranched, linear fashion in fetal erythrocytes (i antigen) and in a branched fashion in adult cells (I antigen).

The glycophorins are the next most abundant family of integral membrane proteins. They provide most of the negative surface charge required by RBCs to avoid sticking to each other and to the vascular wall. They are involved in transmembrane signaling and carry receptors for *Plasmodium falciparum*, a number of viruses and bacteria, and several blood group antigens.

Peripheral Membrane Proteins

Spectrin is the major component of the membrane skeleton. It is composed of two subunits, α and β spectrin, that are structurally related but functionally distinct. Spectrin is highly flexible and assumes a variety of conformations, an unusual property that may be critical for normal membrane pliancy. The spectrin-based membrane skeleton is linked to the plasma membrane through the actin–protein 4.1 junctional complex; through spectrin–ankyrin interactions; and through binding of a multiprotein complex containing Rh proteins, Rh-associated glycoproteins, CD47, LW, glycophorin B, and protein 4.2 to ankyrin. Protein 4.1, a protein necessary for normal membrane stability, interacts with spectrin, actin, and other proteins of the RBC membrane. Ankyrin serves as the primary linkage protein for the high-affinity binding of spectrin to the inner membrane through interactions with the cytoplasmic domain of band 3. Protein 4.2 is a peripheral membrane protein that helps link the skeleton to the lipid bilayer through interactions with ankyrin and band 3.

Erythrocyte membrane disorders result from alterations in the quantity or quality (or both) of individual proteins and their dynamic interactions with each other. Disruption of the vertical protein–protein interactions of the membrane, that is, the spectrin-ankyrin–band 3 linkage or the band 3–protein 4.2 interaction, leads to uncoupling of the membrane skeleton from the lipid bilayer. This leads to membrane instability with loss of lipids and some integral membrane proteins, resulting in loss of membrane surface area and the phenotype of spherocytosis. Disruption of the horizontal interactions of membrane skeleton proteins, including perturbation of spectrin self-association or junctional complex protein–protein interactions, leads to membrane instability, altered membrane deformability and mechanical properties, and the phenotype of elliptocytosis.

DISORDERS OF THE ERYTHROCYTE MEMBRANE

Hemolytic anemias caused by defects in the erythrocyte membrane comprise an important group of hereditary anemias. Hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and hereditary pyropoikilocytosis (HPP) are the most common disorders among this group.[1] Detailed clinical studies carried out years ago have now been complemented by biochemical and genetic studies, providing both a better understanding of the pathogenesis of these disorders and a better understanding of the normal biology of the erythrocyte membrane.

Hereditary Spherocytosis

DEFINITION

Hereditary spherocytosis is a group of disorders characterized by spherical erythrocytes on the peripheral blood smear. Clinical, laboratory, and genetic heterogeneity characterize this group of disorders.

EPIDEMIOLOGY

Hereditary spherocytosis affects approximately one in 2000 to 3000 individuals of northern European ancestry. Found worldwide, it is much more common in whites than individuals of African ancestry.

PATHOBIOLOGY

The primary defect in HS is the loss of erythrocyte membrane surface area caused by defects in erythrocyte membrane proteins, including α spectrin, β spectrin, ankyrin, band 3, and protein 4.2. Qualitative or quantitative defects of one or more of these membrane proteins lead to membrane instability, which, in turn, leads to membrane loss. In approximately two thirds of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is nondominant owing to a de novo mutation or autosomal recessive inheritance. Cases with autosomal recessive inheritance are caused by defects in either α spectrin or protein 4.2. Rare cases of homozygous HS have been reported, resulting in fetal death or severe hemolytic anemia. In most cases, HS mutations are "private," that is, each individual has a unique mutation, implying that there is no selective advantage to HS.

The spleen plays a critical, albeit secondary, role in the pathophysiology of HS. Splenic destruction of poorly deformable spherocytes is the primary cause of hemolysis experienced by HS patients. Abnormal erythrocytes are trapped in the splenic microcirculation and ingested by phagocytes. Moreover, the splenic environment is hostile to erythrocytes, with low pH, low glucose, and low ATP concentrations and high local concentrations of toxic free radicals produced by adjacent phagocytes, all contributing to membrane damage.

CLINICAL MANIFESTATIONS

The clinical manifestations of the spherocytosis syndromes vary widely.[2] The classic triad of HS is anemia, jaundice, and splenomegaly. Rarely, patients may have severe hemolytic anemia presenting in utero or shortly after birth and continuing through the first year of life. These patients may require multiple blood transfusions, and in some cases, splenectomy in the first year of life. Many patients with HS escape detection throughout childhood. In these patients, the diagnosis of HS may not be made until they are being evaluated for unrelated disorders later in life or when complications related to anemia or chronic hemolysis occur. Although the lifespan of an erythrocyte in these patients may be shortened to only 20 to 30 days, they adequately compensate for their hemolysis with increased bone marrow erythropoiesis.

Chronic hemolysis leads to the formation of bilirubinate gallstones, the most frequently reported complication in patients with HS. Although gallstones have been observed in early childhood, most appear in adolescents and young adults. Routine interval ultrasonography to detect gallstones should be performed even if patients are asymptomatic.

Other complications of HS include aplastic, hemolytic, and megaloblastic crises. Aplastic crises occur after virally induced bone marrow suppression and present with anemia, jaundice, fever, and vomiting. The most common etiologic agent in these cases is parvovirus B19 (Chapter 371). Hemolytic crises, usually associated with viral illnesses and occurring before 6 years of age, are generally mild and present with jaundice, increased spleen size, and a decrease in hematocrit. Megaloblastic crises occur in HS patients with increased folate demands, such as the pregnant patient, growing children, or patients recovering from an aplastic crisis.

Uncommon manifestations of HS include skin ulceration, gout, chronic leg dermatitis, cardiomyopathy, spinal cord dysfunction, movement disorders, and extramedullary erythropoiesis. In patients with untreated severe HS, poor growth and findings attributable to extramedullary hematopoiesis, such as hand and skull deformities, may be found.

DIAGNOSIS

Patients with HS may present at any age, usually with anemia, hyperbilirubinemia, or an abnormal blood smear. In evaluating a patient with suspected HS, particular attention should be paid to the family history, including questions about anemia, jaundice, gallstones, and splenectomy. The initial laboratory investigation should include a complete blood count with a peripheral smear, reticulocyte count, direct antiglobulin test (Coombs test), and serum bilirubin. When the peripheral smear or family history is suggestive of HS, an incubated osmotic fragility test or flow cytometric analysis of eosin-5-maleimide–labeled erythrocytes (EMA binding) (discussed later) should be obtained. Rarely, additional, specialized testing is required to confirm the diagnosis.

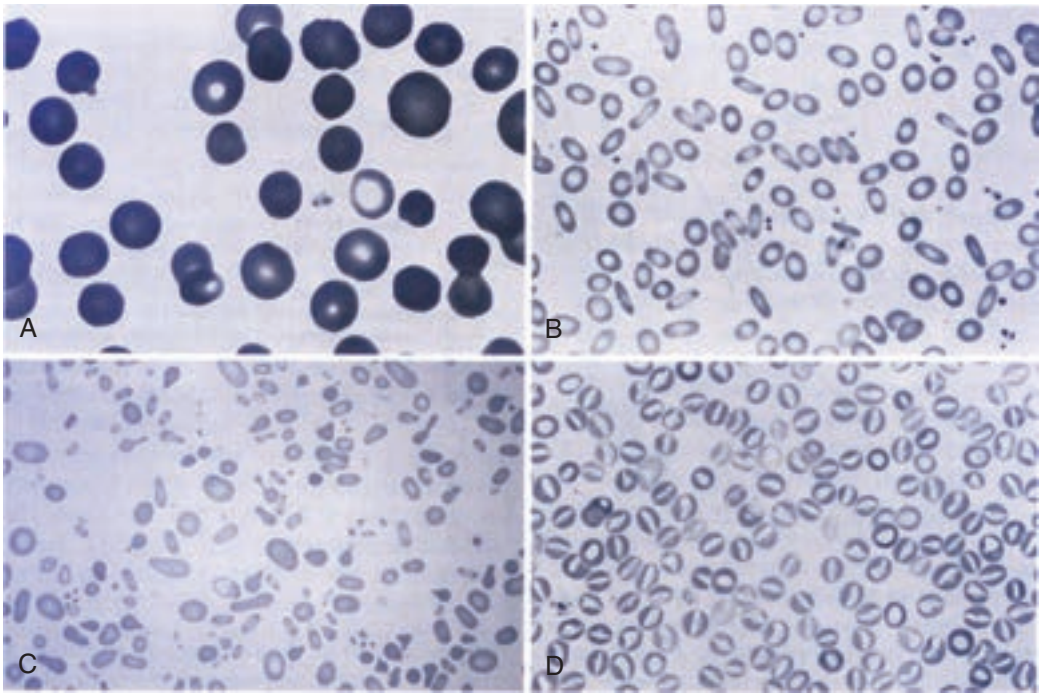

FIGURE 161-2. Peripheral blood smears in disorders of erythrocyte shape. A, Hereditary spherocytosis. Characteristic spherocytes lacking central pallor are seen. **B,** Hereditary elliptocytosis. Smooth, cigar-shaped elliptocytes are seen. **C,** Hereditary pyropoikilocytosis. Pronounced microcytosis, poikilocytosis, fragmentation of erythrocytes, and elliptocytes are seen. **D,** Hereditary stomatocytosis.

Overall, laboratory findings in HS are heterogeneous. Erythrocyte morphology is distinctive but not diagnostic (Fig. 161-2, *A*). Typical HS patients have blood smears with easily identifiable spherocytes lacking central pallor. Some patients present with only a few spherocytes on peripheral smear, but others present with numerous small, dense spherocytes and bizarre erythrocyte morphology. Specific morphologic findings have been identified in patients with certain membrane protein defects such as pincered erythrocytes (band 3) or spherocytic acanthocytes (β spectrin). When examining a smear in a case of suspected spherocytosis, it is important to have a high-quality smear with the erythrocytes well separated and some cells with central pallor in the field of examination because spherocytes are a common artifact on peripheral blood smears. The presence of spherocytosis on peripheral blood smear is not diagnostic of HS. Other disorders with spherocytes on peripheral blood smear are listed in Table 161-1.

The mean corpuscular hemoglobin concentration (MCHC) is increased (between 34.5 and 38) owing to relative cellular dehydration.[3] The mean corpuscular volume (MCV) is usually normal or slightly decreased.[4] Many cell counters provide a histogram of MCHCs claimed to be accurate enough to identify nearly all patients with HS.

In a normal erythrocyte, a redundancy of cell membrane gives the cell its characteristic discoid shape and provides it abundant surface area. In spherocytes, there is a decrease in surface area relative to cell volume, resulting in their abnormal shape. This change is reflected in the increased osmotic fragility found in these cells. Osmotic fragility is tested by adding increasingly hypotonic concentrations of saline to RBCs. Normal erythrocytes are able to increase their volume by swelling, but spherocytes, which are already at maximal volume for surface area, burst at higher saline concentrations than normal. Approximately one fourth of HS individuals will have a normal osmotic fragility on freshly drawn RBCs, with the osmotic fragility curve approximating the number of spherocytes seen on peripheral smear. However, after incubation at 37° C for 24 hours, HS RBCs lose membrane surface area more readily than normal because their membranes have become leaky and unstable. Thus, incubation accentuates the defect in HS erythrocytes and brings out the defect on osmotic fragility, making incubated osmotic fragility the standard test in diagnosing HS (Fig. 161-3, *bottom panel*). When the spleen is present, a subpopulation of very fragile erythrocytes that have been conditioned by the spleen form the tail of the osmotic fragility curve. This tail disappears after splenectomy. The osmotic fragility test suffers from poor sensitivity, with as many as 20% of mild cases of HS missed after incubation. It is unreliable in patients who have small numbers of spherocytes and in patients who have been recently transfused. It is abnormal in other conditions in which spherocytes are present.

TABLE 161-1 DISORDERS WITH SPHEROCYTES ON PERIPHERAL BLOOD FILM

Hereditary spherocytosis
Autoimmune hemolytic anemia
Thermal injuries
Microangiopathic and macroangiopathic hemolytic anemias
Hepatic disease
Clostridial septicemia
Transfusion reactions with hemolysis
Poisoning with certain snake, spider, and *Hymenoptera* venoms
Severe hypophosphatemia
Heinz body anemias
ABO incompatibility (neonates)

Eosin-5-maleimide binding is a flow cytometry–based test used in the diagnosis of HS.[5] EMA is a fluorescent dye that binds to band 3 and Rh-related proteins in the erythrocyte membrane. In HS, the mean fluorescence of EMA-stained erythrocytes is lower compared with control because of the reduction of band 3 and related proteins, typically decreased to approximately 65% of normal (Fig. 161-3, *top panel*). Although primary defects of band 3 protein are seen in only about 25% of HS patients, decreased fluorescence intensity is also observed in the erythrocyte membranes of HS patients with defects in other membrane proteins such as ankyrin and spectrin. This is thought to be attributable to transmission of long-range effects of mutant protein defects across the membrane lattice, ultimately influencing the amount of EMA binding to band 3. EMA binding has good sensitivity and specificity and is simple and rapidly performed.

Specialized testing is available for studying difficult cases or cases in which additional information is desired. Useful tests for these purposes include structural and functional studies of erythrocyte membrane proteins, such as protein quantitation, limited tryptic digestion of spectrin, spectrin, and ion transport. Membrane frigidity and fragility may be examined using an ektacytometer. Complementary DNA and genomic DNA analyses are available when a molecular diagnosis is desired.

Other laboratory manifestations in HS are manifestations of ongoing hemolysis. Increased serum bilirubin, increased lactate dehydrogenase,

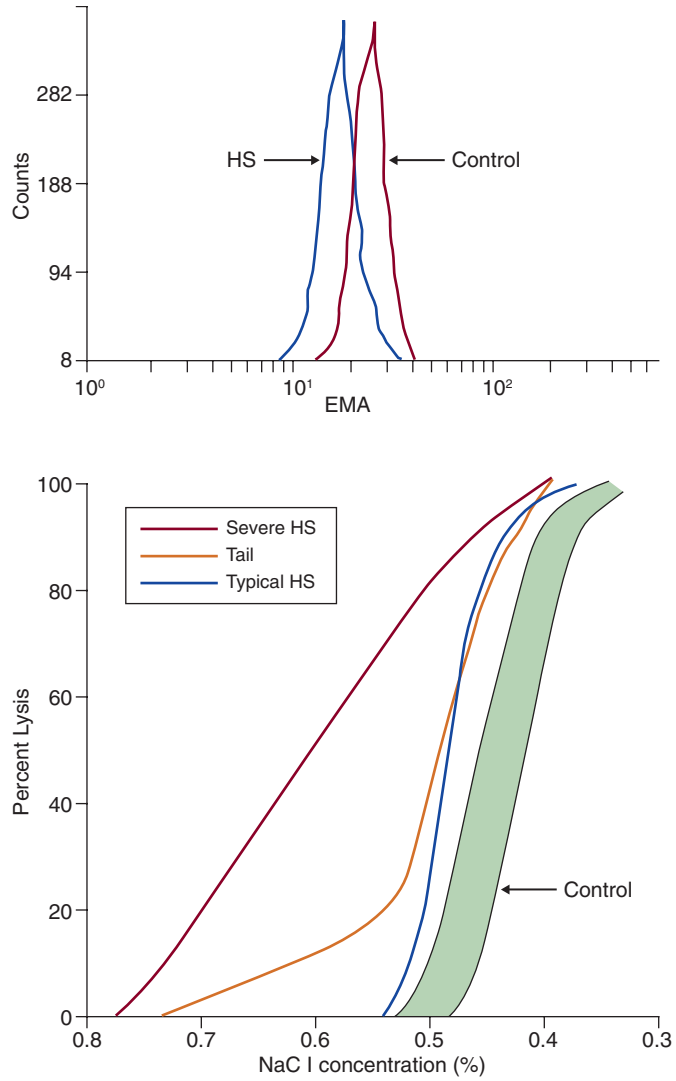

FIGURE 161-3. Testing in hereditary spherocytosis. ***Top panel,*** **Eosin-5-maleimide (EMA) binding. Decreased fluorescence in observed from HS erythrocytes.** ***Bottom panel,*** **Osmotic fragility curves in hereditary spherocytosis. The *shaded region* is the normal range. Results representative of both typical, and severe spherocytosis are shown. A tail, representing fragile erythrocytes conditioned by the spleen, is common in spherocytosis patients prior to splenectomy. (From Gallagher PG. Abnormalities of the erythrocyte membrane. *Pediatr Clin North Am* 2013;60:1349-1352.)**

increased urinary and fecal urobilinogen, and decreased serum haptoglobin reflect increased erythrocyte destruction.

After diagnosing a patient with HS, family members should be examined for the presence of HS. This can be of great epidemiologic importance, particularly for very old and very young patients. Prenatal diagnosis of HS has been made in a few cases, but this is rarely necessary.

TREATMENT AND PROGNOSIS

Rx

Splenic sequestration and destruction is the primary determinant of erythrocyte survival in HS patients. Splenectomy cures or alleviates anemia in most patients, reducing or eliminating the need for transfusions. The risk for cholelithiasis is also decreased to nearly background levels. After splenectomy, spherocytes remain in the peripheral blood, but their lifespan becomes near normal.

In the past, splenectomy was routinely performed in all HS patients. However, the risk of overwhelming postsplenectomy infection; the emergence of penicillin-resistant pneumococci; and the growing recognition of the increased risk of postsplenectomy cardiovascular disease, particularly thrombosis and pulmonary hypertension, have led to reevaluation of the role of splenectomy in the treatment of HS. In addition, with growing globalization, the important role of the spleen in protection of individuals living in or traveling to geographic regions where parasitic diseases such as malaria or babesiosis occur has reemerged. When splenectomy is considered, health care providers, the patient, and family members must review and weigh the benefits of splenectomy against the immediate and long-term risks of the procedure. Considering the risks and benefits, a reasonable approach is to splenectomize all patients with severe spherocytosis and all patients who have significant signs or symptoms of anemia, including growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors. Other candidates for splenectomy are older HS patients who have vascular compromise of vital organs. Whether patients with moderate HS and compensated, asymptomatic anemia should undergo splenectomy is controversial.[6]

When splenectomy is indicated, laparoscopic splenectomy has become the method of choice. This technique results in less postoperative discomfort, a quicker return to preoperative diet and activities, shorter hospitalization, decreased costs, and smaller scars. Even massive spleens can be removed laparoscopically because the spleen is placed in a large bag, diced intraoperatively, and eliminated through suction catheters. Partial splenectomy, initially advocated for infants and young children with significant anemia associated with erythrocyte membrane disorders to allow for palliation of hemolysis and anemia while maintaining some residual splenic immune function, is now being suggested by some for most HS patients. Updated UK guidelines,[7] which reflect changes in current opinion about surgical management, include (1) preference for a laparoscopic approach, (2) performance of splenectomy ideally after the age of 6 years, (3) no indication for extended thrombosis prophylaxis after splenectomy for HS, and (4) avoidance of splenectomy in patients with some forms of hereditary stomatocytosis because of an increased risk of venous thromboembolism.

Before splenectomy, patients should be immunized with vaccines against pneumococcus, *Haemophilus influenzae* type B, and meningococcus. Postsplenectomy care includes counseling of patients or parents to seek prompt medical care in case of febrile illness. Use of routine antibiotics after splenectomy for prevention of pneumococcal sepsis is controversial. Data are lacking to indicate or refute their prescription. Before splenectomy and, in severe cases, after splenectomy, HS patients should take folic acid (1 mg/day orally) to prevent folate deficiency.

Hereditary Elliptocytosis and Related Disorders

DEFINITION

Hereditary elliptocytosis is characterized by the presence of elliptical or oval cigar-shaped erythrocytes on peripheral blood smears of affected individuals (see Fig. 161-2, *B*).

EPIDEMIOLOGY

Hereditary elliptocytosis has been estimated to occur in approximately one in 2000 to 4000 individuals. The true incidence of HE is unknown because its clinical severity is heterogeneous, and many patients are asymptomatic. It is common in African Americans and people of Mediterranean ancestry, presumably because elliptocytes confer some resistance to malaria. In parts of Africa, the incidence of HE approaches one in 100.

PATHOBIOLOGY

The principal defect in HE is mechanical weakness or fragility of the erythrocyte membrane skeleton. Qualitative and quantitative defects in a number of RBC membrane proteins have been described in HE, including α spectrin, β spectrin, protein 4.1, and glycophorin C. Most defects occur in spectrin, the principal structural protein of the erythrocyte membrane skeleton. αβ Spectrin heterodimers self-associate into tetramers and higher order oligomers that are critical for erythrocyte membrane stability as well as erythrocyte shape and function. Most spectrin defects in HE impair the ability of spectrin dimers to self-associate into tetramers and oligomers, thereby disrupting the membrane skeleton. Structural and functional defects of protein 4.1 appear to disrupt the spectrin–actin contact in the membrane skeleton. Glycophorin C variants are also deficient in protein 4.1. The precise pathobiology of how elliptocytes are formed in these syndromes is unclear.

Genetically, HE is heterogeneous with multiple genetic loci. A wide variety of mutations have been described in the α spectrin, β spectrin, protein 4.1, and glycophorin C genes, including point mutations, gene deletions and insertions, and messenger RNA processing defects. Several mutations have been identified in a number of individuals of the same genetic background, suggesting a "founder effect" for these mutants, which supports the

hypothesis that there has been genetic selection for elliptocytosis because these RBCs confer some resistance to malaria. Most cases of HE are inherited in an autosomal dominant pattern, with rare cases of de novo mutations.

CLINICAL MANIFESTATIONS

The clinical presentation of HE is heterogeneous, ranging from asymptomatic carriers to patients with severe, life-threatening anemia. Most patients with HE are asymptomatic and are diagnosed incidentally during testing for unrelated conditions. Asymptomatic carriers have been identified who possess the same molecular defect as an affected HE relative but who have normal peripheral blood smears. The erythrocyte lifespan, normal in most patients, is decreased in only about 10% of patients. This subset of HE patients with decreased erythrocyte lifespan experience hemolysis, anemia, splenomegaly, and intermittent jaundice. Many of these patients have parents with typical HE and thus are homozygotes or compound heterozygotes for defects inherited from each of the parents. Symptoms may vary among members of the same family, indeed, they may vary in the same individual at different times.

Hereditary Pyropoikilocytosis

Hereditary pyropoikilocytosis is a rare cause of anemia with distinctive erythrocyte morphology on peripheral blood smear (see Fig. 161-2, *C*) and has a picture similar to that seen in patients with severe burns. Patients typically present in infancy with severe anemia and peripheral blood smear findings of elliptocytosis, poikilocytosis, pyknocytosis, and fragmentation. Microspherocytosis is common, and the MCV is usually very low (50-70 fL). Most patients are of African ancestry, and at least one third of HPP patients have a parent or sibling with typical HE. Patients with HPP tend to experience severe hemolysis and anemia in infancy that gradually improves, evolving toward typical HE later in life.

DIAGNOSIS

Cigar-shaped elliptocytes on peripheral blood smear are the hallmark of HE (see Fig. 161-2, *B*). These normochromic, normocytic elliptocytes vary in number from a few to 100%, with the likelihood of hemolysis not correlating with the number of elliptocytes present. Ovalocytes, spherocytes, stomatocytes, and fragmented cells may also be seen. In some cases, pyknocytes may be prominent. Elliptocytes may be seen in association with other disorders, including megaloblastic anemias, hypochromic microcytic anemias (iron deficiency anemia and thalassemia), myelodysplastic syndromes, and myelofibrosis; however, elliptocytes generally make up less fewer one third of RBCs in these conditions. History and additional laboratory testing usually clarify the diagnosis of these disorders. In typical cases, the incubated osmotic fragility is normal, but in severe HE and HPP, incubated osmotic fragility is increased, and EMA binding is decreased.

Other laboratory findings in HE are similar to those found in other hemolytic anemias and are nonspecific markers of increased erythrocyte production and destruction. The reticulocyte count generally is less than 5% but may be higher when hemolysis is severe.

Similar to HS, specialized laboratory procedures are available to study the erythrocyte membranes of HE and HPP patients. These studies are not routinely required to make the diagnosis of HE or HPP, but they may be helpful in studying problematic cases and in elucidating the underlying molecular defects.

TREATMENT

Rx

Therapy is rarely needed in patients with HE. In rare cases, occasional RBCs transfusions may be required. In cases of severe HE and HPP, splenectomy has been palliative because the spleen is the site of erythrocyte sequestration and destruction. Many practitioners think that the same indications for splenectomy in HS should be applied to patients with symptomatic HE or HPP. Post-splenectomy patients with HE or HPP experience increased hematocrits, decreased reticulocyte counts, and improvement in clinical symptoms.

Patients should be followed for signs of decompensation during acute illnesses. Interval ultrasonography to detect gallstones should be performed. In patients with significant hemolysis, folate should be administered daily.

Hereditary Stomatocytosis Syndromes

Red blood cell hydration is primarily determined by the intracellular concentration of monovalent cations. A net increase in sodium and potassium ions causes water to enter, forming *stomatocytes* (see Fig. 161-2, *D*) or *hydrocytes*, but a net loss of sodium and potassium produces dehydrated RBCs, or *xerocytes*. Numerous descriptions of congenital or familial hemolytic anemias associated with abnormal cation permeability and, in some cases, disturbed RBC hydration have been reported.[8] These span the range from severe hydrocytosis to severe xerocytosis. In many cases, the molecular bases of this group of disorders are unknown. An unusual characteristic of the stomatocytosis syndromes is a predisposition to thrombosis after splenectomy. Acquired stomatocytosis has been associated with acute alcoholism and hepatobiliary disease, vinca alkaloid administration, neoplasms, and cardiovascular disease. Stomatocytosis is also sometimes observed as a processing artifact.

OVERHYDRATED HEREDITARY STOMATOCYTOSIS (HYDROCYTOSIS)

This group of disorders is characterized by stomatocytes, erythrocytes with a mouth-shaped (stoma) area of central pallor on peripheral blood smear (see Fig. 161-2, *D*), severe hemolysis, macrocytosis (110-150 fL), elevated erythrocyte sodium concentration, reduced potassium concentration, and increased total Na^+ and K^+ content. The excess cations expand cell water, producing large, osmotically fragile cells with low MCHCs (24%-30%). The clinical severity of overhydrated hereditary stomatocytosis is variable; some patients experience hemolysis and anemia, but others are asymptomatic. Missense mutations in the Rh-associated glycoprotein (RhAG) have been identified in a subset of hydrocytosis patients.

DEHYDRATED HEREDITARY STOMATOCYTOSIS (XEROCYTOSIS)

Blood smears from patients with dehydrated hereditary stomatocytosis exhibit contracted and spiculated RBCs, dessicytes, a variable number of stomatocytes, and target cells. Most patients have nearly normal erythrocyte morphology, with only a few target cells and an occasional echinocyte or stomatocyte. The MCV (95-115 fL) and MCHC are increased, and the osmotic fragility is reduced (i.e., resistance to osmotic lysis). The characteristic biochemical abnormality is a decreased potassium concentration and total monovalent cation content. Dominantly inherited mutations in PIEZO1, encoded by the *FAM38A* gene, have been identified in xerocytosis patients. PIEZO proteins are the recently identified pore-forming subunits of channels that mediate mechanotransduction in mammalian cells. Association of PIEZO variants with changes in erythrocyte hydration suggest that these proteins play an important role in erythrocyte volume homeostasis.

INTERMEDIATE SYNDROMES AND HEREDITARY STOMATOCYTOSIS VARIANTS

Hydrocytosis and xerocytosis represent the extremes of a spectrum of RBC permeability defects. A number of families with features of both conditions have been reported. Some patients with severe permeability defects have little or no hemolysis. The proportion of stomatocytes and the degree of sodium influx do not correlate with each other, and neither correlates with the amount of hemolysis or anemia.

ERYTHROCYTE METABOLISM

The primary functions of the erythrocyte, gas transport and exchange, are maintained without a net change in energy state. However, several critical functions of the erythrocyte depend on the production and expenditure of energy. As erythrocytes age, glucose utilization and ATP levels fall, leading to decreased membrane deformability and, ultimately, a shortened lifespan. Lower potassium levels, higher sodium levels, and decreased membrane lipids are also seen in ATP-deficient, aging erythrocytes.

Erythrocytes do not undergo oxidative phosphorylation and do not store glycogen; thus, they must constantly catabolize glucose from the blood stream through the Embden-Meyerhof pathway and the HMP shunt as a source of energy (Fig. 161-4). Erythrocytes incorporate glucose from the plasma through facilitated transfer, with erythrocyte glucose levels rapidly equilibrating with changes in blood glucose levels. Glucose is the preferred carbohydrate of the RBC, but fructose and mannose are metabolized almost as readily. Inside the erythrocyte, glucose is converted to glucose-6-phosphate or to fructose by sorbitol. Glucose-6-phosphate follows one of three pathways: (1) most (~90%) enters the Embden-Meyerhof pathway, where it is converted into lactate, pyruvate, and ATP; (2) some (~5%-10%) enters the HMP shunt to produce reduced intermediates and ribulose 5-phosphate, the latter of which eventually enters the Embden-Meyerhof pathway; and (3) a tiny fraction (<1%) is converted to glucose-1-phosphate and then to glycogen.

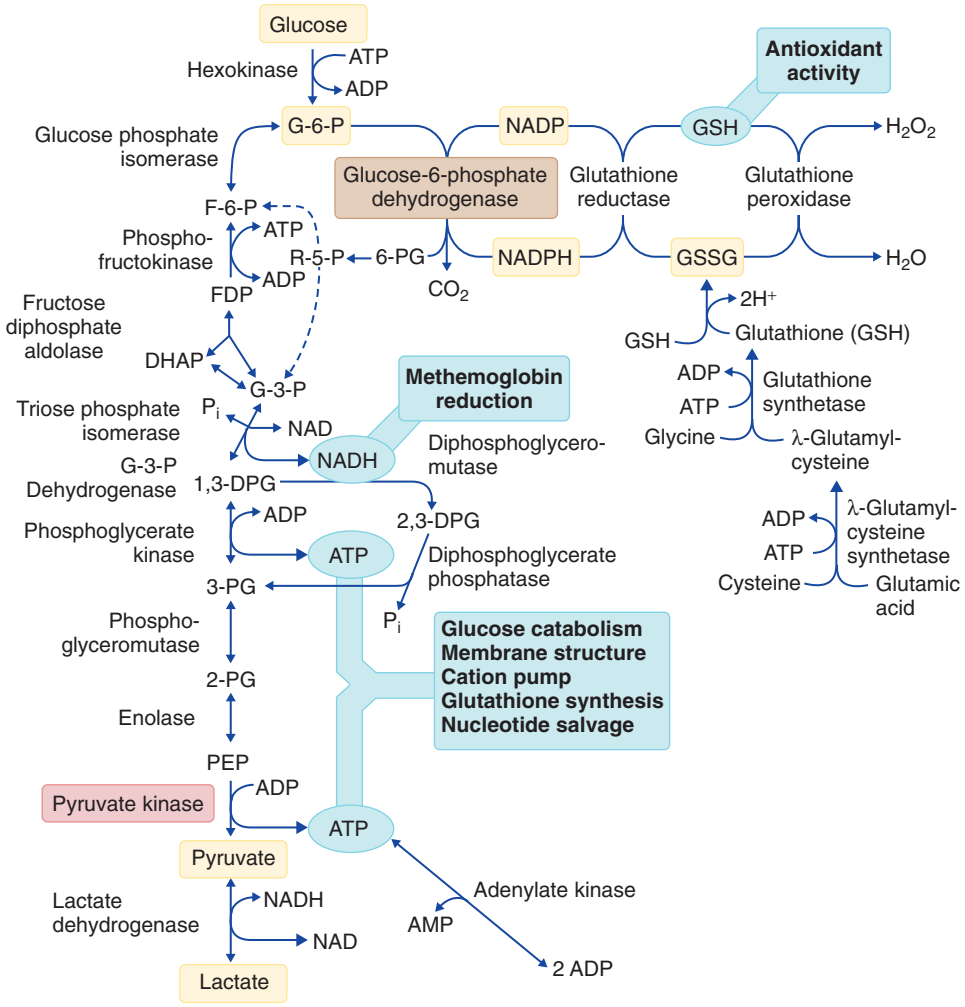

FIGURE 161-4. Pathways of energy metabolism in the erythrocyte. Glucose-6-phosphate may be degraded anaerobically to lactate through the Embden-Meyerhof pathway or oxidatively through the hexose monophosphate shunt. Pentose phosphates (R-5-P) can reenter anaerobic glycolysis as fructose-6-phosphate (F-6-P) and glyceraldehyde-3-phosphate (G-3-P) after conversion by enzymes of the terminal pentose phosphate pathway or as a product of adenosine or inosine degradation. 2,3-Diphosphoglycerate (2,3-DPG) may be generated instead of adenosine triphosphate (ATP) through diversion of triose through the Rapoport-Luebering shunt. Glutathione may be synthesized directly from constituent amino acids; its cycling from oxidized (GSSG) to reduced forms (GSH) depends on reduced pyridine cofactor (NADPH) generation. ADP = adenosine diphosphate; DHAP = dihydroxyacetone phosphate; FDP = fructose-1,6-diphosphate; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = nicotinamide adenine dinucleotide phosphate, reduced form; PEP = polyestradiol phosphate.

Embden-Meyerhof Pathway

The Embden-Meyerhof pathway of glycolysis is the primary source of ATP, 2,3-DPG and nicotinamide adenine dinucleotide, reduced form (NADH) in erythrocytes (see Fig. 161-4). Most of the energy generated by erythrocytes is through the Embden-Meyerhof pathway followed by storage as high-energy phosphates such as ATP or as reducing energy in the form of glutathione or pyridine nucleotides (NADH and nicotinamide adenine dinucleotide phosphate, reduced form [NADPH]). This pathway metabolizes about 90% of erythrocyte glucose with the catabolism of 1 mole of glucose yielding 2 moles of ATP and 2 moles of lactate. Two moles of ATP per mole of metabolized glucose seems insignificant compared with the Krebs cycle of intermediary metabolism, in which 1 mole of glucose metabolized produces 38 moles of ATP. However, this ATP production is adequate to renew 150% to 200% of the total RBC ATP every hour.

The Embden-Meyerhof pathway is also the primary source of NADH, a necessary cofactor for NADH methemoglobin reductase, which maintains heme iron in the reduced state. Without this reaction, heme iron would be oxidized to methemoglobin, which is not a functional oxygen transporter.

Finally, the Rapoport-Luebering shunt of the Embden-Meyerhof pathway (see Fig. 161-4) produces 2,3-DPG, a compound found in high concentrations in erythrocytes but in low concentrations in other cells. After it is formed, under physiologic conditions of pH and solute concentrations, 2,3-DPG binds reversibly to tetramers of deoxyhemoglobin with greater affinity than it does to oxyhemoglobin. By binding to deoxyhemoglobin, it allosterically upregulates the release of the remaining oxygen bound to the Hb, enhancing the ability of erythrocytes to release oxygen near tissues that need it most.

Hexose Monophosphate Shunt (Pentose Phosphate Pathway)

In the HMP shunt (see Fig. 161-4), glucose-6-phosphate undergoes oxidation followed by a series of reactions to yield fructose-6-phosphate and glyceraldehyde-3-phosphate, intermediates in the glycolytic pathway. The HMP shunt is the primary source of erythrocyte NADPH, with 2 moles of NADPH produced for each mole of glucose metabolized. NADPH is required for the reduction of oxidized glutathione and some protein sulfhydryl groups.

Mature erythrocytes synthesize large amounts of reduced glutathione (GSH). GSH protects erythrocytes from oxidants, including hydrogen peroxide (H_2O_2), superoxide anions (O_2^-), and hydroxyl radicals (OH), which are produced as byproducts of the oxidation of heme by oxygen. Oxidants are also produced by activated phagocytes (e.g., during infection) and by erythrocytes after exposure to certain agents. When oxidants accumulate, they damage cellular proteins and lipids. Detoxification of H_2O_2 is significantly enhanced by glutathione peroxidase. GSH is converted to oxidized glutathione (GSSG) and to mixed disulfides with protein thiols. GSH levels are restored by glutathione reductase. In this process, NADPH is oxidized to nicotinamide adenine dinucleotide phosphate (NADP), which stimulates the HMP shunt to regenerate NADPH.[9] After oxidant stress, hypoxia, or acidosis, erythrocytes can increase the amount of glucose metabolized through the HMP shunt up to 10- to 20-fold to generate

increased amounts of reduced glutathione. The tight coupling of glutathione metabolism with the HMP shunt protects the mature erythrocyte from oxidative stress.

DISORDERS OF ERYTHROCYTE METABOLISM

Congenital nonspherocytic hemolytic anemia (CNSHA) traditionally includes erythrocyte disorders not due to defects of the RBC membrane or Hb, immune-mediated disease, or other diseases such as paroxysmal nocturnal hemoglobinuria. CNSHA is a heterogeneous group of disorders associated with various metabolic abnormalities of the erythrocytes, including enzymopathies of glucose, glutathione, and nucleotide metabolism. Similar to the membrane disorders, clinical, biochemical, and genetic heterogeneity are typical within the enzymopathies. Hemolysis may develop as a result of either enzyme or antioxidant deficiency or dysfunction (e.g., abnormal substrate or cofactor binding), altered activation or inhibition characteristics, or decreased stability or specific activity.

Peripheral blood smears in CNSHA, with the exception of pyrimidine 5′-nucleotidase (P5N) deficiency, are unremarkable. Osmotic fragility of fresh erythrocytes is normal. Response to splenectomy is variable. Inheritance is heterogeneous. A thorough family history is important and may be of assistance in determining the diagnosis. Manifestations of the metabolic defect are usually confined to the erythrocyte but may occasionally involve nonerythroid cells.

Definitive diagnosis of metabolic abnormalities of the RBCs depends on qualitative or quantitative assays of specific enzyme activity or identification of the specific genetic mutation by DNA analysis. Results of enzyme assays should be interpreted with caution because (1) they only sample surviving RBCs in the peripheral blood, and the metabolic milieu of these cells is not necessarily comparable to cells already hemolyzed; (2) in vitro enzyme assay conditions may not accurately reflect the in vivo environment; (3) transfusions before the assay may obscure the underlying metabolic defect, and (4) leukocyte contamination may lead to spurious results. Finally, average enzyme activity may not accurately reflect activity in subpopulations of erythrocytes. This is particularly true when there is reticulocytosis, which may yield artificially elevated mean enzyme activity owing to higher enzyme levels found in reticulocytes.

Disorders of the Embden-Meyerhof Pathway

Defects of the Embden-Meyerhof pathway are inherited in an autosomal recessive fashion, and usually hemolysis is seen only in homozygotes or compound heterozygotes.[10] Heterozygotes, whose erythrocytes contain less than normal amounts of mutant enzyme, are clinically normal.

An exception is phosphoglycerate kinase deficiency, an X-linked disorder with hemolysis found only in males. In this group of disorders, hemolysis is chronic, is not typically influenced by drugs or other inciting agents, and is attributed to insufficient levels of erythrocyte ATP. Splenomegaly from trapping of mutant erythrocytes is common. The hostile splenic environment contributes to the shortened erythrocyte lifespan. When performing specific diagnostic enzyme assays, measurement of glycolytic intermediates may assist in diagnosis because concentrations of intermediates are increased upstream of a defect and decreased downstream of a defect.

PYRUVATE KINASE DEFICIENCY

Pyruvate kinase (PK) deficiency accounts for approximately 90% of inherited defects of the Embden-Meyerhof pathway and is the second most common inherited erythrocyte enzymopathy associated with anemia after glucose-6-phosphate dehydrogenase (G6PD) deficiency (see later). PK deficiency is found worldwide, but it is most common in individuals of northern European descent.

PATHOBIOLOGY

Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate (PEP) to pyruvate, generating ATP. Deficient or defective PK leads to decreased levels of erythrocyte ATP, disturbing many cellular processes such as signaling and maintenance of water and ion content, leading to energy failure and dehydration. Upstream catabolites accumulate in the erythrocyte, including 2,3-DPG, which shifts the oxygen dissociation curve to the right, enhancing tissue oxygenation and ameliorating some of the physiologic effects of anemia. Early PK-deficient reticulocytes retain the ability to use oxidative phosphorylation to produce ATP, bypassing their defect. This ability is lost as reticulocytes mature and is markedly dampened in the hypoxic environment of the spleen.

Pyruvate kinase deficiency is inherited in an autosomal recessive manner. Affected individuals are homozygous or compound heterozygotes for PK defects. Heterozygotes are clinically normal or exhibit very minimal hemolysis.

CLINICAL MANIFESTATIONS

Clinical manifestations in PK deficiency are heterogeneous, ranging from asymptomatic to transfusion-dependent hemolytic anemia.[11] More severely affected patients present in infancy or early childhood with anemia, jaundice, and splenomegaly. Occasionally, patients may escape detection until later in life when complications related to anemia and chronic hemolysis occur such as cholelithiasis or aplastic crisis or when the diagnosis is made during evaluation of the patient for another condition.

DIAGNOSIS

The peripheral blood smear demonstrates normocytic, normochromic erythrocytes, sometimes with spiculations (Fig. 161-5, *A*). Poikilocytes and acanthocytes may also be seen. Reticulocytosis is common. Osmotic fragility of fresh erythrocytes is usually normal. Occasional patients exhibit a population of osmotically fragile cells after incubation.

NADH fluorescence under ultraviolet light is a commonly used screening test for PK deficiency. PEP and NADH are mixed with the patient's blood, incubated, and spotted on filter paper, and fluorescence is measured. Direct enzyme assay, which uses PEP as substrate for PK, can be performed on leukocyte-free hemolysate to confirm abnormal fluorescence tests. Leukocytes must be carefully depleted from the samples because they contain more than 300 times the PK activity of erythrocytes.

TREATMENT

Rx

Most patients require only expectant management, with only rare transfusions, such as during an aplastic episode. In severe cases, patients may be transfusion dependent. In these cases, splenectomy typically lessens hemolysis and ameliorates the anemia. After splenectomy, some patients develop marked reticulocytosis, up to 50% to 70%. This paradoxical reticulocytosis is attributed to increased reticulocyte survival after removal of the hostile splenic environment.

OTHER DISORDERS OF THE EMBDEN-MEYERHOF PATHWAY

Other abnormalities of the Embden-Meyerhof pathway have been described. Hexokinase deficiency is quite uncommon, with great phenotypic variability in reported cases. Severely affected patients have had anemia beginning in infancy and may require blood transfusions. Glucose phosphate isomerase (GPI) deficiency is the third most common hemolytic enzymopathy. GPI deficiency usually presents in infancy or early childhood with moderate to severe hemolytic anemia. Rare cases of GPI deficiency may also be complicated by neurologic symptomatology. Phosphofructokinase deficiency may involve erythrocytes, muscle, or both. The presentation is usually in adolescence with exertional myopathy (Chapter 207). Hemolytic anemia has been described in isolated cases of 2,3-bisphosphoglycerate mutase deficiency and phosphoglycerate kinase deficiency.

Disorders of Nucleotide Metabolism

Mature erythrocytes lack the ability to synthesize purine and pyrimidine nucleotides de novo. However, they are able to form some nucleotides through salvage pathways.

PYRIMIDINE 5′-NUCLEOTIDASE DEFICIENCY

Pyrimidine 5′-nucleotidase degrades the pyrimidine nucleotides of RNA to cytidine and uridine, which can diffuse out of the cell. When P5N is deficient, nondiffusible, partially degraded RNAs accumulate, leading to the marked basophilic stippling characteristic of P5N-deficient erythrocytes (see Fig. 161-5, *B*). These accumulated pyrimidine nucleotides inhibit the transport of GSSG (oxidized glutathione) out of RBCs, leading to high levels of erythrocyte glutathione. Clinically, the patient has mild to moderate hemolytic anemia and splenomegaly. The cause of the hemolysis remains cryptic. Typically, splenectomy does not ameliorate the hemolysis and anemia.

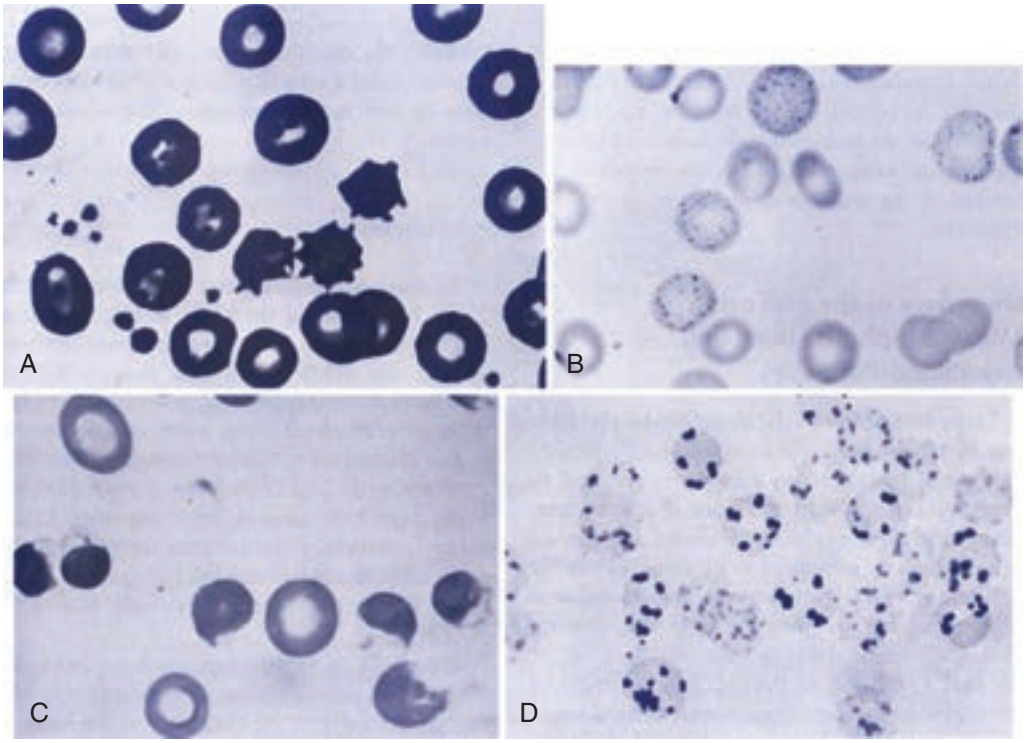

FIGURE 161-5, Peripheral blood smears in erythrocyte enzymopathies. A, Pyruvate kinase deficiency. **B,** Pyrimidine 5′-nucleotidase deficiency; **C,** Glucose-6-phosphate dehydrogenase (G6PD) deficiency. **D,** Heinz bodies in G6PD deficiency. (**B** from Paglia DE. Disorders of erythrocyte glycolysis and nucleotide metabolism. In: Handin RI, Lux SE, Stossel TP, eds. *Blood: Principles and Practice of Hematology*. Philadelphia: JB Lippincott; 1995:1877-1896.)

Disorders of the Hexose Monophosphate Shunt (Pentose Phosphate Pathway) and Associated Pathways

Disorders of the HMP shunt or of the glutathione metabolic pathways (see Fig. 161-4) compromise the ability of the RBC to respond adequately to oxidative stress. In normal erythrocytes, GSH detoxifies oxidants produced by various agents and infection. In G6PD-deficient erythrocytes, because of the inability to generate NADPH, GSH levels are inadequate, leaving the cell susceptible to oxidant stress. Oxidation of Hb sulfhydryl groups leads to the production of methemoglobin and intracellular Hb precipitates called *Heinz bodies*. Heinz bodies (see Fig. 161-5, *D*), usually visualized on peripheral blood smears with supravital stains such as methyl violet, attach to and damage the erythrocyte membrane. They induce clustering of immunoglobulins and band 3 protein, marking the erythrocyte for opsonization by phagocytes and eventual removal from the circulation. Heinz bodies are "pitted" from circulating cells by the spleen and are commonly seen on smears of patients after splenectomy. "Bite cells," erythrocytes with localized invaginations, possibly at the site of Heinz body injury or removal, are seen during acute hemolytic episodes. In addition to damage from Heinz body formation, GSH-deficient erythrocytes undergo peroxidation of membrane phospholipids and oxidative cross-linking of spectrin, decreasing membrane deformability and further promoting splenic trapping.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency is the most common inherited disorder of erythrocyte metabolism, affecting more than 400 million people worldwide.[12] The high prevalence of G6PD deficiency is thought to be attributable to genetic selection because G6PD-deficient erythrocytes have a selective advantage against invasion by the malaria parasite *Plasmodium falciparum*.

EPIDEMIOLOGY AND PATHOBIOLOGY

G6PD is the initial and rate-limiting step in the HMP shunt (see Fig. 161-4), which converts NADP into NADPH. NADPH is required for the generation of glutathione, a critical constituent in the prevention of oxidative damage to the cell. G6PD-deficient patients may develop acute hemolytic anemia after exposure to oxidative stress. Although G6PD is a ubiquitous enzyme, erythroid cells are particularly susceptible to oxidative stress because the HMP shunt is their only source of NADPH.

Hundreds of G6PD variants have been described, but only a few are common. Variants are classified on the basis of biochemical characteristics; electrophoretic mobility; ability to use substrate analogue, Km for NADP and G6PD; pH activity profile; and thermal stability. The normal enzyme, Gd^{B}, is present in 99% of white Americans and 70% of African Americans. A normal variant, Gd^{A+}, found in 20% of African Americans, has a faster electrophoretic mobility than Gd^{B}. Gd^{A-}, the most common variant associated with hemolysis, is found in about 10% of African Americans and in many Africans. Gd^{A-} has decreased catalytic ability compared with Gd^{A+}. Gd^{Med}, the second most common variant associated with hemolysis, is common in the Mediterranean area, in India, and in Southeast Asia, with a prevalence of up to 5% to 50%. Gd^{Med} exhibits markedly decreased catalytic activity. Gd^{Canton}, a variant common in Asian populations, produces a clinical syndrome similar to Gd^{A-}.[13,14]

Gd^{B} activity decreases as normal cells age, with a half-life of approximately 60 days. Despite very low levels of or no active G6PD, older erythrocytes maintain the ability to produce NADPH and maintain a GSH response to oxidative stress. The Gd^{A-} variant has a half-life of only 13 days, so young cells have a normal amount of enzyme activity, but older RBCs are grossly deficient. Because of this heterogeneity in G6PD levels, individuals with the Gd^{A-} variant experience only limited hemolysis after oxidant exposure.

More than 100 mutations in the *G6PD* gene, localized to Xq28, have been described. Most mutations are amino acid substitutions that influence enzyme kinetics, stability, or both, with a few rare deletions and splicing mutations described. Because it is X-linked, G6PD deficiency primarily affects males. Males have only one G6PD allele and express only one G6PD type. Females can express one or two G6PD types. The Lyon hypothesis specifies that only one X chromosome is active in any given cell; thus, any given cell in a heterozygous female is either normal or deficient. In females who are heterozygous for G6PD deficiency, average G6PD activity may be normal or mildly, moderately, or severely reduced, depending on the degree of lyonization. G6PD-deficient erythrocytes in heterozygous females are susceptible to the same oxidant stress as G6PD-deficient cells in males, but, typically, the overall degree of hemolysis is less because there is a smaller population of vulnerable cells.

CLINICAL MANIFESTATIONS

G6PD deficiency is divided into five classes based on clinical severity and degree of enzyme deficiency. Class I is characterized by CNSHA without precipitating cause and severe G6PD deficiency. Class II is characterized by intermittent hemolysis and severe G6PD deficiency. Class III is characterized by hemolysis after oxidant stress and mild G6PD deficiency. Class II and III

together represent more than 90% of G6PD variants. Classes IV and V are clinically asymptomatic. The most clinically significant syndromes of G6PD deficiency are acute hemolytic anemia (AHA); neonatal jaundice (NNJ); and rarely, CNSHA.

Acute hemolytic anemia is the most dramatic clinical presentation of G6PD deficiency with acute intravascular hemolysis after exposure to an oxidative stress.[15] Oxidative stresses include ingestion of certain drugs such as primaquine or sulfa-containing compounds, exposure to naphthalene (mothballs), ingestion of fava beans, or infection, the latter being the most common cause of hemolysis. Table 161-2 lists drugs that should be avoided in G6PD-deficient patients. Presenting symptoms include irritability, fever, nausea, abdominal pain, and diarrhea within 48 hours of oxidant exposure. Hemoglobinuria, jaundice, and anemia ensue. The spleen and liver may be enlarged and tender. Cases with severe anemia may precipitate congestive heart failure. Laboratory findings include a normochromic, normocytic anemia with anisocytosis and reticulocytosis. Poikilocytes and bite cells may be seen. Heinz bodies, a classic finding in G6PD deficiency, may be seen but are an inconsistent finding because these damaged cells are rapidly cleared from the circulation in the spleen. Additional laboratory findings may include hemoglobinuria and the presence of free Hb in the blood.

Another clinically significant syndrome of G6PD deficiency is NNJ. Jaundice is seldom present at birth, with the peak incidence of onset between days 2 and 3 of life. The severity of hyperbilirubinemia is variable. It may be severe, resulting in kernicterus or even death. In most cases, however, hyperbilirubinemia is adequately treated with phototherapy. In NNJ, it is important to note that the anemia is very rarely severe. The etiology of NNJ remains controversial. NNJ is increased in G6PD-deficient infants who also carry a polymorphism of the uridine diphosphoglucuronyl transferase (*UDPGT1*) gene associated with Gilbert syndrome.

Chronic nonspherocytic hemolytic anemia is associated with uncommon variants of G6PD deficiency, usually mutant enzymes unable to maintain basal NADPH production. Presentation may be in the neonatal period when NNJ is accompanied by anemia in a male. The degree of chronic anemia in CNSHA caused by G6PD deficiency has been variable. Some patients have compensated hemolysis, but others require intermittent transfusions. Transfusion dependence occurs in the most severe cases.

TABLE 161-2 AGENTS TO BE AVOIDED BY GLUCOSE-6-PHOSPHATE DEHYDROGENASE–DEFICIENT PATIENTS*

ANTIMALARIALS
Primaquine (people with the African A⁻ variant may take it at reduced dosage, under surveillance)
Pamaquine
Chloroquine (may be used under surveillance when required for prophylaxis or treatment of malaria)
SULFONAMIDES AND SULFONES
Sulfanilamide
Sulfapyridine
Sulfadimidine
Sulfacetamide (Albucid)
Acetyl sulfisoxazole (Gantrisin)
Salicylazosulfapyridine (Salazopyrin)
Dapsone
Sulfoxone
Glucosulfone sodium (Promin)
Sulfamethoxazole-trimethoprim (Septrin)
OTHER ANTIBACTERIAL COMPOUNDS
Nitrofurans—nitrofurantoin, furazolidone, nitrofurazone
[Nalidixic acid]
Chloramphenicol
p-Aminosalicylic acid
ANALGESICS
Acetylsalicylic acid (aspirin): moderate doses can be used
Acetophenetidin (Phenacetin)
Safe alternative: Paracetamol
ANTHELMINTICS
β-Naphthol
Stibophen
Niridazole
MISCELLANEOUS
Vitamin K analogues (1 mg of menaphthone can be given to babies)
Naphthalene (moth balls)
Probenecid
Dimercaprol (BAL)
Methylene blue
Arsine†
Phenylhydrazine†
Acetylphenylhydrazine†
Toluidine blue
Mepacrine

*Drugs in bold print should be avoided by people with all forms of glucose-6-phosphate dehydrogenase (G6PD) deficiency. Drugs in normal print should be avoided, in addition, by G6PD-deficient people of Mediterranean, Middle Eastern, and Asian origin. Items in normal print and within square brackets apply only to people with the African A⁻ variant.
†These drugs or chemicals may cause hemolysis in normal people if given in large doses. Many other drugs may produce hemolysis in certain individuals.

DIAGNOSIS

The G6PD reaction (glucose-6-phosphate + $NADP^+$ → 6-phosphogluconolactone + NADPH + H^+) reduces $NADP^+$ to NADPH. Formation of NADPH and NADH can be observed directly because they fluoresce in the visible spectrum when illuminated with long-wave ultraviolet light. Based on this observation, several simple screening tests performed using inexpensive long-wave ultraviolet light have been devised. These tests are semiquantitative, categorizing a sample as normal or deficient. They are unreliable after an acute hemolytic episode and do not typically detect female heterozygotes. Positive screening test results should be confirmed by spectrophotometric assay or DNA studies.

Definitive assay of the enzyme depends on direct spectrophotometric measurement of NADPH production. Although more sensitive than screening tests, this still requires 20% to 30% G6PD-deficient cells to obtain an abnormal result. Sensitivity can be increased by comparing the level of G6PD deficiency with levels of other age-dependent erythrocyte enzymes, especially when testing is temporally in close proximity to an acute hemolytic episode. The cyanide-ascorbate test measures the ability of erythrocytes to prevent the oxidation of Hb by ascorbate. Using intact erythrocytes, as few as 10% to 15% deficient cells can be detected, making this test useful for detecting female heterozygotes and males after a hemolytic episode. This test also detects other perturbations of the HMP shunt or glutathione metabolism.

TREATMENT

Rx

The best treatment for an individual with AHA is careful prescription of medications and avoidance of inciting agents (see Table 161-2). Outside of acute hemolytic episodes, these patients do not require any special therapy. AHA episodes are managed with particular attention to hematologic, cardiopulmonary, and renal complications of hemolysis. Management of NNJ does not differ from that recommended for other causes of neonatal hyperbilirubinemia. In CNSHA, management is expectant. Exposure to oxidant stresses should be avoided. Blood transfusions may be necessary during acute hemolytic episodes. In severe cases of CNSHA, splenectomy may ameliorate the anemia.

Disorders of Glutathione Metabolism

Defects of glutathione metabolism may be associated with hemolysis. Erythrocytes from patients lacking glutathione synthetase or γ-glutamylcysteine synthetase, enzymes involved in glutathione synthesis, have very low levels of GSH. Clinically, these disorders resemble G6PD deficiency. There is mild to moderate chronic hemolytic anemia with increased susceptibility to oxidant stress.

REVIEW QUESTIONS

1. A man recently diagnosed with glucose-6-phosphate dehydrogenase (G6PD) deficiency after an episode of hemolysis after taking chloroquine malaria prophylaxis before visiting Benin. He has many questions, including about starting a family. At the end of the visit, you provide several suggestions. These include all of the following except

A. always inform health care providers that he is G6PD deficient, particularly before they prescribe any medication.
B. seek medical attention if he is feeling tired, short of breath, and experiencing palpitations and if dark-colored urine is observed.
C. he should avoid eating fava beans and fava plant–derived food.
D. if his wife does not have G6PD deficiency, all sons will be unaffected, and all daughters will be carriers.
E. if his wife is a G6PD carrier, one of two daughters will be G6PD deficient, one out of two daughters will be G6PD carriers, and his sons will not be affected.

Answer: E Glucose-6-phosphate dehydrogenase (G6PD) deficiency is inherited in an X-linked manner. Thus, if his wife does not have G6PD deficiency, all sons will be unaffected, and all daughters will be carriers (answer D). However, if his wife is a G6PD carrier, one of two daughters will be G6PD deficient, one of two daughters will be G6PD carriers, one son of two will be G6PD deficient, and one son of two will be unaffected. With the diagnosis of G6PD deficiency, he should always tell his health care providers, especially when they are prescribing medications, and he should avoid fava beans and all fava-derived products. Finally, he should seek medical attention when experiencing the symptoms of a hemolytic reaction, tiredness, shortness of breath, palpitations, and dark-colored urine.

2. You have just diagnosed a 23-year-old patient with hereditary spherocytosis. Which of the following are appropriate actions?

A. Obtain ultrasonography of the spleen and gallbladder.
B. Counsel the patient to avoid oxidant-inducing foods and medications.
C. Determine if other family members could be affected and should be evaluated for the presence of hereditary spherocytosis.
D. Counsel regarding possible occurrence of hemolytic and aplastic crises.
E. A, B, and C
F. A, C, and D
G. All of the above

Answer: F Assessing spleen size and the biliary tract for the presence of cholelithiasis (answer A), determining if other family members could be affected after diagnosing a patient with hereditary spherocytosis (answer C), and counseling regarding hemolytic and aplastic crises (answer D) are all appropriate actions after diagnosing a patient with hereditary spherocytosis. Avoidance of oxidant-inducing food and medications (answer B), which is appropriate in patients with metabolic disease of the erythrocyte, especially glucose-6-phosphate dehydrogenase deficiency, is not necessary in hereditary spherocytosis.

3. You are asked to see a jaundiced 62-year-old man with cirrhotic liver disease complicated by portal hypertension and hepatosplenomegaly because of stomatocytes on peripheral smear. He is being evaluated for splenectomy. His total leukocyte count is 4000/mm^3 and his platelet count is 105,000/m^3. Hemoglobin and hematocrit are 8.4 g/dL and 26%, respectively. Peripheral blood smear shows decreased numbers of leukocytes and platelets. Erythrocyte morphology reveals nearly 100% stomatocytes, erythrocytes with a central bar, and a few target cells. Your most appropriate response would be

A. the presence of stomatocytes makes splenectomy an absolute contraindication.
B. obtain erythrocyte electrolyte determinations.
C. prominent stomatocytosis is common in patients with severe liver disease and no additional specific therapy is indicated.
D. obtain cholesterol and triglyceride levels to correlate with severity of stomatocytes and target cells and consider lipid lowering therapy.
E. obtain osmotic fragility or EMA binding test.

Answer: C Prominent stomatocytosis is common in patients with severe liver disease, and no additional specific therapy is indicated. Marked stomatocytosis is very common in advanced liver disease. Target cells may also be seen in advanced liver disease. Splenectomy is contraindicated in cases of hereditary stomatocytosis, not in cases of acquired stomatocytosis (answer A). Evaluation for hereditary stomatocytosis or hereditary spherocytosis via erythrocyte electrolytes (answer B), osmotic fragility or EMA binding (answer E) without additional historical data is not necessary. Although erythrocyte membrane lipids and cholesterol are perturbed in stomatocytosis, specific therapy is not warranted.

4. A 31-year old woman presents with a history of lifelong hemolytic anemia. Her parents are normal, but a sister also has anemia. She tells you she had a splenectomy as a teenager, but "it didn't work." Laboratory evaluation reveals hemoglobin of 10 g/dL, hematocrit of 31%, mean corpuscular volume of 96 fl, and reticulocyte count of 15%. The lactate dehydrogenase level is 750 IU/L. Peripheral blood smear shows evidence of hemolysis; many erythrocytes show prominent basophilic stippling. Her likely diagnosis is

A. pyruvate kinase deficiency.
B. glucose-6-phosphate dehydrogenase deficiency.
C. hereditary spherocytosis.
D. hereditary stomatocytosis.
E. pyrimidine 5′-nucleotidase deficiency.

Answer: E All of the disorders listed may be associated with a history of lifelong anemia. Pyruvate kinase and pyrimidine 5′-nucleotidase (P5N) deficiency are both recessively inherited (normal parents, affected sister.) Splenectomy failure is typical in P5N deficiency and some cases of hereditary stomatocytosis, in which splenectomy is contraindicated. Basophilic stippling of erythrocytes is a characteristic finding in P5N deficiency because of the accumulation of partially degraded, nondiffusable RNAs in the cell.

5. Evaluation of a patient with hemolytic anemia reveals the presence of spherocytes on peripheral blood smear. Which disorder is NOT in the differential diagnosis?

A. Heinz body hemolytic anemia
B. Autoimmune hemolytic anemia
C. Hereditary stomatocytosis
D. Hereditary spherocytosis
E. Liver disease

Answer: C Although the results of osmotic fragility testing may be similar in patients with hereditary stomatocytosis and hereditary spherocytosis, spherocytes are rarely seen on the peripheral blood smear in those with hereditary stomatocytosis. In addition to hereditary spherocytosis, spherocytes may be seen on the peripheral blood smear of patients with Heinz body hemolytic anemia, autoimmune hemolytic anemia, and liver disease.

162 THE THALASSEMIAS

MARIA DOMENICA CAPPELLINI

DEFINITION

The thalassemias, or more comprehensively the thalassemia syndromes, are a heterogeneous group of inherited hemolytic anemias characterized by deficient or absent production of one of the globin chains of hemoglobin. This leads to imbalanced globin chain synthesis that is the hallmark of all the thalassemia syndromes.

EPIDEMIOLOGY

Taken together, the thalassemias are the most common single-gene disorder in the world population, with estimated carrier numbers of more than 270 million, and more than 300,000 children are born each year with one of the thalassemia syndromes or one of the structural hemoglobin variants. The extremely high frequency of the hemoglobin disorders compared with other monogenic diseases reflects natural selection mediated by the relative resistance of carriers against *Plasmodium falciparum* malaria. Other factors that may be involved include the widespread practice of consanguineous marriage, increased maternal age in the poorer countries, and gene drift and founder effects. For these reasons, the thalassemias are most frequent in southeastern and southern Asia, in the Middle East, in the Mediterranean countries, and in northern and central Africa. However, as the result of mass migrations of African populations from high-prevalence areas, thalassemias are now encountered worldwide.

PATHOBIOLOGY

Normal adult red cells contain 97% adult hemoglobin (HbA: $\alpha_2\beta_2$), with approximately 2.5% of the minor component HbA_2 ($\alpha_2\delta_2$) and a small amount of fetal hemoglobin (HbF: $\alpha_2\gamma_2$). Because the stable tetramer $\alpha_2\beta_2$is the major component of hemoglobin after birth, there are two main forms of thalassemia: α-thalassemias and β-thalassemias. Because β-chain synthesis is fully activated only after birth, it follows that the β-thalassemias are not expressed as a disease in intrauterine life; they are manifested as γ-chain synthesis declines during the first year of life. In contrast, because α chains are shared by both fetal and adult hemoglobin, α-thalassemias are manifested in both fetal and adult life.

As knowledge about their genetic basis and pathophysiologic mechanisms has evolved, the thalassemia syndromes can now be classified at genetic and clinical levels (Table 162-1).[1]

TABLE 162-1 GENETIC AND CLINICAL CLASSIFICATIONS OF THE THALASSEMIAS

	GENETIC	CLINICAL
α-Thalassemias	α^0 α^+ Deletion (−α) Nondeletion (α^T)	α-Minor HbH disease Hydrops fetalis
β-Thalassemias	β^0 β^+ Variant with high HbA_2 Normal HbA_2 Silent Dominant Unlinked to β-gene cluster	β-Minor Thalassemia intermedia Thalassemia major
δβ-Thalassemia	$(\delta\beta)^0$ $(\delta\beta)^+$ $(^A\gamma\delta\beta)^0$	δβ-Minor Thalassemia intermedia
HPFH	Deletion Nondeletion Unlinked to β-gene cluster	Silent increase HbF

HbA = adult hemoglobin; HbF = fetal hemoglobin; HbH = hemoglobin H; HPFH = hereditary persistence of fetal hemoglobin.

Genetics

Six different types of globin chains (α,β,γ,δ,ε,ζ) are found in normal human hemoglobin at different stages of development. In the very early embryo, hemoglobin synthesis is restricted to the yolk sac and the production of hemoglobins Gower 1 ($\zeta_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$). Subsequently, at about 8 weeks of gestation, the fetal liver takes over, synthesizing predominantly HbF ($\alpha_2\gamma_2$) and a small amount (<10%) of HbA. Between about 18 weeks and birth, the liver is progressively replaced by bone marrow as the major site of red cell production; this is accompanied in the later stages of gestation by a reciprocal switch in production of HbF and HbA, which continues until, by the end of the first year, HbF production has dropped to less than 2%. The globin genes are encoded in separate gene clusters. The α cluster (ζ,α_2,α_1) lies at the telomere of chromosome 16; the β cluster ($\varepsilon,^G\gamma$ and $^A\gamma,\delta,\beta$) lies at chromosome 11p15.5. In both clusters, the genes are aligned 5′ to 3′ in the order in which they are expressed during development. Both sets of genes are under the regulation of enhancer-like elements (hypersensitive site [HS]–40 for α cluster and locus control region for β cluster) that lie some distance away at the 5′ end of the cluster. Deletion of these enhancer elements results in inactivation of any related globin gene. There are two α genes/alleles ($\alpha_2$and α_1) that differ by a few nucleotides in intron 2 and the 3′ untranslated region but produce identical protein products. The output of the α_2 gene exceeds that of the α_1 gene by two- to three-fold. The α cluster also contains pseudo-ζ and pseudo-α genes that are not translated into protein products. The region around a DNase1 hypersensitive site at 40 kilobases (kb) upstream of the ζ-globin gene (HS-40) is the major regulator of α-globin gene expression. The β cluster contains a single pseudo-β gene; the βcluster enhancer consists of five elements marked by erythroid-specific DNase1 hypersensitive sites lying 6 to 20 kb upstream of the ε-globin gene, each of which contains several binding sites for erythroid-specific and other transcription factors. All together, these elements are known as the locus control region, and each element contributes to the overall locus control region activity. In addition, there is an erythroid-specific hypersensitive site approximately 20 kb downstream of the β-globin gene; when the cluster is activated, the upstream and downstream hypersensitive sites are brought into proximity with the gene promoters to activate their transcription.

The individual globin genes share many general features; they consist of three coding sequence exons separated by two introns in identical position but of variable length for a total length of approximately 1500 nucleotides. This structure has been highly conserved throughout evolution. The upstream regions flanking the first exon contain a number of sequence motifs that are necessary for specifying correct transcriptional initiation. A TATA box is found at 30 base pairs upstream of the initiation site together with one or more CCAAT sites at 70 base pairs upstream. The gene promoters also contain a CACCC or CCGCCC box that binds erythroid Krüppel-like factor (EKLF) 1, and some have binding sites for erythroid transcription factor GATA-1. In model systems, mutations introduced into such sequences lead to reduction in the level of transcription.[2]

All the thalassemias have a similar pattern of inheritance; in most cases, the gene defects are transmitted in a mendelian autosomal fashion. Thus, the severe, symptomatic varieties usually result from the interaction of more than one genetic determinant. The inheritance of α-thalassemia is more complicated because it involves the products of the linked pairs of α genes (αα) (see Clinical Manifestations).

Molecular Basis of Thalassemias

The α- and β-thalassemias are divided into disorders in which no chains are produced from the affected chromosomes (α^0 and β^0) and those in which the output of the chains is reduced (α^+ and β^+). For the α-thalassemias, the most common molecular defects are deletions of one or both α genes, which are designated −α and − −, respectively. The single α gene is believed to have arisen by crossover between two misaligned α genes on the homologous chromosome that can give rise to chromosomes with either single (−α) or triplicated (ααα) α-globin genes. Depending on the point of crossover, deletions may remove between 2.5 and 5.3 kb of sequence, with the loss of 3.7 ($-\alpha^{3.7}$) or 4.2 ($-\alpha^{4.2}$) kb being the most prevalent. Full duplication of the α-globin gene locus, including the upstream regulatory element, has also been reported in subjects of different ancestry, suggesting that this type of homologous genetic recombination occurs relatively frequently in globin loci. To date, more than 20 different deletions that involve both α genes, resulting from illegitimate or nonhomologous recombination, have been reported. The lengths of deletion vary from 5.2 to more than 40 kb; the most

common are those from Southeast Asia, the Mediterranean, and the Philippines, designated $--^{SEA}$, $--^{MED}$, and $--^{FIL}$, respectively. Nondeletion types of α-thalassemia (α^{α}) are much less common than the deletion forms; in most cases, they result from single oligonucleotide mutations at regions of the α gene sequence that are critical for normal expression. Because expression of the α_2 gene is two to three times greater than that of the α_1 gene, it is not surprising that most of the nondeletion mutants predominantly affect expression of the α_2 gene. The mutations may affect the initiation codon or splicing signals, cause frame shifts, or introduce premature stop codons. At least five single-nucleotide variants affect the natural termination codon (TAA) of the α_2-globin gene. Among these, hemoglobin Constant Spring ($\alpha^{cs}\alpha$) is the most common and extensively studied. Finally, there are several α-globin variants that are so unstable that they undergo rapid, postsynthetic degradation. In such situations, β chains remain in excess within the red cell, and the patient carriers of these α-chain variants, by definition, have α-thalassemia. To date, 17 unstable α variants have been shown to produce the phenotype of α-thalassemia to a greater or lesser extent.[3]

Like the α-thalassemias, the β-thalassemias are classified as β^0 (in which no β-globin is produced) and β^+ (in which some β-globin is produced but less than normal). In some cases, the defects in β-chain production are so mild that they are designated β^{++}. So far, more than 200 different thalassemic mutations of the β-globin gene have been reported; most are point mutations within the gene or its immediate flanking sequence. A few β-thalassemia mutations that segregate independently of the β-globin gene cluster have been described, presumably involving *trans*-acting regulatory factors. The distribution of alleles is highly variable from one population to another, but within each population, there are only a few alleles that are common. The nondeletion forms of β-thalassemia account for most β-thalassemia alleles. An updated list of these mutations is accessible at the Globin Gene Server website (*http://globin.cse.psu.edu*). They include transcriptional mutations, RNA processing mutations, and mutations affecting translation.

Simple deletions of the β-globin gene are rare, ranging in size from 290 base pairs to more than 60 kb. The 619–base pair deletion at the 3′ end of the β gene is relatively common among Sind and Punjabi populations in India and Pakistan. The remaining deletions are restricted to single families, are necessarily β^0-thalassemias, and interestingly are associated with unusually high levels of HbA_2 in heterozygotes. Large deletions that affect the entire β-globin gene cluster $(\varepsilon\gamma\gamma\delta\beta)^0$ are rare and restricted to single families. Finally, some highly unstable β-chain variants may be manifested as a dominant form of β-thalassemia.[4]

The δβ-thalassemias and hereditary persistence of fetal hemoglobin (HPFH) are the result of deletions affecting various parts of the β-globin locus. These deletions are partially compensated by an increased expression of the γ genes that raises the level of HbF. The length of deletion accounts for different forms of δβ-thalassemia, including both $^{G}\gamma$ and $^{A}\gamma$ genes or only $^{A}\gamma$, and varies from 9 to 100 kb. Hemoglobin Lepore is a hybrid of δ and β chains resulting from a crossover between the two misaligned genes; this hemoglobin is synthesized inefficiently and gives rise to a form of δβ-thalassemia. Deletions of δ and β genes are also the molecular basis for many forms of HPFH that, however, usually have higher levels of compensatory HbF production than the δβ-thalassemias. Other HPFHs are due to point mutations in the promoter region upstream from the transcription start site in either the $^{G}\gamma$ or $^{A}\gamma$ genes that alter the binding of one or more transcription factors; they are known as nondeletion HPFHs. Genetic studies have identified three major quantitative trait loci that account for 20 to 50% of the common variation in HbF levels in patients with β-thalassemia and sickle cell disease as well as in healthy adults.

CLINICAL MANIFESTATIONS

The clinical manifestations (phenotype expression) of thalassemia syndromes are extremely variable and depend on the degree of globin chain imbalance.

α-Thalassemias

As previously mentioned, there are two major classes of α-thalassemias: α^0, in which both α genes are inactivated (− −/); and α^+, in which only one of the pair is defective because of α gene deletion or mutation (−α or $\alpha\alpha^T$).[5] The clinical spectrum of α-thalassemias correlates well with the number of the affected α genes, that is, from normal to the loss of all four genes. The inheritance of a normal allele (αα) with one of the α^+ or α^0 alleles most frequently results in α-thalassemia minor (− −/αα; −α/αα; $-\alpha^T/\alpha\alpha$; $\alpha^T\alpha$ /−α;−α/−α). In general, carriers of such genotypes have lower levels of total hemoglobin, mean corpuscular volume, and mean cell hemoglobin but higher red blood cell count than normal. The greatest differences are seen in mean cell hemoglobin, which is usually less than 26 pg. The peripheral blood smear is variable, showing various degrees of hypochromia with some target cells and occasional poikilocytes (Chapter 157). In carriers of α^0-thalassemia (− −/αα), it is possible to generate a few red cell HbH inclusions (β_4). The carriers of nondeletional forms ($\alpha\alpha^T/\alpha\alpha$) show slightly more marked hematologic changes than those for deletional forms. The hemoglobin constitution of adult carriers of α^+- or α^0-thalassemia is indistinguishable from normal but has slightly lower levels of HbA_2. Traces of hemoglobin Bart (γ_4) in the neonatal period are detectable in a large proportion of neonates with α-thalassemia, and they decline during the first 6 months after birth. The α-thalassemias are common in areas where β-thalassemias are also found at a high frequency. Thus, the coinheritance of α- and β-thalassemia trait may occur and even ameliorate the hematologic parameters. In some cases, for genetic counseling in families in which α- and β-thalassemias are present, genotype determination is essential. The unstable mutant Hb^{CT} causes a severe reduction in α_2-globin expression from the affected chromosome; therefore, the carriers and particularly the homozygotes have a more severe phenotype than α-thalassemia minor but not as severe as most cases of HbH disease.

HbH disease most frequently results from the interaction of α^+- and α^0-thalassemia, and not surprisingly most patients originate from the populations of southeastern Asia, the Mediterranean, and the Middle East. HbH disease is a diagnosis attributed to subjects older than 6 months having a sufficient globin imbalance to produce detectable levels of HbH (>1 to 2%) in their peripheral blood together with inclusion bodies (β_4 tetramers) in their red cells. The clinical phenotypes encompass a wide spectrum from mild clinical manifestations to thalassemia intermedia and are included in the so-called non–transfusion-dependent thalassemias.[6] The predominant features of HbH disease are a hypochromic, microcytic anemia with jaundice and hepatosplenomegaly. Because the main mechanism of the anemia is hemolysis rather than dyserythropoiesis, only a few patients have clinical evidence of an expanded erythron. The most common complication of HbH disease is the development of hypersplenism due to severe splenomegaly. Other complications include gallstones, leg ulcers, increased risk of infection, folic acid deficiency, and increased risk of venous thrombosis mainly after splenectomy. Hemoglobin levels range in different series from 3 to 12 g/dL, with fluctuations that may occur after exposure to an oxidant drug, infection, or transient aplasia possibly due to intercurrent viral infection. Rarely, patients with HbH disease require regular blood transfusions. The anemia is associated with reticulocytosis and typical thalassemic changes of the red cell indices. The relative amount of HbH varies from 1 to 40%. The values of HbA_2 are always reduced. The peripheral blood film shows hypochromia with variable anisopoikilocytosis, target cells, and basophilic stippling. The characteristic feature of HbH disease is that it is always possible to generate multiple inclusions in the red cells after incubation with brilliant cresyl blue. The bone marrow shows marked erythroid hyperplasia.[7]

The most severe form of α-thalassemia is hydrops fetalis, in which all four α-globin genes are deleted (genotype − −/− −). It is incompatible with life. In fact, because α-globin chains are absent during gestation, hemoglobin Bart (γ_4) becomes the dominant hemoglobin. Because of its high oxygen affinity, hemoglobin Bart is unable to deliver oxygen to tissues, and the intrauterine consequences are progressive severe anemia, severe ineffective erythropoiesis with marked extramedullary erythropoiesis, massive organomegaly, heart failure, severe hypoalbuminemia, and edema. Infants with hydrops fetalis syndrome die either in utero (30 to 40 weeks of gestation) or soon after birth. The hemoglobin levels range from 3 to 20 g/dL; the peripheral blood film is characterized by marked anisopoikilocytosis, large hypochromic macrocytes, and many nucleated red cells. The hemoglobin consists almost entirely of hemoglobin Bart (80 to 90%), with some remaining HbH and Portland. Mothers of these infants often have a history of previous neonatal deaths. Without medical care, women carrying these fetuses may have delivery and postpartum complications (e.g., retained placenta, eclampsia, sepsis) (Chapter 239).

There are several reports describing α-thalassemia in association with mental retardation (so-called ATR-16 syndrome). These conditions are mainly due to large deletions (one or two megabases) of the tip of chromosome 16 including the α-globin gene cluster. However, several cases have no deletions or other apparent abnormalities of the α-globin gene cluster. It has been shown that these patients with a peculiar phenotype characterized by severe mental retardation, dysmorphic facies, genital abnormalities, and

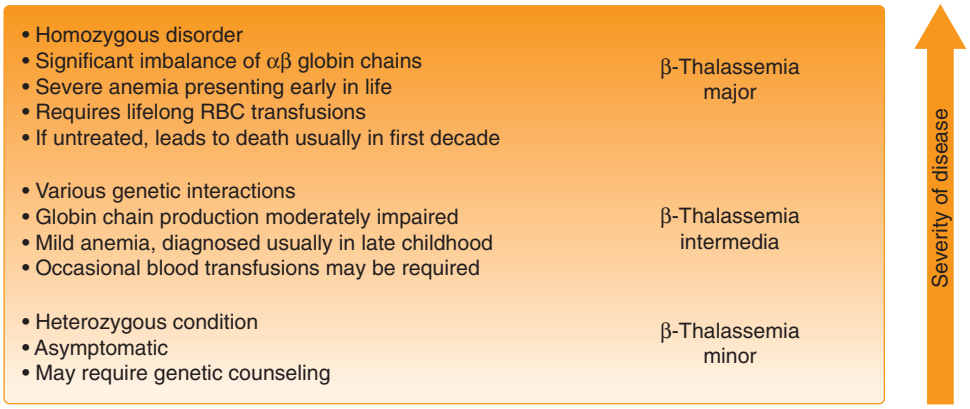
α-thalassemia have a disorder that maps to the X chromosome (ATR-X syndrome).

β–Thalassemias

The β-thalassemias include a considerably heterogeneous group of disorders of hemoglobin synthesis, all of which are characterized by a reduced output of the β chains of adult hemoglobin.[8] The clinical classification includes thalassemia major (TM, transfusion dependent), thalassemia intermedia (TI, of intermediate severity, non–transfusion dependent), and thalassemia minor (asymptomatic) (Fig. 162-1 and Table 162-1). The severity of the clinical manifestations correlates well with the degree of imbalance of globin chains; depending on the β-globin gene defects and their interaction, the production of β-globin chains is quantitatively reduced to different degrees, whereas the synthesis of α-globin continues as normal, resulting in accumulation of excess unmatched α-globin chains in the erythroid precursors. The free α-globin chains are not able to form stable tetramers; they therefore precipitate in the erythroid precursors, forming inclusion bodies that damage the red cell membrane, thereby causing premature destruction of erythroid precursors in the bone marrow (ineffective erythropoiesis). Ineffective erythropoiesis leads to a sequence of events responsible for bone marrow expansion, anemia, hemolysis, splenomegaly, and increased iron absorption. Any factor that reduces the degree of chain imbalance and the magnitude of α-chain excess, such as coinheritance of α-thalassemia or an innate ability to increase fetal hemoglobin, will ameliorate the clinical expression of the disease (Fig. 162-2).

The major forms of β-thalassemia (still sometimes called Cooley anemia) are disorders in which life can be sustained only by regular blood transfusions. This condition usually results from the homozygous state or from the compound heterozygous state for severe β-gene mutations (β^0). The typical forms of TM become manifested during the first year of life, during which γ chains are switched off but not replaced by β-chain synthesis. These infants, left untreated, are incapable of maintaining a hemoglobin level above 5 g/dL and show marked bone deformities and growth retardation. They develop the "thalassemic" facies due to frontal bossing of the skull and protrusion of the jaws and cheekbones. The magnitude of the increase in erythropoiesis may result in extramedullary masses arising usually from the sternum and ribs. Progressive hepatosplenomegaly is a constant finding leading to pancytopenia. The early childhood of the untreated or inadequately treated TM patients is interspersed with various complications including recurrent infections, spontaneous fractures, gallstones, and leg ulcers. The mortality rate in such patients was formerly high around puberty. Fortunately, this is no longer the case in children with well-treated TM. TM children well transfused to maintain a hemoglobin level above 9 g/dL have relatively normal growth and development, and their future course depends on whether they have received adequate iron chelation (see Treatment). Many children who are adequately transfused and are fully compliant with iron chelation therapy develop normally, enter puberty, and become sexually mature. At present, we are dealing with an adult population of TM patients who may suffer from the side effects of long-term treatment, namely, transfusion-associated infections (particularly hepatitis B and C and, in some populations, HIV infection) and organ damage (liver, heart, endocrine glands) due to unsatisfactory long-term iron chelation. The main causes of death in adult TM patients still remain cardiac complications, although liver cirrhosis is also increasing because of the prolongation of life.[9]

Heart failure in these patients is multifactorial, involving chronic anemia, remaining iron overload, myocarditis, pericarditis, and probably other



A

	Thalassemia major more likely	Thalassemia intermedia more likely
Clinical		
Presentation (years)	<2	>2
Hb levels (g/dL)	<7	7-10

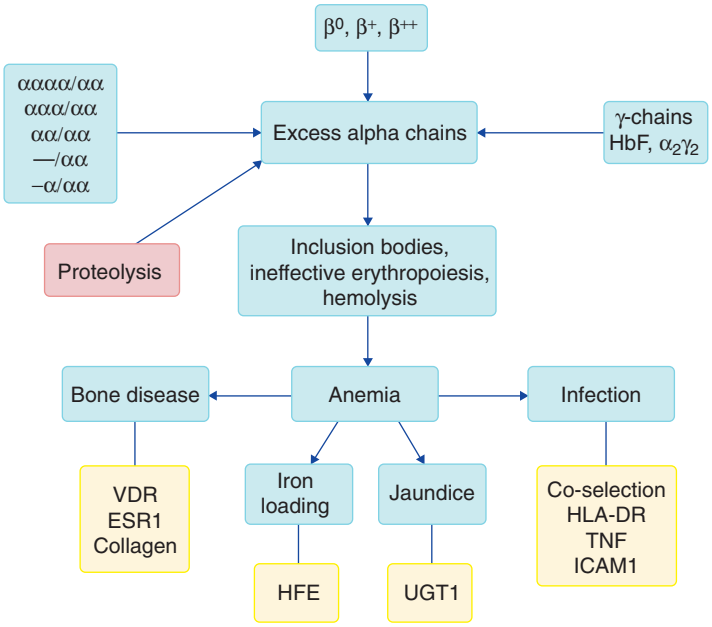

FIGURE 162-2. Pathophysiology of β-thalassemias and modifiers of globin chain imbalance. The severity of ineffective erythropoiesis is dependent on the degree of excess free α chains that result primarily from three different mechanisms: (1) inheritance of severe, mild, or silent β-chain mutations; (2) coinheritance of determinants associated with increased γ-chain production; and (3) coinheritance of α-thalassemia. A phenotype of thalassemia intermedia may result from the increased production of α-globin chains by a triplicated (ααα) or quadruplicated (αααα) α genotype associated with β heterozygosity. Inheritance of polymorphisms or mutations of genes involved in bone, iron, and bilirubin metabolism as well as in infection may contribute to modify the clinical course of the disease. ESR1 = estrogen receptor 1; HbF = fetal hemoglobin; HFE = hereditary hemochromatosis gene; HLA = human leukocyte antigen; ICAM1 = intercellular adhesion molecule 1; TNF = tumor necrosis factor; UGT1 = UDP-glucose : glycoprotein glucosyltransferase 1; VDR = vitamin D receptor.

mechanisms. Furthermore, besides the degree of globin chain imbalance that is dependent on genetic factors linked to the globin genes (coinheritance of α-thalassemia, innate increased synthesis of HbF), there are many other genetic modifiers that at the secondary level may affect the outcome of complications in different ways. For example, the presence of a polymorphic variant in the UGT1A1 promoter responsible for Gilbert syndrome (Chapter 147) may increase the predisposition to cholelithiasis, which is already a common complication in thalassemia. Likewise, polymorphisms in genes involved in iron homeostasis or bone metabolism may affect negatively or positively the degree of iron overload or the osteopenia and osteoporosis, respectively (see Fig. 162-2). Environmental factors, including social conditions, nutrition, and the availability of medical care, have also been implicated in the variable severity of TM clinical manifestations.

TI belongs to the non–transfusion-dependent group of thalassemia disorders; it is a clinical term used to describe patients with anemia and splenomegaly but without the full spectrum of clinical severity found in TM.[10] The clinical phenotypes of TI lie between those of thalassemia minor and major, encompassing a wide clinical spectrum. Mildly affected patients are almost completely asymptomatic until adult life, experiencing only mild anemia and spontaneously maintaining hemoglobin levels between 7 and 10 g/dL. Patients with more severe TI generally present between the ages of 2 and 6 years, and although they are able to survive without regular transfusion therapy, growth and development can be retarded. Most TI patients are homozygotes or compound heterozygotes for mild to moderate β-gene mutations (β^+/β^+;β^0/β^+); less commonly, only a single β-globin gene is affected. Because the clinical severity of the disease is dictated by the different extent of globin chain imbalance, at least three different mechanisms may promote the mild clinical characteristics of TI compared with TM: inheritance of mild or silent β-gene mutations; coinheritance of determinants associated with increased γ-chain production, which contributes to neutralizing the large proportion of unbound α chains; and coinheritance of α-thalassemia, which reduces the synthesis of α chains, thereby reducing the α/non-α chain imbalance.

Three main factors are responsible for the clinical sequelae in TI patients: rate of ineffective erythropoiesis, chronic anemia, and iron overload. The ineffective erythropoiesis primarily depends on the underlying molecular defects as already mentioned and is due to precipitation of free α chains in erythroid precursors in the bone marrow, causing membrane damage and premature cell death in the marrow. The degree of ineffective erythropoiesis is the primary determinant of the anemia of TI; peripheral hemolysis of mature, circulating red cells and an overall reduction in hemoglobin synthesis are secondary. Hemolysis and damaged red cells that expose negatively charged membrane phosphatidyl-serine residues have been linked to the development of the hypercoagulable state and increased risk of pulmonary hypertension in the TI patient population.[11]

Chronic anemia and chronic ineffective erythropoiesis lead to an inappropriate increase in gastrointestinal iron absorption, resulting in iron overload. In contrast, in TM, iron loading mainly results from transfusional iron infusion. It has been shown that chronic anemia and ineffective erythropoiesis, which are characteristic of TI, are associated with reduced expression of hepcidin, a hepatic peptide that plays a central role in iron homeostasis (Chapter 212). Moreover, the growth and differentiation factor 15 (GDF15) secreted by erythroid precursors and overexpressed in the presence of ineffective erythropoiesis may suppress hepcidin synthesis. More recently a molecule named erythroferrone, secreted by erythroblasts, has been identified and may also play a role in hepcidin regulation in TI. Taken together, ineffective erythropoiesis (leading to increased GDF15) and chronic anemia/hypoxia result in hepcidin suppression, increased dietary iron absorption from the gut, and increased release of recycled iron from the reticuloendothelial system, leading to an iron overload situation similar to that observed in patients with hereditary hemochromatosis syndromes (which are characterized by impaired hepcidin production)[12] (Chapter 212).

As a consequence of these pathophysiologic processes, several complications have been identified as unique in TI patients compared with TM patients, especially in splenectomized naïve patients. Cholelithiasis is much more common in TI than in TM because of ineffective erythropoiesis and peripheral hemolysis. Extramedullary hematopoiesis, as a compensatory mechanism, leads to the formation of erythropoietic tissue masses that primarily affect the spleen, liver, lymph nodes, and vertebrae. These masses may cause neurologic problems, such as spinal cord compression (sometimes causing paraplegia) and intrathoracic masses. Leg ulcers that are rare in well-transfused TM patients are common in adult TI patients; it remains unclear why at the same level of hemoglobin and at the same HbF level some patients develop leg ulcers and others do not. Thrombotic risk is definitely increased in TI patients. Several studies have collectively shown that the incidence of thromboembolic events is higher in TI splenectomized patients. Although stroke is rare in TI, asymptomatic brain damage including ischemia has been documented by magnetic resonance imaging (MRI) and computed tomography in TI patients. Pulmonary hypertension (Chapter 68) is prevalent in TI patients (approximately 60%) and is thought to be the primary cause of heart failure in this patient population.[13] Liver disease due to viral infection is less frequent than in TM; however, abnormal liver enzymes are frequently observed in TI patients, primarily because of hepatocyte damage resulting from iron overload. In some of the oldest patients with TI (>40 years), hepatocellular carcinoma (Chapter 196) due to long-term untreated iron accumulation has been detected with resultant cirrhosis in the liver as found in hereditary hemochromatosis (Chapter 212).[14]

Hypogonadism, hypothyroidism, and diabetes mellitus are rare. Although patients with TI generally experience puberty late, they have normal sexual development and are usually fertile. Women with TI may have spontaneous successful pregnancies, although complications during pregnancy may occur.[15]

Thalassemia minor is the heterozygous state of β-thalassemia. Subjects with thalassemia minor are "carriers" of a single β-globin gene defect, and they are usually asymptomatic except for a mild anemia of pregnancy. The carriers are usually identified as part of a family study, incidentally during an intercurrent illness, or as part of a population survey. The anemia is mild, microcytic and hypochromic, and associated with an elevated level of HbA_2. The blood smear shows characteristic microcytosis and hypochromia, with some variation in size and shape of the red cells. The presence of target cells is variable. The hematologic features are remarkably similar among different ethnic group. Carriers of β-thalassemia with normal HbA_2 have been observed in settings in which an individual with mild TI was found to have one parent with typical β-thalassemia minor with elevated HbA_2, whereas the other showed either minimal or no hematologic abnormalities and normal HbA_2. Subjects with normal HbA_2 are usually carriers of silent β^{++} mutations (β^{++}). Coincidental iron deficiency can lower elevated HbA_2 levels to the normal range.

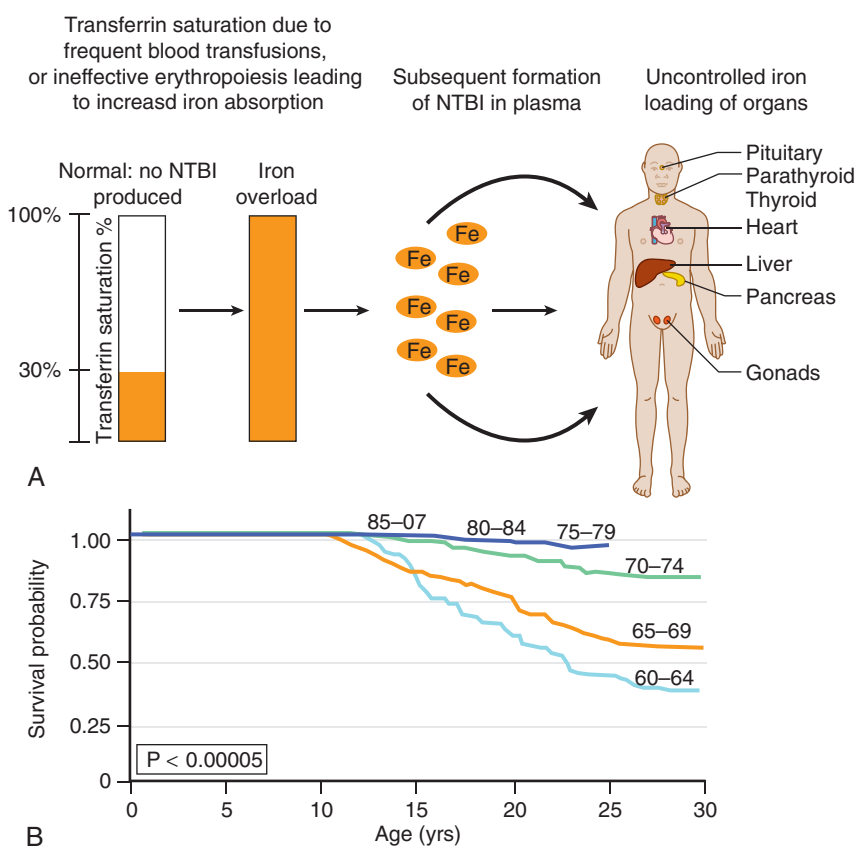

FIGURE 162-3. A, Transfusion iron overload and specific organ loading. B, Survival of Italian thalassemia major patients by cohort of birth. NTBI = non–transferrin-bound iron.

δβ-Thalassemia and Hereditary Persistence of Fetal Hemoglobin

The clinical manifestations of $(\delta\beta)^0$-thalassemias are similar to those of TI, whereas the heterozygotes are distinguished from β-thalassemia heterozygotes by normal levels of HbA_2 together with an increased HbF level of 5 to 20%. Homozygotes for Hb_{Lepore} may have phenotypes similar to either TM or TI. Subjects affected by deletion or nondeletion forms of HPFH are usually asymptomatic.

Any of the β-thalassemia defects may be coinherited with β-chain variants (HbS, HbC, HbE) and cause a clinically relevant β-thalassemia phenotype of different severity. These variants further illustrate that β-thalassemia syndromes have a wide clinical spectrum and that specific therapeutic approaches may completely change the clinical course and the natural history of these disorders (Fig 162-3).

Hemoglobin E and Hemoglobin E Thalassemias

Hemoglobin E (HbE) is caused by a substitution of glutamic acid by lysine at codon 26 of the β-globin gene. It is an common mutation, especially in the Indian subcontinent and Southeast Asia and among people who have emigrated from those regions. The frequency of HbE approaches 60% in many regions of Thailand, Laos, and Cambodia. HbE results in reduced synthesis of the β-E chain and therefore has the phenotype of a mild form of β-thalassemia. HbE trait has little clinical significance; it may be associated with slight microcytosis without anemia, but it could be mistaken for iron deficiency without appropriate laboratory testing. Homozygous HbEE individuals have mild anemia and microcytosis, occasional splenomegaly, and peripheral blood smears showing red cell changes similar to those seen in thalassemia traits, including target cells.

HbE interacts with different forms of α-thalassemia to produce a wide variety of clinical disorders. Its coinheritance with β-thalassemia, a condition called HbE/β-thalassemia, is the most common severe form of β-thalassemia in Asia and globally represents about 50% of the clinically severe β-thalassemias.[16]

DIAGNOSIS

The diagnosis of thalassemia may be required in a patient with an appropriate, suggestive clinical picture or for the identification of a heterozygote subject as part of a family study or population screening program. The general approach is common to any form of thalassemia, regardless of presentation. The primary evaluation is based on hematologic changes; the red cell indices by electronic cell counter and the red cell morphology examined on a well-stained blood film are sufficient to direct further investigations. Individuals with mean corpuscular volume below 80 fL and mean corpuscular hemoglobin below 27 pg with normal iron parameters need to be further investigated. The red blood cell number is usually higher than normal. In the presence of anemia with thalassemic red cell changes, the next step is the evaluation of hemoglobin fractions (HbA, HbA_2, HbF, or hemoglobin variants) by electrophoresis on cellulose acetate at alkaline pH or, even better, by high-performance liquid chromatography that enables the precise measurement of HbA_2, HbF, and HbA and the provisional identification of a large number of hemoglobin variants, including HbE. An HbA_2 level above 3.5% associated with hypochromic microcytic red cells is diagnostic of β-thalassemia minor. HbA_2 values between 3.2 and 3.5% (borderline) should be interpreted with care because they could be due to interaction of more than one thalassemic defect (α and β), a silent β mutation, or concomitant iron deficiency. If iron deficiency is present, it should be corrected and the HbA_2 estimation repeated. The majority of individuals with thalassemic red cell indices with normal or low HbA_2 and normal HbF will be α^0-thalassemia carriers or α^+-thalassemia homozygotes. Carriers of α^0-thalassemia may have a few red cells with HbH inclusions. Microcytosis with low or normal HbA_2 levels with elevated HbF (2 to 20%) indicates heterozygosity for δβ-thalassemia. Patients with HPFH usually have normal red blood cell indices but increased levels of HbF with different intercellular distribution (homogeneous or pancellular with the exception of heterocellular HPFH) compared with δβ-thalassemia (uneven or heterocellular).

A radioactive method for measuring the α/β-globin synthesis ratio was introduced in the mid to late 1960s, and it was largely directed at prenatal diagnosis in the pre-DNA era. Although it gives a quantitative assessment of globin production, today its use is limited to difficult cases because of interaction of different globin chain defects. The definitive diagnosis of the thalassemia syndromes involves the identification of the underlying mutations through DNA analysis. There are several methods available for the diagnosis of any particular mutation, such as polymerase chain reaction (PCR) restriction enzyme analysis, PCR allele-specific oligonucleotides, gap PCR, and

direct sequencing that at present is probably the easiest and most reliable method. For deletion forms of α-thalassemia, the multiplex ligation-dependent probe amplification is a recently introduced, useful method.

During their clinical course, patients affected by different forms of thalassemia develop several complications mainly due to iron overload, which requires monitoring to direct iron chelation therapy. The principal methods of determining body iron levels (Chapter 212) are measurements of serum ferritin level and assessment of liver iron concentration from biopsy tissue or, as an alternative noninvasive method, by R2 MRI. High serum ferritin levels (>2500 μg/L) and high liver iron concentration (>15 g/dry weight) indicate high risk of significant morbidity and mortality. Cardiac iron can be measured by a T2* MRI procedure that allows estimation of the cardiac iron load. MRI T2* values below 10 milliseconds are always associated with severe iron load and high risk of heart failure within 1 year. MRI T2* values above 20 milliseconds are considered normal, meaning no iron in the heart. Echocardiography may also be useful to evaluate functional changes. For other complications, including endocrinopathies, liver disease, lung disease, thrombophilia, and bone disease, the diagnostic approaches are similar to those used in clinical practice; these are performed with consideration of test cost, performance characteristics, and preferences of the patients, as described in the corresponding chapters.

TREATMENT

Conventional Treatment

No specific treatment is required for α- or β-thalassemia heterozygotes (carriers, thalassemia minor), but they should receive appropriate genetic counseling. During pregnancy, thalassemia-carrying women may become more anemic, so they should be observed carefully, mainly during the second and third trimesters, and supported with folic acid. When real iron deficiency is associated with thalassemia traits, iron supplementation should be provided, monitoring transferrin saturation and ferritin. A few cases of in utero blood transfusions have been reported with hemoglobin Bart hydrops fetalis syndrome; most of the infants have been delivered prematurely by cesarean section, subsequent development has been abnormal, and survivors required regular blood transfusions after birth. HbH patients in general have high hemoglobin levels (8 to 9 g/dL) and do not need regular blood transfusion. Supplementation with folic acid (2 to 5 mg/day) is generally recommended, especially in pediatric patients. The major complications in HbH disease are hemolytic crises that may occur during or after acute infections; in such cases, immediate intervention, including blood transfusions and treatment for infections, should be promptly administered.

The clinical management of TM and TI remains the major issue. The quality and duration of life of TM and TI patients have been transformed in this century, with life expectancy increasing well into the third and fourth decades. Nevertheless, prolongation of life is accompanied by several complications, partly due to the underlying disorder and partly as a consequence of the treatment with blood transfusions and iron overload. Moreover, we are starting to deal with aging-related complications in the context of a multiorgan disease that requires management by a team of clinicians who have specific knowledge of thalassemias in adults, working together with different specialists and well-trained nurses. The conventional treatment of TM patients includes regular transfusion therapy and iron chelation. The definition of the optimal transfusion and iron chelation regimen has been the most important advance in the management of TM patients, with the primary objective being to control the ineffective erythropoiesis, its consequences, and the body iron burden. The optimal transfusion regimen involves regular blood transfusions, usually administered every 2 to 5 weeks, to maintain the pretransfusion hemoglobin levels above 9 to 10.5 g/dL. The decision to initiate lifelong transfusion therapy should be based on a definitive diagnosis of severe thalassemia, taking into account the molecular defects, the severity of anemia on repeated measurement, the level of ineffective erythropoiesis, and the clinical criteria (such as failure to thrive or bone changes). It is advisable that TM patients receive leukoreduced packed red cells to minimize transfusion reactions and pathogen transmission. Adverse reactions to red blood cell transfusions may occur during or after transfusion and can be hemolytic and nonhemolytic. Transfusion-related acute lung injury is rare but severe and must be immediately managed (Chapter 177).

Many patients with TM require splenectomy because of hypersplenism. However, optimal clinical management may delay or even obviate the need for splenectomy that was common in the past. Splenectomy should be considered for patients whose annual blood consumption increases progressively and is responsible for significant increases in iron stores despite good chelation therapy or in the presence of symptoms due to spleen enlargement. Clinical problems related to leukopenia or thrombocytopenia due to hypersplenism could also be the reasons for considering splenectomy.[17] The major complication of splenectomy is severe and sometimes overwhelming infection. Because removal of the spleen may reduce the primary immune response to encapsulated organisms, it is advisable to delay splenectomy until patients are at least 5 years old. The mortality rate for postsplenectomy overwhelming infection in thalassemia patients is approximately 50% despite intensive supportive care. Therefore, it is mandatory to adopt preventive measures including immunoprophylaxis (vaccination against *Streptococcus pneumoniae*, pneumococcus, and meningococcus), chemoprophylaxis, and education of the parent and patient to recognize and to report febrile illnesses.

Iron overload is an inevitable and serious complication of long-term blood transfusion therapy and hyperabsorption of dietary iron that requires adequate treatment to prevent early death, mainly from iron-induced cardiac disease. Optimal chelation therapy extends complication-free survival (see Fig. 162-3). The standard chelation therapy for more than 40 years was deferoxamine (DFO), given for 10 to 24 hours daily as a continuous subcutaneous infusion 5 to 7 days per week. The long-term efficacy of DFO has been extensively documented in large cohorts of patients in Italy and elsewhere. Unfortunately, compliance with the rigorous regimen of daily subcutaneous infusions is a serious limiting factor, and life expectancy in noncompliant patients is not different from that in the pre-DFO era. This has been the rationale behind the intensive effort to identify alternative, orally effective iron chelators. At present, two oral iron chelators are on the market: deferiprone (DFP) and deferasirox (DFX). DFP is registered in Europe and more recently in the United States. By the guidelines of the EMEA countries (Europe, Middle East, and Africa), treatment with DFP at doses of 75 to 100 mg/kg/day is restricted to patients unable to use DFO or patients with an unsatisfactory response to DFO as judged by serum ferritin levels and by liver iron concentrations. Studies indicate that DFP may be more effective than DFO in protecting the heart from the accumulation of iron. A potential benefit of combined DFO and DFP therapy has been observed, and according to Thalassemia International Federation guidelines, a combination treatment (DFO and DFP) should be considered for patients with high levels of heart iron or cardiac dysfunction. The new orally effective iron chelator DFX has been shown to be effective and safe in removing excess iron from different organs, including the heart. DFX is now available in most countries throughout the world as first-line treatment. Its use has clearly demonstrated that iron chelation is not a standard treatment, but it should be individualized according to age, history of compliance with previous chelation, and other factors. Monitoring and adjustment of iron chelation by repeated measurements of ferritin, calculation of iron intake by transfusions, and, whenever possible, measurement of cardiac and liver iron at least once by MRI are mandatory.

The management of TI patients is more complicated because of the wide heterogeneity of TI phenotypes. A number of options are currently adopted for treatment of TI patients, including transfusion therapy, splenectomy, modulation of HbF production, and hematopoietic stem cell transplantation (HSCT). However, increasing evidence is documenting the benefit of transfusion therapy in decreasing the incidence of complications. Thus, although the common practice has been to initiate transfusion when complications ensue, it may be worthwhile to start transfusion therapy earlier as a preventive approach, which will also help alleviate the increased risk of alloimmunization with delayed initiation of transfusion. The initiation of iron chelation therapy in patients with TI depends not only on the amount of excess iron but also on the rate of iron accumulation, the duration of exposure to excess iron, and various other factors in individual patients.[18]

Bone Marrow Transplantation and Experimental Therapies

Allogeneic HSCT (Chapter 178) in thalassemia syndromes has been increasingly successful during the last 2 decades, mainly in β-thalassemia major.[19] Predictors of poor transplant outcome are hepatomegaly, history of irregular chelation, and hepatic fibrosis. Patients are categorized into three risk classes. Class 1 patients have none of these adverse risk factors, class 2 patients have one or two adverse risk factors, and class 3 patients have all three. In the most recent update of the Pesaro group's experience, the probability of thalassemia-free survival for patients younger than 17 years at the time of HSCT receiving the allograft from an HLA-identical relative was 87% and 85%, respectively, in patients belonging to class 1 and class 2 and much lower in young patients in class 3. The progressive adjustment of conditioning regimens in class 3 patients and in adults (>17 years) has significantly reduced the incidence of transplant-related mortality in patients in class 3. Only 25 to 30% of patients with diseases potentially curable by HSCT have a suitable HLA-compatible sibling. Bone marrow transplantation from unrelated donors increases significantly the incidence of acute and chronic graft-versus-host disease, particularly in thalassemia. A study from the Eurocord cooperative group reported the outcome of 33 patients with thalassemia belonging to class 1 and class 2 (Pesaro classification) who received cord blood hematopoietic stem cells from an HLA-identical sibling; no patient died of transplant-related complications, suggesting that related cord blood HSCT is a safe procedure for thalassemia patients.[20]

An alternative treatment of β-thalassemia consists of the pharmacologic stimulation of HbF synthesis. In humans, hemoglobin switch from HbF to HbA occurs in the period around birth as a result of γ- to β-globin gene switching. A number of pharmacologic agents able to reactivate HbF synthesis have been identified, including hypomethylating agents, histone deacetylase inhibitors, and hydroxyurea. Whereas the effect of these pharmacologic treatments (particularly hydroxyurea) in sickle cell disease is clear (Chapter 163), their benefit on the clinical course of β-thalassemia is presently limited. The discrepancy between these two conditions in the response to HbF inducers may be mainly related to the higher level of HbF required in β-thalassemia to achieve clinical results compared with those observed in sickle cell disease. The limited clinical response to γ-globin inducers observed in the majority of β-thalassemic patients may be also a reflection of the unfavorable effects of these agents on the other globin genes (i.e., increased α-globin synthesis). A new molecule, sotatercept (ACE-011), an activin-type IIA receptor fusion protein, has recently been shown to increase the release of mature erythrocytes into the circulation by acting mainly on late-stage erythropoiesis. Clinical data in healthy volunteers have shown that treatment with sotatercept results in increased red blood cell parameters. A phase IIa, multicenter, open-label, dose-finding study to determine a safe and active dose level of sotatercept in adult patients with β-thalassemia intermedia is ongoing.

Gene therapy (Chapter 44) is an attractive approach for thalassemia syndromes; however, this strategy poses major challenges in terms of controlling transgene expression, which should be erythroid specific and sustained over time. Treatment of β-thalassemia, sickle cell disease, and other disorders through lentivirus-mediated gene transfer has been reported in murine and primate models, but until now few patients have been treated.

UNSTABLE HEMOGLOBINOPATHIES

More than 80 rare mutant hemoglobins have been reported to cause hemolytic anemia by either amino acid replacements or deletions that significantly lower solubility. These mutant hemoglobins form intracellular precipitates that can be detected as so-called Heinz bodies when the blood smear is exposed to a supravital stain. Structural abnormalities include mutations that weaken the linkage between heme and globin, disrupt secondary (α-helical) structure, or introduce a charged or polar side group into the hydrophobic interior of the globin subunit.

This disorder, sometimes called congenital Heinz body hemolytic anemia, is inherited in an autosomal dominant manner. Severely affected individuals have jaundice, splenomegaly, and, on occasion, dark brown urine due to the release of heme and aberrant conversion to dipyroles. The instability of a few of these globin mutants is so extreme that they cannot be detected by routine laboratory methods. This results in a thalassemia phenotype with microcytosis and ineffective erythropoiesis. Like individuals with glucose-6-phosphate dehydrogenase deficiency (Chapter 161), those with unstable hemoglobin mutants often lack clinical symptoms and signs of hemolysis until they develop an infection or are exposed to an oxidant drug.

The diagnosis can be established by a combination of a positive Heinz body preparation and either abnormal hemoglobin electrophoresis or demonstration of a precipitate after exposure of a hemolysate to heat or isopropanol. Some clinics have access to a reference laboratory that can identify the specific mutation by α- and β-globin DNA sequencing.

Most individuals with this disorder do not require treatment; some are symptomatic from severe anemia. Splenectomy generally results in a significant increase in red cell mass. However, the fraction of Heinz body–positive red cells increases markedly after splenectomy, and these patients are now at significant risk for development of pulmonary hypertension and cor pulmonale.

REVIEW QUESTIONS

1. An 18-year-old woman from Pakistan has been observed for a lifelong severe, microcytic and hypochromic anemia. Her hemoglobin levels have generally been in the range of 7 to 10 g/dL, but she recalls needing blood transfusions only twice in her life, on both occasions after traumatic bone fractures. Throughout childhood, her parents had kept her from playing sports or participating in activities requiring significant physical exertion because they had been told by pediatricians that she had a "weak heart." She had markedly delayed puberty but now had regular menses. Physical examination shows marked hepatosplenomegaly; laboratory test abnormalities include indirect hyperbilirubinemia and hyperglycemia. What is the most likely diagnosis?

A. β-Thalassemia major
B. Homozygosity for hemoglobin E (HbEE)
C. Hemoglobin H (HbH) disease
D. Hydrops fetalis
E. Hereditary juvenile hemochromatosis

Answer: C The clinical picture is most consistent with thalassemia intermedia. In the case of α-thalassemia, this would be most like hemoglobin H disease (most frequently resulting from the interaction of α^+- and α^0-thalassemia), with the β_4 tetramers of hemoglobin H forming red cell inclusion bodies leading to chronic hemolysis. Patients with α- or β-thalassemia intermedia become severely iron overloaded from lifelong hyperabsorption of dietary iron, even without needing blood transfusions. A similar gut hyperabsorption of iron occurs in familial hemochromatosis states, but those individuals are not typically anemic. This patient's hyperglycemia, growth retardation, possibly her bone fragility, and even the history of a "weak heart" (perhaps due to cardiomyopathy) are all manifestations of systemic iron overload. Thalassemias are especially prevalent not only in people of Mediterranean and Middle Eastern origin but also in those from the Indian subcontinent. In contrast to thalassemia intermedia, a patient with β-thalassemia major would be expected to be transfusion dependent throughout life. Hydrops fetalis, in which all four α-globin genes are deleted, is incompatible with life. Hemoglobin E, even in its homozygous state, causes little if any anemia and microcytosis.

2. Which of the following statements is correct regarding hematopoietic stem cell transplantation for thalassemia?

A. It can lead to thalassemia-free survival of at least 85% in low-risk, younger patients.
B. It should not be administered with cord blood for transplantation.
C. It has been mostly effective in the α-thalassemias.
D. It is mostly reserved for thalassemia patients who are poorly iron chelated and have liver involvement.
E. It is associated with a reduced risk of graft-versus-host disease compared with comparable unrelated transplants for other hematologic diseases.

Answer: A The highest risk indicators in hematopoietic stem cell transplantation for thalassemia are hepatomegaly, hepatic fibrosis, and poor iron chelation history. On the other hand, the Pesaro group's experience has demonstrated 87% disease-free survival in thalassemia patients who are younger than 17 years at the time of transplantation, have none of the risk factors noted, and are allografted from an HLA-identical related donor. Early experience with cord blood transplantation has shown it to be a safe procedure for thalassemia patients. Hematopoietic stem cell transplantation has been mainly successful in β-thalassemia. The risk of graft-versus-host disease (acute and chronic) after bone marrow transplantation from unrelated donors is at least as high in thalassemia as it is in other indications for bone marrow transplantation.

3. Heterozygosity for hemoglobin E

A. Is a rare form of unstable hemoglobinopathy
B. Is associated with lifelong, low-grade hemolysis
C. Causes iron overload from hyperabsorption of dietary iron
D. Is frequently associated with iron deficiency
E. Is of little if any clinical significance

Answer: E Hemoglobin E is one of the most common mutations in the world, especially in the Indian subcontinent and Southeast Asia. Its phenotype is that of a mild thalassemia, not an unstable hemoglobinopathy. It is of little if any clinical importance in its heterozygous form (HbE trait); even individuals who are homozygous for hemoglobin E (HbEE) usually have only mild anemia and microcytosis, without any clinical sequelae. Hemoglobin E can be mistaken for iron deficiency in the absence of further laboratory testing, but it is not known to be associated with iron deficiency.

SICKLE CELL DISEASE AND OTHER HEMOGLOBINOPATHIES

MARTIN H. STEINBERG

SICKLE CELL DISEASE

DEFINITION

Sickle cell disease, caused by a mutation in the β-globin gene (*HBB*), consists of a group of chronic hemolytic anemias, all characterized by vaso-occlusive events, hemolytic anemia, vasculopathy, widespread acute and chronic organ damage, and premature mortality.

EPIDEMIOLOGY

The prevalences of the various forms of sickle cell disease and of the sickle cell trait (HbAS), which is not truly a form of sickle cell disease,[1] vary in the United States and worldwide (Table 163-1 and Fig. 163-1). The sickle hemoglobin mutation became prominent in equatorial Africa, the Middle East, and India several thousand years ago, when deforestation, the rise of agriculture, and stagnant pooling of water permitted *Plasmodium falciparum* infection to become endemic. Individuals with HbAS were more likely to survive to reproductive age and had a selective advantage where falciparum malaria was present. Slave trading and war spread this mutation from Africa and other sites of origin to the Americas, throughout the Mediterranean basin, and eastward to the Indian subcontinent. In some sites in Africa, half the population has HbAS. The partial protection provided from severe malaria by HbAS, HbC, HbE, α-thalassemia, and β-thalassemia along with other red blood cell traits is the source of the selective pressure maintaining the high prevalence of these carrier states.

PATHOBIOLOGY

Globin, the protein portion of hemoglobin, harbors the iron-containing porphyrin heme ring and permits the molecule to operate efficiently in oxygen transport and its other physiologic functions (Fig. 163-2). Mutations can alter the primary amino acid sequence of the globin polypeptide, sometimes resulting in clinically significant diseases called hemoglobinopathies, of which sickle cell disease is an example. Sickle hemoglobin (HbS: $\alpha_2\beta_2^S$) is caused by an adenine (A) to thymidine (T) substitution (GAG → GTG) in codon 6 of the β-globin gene (*HBB*), resulting in replacement of the normal glutamic acid residue by a valine (Glu6Val) (Fig. 163-3). HbS polymerizes when it is deoxygenated, a property only of hemoglobin variants that have the *HBB* Glu6Val substitution. Critical amounts of HbS polymer within sickle erythrocytes cause cellular injury and lead to the phenotype of sickle cell disease, which is recognized by hemolytic anemia and vaso-occlusion. Other hemoglobin variants, such as HbE and HbC, are also common. More than 1000 hemoglobin mutations are known, and they can occasionally affect the stability and function of hemoglobin and cause hemolytic anemia (Chapter 158), disordered oxygen transport Chapter 166), or methemoglobinemia (Chapter 158). However, most globin mutations are clinically insignificant. Thalassemias (Chapter 162) are also caused by mutations in globin genes, but these mutations affect globin gene expression, reducing or preventing the synthesis of globin, although the structure of any globin produced is usually normal.

Sickle cell anemia (homozygosity for HbS) is noteworthy for its clinical heterogeneity. Any patient can have almost all known disease complications; some have almost none but die suddenly; some skip one or more

TABLE 163-1 GENETIC AND LABORATORY FEATURES OF COMMON SICKLE HEMOGLOBINOPATHIES*

GENOTYPE	GENETICS	PREVALENCE AMONG AFRICAN AMERICANS†	HEMATOCRIT (%)	MCV (fL)	HbS (%)	HbA_2 (%)	HbF (%)	SEVERITY‡
Sickle cell anemia (HbSS)	Homozygous HbS	1 : 600	18-28	85-95	>85	2-3	2-15	4
HbSS-α-thalassemia	Homozygous HbS α^+-thalassemia	30% of HbSS patients	25-33	70-85	>85	4-6	2-15	4
HbSC disease (HbSC)	Compound heterozygous HbS, HbC	1 : 800	28-40	70-85	50	2-3	1-8	2
HbS-β^0-thalassemia (HbS-β^0-Thal)	Compound heterozygous HbS, β^0-thalassemia	1 : 1600	20-30	65-75	>85	4-6	5-15	4
HbS-β^+-thalassemia (HbS-β^+-Thal)	Compound heterozygous HbS, β^+-thalassemia	1 : 1600	30-40	60-70	70-95	4-6	2-10	1-3
HbSE disease (HbSE)	Compound heterozygous HbS, HbE	Rare§	30-45	70-80	60	2-3	1	1-2
HbS-HPFH	Compound heterozygous HbS and gene deletion HPFH	Rare	38-45	70-80	70	2	20-30	0
Sickle cell trait (HbAS)¶	Heterozygous HbS	1 : 12	38-50	80-90	35-40	2-3	<1	0
Normal (HbAA)	Homozygous HbA	—	38-50	80-90	0	2-3	<1	—

Hb = hemoglobin; HPFH = hereditary persistence of HbF; MCV = mean corpuscular volume.
*Many other abnormal globin genes can be found as compound heterozygotes with the HbS gene. The most common of these are α-thalassemia, HbD, HbO (Arabia), HbG (Philadelphia), HPFH, Hb Hope, and Hb Lepore. Average ranges of laboratory values are shown, but these can vary according to the patient's age.
†These figures differ by the prevalence of the involved genes in the population studied. In West and Central Africa, where the disease is most common, approximately 2% of all newborns have sickle cell disease. The prevalence of the HbC trait in African Americans is 3%, and that of the β-thalassemia trait is 1%. About 30% of African Americans carry an α-thalassemia gene, which can alter the phenotype of sickle cell disease by causing microcytosis, reduced cell density, and less hemolysis.
‡Severity of disease compared with sickle cell anemia, clinically the most severe genotype. This is a qualitative ranking of the clinical severity of each genotype; within each genotype, there is great clinical heterogeneity.
§Although this combination is still a rare genotype, the rising Asian population in the United States (HbE is a Southeastern Asian gene) will make it more frequent with time. With few cases reported compared with the other genotypes, the phenotype of HbSE disease is not totally defined. It may resemble HbS-β^+-thalassemia with symptoms appearing mainly in adults.
¶Sickle cell trait should not be classified as a form of sickle cell disease. About 8% of African Americans are carriers of HbS. Carriers are hematologically normal with a normal life expectancy. The few abnormalities traceable to the presence of HbS besides the renal lesions (see Table 163-3) include a four-fold increased risk of pulmonary embolism, an increased risk of splenic infarction at high altitude, and a higher risk of dying during the course of exertional heat illness.

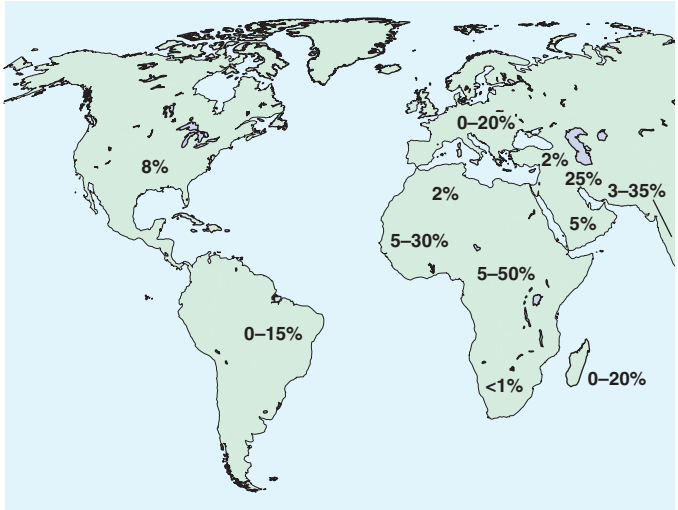

FIGURE 163-1. Worldwide prevalence of the sickle cell trait. Shown are the percentages of individuals with sickle cell trait in regions of the world where the hemoglobin S (HbS) gene is often present. In each geographic area, the prevalence of sickle cell trait can vary markedly according to racial or ethnic group, by historical migration patterns, and even from village to village. Not shown is the high concentration of the HbS gene in areas of Europe such as London, Manchester, and Paris, where migrants from Africa or Afro-Caribbean populations have settled.

complications of the disease but suffer intensely from others. Thus, this prototypical single-gene, mendelian disorder has exceptional phenotypic variability. Understanding of the pathobiology of the disease suggests many loci where the disease phenotype can be influenced by modifying genes. These genes affect the pathogenesis of sickle cell anemia by modulating fetal hemoglobin (HbF) concentration and mean corpuscular HbS concentration, and polymorphisms have also been noted in some genes that affect inflammation, oxidant injury, nitric oxide (NO) biology, vasoregulation, cell-cell interaction, blood coagulation, and hemostasis.[2]

HbF concentrations vary among patients with sickle cell anemia and among the erythrocytes of each individual.[3,4] Because HbF reduces HbS concentration and also directly inhibits HbS polymerization, its concentration within each cell and its distribution among all cells influence cellular heterogeneity. The sickle mutation is found on several different haplotypes of the β-globin gene cluster, reflecting different origins of the mutation in Africa and the Middle East; these haplotypes are associated with different HbF levels. The Senegal haplotype is associated with higher HbF levels than other African haplotypes are. The Arab-Indian haplotype, reflective of the HbS mutation that originates outside Africa, is associated with average HbF levels two to five times greater than in African haplotypes. Generally speaking, patients with higher HbF are more likely to have a less severe clinical course. Conversely, the Bantu haplotype, with lower HbF levels, may be associated with more disease complications. Nevertheless, there is great phenotypic heterogeneity within a particular haplotype group.

In sickle cell disease, erythrocytes are heterogeneous as a result of the highly variable cellular distribution and concentration of HbF and the varying increments of membrane damage. Cation homeostasis is impaired in some sickle cells.[5] A reduced capacity of sickle cells to maintain normal potassium gradients is mediated by activation of the Gardos, K^+/Cl^-, and other cotransport channels. As a result, sickle erythrocytes vary in their density and deformability. Irreversibly sickled cells (Fig. 163-4) always appear deformed because of permanent membrane damage, even though they may not contain HbS polymer. In some dense cells, the mean corpuscular hemoglobin concentration reaches 50 g/dL (normal, 27 to 38 g/dL), and deoxyHbS polymerization is exquisitely sensitive to the mean corpuscular hemoglobin concentration. Individuals with the highest numbers of irreversibly sickled cells and dense cells have the most hemolysis and anemia but not necessarily the highest incidence of acute vaso-occlusive events like painful episodes.

Hemolysis is mainly extravascular because of erythrophagocytosis by macrophages that recognize the damaged sickle erythrocyte. A variable amount of hemolysis is intravascular, and this liberates excessive amounts of hemoglobin into the circulation, thereby depleting haptoglobin and scavenging NO. This process promotes a vasoconstrictive, proinflammatory phenotype (Fig. 163-3). Certain complications of sickle disease, such as pulmonary

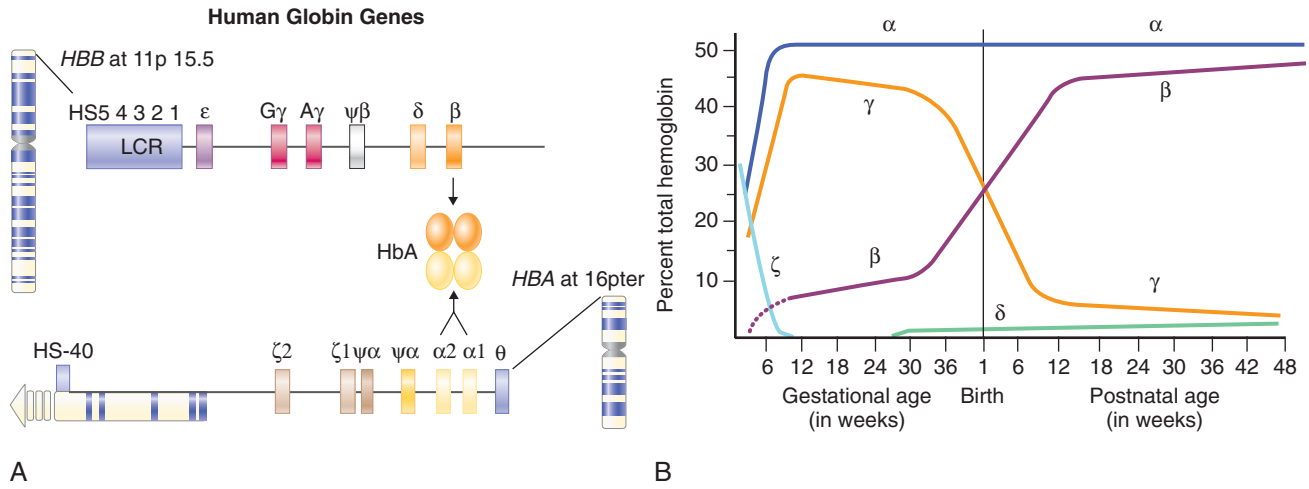

FIGURE 163-2. Human globin genes. A, The β-like globin gene cluster on chromosome 11 (*top*) and the α-like globin gene cluster (*bottom*) are shown. Two β-globin chains and two α-globin chains combine to form the normal hemoglobin A (HbA) tetramer, represented between the globin genes. Each globin chain contains one heme group, and oxygen transport takes place sequentially at the four iron-containing heme groups. Fetal hemoglobin (HbF) is composed of two α-globin and two γ-globin chains; the minor hemoglobin of adults, HbA_2, contains two α-globin and two δ-globin chains. Normally present at a level of only 2 to 3%, HbA_2 concentration is increased to 4 to 6% in most carriers of β-thalassemia. The ζ (*HBZ*) and ε (*HBE1*) genes are normally expressed only in the embryo. The 5′ ψα gene has been found to be expressed at a very low level and is now called the μ-globin gene (*HBM*). The θ-globin gene (*HBQ1*) is also expressed at low levels. Neither the θ nor the μ gene has been found in a functional hemoglobin. Any of the globin chains participating in hemoglobin formation may have a mutation altering its amino acid sequence. HbS, HbE, and HbC mutations affect the β-globin gene (*HBB*). Other mutations can affect the α-globin (*HBA1*, *HBA2*), γ-globin (*HBG1*, *HBG2*), and δ-globin (*HBD*) genes. LCR = locus control region. **B,** Expression of globin genes during development. The α chains are expressed throughout gestation and adult life, the fetal γ-globin chains are expressed predominantly in utero, and the β-globin and δ-globin genes are expressed mainly postnatally. This switching of gene expression patterns accounts for the different hemoglobins present in the embryo, fetus, and adult. It also accounts for the observation that disorders of α-globin can affect both fetus and adult, whereas β-globin chain diseases usually are not clinically apparent in the first months of life, when HbF levels are still high.

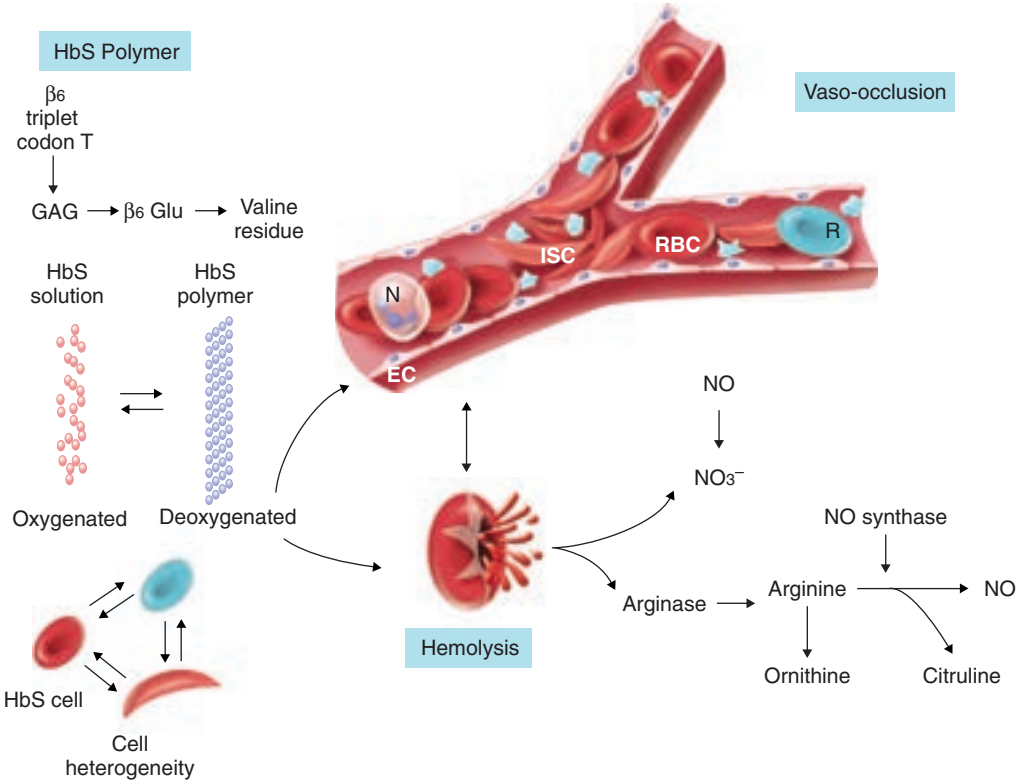

FIGURE 163-3. Pathophysiology of sickle cell disease. An adenine (A) to thymidine (T) transversion (A6T) at codon 6 in the β-hemoglobin gene on chromosome 11 (*HBB*) leads to the substitution of a glutamic acid codon by a valine codon. β^6 valine allows the hemoglobin S (HbS) molecule ($\alpha_2\beta_2^S$) to polymerize when it is deoxygenated. DeoxyHbS polymer injures the erythrocyte and leads to a heterogeneous population of sickle cells with damaged membrane cytoskeleton, reduced cation and water content, and altered distribution of membrane lipids. In the vasculature, sickle cells interact with endothelium and other blood cells to cause vaso-occlusion. Some damaged erythrocytes hemolyze intravascularly, thereby releasing heme into the plasma to scavenge nitric oxide (NO) and to reduce hemoglobin to methemoglobin and nitrate. NO, by binding soluble guanylate cyclase, converts cyclic guanosine triphosphate to guanosine monophosphate, thereby relaxing vascular smooth muscle and causing vasodilation. A state of reduced endothelial NO bioavailability in sickle cell disease impairs the homeostatic vascular functions of NO, such as inhibition of platelet activation and aggregation and transcriptional repression of genes transcribing cell adhesion molecules. Hemoglobin, heme, and heme iron catalyze the production of oxygen radicals and protein nitration, potentially further limiting NO bioavailability and activating endothelium. Lysed erythrocytes also liberate arginase, which destroys L-arginine, the substrate for NO production, providing another mechanism for endothelial NO deficiency. The normal balance of vasoconstriction versus vasodilation is therefore skewed toward vasoconstriction as well as endothelial activation and proliferation. EC = epithelial cell; ISC = irreversibly sickled cell; N = neutrophil; R = reticulocyte; RBC = red blood cell.

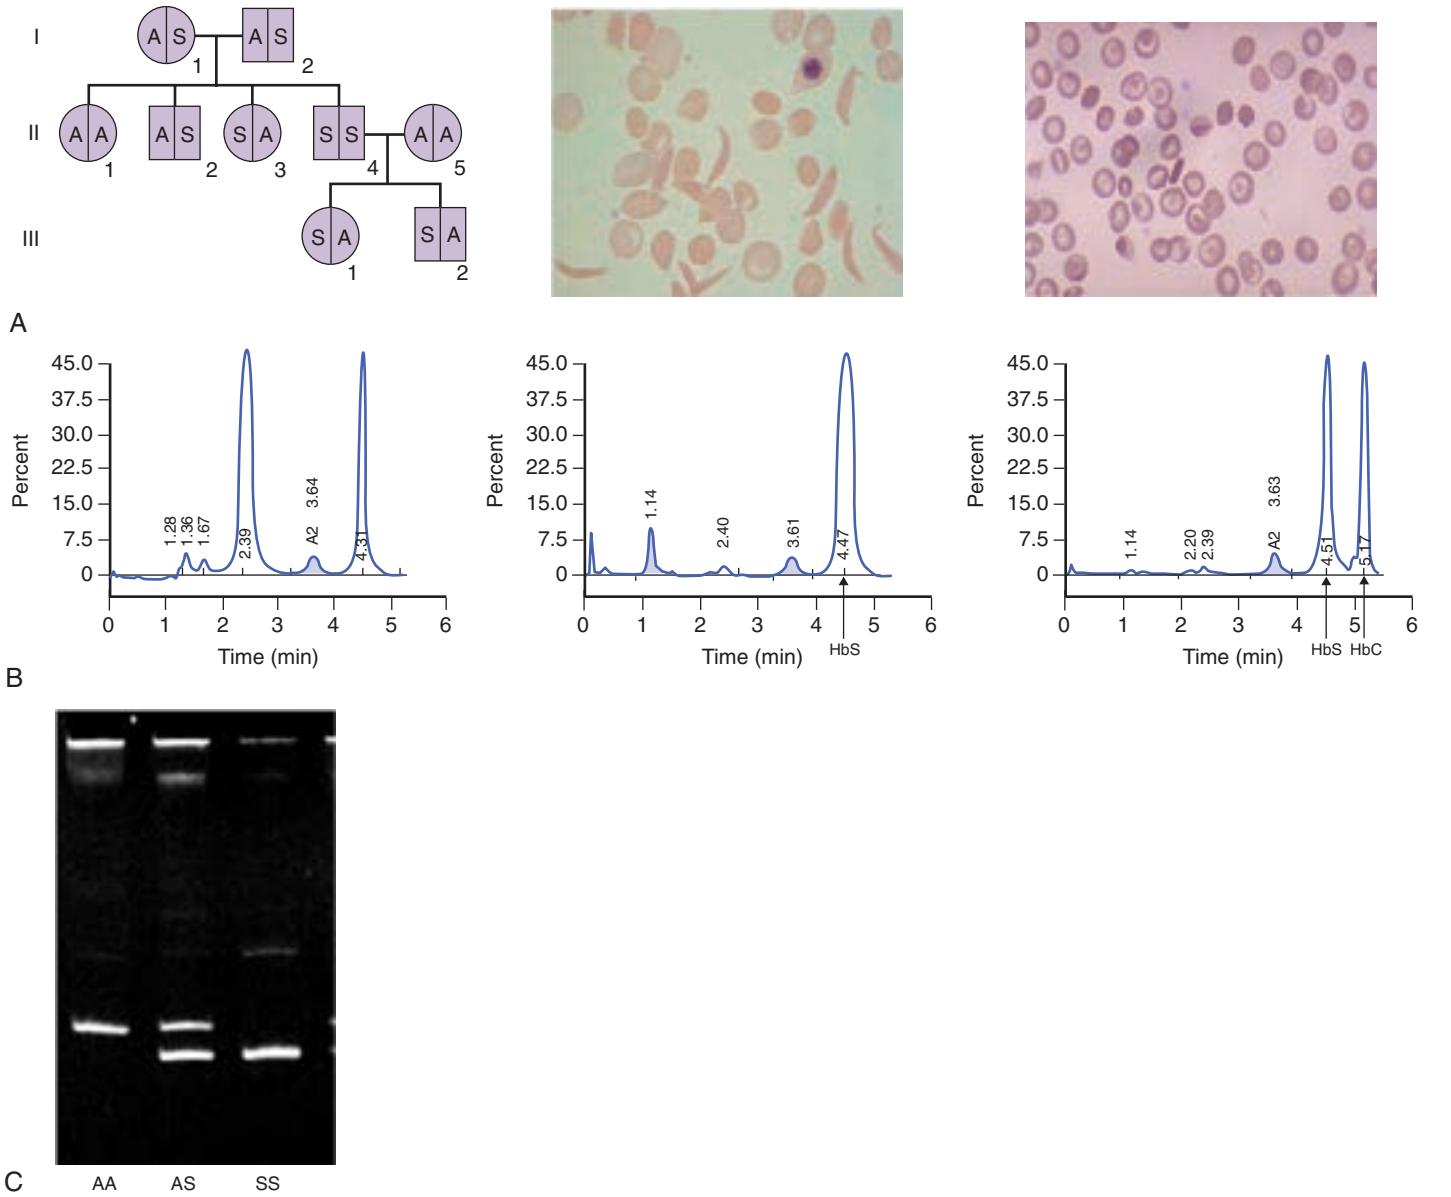

FIGURE 163-4. Diagnosis of sickle cell disease. A, A prototypical family structure in which both parents (I) have sickle cell trait and each offspring (II) has a 25% chance of having sickle cell anemia (SS). Each child of an affected parent (III) will have sickle cell trait (SA) if the other parent has a normal hemoglobin (AA) genotype. The blood films (*center and right*) are from patients with sickle cell anemia and HbSC disease, respectively. Note the irreversibly sickled cells in the former and the hemoglobin C (HbC) crystal and target cells in the latter. **B**, High-performance liquid chromatography profiles from patients with sickle cell trait (*left*), sickle cell anemia (*center*), and HbSC disease (*right*). **C**, Amplification refractory mutation system–based separation of the β-globin genes from a normal subject (AA), a carrier of sickle cell trait (AS), and a patient with sickle cell anemia (SS).

hypertension, priapism, leg ulcer, nephropathy, and stroke, are epidemiologically linked to the intensity of intravascular hemolysis, whereas other complications, such as painful episodes, acute chest syndrome, and osteonecrosis, are associated with high blood viscosity and the interactions among sickle cells, leukocytes, and the endothelium. Sickle vaso-occlusion and hemolysis are inextricably linked.

Vaso-occlusive events probably depend on features intrinsic to the sickle erythrocyte, such as polymer content and the degree of cellular damage, interacting with factors in the cell's environment, such as endothelial injury, vascular tone, and other blood cells. In the first hours of a painful episode, the number of dense erythrocytes falls; it rises again as pain resolves. These observations suggest the possibility that more deformable, more adherent cells might initiate vaso-occlusion, whereas dense cells become sequestered or destroyed in the microvasculature. Endothelial cells are responsive to many biologic modifiers that can be generated during sickle vaso-occlusive episodes and inflammation. Their activation and damage may be provoked by adherent sickle cells and shear stresses that cause release of oxidant radicals, expression of endothelin, and disturbed NO balance. Cellular damage enables adhesive interactions among sickle cells, endothelial cells, and leukocytes. Reperfusion injury can also induce endothelial activation and inflammation. The association of sickle and endothelial cells by a variety of adhesion molecules and their ligands may sufficiently delay cellular passage so that HbS polymerization, cell sickling, and vaso-occlusion happen before transit through the microvasculature is complete. Reticulocytes that are prematurely released from bone marrow display adhesive ligands that facilitate erythrocyte–endothelial cell interactions. Individuals with the greatest amount of hemolysis have the highest reticulocyte counts, and these adherent cells provide another link of hemolysis with vaso-occlusion. Neutrophils, which are modulators of inflammation and tissue damage, are increased in patients who have the acute chest syndrome, priapism, or stroke, and their numbers at baseline are a risk factor for survival.

CLINICAL MANIFESTATIONS

Sickle cell disease is a phenotype that results from different genotypes. Most patients have sickle cell anemia, HbSC disease, or HbS-β-thalassemia (see Table 163-1). Although the complications of disease are found in all genotypes, genotypes with higher cellular concentration of HbS are clinically more severe. Within milliseconds to seconds after HbS deoxygenation, depending on the intracellular concentration of HbS, HbS polymer appears in the sickle erythrocyte. In HbAS, each cell contains only 30 to 40% HbS, so polymer is not found under most conditions (see Fig. 163-4). Therefore, carriers have only subtle abnormalities and a normal life expectancy.

TABLE 163-2 FEATURES OF SICKLE CELL ANEMIA

Painful episodes: associated with higher hemoglobin and beneficially affected by high HbF
Acute chest syndrome: associated with higher hemoglobin and beneficially affected by high HbF
Stroke: associated with lower hemoglobin and little affected by HbF
Osteonecrosis: associated with higher hemoglobin and beneficially affected by high HbF
Priapism: associated with lower hemoglobin and little affected by HbF
Proliferative retinopathy: associated with higher hemoglobin and HbSC disease
Splenic infarction and sequestration more common in HbSC disease
Leg ulcers: associated with lower hemoglobin and beneficially affected by high HbF
Gallstones
Aplastic crisis due to B19 parvovirus
Osteopenia: bone marrow hyperplasia
Nutritional deficiencies: folic acid, zinc, calories
Pneumococcal disease and sepsis
Placental insufficiency

The features of sickle cell anemia change as life advances (Table 163-2). The switch from HbF to HbS underlies the clinical shift in life's first decade. This time is typified by acute problems: high risks of severe life-threatening infection, acute chest syndrome, splenic sequestration, and stroke. Chronic organ damage (renal failure, pulmonary hypertension, and late effects of previous cerebrovascular disease) becomes paramount in adults.

Most patients with sickle cell anemia have moderate anemia with a hematocrit between 25 and 30%. Some patients appear to have more severe hemolysis, with hematocrits less than 20%, marked reticulocytosis, and extreme elevation of serum lactate dehydrogenase. Patients with the most profound hemolysis appear more likely to have stroke, pulmonary hypertension, priapism, and leg ulcers (Fig. 163-5). Many patients with HbSC disease, especially adult men, have almost normal hematocrits and may have a higher incidence of sickle retinopathy, perhaps owing to their increased blood viscosity. Symptoms of anemia, such as weakness and dyspnea, are not the hallmarks of sickle cell disease, yet hemoglobin concentration can be a prognostic indicator for certain complications (see Table 163-2). A consequence of hemolysis is increased turnover of bile pigments, regulated in part by promoter polymorphisms in the uridine diphosphate glucuronosyltransferase 1A (*UGT1A*) gene, which is also associated with unconjugated hyperbilirubinemia and Gilbert syndrome (Chapter 147). As a result, more than half of all adults have cholelithiasis (Chapter 155). Hemolytic anemia places patients at risk for acute development of severe anemia when erythropoiesis is temporarily interrupted by parvovirus B19 infection (Chapter 371), which is the predominant cause of the aplastic crisis. Aplastic crisis is typified by a plummeting hematocrit, reticulocytopenia, and a bone marrow without erythroid precursors. It is a transient process, most common in children, and often requires blood transfusion to maintain circulatory competence until a spontaneous recovery follows. Rarely, if a patient's diet is inadequate, hemolysis-induced accelerated turnover of erythrocytes causes folic acid deficiency and megaloblastic anemia (Chapter 164).

Much of the epidemiologic data on the rate of complications in sickle cell disease discussed here antedates the widespread use of hydroxyurea in adults and its increasing use in very young children who have not yet developed complications of this disease. This, plus the use of chronic transfusions for prevention of stroke in many children, will change the phenotype of disease as these individuals advance to adulthood.

Ages 20 to 40 Years

Although any complication can occur at any age, certain events tend to predominate in different age groups. In the absence of hydroxyurea treatment or chronic transfusion, life's first decades are characterized by acute painful episodes, acute chest syndrome, and stroke. Delayed growth and sexual development, more severe in patients with sickle cell anemia than in those with HbSC disease, become major issues of concern to the adolescent, but sexual maturation is eventually achieved.

Psychosocial problems are common in adolescents with sickle cell disease. Difficulties with medical staff often begin in adolescence and frequently center on issues of pain management and inpatient stay.

The Painful Episode

Pain, presumed to be initiated by sickle vaso-occlusion, often starts in young children as the hand-foot syndrome or dactylitis: painful swelling of the hands and feet caused by inflammation of the metacarpal and metatarsal periosteum. Acute painful episodes are the most commonly encountered vaso-occlusive events in patients of all ages, but what triggers an acute painful episode is usually unknown. Commonly, painful episodes begin with little warning; some patients, however, may sense one in the offing. These episodes, which last hours to many days, can wax and wane in intensity and migrate from site to site. No useful laboratory test can tell whether a vaso-occlusive pain episode is occurring, and the history remains the best clue. Sickle cell pain is described as worse than postoperative or traumatic pain. Some women describe the pain of childbirth as paling in comparison with the pain experienced during painful episodes. These agonizing attacks of acute pain must be separated from chronic pain perhaps caused by osteoporosis of the spine, pain associated with osteonecrosis of the hips and shoulders, neuropathic pain, opioid-induced hyperalgesia, and the milder aches, pains, and soreness that are frequently present between severe episodes.

Almost all patients have acute painful episodes, but they vary greatly in number, severity, and frequency. Painful episodes are often stereotypical, affecting individuals in the same manner from episode to episode. Patients usually know whether the pain they are experiencing is different from their typical painful episode, and the wise physician should heed a patient's advice about the need for hospitalization or the likelihood that the pain has an alternative explanation.

In studies antedating the widespread use of hydroxyurea (see later), about 40% of patients did not have pain requiring a hospital visit in a given year, whereas 3% had more than six painful episodes per year. Having more than three pain episodes requiring hospitalization per year was associated with increased mortality among patients 20 years and older. Studies based on pain diaries suggest that pain is present on about half of all days and that most episodes are managed at home and not in a medical setting, so hospital visits underestimate the frequency of pain.

Most studies show that HbF levels are inversely related to the frequency of painful episodes. Concurrent α-thalassemia may increase the pain rate because it is associated with increased hematocrit. The day-to-day management of sickle cell disease often equates with the management of acute and chronic pain.

The pain accompanying acute chest syndrome, acute cholecystitis, splenic sequestration crisis, splenic infarction, or right upper quadrant syndrome may sometimes be mistaken for an uncomplicated pain episode. Acute painful episodes often precede the acute chest syndrome by 24 to 72 hours, and pain episodes occasionally end with multiorgan failure. Unexplained death can occur during acute painful episodes, perhaps as a result of an arrhythmia secondary to unrecognizable myocardial damage or perhaps as a sequela of pulmonary hypertension. Currently, it is not possible to foretell whether a "usual" pain episode will have an unexpected mortal outcome or presage acute chest syndrome, but the presence of atypically severe pain or an uncommonly high leukocyte count, low hematocrit, and thrombocytopenia should be cause for extra scrutiny.

Cerebrovascular Disease

A major complication of sickle cell anemia in early life is cerebrovascular disease that includes silent cerebral infarction and stroke caused by stenosis and occlusion of large vessels (Chapter 407).[6] Sickle erythrocytes and anemia-related high blood flow velocity lead to vascular damage. Hemorrhagic stroke in adults is a result of rupture of aneurysms or moyamoya disease, a proliferation of small vessels secondary to stenotic lesions (Chapter 407), and is associated with a mortality rate of more than 20%. Stroke is most common in HbS homozygotes, with much lower rates among those with HbSC disease or HbS-β^+-thalassemia. In the pre-hydroxyurea and pre–transcranial Doppler screening era, the incidence of stroke in sickle cell anemia was approximately 0.5 event per 100 patient-years until the age of 40 years, and the risk of having a first stroke was 11% by age 20 years, 15% by age 30 years, and 24% by age 45 years. These statistics have changed as a result of the use of transfusion to reduce the occurrence of stroke in children found to be at high risk by transcranial Doppler screening. Severe anemia, acute chest syndrome, and elevated systolic blood pressure are associated with ischemic strokes, whereas an elevated leukocyte count is a risk factor for hemorrhagic stroke. Concurrent α-thalassemia may protect patients with sickle cell anemia from stroke, perhaps because these patients have less hemolysis and a higher hematocrit. Subclinical neurologic events and silent cerebral infarction are even more common than stroke and are associated with decreased intellect and an increased likelihood of overt stroke. Neurologically

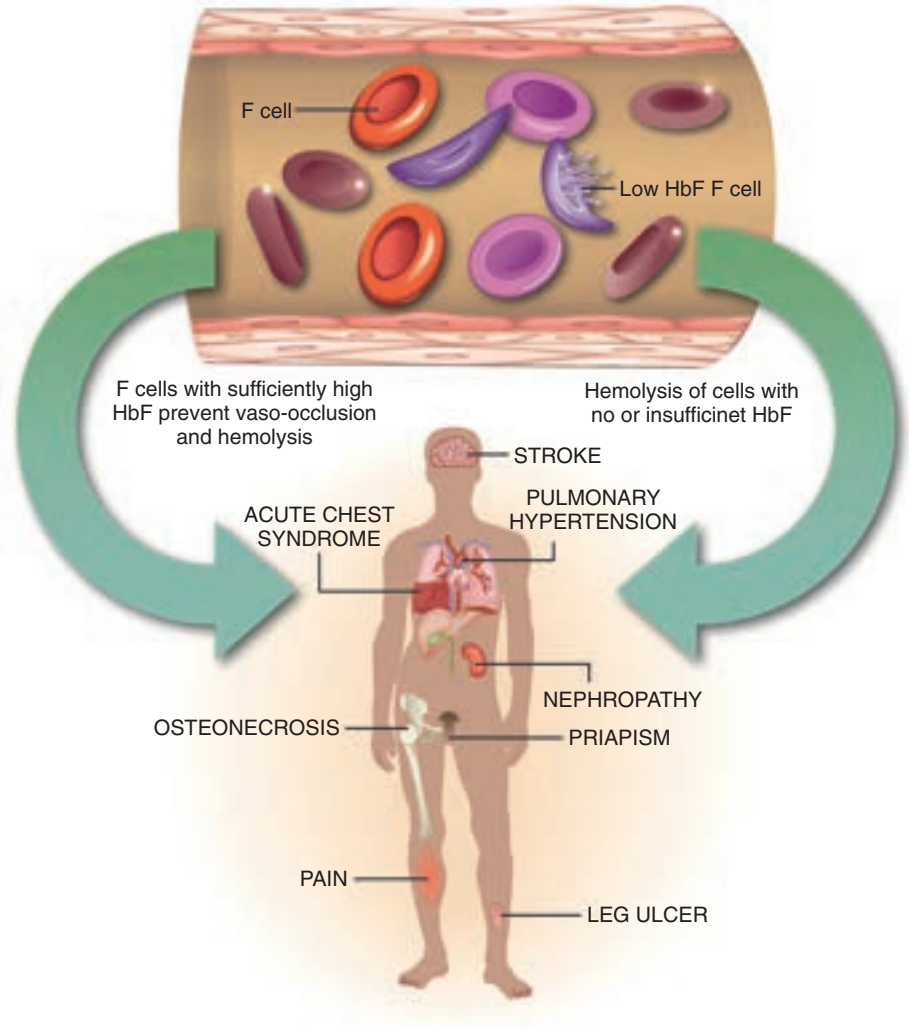

FIGURE 163-5. F cells and the subphenotypes of sickle cell anemia. The amount of HbF/F cell and the distribution of F cells vary among patients. In the example shown, some F cells have sufficiently high HbF concentration (bright red and magenta F cells), and their HbS will not polymerize or contains little polymer at physiologically relevant oxygen saturations. In some F cells (darker and brownish red), HbS polymerization will occur at venous oxygen saturations. Other cells with little or no HbF will have HbS polymers and sickle at high oxygen saturation; some of these cells will hemolyze intravascularly. Such cells, by releasing their hemoglobin intravascularly, can provoke certain subphenotypes of sickle cell disease. HbF = fetal hemoglobin.

intact adults without a stroke history have poorer cognitive performance than that of healthy controls.[7]

Acute Chest Syndrome

Acute chest syndrome, characterized by fever, chest pain, wheezing, cough, hypoxia, and a new lung infiltrate, is a sometimes lethal complication that affects more than half of all patients with sickle cell anemia.[8] It is the second most common reason for hospitalization and is a frequent cause of death in adults. The syndrome is more frequent in children, in whom its course is often mild, than in adults, in whom it tends to be more severe.

Commonly, acute chest syndrome develops after several days in individuals hospitalized for an acute painful episode (see earlier discussion). Acute chest syndrome also often occurs postoperatively, even when patients are properly prepared with blood transfusion. Other causes include rib infarction with atelectasis and regional hypoxia; fat emboli from the bone marrow (Chapter 98); infection with chlamydia, parvovirus B19, or other viral agents; microvascular or large-vessel in situ thrombosis; thromboembolic disease[9]; and vascular injury and inflammation. Fat embolism can be identified by finding lipid within pulmonary macrophages obtained by bronchopulmonary lavage, but this nonstandardized test is not recommended.

In most cases of acute chest syndrome, a cause cannot be found early enough to guide treatment.

Acute Anemia

Acute anemia can result from sequestration of blood in the spleen or liver; an aplastic crisis caused by parvovirus B19 infection (Chapter 371); or a severe vaso-occlusive event, such as acute chest syndrome or multiorgan failure. Transfusion may be needed. Megaloblastic arrest of erythropoiesis is uncommon if the diet is adequate in folic acid.

Infection

Because patients with sickle cell anemia are functionally asplenic early in life and hyposplenic later, they have increased susceptibility to infection with encapsulated bacteria. Persistent splenomegaly but not normal splenic function is common in patients with sickle cell disease in Africa, related to endemic malaria, and in Saudi Arabia, where half of the sickle cell disease population has α-thalassemia. Splenomegaly and splenic function often persist in patients with HbSC disease—hence the reduced incidence of infection but increased risk of splenic sequestration and infarction in adults. Prevention of mortality from pneumococcal infection is the basis for screening of newborns for sickle cell disease and the use of prophylactic oral penicillin in affected individuals. Pneumococcal vaccines (Chapter 18) are also recommended.

Pregnancy

There is no absolute contraindication to pregnancy for patients with sickle cell anemia, and fertility is probably normal. All approved methods of contraception can be used satisfactorily.

These are "high-risk" pregnancies, and close cooperation between the hematologist and obstetrician generally achieves good results; but the rates of pyelonephritis, pregnancy-induced hypertension (Chapter 239), and cesarean section are increased, and babies are more likely to have low birthweight. Limited data suggest that with good prenatal care, transfusions do not improve the outcome.

Osteonecrosis and Bone Diseases

Osteonecrosis of the hip and shoulder joints (Chapter 248) affects about half of all patients with sickle cell anemia or HbSC disease. Its onset is insidious but progressive, and most patients with early-stage disease progress to collapse of the femoral head within 2 years. Osteonecrosis of the hip usually is manifested with pain in and around the affected joint or at times with spasm of the surrounding muscles. Patients with higher hematocrits and with sickle cell anemia–α-thalassemia have the highest prevalence of osteonecrosis. Osteonecrosis can be detected very early by magnetic resonance imaging, but only more advanced disease is visible on plain radiographs.

Osteomyelitis (Chapter 272) is often difficult to distinguish from bone infarction. Osteomyelitis is usually caused by staphylococcal infection, but salmonella infection is a particular cause of sickle cell osteomyelitis.

Leg Ulcers

About 5 to 10% of patients with sickle cell anemia older than 10 years develop leg ulcers, but leg ulcers are rare in HbSC disease, in HbS-β^+-thalassemia, in Saudi Arabs with sickle cell disease, and in children before the age of 10 years. In the tropics, leg ulcers are more common. Small and superficial leg ulcers heal spontaneously with rest and careful local hygiene. Control of local inflammation and infection remains the mainstay of treatment. Dressing the ulcer with an Unna boot protects the involved area and is a reasonable method of conservative management. Deep, large, painful ulcers may require large doses of narcotic analgesics, prolonged bedrest, and even surgery.

Priapism

Priapism, a prolonged undesirable painful erection, may be seen in 40% of men with sickle cell anemia. Priapism in sickle cell anemia is usually bicorporal, with only the corpora cavernosa affected. Venous outflow is obstructed rather than arterial flow increased. In bicorporal priapism, the glans remains soft, and urination is normal. Recurrent, self-limited attacks of priapism can last for several hours with tolerable discomfort. These episodes have been termed stuttering priapism and usually have a nocturnal onset. Erectile function is usually preserved between attacks. Major episodes of priapism often but not always follow a history of stuttering attacks, last for days, and can be excruciatingly painful; they often end in impotency. Affected patients have a higher incidence of stroke, pulmonary hypertension, renal failure, leg ulcers, and premature death than individuals without priapism do, perhaps reflecting the severity of vasculopathy.

Digestive Diseases

Sickle hepatopathy, hepatic crisis, and right upper quadrant syndrome are terms applied to sickle cell–associated liver disease.[10] Liver disease may be related to intrahepatic and extrahepatic cholestasis, viral hepatitis (Chapter 148), cirrhosis, hypoxia, infarction, erythrocyte sequestration, iron overload (Chapter 212), or drug reactions (Chapter 150). Bilirubin levels can top 60 mg/dL, and such high levels are a poor prognostic sign portending liver failure. Differentiation among these potential causes can be difficult. Increased bilirubin levels (Chapter 147) are often a manifestation of hemolytic anemia and are related to polymorphisms of the UGT1A1 promoter.

Gallstones

Cholelithiasis (Chapter 155), a consequence of the accelerated bile pigment turnover typical of hemolytic anemia, can appear in the first decade of life, and more than half of all adults are affected. Depending on the degree of calcification, pigmented gallstones may be either radiopaque or radiolucent. Ultrasonography is the preferred means of detection, and laparoscopic cholecystectomy is the preferred method of dealing with symptomatic stones. Documented episodes of acute cholecystitis and typical obstructive jaundice are much less frequent than the presence of stones. If stones are asymptomatic or symptoms and laboratory findings suggesting cholecystitis are equivocal, careful observation may be the best course.

Beyond the Fifth Decade

Pulmonary Hypertension

Echocardiographic studies show that 30 to 43% of adults with sickle cell anemia have a tricuspid regurgitant jet velocity of more than 2.5 m/second (Chapter 55), and 5 to 10% of patients will have cardiac catheterization–documented pulmonary hypertension (Chapter 68). Both elevated tricuspid regurgitant jet velocity and true pulmonary hypertension are associated with a six- to ten-fold increased risk in mortality.[11] Increased tricuspid regurgitant jet velocity and the coexistence of relative systemic hypertension, renal disease, and intimal and smooth muscle proliferative changes in conduit vessels suggest the presence of a more widespread vasculopathy, which may be responsible for the observed mortality risk. Sickle cell anemia patients with pulmonary arterial hypertension have milder hemodynamics and symptoms compared with patients with idiopathic pulmonary arterial hypertension, particularly early in the course of disease, yet their survival is similar.

TABLE 163-3 RENAL ABNORMALITIES IN SICKLE CELL DISEASE*

Distal nephron
Impaired urine concentrating ability (hyposthenuria)
Impaired urine acidification—incomplete renal tubular acidosis
Impaired K^+ excretion
Hematuria
Papillary necrosis
Proximal tubule
Increased phosphate reabsorption
Increased β_2-microglobulin reabsorption
Increased uric acid secretion
Increased creatinine secretion
Hemodynamic changes
Increased glomerular filtration rate
Increased renal plasma flow
Decreased filtration fraction
Glomerular abnormalities
Proteinuria
Nephrotic syndrome with focal glomerular sclerosis
Chronic renal failure

*In carriers of sickle cell trait, because of its hypertonicity and oxygen content, HbS can polymerize in the renal medulla and lead to hyposthenuria, possibly an increased risk of urinary tract infection during pregnancy, papillary necrosis, and hematuria. A rare tumor, medullary carcinoma, arises from distal nephrons and is associated with sickle cell trait.

Nephropathy

Hyposthenuria is present in almost all patients with sickle cell anemia and even in most people with HbAS (Table 163-3). Clinically, the loss of urine concentrating ability is not important unless access to fluid is restricted. Isosthenuria, distal renal tubular acidosis, and impaired potassium excretion are signs of medullary dysfunction.

Glomerular hyperfiltration, increased creatinine secretion, and a very low serum creatinine concentration are characteristic of young patients with sickle cell anemia, so renal dysfunction can be present even with normal serum creatinine values. Glomerulopathy begins very early in life, but an increasing prevalence of renal failure is a hallmark of an aging population of sickle cell anemia patients. About 4% of patients with sickle cell anemia and 2% of those with HbSC develop renal failure, at median ages of 23 and 50 years, respectively. Among sickle cell anemia patients, 60% of those older than 40 years have proteinuria and 30% have renal insufficiency. Nephrotic syndrome is found in 40% of adults with creatinine levels above 1.5 mg/dL. Survival time for patients with sickle cell anemia after the diagnosis of sickle renal failure is 4 years, even with dialysis.

Eye Disease

Proliferative sickle retinopathy is present in less than 20% of patients with sickle cell anemia but in more than 40% of those with HbSC disease by the third decade of life. Vitreal hemorrhage and retinal detachment can occasionally lead to visual loss, but proliferative lesions may regress spontaneously. Screening for proliferative retinopathy by fluorescence angiography is recommended in patients with HbSC disease to guide possible laser photocoagulation.

Cardiovascular Complications

Cardiac complications of sickle cell disease are complex and can be manifested as both right and left ventricular systolic and diastolic dysfunction, elevated cardiac output, cardiomegaly, and myocardial ischemia. Progressive heart damage may result from iron overload in heavily transfused and poorly chelated patients, although this seems far less common than in β-thalassemia.

The heart is usually enlarged, with a hyperactive precordium and systolic ejection murmurs. Myocardial infarction is rare and when present suggests small-vessel disease.

Patients with sickle cell anemia usually have blood pressures that are in the normal range yet inappropriately high compared with controls who have similar levels of anemia. "Relative" hypertension in sickle cell anemia may reflect endothelial cell damage and increased NO scavenging by plasma hemoglobin. Survival is decreased, and the risk of stroke is increased as blood pressure rises. Treatment goals of 120/80 mm Hg or lower are generally the same as for other patients (Chapter 67).

DIAGNOSIS

Normocytic, microcytic, or macrocytic hemolytic anemia with reticulocytosis, increased levels of lactate dehydrogenase and aspartate aminotransferase, and a compatible clinical history should suggest the presence of sickle cell disease. Nevertheless, because of the multiple genotypes and considerable clinical heterogeneity of each genotype, milder cases may not be diagnosed for many years.

The Blood

In sickle cell anemia, the erythrocytes are normocytic or macrocytic, depending on the reticulocyte count. Microcytosis in a suspected case of sickle cell disease can be seen early in life, when iron deficiency has developed, or when β-thalassemia or α-thalassemia coexists with HbS. Sickled cells are usually present in the peripheral blood smear in sickle cell anemia and in HbS-β^0-thalassemia (see Fig. 163-4A) but are less common in other forms of sickle cell disease. In HbSC disease, target cells are prominent, and HbC crystallizes in some cells (see Fig. 163-4A). Irreversibly sickled cell numbers remain relatively constant over time, and their presence has no value for establishing whether a patient is experiencing a vaso-occlusive episode.

Hemoglobin Composition of the Blood

After 1 year of age, hemoglobin fractions are sufficiently stable to be relied on for diagnosis, but the high HbF concentrations of early infancy often make the results of hemoglobin analysis at that time difficult to interpret. In patients with sickle cell anemia, except in infancy, HbS almost always forms more than 80% of the hemolysate. HbS is best detected by high-performance liquid chromatography, which is also the method of choice for quantitation of the hemoglobin fractions in newborns and adults (see Fig. 163-4B). High-performance liquid chromatography provides excellent resolution of hemoglobin fractions, gives quantitative results, and is automated. HbF levels in adults average about 6% but can vary between 1 and 20%. DNA-based methods of detecting HbS are specific but usually are not needed for uncomplicated cases. Nevertheless, they are necessary for antenatal diagnosis and, sometimes, for genetic counseling (see Fig. 163-4C).

Family Studies

Hemoglobinopathies are inherited as codominant traits (see Fig. 163-2), implying that both normal and mutant alleles are expressed and are easily detectable. However, the sickle cell phenotype (see Table 163-1) is present only in homozygotes for HbS and in compound heterozygotes like HbSC disease. Family studies (see Fig. 163-4) can suggest a patient's hemoglobin genotype.

PREVENTION AND TREATMENT

Rx

Primary Prevention

In populations with a high prevalence of the HbS gene, heterozygote detection is simple, but there is little proven benefit of a broad screening effort to detect carriers. A preferred approach consists of educational programs about sickle cell disease and HbAS, followed by counseling for couples who are planning families. These couples are offered the choice of testing, after which the risks of having affected fetuses can be discussed and the availability of antenatal diagnosis presented.

General Measures

Sickle cell disease is a chronic disorder for which good nutrition and timely immunizations are critical. Work should be encouraged.

Children beyond the age of 5 years do not routinely need continued antibiotic prophylaxis. Neonatal screening to detect newborns with sickle cell disease allows early administration of prophylactic penicillin and antipneumococcal immunization. These measures reduce the incidence of and mortality from pneumococcal bacteremia in children younger than 5 years who have sickle cell anemia.

Because of increased rates of red blood cell production and inadequate nutrition, folic acid, 1 mg daily, is generally recommended but may not be necessary with a good dietary intake. There is no evidence that high concentrations of inhaled oxygen are of preventive value.

The transition from pediatric to adult care is a time of heightened vulnerability, and this period should be managed jointly by pediatric and adult providers in a structured program.

Hydroxyurea

Hydroxyurea, the sole drug approved by the U.S. Food and Drug Administration for treatment of sickle cell anemia, increases HbF in most patients. In a multicenter trial in adults with sickle cell anemia, hydroxyurea reduced the incidence of pain and acute chest syndrome by almost 50%, with little risk during more than 17.5 years of observation.[■] In follow-up studies, cumulative mortality was reduced almost 40%, and the favorable result was related to the ability of the drug to increase HbF and to reduce painful episodes and the acute chest syndrome.[■] Children have a more robust HbF response to hydroxyurea than adults do, and a study in children with a mean age of 13 months showed clinical results similar to those of the adult multicenter trial, whereas hemoglobin concentration and HbF levels were higher than those of placebo-treated controls.[■] Cancer and leukemia have been reported in adults with sickle cell disease treated with hydroxyurea, but whether the incidence is higher than in the general population is not known. Hydroxyurea should be used in nearly all adults and children with sickle cell anemia and HbS-β^0-thalassemia (Table 163-4).[12] However, not all patients who might benefit from this treatment receive it. A controlled clinical trial of hydroxyurea in HbSC disease has not been done.

Treatment of Common Complications

Painful Episodes

A decision as to whether hospitalization is needed can be made after an assessment of the duration and severity of the pain and the response to treatment. Associated factors, such as excessive tachycardia, hypotension, body temperature higher than 38.3°C (101°F), marked leukocytosis, fall in the hematocrit and platelet count, hypoxia, or new infiltrate on chest radiography, should prompt admission. On physical examination, there is sometimes localized swelling and pain over an involved bone. Low-grade fever and a mild increase in leukocytosis above baseline can accompany uncomplicated painful episodes, but higher temperature elevations may point to infection or extensive tissue damage.

The cornerstones of pain management (Chapter 30) are fluid replacement and opioid analgesics. Because almost every patient is hyposthenuric, urinary output in patients with sickle cell anemia may exceed 2 L/day, making them susceptible to dehydration. Pain is often accompanied by reduced fluid intake and increased water losses, so increased fluid intake is essential. Administration of 5% dextrose in water or 0.25 to 0.5 normal saline should be used for

TABLE 163-4 HYDROXYUREA TREATMENT IN SICKLE CELL ANEMIA*

BASELINE EVALUATION
Blood counts, RBC indices, HbF level, serum chemistries, pregnancy test, willingness to adhere to all recommendations for treatment, not receiving chronic RBC transfusions
INITIATION OF TREATMENT
Hydroxyurea 10-15 mg/kg/day or, for adults, 500 mg every morning for 6-8 wk
CONTINUATION OF TREATMENT
If counts are acceptable by CBC every 2 wk (granulocytes, ≥2000/mm^3; platelets, ≥80,000/mm^3), escalate dose in increments of 200 to 500 mg every 6-8 wk.
When a stable nontoxic dose of hydroxyurea is reached, CBC may be done at 4- to 8-wk intervals.
Most good responses require 1000 to 2000 mg/day, and a final dose of 30 mg/kg/day should be the maximum.
GOALS OF TREATMENT
Less pain, increase in HbF (usually measured every 6-8 wk) or MCV, increased hematocrit if severely anemic, acceptable toxicity
Failure of HbF to increase may be due to biologic inability to respond to treatment or, more often, to poor compliance with treatment. If compliance is documented, the dose can be increased cautiously to 2000-2500 mg/day (maximum dose, 30 mg/kg).

CBC = complete blood count; HbF = fetal hemoglobin; MCV = mean corpuscular volume; RBC = red blood cell.
*Special caution should be exercised in patients with compromised renal or hepatic function and in those who are habituated to narcotics. Contraception should be practiced by both men and women. Without chronic RBC transfusions or an intercurrent illness suppressing erythropoiesis, a trial period of 6 to 12 months is probably adequate.

initial fluid replacement. Although needs vary, hydration and serum electrolyte values should be monitored closely to avoid iatrogenic heart failure or electrolyte imbalance. The daily fluid intake should be approximately 3 to 5 L for adults and 100 to 150 mL/kg for children. Oxygen should be reserved for patients who are hypoxic or have acute respiratory distress. Infection should always be considered and treated early if it is present. Treatment with intravenous magnesium sulfate in addition to standard therapy for vaso-occlusive episodes in children aged 4 to 18 years has been found to have no effect on hospital length of stay, pain scores, or cumulative analgesia.

Analgesic management presupposes that other treatments, such as hydration, oxygen, and antimicrobial agents, are used if needed. The key to successful pain management is individualized treatment and dosing, taking into account prior pain management and prior use of opioids. Patient-controlled analgesia and a scheduled regimen of drug dosing are preferable, and analgesics on an as-needed basis should be avoided. Frequent reassessment of the effects of treatment is paramount so that opioid doses can be titrated for pain relief and tapered when relief is obtained. Morphine and hydromorphone are the principal opioids used; meperidine should be avoided because its metabolites (e.g., normeperidine) can cause central nervous system excitation. Pain management (Chapter 30) is complicated by the influence of learned pain behavior, pain memories, and pain therapy–induced pain. Management proves extremely difficult in perhaps 10% of all patients, and enormous doses of opioids are often required for relief. High opioid doses are associated with allodynia (pain produced by a non-noxious stimulus to the skin), opioid-induced hyperalgesia, and neuropathic pain.

Stroke

For new strokes due to cerebral infarction, after initial stabilization and transfusion, chronic red blood cell transfusion reduces the chance of recurrence. Long-term management of hemorrhagic stroke is unclear, and whether transfusion reduces its recurrence is unknown. Increased intracranial flow velocity, measurable by transcranial Doppler flow measurement only in children, increases the risk of stroke, but its sensitivity is only 10%, with a far from perfect specificity. Children found to be at risk for stroke by transcranial Doppler flow velocities should be started on chronic transfusions, but it is unclear whether or when such transfusions may be discontinued.

Acute Chest Syndrome

Routine treatments for acute chest syndrome initially include bronchodilators (e.g., albuterol nebulizer, 0.25 mL in 2.5 mL normal saline, or albuterol metered-dose inhaler during the acute episode), incentive spirometry, empirical antimicrobial agents in febrile patients as used for community-acquired pneumonia (e.g., ceftriaxone or azithromycin or levofloxacin for 5 to 7 days [Chapter 97]), and supplemental oxygen when hypoxia is noted by continuous or frequent monitoring of blood oxygen saturation. Opioids are often needed, but their dose should be titrated carefully to avoid respiratory depression and worsening of hypoxia.

Blood transfusion is the cornerstone of treatment when a patient becomes hypoxic, develops respiratory distress, has a clinically significant fall in the hematocrit and platelet count or increase in leukocyte count, or shows any sign of multiorgan failure, such as impaired mentation, rhabdomyolysis, renal failure, or liver failure. Both simple transfusion and exchange transfusions appear to reverse many adverse findings of the acute chest syndrome, but controlled studies have never tested the superiority of either method. Although the death rate in acute chest syndrome is less than 10%, a few patients have a rapidly deteriorating course with sudden development of the acute respiratory distress syndrome (Chapter 104), as manifested by increased oxygen requirements, extensive pulmonary opacification, and multiorgan failure. Excessive hydration, fat emboli, and widespread vaso-occlusion are potential contributing causes. Successful management of severe acute chest syndrome and acute respiratory distress syndrome requires close coordination among physicians and nurses. Some patients have repeated episodes of severe acute chest syndrome, and chronic transfusion can reduce the recurrence rate. Hydroxyurea also reduces the rate of acute chest syndrome by about 50%.

Osteonecrosis and Bone Disease

Treatment with reduced weight bearing, nonsteroidal anti-inflammatory drugs, and physical therapy is the mainstay of conservative management but does not retard progression of osteonecrosis and bone disease. Total hip arthroplasty can be successful, but about one third of prostheses fail within 4 to 5 years.

Diffuse osteoporosis (Chapter 243) is usually present, and osteomalacia (Chapter 244) due to vitamin D deficiency is common in both children and adults. If vitamin D deficiency is present, treatment with calcium (1000 mg PO daily) and vitamin D (50,000 IU PO every week for 2 months, then 50,000 IU PO every other week) is reasonable.

Priapism

Conservative treatment of priapism includes analgesics and hydration. No evidence supports the use of transfusion. Aspiration and irrigation of the corporeal bodies should be performed if more than 4 hours have elapsed from the onset of erection if the episode differs from prior episodes of stuttering priapism. Operative treatment, which should be considered after 24 to 48 hours of priapism, includes the creation of shunts between the corpora cavernosa and corpus spongiosum. Oral α-adrenergic agonists, such as etilefrine and pseudoephedrine, and phosphodiesterase-5 inhibitors, like sildenafil and tadalafil, have been used successfully to prevent severe acute attacks but are not useful for treating acute major priapism once it has occurred.[13]

Pulmonary Hypertension

Pulmonary arterial hypertension can be determined definitively only by right-sided heart catheterization, although echocardiography or measurement of blood N-terminal pro-brain natriuretic peptide levels can suggest its existence. As these patients are often asymptomatic early in the course of their disease, a consensus group convened by the American Thoracic Society recommended echocardiography for risk stratification in sickle cell disease adults every 1 to 3 years.[14]

Management of patients with few symptoms and minimally elevated tricuspid regurgitant jet velocity is not informed by clinical trials. For symptomatic individuals, optimization of hydroxyurea, transfusions, anticoagulation, bosentan, and epoprostenol have all been used. A controlled trial of sildenafil based on tricuspid regurgitant jet velocity and low exercise capacity was stopped early because of increased hospitalization for pain[A5] (Table 163-5).

Renal Disease

In a small randomized trial, 6 months' treatment with 25 mg/day of captopril caused a 37% reduction in microalbuminuria, compared with a 17% increase in placebo-treated patients; such treatment would be reasonable in patients with known microalbuminuria, but whether screening for this or long-term treatment is worthwhile is unknown. Nonsteroidal anti-inflammatory drugs reduce the glomerular filtration rate in sickle cell anemia and should be avoided in older individuals with creatinine levels of 1.2 mg/dL or higher. Dialysis and renal transplantation are used in end-stage sickle cell nephropathy, but with outcomes less favorable than in other types of renal failure.

Surgery and Anesthesia

Blood transfusion should be given before all surgeries requiring general anesthesia and selected other surgeries. Simple transfusion to a hematocrit of about 30% before surgery is as effective as exchange transfusion in preventing postoperative complications and causes fewer transfusion-related complications. In some low-risk surgeries, preoperative transfusion might not be necessary.

Implantable infusion ports and catheters have higher risks of complications in sickle cell anemia, including thrombosis of large veins and bacteremia. Low-dose warfarin may retard thrombosis of these devices.

Red Blood Cell Transfusion and Iron Chelation Therapy

Acute transfusions of packed red blood cells can be life-saving, and chronic transfusions reduce the incidence of stroke and severity of most complications of sickle cell disease. However, repeated transfusions produce iron overload, alloimmunization, loss of venous access, and viral infection. Whether exchange transfusion is preferable to simple transfusion in the acute chest syndrome or other acute complications has not been tested in clinical trials. For severe symptomatic anemia and stroke prophylaxis, simple transfusions are preferred. The customary level of chronic stable anemia alone is seldom

TABLE 163-5 PULMONARY COMPLICATIONS OF SICKLE CELL DISEASE

ACUTE CHEST SYNDROME
Diagnosis: chest pain, fever, cough, wheezing, new infiltrate on chest radiograph, hypoxemia
Management: simple or exchange transfusions, pain relief, oxygen if hypoxemic, bronchodilators, incentive spirometry, antibiotics (broad coverage)
PULMONARY HYPERTENSION
Screening evaluation: echocardiography with tricuspid regurgitant jet velocity ≥ 2.5 m/sec; elevated N-terminal pro-brain natriuretic peptide (≥160 pg/mL); reduced 6-minute walk distance (≤350 m)
Definitive diagnosis: screen by echocardiography beginning at age 18 yr; repeat echocardiography periodically according to symptoms or every 1 to 3 years. If tricuspid regurgitant jet velocity > 3.0 m/sec, refer for right-sided heart catheterization that provides a definitive diagnosis.
Management: Consider anticoagulation, treatment of iron overload and nocturnal hypoxemia. Optimize hydroxyurea, consider chronic transfusions and pulmonary vasodilator therapy.
ASTHMA
ABNORMAL PULMONARY FUNCTION

an indication for transfusion. With aging and the onset of renal failure, anemia worsens and can become symptomatic. Transfusion may become necessary, although judicious use of erythropoietin (e.g., darbepoetin, 0.45 µg/kg every 2 weeks, increased as needed) can often restore the hematocrit to prerenal failure levels only and should not be targeted at even higher levels because of the potential adverse effects of hyperviscosity.

It is advised that patients undergo erythrocyte phenotyping to determine their red blood cell antigens before embarking on a chronic transfusion program. Otherwise, alloimmunization occurs in about one fourth of frequently transfused patients. In the presence of multiple alloantibodies, it may be difficult to find compatible blood.[15]

With repeated transfusion, iron overload inevitably develops and can result in heart and liver failure and many other complications (Chapter 212). Serum ferritin is an inaccurate means of estimating tissue iron burden. For deciding when to begin iron chelation and for observing the effects of chelation, magnetic resonance imaging is now the standard, leaving little indication for liver biopsy to measure iron concentration.

Chelation of excessive iron can be achieved with deferasirox (20 mg/kg orally daily).■ Increases in serum creatinine concentration and proteinuria occur in about 40% of patients. Desferrioxamine is a parenteral chelator and is usually started at a dose of 25 to 30 mg/kg given subcutaneously five times per week as 8- to 12-hour continuous infusions (Chapter 212). Side effects include gastrointestinal and skin reactions, ototoxicity, retinal toxicity, bone and growth abnormalities, and *Yersinia* infection resulting from the sudden mobilization of iron. Another oral chelator, deferiprone, is less potent than deferasirox or desferrioxamine but is especially useful when magnetic resonance imaging shows high levels of cardiac iron. Side effects requiring discontinuation of deferiprone, seen in 5 to 10% of patients, include agranulocytosis, neutropenia, arthropathy, and gastrointestinal symptoms.[16]

Stem Cell Transplantation

Successful stem cell transplantation (Chapter 178) can cure sickle cell anemia, but only about 10% of patients have suitable donors. Myeloablative stem cell transplantation carries a 5 to 10% mortality rate and is poorly tolerated in adults. A nonmyeloablative regimen that uses total body irradiation and treatment with alemtuzumab and sirolimus has led to stable mixed chimerism in about 50% of adults transplanted with an HLA-identical family donor, with no graft-versus-host disease observed.[17] In another small study, similar results were observed for HLA-haploidentical transplants, thereby expanding the numbers of patients who could be offered this treatment.[18]

Future Directions

Experimental treatments to induce higher levels of HbF (thereby reducing HbS polymer), to decrease the adherence of sickle erythrocytes to endothelium, and to modulate the oxygen affinity of hemoglobin in the sickle cell are undergoing clinical trials. Where malaria is endemic, antimalaria prophylaxis reduces episodes of malaria and increases mean hemoglobin levels. Gene therapy, tried in a few patients with β-thalassemia syndromes with some early success, has not yet been reported in sickle cell disease, but trials should soon begin.

PROGNOSIS

Average life expectancy for patients with sickle cell anemia in the United States was reported to be between 50 and 60 years, but these figures do not reflect better supportive care or widespread use of hydroxyurea; patients with HbSC disease typically live 60 to 70 years. Patients with HbS-β^0-thalassemia are likely to have a life expectancy similar to that of those with sickle cell anemia, and the lifespan for patients with the HbS-β^+-thalassemia may resemble that of patients with HbSC disease. Death is often caused by pulmonary disease and infection, and another 20% of deaths are related to organ failure. However, death in adults often is unexpected, happening in the midst of an acute event such as an acute painful episode and occurring within the first 24 hours of hospitalization. In areas of the developing world without access to modern medical care, death in childhood is still common.

OTHER HEMOGLOBINOPATHIES

Hemoglobinopathies other than those associated with HbS, HbE (Chapter 162), and HbC rarely cause clinically recognizable disorders. HbC (*HBB* Glu6Lys) and HbE (*HBB* Glu26Lys) are common β-globin variants. HbC is present in about 2% of African Americans, and HbE is seen in Southeast Asia, where, in some areas, the gene frequency may reach 50%. HbE is a β-hemoglobin variant that is produced at a slightly reduced rate and hence has the phenotype of a mild form of β-thalassemia.[19] Heterozygotes with HbC or HbE are asymptomatic, although the blood of HbC trait carriers contains target cells, and HbE carriers may have mild anemia and microcytosis. Even homozygotes for HbC and HbE have virtually no clinical disease, only mild hematologic abnormalities such as microcytosis, target cells, and mild anemia. Screening testing can be done by high performance liquid chromatography.

Compound heterozygotes for HbE and β-thalassemia usually have the phenotype of transfusion-dependent β-thalassemia, although genotype-phenotype correlations are difficult to make because of the likelihood that other genes affect the expression of disease. Because of immigration from Southeast Asia, HbSE disease is increasingly common in North America and Europe. It resembles HbS-β^+-thalassemia.

Rare hemoglobinopathies may change the affinity of hemoglobin for oxygen, render it susceptible to oxidation, or cause molecular instability. Amino acid substitutions involving heme-binding residues may lead to irreversible iron oxidation, methemoglobinemia, and cyanosis (Chapter 158). Patients with these conditions have congenital pseudocyanosis but are usually asymptomatic and need no treatment.

Substitutions at contacts between globin subunits may alter the affinity of hemoglobin for oxygen. When hemoglobin-oxygen affinity is increased, less oxygen is available in tissues, erythropoietin production is enhanced, and erythrocytosis results (Chapter 166). No treatment is usually required because the erythrocytosis is mild. Hemoglobin-oxygen affinity may also be reduced by some mutations, resulting in anemia or cyanosis. Hemoglobin instability, produced by several molecular mechanisms (including introduction of proline residues into the α-helix, substitutions near the heme ring, and deletion or addition of amino acids), often causes loss of heme from the molecule and hemolytic anemia. Hemoglobin Köln is the most common example of this class of hemoglobinopathy, but more than 200 unstable variants have been described. Oxidant drugs sometimes provoke increased hemolysis. Splenectomy is sometimes an effective treatment when the anemia is severe.

REVIEW QUESTIONS

1. A 40-year-old man with sickle cell anemia (HbSS) requires open lung resection of a newly diagnosed and localized non–small cell lung cancer. He has had numerous hospitalizations in the past for sickle crises, including acute chest syndrome, and was taking hydroxyurea until about 3 years ago, when he discontinued it and was lost to follow-up. His complete blood count now is as follows: white blood cells, 11,000; hemoglobin, 9.5; hematocrit, 25.5; platelets, 420,000; reticulocytes, 4.5%. These values are similar to those he has had in the past. What preoperative management related to his sickle cell anemia should be recommended?

A. Transfusion of red blood cells to a hematocrit of about 30%
B. Exchange transfusions and initiation of iron chelation therapy
C. Hydroxyurea with a loading dose and then his previous maintenance dose
D. Erythropoietin therapy
E. None of the above but close hemodynamic and hematologic monitoring

Answer: A Cautious preoperative blood transfusion can improve surgical outcomes. Simple preoperative red cell transfusions to a hematocrit of about 30% are as effective as exchange transfusions to prevent postoperative complications, and they cause fewer transfusion-related complications. See the section Surgery and Anesthesia and reference A7 to the Transfusion Alternatives Preoperatively in Sickle Cell Disease ((TAPS) study, a randomized, controlled, multicenter clinical trial. Chronic iron chelation therapy is effective in the treatment of transfusional iron overload, but it is not urgent to begin it preoperatively, especially because he has not even had baseline magnetic resonance imaging evaluation for his level of iron overload (see the section Red Blood Cell Transfusion and Iron Chelation Therapy). Judicious use of erythropoietin therapy may be considered in sickle cell disease patients with renal failure, but even in those individuals, its effects on increasing the hematocrit are gradual in onset and unpredictable.

2. A 25-year-old woman with sickle cell anemia (HbSS) is brought to the emergency department after an episode of syncope. She has been observed regularly in the comprehensive sickle cell center of the hospital and has been taking hydroxyurea 500 mg daily for the past 4 years, which has been associated with a marked decrease in painful sickle crises. Blood counts have been regularly monitored during the hydroxyurea therapy, and the most recent complete blood count 1 week ago showed the following: white blood cells, 7500; hemoglobin, 9.9; hematocrit, 28.5; mean corpuscular volume, 106; platelets, 320,000; reticulocytes, 6.5%. On examination in the emergency department, she is sluggishly responsive, is hypotensive, and has a thread pulse with a rate of 140. There is mild, diffuse abdominal tenderness but no organomegaly or mass palpable. Stat complete blood count now shows the following: white blood cells, 8500; hemoglobin, 3.8; hematocrit, 17.2; reticulocytes, 0.2%; platelets, 410,000. What is the most likely diagnosis?

A. Acute vaso-occlusive crisis
B. Sequestration crisis
C. Marrow suppression by hydroxyurea
D. Aplastic crisis
E. Hyperhemolytic crisis

Answer D Acute anemia in patients with HbSS can have several causes, as described in the section Acute Anemia. A simple vaso-occlusive crisis should not be accompanied by an acute drop in hemoglobin and hematocrit. Sequestration crisis occurs in young children (peak age, 2 years) who still have a functioning spleen; they present with massive and painful enlargement of the spleen, not seen in this case, due to trapping of sickle cells in splenic sinusoids. Myelosuppression by hydroxyurea is always a concern, but her blood counts have been closely monitored and were unchanged just a week ago; and even if she happened to take an inadvertently high dose of the drug in the interval, her severe anemia should have been accompanied by major decreases in the white blood cell and platelet counts as well. Hemolytic crisis is essentially ruled out by the very low reticulocyte count. Aplastic crisis in HbSS patients is a rare but life-threatening emergency that is characterized by pure red cell aplasia typically as a result of parvovirus B19 infection. Parvovirus B19 has characteristic tropism for erythroid precursors and therefore causes severe erythroblastopenia in the bone marrow. Coupled with the ongoing brisk hemolysis of sickle cell disease, an abrupt shutdown of red cell production by the marrow leads to a precipitous fall in hemoglobin and hematocrit. In addition to aggressive but cautious red cell transfusions (to avoid fluid overload), intravenous immune globulin has been found to be effective by providing a large bolus of neutralizing antibodies to accelerate clearance of parvovirus B19.

MEGALOBLASTIC ANEMIAS

AŚOK C. ANTONY

DEFINITION

Megaloblastic anemias, a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells, are commonly due to a deficiency of vitamin B_{12} (cobalamin) or folate. These anemias are globally prevalent and carry a significant burden of morbidity. Folate and cobalamin are both required to sustain one-carbon metabolism, which involves the transfer of one-carbon groups such as methyl-, formyl-, methylene-, methenyl-, and

formimino- in enzyme reactions essential for pyrimidine and purine biosynthesis, including the synthesis of three of the four nucleotides of DNA. Thus, a deficiency in cobalamin or folate results in the common biochemical feature of a defect in DNA synthesis along with lesser alterations in RNA and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. The majority of megaloblastic cells have DNA values between 2 and 4 N because of delayed cell division. This is morphologically expressed as larger-than-normal "immature" nuclei with finely particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater "mature" cytoplasm and cell volume. The microscopic appearance of this nuclear-cytoplasmic asynchrony (or dissociation) is morphologically described as *megaloblastic*. Megaloblastic hematopoiesis commonly is manifested with anemia, the most easily recognized clinical manifestation of a global defect in DNA synthesis affecting all rapidly proliferating cells. Precise identification of the deficient vitamin and the cause of the deficiency (Table 164-1) dictates the dose and duration of replacement therapy.

EPIDEMIOLOGY

Cobalamin

Nutrition

Cobalamin is a red, water-soluble vitamin with a complex structure that generally resembles the heme molecule but with cobalt replacing iron in the center of the pyrrole ring. The recommended daily allowance of cobalamin is 2.4 µg for men and nonpregnant women, 2.6 µg for pregnant women, 2.8 µg for lactating women, and between 1.5 and 2 µg for children 9 to 18 years old. Cobalamin is produced in nature only by microorganisms, and humans receive cobalamin solely from the diet. Meat from parenchymal organs is richest in cobalamin (>10 µg/100 g wet weight); fish and animal muscle, milk products, and egg yolks have 1 to 10 µg/100 g wet weight. An average nonvegetarian Western diet with abundant meat, milk, and other dairy products and eggs contains 5 to 7 µg/day of cobalamin, which is adequate to sustain normal cobalamin equilibrium. Herbivores can receive minuscule amounts of cobalamin from nitrogen-fixing soil bacteria (genus *Rhizobium*) present in the roots and nodules of legumes; from fresh produce contaminated by tiny insects or cobalamin-rich manure; from dried seaweed varieties (nori, chlorella, and spirulina); and from tempeh (fermented soybean cake). However, these are not reliable sources of cobalamin. For vegetarians, the consumption of eggs, milk, and dairy products generally provides less than 0.5 µg/day of cobalamin and cannot sustain cobalamin balance.[1] Near-vegetarians who infrequently consume animal-source foods (often because of poverty) also have a cobalamin status that is only marginally better than that of lacto-ovovegetarians and are also at risk for cobalamin deficiency.

Cobalamin is stored exceptionally well in tissues. Of the total body content of 2 to 5 mg in adults, half is in the liver. With a daily loss of 1 µg, dietary

TABLE 164-1 ETIOPATHOPHYSIOLOGIC CLASSIFICATION OF COBALAMIN AND FOLATE DEFICIENCIES

COBALAMIN DEFICIENCY
Nutritional cobalamin deficiency (insufficient cobalamin intake): vegetarians, poverty-imposed near-vegetarians, breast-fed infants of mothers with pernicious anemia
Abnormal intragastric events (inadequate proteolysis of food cobalamin): atrophic gastritis, hypochlorhydria, proton pump inhibitors, H_2-blockers
Loss/atrophy of gastric oxyntic mucosa (deficient intrinsic factor molecules): total or partial gastrectomy, adult and juvenile pernicious anemia, caustic destruction (lye)
Abnormal events in the small bowel lumen
Inadequate pancreatic protease (R-factor-bound cobalamin not degraded, cobalamin not transferred to intrinsic factor)
Insufficient pancreatic protease: pancreatic insufficiency
Inactivation of pancreatic protease: Zollinger-Ellison syndrome
Usurping of luminal cobalamin (inadequate binding of cobalamin to intrinsic factor)
By bacteria: stasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (scleroderma), hypogammaglobulinemia
By *Diphyllobothrium latum* (fish tapeworm)
Disorders of ileal mucosa/intrinsic factor–cobalamin receptors (intrinsic factor–cobalamin not bound to intrinsic factor–cobalamin receptors [also known as cubam receptors])
Diminished or absent cubam receptors: ileal bypass, resection, fistula
Abnormal mucosal architecture or function: tropical/nontropical sprue, Crohn disease, tuberculous ileitis, amyloidosis
Cubam receptor defects: Imerslund-Gräsbeck syndrome, hereditary megaloblastic anemia
Drug effects: metformin, cholestyramine, colchicine, neomycin
Disorders of plasma cobalamin transport (TCII-cobalamin not delivered to TCII receptors): congenital TCII deficiency, defective binding of TCII-cobalamin to TCII receptors (rare)
Metabolic disorders (cobalamin not used by cells)
Inborn enzyme errors (rare)
Acquired disorders (cobalamin functionally inactivated by irreversible oxidation): nitrous oxide inhalation
FOLATE DEFICIENCY
Nutritional causes
Decreased dietary intake: poverty and famine, institutionalization (psychiatric facilities, nursing homes), chronic debilitating disease, prolonged feeding of infants with goat's milk, special slimming diets or fad foods (folate-rich foods not consumed), cultural or ethnic cooking techniques (food folate destroyed)
Decreased dietary intake and increased requirements
Physiologic: pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy
Pathologic
Intrinsic hematologic diseases involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration by malignant disease
Dermatologic disease: psoriasis
Folate malabsorption
With normal intestinal mucosa
Drugs: pyrimethamine, proton pump inhibitors (by inhibition of proton-coupled folate transporters); anticonvulsants (reduced absorption and induction of microsomal liver enzymes)
Hereditary folate malabsorption (mutations in proton-coupled folate transporters) (rare)
With mucosal abnormalities: tropical and nontropical sprue, regional enteritis
Defective CSF folate transport: cerebral folate deficiency (mutation or autoantibodies to folate receptors) (rare)
Inadequate cellular utilization
Folate antagonists (methotrexate)
Hereditary enzyme deficiencies involving folate
Drugs (multiple effects on folate metabolism): alcohol, sulfasalazine, triamterene, pyrimethamine, trimethoprim-sulfamethoxazole, phenytoin, barbiturates
MISCELLANEOUS MEGALOBLASTIC ANEMIAS NOT CAUSED BY COBALAMIN OR FOLATE DEFICIENCY
Congenital disorders of DNA synthesis
Orotic aciduria
Lesch-Nyhan syndrome
Congenital dyserythropoietic anemia
Acquired disorders of DNA synthesis
Deficiency: thiamine-responsive megaloblastic anemia (thiamine transporter 1 mutation)
Erythroleukemia; refractory sideroblastic anemias (pyridoxine responsive?)

CSF = cerebrospinal fluid; TCII = transcobalamin II.

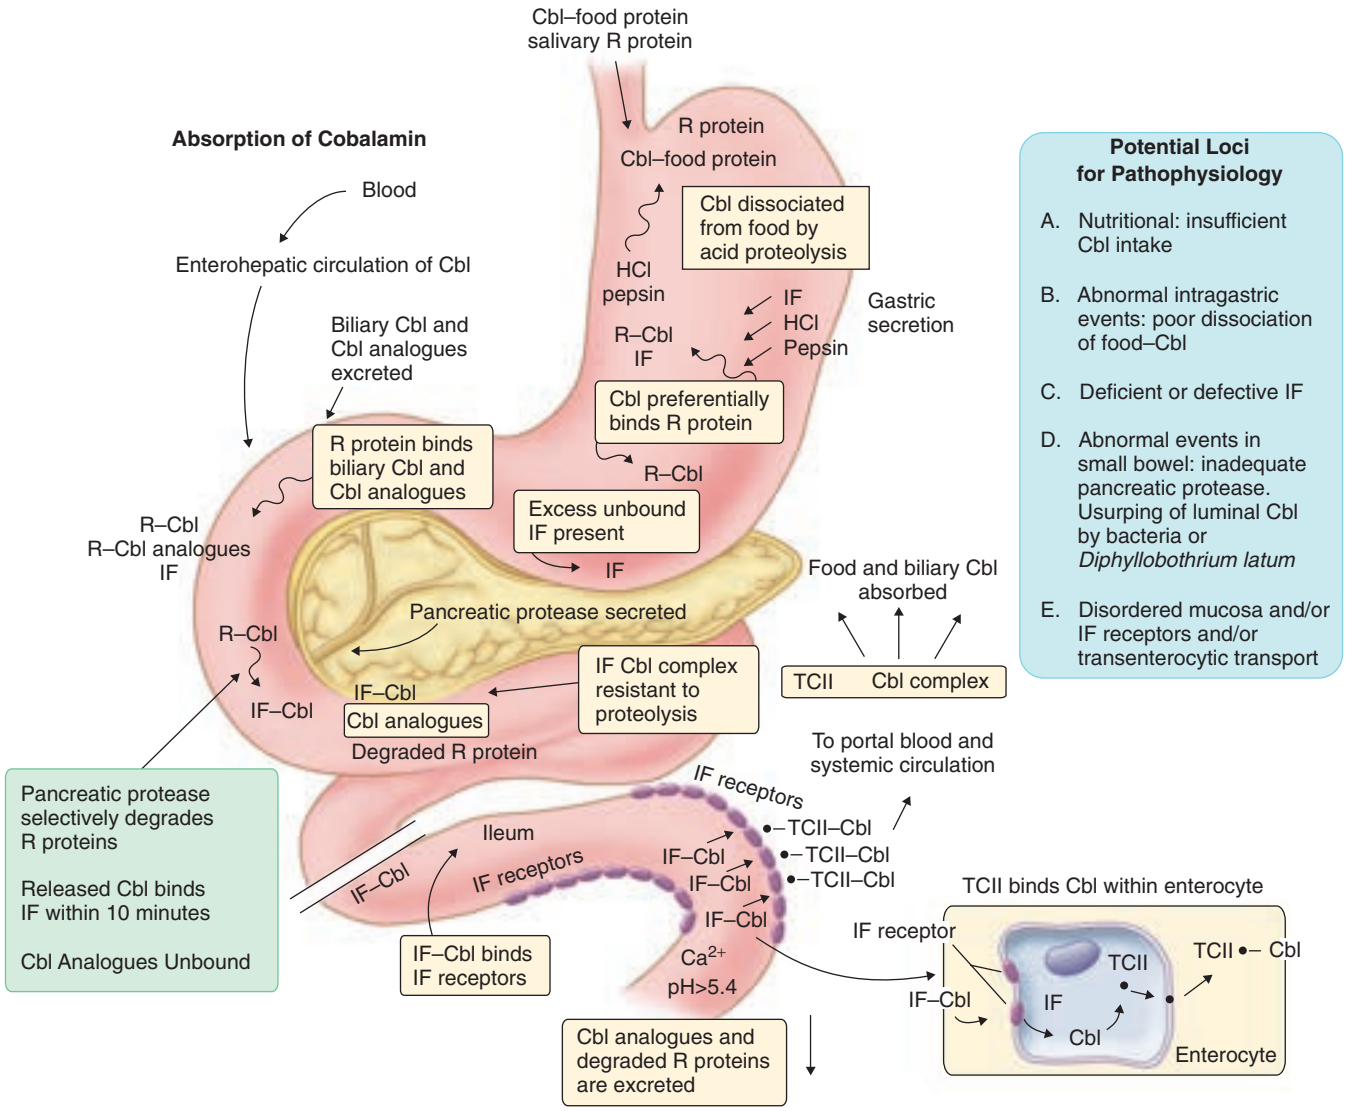

FIGURE 164-1. Components and mechanism of cobalamin absorption, with an indication of the locus for malabsorption. Cbl = cobalamin; IF = intrinsic factor; TCII = transcobalamin II. (From Antony AC. Megaloblastic anemias. In: Hoffman R, Benz EJ Jr, Silberstein LE, et al, eds. Hematology: Basic Principles and Practice. 6th ed. Philadelphia: Elsevier Saunders; 2013:473-504.)

cobalamin deficiency can take 5 to 10 years to become apparent. However, it takes about 3 to 4 years to deplete cobalamin stores if dietary cobalamin is abruptly malabsorbed (e.g., ileal resection), thereby interfering with an efficient enterohepatic circulation, which accounts for the turnover of 5 to 10 µg of cobalamin per day and reabsorption of 75% of cobalamin secreted into bile. Although cobalamin resists high-temperature cooking, it is unstable to light and can be converted to inactive analogues.

Folates

Nutrition

Folates are synthesized by microorganisms and plants. Rich food sources include green leafy vegetables (spinach, lettuce, broccoli), beans, fruit (bananas, melons, lemons), yeast, mushrooms, and animal protein (muscle, liver, kidney). The recommended daily allowance of folate is 400 µg for adult men and nonpregnant women, 600 µg for pregnant women, 500 µg for lactating women, and 300 to 400 µg for children 9 to 18 years of age. A balanced Western diet can prevent folate deficiency, but the net dietary intake of folate in many developing countries is more often grossly insufficient to sustain folate balance. Folates are susceptible to breakdown during prolonged cooking (boiling for more than 15 minutes), which can destroy 50 to 95% of folate.

PATHOBIOLOGY

Cobalamin

Normal Physiology

There are specialized protein chaperones that sequentially bind, sequester, and thereby protect cobalamin through its long odyssey—from the moment it is dissociated from food in the stomach to its final destination within cells as a cofactor for crucial enzyme reactions.

Absorption and Transport

Cobalamin in food is usually in coenzyme form (as deoxyadenosylcobalamin and methylcobalamin) and bound to proteins (Fig. 164-1). In the stomach, peptic digestion at low pH is a prerequisite for the release of cobalamin from food protein. Once it is released, cobalamin preferentially binds a high-affinity cobalamin-binding protein called R protein, which is secreted in salivary and gastric juice. These cobalamin–R protein complexes, along with unbound intrinsic factor, which is secreted by gastric parietal cells, pass into the duodenum, where pancreatic proteases degrade R proteins. This allows transfer of cobalamin to intrinsic factor.

The stable intrinsic factor–cobalamin complexes then pass through the jejunum to the ileum, where they specifically bind to intrinsic factor–cobalamin receptors (also called cubam receptors—a complex of two proteins, cubilin and amnionless) on the microvilli of ileal mucosal cells. Within enterocytes, cobalamin is transferred to transcobalamin II; this complex is then released into the circulation, from which it efficiently binds to high-affinity transcobalamin II receptors on cell surfaces. When cobalamin status is compromised, this is the fraction that is primarily reduced. There is, however, another protein, transcobalamin I, that binds the bulk (approximately 75%) of serum cobalamin but does not deliver it to cells, so it functions much like a storage protein for the cobalamin in blood. Because the cobalamin from this compartment of transcobalamin I–bound cobalamin—which is relatively invariant in serum—is also measured in serum cobalamin

assays, this accounts for the relative insensitivity of this test, which aims to discover if there is a reduction in the functionally relevant transcobalamin II–bound cobalamin.[1,2] A third minor protein, transcobalamin III, binds a wide spectrum of cobalamin analogues that are rapidly cleared by the liver into bile for efficient fecal excretion.

Cellular Processing

More than 95% of intracellular cobalamin is bound to two intracellular enzymes: methylmalonyl coenzyme A (CoA) mutase and methionine synthase. In mitochondria, deoxyadenosylcobalamin is a coenzyme for methylmalonyl-CoA mutase, which converts methylmalonyl-CoA to succinyl-CoA so that it can be easily metabolized. In the cytoplasm, methylcobalamin is a coenzyme for methionine synthase, which catalyzes the transfer of methyl groups from methylcobalamin to homocysteine to form methionine. The methyl group of 5-methyltetrahydrofolate (methyl-THF) is donated to regenerate methylcobalamin, thereby forming the THF that is essential to sustain one-carbon metabolism. The methionine so formed can be adenylated to *S*-adenosylmethionine, which donates its methyl group in a critical series of biologic methylation reactions involving more than 80 proteins, phospholipids, neurotransmitters, RNA, and DNA. The close functional interrelationship between cobalamin and folate within cells (involving the common enzyme methionine synthase, the single enzymatic reaction of which is a metabolic step for which both cobalamin and folate are essential) explains why cobalamin deficiency leads to a functional folate deficiency and is also the basis for similar clinical (hematologic) manifestations involving perturbed DNA.

Pathogenesis of Cobalamin Deficiency

Nutritional Cobalamin Deficiency

Severe cobalamin deficiency in the West is likely to be pernicious anemia.[2] However, vegetarianism and poverty-imposed near-vegetarianism are more common causes worldwide in all age groups. Up to three quarters of the population in resource-limited countries (particularly women and children), who subsist on a monotonous diet low in animal-source foods, have subtle evidence of cobalamin deficiency; many also have folate and iron deficiency.[3] Low maternal cobalamin status compromises the amount of cobalamin delivered to the fetus; moreover, low cobalamin content of breast milk predisposes one third of their infants to cobalamin deficiency, thereby establishing a vicious intergenerational circle of cobalamin (and multiple nutrient) deficiency. As large swaths of the populations are exposed to war or famine, those teetering on the brink of cobalamin (and folate) deficiency will eventually come to light clinically.

Inadequate Dissociation of Cobalamin from Food Protein

In affluent countries, failure to fully release food cobalamin because of chronic gastric atrophy and achlorhydria is common among one third to one half of elderly individuals with low cobalamin status. This is estimated to be 10-fold more common than pernicious anemia.

Absent Secretion of Acid and Intrinsic Factor

Total gastrectomy invariably leads to cobalamin deficiency in 2 to 10 years, thus warranting prophylactic cobalamin (and iron) replacement. After partial gastrectomy or bariatric gastric bypass surgery (Chapter 220) and in those receiving long-term H_2-blockers or proton pump inhibitors, multifactorial cobalamin deficiency may result from decreased secretion of intrinsic factor, hypochlorhydria, or intestinal bacterial overgrowth of cobalamin-consuming organisms.

In pernicious anemia, autoimmune gastritis involving destruction of the gastric parietal cell mass leads to atrophy of the fundus and body of the stomach, absence of intrinsic factor and hydrochloric acid, and eventually severe cobalamin malabsorption and deficiency. Pernicious anemia is found in persons of all ages, races, and ethnic origins; however, the precise global incidence is not known because population-based studies, which rely on finding diagnostic serum anti–intrinsic factor antibodies (found in serum of 60% and gastric juice of 75%), will miss a substantial number of patients. Nevertheless, with this approach, nearly 2% of free-living individuals older than 60 years in southern California had undiagnosed pernicious anemia, with minimal clinical manifestations of cobalamin deficiency; significantly, in this cohort, 4% of white and African American women had pernicious anemia. About 30% of patients have a positive family history, and there is an association with other autoimmune diseases (e.g., polyglandular autoimmune syndrome, Graves disease, Hashimoto thyroiditis, vitiligo, Addison disease, idiopathic hypoparathyroidism, myasthenia gravis, and type 1 diabetes).

Abnormal Events Precluding Absorption of Cobalamin

Although pancreatic insufficiency (Chapter 140) can preclude transfer of R protein–bound cobalamin to intrinsic factor, with the early use of pancreatic protease replacement, cobalamin deficiency is uncommon. Endogenous pancreatic protease can, however, be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger-Ellison syndrome (Chapter 195). Further, if the pH of the luminal contents in the ileum is less than 5.4, the binding of the intrinsic factor–cobalamin complex to cubam receptors will be precluded.

Bacterial overgrowth in the small bowel (arising from stasis, impaired motility, and hypogammaglobulinemia; Chapter 142) favors colonization by bacteria, which can usurp free cobalamin before it can bind to intrinsic factor. This can be reversed by a short course of antibiotics. Individuals heavily infested with the fish tapeworm *Diphyllobothrium latum* (acquired by consuming raw or partially cooked freshwater fish) can become cobalamin deficient when these long (10 m) adult worms in the jejunum avidly usurp cobalamin. After expulsion of worms (with an oral dose of praziquantel 10 to 20 mg/kg), cobalamin replenishment is curative.

Disorders of the Intrinsic Factor Receptors or Mucosa

Because the distal ileum has the greatest density of cubam receptors, the removal, bypass, or dysfunction of only 1 to 2 feet of terminal ileum will result in cobalamin malabsorption. Among drugs (see Table 164-1), metformin, when it is used in full doses for type 2 diabetes, is notorious for inducing cobalamin malabsorption and low cobalamin levels after 5 years or more.[4] Although it is preventable by calcium (1.2 g/day), many with metformin-induced low cobalamin levels will progress to cobalamin deficiency, warranting cobalamin replacement and prophylaxis.

Acquired Cobalamin Deficiency

Nitrous oxide (N_2O) irreversibly inactivates cobalamin and results in a state of functional intracellular cobalamin deficiency, which can be bypassed by the administration of 5-formyl-THF (leucovorin). N_2O exposure can induce megaloblastosis in those with marginal or low cobalamin stores, but chronic intermittent (surreptitious, accidental, or occupational) exposure more frequently leads to neuromyelopathic manifestations. Capsules used for making whipped cream are a cheap and easy source of N_2O, allowing for abuse in the community.

Folates

Normal Physiology

Specialized mechanisms also exist to ensure the digestion, absorption, and uptake of folates into cells—and across both the placenta to the fetus and the choroid plexus into the nervous system—to support intracellular enzymes that are critical for synthesis of DNA.

Absorption and Transport

In general, only half the folate in food, which is mainly in polyglutamylated form, is nutritionally available (bioavailable), whereas 85% of folic acid added to food or ingested as a supplement is bioavailable. The small intestine can absorb folic acid unchanged, but food folate polyglutamates must be hydrolyzed to monoglutamate by folate polyglutamate hydrolase at the brush border before transport into enterocytes, so food preparation (dicing, puréeing) can facilitate absorption. A jejunal luminal surface proton-coupled folate transporter, which has a low pH optimum, facilitates the efficient transport of folate into enterocytes, where it is reduced to THF and methylated before release by a cellular exporter protein into plasma as methyl-THF.[5] The serum folate level is maintained by dietary folate intake and an efficient enterohepatic circulation. From plasma, there is a rapid uptake of folates into tissues by cell membrane–associated folate receptors, which bind physiologically relevant methyl-THF, folic acid, and some newer antifolates with high affinity at concentrations found in serum. After folate receptor–mediated endocytosis, a proton-coupled folate transporter then helps export folate from acidified endosomes into the cytoplasm of cells. The sequentially coordinated function of folate receptors and proton-coupled folate transporters of the choroid plexus is also required to maintain the ratio of cerebrospinal fluid (CSF) folate to blood folate of up to 3 : 1. After glomerular filtration, folate receptors on the brush border membranes of proximal renal tubular cells bind luminal folate and transport it back into blood. Cells have an exquisite

molecular mechanism for sensing and responding to folate deficiency by upregulating folate receptors to restore folate homeostasis. Reduced-folate carriers are also folate transporters that primarily mediate the uptake of pharmacologic folates (methotrexate and folinic acid) into cells. Passive diffusion also operates to transport folate across biologic membranes at supraphysiologic folate concentrations.

Intracellular Metabolism and Cobalamin-Folate Interactions

After cellular uptake, methyl-THF must first be converted to THF by methionine synthase. Only then can the THF be polyglutamylated by folate polyglutamate synthase, which allows it to be retained intracellularly to play a central role in one-carbon metabolism. THF can be converted to 10-formyl-THF (for de novo biosynthesis of purines) and to methylene-THF.

The central role of methylene-THF is that it can be used either in the thymidylate cycle via thymidylate synthase for the synthesis of thymidine and DNA or in the methylation cycle via methionine synthase (but only after its conversion to methyl-THF by methylene-THF reductase). Inactivation of methionine synthase during cobalamin deficiency results in accumulation of the substrate methyl-THF, which cannot be polyglutamylated and thus leaks out of the cell, resulting in an intracellular THF deficiency and compromised one-carbon metabolism (E-Table 164-1).

Pathogenesis of Folate Deficiency

Folate deficiency can arise from decreased supply (reduced intake, absorption, transport, or utilization) or increased requirements (from metabolic consumption, destruction, or excretion). One individual may have multiple causes of folate deficiency, but specific tests to define each mechanism are not available clinically. Nutritional folate insufficiency is the most common cause of folate deficiency worldwide in all age groups, with women and children in resource-limited (developing) countries at highest risk. Indeed, more than 90% of pregnant women in resource-limited countries consume less than the estimated average requirement of folate, cobalamin, and iron. Although fortification of food with folate has dramatically reduced the prevalence of folate deficiency in the United States, it can still be found among some chronic alcoholics and the elderly, infirm, or socially isolated individuals who consume imbalanced diets.

Nutritional Causes (Decreased Intake or Increased Requirements)

With an abrupt reduction in folate consumption, body stores of folate are adequate for approximately 4 months. However, these stores are depleted faster in individuals in chronically negative folate balance who often have multiple nutritional deficiencies (and diseases) that tip them into frank folate deficiency. A seasonal reduction in folate-rich foods, poverty, cultural or ethnic diets that are intrinsically low in folates, cooking techniques that destroy folate, and anorexia that accompanies chronic illnesses are among the many reasons for folate deficiency.

Patients with intrinsic hematologic diseases involving increased cell proliferation or with increased compensatory erythropoiesis in response to chronic peripheral red blood cell destruction have increased requirements for folate. Indeed, folate deficiency in the face of chronic hemolysis can lead to an acute reticulocytopenic (aplastic) crisis, an unexpected increase in transfusion requirements, or a fall in platelets. Exfoliative skin diseases (Chapter 436) also cause folate deficiency when there is an increased demand from excess loss of skin cells.

Pregnancy and Infancy

Poor folate intake during pregnancy is a common cause of megaloblastic anemia in developing countries because pregnancy and lactation require additional folate for growth of the fetus and maternal tissues. Physiologic transplacental folate transport by folate receptors relies on the continued intake of adequate dietary folate by the mother; if it is compromised by poor nutrition or increased needs (short intervals between pregnancies, twin pregnancies), poor pregnancy outcomes will result. This can be manifested by premature, low-birthweight infants and other midline developmental abnormalities in the fetus ranging from neural tube defects (such as anencephaly, encephalocele, meningocele, and spina bifida) to neurocristopathies (such as ventricular septal defects, cleft lip, and cleft palate). Periconceptional folate supplementation studies suggest that mothers who fail to consume sufficient folate during pregnancy have children who exhibit subtle changes that are manifested in early childhood; these include behavioral abnormalities (hyperactive/inattentive with peer problems, emotionally reactive, aggressive, anxious/depressed symptoms, and somatic complaints or withdrawn[6] and autistic disorder[7]) as well as cognitive dysfunction,[8] poor academic performance, and delayed language acquisition.

Cerebral folate deficiency can be caused either by a congenital mutation in folate receptors or by autoantibodies to folate receptors, which perturbs folate transport into the CSF, leading to severe developmental regression in early childhood associated with movement disturbances, epilepsy, and leukodystrophy. Blocking autoantibodies to folate receptors, which develop against consumed bovine milk folate-binding proteins that share epitopes with human folate receptors, can also be found in two autism spectrum disorders: Rett syndrome and infantile low-functioning autism with neurologic abnormalities. When it is diagnosed early, cerebral folate deficiency responds to high doses of folinic acid, which normalizes CSF folates and induces a partial to complete recovery in 12 months. When it is induced by autoantibodies, a bovine milk–free diet will also help decrease the autoantibody titer.

Hereditary folate malabsorption, which is due to a mutation in the proton-coupled folate transporter, results in compromised intestinal folate absorption and folate transfer into the CSF. Patients present with folate deficiency anemia, hypoimmunoglobulinemia with recurrent infections, chronic diarrhea, neurologic abnormalities (seizures or mental retardation), and low to undetectable CSF folate levels. High parenteral doses of folinic acid can ensure passive diffusion into the CSF and lead to significant clinical improvement in these children.

Tropical and Nontropical (Celiac) Sprue

With the development of intestinal mucosal abnormalities, patients are at increased risk for folate malabsorption. In tropical sprue (Chapter 140), a dramatic response to a 4- to 6-month course of oral folic acid (5 mg/day) plus tetracycline (250 mg four times a day) can effect a cure in 60% or more of patients. When it is prolonged (>3 years), malabsorption of cobalamin can develop together with iron deficiency (Chapter 159), pellagra, and beriberi (Chapter 218).

Drugs

Excess alcohol consumption at the expense of a balanced diet is a common cause of folate deficiency in the United States. Inhibition of dihydrofolate reductase by trimethoprim and pyrimethamine or methotrexate can be acutely reversed by folinic acid. Pyrimethamine and proton pump inhibitors inhibit the proton-coupled folate transporter, whereas anticonvulsants can reduce folate absorption and induce microsomal liver enzymes. Antineoplastics and antiretroviral antinucleosides can also induce megaloblastosis by perturbing DNA synthesis.

CLINICAL MANIFESTATIONS

The finding of macrocytosis (increased mean corpuscular volume [MCV]) on a routine complete blood count may be the first clinical manifestation. In other patients, the findings may be dominated by the condition causing the deficiency of cobalamin or folate, such as malabsorption, alcoholism, or malnutrition (see Table 164-1).

The clinical manifestations of folate deficiency may include hematologic (pancytopenia with megaloblastic bone marrow), cardiopulmonary (secondary to anemia), gastrointestinal (megaloblastosis with or without malabsorption), dermatologic (hyperpigmentation of the skin, premature graying), infertility (sterility), and psychiatric (primarily a flat affect) symptoms. If such patients have additional neurologic findings, either associated cobalamin deficiency or other diseases that predispose to folate deficiency must be considered, such as alcoholism with thiamine deficiency, which may result in peripheral neuropathy (dry beriberi) with Wernicke-Korsakoff syndrome, with or without heart failure from cardiovascular disease (wet beriberi) (Chapters 218 and 416). Because megaloblastosis due to either folate or cobalamin deficiency results in functional folate deficiency, the hematologic manifestations of both deficiencies, including pancytopenia with megaloblastic bone marrow, are indistinguishable. However, only cobalamin deficiency results in a patchy but widespread demyelinating process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord (Chapter 416). Either hematologic or neurologic manifestations may dominate the clinical picture.

Chronic hyperhomocysteinemia (Chapter 209) is a risk factor for several diseases (Table 164-2), many of which are benefited by folate supplementation or homocysteine-lowering therapy with combined folic acid, cobalamin, and pyridoxine. Thus, by inference, patients can present with any of these conditions arising from long-standing hyperhomocysteinemia or poor folate status.

E-TABLE 164-1 SERUM FOLATE LEVELS ARE MISLEADINGLY ELEVATED IN COBALAMIN DEFICIENCY AND MALARIA, WHICH ARE BOTH COMMON IN RESOURCE-LIMITED SETTINGS*,†

	SERUM FOLATE LEVEL	RBC FOLATE LEVEL	SERUM COBALAMIN LEVEL
Pure folate deficiency	Low	Low	Normal/low*
Pure cobalamin deficiency‡	Normal/high*,‡	Low*,‡	Low
Folate plus cobalamin deficiency	Normal*	Low	Low
Pure malaria	Normal*/high*,§	High*,‖,¶	Normal
Malaria plus folate deficiency	Normal*	Normal*/high*/low	Normal
Malaria plus cobalamin deficiency	Normal*/high*,§	Normal*/high*,¶	Low
Malaria plus folate plus cobalamin deficiency	Normal*/high*,§	Low/normal*,¶	Low

RBC = red blood cell.
*The *asterisk* indicates misleading values in the clinical settings shown on the *left*.
†Both cobalamin deficiency and clinical malaria and other hemolytic states can complicate the diagnosis of folate deficiency with tests for serum or RBC folate.
‡Cobalamin deficiency is accompanied by inability to use folate, so RBC folate leaks out into serum.
§Release of the 30-fold excess folate from RBCs during hemolysis raises serum folate. An as yet unknown quantity of folate is released into blood when folate-rich hepatocytes are destroyed during the exoerythrocytic hepatic phase of malaria.
‖Hemolysis induces a compensatory reticulocytosis; these reticulocytes are richer in folate than mature RBCs.
¶*Plasmodium falciparum* can synthesize folate in RBC cultures in vitro and raises RBC folate in animal models with high levels of parasitemia; conversely, RBC folate has been normalized after therapy with chloroquine. Reticulocytopenia in severe *Plasmodium falciparum* malaria—due to combined cobalamin deficiency plus folate deficiency that can trigger a reticulocytopenic (megaloblastic) crisis, other nutrient deficiency, or cytokine-induced inhibition of hematopoiesis—will negate a rise in RBC folate.

DIAGNOSIS

Diagnostic Approach to the Patient

The general approach to a patient with megaloblastic anemia is first to recognize that megaloblastic anemia is present; then to distinguish whether folate, cobalamin, or combined folate and cobalamin deficiencies have led to the anemia; and finally to diagnose the underlying disease and mechanism causing the deficiency[9] (see Table 164-1).

TABLE 164-2 EFFECTS OF HOMOCYSTEINE-LOWERING THERAPY ON NONHEMATOPOIETIC SYSTEMS

FOLIC ACID, COBALAMIN, AND PYRIDOXINE SUPPLEMENTATION
Reduction in hip fracture
Reduction in progression of carotid intima-media thickness (a surrogate marker of early subclinical arteriosclerosis)
Reduction in age-related macular degeneration
Reduction in rate of brain atrophy
Reduction in rate of cognitive decline (folate plus cobalamin only)
FOLIC ACID SUPPLEMENTATION
Reduction in stroke
Reduction in age-related (sensorineural) hearing loss
Reduction in phenytoin-induced gingival hyperplasia
FOLIC ACID FORTIFICATION OF FOOD (POPULATION-BASED STUDIES)
Reduction in neural tube defects (anencephaly, spina bifida, encephalocele, meningocele, iniencephaly)
Reduction in cleft lip with or without cleft palate
Reduction in severe congenital heart disease (endocardial cushion defects, conotruncal defects)
Reduction in congenital pyloric stenosis, stenosis of the pelvic-ureteric junction, limb reduction defects, omphalocele
Reduction in stroke mortality
Decreased risk of preterm births, low-birthweight and small-for-gestational-age babies
No evidence of increase in cancer
DELETERIOUS EFFECT OF HOMOCYSTEINE-LOWERING THERAPY
Diabetic nephropathy

Although deficiencies of cobalamin and folate are only two of the many causes of macrocytosis (Fig. 164-2), they become increasingly more likely as the MCV increases. Because perturbed DNA synthesis from any cause (including folate and cobalamin deficiency) results in megaloblastosis of bone marrow precursor cells, the red cells released into the circulation have an MCV that is often greater than 110 fL; on the peripheral blood smear, these large cells appear oval (macro-ovalocytes). Compared with mature red cells, which normally have a central area of pallor that occupies about one third of the cell diameter, the central pallor of macro-ovalocytes is significantly reduced. By contrast, thin macrocytes, which contain an increased cell surface without a proportionate increase in volume, have a much larger area of central pallor (more than one-third the cell diameter). When reticulocytes, which are normally 20% larger than mature red cells, are prematurely released from the bone marrow during the stress of acute blood loss or hemolysis, these so-called shift reticulocytes are even larger. Therefore, assessment of the corrected reticulocyte count is a good starting point to distinguish whether the macrocytic anemia is due to increased reticulocytosis (see Fig. 164-2); if reticulocytopenia is evident, data from the history, physical findings, and peripheral smear showing either thin macrocytes or macro-ovalocytes will help narrow the differential diagnosis. The frequency with which a high MCV is found depends on the patient population studied. In U.S. hospitals, up to two thirds of cases of macrocytosis (MCV ≥100) can be due to chemotherapy or antiretroviral therapy, alcoholism, or liver disease. In resource-limited regions, insufficient intake of cobalamin, folate, and iron can result in a dimorphic anemia (with a large red cell distribution width from a mix of macro-ovalocytic and microcytic cells).

History and Physical Examination

The underlying condition predisposing to folate deficiency usually began within the previous 6 months and often dominates the overall clinical picture. By contrast, cobalamin deficiency takes several years to be manifested clinically. Therefore, the underlying condition is more chronic and symptoms develop more insidiously; defining the cause is a clinical challenge that necessitates a detailed history, physical findings, and the judicious use of laboratory studies.

The dietary history may be revealing (food faddism, vegetarianism), whereas the medical or family history may uncover gluten sensitivity, autoimmune diseases, epilepsy treated with an anticonvulsant, use of offending

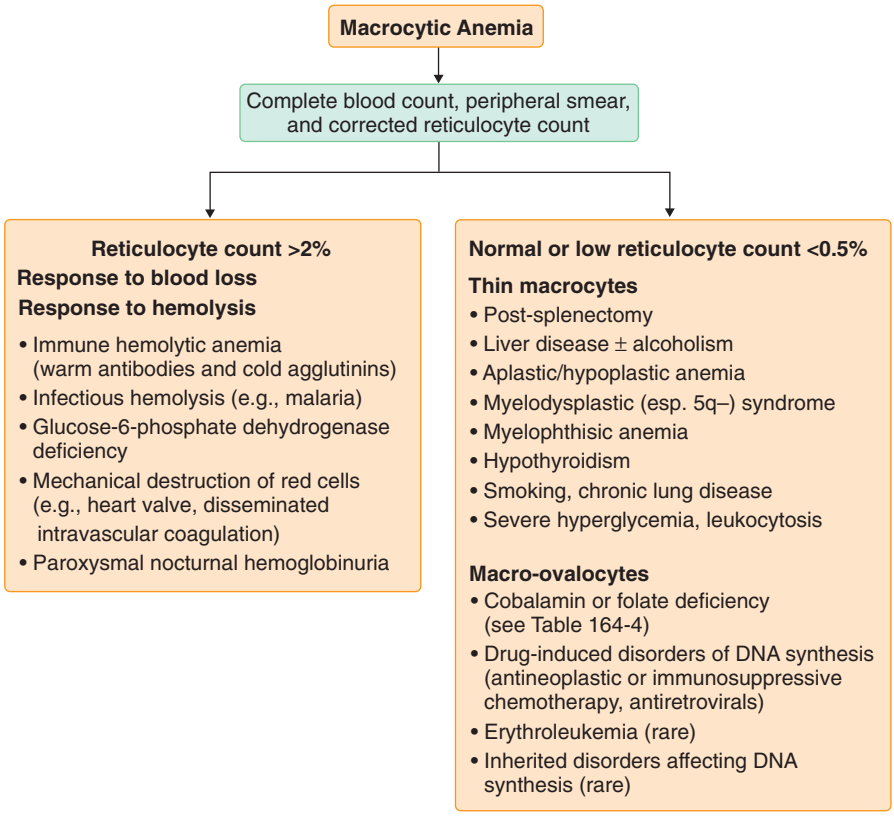

FIGURE 164-2. Algorithm for the evaluation of patients with macrocytosis.

drugs, hemolytic anemia, past surgery (e.g., gastrectomy, fistula, bowel resection), inhalation of N_2O, or travel history predictive for tropical sprue.

Physical examination of cobalamin-deficient vegetarians or those with pernicious anemia may reveal well-nourished individuals. By contrast, patients with folate deficiency are poorly nourished and may have other stigmata of multiple deficiencies from malabsorption (Chapter 140). Associated deficiency of iron and vitamins A, D, and K or protein-calorie malnutrition, or both, may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Varying degrees of pallor with lemon-tint icterus (a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis. The skin may reveal either a diffuse brownish pigmentation or abnormal blotchy tanning. Premature graying is observed in both light- and dark-haired individuals. Examination of the mouth may reveal glossitis, with a smooth (depapillated), beefy-red tongue with occasional ulceration of the lateral surface. Thyromegaly may be observed with pernicious anemia and associated autoimmune thyroid disease. Heart failure from severe anemia may be accompanied by mild splenomegaly reflecting extramedullary hematopoiesis.

In prolonged cobalamin deficiency, neurologic examination reveals evidence of involvement of the posterior columns as well as of the pyramidal, spinocerebellar, and spinothalamic tracts. Posterior column dysfunction results in loss of position sense in the index toes (before great toe involvement) (Chapter 416) and loss of the ability to discern vibration of a high-pitched (256 cycles/second) tuning fork. Diminished vibratory sensation and proprioception of the lower extremities are the most common early objective signs. Neuropathic involvement of the legs precedes that of the arms. Upper motor neuron signs may be modulated by the subsequent involvement of peripheral nerves. A Romberg sign and a Lhermitte sign may be elicited. Loss of sphincter and bowel control or involvement of cranial nerves, such as optic neuritis, may be accompanied by other dysfunction of the cerebral cortex, including dementia, psychoses, and disturbances of mood. Cognitive impairment is not uncommon among vegetarians with cobalamin deficiency; a study reported that half had impaired recall and serial sevens, and one quarter had impaired naming. Objective findings of abnormal evoked potential (by the auditory oddball paradigm with P300 latency) are seen in half of these patients. The coexistence of folate deficiency with neurologic disease should prompt investigations to exclude cobalamin and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

Nutritional cobalamin deficiency in resource-limited countries can be manifested as florid pancytopenia, mild hepatosplenomegaly, fever, and thrombocytopenia, with the neuropsychiatric syndrome developing as a later manifestation. Many of these individuals will have associated folate and iron deficiency. However, cobalamin-related neurologic disease has also been found in patients with only mild to moderate anemia secondary to cobalamin deficiency in both developing and developed countries. Indeed, in the United States, between 25 and 50% of patients who have neuropsychiatric abnormalities attributable to cobalamin deficiency may have a normal hematocrit and MCV. There is often an inverse correlation between the hematocrit and neurologic disease in cobalamin deficiency; most subjects have mild neurologic deficits, and 25% have only moderate deficits, with paresthesias or ataxia as the initial symptoms.

Laboratory Tests

Megaloblastosis

To establish the diagnosis of megaloblastosis, the evaluation begins with a complete blood count, MCV (which often reveals a steady increase during a period of several months or years), examination of the peripheral smear, and reticulocyte count; a low reticulocyte count with macro-ovalocytes suggests an underlying megaloblastic anemia (see Fig. 164-2). Classic megaloblastosis from cobalamin or folate deficiency may be accompanied by a hemoglobin level of less than 5 g/dL. Neutropenia and thrombocytopenia occur less commonly than anemia and are usually not severe. On occasion, neutrophil counts less than 1000/μL and platelet counts less than 50,000/μL can be seen. Additional abnormalities supporting intramedullary hemolysis include elevated levels of serum lactate dehydrogenase and bilirubin as well as decreased serum haptoglobin levels.

Peripheral Smear

In peripheral blood, the earliest manifestation of megaloblastosis is an increase in MCV with macro-ovalocytes (up to 14 μm). Nuclear hypersegmentation of neutrophils, diagnosed if more than 5% of polymorphonuclear leukocytes have five lobes or if 1% have six lobes on the smear (Fig. 164-3), strongly suggests megaloblastosis, especially in association with macro-ovalocytosis. However, neutrophil hypersegmentation is not sensitive for the diagnosis of mild cobalamin deficiency, and macrocytosis is absent in nearly 50% of cases. There may be associated teardrop-shaped erythrocytes and anisocytosis with leukopenia and thrombocytopenia.

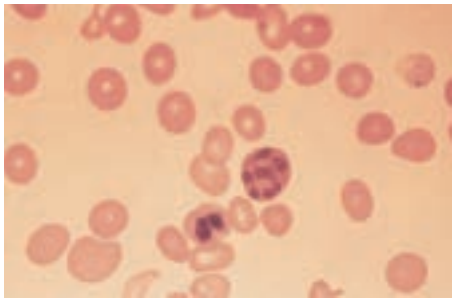

FIGURE 164-3. Megaloblastic anemia. The peripheral blood has oval macrocytes (large red blood cells) and marked neutrophil hypersegmentation.

TABLE 164-3 COMMON CONDITIONS PREDISPOSING TO MASKED MEGALOBLASTOSIS

Inadequate dietary intake of cobalamin, folate, and iron
Vegetarianism
Near-vegetarianism (in resource-limited settings)
Cobalamin *plus* iron deficiency
Post-gastrectomy
Pernicious anemia
Celiac disease (late manifestation)
Folate *plus* iron deficiency
Celiac disease (early manifestation)
Pregnancy in a woman not taking iron and folate supplements
Alcoholism with liver disease and gastrointestinal bleeding
Miscellaneous common clinical combinations
Rheumatoid arthritis with NSAIDs and gastrointestinal bleeding with methotrexate
Thalassemia with folate or cobalamin deficiency
Any patient with cancer receiving chemotherapy with chronic bleeding or iron deficiency
Antiretroviral therapy plus iron deficiency/thalassemia

NSAIDs = nonsteroidal anti-inflammatory drugs.

Megaloblastic anemia can be masked (Table 164-3) when there is a coexisting condition that neutralizes the tendency to generate large cells, such as iron deficiency (Chapter 159) or thalassemia (Chapter 162). In these situations, giant myelocytes and metamyelocytes in bone marrow and hypersegmented polymorphonuclear neutrophils in bone marrow and peripheral blood (see Fig. 164-3) are important clues to a masked megaloblastosis. This problem is clinically relevant because appropriate replacement with cobalamin or folate elicits a maximal hematologic response only when any associated iron deficiency is corrected. Conversely, if a combined iron and cobalamin deficiency (after gastrectomy) or iron and folate deficiency (with pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

Cobalamin and Folate Levels

Laboratory evaluation of suspected cobalamin or folate deficiency begins with measurement of the serum levels of these vitamins. If any of these results are borderline, one can proceed to confirmatory tests by serum levels of metabolites (homocysteine and methylmalonic acid) (Table 164-4). Use of clinical information will improve the pretest probability of low serum cobalamin and folate levels in diagnosis of deficiency. Indeed, without detailed clinical information, the combined results of serum cobalamin, folate, and metabolite tests are not sufficiently unambiguous to diagnose cobalamin deficiency and to distinguish it from combined cobalamin plus folate deficiency.

Serum Cobalamin Levels

A low serum cobalamin level (<200 pg/mL) is a valuable clinical indicator of true tissue cobalamin deficiency in about 90% of patients. It is, however, relatively less sensitive compared with metabolite levels. Even among 173 unambiguously cobalamin-deficient patients, about 5% had normal cobalamin levels. Serum cobalamin is less than 300 pg/mL in 99% of patients

TABLE 164-4 STEPWISE APPROACH TO THE DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCY

MEGALOBLASTIC ANEMIA OR NEUROLOGIC-PSYCHIATRIC MANIFESTATIONS CONSISTENT WITH COBALAMIN DEFICIENCY *PLUS* TEST RESULTS OF SERUM COBALAMIN AND SERUM FOLATE			
Cobalamin* (pg/mL)	**Folate† (ng/mL)**	**Provisional Diagnosis**	**Proceed with Metabolites?‡**
>300	>4	Cobalamin or folate deficiency unlikely	No
<200	>4	Consistent with cobalamin deficiency	No
200-300	>4	Rule out cobalamin deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with combined cobalamin plus folate deficiency or with isolated folate deficiency	Yes
>300	2-4	Consistent with folate deficiency or with anemia unrelated to vitamin deficiency	Yes

TEST RESULTS OF METABOLITES: SERUM METHYLMALONIC ACID AND TOTAL HOMOCYSTEINE		
Methylmalonic Acid (normal = 70-270 nM)	**Total Homocysteine (normal = 5-14 µM)**	**Diagnosis**
Increased	Increased	Cobalamin deficiency confirmed; folate deficiency still possible (i.e., combined cobalamin plus folate deficiency possible)
Normal	Increased	Folate deficiency likely; <5% may have cobalamin deficiency
Normal	Normal	Cobalamin and folate deficiencies excluded

*Serum cobalamin levels: abnormally low, <200 pg/mL; clinically relevant low-normal range, 200-300 pg/mL. Methylmalonic acid is usually above 1000 nM in clinical cobalamin deficiency
†Serum folate levels: abnormally low, <2 ng/mL; clinically relevant low-normal range, 2-4 ng/mL. Homocysteine is usually above 25 µM in clinical folate deficiency. See E-Table 164-1 for additional limitations in the clinical interpretation of serum folate concentrations.
‡Any frozen-over sample from the serum folate or cobalamin determination can be subjected to metabolite tests.

with clinical hematologic or neurologic manifestations of cobalamin deficiency, whereas a cobalamin level above 300 pg/mL suggests folate deficiency or another cause of macrocytosis or neurologic disease. There have recently been several reports of patients who have had florid clinical evidence of cobalamin deficiency but whose serum cobalamin levels (by competitive binding luminescence assays) were either normal or in the high-normal range[10]; this is apparently due to the interference with the test by high titers of anti–intrinsic factor antibodies associated with pernicious anemia, a serious instance of a false-negative test result. This will lead to clinical manifestations if it is uncorrected. Therefore, if the clinical scenario is strongly suggestive of cobalamin deficiency but the test result is normal, the patient deserves a therapeutic trial with cobalamin. Confirmation of cobalamin deficiency with metabolites and detection of anti–intrinsic factor antibodies can allow retrospective diagnosis of pernicious anemia. Individuals with neuropsychiatric disorders attributed to cobalamin deficiency may not have anemia and only minimally depressed cobalamin levels. The serum cobalamin concentration can be falsely low in the absence of true cobalamin deficiency in patients with folate deficiency (one third of patients), pregnancy, multiple myeloma, transcobalamin I deficiency, and megadose vitamin C therapy.

An increase in cobalamin levels may be an unexpected finding in patients tested for cobalamin deficiency, for example, with high transcobalamin I and II levels (in myeloproliferative neoplasms, hepatic tumors, or active liver disease) and when transcobalamin II–producing macrophages are activated (in autoimmune diseases, monoblastic leukemias, and lymphomas). Approximately 10% of the U.S. population, especially the elderly, probably have metabolic evidence of true cobalamin deficiency.

Serum Folate Levels

In combination with a clinical picture of megaloblastic anemia and measurement of serum cobalamin, the serum folate level is the cheapest and best initial test for diagnosis of folate deficiency. Although red blood cell folate levels by earlier microbiologic assays correlated well with hepatic folate stores, the current assays for red blood cell folates are unreliable for routine clinical use.

The serum folate level is highly sensitive to the intake of a single folate-rich meal. Nutritional folate deficiency first leads to a decline in the serum folate level below normal (<2 ng/mL) in about 3 weeks; thus, it is a sensitive indicator of negative folate balance. Isolated reduction of serum folate in the absence of megaloblastosis (i.e., a false-positive result) occurs in one third of hospitalized patients with anorexia and acute alcohol consumption, in normal pregnancy, and in those using anticonvulsants. Because these groups are also at high risk for folate deficiency, additional testing with metabolites or an empirical therapeutic trial is indicated. Both cobalamin deficiency and malaria, which are common in resource-limited countries, can falsely elevate serum folate levels and mask the diagnosis of folate deficiency. In this scenario, the dietary history of folate intake is a better predictor of folate deficiency (see later).

Metabolite Levels: Homocysteine and Methylmalonic Acid

The serum methylmalonic acid (MMA) and homocysteine levels are highly sensitive tests, both of which rise in proportion to the severity of cobalamin deficiency; by contrast, the serum homocysteine level alone rises with folate deficiency (see Table 164-4). Therefore, an increase in both metabolites cannot differentiate between isolated cobalamin deficiency and combined cobalamin plus folate deficiency. These are too expensive to use as initial screening tests. Serum MMA levels are elevated in more than 95% of patients with clinically confirmed cobalamin deficiency (with median values of 3500 nM). Serum homocysteine concentrations are elevated in both cobalamin deficiency (median values of 70 µM) and folate deficiency (median values of 50 µM). Both homocysteine and MMA rise with dehydration or renal failure. Propionic acid, derived from anaerobic fecal bacterial metabolism, can raise MMA, which can be lowered by a course of metronidazole. The abnormally high metabolites return to normal in a week with the appropriate (deficient) vitamin replacement.

Clinicians can use serum MMA and homocysteine to assist in the diagnosis of patients with the following: borderline cobalamin and folate levels (see Table 164-4); existing conditions known to perturb folate and cobalamin tests, leading to difficulties in interpreting the results; low levels of both cobalamin and folate, in which case a high MMA level is useful to confirm cobalamin deficiency (rather than attributing the condition to folate deficiency alone); and low serum cobalamin levels when there is an alternative explanation for the syndrome that led to the test (e.g., a diabetic or alcoholic patient with peripheral neuropathy, or an alcoholic patient with a high MCV and low cobalamin level without anemia).

Bone Marrow Examination

In a plausible clinical setting for a patient with severe hematologic disease, the identification of nucleated red cells with megaloblastic features in the peripheral smear and classic macro-ovalocytes and hypersegmented polymorphonuclear neutrophils—which reflects the morphology in the bone marrow—can help clinch the diagnosis of megaloblastosis. If they are not found, a bone marrow aspirate can be invaluable in making a rapid diagnosis of megaloblastosis in a patient with severe anemia lacking classic findings. In the outpatient setting, when there is less urgency and anemia is only mild to moderate in a patient with a suggestive peripheral smear or when the clinical presentation is primarily neuropsychiatric, a good case can be made to initiate the sequence of diagnostic tests without bone marrow aspiration and to proceed with the measurement of serum levels of vitamins or metabolites (see Table 164-4 and Fig. 164-2).

On the bone marrow aspirate (Fig. 164-4), which is better than biopsy for observing megaloblastosis, the cells are actually proliferating very slowly despite what looks like exuberant cell proliferation with numerous mitotic figures. In early cobalamin or folate deficiency, normoblasts may dominate the marrow, with only a few megaloblasts seen, but the full spectrum of megaloblastic hematopoiesis is observed in severe deficiency and is accompanied by varying degrees of pancytopenia. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, sieve-like pattern. The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large, sieve-like immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. Up to 90% of megaloblastic cells die in the bone marrow, with remnants of apoptotic cells giving an impression of myelodysplastic syndrome. These are scavenged by macrophages in a process

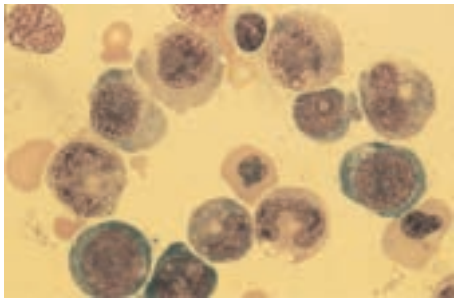

FIGURE 164-4. Megaloblastic anemia. A bone marrow aspirate shows red blood cell precursors that are giant megaloblasts with nuclear-cytoplasmic dissociation (nuclear maturation lagging behind cytoplasmic maturation). Megaloblastic changes in the leukocyte series are shown by the "giant metamyelocyte."

called ineffective erythropoiesis or intramedullary hemolysis. There is an increase in white blood cell production, with megaloblastic leukocytes also having a sieve-like chromatin. Giant (20 to 30 μm) metamyelocytes and "band" forms are pathognomonic for megaloblastosis. Hypersegmented polymorphonuclear leukocytes will be seen in the marrow and peripheral blood. Megakaryocytes may be normal or increased in number and can exhibit complex hypersegmentation, with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is decreased in severe megaloblastosis.

Determining the Cause of the Vitamin Deficiency

By the time that megaloblastic anemia is established, the cause of folate deficiency is usually clear from the history, physical examination, and clinical setting. With rare exceptions, adults with cobalamin deficiency have either cobalamin malabsorption or dietary cobalamin insufficiency. Whereas dietary cobalamin insufficiency is diagnosed by a dietary history and is easily prevented by small doses of prophylactic daily oral cobalamin, all other causes of cobalamin malabsorption respond to either parenteral cobalamin (warranting multiple loading doses followed by monthly maintenance) or daily high doses of oral cobalamin (1 to 2 mg/day). This raises a fundamental question: Why do we need to pursue the cause of cobalamin malabsorption? One practical reason is to determine the need for additional diagnostic tests (e.g., intestinal biopsy, examination of stool for malabsorption or *D. latum* infestation) to institute specific therapy (e.g., gluten-free diet, folate, antibiotics, anthelmintics). This evaluation, in turn, dictates whether cobalamin replacement should be lifelong.

The Schilling test, which was discontinued in 2003, provided such leads on the locus and mechanism of cobalamin malabsorption. Nowadays, without this test, the low sensitivity of serum anti–intrinsic factor antibodies allows only 60% of patients with pernicious anemia to be confidently identified through this measurement. Even poorer performance characteristics have rendered serum antiparietal cell antibodies diagnostically unhelpful. Although increased fasting levels of gastrin and low levels of pepsinogen I (a combination that suggests oxyntic gastric mucosal damage, like atrophy and hypochlorhydria) lack specificity, their sensitivity for detection of pernicious anemia is 90 to 92%. Therefore, some hematologists combine the specific but insensitive serum anti–intrinsic factor antibody test with the sensitive but nonspecific serum gastrin or pepsinogen I abnormalities to rule out pernicious anemia in patients with cobalamin deficiency in view of the loss of availability of the Schilling test.[11]

Because most of the conditions predisposing to cobalamin deficiency (see Table 164-1) should be clinically evident by the time that cobalamin deficiency is apparent, it is possible to identify several conditions through a detailed dietary history or past medical history. Such an exercise can point to esophagogastroduodenal disease, pancreatic insufficiency, impaired bowel motility, or other autoimmune diseases. The physical examination can also provide additional clues and suggest focused testing for rarer conditions (stool for ova; serum anti–tissue transglutaminase antibodies, lipase, or gastrin; intestinal biopsy; or radiographic contrast studies for stasis, strictures, or fistulas). Thus, by this classical medicine approach, it should be possible to identify the basis for cobalamin malabsorption and the duration of therapy in most instances (even without the Schilling test). For the younger patient with megaloblastic anemia, distinguishing juvenile pernicious anemia from congenital intrinsic factor deficiency warrants measurement of gastric juice for intrinsic factor and achlorhydria, and Imerslund-Gräsbeck syndrome requires DNA to detect mutations in cubam receptor (amnionless, cubilin) genes (see Table 164-1).

The utility of measurement of blood levels of holotranscobalamin (cobalamin-bound transcobalamin II) to evaluate cobalamin deficiency requires further clinical validation.

TABLE 164-5 CAUSES OF MEGALOBLASTIC ANEMIA NOT RESPONDING TO THERAPY WITH COBALAMIN OR FOLATE

Wrong diagnosis
Combined folate and cobalamin deficiencies being treated with only one vitamin
Associated iron deficiency
Associated hemoglobinopathy (e.g., sickle cell disease, thalassemia)
Associated anemia of chronic disease
Associated hypothyroidism

TREATMENT

If a severely anemic patient is decompensated or decompensation is imminent, after blood is drawn for diagnostic studies, the patient is transfused slowly with initially only 1 U of packed red cells under diuretic coverage, and both cobalamin and folate are immediately started at full doses (parenteral cobalamin 1 mg/day plus folic acid 1 mg/day), even before the type of vitamin deficiency has been established. If the patient is only moderately symptomatic, transfusions should be avoided because a dramatic improvement in well-being is likely to occur within 2 to 3 days of starting full-dose vitamin replacement, even before hematologic improvement. If the patient is well compensated or in the ambulatory setting, diagnostic testing should proceed in an orderly sequence (see Fig. 164-2 and Table 164-4) before therapy is initiated.

Drug Dosage

Established Cobalamin Deficiency

For patients with severe cobalamin deficiency from any cause, an aggressive scheme to replace cobalamin rapidly is 1 mg/day of intramuscular or subcutaneous cyanocobalamin (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg/month for life. For mild cobalamin deficiency, one can employ oral cobalamin 2 mg/day for 3 months, which exploits passive intestinal diffusion, through which 1 to 2% of the oral dose is absorbed. Once stores are fully replenished, those with cobalamin malabsorption can either continue with monthly maintenance or be switched to daily oral cobalamin 2 mg/day. For nutritional cobalamin deficiency, lifelong daily oral cobalamin (5 to 10 μg), with either tablets or equivalent cobalamin-fortified foods, should be instituted, but only after cobalamin stores are replenished. It is worth reminding patients that food intake reduces absorption of oral cobalamin by 50%.

In cobalamin deficiency associated with either pernicious anemia or food cobalamin malabsorption, the malabsorption of iron (due to achlorhydria) requires oral iron coadministered with organic acids (e.g., ascorbic acid) or total-dose parenteral iron replacement (e.g., low-molecular-weight iron dextran) (Chapter 159) to elicit a complete hematologic response.

An incomplete response must trigger a search for additional conditions (Table 164-5).

Subclinical Cobalamin Deficiency

The entity of subclinical cobalamin deficiency is encountered when an apparently asymptomatic patient has serum cobalamin values that either hover or fluctuate just above or just below normal cutoff values for many months and sometimes even inexplicably return to the normal range. This can sometimes be due to a deficiency of transcobalamin I, which binds the bulk of serum cobalamin but is of little clinical significance. Some experts proceed to obtain metabolite studies and then ignore cobalamin values if the MMA level is normal. Others periodically observe these patients and treat with cobalamin only when patients exhibit symptoms or signs of frank cobalamin deficiency. Yet others err on the side of caution, preferring to preemptively replenish depleted cobalamin stores and thereby circumvent any potential for the patient to develop impaired cognitive function, which can be detected only by specialized neurophysiologic testing, or even frank cerebral atrophy, which has been documented by magnetic resonance imaging. Accordingly, they empirically treat those with borderline cobalamin levels for 6 months with oral cobalamin (1 to 2 mg/day) and reassess serum cobalamin levels to ensure that values have returned to a mid to upper end of the normal range. This approach warrants repeated testing of cobalamin levels 6 to 12 months later to evaluate whether there has been an interim fall in cobalamin levels. At that time, options of either instituting cobalamin for the long term or

alternating treatment for the first 6 months with no treatment for the next 6 months can be discussed with the patient.

Established Folate Deficiency

Oral folate (folic acid) at doses of 1 mg/day results in adequate absorption despite intestinal malabsorption of physiologic food folate. Therapy should be continued until complete hematologic recovery is documented; the subsequent duration of therapy is dictated by the cause. Folinic acid bypasses any block in one-carbon metabolism induced by methotrexate, trimethoprim-sulfamethoxazole, or N_2O.

Prophylaxis with Cobalamin or Folate

Several conditions are prevented by specific treatment designed either to lower homocysteine or to improve folate status (E-Table 164-2; see also Table 164-2). As one example, in elderly subjects with mild cognitive impairment, homocysteine lowering by a cocktail that included cobalamin and folate during 2 years did slow the rate of brain atrophy by almost 30%.[A4] For vegetarians, cobalamin-fortified foods (soy or rice beverages, fortified cereals, nutritional yeast) or oral cobalamin tablets 5 to 10 µg/day should suffice. For those with malabsorption of cobalamin from any other mechanism (see Table 164-1), cobalamin replacement is achieved with 1- to 2-mg tablets taken orally each day.

Periconceptional folate supplementation for all normal women (400 µg/day of folic acid) and for women who have previously delivered a baby with a neural tube defect (4 mg/day of folic acid) is now standard and prevents nearly three quarters of neural tube defects. Women of childbearing age who are taking anticonvulsant medications (phenytoin, phenobarbital, carbamazepine) are also at increased risk for delivering babies with neural tube defects and should routinely take 1 mg of folic acid daily. Moreover, administration of folic acid before initiation of phenytoin can eliminate the risk of gingival hyperplasia.[A5] Folate supplementation throughout pregnancy also helps prevent premature delivery of low-birthweight infants and is recommended for premature infants and lactating mothers. Folic acid supplements (1 mg/day orally) are taken by patients with hemolysis or myeloproliferative diseases and also to reduce the toxicity of methotrexate in patients with rheumatoid arthritis and psoriasis. Those individuals in whom cobalamin deficiency develops while they are receiving long-term folate replacement will present with a pure neurologic syndrome and not necessarily anemia.

The mandatory fortification of food (flour, enriched pasta, cornmeal, cereal foods) with 140 and 150 µg of folic acid per 100 g in the United States and Canada, respectively, has led to several beneficial effects (see Table 164-2). Indeed, 94% of U.S. adults who do not consume supplements or consume less than 400 µg/day of folic acid from supplements do not exceed the upper intake limit for folic acid (>1 mg/day), which has potential to mask cobalamin deficiency. Studies that have investigated adverse effects of fortification on development or progression of cancer have not identified that this is an issue.[A6] Moreover, folate deficiency–related anemia has nearly been eliminated in older U.S. adults after folate fortification.[12]

Prophylaxis in Resource-Limited Settings

Children of mothers from resource-limited countries with nutritional folate and cobalamin deficiency are at risk for cognitive dysfunction as toddlers and as young children[13]; hence, they deserve early prophylaxis with both folate and cobalamin. The serious and chronic problem of iron, folate, and cobalamin deficiency, especially among women in North India, which is due to poor dietary intake, and the high incidence of neural tube defects[14] warrant improving their nutrition through the use of iron, folate, and vitamin B_{12} supplements. Moreover, all pregnant women living in resource-limited malarious areas are at risk for iron, folate, and vitamin B_{12} deficiency[15] and malaria, so they should routinely be given intermittent preventive treatment according to the latest guidelines; currently, it is sulfadoxine-pyrimethamine (Chapter 345) together with insecticide-treated bed nets, plus 1 mg folic acid, prophylactic vitamin B_{12} (~10 to 25 µg), and replacement doses of oral iron. Likewise, women requiring antimalarial treatment should also be given iron, folate, and vitamin B_{12} to enable optimal hematopoiesis. Finally, although *Plasmodium falciparum* possesses two folate transporter proteins, in vitro as well as clinical studies using low-dose folic acid (1 mg/day) in 467 pregnant women with malaria have demonstrated benefit; by contrast, high-dose folic acid (5 mg/day) can "feed the parasite" and is contraindicated. Finally, optimizing the nutrition of the approximately 500 million adolescent girls before they become pregnant is a priority because maternal death is one of the most common causes of death for teenage girls between 15 and 19 years of age.

PROGNOSIS

The general response to cobalamin replacement is a dramatic improvement in well-being, with alertness, a good appetite, and resolution of a sore tongue. Megaloblastic hematopoiesis reverts to normal within 12 hours and resolves by 48 hours; the only persistent findings may be giant metamyelocytes in the bone marrow and hypersegmented neutrophils in the blood for up to 14 days. The reticulocyte count peaks by days 5 to 8, followed by a rise in the red cell count, hemoglobin level, and hematocrit. By the end of the first week, the white blood cell count rises, sometimes with a transient left shift, as does the platelet count; all three cell counts should normalize in 2 months.

With cobalamin replacement, the degree of reversal of neurologic damage is generally inversely related to the extent of disease and the duration of signs and symptoms. Most neurologic abnormalities improve in up to 90% of patients with documented subacute combined degeneration, and most signs and symptoms of less than 3 months' duration are reversible. With signs and symptoms of longer duration, there is invariably some residual neurologic dysfunction. The maximal response often takes up to 6 months, but recovery beyond 12 months is unusual.

Incorrect treatment of cobalamin deficiency with folate does not improve the neuropsychiatric abnormalities, which will continue to progress; hematologic improvements often occur, however. Alternatively, there may be associated iron deficiency or hypothyroidism that needs specific replacement or another hemoglobinopathy (e.g., sickle cell disease, thalassemia) that limits the normalization of hemoglobin values (see Tables 164-3 and 164-5).

In patients with pernicious anemia, subsequent iron deficiency anemia (Chapter 159), osteoporosis (Chapter 243) with fractures of the proximal end of the femur and vertebrae, gastrinoma and gastric cancer (Chapter 192), and cancer of the buccal cavity and pharynx can develop. Some experts recommend periodic upper endoscopic surveillance.

CLINICAL PRACTICE IN RESOURCE-LIMITED SETTINGS

Masking of Folate Deficiency with Associated Cobalamin Deficiency or Malaria

In resource-limited settings where vegetarianism or poverty-imposed near-vegetarianism is common, nutritional cobalamin as well as folate deficiency and hemolysis accompanying malaria often coexist. In such settings, the serum folate level is artificially raised in cobalamin deficiency and returns to baseline only after cobalamin replacement; likewise, the serum folate level is increased during hemolysis, which releases the extant 30-fold higher erythrocyte folate concentration into plasma. In this setting, measurement of the serum folate concentration will reveal normal to high values, predictably underestimate the tissue folate status, and completely miss the diagnosis of mild to moderate folate deficiency (see E-Table 164-1). By contrast, the dietary history or more formal assessment with a variety of methods (such as 24-hour recall, estimated/weighed record, or locally validated food frequency questionnaires), which are established methods to evaluate the quality and quantity of nutrients consumed, can predict the dietary folate and cobalamin intake of a population and identify those at risk for nutritional insufficiency.[15] Indeed, knowledge of dietary folate and cobalamin intake trumps the results of conventional blood tests for folate deficiency, which are seriously flawed in this clinical setting. In summary, all individuals at risk for nutritional anemia due to deficiency of iron, folate, and cobalamin (both adults and children) should be given prophylactic oral cobalamin, folate, and iron replacement; and in malarious zones, these should be combined with antimalarial drugs and insecticide-treated bed nets.

E-TABLE 164-2 INDICATIONS FOR PROPHYLAXIS WITH COBALAMIN OR FOLATE

PROPHYLAXIS WITH COBALAMIN
Infants on specialized diets*
Premature infants
Infants of mothers with pernicious anemia*
Infants and children of mothers with nutritional cobalamin deficiency
Vegetarianism and poverty-imposed near-vegetarianism*
Total gastrectomy†
PROPHYLAXIS WITH FOLIC ACID‡
All women contemplating pregnancy (at least 400 μg/day)
Pregnancy and lactation, premature infants
Mothers at risk for delivery of infants with neural tube defects
Hemolytic anemias/hyperproliferative hematologic states
Patients with rheumatoid arthritis or psoriasis receiving therapy with methotrexate§
Patients receiving antiepileptic drugs
Patients with ulcerative colitis

*For vegetarians, prophylaxis with cobalamin (5- to 10-μg tablet/day) orally should suffice. In all other conditions of cobalamin malabsorption, cobalamin tablets of 1000 μg/day should be administered to meet daily needs.
†Consider late development of cobalamin deficiency and iron malabsorption (prophylaxis with oral cobalamin and iron).
‡Ensure that the patient does not have a cobalamin deficiency before initiation of long-term folate prophylaxis.
§To reduce toxicity of the antifolate.

REVIEW QUESTIONS

1. A 42-year-old Asian woman presents with an 8-month history of progressive lethargy and fatigue, anhedonia, forgetfulness, menorrhagia, abdominal bloating and occasional diarrhea, paresthesias, and staggering in the dark. Physical examination reveals anemia with lateral tongue ulcers, mild vitiligo, thyromegaly, delayed ankle reflexes, and reduced vibration sense and proprioception. The hemoglobin level is 5 g/dL, the white blood cell count is 3000/mm^3, and the platelet count is 130,000/mm^3. The peripheral smear reveals a dimorphic picture with macro-ovalocytes and hypochromic microcytic red cells with marked anisocytosis and occasional teardrop cells. Several five-lobed and one six-lobed polymorphonuclear neutrophils are noted. Serum ferritin level is 5 ng/mL, serum cobalamin level is 800 pg/mL, and serum folate level is 5 ng/mL (lower limit of normal, <2.4 ng/mL). The thyroid-stimulating hormone concentration is 15 mIU/L. Which of the following is an *incorrect* statement?

A. Vegetarianism, pernicious anemia with or without hypothyroidism, celiac disease, and pregnancy in women not taking supplemental iron or folate can give a similar picture of dimorphic red cells on a peripheral blood smear.
B. Even without the Schilling test, it is possible to make the diagnosis of pernicious anemia with a noninvasive blood test.
C. Antiparietal cell antibodies, which are diagnostic for pernicious anemia, can interfere with the current serum tests for cobalamin deficiency.
D. The possibility of folate deficiency cannot be ruled out, given the current serum folate level.
E. Treatment with a combination of iron and ascorbic acid plus L-thyroxine alone will not resolve this patient's anemia because it is likely she has an added dietary deficiency of cobalamin.

Answer: C Anti–intrinsic factor antibodies can interfere with the cobalamin-binding luminescence assays and lead to a failure in diagnosis of pernicious anemia in those with classic symptoms and sign (as in this patient). By contrast, antiparietal cell antibodies have no influence on this test. The identification of serum anti–intrinsic factor antibodies is highly specific and diagnostic for pernicious anemia; by contrast, antiparietal antibodies are only about 50% specific for pernicious anemia. The presence of cobalamin deficiency can falsely raise the serum folate level, which could drop below normal on replenishment of cobalamin. This patient probably has a cobalamin deficiency due to either vegetarianism (and even near-vegetarianism) or a combination of pernicious anemia with hypothyroidism and vitiligo (commonly associated autoimmune diseases); in addition to iron, replacement of cobalamin will be needed for a full hematologic response. A dimorphic picture due to iron deficiency and either folate or cobalamin deficiency is found in all the conditions listed in A.

2. An 18-year-old unemployed white woman is to be prescribed generic phenytoin for epilepsy. She is asymptomatic except for passing clots during her periods and "memory problems," and she has a hemoglobin level of 11 g/dL. She used to eat a balanced diet but has been on a vegetarian "low-carb diet" for the past 2 years ever since she learned two things from her favorite Hollywood actress: (1) her idol watches her weight by consuming small servings of salads and other organic-natural foods, and (2) she recently spoke out on a daytime television show about "our wanton exploitation of animals as a food source." The patient has lost 10 pounds in the past 8 months. She has had occasionally irregular periods and is concerned about pregnancy because her boyfriend does not like condoms. Which of the following statements is *not* true?

A. This patient's anemia is likely to be due to a combined deficiency of iron, cobalamin, and folate.
B. This patient is at risk for having a baby with neural tube defects because her diet is likely to be low in folate, and phenytoin can induce a folate deficiency.
C. Taking folate before and during administration of phenytoin will reduce the possibility that she will develop gingival hyperplasia.
D. The patient should be taking supplements of iron, cobalamin, and folate because her diet is likely to be low in these nutrients.
E. At this time, the patient's memory problems can be attributed to iron deficiency but not to either folate deficiency or cobalamin deficiency.

Answer: A Because she switched from a balanced diet to a vegetarian diet only 2 years ago, she is not at risk for dietary cobalamin deficiency; however, with prolonged vegetarianism for 5 years, she will need to be taking cobalamin supplements. Vegetarian diets are intrinsically low in bioavailable iron, but earlier she used to eat a balanced diet. Because carbohydrate (flour that makes bread and pasta) is the food source that is fortified with folic acid, her low-carb diet could be low in folate, even though she consumes "small servings of salads." Because she does not take folate supplements, the impending initiation of phenytoin, which interferes with folate absorption, places her at risk for having a baby with a neural tube defect. Recent studies show that taking folate before and during administration of phenytoin will reduce the possibility that she will develop gingival hyperplasia. Although folate deficiency does not cause neuropsychiatric problems in adults, iron deficiency is notorious for cognitive problems in young women with minimal (iron deficiency–induced) anemia.

3. A 29-year-old Kenyan postgraduate year 2 medical resident at a major university hospital in the Midwest with known thalassemia minor is referred to you for advice. She was admitted a month ago with high fever and chills with drenching sweats. She had recently returned from a trip home, where she also got married. She mentioned that she had been bitten several times by mosquitoes during her honeymoon. Her dietary history is significant only for the fact that she cooks all her meals and subsists "mostly on *ugali* (organic cornmeal without additives) and kale or other sautéed vegetables, occasional (once per week) small servings of meat, and lots of tea." In the hospital, a diagnosis of falciparum malaria was made on the basis of finding parasites on a peripheral smear. The accompanying laboratory results showed a hemoglobin level of 6 g/dL, mean corpuscular volume (MCV) of 90, and corrected reticulocyte count of 15%; lactate dehydrogenase was high, and haptoglobin was low. The serum folate level was well within the normal range (12 ng/mL; normal, >2 ng/mL), the cobalamin level was borderline low (202 pg/mL), and the serum ferritin level was high (300 ng/mL). Although antimalarials led to an eradication of malaria, the patient has still not significantly improved her hemoglobin level above 9 g/dL 2 months later. All of the following are true *except* which one?

A. The patient is at risk for deficiencies of folate, cobalamin, and iron because her native Kenyan diet is monotonous and relatively low in both animal-source foods and fresh produce.
B. The patient could have had a Coombs-positive as well as a Coombs-negative hemolytic anemia associated with falciparum malaria and should be prescribed both antimalarials and micronutrients to support compensatory hematopoiesis.
C. At presentation in the hospital, the folate value rules out the possibility of folate deficiency and argues against administration of folic acid.
D. If the patient is taking long-term folic acid in planning for a pregnancy, the development of neurologic symptoms should immediately trigger concerns of a cobalamin deficiency.
E. She should now be treated with iron, cobalamin, and folate to effect a complete resolution of the anemia and then be maintained with these supplements to optimize her nutrition.

Answer: C Red cells normally contain 30-fold more folate than what is present in the serum. Therefore, hemolysis associated with malaria will release the 30-fold excess folate from red cells into the circulation and result in a falsely high serum folate value. Hence, the serum folate level is a poor test to use in this setting because it is falsely elevated in both malaria and cobalamin deficiency. In addition, the patient is likely to have a diet that is low in all three nutrients (folate, cobalamin, and iron); food frequency questionnaire–derived estimates from resource-limited countries (including Kenya) indicate that most women consume less than what is optimum. Near-vegetarian and vegetarian diets predispose to cobalamin and iron deficiency. The borderline nutritional cobalamin deficiency can also contribute to a falsely elevated folate level. Because the cornmeal she purchases has no additives (i.e., no folic acid), she will need to take folate supplements in preparation for pregnancy.

4. A 29-year-old white woman is referred because of easy fatigue and anorexia. During the past 5 years, she has noticed abdominal bloating and diarrhea that are closely linked to consumption of gluten-containing foods. There is pallor, and the hemoglobin level is 9 with an MCV of 90 and a serum ferritin level of 10 ng/mL. The serum anti–tissue transglutaminase antibody test result is positive. All of the following are true *except* which one?

A. Treatment of the patient with total-dose parenteral iron will resolve the iron deficiency, but the anemia will likely persist.
B. Treatment with iron alone will result in a progressive increase in MCV, which reflects unmasking of a megaloblastic anemia.
C. The serum homocysteine and methylmalonic acid levels are likely to be increased and signify metabolic evidence of cobalamin deficiency.
D. Folate deficiency is unlikely to be present in a patient with elevated methylmalonic acid and homocysteine from cobalamin deficiency.
E. Folates are absorbed through the proton-coupled folate transporter in the jejunum, which can be involved in celiac disease.

Answer: D Because this patient has celiac disease, in the short term, folate deficiency can develop; but in the long term, with more extensive intestinal involvement that includes the ileum, cobalamin deficiency can eventually develop. The existence of high methylmalonic acid and homocysteine values, although confirming cobalamin deficiency, does not rule out an associated folate deficiency, which is associated with high homocysteine values. Despite low ferritin values consistent with iron deficiency from celiac disease, the normal MCV probably reflects an underlying folate or cobalamin deficiency. Treatment with parenteral iron will unmask the hematologic features of megaloblastic anemia.

5. A 58-year-old white man with type 2 diabetes for 15 years is evaluated for a 6- to 8-month history of slowly progressive fatigue, anemia, and mild peripheral neuropathy of both lower extremities. He had been well controlled with metformin 850 mg three times daily and only recently began taking a single dose of long-acting insulin at night because the latest hemoglobin A_{1c} level was 10. He does not take supplements, and his diet has been well balanced. He regularly makes his own bread every 2 or 3 days. He has recently been prescribed proton pump inhibitors and an H_2-blocker for dyspeptic symptoms. The hemoglobin level is 11 with an MCV of 108, with macro-ovalocytes and several five-lobed hypersegmented polymorphonuclear neutrophils seen on the peripheral blood smear. All of the following are true *except* which one?

A. The patient has features of megaloblastic anemia and should have a bone marrow examination to confirm the diagnosis.
B. The serum cobalamin level is likely to be low, but the serum folate level is likely to be in the high-normal range.
C. This patient could have food cobalamin malabsorption because of inhibition of acid in the stomach.
D. This patient could have cobalamin malabsorption at the level of cubam receptors in the ileum.
E. Upper endoscopy is indicated to look for gastrinomas or gastric cancer if anti–intrinsic factor antibodies are found.

Answer: A In view of the slowly progressive nature of the anemia, the characteristic findings of a megaloblastic anemia on the peripheral smear, and the known effect of metformin in interfering with trans-enterocytic transport of cobalamin (at the ileal level), there is no reason to proceed with a bone marrow examination. The serum cobalamin level is likely to be low after consumption of metformin for 5 years (this patient has been taking metformin for much longer—15 years); the serum folate level is likely to be high-normal among those consuming a balanced diet because of food fortification with folic acid (remember, he makes his own bread). The malabsorption of cobalamin in the stomach induced by a reduction of acid can, during several years, lead to symptoms of deficiency. Proton pump inhibitors and H_2-blockers can induce malabsorption. However, the primary mechanism of metformin is believed to be at the level of cubam receptors in the ileum, where supplemental calcium (1.2 g/day) taken with the drug can prevent this well-recognized, potentially serious but reversible, delayed adverse effect of metformin.

165

APLASTIC ANEMIA AND RELATED BONE MARROW FAILURE STATES

GROVER C. BAGBY

DEFINITION

Aplastic anemia is a life-threatening syndrome characterized by failure of the bone marrow to produce peripheral blood cells and their progenitors. Diverse diseases and environmental factors can cause this syndrome, but its hallmark is bone marrow hypocellularity and hypoplasia of the erythroid, myeloid, and megakaryocyte lines (Fig. 165-1).

EPIDEMIOLOGY

The annual incidence is 2 per 1 million persons in Europe and North America and 4 to 7 per 1 million persons in Asia. No age group is exempt, and although the syndrome occurs most often in young adults, the age distribution of newly diagnosed patients is bimodal, with peaks at 15 to 25 years and at 60 to 65 years.

PATHOBIOLOGY

Pathology

Peripheral blood pancytopenia is universally present in patients with aplastic anemia, but because other disorders can cause pancytopenia, bone marrow biopsy is required to establish the diagnosis. The diagnosis will be clear-cut if the biopsy specimen is of sufficient size and has been obtained from an anatomic site that has never been exposed to extensive trauma or irradiation. As shown in Figure 165-1B, some residual lymphoid cell populations can be found in marrow specimens. Although these lymphoid cells may be of pathophysiologic importance, it is the absence of *nonlymphoid* hematopoietic cells that is important in establishing the diagnosis of this syndrome. However, if the hematopoietic marrow has been suppressed (or "replaced") by the infiltration of neoplastic cells or fibroblasts, the diagnosis of aplastic anemia cannot be made. Therefore, the diagnosis requires not only a dearth of hematopoietic cells in the marrow but also an "empty" bone marrow.

Some bone marrow failure syndromes affect only one lineage. In those cases, only the marrow precursors of that lineage are missing. In patients with agranulocytosis, for example, there are rare neutrophils and neutrophil precursors present, and the ratio of erythroid to myeloid cells is very high. Likewise, in patients with the disorder known as pure red cell aplasia, few erythroid cells are detectable in the marrow, but the other lineages are well represented and functional. These two disorders are examples of bone marrow failure syndromes but are not examples of aplastic anemia, which involves global suppression of all hematopoietic lineages.

Pathophysiology

Marrow aplasia in a few patients (10 to 15%) can be attributed to an inherited bone marrow failure syndrome,[1] but most cases are acquired. In all cases, it is clear that the causative factors, genetic or environmental, injure pluripotent hematopoietic stem cells. This is in contrast to the case of the lineage-restricted disorders, wherein the causative agents and factors suppress the growth and development of unipotent progenitor cells committed to that particular lineage. Radiation, viral diseases, cytotoxic drugs, and chemicals are known causes of aplastic anemia, but the most common form of acquired aplastic anemia is immunologically mediated, and evidence is emerging that some marrow failure states attributed to viral infection or to idiosyncratic drug reactions may also result from immune suppression of hematopoiesis. The pathogenesis of the major causes of aplastic anemia and related bone marrow failure states is outlined in Table 165-1.

Pathogenesis

Autoimmune Aplastic Anemia

Acquired Aplastic Anemia

In patients with the most common form of acquired aplastic anemia, autologous T lymphocytes suppress the replicative activity and induce the death of hematopoietic stem and progenitor cells. Evidence supporting this model is found in studies demonstrating the following: removal of T lymphocytes from cultured bone marrow cells enhances hematopoiesis in vitro; patients with aplastic anemia can be effectively treated with immunosuppressive therapy alone[2]; oligoclonal T cells in the marrow and blood of aplastic anemia

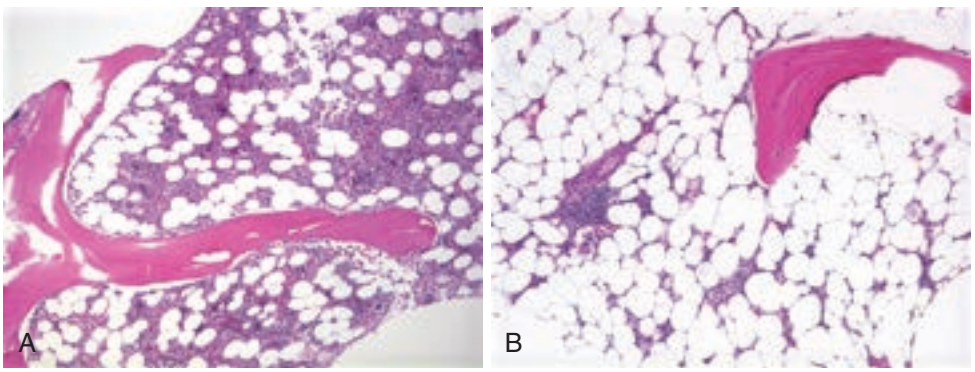

FIGURE 165-1. Two bone marrow biopsy samples from different patients. A, This specimen, from a normal individual, shows an abundance of hematopoietic cells, including myeloid and erythroid precursors and normal-appearing megakaryocytes. **B,** A specimen from a patient with severe aplastic anemia shows few detectable hematopoietic cells, and those that can be seen (one small nest) are largely lymphocytes. Lymphoid cells are often detectable and probably play an important pathophysiologic role in many cases of acquired idiopathic aplastic anemia, a disorder that is most often immunologically mediated. (Courtesy Dr. Ken Gatter, Oregon Health and Science University.)

patients contain high intracellular levels of the myelosuppressive cytokines interferon-γ and tumor necrosis factor-α; the interferon-γ/tumor necrosis factor-α–positive T-cell populations are suppressed in patients who respond to immunosuppressive therapy but are not suppressed in patients who do not respond; and the syndrome can be modeled in mice by infusing alloreactive lymphocytes that induce marrow failure. The mechanisms by which such autoinhibitory T-cell clones arise are unclear, but a loss of function in the regulatory T-cell population may play a role.[3]

Drug Induced

Although a wide variety of drugs have been associated with aplastic anemia, the association is loose. Much of the evidence is circumstantial, and apart from drugs that are known to be directly toxic to the marrow (e.g., chemotherapeutic agents; Table 165-2), the cases are not related to total dose of the suspect agent. These "idiosyncratic" reactions are likely to be autoimmune. Some agents, chloramphenicol being the classic example, are capable of inducing both types of injury. High doses can lead to myelosuppression in all treated patients (which abates after discontinuation of the drug), but even low doses can cause rare idiosyncratic aplastic responses as well (which do not remit after discontinuation of the agent). Drugs that have been repeatedly associated with aplastic anemia are listed in Table 165-2.

Infections

HEPATITIS. About 2 to 5% of patients with severe aplastic anemia have had viral hepatitis (Chapters 148 and 149). Some cases were associated with hepatitis A or B, but most patients with the hepatitis-aplasia syndrome have had hepatitis of unclear type (non-A, -B, -C, -E, or -G). Most patients with this syndrome are younger than 20 years. The natural course is rapid, with a 1-year mortality rate of more than 90%. The immune system is probably involved in the pathophysiologic mechanism of this syndrome because T-cell clonotypes are shared among patients with this type of aplasia[4] and immunosuppressive therapy has been reported to induce meaningful remissions.

EPSTEIN-BARR VIRUS. In rare patients with aplastic anemia, evidence of active Epstein-Barr virus (EBV) infection has been discovered (Chapter 377). Because the virus does not infect progenitor cells or stem cells, it is most likely that EBV induces an aberrant immune response that generates either immunoglobulin- or T-lymphocyte–mediated hematopoietic suppression. Because only a minority of EBV-infected aplastic patients describe a history of typical infectious mononucleosis, it is equally likely that the aplastic state came first and that EBV infection or reactivation was a second event.

TABLE 165-2 DRUGS AND TOXINS ASSOCIATED WITH APLASTIC ANEMIA

DOSE DEPENDENT

Antineoplastic Agents

Antimetabolites: fluorouracil, mercaptopurine, 6-thioguanine, methotrexate, cytosine arabinoside, gemcitabine, fludarabine, cladribine, pentostatin, hydroxyurea

Alkylating and cross-linking agents: busulfan, cyclophosphamide, chlorambucil, nitrogen mustard, melphalan, cisplatin, carboplatin, ifosfamide, nitrosoureas (BCNU and CCNU), mitomycin C

Cytotoxic antibiotics: daunorubicin, doxorubicin, mitoxantrone

Plant alkaloids: vinblastine, paclitaxel

Topoisomerase inhibitors: etoposide

Antimicrobial Agents

Chloramphenicol, dapsone, fluorocytosine

Anti-inflammatory and Antirheumatic Agents

Colchicine

Insecticides

Chlordane, chlorophenothane (DDT), lindane, parathion

Other Chemicals

Benzene

Benzene-containing chemicals: kerosene, chlorophenols, carbon tetrachloride

DOSE INDEPENDENT

Idiosyncratic, likely immune mediated

(*Note:* Most agents on this list should be considered to be possibly associated with aplastic anemia.)

Antimicrobial Agents

Chloramphenicol, dapsone, sulfonamides, tetracycline, methicillin, amphotericin, quinacrine, chloroquine, pyrimethamine

Anticonvulsants

Hydantoins, carbamazepine, phenacemide, primidone, ethosuximide

Anti-inflammatory Agents

Phenylbutazone, indomethacin, ibuprofen, oxyphenbutazone, sulindac, naproxen

Antiarrhythmic Drugs

Quinidine, tocainide, procainamide

Metals

Gold, arsenic, mercury, bismuth

Antihistamines

Cimetidine, ranitidine, chlorpheniramine, pyrilamine, tripelennamine

Diuretics

Acetazolamide, furosemide, chlorothiazide, methazolamide

Hypoglycemic Agents

Chlorpropamide, tolbutamide

Antithyroid Drugs

Propylthiouracil, potassium perchlorate, methylthiouracil, methimazole, carbimazole

Antihypertensive Agents

Methyldopa, enalapril, captopril

Sedatives

Chlordiazepoxide, chlorpromazine, meprobamate, prochlorperazine

Autoimmune-Mediated Failure of Single Hematopoietic Lineages

Agranulocytosis

Agranulocytosis is characterized by severe neutropenia and suppression of granulopoiesis (also see Chapter 167). This disorder can be an idiosyncratic reaction to certain drugs and most likely involves immune suppression of granulopoietic progenitor cells. The disease almost always abates when the offending drug is discontinued. Agranulocytosis also occurs in patients with established autoimmune diseases, including systemic lupus erythematosus, Sjögren syndrome, and rheumatoid arthritis. In some cases, the disorder is caused by myelosuppressive antibodies; in others, it is caused by T lymphocytes that suppress granulopoiesis. Immunosuppressive therapy is often effective in such patients and should be used in patients whose agranulocytosis is severe and associated with recurrent infections.

Pure Red Cell Aplasia

Severe normochromic, normocytic anemia (Chapter 158) with a marked decrease in reticulocyte number is sometimes associated with selective hypoplasia of the erythroid marrow without loss of megakaryocytes and myeloid precursor cells. In immunocompromised hosts and patients with chronic hemolytic diseases, this disorder, known as pure red cell aplasia, can be caused by parvovirus B19 infection (Chapter 371), an agent that infects erythroid precursor cells and likely generates an erythroid suppressive immune response. This disease can also be mediated by T lymphocytes or natural killer cells that suppress cells of the erythroid lineage and in more uncommon cases by antibody-dependent suppression of erythropoiesis. Pure red cell aplasia can also develop as a complication of thymoma (Chapter 99) and in these circumstances is likewise caused by oligoclonal T-cell expansion that specifically suppresses erythroid progenitor cells. This disorder can also be associated with drug exposure (e.g., isoniazid, chlorpropamide, and phenytoin), lymphoid neoplasms (chronic lymphocytic leukemia; Chapter 184), and myelodysplasia (Chapter 182). Rarely, adults with Diamond-Blackfan anemia present with isolated erythroid suppression, but the degree to which the erythroid marrow is suppressed in such patients rarely matches the profound suppression seen in acquired cases of immune-mediated pure red cell aplasia.

Direct Stem Cell Toxicity

Radiation

The severity of myelosuppression induced by radiation and the degree to which the marrow can recover from that injury depend on the radiation dose, the timing of exposure, and the fraction of hematopoietic tissues exposed. Low-dose total body radiation causes transient marrow suppression. High doses of total body radiation (700 to 1000 cGy) induce severe injury to the stem cell pool with persistent and life-threatening marrow failure. In the past, direct radiation injury to hematopoietic stem cells was the accepted explanation for stem cell injury, but recent evidence indicates that injury to other tissues (especially the gut) results in the release of endogenous factors that themselves suppress hematopoiesis.[5] When limited bone marrow sites are irradiated to very high doses (4000 cGy or more), the relatively radioresistant bone marrow stromal cells are eradicated, and thereafter that marrow space can never fully support hematopoietic activity.

Chemicals

Benzene suppresses the bone marrow in a dose-dependent manner, and chronic exposure to it has been linked with aplastic anemia and myeloid leukemogenesis. Benzene and many of its catabolites are directly toxic to stem

cells, damage DNA, suppress the supportive function of the bone marrow microenvironment, and accentuate the responsiveness of hematopoietic progenitor cells to intramedullary apoptotic cues that arise during the inflammatory response. Kerosene, carbon tetrachloride, and chlorophenols contain benzene, as do many other like products used for paint stripping, refinishing, and degreasing (see Table 165-2).

Drugs

Many agents in use for the treatment of malignant diseases are predictably myelosuppressive and can induce aplastic anemia because they are directly toxic to stem and progenitor cells in the marrow (see Table 165-2). These myelosuppressive responses are completely predictable and dose dependent. In practical terms, unless the patient receives a drug overdose or has an undiagnosed genetic disorder that predisposes the patient to respond to the agent in an exaggerated way (e.g., Fanconi anemia [FA]), most patients treated for neoplastic diseases develop reversible bone marrow aplasia or hypoplasia and recover bone marrow function within a matter of days.

Other Aplastic States

Pregnancy

Aplastic anemia can be diagnosed in pregnancy. In addition, some patients with aplastic anemia have become pregnant after the diagnosis. The prognosis in both instances is poor, and most fatal outcomes are due to bleeding complications. Some women who have been fortunate enough to recover bone marrow function post partum develop aplastic anemia with a subsequent pregnancy. The pathogenesis and causal relationship between pregnancy and aplastic anemia remain unknown but may reflect a high level of immunologic activation during pregnancy.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disorder that results from the expansion of a clone of hematopoietic stem cells whose progeny are incapable of anchoring essential proteins to their membranes (Chapter 160).[6] The defect is caused by an inactivating somatic mutation of *PIGA*, an X-linked gene that encodes a protein essential for synthesis of the membrane anchor glycosyl phosphatidylinositol (GPI). Some of the GPI-anchored proteins (e.g., CD55 and CD59) are important in normal red cells to protect them from activated complement. Consequently, the loss of CD55 and CD59 results in chronic intravascular hemolysis. Two less clearly defined features of PNH are high relative risks of thromboembolism (Chapter 176) and aplastic anemia. The emergence of "PNH clones" is not uncommon in patients with acquired aplastic anemia, and experimental evidence supports the idea that the evolution of *PIGA*-deficient stem cells is an adaptive response to the immune attack. How the *PIGA*-deficient cells fend off cytotoxic T cells is less clear, but it is likely that their pool expands because they accomplish that task somehow. The most reasonable model is one in which, in the setting of an immune attack, *PIGA*-deficient stem cells are more fit than normal stem cells, but the complement-sensitive red cells to which they give rise as a result of this "tradeoff" have an unusually short lifespan.

Inherited Bone Marrow Failure Syndromes

Some inherited bone marrow failure syndromes can be manifested in adolescence and adulthood. They include dyskeratosis congenita, FA, and Diamond-Blackfan anemia. The molecular pathogenesis of the bone marrow failure seen in these diseases is under active investigation.[7] Although the genetic basis of these disorders has been well defined in the past decade, the canonical functions of the proteins encoded by these genes is distinct (Table 165-3) for each disease. For example, in dyskeratosis, the mutations occur in genes that encode proteins and RNAs involved in telomere maintenance. In FA, the mutations involve proteins involved in the DNA damage response, and in Diamond-Blackfan anemia, inactivating mutations involve ribosomal proteins known to be involved in ribosome biogenesis.[8] Whether loss of these canonical functions is linked with the pathogenesis of marrow failure is

TABLE 165-3 DISTINGUISHING CLINICAL FEATURES OF THE INHERITED BONE MARROW FAILURE SYNDROMES THAT MAY BE INITIALLY DIAGNOSED IN ADULTHOOD

DISTINGUISHING FEATURES	*DISEASES*		
	FANCONI ANEMIA	**DYSKERATOSIS CONGENITA**	**DIAMOND-BLACKFAN ANEMIA**
History	Skeletal and renal malformations, low birthweight, pancytopenia, family member with bone marrow failure, myelodysplasia, acute myelogenous leukemia, or squamous cell carcinoma at an early age Family member with Fanconi anemia	Intrauterine growth retardation, developmental delay, and short stature Family history of myelodysplasia, acute myelogenous leukemia, marrow failure, abnormal fingernails or toenails, leukoplakia, head and neck cancer, or pulmonary fibrosis	Low birthweight, arm and thumb deformities at birth
Physical findings	Thumb and radial malformations, hyperpigmented skin lesions (cafe au lait spots), short stature, myelodysplasia, acute myelogenous leukemia, squamous cell carcinoma at young age, renal and cardiac malformations, microcephaly, hypogonadism	Lacy reticular pigmentation of skin, dystrophic fingernails and toenails, premature graying of hair, hair loss, short stature, oral leukoplakia, squamous cell cancer of head and neck, pulmonary fibrosis, osteopenia, hypogonadism	Triphalangeal thumbs, short stature, arm anomalies
Genes inactivated	*FANCA, FANCB, FANCC, FANCD1* (also known as *BRCA2*), *FANCD2, FANCE, FANCF, FANCG* (also known as *BRCA2, FANCD2, FANCE, FANCF XRCC9*), *FANCI, FANCJ* (also known as *BRCA2, FANCD2, FANCE, FANCF BACH1,* and *BRIP1*), *FANCL* (also known as *PHF9* and *POG*), *FANCM* (also known as *Hef*), *FANCN* (also known as *PALB2*), *FANCO* (also known as *RAD51C*), and *FANCP* (also known as *BRCA2, FANCD2, FANCE, FANCF SLX4*) These genes encode proteins known to protect the genome from excessive damage induced by chemical cross-linking agents. These genes account for most cases of Fanconi anemia.	*DKC1, TERC, TERT, TINF2, NOLA2* (also known as *NHP2*) and *NOLA3* (also known as *NOP10*), and *WRAP53* These genes encode proteins known to participate in maintenance of telomeres. They account for only half of dyskeratosis cases, so there are additional genes to be discovered.	*RPS7, RPS10, RPS17, RPS19, RPS24, RPS26, RPL5, RPL11, RPL26,* and *RPL35A* These genes encode ribosomal proteins. They account for only half of cases, so there are additional genes to be discovered.
Screening and diagnostic tests	1. Chromosomal breakage test on skin fibroblasts or peripheral blood lymphocytes (in response to mitomycin C or diepoxybutane) 2. Complementation analysis (flow cytometric analysis of G_2 arrest in melphalan-exposed cells after transduction with retroviral vectors expressing normal Fanconi anemia genes) 3. Gene sequencing	1. Quantitative analysis of telomere length (flow-FISH) in lymphocytes 2. Gene sequencing	*Note:* Isolated erythroid failure is more common than full-blown aplastic anemia. 1. There are no screening tests, although serum ADA is often elevated. 2. Gene sequencing

ADA = adenosine deaminase; FISH = fluorescent in situ hybridization.

unclear. In fact, studies on hematopoietic cells have revealed noncanonical functions of some of these proteins. Some of the FA proteins, for example, participate directly or indirectly in stem cell survival signaling pathways. Interestingly, some of the pathways disrupted in mutant cells result in hyperactivation of precisely those same cytokine signaling pathways involved in the pathogenesis of acquired autoimmune aplastic anemia.[9]

Genetics

The genetic basis of inherited bone marrow failure syndromes is being rapidly solved. Some of these syndromes (e.g., Shwachman-Diamond syndrome, amegakaryocytic thrombocytopenia, and severe congenital neutropenia) are almost always diagnosed in early life. However, some may be first diagnosed in adulthood (e.g., dyskeratosis congenita, FA, and Diamond-Blackfan anemia). It is critically important to consider these three disorders early in the evaluation of adults with aplastic anemia because the treatment of such patients with conventional stem cell transplantation regimens is associated with high mortality rates (especially in dyskeratosis congenita and FA). Furthermore, current immunosuppressive therapy, an important therapeutic option in patients with acquired aplastic anemia, plays no role in these diseases. The clinical and laboratory manifestations of these three diseases and the findings that should prompt genetic testing in such patients are reviewed in Table 165-3. Whereas the stem cell defects can be identified during fetal development, adults who present with these diseases were not born with aplastic anemia. Instead, aplasia develops over time and can give rise to symptoms in adulthood. Prospective studies of children and adults who present with bone marrow failure have indicated that nearly 10% will have previously unsuspected FA. Diagnostic consideration of a hereditary form of aplastic anemia should not be limited to children.

CLINICAL MANIFESTATIONS

The natural course of aplastic anemia is influenced by its severity. Patients with hypoplastic bone marrows have severe aplastic anemia if they meet two of the following laboratory criteria: absolute neutrophil count of less than 0.5×10^9/L; platelet count of less than 20×10^9/L; or reticulocyte count of less than 20×10^9/L. Patients who do not have severe aplastic anemia often progress to severe aplasia, but the pace is slow (about 40% will have progressed in 5 years). Severe aplastic anemia is a life-threatening condition that, untreated, is associated with a mortality rate of 80% in the 24 months after diagnosis. Treatment of any cohort of patients with severe aplastic anemia will prolong life, and many patients, particularly those who have received stem cell transplants, will be cured.

History

Symptoms of this syndrome, cause notwithstanding, are almost always reflective of low blood counts. The most common presenting symptoms are those associated with thrombocytopenia and anemia. Low platelet counts are associated with bleeding, often epistaxis and bleeding gums, bruising with minor or no trauma, and menorrhagia. Anemia accounts for the nearly universal symptoms of fatigue and dyspnea on mild exertion. Some aplastic patients may present with intercurrent bacterial or fungal infection (because of severe neutropenia), but these cases are less common. Family histories that include any of the features listed in Table 165-3 should raise suspicion of an inherited bone marrow failure syndrome.

Physical Examination

Pallor and tachycardia at rest are common signs of anemia but can be absent or unnoticeable in younger patients and in patients whose aplasia is of recent onset. Hemorrhagic manifestations classic for thrombocytopenia are often found: petechiae (cutaneous or palatal), ecchymoses, and epistaxis. The most common form of aplastic anemia, autoimmune, is rarely associated with lymphadenopathy or hepatosplenomegaly, and when such findings are present, alternative diagnoses should be considered and painstakingly ruled out. Likewise, concerns of an inherited bone marrow failure disease should be triggered by the following: short stature; endocrinopathies; osteopenia; findings of developmental anomalies of the skin, nails, hands, or arms; and malformations of the heart, liver, or genitourinary tract (see Table 165-3).

Initial Laboratory Findings

Pancytopenia (anemia, leukopenia, and thrombocytopenia) is a universal presenting finding. The morphology of neutrophils, platelets, and red cells on peripheral blood smear is usually normal unless there is concurrent iron deficiency due to bleeding.

DIAGNOSIS

The evaluation of pancytopenic patients first requires examination of the peripheral blood smear. If there are morphologic or clinical signs of vitamin B_{12} or folic acid deficiency (e.g., hypersegmented neutrophils and oval macrocytes), those disorders should be ruled out because a bone marrow aspiration and biopsy would not be required in those conditions. In severe aplastic anemia, the peripheral blood smear will not show nucleated red blood cells or other signs that the marrow might be infiltrated with abnormal cells. All patients in whom vitamin B_{12} and folate deficiency have been ruled out (Chapter 164) require a bone marrow aspiration and biopsy. Obtaining both types of samples is important. The biopsy best assesses overall bone marrow cellularity and provides the most sensitive evidence for some infiltrative processes. The aspirated sample can be examined microscopically for the presence of abnormal cells but also provides cells for cytogenetic analyses (which can provide evidence supporting hypoplastic myelodysplasia and acute leukemia). Rarely in the early stages of aplasia, the biopsy finding can be somewhat cellular. A repeated biopsy in 1 to 2 weeks might be required to establish the diagnosis clearly. As summarized in Figure 165-2, once the diagnosis of aplastic anemia has been made, a series of additional tests must be obtained. In light of the life-threatening nature of this disease, the tests must be obtained simultaneously, but they serve three distinct purposes.

Ruling Out Aplastic Anemia Variants That Must Be Treated Differently

The best therapeutic option for many different aplastic states is often matched sibling donor stem cell transplantation, but there are some aplastic states that are managed differently. For example, a child with an inherited marrow failure syndrome might have a human leukocyte antigen (HLA)–identical sibling who also has the same genetic defect. If such a diagnosis has been overlooked in the recipient and donor, the recipient will most likely die because the donor cells are unfit for transplantation and the conditioning regimen will be too toxic. For example, patients with FA are highly intolerant of radiation and cross-linking agents used in conventional conditioning regimens, and patients with dyskeratosis suffer excessive post-transplantation morbidity and mortality. Patients with dyskeratosis congenita and children with the Shwachman-Diamond syndrome are also intolerant of conventional transplantation regimens and often suffer severe pulmonary and hepatic toxicity. Although patients with Diamond-Blackfan anemia are more tolerant of standard conditioning regimens, they are more apt to respond to glucocorticosteroid therapy, and if they are transplanted with stem cells from an undiagnosed affected sibling, they too will do poorly. Finally, patients with PNH should be identified with flow cytometric quantification of CD55- and CD59-deficient hematopoietic cells because more than half of patients with severe aplastic anemia will have PNH clones, and on treatment with immunosuppressive therapy, the PNH clone often expands, resulting in hemolysis and thrombosis.

Tests Helpful in Supportive Care

At some point during the course of the disease, red cell and platelet transfusions will be necessary. Irradiated and filtered blood products are used to prevent transfusion-associated graft-versus-host disease (GVHD), to reduce alloimmunization, and to reduce the complication of cytomegalovirus (CMV) infection. ABO and HLA typing are required. Infections can be of bacterial, viral, or fungal origin and must be quickly diagnosed and treated not only because the patients are often neutropenic but also because, once definitive therapy begins, the patient will be immunosuppressed. In the acutely infected, severely neutropenic patient, once culture and biopsy specimens are obtained, empirical antibiotic therapy should be given without waiting for the culture results. Post-transplantation CMV infection is best avoided in CMV-seronegative recipients by use of CMV-negative blood products (Chapter 177).

Evaluating the Patient as a Candidate for Stem Cell Transplantation

Timing of treatment depends on the severity of the aplastic anemia and the age of the patient (Table 165-4). Patients with mild marrow hypoplasia and mild bone marrow suppression can be observed closely to determine what the pace of hypoplasia might be. In patients up to 40 years of age with either severe acquired aplastic anemia or transfusion dependence, steps should be taken to evaluate them promptly for stem cell transplantation therapy by

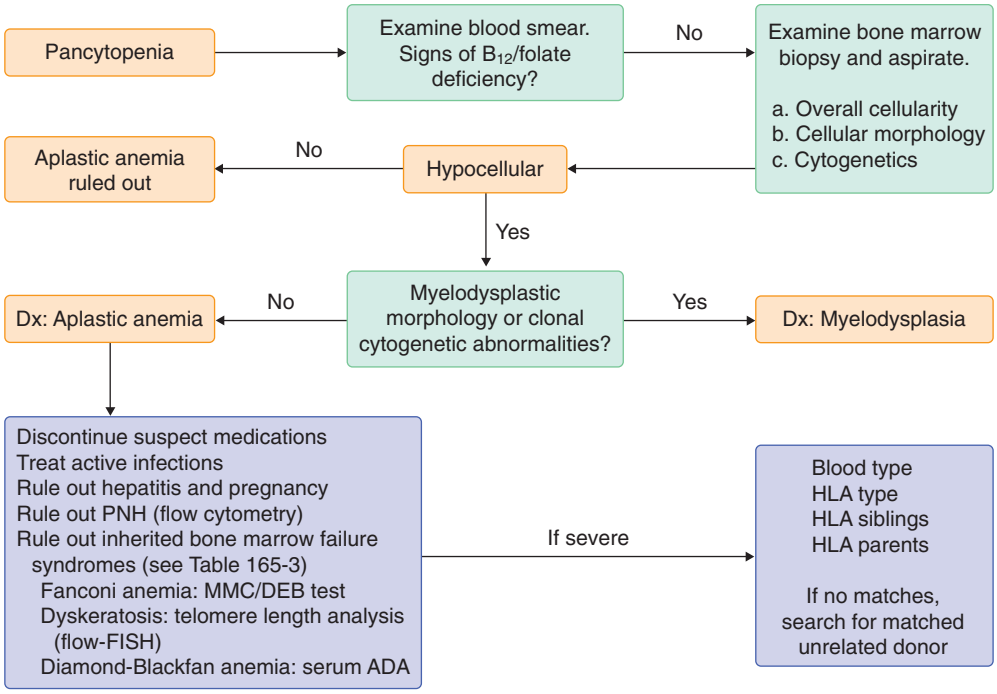

FIGURE 165-2. Diagnostic management of patients with aplastic anemia. Patients who present with pancytopenia will require bone marrow biopsy and aspiration unless there are signs of vitamin B_{12} or folate deficiency. If the bone marrow is as cellular as that shown in Figure 165-1A, the diagnosis of aplastic anemia has been effectively ruled out because the diagnosis requires bone marrow hypocellularity (see Fig. 165-1B). In all patients, regardless of severity, suspect medications should be discontinued, active infections should be treated without delay, and paroxysmal nocturnal hemoglobinuria (PNH) should be excluded, as should pregnancy and hepatitis. Microscopic evidence in the bone marrow sample of myelodysplastic changes and evidence of a clonal chromosomal abnormality indicate that the patient has "hypoplastic" myelodysplasia and should be treated accordingly. For patients with positive family histories or any one of the findings listed in Table 165-3 and for all patients younger than 40 years, inherited marrow failure syndromes should be ruled out with screening tests. Patients with severe aplastic anemia are those who have at least two of the following: absolute neutrophil count of less than 0.5×10^9/L, platelet count of less than 20×10^9/L, or reticulocyte count of less than 20×10^9/L. These patients must be treated with definitive therapy and should be evaluated for stem cell transplantation with human leukocyte antigen (HLA) typing (patient and family members) and, if necessary, a search for matched unrelated donors. ADA = adenosine deaminase; DEB = diepoxybutane; FISH = fluorescent in situ hybridization; MMC = mitomycin C.

TABLE 165-4 TREATMENT RECOMMENDATIONS FOR PATIENTS WITH SEVERE ACQUIRED IDIOPATHIC APLASTIC ANEMIA*

	AGE < 20 YEARS		AGE 20-40 YEARS		AGE > 40 YEARS	
HLA-identical sibling?	Yes	No	Yes	No	Yes	No
First-line treatment	MSBMT	IST	MSBMT	IST	IST	IST
Second-line treatment	IST or second MSBMT	IST or MUDT or CBT	IST	IST, eltrombopag, or MUDT	MSBMT	IST For failures, consider eltrombopag, clinical trials, or MUDT

*This general set of recommendations cannot be applied to patients with inherited bone marrow failure syndromes because they do not respond to immunosuppressive therapy.
CBT = umbilical cord blood transplantation; HLA = human leukocyte antigen; IST = immunosuppressive therapy; MSBMT = matched sibling bone marrow transplant; MUDT = matched unrelated donor transplant.
Modified from Bacigalupo A, Passweg J. Diagnosis and treatment of acquired aplastic anemia. *Hematol Oncol Clin North Am.* 2009;23:159-170.

seeking HLA-identical siblings and, in appropriate cases, searching for matched unrelated donors.

Differential Diagnosis

Most classic aplastic anemia patients have immunologically mediated disease. Notwithstanding strong evidence in support of this mechanism from some research laboratories during the past 30 years, there exists no validated screening tool or certified test that can either rule in or rule out immune-mediated disease, a fact complicated by the evidence that some cases of drug- and virus-induced disease are also immunologically mediated. Therefore, idiopathic autoimmune aplastic anemia remains a diagnosis of exclusion. For this reason, the obligation of the diagnostician is to consider disease induced by chemical or viral agents and radiation and disease associated with pregnancy. It is also most important to rule out PNH and inherited bone marrow failure syndromes (see Fig. 165-2).

Cytotoxic Drugs, Chemicals, and Radiation

A fastidiously obtained medication history is important. Any drug with the potential of inducing aplastic anemia should be discontinued. It is equally important to ask patients about alternative therapies that they might not consider to be "medicines." Some herbal remedies are known to contain molecules (e.g., phenylbutazone) not listed on the label but that are associated with aplasia (see Table 165-2). A history of exposure to radiation or to chemicals with myelosuppressive capacities (see Table 165-2) should likewise be obtained. Tests for benzene metabolites detect only acute exposure and are not reliable indicators of cumulative exposure in individual patients. Although it is intuitively obvious and prudent to discontinue the use of agents that might have inflicted severe stem cell injury, by the time the injury has progressed to the point of severe aplastic anemia, most of these patients are in need of the same types of therapy prescribed for patients with autoimmune aplastic anemia.

Idiosyncratic Drug Responses

If a medication history uncovers an exposure to an agent known to be associated with idiosyncratic (not related to dose) responses, the agent must likewise be discontinued. Because it is likely that these responses are immunologically mediated, the patient should be treated no differently from patients with severe idiopathic aplastic anemia, and the patient should be evaluated as a stem cell transplantation candidate. If, during the diagnostic evaluation of the patient and potential donors, there are signs that the marrow is recovering on its own, a more conservative approach can be taken.

Paroxysmal Nocturnal Hemoglobinuria

PNH can be ruled out by screening for CD55 and CD59 on the surface of granulocytes, monocytes, and red cells by flow cytometry. The proper diagnosis of PNH requires the absence of these or other GPI-anchored proteins on at least two hematopoietic cell types. Other characteristic features of this syndrome can be a high low-density lipoprotein level, high indirect bilirubin, low haptoglobin, and a positive urine hemosiderin test result.

Fanconi Anemia

FA should be considered in any adult of any age with a family history of aplastic anemia, acute myelogenous leukemia or myelodysplasia, or squamous cell carcinoma at an unusually young age. This disease should also be considered in any patient with any physical finding listed in Table 165-3 or in patients with a family member who has any of these findings. Unfortunately, some patients with FA meet none of these criteria, so some hematologists, including this author, advocate testing for FA in all patients with aplastic anemia younger than 40 years. This disease can be ruled out by obtaining a chromosomal breakage test (see Table 165-3). Here, either lymphocytes or skin fibroblasts are exposed to cross-linking agents (e.g., mitomycin C or diepoxybutane) for a period of 2 to 3 days, after which metaphase chromosomes are examined for chromosomal breaks and quadriradial forms (four-armed interchromosomal structures). If the clinical context is suggestive (see Table 165-3) but results of the lymphocyte chromosomal breakage test are negative or equivocal, testing of skin fibroblasts is required to rule out the diagnosis. Once the diagnosis is made, history, physical examination, blood counts, and chromosomal breakage tests should be performed on all immediate family members.

There are at least 15 different FA genes (see Table 165-3), and sequencing of them all with cells from every patient is not practical at this time. Fortunately, the involved gene can be first identified by a variety of more affordable complementation analyses. In this type of test, normal FA genes are introduced into primary cells of the patient in vitro, and the one gene that corrects the defect (i.e., reduces hypersensitivity to cross-linking agents [melphalan, mitomycin C, or diepoxybutane]) represents the gene of interest. That gene can then be fully sequenced to identify the precise mutation, information that will be of value to family members. In rare instances, it can also aid in applying preimplantation genetic diagnosis and in vitro fertilization, a process that has successfully resulted in unaffected offspring and ideal cord blood stem cell donors for transplantation of an affected sibling.

Dyskeratosis Congenita

Dyskeratosis congenita should be considered in any aplastic adult of any age with a family member who has had aplastic anemia. It should likewise be considered if either the patient or a family member has had acute myelogenous leukemia, myelodysplasia, nail dystrophy, lacy skin pigmentation, pulmonary fibrosis, oral leukoplakia, squamous cell carcinoma at an unusually young age, or any other physical finding listed in Table 165-3. This disease can be frequently ruled out by quantifying the length of telomeres in circulating white cells by a flow cytometric method. Because some of the physical findings overlap, FA should be ruled out in all patients being evaluated for dyskeratosis congenita. The dyskeratosis test quantifies telomere length with fluorescence in situ hybridization. Lymphocytes from dyskeratosis patients have extremely short telomeres (i.e., at or less than the first percentile). If two or three leukocyte types from a given patient are above the first percentile, the diagnosis of dyskeratosis is unlikely. If telomeres are in the diagnostic range, genetic testing is warranted. It is not yet known whether this test will become a "gold standard" test as reliable as the chromosomal breakage test is for FA because some investigators report that very short telomeres can be found in patients who have other causes of bone marrow failure. Unlike the genetic strategy employed with FA (at least today), complementation analyses are not routinely performed in dyskeratosis. The molecular diagnosis is based on gene sequencing. Once the diagnosis is made and even before the establishment of a molecular genetic diagnosis (see Table 165-3), all immediate family members of the patient should be seen individually, their history taken, and their physical examination performed along with peripheral blood counts and telomere length analysis.

Diamond-Blackfan Anemia

Diamond-Blackfan anemia is an inherited bone marrow failure syndrome that more often exhibits selective erythroid failure and is therefore an unusual cause of full-blown severe aplastic anemia. Although some patients can present in adulthood, most are discovered within the first year of life and present with anemia but less commonly neutropenia and thrombocytopenia. Phenotypic abnormalities like short stature and skeletal defects are the exception in this disease. Caused by mutations in one of at least 10 ribosomal proteins, there are no simple screening tests as reliable as those used for FA and dyskeratosis congenita. However, in patients with unexplained erythroid failure, the finding of an elevated adenosine deaminase level in the serum, although unexplained, is strongly suggestive of this disease, and genetic diagnosis should be considered. Because no validated screening test exists yet, there are no reliable or standardized complementation tests, and genetic diagnosis requires the application of gene sequencing methods (see Table 165-3).

Other Diagnostic Considerations

Aplastic anemia has been reported in recipients of organ allografts, in which mismatched T cells (either from the donated graft or from blood products that had not been irradiated) induce severe aplasia; in patients with myelodysplasia (Chapter 182); in patients with congenital and acquired immunodeficiency states (Chapter 250); and in patients with established autoimmune diseases including systemic lupus erythematosus (Chapter 266) and eosinophilic fasciitis[10] (Chapter 440), a disease characterized by painful swelling of the skin and subcutaneous tissue.

TREATMENT Rx

For patients with milder forms of aplastic anemia, aggressive therapy may not be indicated. A passive approach is more problematic in patients with FA and dyskeratosis congenita because transplantation early in life is better tolerated, immunosuppressive therapy is ineffective, and stem cell transplantation provides the only hope for cure of bone marrow failure. If there is evidence of an underlying autoimmune-mediated disease (e.g., isolated granulopoietic or erythroid failure in patients with rheumatic diseases or thymoma), immunosuppressive therapy alone is often highly effective. In fact, for severe aplastic anemia, immunosuppressive therapy either alone or associated with stem cell transplantation is required. Hematopoietic growth factors alone have been disappointingly ineffective until recently in studies using eltrombopag, a small-molecule agonist of the thrombopoietin receptor (Chapter 172). In a phase II study (starting with 50 mg daily and increasing as needed to a maximum of 150 mg daily, for a total of 12 weeks), this agent induced responses in at least one cell lineage in 44% of patients with refractory severe aplastic anemia,[11] and some responders have done well for two or more years.[12] Because of the theoretical potential for this agent to enhance clonal evolution, its role in the treatment of patients remains to be elucidated, and there are ongoing clinical trials being conducted to that end. Eltrombopag also can restore trilineage hematopoiesis in a subset of patients who are refractory to immunosuppressive therapy.

Hematopoietic Stem Cell Transplantation: Matched Sibling Donor

For patients with severe aplastic anemia, stem cell transplantation offers the advantages of immunosuppression, an infusion of new "healthy" stem cells, and the expectation that the lymphoid cells that suppressed the marrow in the first place will be replaced by more normal cells that have no myelosuppressive capacity. This expectation is supported by large retrospective studies suggesting that stem cell transplantation is superior to immunosuppressive therapy alone for the treatment of severe aplastic anemia, especially in patients younger than 40 years. In the past, this approach was relevant to a minority of patients because only 25 to 30% will have an HLA-matched sibling, but substantial improvements in outcomes for recipients of matched unrelated stem cell transplants have made such stem cell sources reasonable to consider, particularly in patients who have failed to respond to immunosuppressive therapy.[13] No perfectly designed study comparing "front-end" immunosuppressive therapy with stem cell transplantation has been conducted, so patients need to be clearly informed about the risks and benefits of each approach. For patients considering transplantation as a first-line therapy, the unique risks of early treatment-related mortality and later risk of GVHD should be reviewed (Chapter 178). Patients considering immunosuppressive therapy without transplant should be aware of the risks of recurrence and late life-threatening clonal evolution to myelodysplasia or acute leukemia.

Unless the donor is a twin (in which case, peripheral blood–derived stem cells may be preferable[14]), stem cells derived from the bone marrow, not the peripheral blood, should be the source of donor cells.[15] Studies testing the comparative effectiveness of peripheral blood as a source of stem cells have reported that the peripheral blood source is associated with excess mortality stemming from an increased incidence of chronic GVHD. The recipient (in whom congenital marrow failure syndromes have been ruled out) initially receives high-dose cyclophosphamide with either horse antithymocyte

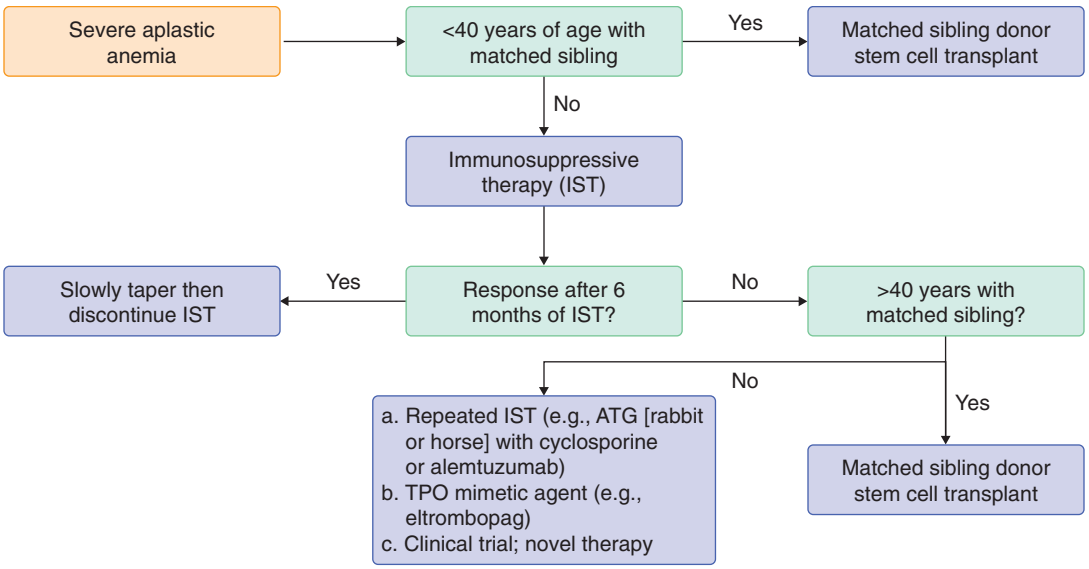

FIGURE 165-3. A therapeutic approach to management of severe aplastic anemia. There are no published results that clarify whether first-line therapy with immunosuppressive therapy (IST) alone is inferior to stem cell transplantation for patients with aplastic anemia. One accepted approach[18] takes into account the high incidence of complications in older patients receiving transplants and suggests matched sibling donor stem cell transplants for any patient younger than 40 years. The remainder receive IST. Because remissions can occur late, 6 months of therapy is required. If there is no response in a patient older than 40 years who also has a matched sibling, stem cell transplantation can be considered at that time. For those without a matched donor, reasonable alternatives are repeated IST, eltrombopag, and enrollment in a clinical trial of novel therapy. A similar approach focusing on the patient's age as a key element in the decision tree is outlined in Table 165-4. ATG = antithymocyte globulin; TPO = thrombopoietin.

globulin (ATG) or alemtuzumab[16,17] as the preparative regimen. Immunosuppressive therapy begins 2 to 4 days before infusion of stem cells. Common post-transplantation immunosuppression combines cyclosporine and methotrexate. The complication of graft failure with this approach is infrequently seen (<5%), grades II to IV acute GVHD is seen in 30 to 50% of recipients, 25% have chronic GVHD, and short-term (2-year) survival after transplantation is nearly 90%. Ten-year survival rates are highly age dependent: 83%, 73%, and 68% for recipients in the first, second, and third decades of life, respectively. In patients 40 years of age or older, the 10-year survival rate is only 51%. Treatment choices adjusted for age of the patient are presented in Table 165-4.

Hematopoietic Stem Cell Transplantation: Matched Unrelated Donor

The use of bone marrow from an HLA-matched unrelated donor should be considered for patients who have no HLA-identical siblings, have failed to respond to immunosuppressive therapy, and are refractory to transfused platelets. As it is with matched related donors, the use of peripheral blood–derived stem cells is associated with higher mortality than is seen with marrow-derived stem cells. Results have not been as favorable as those associated with the use of marrow from HLA-identical siblings, but this strategy has improved in the past decade in part because of more accurate selection of HLA-matched donors and in part because of adjustments made with pretransplantation conditioning regimens. In fact, in some pediatric populations, some centers are now reporting identical outcomes in children transplanted with marrow cells from HLA-matched related and matched unrelated donors. Conditioning regimens that exclude ATG are associated with inferior outcomes, and less toxic conditioning regimens appear to have improved survival (65% for patients older than 16 years and 75% for those 16 years of age or younger). The improvements have been encouraging enough to recommend strongly that unrelated donor searches be initiated at the time of diagnosis for any patient younger than 30 years. Adults older than 30 years should be considered candidates for alternative donor stem cell transplantation if two attempts at immunosuppressive therapy have failed because newer fludarabine-based conditioning regimens have improved outcomes of matched unrelated donor transplants substantially.

Immunosuppressive Therapy

Treatment with ATG alone prolongs survival compared with supportive care alone, and for patients with mild aplastic anemia (not severe), either no treatment or ATG alone is sufficient. In patients with severe aplastic anemia, however, the combination of ATG and cyclosporine is superior to treatment with ATG alone.[16] The combination reduces mortality and induces more rapid and higher overall response rates than does ATG as a single agent. Doses vary from center to center, but ATG is given at doses of 12 to 40 mg/kg/day for 4 to 5 days, and cyclosporine doses of 5 to 10 mg/kg/day (targeting blood levels of 150 to 250 ng/mL) are prescribed for 6 months, after which cyclosporine is slowly tapered during a period of 1 year or more. The median time to response is 120 days. Complete responses are defined as the resolution of pancytopenia and the development of normal blood counts. Relapses are uncommon in complete responders (10%). Partial responders are those whose counts do not normalize but who no longer require transfusion support. Forty percent to 60% of these patients will relapse in 5 years, but most will respond to a repeated course of immunosuppressive therapy. Some will require chronic immunosuppressive therapy with cyclosporine to remain transfusion independent. Those with unresponsive relapses have a poor prognosis. The humanized anti-CD52 monoclonal antibody alemtuzumab is also effective in severe acquired aplastic anemia, although best results are obtained in the relapsed and refractory settings. Its activity has been attributed to its lymphocytotoxic properties. In a conditioning regimen in transplantation trials, it has reduced the incidence of chronic GVHD, so its use is increasing in practice both for immunosuppressive therapy alone and for stem cell transplantation.

All age groups can benefit from immunosuppressive therapy. Long-term survival rates do vary with the age of the treated population. In patients younger than 20 years, 10-year survival rates are 80%, but these rates progressively decline to 25% in patients older than 70 years. However, when adjusted for the survival of an age-matched population by the standardized mortality ratio, the corrected risk for death is highest in young patients and declines as age increases. Advanced age is not a contraindication to the prescription of immunosuppressive therapy.

There are some caveats of importance related to the use of immunosuppressive therapy in aplastic anemia patients. First, patients may experience allergic reactions during infusions of ATG. This should not necessarily dissuade one from continuing this agent. Slowing the infusion after premedication with glucocorticosteroids and antihistamines often solves this problem. Fever and rigor can be signs of cytokine release from damaged cells in the T-cell pool, so they likewise should not be used as a reason to stop treatment. Second, if a responsive patient later relapses, a second course of ATG is frequently effective and can be used, although alemtuzumab is effective in relapsing patients as well. Third, it seems clear that a long interval between diagnosis of aplastic anemia and the initiation of immunosuppressive therapy is a negative predictor of response. Treatment should begin as soon as possible, certainly within 3 weeks of initial diagnosis. Fourth, the inclusion of hematopoietic growth factors during immunosuppressive therapy provides no benefit.

An approach to the management of severe aplastic anemia is shown in Figure 165-3, which complements Table 165-4.

Diamond-Blackfan Anemia

Although the mechanism by which glucocorticosteroids induce remissions in patients with Diamond-Blackfan anemia is unknown, nearly 80% of patients initially respond. Prednisone treatment is started at 2 mg/kg/day and is tapered after the hemoglobin increases to 10 g/dL. Most patients require a low every-other-day dose, but 15% remain in remission off steroids altogether. In those cases, survival to 40 years of age is nearly universal. Of patients who require ongoing steroid support, 75% reach the age of 40 years. Only half of the patients with steroid-resistant severe anemia survive to the age of 40 years. Pure red cell aplasia may respond to a synthetic erythropoietin receptor agonist.

Supportive Care

Platelet Transfusions

In the absence of bleeding or infection, platelet transfusions are commonly administered only when the platelet count declines to 10,000/mL or less (Chapters 172 and 177), but in the presence of active infection or bleeding, transfusion thresholds are often set at 20,000/mL or higher. If bleeding and infection coexist, it is prudent to rule out disseminated intravascular coagulation because fresh-frozen plasma or cryoprecipitate may be required along with platelet transfusions. Drugs (e.g., aspirin) that inhibit platelet function should be avoided, as should activities that might result in trauma. Menstrual activity should be suppressed with oral contraceptives or other agents.

Red Cell Transfusions

Filtered packed red blood cells should be provided to meet the needs of the patient's daily activities. Because there is substantial interindividual variation and because comorbidities influence exercise tolerance, there can be no firmly established hemoglobin target number for everyone. As a general rule, however, the number is higher in elderly patients than in young patients. Children with hemoglobin levels as low as 6 g/dL can compensate reasonably. Adults with underlying cardiopulmonary disease may have symptomatic anemia at 8 g/dL. If chronic transfusion therapy is required, the development of iron overload may require chelation therapy.

Management of Infections

The major infectious challenges result from the immunosuppression used (either as primary therapy or as a component of a stem cell transplantation regimen) more than from the neutropenia. For that reason, antibacterial, antiviral, and antifungal prophylaxis is routinely used in transplant recipients. In many centers, patients treated with immunosuppressive therapy alone are treated similarly for a 2- to 3-month period after ATG administration. Importantly, the onset of fever requires prompt clinical evaluation and antibiotic therapy as described in Chapter 281.

PREVENTION

Apart from public health measures controlling exposures to benzene, aromatic hydrocarbons, and radiation, little can be done to prevent acquired aplastic anemia. In the inherited bone marrow failure syndromes, prevention is achievable. Once the proband is identified, other affected family members, carriers, and siblings with no mutant allele can be identified, and genetic results can be applied in family planning even to the extent of preimplantation genetic diagnosis followed by in vitro fertilization. Because all somatic cells of children and adults with FA are hypersensitive to alkylating agents and oxidative stress, they must not receive standard doses of radiation or alkylating agents either for transplant conditioning or for treatment of squamous cell carcinoma.

Clonal evolution (e.g., to myelodysplasia and acute leukemia) occurs in 10 to 20% of patients with acquired aplastic anemia and up to 40% of children and adults with dyskeratosis congenita and FA. This complication likely evolves through a process of clonal selection and adaptation and for that reason is seen less commonly in patients completely responsive to treatment than in those with less than complete responses (who therefore have ongoing suppression of hematopoiesis). This suggests that more effective strategies of immunosuppressive therapy may better control ongoing marrow damage and decrease the incidence of clonal evolution.

PROGNOSIS

Acquired Idiopathic Aplastic Anemia

The severity of aplastic anemia and age are key determinants of long-term survival. Both these factors influence the choice of therapy (see Table 165-4). Early intervention is associated with a better prognosis, which should dictate the pace of diagnostic evaluation. Matched sibling donor transplants are associated with higher response rates, lower relapse rates, long-term survival rates approximating 80%, and lower incidence of clonal evolution. Immunosuppressive therapy is associated with long-term (10-year) survival rates of 70 to 75% in responders. Infection represents the most common cause of death in patients of any age treated with either immunosuppression alone or stem cell transplantation. Somatic mutations can identify patients with markedly increased risks of progressing to a myelodysplastic syndrome.[19]

Inherited Bone Marrow Failure Syndromes

Patients with dyskeratosis congenita and FA will not respond to immunosuppressive therapy. Stem cell transplantation with nonmyeloablative approaches has the potential of curing the marrow failure component of these diseases but does nothing to reduce the other common life-threatening complication of squamous cell carcinoma. There are good theoretical reasons for anticipating that successful transplantation will reduce the likelihood of clonal evolution to myelodysplasia and acute leukemia. Unfortunately, the decision to transplant is influenced by other key factors, as described earlier. In light of these complexities, no clear-cut when-to-transplant rule can be applied to all patients with these diseases, but it is generally accepted that transplantation early in childhood is associated with fewer short- and long-term complications. Taking these difficult issues into account, all patients should be evaluated early in an experienced transplantation center, and family members should be screened by hematologists, geneticists, and genetic counselors with use of specialty laboratories.

In patients with dyskeratosis, small case series report good outcomes after fludarabine-containing nonmyeloablative conditioning regimens, but studies of sufficient size are not available to permit concrete recommendations except that patients should be referred to an experienced center in light of the other organ systems at risk (e.g., lung). In patients with FA, with proper conditioning regimens, matched sibling donor transplant recipients have expected 3-year survival rates of about 85%, and matched unrelated recipients (when fludarabine-containing nonmyeloablative approaches are used) have 3-year survival rates of 50%. In patients with Diamond-Blackfan anemia, sibling donor transplant recipients have 3-year survival rates of about 80%, but disease-free survival rates after matched unrelated donor transplants have been poor (20 to 30%).

Future Treatments

For patients with acquired aplastic anemia, studies designed to selectively target the T-cell clones responsible for hematopoietic suppression may provide more effective and less toxic strategies for immunosuppressive therapy. For all patients with aplastic anemia, further improvements in matched unrelated transplantation should make this modality more widely available for patients who are not now considered optimal candidates. GVHD control will continue to improve. For children with nonsevere aplastic anemia, the 10-year progression-free survival rate is only about 25%, suggesting that prospective trials of early intervention are warranted. For patients with inherited bone marrow failure syndromes, the genes for which have been largely identified, the possibility of stem cell gene therapy holds enormous theoretical promise and has been nicely validated in murine models of the disease.

REVIEW QUESTIONS

1. A 20-year-old man with severe aplastic anemia is diagnosed by chromosomal breakage testing to have Fanconi anemia. Which of the following would be the preferred first-line treatment?

A. Antithymocyte globulin (ATG)
B. Bone marrow transplant from a matched related donor after fludarabine-based conditioning
C. Cord blood hematopoietic stem cell transplant after conditioning that includes irradiation
D. Supportive therapy with erythropoiesis-stimulating agents (ESAs) and granulocyte colony-stimulating factor (G-CSF)
E. Cyclosporine

Answer: B None of these is an entirely satisfactory first-line therapy for aplastic anemia caused by an inherited bone marrow failure syndrome (Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan anemia), as in this case. These patients do not respond to ATG and other immunosuppressive therapies (including cyclosporine). Growth factors like ESAs and G-CSF are generally ineffective in severe aplastic anemia. Hematopoietic stem cell transplantation (HSCT) that includes irradiation in the conditioning regimen exposes the patient to an additional risk factor interacting with the main underlying biologic defect of Fanconi anemia, the DNA repair process. The use of specifically bone marrow as the source of HSCT and reduced-intensity conditioning regimens with fludarabine appear to have the most favorable outcome at this point, although it will not reduce the subsequent risk of a second malignant neoplasm. (Peffault de Latour R, Porcher R, Dalle JH, et al. Allogeneic hematopoietic stem cell transplantation in Fanconi anemia: the European Group for Blood and Marrow Transplantation experience. Blood. 2013;122:4279-4286).

2. Which of the following statements is not correct regarding inherited bone marrow failure syndromes?

A. Most of the known genes inactivated in Fanconi anemia encode proteins that protect the genome from excessive damage induced by chemical cross-linking agents.
B. Most of the known genes inactivated in dyskeratosis congenita encode proteins that participate in the maintenance of telomeres.
C. Most of the known genes inactivated in Diamond-Blackfan anemia encode ribosomal proteins.
D. The best screening test for Diamond-Blackfan anemia is the chromosomal breakage test.
E. The best screening test for dyskeratosis congenita is quantitative analysis of telomere length (flow-FISH) in lymphocytes.

Answer: D Gene mutations for these three syndromes mostly involve inactivations of specific genes that encode the key proteins involved in their molecular pathogenesis, respectively, as correctly indicated in choices A to C. These also form the basis of screening tests for Fanconi anemia and dyskeratosis congenita; however, there are no adequate screening tests for Diamond-Blackfan anemia. (For Diamond-Blackfan anemia, serum adenosine deaminase is often elevated, but this does not represent a screening test.) Gene sequencing can provide specific mutation analysis for all three of these syndromes, when needed.

3. In a patient with pancytopenia, which of the following abnormalities in the peripheral blood smear would provide a useful indicator that the cause of the pancytopenia is aplastic anemia?

A. Hypersegmented polymorphonuclear leukocytes
B. Nucleated red cells
C. Teardrop-shaped red cells
D. Giant platelets
E. None of the above

Answer: E The peripheral blood smear in aplastic anemia is generally normal, even in severe cases. This does not mean that the peripheral blood smear does not provide useful information about the etiology of pancytopenia in many cases. For example, hypersegmented polymorphonuclear leukocytes (A) suggest megaloblastic anemia (which in more advanced stages can cause pancytopenia, not just anemia). Nucleated (B) and teardrop-shaped (C) red cells suggest a "myelophthisic" process that involves invasion of the bone marrow by "foreign" elements (like metastatic cancer, fibrosis, or granulomas).

POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

AYALEW TEFFERI

DEFINITION

Polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF) belong to the category of myeloproliferative neoplasms (MPNs), under the 2008 World Health Organization (WHO) classification system for hematologic malignancies (Table 166-1). These disorders represent stem cell–derived clonal myeloproliferation with a propensity to evolve into acute myeloid leukemia (AML), also called blast-phase MPN. PV, ET, and PMF, together with chronic myelogenous leukemia (CML), used to be

TABLE 166-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELOID MALIGNANCIES

     - 4.4.1. Provisional entity: refractory anemia with ring sideroblasts associated with marked thrombocytosis (RARS-T)
5. Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*,‡ *PDGFRB*,‡ or *FGFR1*‡ (Chapter 170)
   - 5.1. Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement
   - 5.2. Myeloid neoplasms with *PDGFRB* rearrangement
   - 5.3. Myeloid and lymphoid neoplasms with *FGFR1* abnormalities

*Acute myeloid leukemia–related precursor neoplasms include "therapy-related myelodysplastic syndrome" and "myeloid sarcoma."
†Either mono- or bicytopenia: hemoglobin level <10 g/dL, absolute neutrophil count $<1.8 \times 10^9$/L, or platelet count $<100 \times 10^9$/L. However, higher blood counts do not exclude the diagnosis in the presence of unequivocal histologic or cytogenetic evidence for myelodysplastic syndrome.
‡Genetic rearrangements involving platelet-derived growth factor receptor α/β (*PDGFRA*/*PDGFRB*) or fibroblast growth factor receptor 1 (*FGFR1*).

referred to as "myeloproliferative disorders." Because CML is invariably linked to the Philadelphia translocation (i.e., *BCR-ABL1*), the other three are operationally labeled "*BCR-ABL1*–negative MPN."

EPIDEMIOLOGY

According to a recent systematic review, reported annual incidence rates ranged from 0.01 to 2.61, 0.21 to 2.27, and 0.22 to 0.99 per 100,000 for PV, ET, and PMF, respectively.[1] The combined annual incidence rates for PV, ET, and PMF are 0.84, 1.03, and 0.47 per 100,000, respectively. Population-based studies suggest a median age at diagnosis of approximately 71 years when all three MPN variants are considered together and a male-to-female ratio of approximately 50%. Other studies indicate a lower age distribution for ET and a slight male preponderance for PMF. Family studies suggest a five- to sevenfold increased risk of MPN among first-degree relatives of patients with *BCR-ABL1*–negative MPN and the possibility of a hereditary component to disease susceptibility was further elaborated by *JAK2* haplotype studies. PMF has been associated with exposure to ionizing radiation (e.g., in Hiroshima survivors), heavy exposure to petroleum derivatives, and thorium dioxide (Thorotrast) contrast medium, but in the vast majority of cases, there is no such exposure history.

PATHOBIOLOGY

These diseases are clonal in nature, deriving from a genetically transformed hematopoietic, bone marrow stem cell that results in clonal myeloproliferation. In 2005, a *JAK2* gain-of-function mutation (*JAK2*V617F) was reported in *BCR-ABL1*–negative MPN. Subsequent studies using sensitive assays have revealed the presence of this mutation in approximately 95% of patients with PV and 60% of those with ET or PMF. Most of the remaining 5% of patients with PV carry another *JAK2* mutation (*JAK2* exon 12). In other words, virtually all patients with PV carry a *JAK2* mutation. Approximately 5% to 10% of *JAK2*V617F-negative patients with ET or PMF carry a *MPL*W515 mutation, which is equally JAK-STAT relevant (Table 166-2). In 2013, calreticulin (*CALR*) mutations were discovered in the majority of patients with ET or PMF who do not express *JAK2* or *MPL* mutations.[2] *CALR* mutations are relatively specific to ET and PMF and display mutational frequencies of approximately 20% and 25%, respectively. Additional mutations seen in MPN are listed in Table 166-2. Most of these latter mutations originate at the progenitor cell level, but they do not necessarily represent the primary clonogenic event, are not mutually exclusive, or follow a predictable hierarchy.

The above-listed molecular alterations in *BCR-ABL1*–negative MPN induce biologic changes that are demonstrated in animal models or ex vivo. For example, *JAK2* or *MPL* mutations induce PV-, ET-, or PMF-like disease in mice by experimental manipulation of mutant allele burden. These mutations are also believed to contribute to the growth factor independence or hypersensitivity of erythroid or megakaryocyte colony-forming progenitor cells. Bone marrow fibrosis, osteosclerosis, and angiogenesis in PMF are currently believed to be reactive and cytokine mediated.

FIGURE 166-1. Erythromelalgia: painful red discoloration of the hands or, more commonly, the toes.

CLINICAL MANIFESTATIONS

Essential Thrombocythemia

At presentation, microvascular and vasomotor symptoms are found in 25% to 50% of ET patients. Major thrombosis is seen in 11% to 25% of patients at diagnosis and 10% to 22% during follow-up, and major hemorrhage is observed in 2% to 5% at diagnosis and 1% to 7% during follow-up. Vasomotor disturbances (e.g., headaches, lightheadedness, visual symptoms such as blurring and scotomata, palpitations, chest pain, erythromelalgia, and distal paresthesias) are not infrequent in ET and might be the result of abnormal platelet–endothelium interactions. Erythromelalgia (Fig. 166-1) is the most dramatic vasomotor symptom, characterized by erythema, warmth, and pain in the distal extremities; this symptom is rare but not entirely specific for ET. Life-threatening complications of ET include large-vessel thrombosis (both arterial and venous), hemorrhage, and transformation of the disease into either a fibrotic phase resembling PMF or AML. Venous thrombosis in ET occurs both in sites common to other thrombotic diatheses (e.g., pulmonary embolism and lower extremity deep vein thrombosis and pulmonary embolism) but also in more unusual sites (e.g., cerebral sinus thrombosis, retinal vein thrombosis, and hepatic and portal vein thrombosis).

Major hemorrhage in ET is most common in the gastrointestinal (GI) tract and may be precipitated by aspirin (ASA) or nonsteroidal antiinflammatory drug (NSAID) use. Hemorrhage also occurs in the central nervous system (CNS) and the retina, but such events are, fortunately, uncommon. Paradoxically, patients with extreme thrombocytosis may be at special risk for bleeding, in part related to the development of an acquired von Willebrand syndrome that is thought to be related to platelet adsorption of large multimers of von Willebrand protein (Chapter 173). Fibrotic and leukemic transformations of ET are rare events (<5% of patients) during the first 10 years after diagnosis, but the risk increases with time.

TABLE 166-2 SOMATIC MUTATIONS IN *BCR-ABL1*–NEGATIVE MYELOPROLIFERATIVE NEOPLASMS (MPN), INCLUDING POLYCYTHEMIA VERA (PV), ESSENTIAL THROMBOCYTHEMIA (ET), AND PRIMARY MYELOFIBROSIS (PMF). MUTATIONAL FREQUENCIES IN BLAST PHASE (BP) DISEASE ARE ALSO PROVIDED*

MUTATIONS	CHROMOSOME LOCATION	MUTATIONAL FREQUENCY	PATHOGENETIC RELEVANCE
JAK2 (Janus kinase 2): *V617F*	9p24	PV: ~96% ET:~55% PMF: ~65%	Contributes to abnormal myeloproliferation and progenitor cell growth factor hypersensitivity
JAK2 exon 12 mutation	9p24	PV: ~3%	Contributes to primarily erythroid myeloproliferation
CALR (Calreticulin): exon 9 deletions and insertions	19p13.2	PMF: ~25% ET: ~20% PV: 0%	Wild-type *CALR* is a multifunctional Ca^{2+} binding protein chaperone mostly localized in the endoplasmic reticulum
MPL (myeloproliferative leukemia virus oncogene): MPN-associated *MPL* mutations involve exon 10	1p34	ET:~3% PMF: ~10%	Contributes to primarily megakaryocytic myeloproliferation
LNK (as in links), or *SH2B3* (a membrane-bound adaptor protein): MPN-associated mutations are monoallelic and involve exon 2	12q24.12	PV: rare ET: rare PMF: rare BP-MPN: ~10%	Wild-type *LNK* is a negative regulator of JAK2 signaling.
TET2 (TET oncogene family member 2): mutations involve several exons	4q24	PV: ~16% ET: ~5% PMF: ~17% BP-MPN: ~17%	TET proteins catalyze conversion of 5mC to 5hmC, which favors demethylated DNA. Both TET1 and TET2 display this catalytic activity. *IDH* and *TET2* mutations might share a common pathogenetic effect.
ASXL1 (additional sex combs-like 1): exon 12 mutations	20q11.1	ET: ~3% PMF: ~13% BP-MPN: ~18%	Wild-type *ASXL1* is needed for normal hematopoiesis and might be involved in coactivation of transcription factors and transcriptional repression.
IDH1/IDH2 (isocitrate dehydrogenase): exon 4 mutations	2q33.3/15q26.1	PV: ~2% ET: ~1% PMF: ~4% BP-MPN: ~20%	*IDH* mutations induce loss of activity for the conversion of isocitrate to 2-KG and gain of function in the conversion of 2-KG to 2-HG. 2-HG might be the mediator of impaired TET2 function in cells with mutant *IDH* expression.
EZH2 (enhancer of zeste homolog 2): mutations involve several exons	7q36.1	PV: ~3% PMF: ~7% MDS: ~6%	Wild-type *EZH2* is part of a histone methyltransferase (polycomb repressive complex 2 associated with H3 Lys-27 trimethylation). MPN-associated *EZH2* mutations might have a tumor suppressor activity, which contrasts with the gain-of-function activity for lymphoma-associated *EZH2* mutations.
DNMT3A (DNA cytosine methyltransferase 3a): most frequent mutations affect amino acid R882	2p23	PV: ~7% PMF: ~7% BP-MPN: ~14%	DNA methyl transferases are essential In establishing and maintaining DNA methylation patterns in mammals
CBL (Casitas B-lineage lymphoma proto-oncogene): exon 8/9 mutations	11q23.3	PV: rare ET:rare MF: ~6%	CBL is an E3 ubiquitin ligase that marks mutant kinases for degradation. Transforming activity requires loss of this function.
IKZF1 (IKAROS family zinc finger 1): mostly deletions including intragenic	7p12	CP-MPN: rare BP-MPN: ~19%	IKZF1 is a transcription regulator and putative tumor suppressor
TP53 (tumor protein p53): exons 4 through 9	17p13.1	PMF: ~4% BP-MPN ~27%	A tumor suppressor protein that targets genes that regulate cell cycle arrest, apoptosis, and DNA repair
SF3B1 (splicing factor 3B subunit 1): mostly exons 14 and 15	2q33.1	PMF: ~7%	SF3B1 is a component of the RNA spliceosome. *SF3B1* mutations are closely associated with ring sideroblasts.
SRSF2 (serine/arginine-rich splicing factor 2): exon 2	17q25.1	PMF: ~17%	SRSF2 is a component of the RNA spliceosome, whose dysfunction promotes defects in alternative splicing.
U2AF1 (U2 small nuclear RNA auxiliary factor 1)	21q22.3	PMF: ~16%	U2AF1 is a subunit of the U2 small nuclear ribonucleoprotein auxiliary factor involved in pre-mRNA processing

*See text for references.
BP-MPN = blast phase MPN; CP-MPN= chronic phase MPN; ET = essential thrombocythemia; 5hmC = 5-hydroxymethylcytosine; 5mC = 5-methylcytosine; MF includes both PMF and post-ET/PV myelofibrosis; MPN = myeloproliferative neoplasms; PMF = primary myelofibrosis; PV = polycythemia vera; 2-KG = 2-ketoglutarate; 2-HG = 2-hydroxyglutarate.

Polycythemia Vera

Table 166-3 lists the typical clinical and laboratory features of PV. Increased red blood cell (RBC) mass in PV might result in blood hyperviscosity, which leads to a plethora of symptoms and signs. Headaches are frequent, but blurry vision, altered hearing, mucous membrane bleeding, shortness of breath, and malaise are also observed. At least two thirds of PV patients have splenomegaly. Thrombosis occurs, most commonly arterial thrombosis, in about 40% of patients. As in ET, venous thrombosis can occur in unusual sites, such as mesenteric, portal, or hepatic veins (the latter also being called Budd-Chiari syndrome). Bleeding, especially from the GI tract, is seen in PV but less often than thrombosis. Pruritus is common in PV and may be provoked by warm water ("aquagenic"). Erythromelalgia (described earlier under ET) might also trouble some patients with PV, as do other vasomotor symptoms, such as paresthesias and headaches.

TABLE 166-3 CLINICAL AND LABORATORY FEATURES OF POLYCYTHEMIA VERA

Persistent leukocytosis
Persistent thrombocytosis
Microcytosis secondary to iron deficiency
Increased red blood cell mass
JAK2 mutations
Increased leukocyte alkaline phosphatase
Splenomegaly
Generalized pruritus (usually after bathing)
Arterial and venous thrombosis, including unusual thrombosis (e.g., Budd-Chiari syndrome)
Erythromelalgia (acral dysesthesia and erythema; see Fig. 166-1)

Primary Myelofibrosis

Most patients with PMF present with anemia and marked splenomegaly. The anemia of PMF is multifactorial. Contributing factors include ineffective hematopoiesis and hypersplenism. Spleen and liver enlargement in PMF is secondary to extramedullary hematopoiesis (EMH) and may be associated with hypercatabolic symptoms, including profound fatigue, weight loss, night sweats, and low-grade fever. Patients also experience peripheral edema; diarrhea; early satiety; and, occasionally, complications of portal hypertension, including variceal bleeding and ascites.

Splenomegaly in PMF may be complicated by splenic infarction manifested by left upper quadrant abdominal pain and referred left shoulder pain. CT imaging in such cases can be unremarkable or may show wedge-shaped or rounded low-attenuation lesions in the spleen. EMH occurs in a great diversity of sites throughout the body. Common sites besides the spleen and liver include lymph nodes, skin, pleura, peritoneum, lung, and paraspinal and epidural spaces. The latter may result in spinal cord or nerve root compression, which is a medical emergency requiring corticosteroids to reduce edema and immediate radiotherapy. Other clinical features of PMF include diffuse and sometimes regional bone and joint pain.

DIAGNOSIS

At present, the 2008 WHO criteria are used for the diagnosis of ET, PV, and PMF (Table 166-4). These criteria are based on morphology and cytogenetic and molecular studies (Fig. 166-2). Almost all patients with PV carry a *JAK2* mutation (*JAK2*V617F or *JAK2* exon 12 mutations). *JAK2*V617F is, however, not specific to PV and is also found in ET (~60% of cases), PMF (~60% of cases), and other myeloid neoplasms (usually <5% of cases). *JAK2* exon 12 mutations are relatively specific to *JAK2*V617F-negative PV and occur in approximately 3% of all patients with PV. *JAK2* exon 12 mutation-positive PV patients are characterized by predominantly erythroid myelopoiesis, subnormal serum erythropoietin (Epo) levels, and younger age at diagnosis. Taken together, the presence of a *JAK2* mutation excludes secondary myeloproliferation (e.g., secondary polycythemia or reactive thrombocytosis; see later discussion), and its absence makes a diagnosis of PV very unlikely. Among the 30% to 40% of ET or PMF patients who do not harbor *JAK2* mutations, the majority (60% to 70%) carry *CALR* mutations, and 5% to 10% carry *MPL* mutations. In other words, 80% to 90% of patients with ET or PMF carry one of the three MPN-specific mutations: *JAK2, CALR,* or *MPL*.

As outlined in Figure 166-2, the diagnostic work-up for suspected MPN, including PV, ET, and PMF, should start with peripheral blood mutation screening for *JAK2*V617F.[3] The presence of the mutation confirms the presence of an underlying MPN, but it is not specific to any one of the three MPN variants. In the absence of *JAK2*V617F, the next step is to screen for *JAK2* exon 12 mutation for PV and *CALR* mutations for ET and PMF (see Fig. 166-2). *MPL* mutations are studied only when both *JAK2* and *CALR* mutations are absent in suspected cases of ET or PMF. Bone marrow examination is recommended to confirm the diagnosis in triple-negative cases (i.e., wild type for *JAK2, CALR,* and *MPL*) and to distinguish between ET and prefibrotic PMF. Clinically, patients with ET and PV present with thrombocytosis and erythrocytosis, respectively. Patients with PMF usually present with peripheral blood leukoerythroblastosis (i.e., presence of nucleated RBCs, metamyelocytes, or myelocytes [Fig. 166-3] and bone marrow fibrosis with morphologically atypical megakaryocytes [Fig. 166-4]). Bone marrow morphology can also help distinguish clonal from reactive myeloproliferation (Fig. 166-5).

Table 166-5 includes a comprehensive list of causes of erythrocytosis,[4] including congenital and secondary polycythemia. The diagnostic approach to congenital polycythemia should start with measurement of serum Epo level. The presence of a subnormal serum Epo level, in the absence of PV, suggests the presence of a germline mutation of the erythropoietin receptor. If the serum Epo level is normal or elevated, the next step is to measure the p50 (the oxygen tension at which hemoglobin is 50% saturated). Decreased p50 suggests the presence of either high oxygen-affinity hemoglobinopathy or 2,3-bisphosphoglycerate (2,3-BPG) deficiency. If the p50 is normal, then the possibility of *VHL* mutations (usually associated with increased serum Epo level) should be considered first because they constitute the most frequent mutations in congenital polycythemia. Gene expression studies can identify two different phenotypic expressions of polycythemia vera in terms of disease duration, hemoglobin level, splenomegaly, and the risk of thromboembolism.[5]

Table 166-6 outlines the different causes of thrombocytosis, and Figure 166-5 provides an algorithmic approach to its diagnosis. Figure 166-6 illustrates the value of peripheral blood smear examination in the differential diagnosis of thrombocytosis. Other causes of bone marrow fibrosis are outlined in Table 166-7. The diagnosis of post-PV or post-ET myelofibrosis requires full documentation of a previous morphologic diagnosis of PV or ET, respectively.

TABLE 166-4 THE 2008 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

CRITERIA	POLYCYTHEMIA VERA*	ESSENTIAL THROMBOCYTHEMIA*	PRIMARY MYELOFIBROSIS*
Major criteria	1. Hb >18.5 g/dL (men); >16.5 g/dL (women) *or* Hb/Hct >99th percentile of reference range *or* Hb >17 g/dL (men) or>15 g/dL (women) if associated with a sustained increase of ≥2 g/dL from baseline, not otherwise explained *or* Elevated RBC mass >25% above mean normal predicted value	1. Platelet count ≥450 × 10^9/L	1. Megakaryocyte proliferation and atypia† accompanied by either reticulin or collagen fibrosis *or* In the absence of fibrosis, megakaryocyte changes accompanied by increased marrow cellularity and granulocytic proliferation
	2. Presence of *JAK2*V617F or similar mutation	2. Megakaryocyte proliferation with large and mature morphology; no or little granulocyte or erythroid proliferation	2. Not meeting WHO criteria for CML, PV, MDS, or other myeloid neoplasm
		3. Not meeting WHO criteria for CML, PV, PMF, MDS, or other myeloid neoplasm	3. Demonstration of *JAK2*V617F or other clonal marker *or* No evidence of reactive marrow fibrosis
		4. Demonstration of *JAK2*V617F or other clonal marker *or* No evidence of reactive thrombocytosis	
Minor criteria	1. BM trilineage myeloproliferation 2. Subnormal serum Epo level 3. EEC growth		1. Leukoerythroblastosis 2. Increased serum LDH 3. Anemia 4. Palpable splenomegaly

*Diagnosis of polycythemia vera (PV) requires meeting either both major criteria and one minor criterion or the first major criterion and two minor criteria. Diagnosis of essential thrombocythemia requires meeting all four major criteria. Diagnosis of primary myelofibrosis (PMF) requires meeting all three major criteria and two minor criteria.

†Small to large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic and irregularly folded nuclei and dense clustering.

CML = chronic myelogenous leukemia; EEC = endogenous erythroid colony; Epo = erythropoietin; Hct = hematocrit; Hb = hemoglobin; LDH = lactate dehydrogenase; MDS = myelodysplastic syndrome; RBC = red blood cell; WHO =World Health Organization.

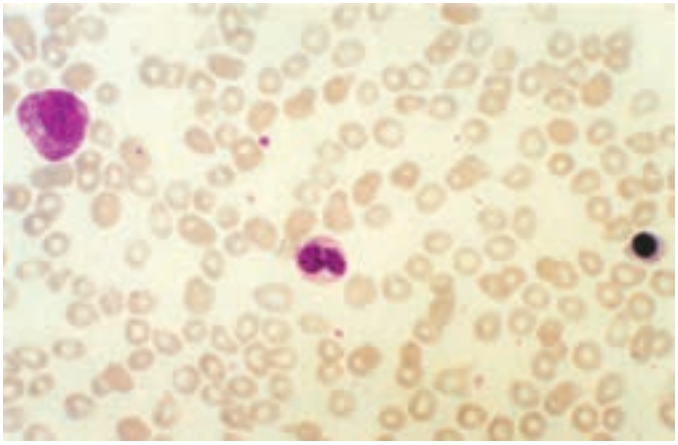

FIGURE 166-3. Myeloproliferative neoplasm. A peripheral blood smear from a patient with agnogenic myeloid metaplasia shows a leukoerythroblastic picture. The characteristic findings are teardrop-shaped red blood cells (dacryocytes), nucleated red blood cells (erythroblasts), and immature granulocyte precursors.

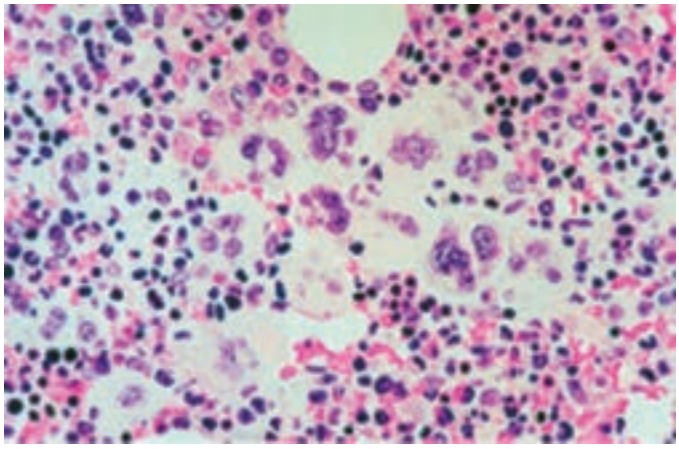

FIGURE 166-5. Myeloproliferative neoplasm. Bone marrow shows megakaryocytic clusters seen in essential thrombocythemia and other conditions associated with clonal thrombocytosis. These are not typically found in the bone marrow of individuals with other (secondary or reactive) types of thrombocytosis.

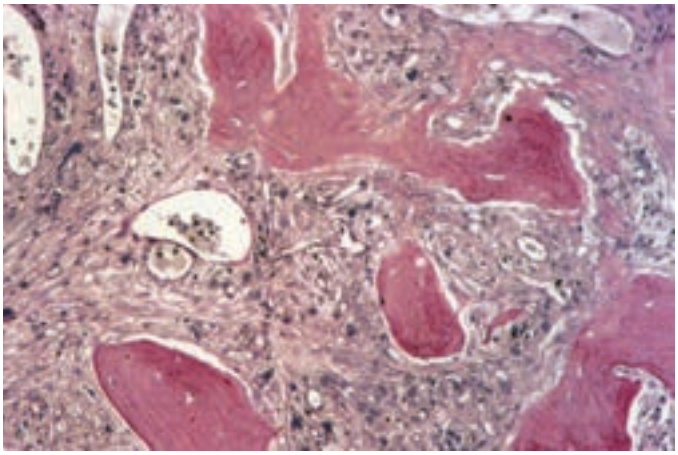

FIGURE 166-4. A bone marrow biopsy specimen from a patient with primary myelofibrosis shows reticulin fibrosis, osteosclerosis, and intrasinusoidal hematopoiesis.

TREATMENT

Essential Thrombocythemia and Polycythemia Vera

Drug therapy in ET or PV has not been shown to either improve survival or prevent disease transformation into post-ET or post-PV MF or blast-phase MPN. Instead, the main objective of specific therapy in ET or PV is either to prevent thrombosis in high-risk patients (i.e., age 60 years or older or presence of thrombosis history) or alleviate non–life-threatening symptoms, including microvascular disturbances (e.g., headaches, acral paresthesia, erythromelalgia), pruritus, or symptomatic splenomegaly. Microvascular symptoms are usually effectively treated with low-dose aspirin (81 mg/day). The cause of MPN-associated pruritus is poorly understood, but its dramatic response to JAK inhibitor therapy (see later discussion) suggests a causal relationship to cytokines that use JAK-STAT signaling. Other therapies for MPN-associated pruritus include antihistamines, selective serotonin reuptake inhibitors, interferon- (INF-α), and phototherapy. Symptomatic splenomegaly is usually managed by treatment with hydroxyurea (starting dose, 500 mg orally twice a day).

Observation alone is acceptable in asymptomatic young ET patients without a history of thrombosis[6]; the presence of microvascular symptoms,

TABLE 166-5 CLASSIFICATION OF ERYTHROCYTOSIS

1. Congenital erythrocytosis
   a. Associated with reduced P50 (partial pressure of oxygen at which 50% of hemoglobin is saturated with oxygen)
      i. High oxygen affinity hemoglobinopathy (usually autosomal dominant)
      ii. 2,3-Bisphosphoglycerate deficiency (usually autosomal recessive)
      iii. Methemoglobinemia
   b. Associated with normal P50
      i. *VHL* mutations, including Chuvash polycythemia (usually autosomal recessive)
      ii. *PHD2* mutations
      iii. *HIF2-α* mutations
      iv. *EPOR* mutations (usually autosomal dominant)
2. Acquired erythrocytosis
   a. Clonal (polycythemia vera)
   b. Secondary
      i. Hypoxia driven
         (1) Chronic lung disease
         (2) Right-to-left cardiopulmonary shunts
         (3) High-altitude habitat
         (4) Tobacco use or carbon monoxide poisoning
         (5) Sleep apnea or hypoventilation syndrome
         (6) Renal artery stenosis
      ii. Hypoxia independent
         (1) Use of androgen preparations or erythropoietin injection
         (2) After renal transplant
         (3) Cerebellar hemangioblastoma or meningioma
         (4) Pheochromocytoma, uterine leiomyoma, renal cysts, or parathyroid adenoma
         (5) Hepatocellular carcinoma or renal cell carcinoma

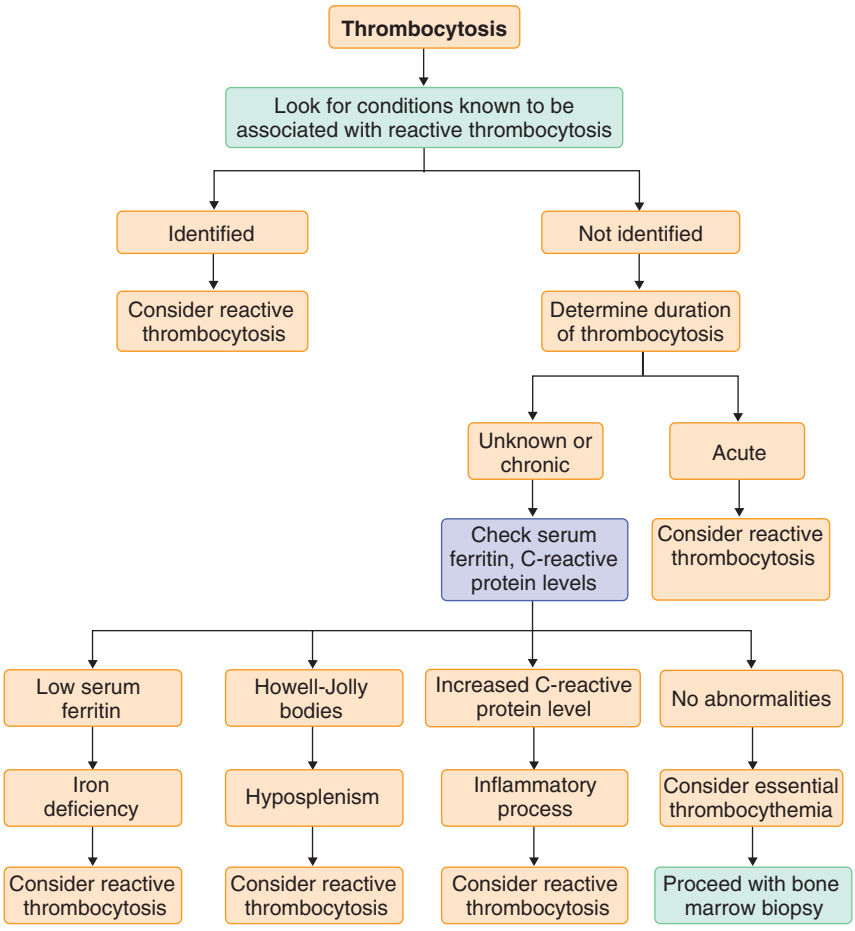

FIGURE 166-6. Diagnostic evaluation of thrombocytosis in routine clinical practice.

cardiovascular risk factors, or the *JAK2*V617F mutation justifies the use of once-daily aspirin therapy. Cytoreductive therapy for the prevention of thrombosis is indicated only in the presence of high-risk disease (Table 166-8). Randomized studies have demonstrated the value of low-dose aspirin (40-100 mg/day) in PV and hydroxyurea (starting dose, 500 mg orally twice a day) or anagrelide (starting at 1 mg daily) in high-risk patients with ET. Based on noncontrolled but prospective evidence, most experts agree that low-dose aspirin therapy (81 mg/day) should also be considered for ET and hydroxyurea therapy for high-risk PV (see Table 166-8). In addition, treatment with phlebotomy is required for all patients with PV, and the target hematocrit count in aspirin-treated patients should be less than 45% based on the most recent information from a controlled study.

In high-risk patients with ET in whom cytoreductive therapy is indicated, a platelet target of less than 400×10^9/L is reasonable and supported by data from retrospective studies. Hydroxyurea remains the first drug of choice for both high-risk ET and PV. High-risk PV or ET patients who are either intolerant or resistant to hydroxyurea are effectively managed by INF-α or busulfan.

Enthusiasm for the use of recombinant IFN in the MPNs was dampened by drug toxicity that often led to its discontinuation. The addition of a polyethylene glycol (PEG) moiety to IFN-α results in a longer half-life, allowing less frequent administration, more drug stability, less immunogenicity, and less toxicity, leading to the increased use of PEG-IFN-α instead of recombinant IFN.

Among the two second-line drugs, this author prefers the use of INF-α for patients younger than age 65 years and busulfan in the older age group. Because the long-term health effects of INF-α and impact on survival and disease complications are unknown, a controlled study is needed before INF-α is recommended for first-line therapy in either PV or ET. Busulfan is started at 4 mg/day orally and withheld in the presence of platelets below 100×10^9/L or white blood cell count below 3×10^9/L, and the dose is reduced to 2 mg/day if the corresponding levels are less than 150×10^9/L and less than 5×10^9/L.

There is unsubstantiated fear among primary caregivers regarding drug leukemogenicity with use of hydroxyurea or busulfan; there are no controlled studies in either PV or ET that shows this to be the case. A recent large retrospective study in PV, involving more than 1500 patients showed no evidence for leukemogenicity attached to either hydroxyurea or busulfan. Pregnancy in ET is associated with increased risk (~35% vs. approximately 15% in the control population) of first trimester spontaneous abortion. There is no association between the increased risk of spontaneous abortion and the degree of thrombocytosis. Low-risk pregnant patients with ET or PV are managed the same way as their nonpregnant counterparts, and the use of low-dose aspirin has been associated with a decreased prevalence of first trimester miscarriages in retrospective studies. High-risk pregnant women with ET (i.e., women with previous thrombosis) require cytoreductive therapy just like other high-risk patients. In such patients, there is anecdotal evidence on the safety of using IFN-α.

Major bleeding occurs in fewer than 10% of ET patients. Extreme thrombocytosis (i.e., platelet count >1 million/μL) appears to be a risk factor for

TABLE 166-8 RISK STRATIFICATION AND RISK-ADAPTED THERAPY IN ESSENTIAL THROMBOCYTHEMIA, POLYCYTHEMIA VERA, AND PRIMARY MYELOFIBROSIS

RISK GROUPS: PV AND ET	MANAGEMENT: ET	MANAGEMENT: PV	MANAGEMENT: PMF	IPSS RISK GROUPS: PMF
Low risk (age <60 yr *and* no thrombosis history)	Low-dose aspirin	Low-dose aspirin + phlebotomy[§]	Observation	Low-risk (no risk factors[¶])
Low risk with extreme thrombocytosis[*]	Low-dose aspirin[†]	Low-dose aspirin[†] + phlebotomy	Conventional management[‖]	Intermediate-1 risk (one risk factor[¶])
High-risk (age ≥60 yr *or* thrombosis history)	Low-dose aspirin + hydroxyurea[‡]	Low-dose aspirin + phlebotomy + hydroxyurea[‡]	Allo-SCT if age <65 yr or experimental therapy Allo-SCT if age <65 years or experimental therapy Allo-SCT if age <65 yr or experimental therapy	Intermediate-1 risk with transfusions or unfavorable karyotype Intermediate-2 risk (2 risk factors[¶]) High-risk (≥3 risk factors[¶])

*Extreme thrombocytosis is defined as a platelet count of $>1000 \times 10^9$/L.
†Clinically significant acquired von Willebrand syndrome (ristocetin co-factor activity <30%) should be excluded before the use of aspirin in patients with extreme thrombocytosis because of bleeding risk.
‡In hydroxyurea-intolerant or -resistant patients, interferon-α (age < 60 years) or busulfan or pipobroman (age older than 60 years) might be used.
§In the presence of aspirin therapy, the hematocrit target can range between 38% and 50% and is set at a level that maintains best performance status.
‖Androgen preparations or thalidomide with prednisone for anemia; hydroxyurea for symptomatic splenomegaly.
¶The International Prognostic Scoring System (IPSS) uses five risk factors for inferior survival: age older than 65 years, hemoglobin <10 g/dL, leukocyte count $>25 \times 10^9$/L, circulating blasts ≥1%, and presence of constitutional symptoms.
Allo-SCT = allogeneic stem cell transplantation; ET = essential thrombocythemia; PMF = primary myelofibrosis; PV = polycythemia vera.

bleeding, in part because of the acquired von Willebrand disease syndrome. Measuring ristocetin cofactor activity in patients with extreme thrombocytosis and holding the use of aspirin therapy if the value is less than 30% have been recommended.

Primary Myelofibrosis

Conventional therapy for PMF is largely palliative and has not been shown to improve survival. Anemia and symptomatic splenomegaly are the main indications for treatment in PMF. Conventional drugs used for the treatment of PMF-associated anemia include androgen preparations (e.g., oral fluoxymesterone 10 mg two times a day), danazol (400-600 mg/day orally), prednisone (30-40 mg/day), and erythropoiesis-stimulating agents (ESAs).[7] The use of ESAs may exacerbate PMF-associated splenomegaly, and it is ineffective in transfusion-dependent patients. Prostate cancer screening in men is necessary when considering treatment with androgen preparations. Response rates to prednisone, androgen preparations, or danazol are in the vicinity of 20% and response durations average about one to two years.

Recent studies have shown the value of thalidomide and thalidomide-like drugs such as lenalidomide in the treatment of anemia in PMF. Thalidomide as a single agent (50-200 mg/day orally) is not as effective as the drug combined with prednisone (30 mg/day) where reported response rates range from 20% to 62% for anemia, 25% to 80% for thrombocytopenia, and 7% to 30% for splenomegaly. Response rates with lenalidomide are somewhat similar, but the drug works best in the presence of del(5q) cytogenetic abnormality (see Chapter 182 on myelodysplastic syndrome.) The occurrence of peripheral neuropathy with thalidomide and severe pancytopenia with lenalidomide therapy has limited their use in most patients with the disease.

The drug of choice for symptomatic splenomegaly in PMF is hydroxyurea (starting dose, 500 mg orally twice a day). Hydroxyurea-refractory cases have been often managed by splenectomy in the past since the value of other conventional drugs in this regard has been limited (see section below on experimental drug therapy). Indications for splenectomy in PMF have included mechanical discomfort, symptomatic portal hypertension (i.e., associated with ascites or variceal bleeding), and frequent RBC transfusions. The perioperative mortality rate of splenectomy in PMF is between 5% and 10%. Postsplenectomy complications occur in approximately 50% of the patients and include bleeding, thrombosis, hepatomegaly, extreme thrombocytosis, leukocytosis, and an increase in circulating blasts. Prophylactic therapy with hydroxyurea has been advised to prevent postsplenectomy thrombocytosis. Transjugular intrahepatic portosystemic shunt might be considered to alleviate symptoms of portal hypertension.

Extramedullary hematopoiesis is the main cause of hepatosplenomegaly in PMF and post-PV or post-ET MF. Nonhepatosplenic EMH also occurs in PMF and might involve the vertebral column (spinal cord compression) lymph nodes, lung (pulmonary hypertension), pleura (effusion), small bowel, peritoneum (ascites), urogenital tract, skin, or heart. Diagnosis is usually tissue based, but imaging studies are sometimes used; MF-associated pulmonary hypertension can be confirmed by a technetium-99m sulphur colloid scintigraphy, which shows diffuse pulmonary uptake.

Radiotherapy has been a treatment option in both hepatosplenic and nonhepatosplenic EMH. Splenic irradiation (100-500 cGy in 5-10 fractions) induces transient reduction in spleen size but might be associated with life-threatening pancytopenia. More recent studies suggest the relative safety and value of lower dose treatment (100 cGy total dose in four daily fractions of 25 cGy). Radiation therapy works best for nonhepatosplenic EMH. Single-fraction (100-400 cGy) involved field therapy has also been shown to benefit patients with MF-associated pulmonary hypertension or extremity pain.

Quality of life–relevant symptoms in MF include profound fatigue, night sweats, weight loss, pruritus, bone pain, and nonproductive cough. Conventional drug therapy is inadequate in the management of these symptoms. Recent studies of JAK inhibitor therapy in PMF or post-PV, or post-ET MF suggest major benefit in terms of constitutional symptoms and cachexia.

Experimental Drug Therapy in Myeloproliferative Neoplasms

JAK-inhibiting ATP mimetics currently represent the most popular investigational drug therapy in MF.[8] Ruxolitinib is now approved by the Food and Drug Administration for use in MF, and momelotinib is currently being compared with ruxolitinib in a randomized phase 3 study. Ruxolitinib is a JAK1/JAK2 inhibitor. Two randomized studies comparing ruxolitinib with either placebo or best supportive care have now been published. In the COMFORT-1 trial that compared the drug with placebo, the spleen size reduction response rate was approximately 42% for ruxolitinib versus less than 1% for placebo. In addition, about 46% of patients experienced substantial improvement in their constitutional symptoms, such as night sweats, pruritus, and fatigue. However, the use of the drug versus placebo was associated with anemia (31% vs. 13.9%) and thrombocytopenia (34.2% vs. 9.3%). The COMFORT-2 trial compared ruxolitinib with "best available therapy." The spleen size reduction response was 28.5% with ruxolitinib versus 0% otherwise, and the use of the drug was associated with thrombocytopenia (44.5% vs. 9.6%), anemia (40.4% vs. 12.3%), and diarrhea (24.0% vs. 11.0%). The long-term outcome of ruxolitinib is associated with high treatment discontinuation rate and the occurrence of severe withdrawal symptoms during ruxolitinib treatment discontinuation ("ruxolitinib withdrawal syndrome"), characterized by acute relapse of disease symptoms, accelerated splenomegaly, worsening of cytopenias, and occasional hemodynamic decompensation. The 3-year follow-up information on COMFORT-2 suggested a 55% drug discontinuation rate and a slight but significant improvement in survival without any evidence of drug effect on *JAK2*V617F allele burden or bone marrow fibrosis. Furthermore, reports have now associated ruxolitinib therapy with serious opportunistic infections.

Momelotinib (MMB, GS-0387, CYT387) is a JAK1 and JAK2 inhibitor. Among the first 60 patients treated in a phase 1 and 2 study,[9] Dose-limiting toxicities included grade 3 headache and hyperlipasemia (elevated lipase). Anemia and spleen responses were 59% and 48%, respectively. Most patients experienced constitutional symptoms improvement. The drug is currently undergoing phase 3 study and being compared with ruxolitinib.There is clearly a need to evaluate more drugs before making any conclusions regarding the value of anti-JAK2 therapy in MF or related MPN. It is also becoming evident that some of the salutary effects of these drugs might be the result of a potent anticytokine activity.

Allogeneic Stem Cell Transplantation

Allogenic stem cell transplant is a reasonable treatment modality in PMF, especially in the presence of high-risk disease.[10] However, there is a nontrivial risk of treatment-associated mortality and morbidity. In one study, for example, 5-year disease-free survival and treatment-related mortality rates were 33% and 35% for matched related and 27% and 50% for unrelated transplants, respectively. The respective chronic graft-versus-host disease and relapse rates for matched related transplants were 40% and 32%, respectively. Outcome did not appear to be favorably affected by reduced intensity conditioning (RIC). In another RIC transplant study, the 5-year disease-free survival rate was estimated at 51%, chronic graft-versus-host disease at 49%, and relapse at 29%. Splenectomy before transplant might not affect outcome. There is currently much interest in evaluating the use of JAK inhibitors before transplant with favorable and unfavorable experiences reported by different investigators, warranting the need for more studies before recommending such a strategy.

PROGNOSIS

Essential Thrombocythemia and Polycythemia Vera

Neither ET nor PV is currently a curable disease, and current therapy has not been shown to prolong survival. In a study of 1545 patients with PV, survival was adversely affected by older age, leukocytosis, abnormal karyotype, and venous thrombosis.[11] The first three also predicted leukemic transformation, which was 2.3% at 10 years and 5.5% at 15 years. Leukemic transformation was associated with treatment exposure to pipobroman or P32/chlorambucil but not to hydroxyurea or busulfan.

In WHO-defined ET, an international study identified age 60 years or older, thrombosis history, cardiovascular risk factors (CVR), leukocyte count greater than $11 \times 10(9)/L$, and the presence of *JAK2*V617F as independent predictors of arterial thrombosis and male gender as a predictor of venous thrombosis.[12] In a subsequent prognostic model,[13] thrombosis risk was lowest in the absence of these risk factors and intermediate or high otherwise. In ET, *CALR* mutations have been correlated with male sex, younger age, lower leukocyte count, lower hemoglobin level, higher platelet count, and longer thrombosis-free survival time.[14] Fibrotic or leukemic transformation in ET or PV is relatively infrequent (a combined rate of <10% in the first 15 years of disease).

Current risk stratification in PV and ET is designed to estimate the risk of thrombosis (see Table 166-8). Age 60 years or older and history of thrombosis are the two key risk factors used to classify patients with PV or ET into low- (no risk factors) and high- (one or two risk factors) risk groups. In addition, because of the potential risk for bleeding, low-risk patients with extreme thrombocytosis (platelet count $>1000 \times 10^9/L$) are considered separately. With the recent discovery of *CALR* mutations and their association with lower risk of thrombosis, the thrombogenic effect of *JAK2*V617F is increasingly being realized. Accordingly, more recent studies have identified the presence of *JAK2*V617F or cardiovascular risk factors as additional risk factors for thrombosis in ET.

Primary Myelofibrosis

The most robust prognostic model for PMF is the Dynamic International Prognostic Scoring System (DIPSS)-plus, which relies on eight adverse

parameters: age older than 65 years, hemoglobin less than 10 g/dL, leukocyte count greater than 25×10^9/L, circulating blasts 1% or greater, constitutional symptoms, unfavorable karyotype, RBC transfusion need, and platelet count less than 100×10^9/L. The four DIPSS-plus risk categories based on these risk factors are low (no risk factors), intermediate-1 (one risk factor), intermediate-2 (two or three risk factors), and high (four or more risk factors), with respective median survival periods of 15.4, 6.5, 2.9, and 1.3 years. More recently, *ASXL1* mutations have been identified as a DIPSS-plus independent risk factor. Furthermore, *CALR* mutations in PMF were associated with younger age; higher platelet count; and lower incidences of anemia, leukocytosis, and spliceosome mutations and longer overall survival time. The best survival in PMK was found in the presence of *CALR* and absence of *ASXL1* mutation (i.e., $CALR^{+}ASXL1^{-}$) and worst survival in patients with $CALR^{-}ASXL1^{+}$ mutational status.[15]

CONCLUDING COMMENTS

Despite the seminal discoveries of *JAK2, MPL,* and *CALR* mutations, the pathogenesis of *BCR-ABL1*–negative MPN remains complex and poorly understood. It is becoming increasingly evident that *JAK2* is not the whole story with these diseases, and we should therefore curb our expectations from anti-JAK2 treatment strategies and instead pay attention to additional pathogenetic insight from correlative laboratory studies. In the end, one must recognize the relatively indolent natural history of ET and PV and avoid unnecessary treatment, especially in low-risk patients. There is currently an unmet need for treatment in PMF, and this is where the real challenge is and where progress is needed. It is hoped that that next-generation sequencing will help identify additional new mutations and prognostically relevant molecular signatures in MPN.

REVIEW QUESTIONS

1. A 65-year-old man with coronary artery disease, hypertension, chronic obstructive pulmonary disease, and an active 40 pack year smoking history is referred by his primary care physician because of gradually increasing hemoglobin and hematocrit over the past 5 years. On physical examination, his spleen is not palpable. His blood counts now are hemoglobin, 18.9 g/dL; hematocrit, 60.5%; MCV = 78; white blood cell count, 11,200/μL (normal differential); and platelets, 485,000/μL. You are asked to evaluate the cause of this patient's polycythemia. Which of the following tests is most likely to either make or rule out the diagnosis of polycythemia vera in this case?

A. Carboxyhemoglobin level
B. Abdominal ultrasonography findings for spleen size
C. PCR for *JAK2-V617F*
D. Bone marrow aspirate and biopsy with cytogenetics
E. Red blood cell mass

Answer: C Although it is not specific for polycythemia vera (PV), almost all patients with PV carry a *JAK2* mutation, and its absence makes the diagnosis questionable. (The *JAK2-V617F* mutation also occurs in about 60% of patients with essential thrombocythemia and 50% to 60% with primary myelofibrosis.) Differentiating PV from other secondary causes of polycythemia (see Table 166-5) can be challenging if the individual is negative for a *JAK2* mutation. Bone marrow aspirate and biopsy with cytogenetics can sometimes demonstrate characteristic findings of an myeloproliferative neoplasms, including trilineage hyperplasia (as opposed to just erythroid hyperplasia, the latter being what would be expected for the secondary polycythemias), as well as morphologic changes, but these are rarely absolutely diagnostic; furthermore, cytogenetic studies usually do not add to making or ruling out the diagnosis of PV. A red blood cell (RBC) mass determination is almost superfluous in this case because the great majority of patients with this degree of erythrocytosis, regardless of cause, will have elevated RBC masses. The finding of splenomegaly is neither specific nor sensitive for a diagnosis of PV, whether it is assessed by physical examination or by imaging. It would not be surprising to find an elevated level of carboxyhemoglobin in this smoker, but that would not be a conclusive finding for the diagnosis of his polycythemia. Bot mentioned among the choices, a serum erythropoietin would be a helpful ancillary test in a case like this; in general, it would be expected to be elevated in virtually all of the polycythemias but low in PV (the latter because of feedback inhibition of erythropoietin by the kidneys as a result of the primary myeloproliferative process of PV).

2. Which of the following is *not* a known complication of polycythemia vera (PV) and essential thrombocythemia (ET)?

A. Budd-Chiari syndrome
B. Aplastic anemia
C. Erythromelalgia
D. Marrow fibrosis
E. Acute leukemia

Answer: B Thrombosis is the major cause of morbidity and mortality in the myeloproliferative neoplasms, and it often presents in unusual intraabdominal sites such as hepatic vein thrombosis (Budd-Chiari syndrome) and portal and mesenteric vein thrombosis. Erythromelalgia is a striking and characteristic (but not specific) syndrome of microvascular vasomotor and occlusive disease, mostly affecting the dependent parts of the extremities, typically the feet and sometimes the hands. It is characterized by excruciating pain and tenderness in a patchy distribution, sometimes accompanied by corresponding patches of erythema and warmth. The large vessel peripheral pulses are usually intact. Erythromelalgia is generally very sensitive to prompt response to aspirin. Both marrow fibrosis and spontaneous transformation to acute leukemia are unusual but well-described feared complications of PV and ET. However, aplastic anemia is not associated with these diseases (in contrast to its association with a different bone marrow stem cell disease, paroxysmal nocturnal hemoglobinuria.)

3. Massive, painful splenomegaly develops in a 70-year-old woman with an established diagnosis of primary myelofibrosis (PMF). She is *JAK2-V617F* mutation negative but *CALR* mutation positive. She has become transfusion dependent and has been unresponsive to medical management of the splenomegaly. After much consideration of risks and benefits, it is decided to do a splenectomy. Which of the following are you most likely to find in the spleen on pathologic examination in this case?

A. Megakaryocytes
B. Fibrosis
C. Hemophagocytosis
D. Clonal lymphocytic infiltration
E. Storage cells

Answer: A A major cause of this PMF patient's massive splenomegaly is likely to be extensive "extramedullary hematopoiesis" (EMH) within the spleen. EMH occurs in myeloid metaplasia with or without myelofibrosis. It represents essentially "ectopic" sites of renew hematopoiesis, recapitulating the normal fetal state where hematopoiesis was not restricted to bone marrow but also occurred in other organs such as the spleen and liver. Therefore, histopathology of this patient's spleen is likely to demonstrate many blood cell precursors, including megakaryocytes. Fibrosis, hemophagocytosis, and infiltration with storage cells are not characteristic findings in PMF (or any of the other myeloproliferative neoplasms [MPNs]). Clonal lymphocytic infiltration can cause splenomegaly in the lymphomas but not in the MPNs, which are clonal myeloproliferative, not lymphoproliferative, disorders.

4. A 72-year-old woman has been followed by her hematologist for more than 15 years with the diagnosis of polycythemia vera (PV) (recently confirmed by the finding of the *JAK2-V617F* mutation). Her only treatments during this time have been periodic phlebotomies as needed to maintain a hematocrit below 45%, varying doses of hydroxyurea, and one aspirin daily. Her blood counts have been well controlled, and she has been largely asymptomatic. Over the past several months, despite lowering the hydroxyurea dose from 2 g/day to 1 g/day to 500 mg/day and now to 500 mg on alternate days, the patient has been noted to be actually anemic. Her only new symptoms are increasing fatigue. Her hematocrits have been ranging from 35% to 40% over this time. She reports no signs or symptoms of bleeding, her stools are negative for occult blood, and her serum ferritin level is within normal limits. What would you do now?

A. Carefully examine the peripheral blood smear.
B. Do evaluation for occult malignancy, including imaging of chest, abdomen, and pelvis.
C. Perform bone marrow aspirate and biopsy.
D. Check CALR (calreticulin gene) mutation status to rule out clonal evolution of disease.
E. Stop hydroxyurea completely and observe course of the anemia.

Answer: C The most likely diagnosis is that this patient's PV is now transforming to either myelofibrosis or acute leukemia (or myelodysplasia). This is the natural history of the disease in a small minority of patients with PV even in the absence of previous treatments with known leukemogenic agents (e.g., P32, alkylating agents). A peripheral blood smear is important and can provide important clues, including leukoerythroblastic or myelophthisic changes (e.g., teardrop-shaped red blood cells, nucleated red cells, and immature myeloid precursors) could indicate development of fibrosis; the presence of circulating blasts could indicate conversion to acute leukemia. However, whether or not one sees these changes on the blood smear, a bone marrow aspirate and biopsy are indicated as the definitive test. There is no clear evidence that patients with myeloproliferative neoplasms (MPNs) are predisposed to second solid tumor malignancies; therefore, other than conducting a thorough history and physical examination and then pursuing any leads found with further testing, general body imaging to look for occult malignancy is not indicated. Clonal evolution does occur in PV and the other MPNs, and new mutations can be acquired during the course of the disease. However, at this point, it appears that the *JAK2-V617F* and *CALR* mutations are mutually exclusive in the MPNs. Even if stopping the hydroxyurea slightly improves the anemia, the striking history of increasing sensitivity to hydroxyurea suggests that something unfavorable is happening in this patient's bone marrow.

LEUKOCYTOSIS AND LEUKOPENIA

NANCY BERLINER

The normal peripheral white blood cell count (WBC) ranges between 4500/μL and 10,000/μL, with a mean of 7500/μL, and is composed of neutrophils, lymphocytes, monocytes, basophils, and eosinophils. Because neutrophils usually represent about 60% of the peripheral WBC, derangement in the WBC usually reflects elevation or reduction in the absolute neutrophil count. Leukocytosis, an elevated WBC, and leukopenia, a depressed WBC, may be secondary to an underlying disease or exposure, or they may be manifestations of a primary hematologic disorder. This chapter outlines both the primary and secondary causes of leukocytosis and leukopenia, focusing particularly on neutrophilia and neutropenia.

NORMAL NEUTROPHIL DYNAMICS

Neutrophils arise from multipotent progenitor cells in the bone marrow that also give rise to erythrocytes, megakaryocytes, eosinophils, basophils, and monocytes. Neutrophil precursors in the marrow mature over 6 to 10 days to form a storage pool of mature neutrophils (Fig. 167-1). Together the marrow populations make up about 95% of the body's total granulocyte mass (20% neutrophil precursors, 75% mature bands and neutrophils). The circulating neutrophil pool thus represents only the remaining approximately 5% of the body's total neutrophils, just over half of which at any given time are adherent to the vascular endothelium and the spleen, a phenomenon termed *margination*. These marginated neutrophils are poised for immediate release into the circulation during times of stress. The remaining neutrophils circulate freely in the blood. The lifespan of neutrophils in the peripheral blood was thought to be very short, only 6 to 12 hours; however, newer in vivo studies suggest that they circulate for up to 3 to 4 days.[1] They subsequently migrate into tissues, where they can survive for 1 to 4 days. Changes in neutrophil number reflect these dynamics. Neutrophilia can occur as the result of increased marrow production, increased release of neutrophils from the storage pool, or mobilization of neutrophils from the marginated pool. Neutropenia, on the other hand, may be due to decreased marrow production, increased margination with or without sequestration by the spleen, or increased destruction of peripheral cells.

NEUTROPHILIA

Most cases of neutrophilia are reactive or secondary to an underlying inflammatory process. This includes neutrophilia due to infection, chronic inflammation, stress, drugs, nonhematologic malignancy, marrow stimulation (as in hemolysis or idiopathic thrombocytopenic purpura), or splenectomy. Primary causes of neutrophilia may be congenital, including hereditary neutrophilia, Down syndrome, and leukocyte adhesion deficiency (LAD), or acquired as in the case of chronic myelogenous leukemia and other myeloproliferative neoplasms (Table 167-1).

TABLE 167-1 DIFFERENTIAL DIAGNOSIS OF NEUTROPHILIA

- Primary hematologic etiologies
  - Congenital neutrophilia
    - Hereditary neutrophilia
    - Chronic idiopathic neutrophilia
    - Down syndrome
    - Leukocyte adhesion deficiency (LAD)
      - LAD-1
      - LAD-2
  - Acquired hematologic neoplasms
    - Myeloproliferative neoplasm
      - Chronic myelogenous leukemia
      - Polycythemia vera
- Secondary to other disease entities
  - Infection
    - Acute via release from marginated and storage pools
    - Chronic via increased myelopoiesis (e.g., tuberculosis, fungal infection, chronic abscess, other chronic infections)
  - Chronic inflammation
    - Rheumatic disease: juvenile rheumatoid arthritis, rheumatoid arthritis, Still disease, and others
    - Inflammatory bowel disease
    - Granulomatous disease
    - Chronic hepatitis
  - Cigarette smoking
  - Stress
  - Drug induced
    - Corticosteroids
    - β-Agonists
    - Lithium
    - Recombinant cytokine administration
  - Nonhematologic malignancy
    - Cytokine-secreting tumors (lung, tongue, kidney, urothelial tumors)
    - Marrow metastasis (myelophthisis)
  - Marrow stimulation
    - Hemolytic anemia, immune thrombocytopenia
    - Recovery from marrow suppression
    - Recombinant cytokine administration
  - Post-splenectomy

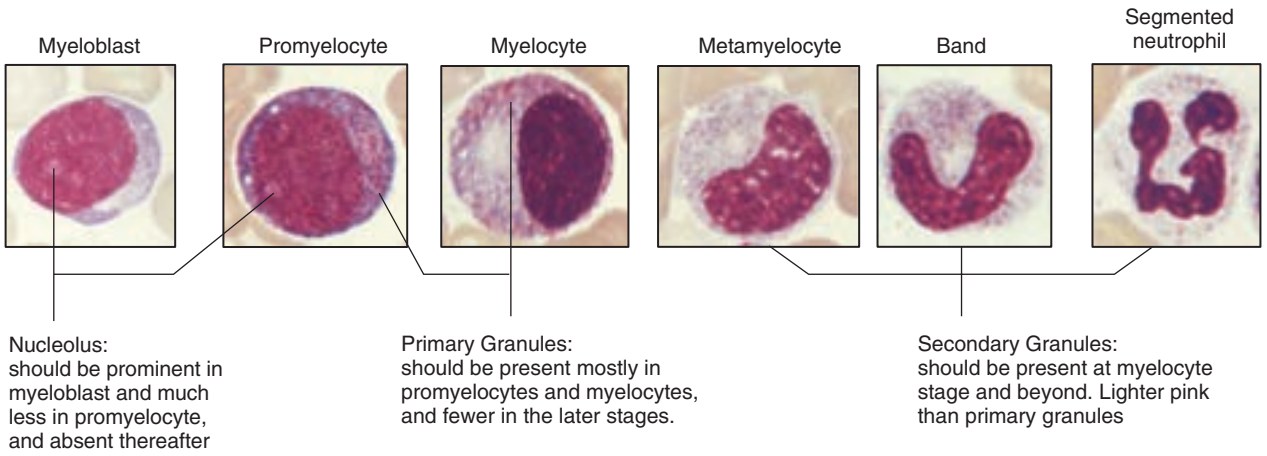

FIGURE 167-1. Myeloid maturation in the bone marrow. Nucleoli are prominent in myeloblasts, much less frequent in promyelocytes, and absent in more mature forms. Primary granules are present in the cytoplasm of promyelocytes and myelocytes, and secondary granules predominate beyond the myelocyte stage.

ETIOLOGY

Secondary Causes of Neutrophilia

Infection

Many acute bacterial infections can present with a modest leukocytosis with a "left shift," referring to the circulation of more immature myeloid cells. This left shift most commonly is restricted to release of an increased number of band forms; however, in severe stress, one may see circulating metamyelocytes and even earlier cells (see Fig. 167-1) in the peripheral blood. Leukocytosis occurs within minutes to hours of infection owing to release of neutrophils from both the marrow and marginated pools. Examination of these neutrophils on peripheral smear may reveal evidence of toxic granulation (see Fig. 157-18), Döhle bodies (see Fig. 157-19), and cytoplasmic vacuoles. Certain infections (e.g., *Clostridium difficile* or tuberculosis in particular) are known to cause elevations in the WBC to greater than 30,000/μL in about one fourth of infected patients and may result in a *leukemoid reaction*, defined as a WBC of greater than 50,000/μL with a pronounced left shift (Fig. 167-2).

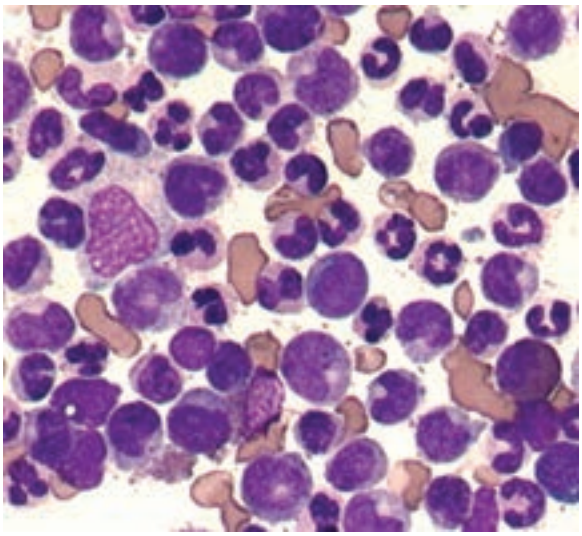

FIGURE 167-2. Peripheral blood from a patient with leukemoid reaction. From this smear, it would be impossible to distinguish this from chronic phase chronic myelogenous leukemia (Chapter 184). Distinction would depend on determination of presence or absence of *BCR-ABL* fusion.

Chronic Inflammation

Leukocytosis due to chronic inflammation results from increased leukocyte (specifically neutrophil and monocyte) production as opposed to altered neutrophil distribution. Mature neutrophil pools become depleted with ongoing inflammation, and the myeloid compartment of the marrow expands to increase neutrophil production. Myriad cytokines, including tumor necrosis factor-α (TNF-α), granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage inflammatory protein-1 (MIP-1), interleukin-1 (IL-1), IL-6, and IL-8, have been implicated in this marrow stimulation (Chapter 156). Chronic inflammatory conditions that are particularly associated with leukocytosis and neutrophilia include juvenile rheumatoid arthritis, rheumatoid arthritis, Still disease, Crohn disease, ulcerative colitis, granulomatous infection, and chronic hepatitis. The WBC and neutrophil elevation in these cases is typically more modest than that seen in acute infection or inflammation.

Cigarette Smoking

Cigarette smoking can cause a leukocytosis and neutrophilia in about 25 to 50% of chronic smokers that can persist for even up to 5 years after quitting smoking. The mechanism by which this occurs is unknown, although there is recent evidence that cigarette smoke slows neutrophil apoptosis.[2]

Stress

Within minutes of exercise, surgery, or stress, one can see an elevation in circulating neutrophils. This is presumed to be due to the effects of catecholamines on marginated neutrophils, with release of neutrophils into the circulation. Some cases of stress-induced neutrophilia can be prevented by pretreatment with β-adrenergic antagonists (e.g., propranolol), supporting the role of catecholamines in the process. Exercise-induced neutrophilia, however, is not blocked by propranolol, suggesting that it may instead be due to flow and mechanical perturbation of neutrophils in the lungs. An elevated WBC has also been noted in the setting of acute myocardial infarction, but whether this is a risk factor for cardiac ischemia or a result of inflammation is unclear.

Drug Induced

Probably the most well-known and widely used drugs associated with leukocytosis are corticosteroids. Other drugs that are associated with elevations in the neutrophil count include β-agonists and lithium. Lithium causes neutrophilia by increasing the production of endogenous colony-stimulating factors (CSFs). G-CSF or GM-CSF treatment likewise may result in neutrophilia, and although this is the desired effect, the neutrophilia can be quite pronounced if not appropriately monitored.

Nonhematologic Malignancy

Leukocytosis can be seen in a number of nonhematologic malignancies. Some tumors (lung, tongue, kidney, bladder) are thought to secrete G-CSF as an ectopic hematopoietic growth factor. Other tumors (lung, stomach, breast), when metastasized to the bone and bone marrow, can cause a *leukoerythroblastic reaction*, characterized by left-shifted leukocytosis, thrombocytosis, and red cell abnormalities including nucleated and teardrop-shaped red blood cells (Fig. 167-3). The presence of nonhematopoietic entities invading the bone marrow (metastatic cancer, fibrosis, granulomatous disease) is termed *myelophthisis*.

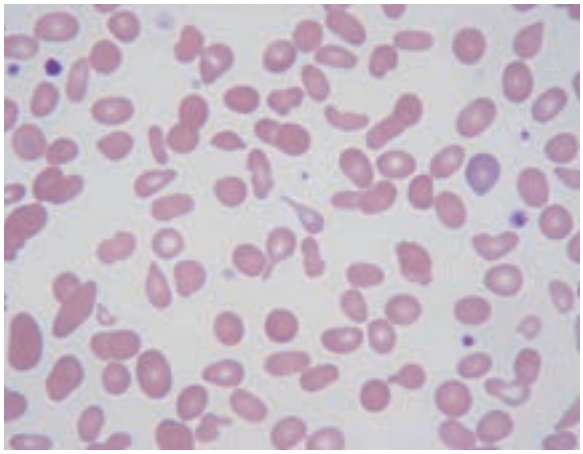

FIGURE 167-3. Myelophthisic changes in erythrocyte morphology. Note prominent teardrop forms. (From Rose M, Berliner N. Disorders of red blood cells. In: Andreoli TE, Benjamin IJ, Griggs RC, et al, eds. *Andreoli and Carpenter's Cecil Essentials of Medicine,* 8th ed. Philadelphia: Saunders; 2010:522, Fig. 49-2.)

Marrow Stimulation

Peripheral destruction of red cells and platelets, as seen with hemolytic anemia and idiopathic thrombocytopenic purpura, can result in stimulation of the bone marrow and a "spillover" leukocytosis. Recovery of cell counts following marrow suppression, as in the case of chemotherapy, can result in a rebound leukocytosis that may last several weeks.

Primary Causes of Neutrophilia

Hereditary Neutrophilia

Hereditary neutrophilia is an autosomal dominant genetic disease that is characterized by an elevated WBC in the 20,000 to 100,000/μL range with splenomegaly and widened diploe of the skull. The neutrophils in this disorder appear to function normally, and patients have no increased risk for bacterial infection or other sequelae. Hereditary neutrophilia caused by an autosomal-dominant *GCSF3* gene mutation has been reported, causing constitutive activation of the G-CSF receptor.

Chronic Idiopathic Neutrophilia

Chronic idiopathic neutrophilia is a condition marked by leukocytosis in the 11,000 to 40,000/μL range with a normal bone marrow biopsy. In one series with a 20-year follow-up, patients with this condition had no medical sequelae from this elevated WBC.

Pelger-Huët Anomaly

Patients with the Pelger-Huët anomaly (PHA) are often misdiagnosed as having a left-shifted WBC because many of their mature neutrophils are misinterpreted as band forms. Although these patients do not actually have leukocytosis, the anomaly often raises suspicion for an acute infection or inflammatory process because of this apparent left shift. PHA is due to a mutation in the lamin B receptor gene and manifests with mature neutrophils and condensed, clumped chromatin within a bilobed nucleus (see Fig. 157-20). These neutrophils, however, function normally. A number of drugs can reversibly induce pseudo-PHA, including colchicine, sulfonamides, ibuprofen, taxoids, and valproate. Pseudo-PHA is also seen in some patients with myelodysplasia (Chapter 182). Vitamin B_{12} or folate deficiency can cause increased nuclear lobation of neutrophils in patients with PHA, perhaps leading to a missed diagnosis. With correction of the vitamin deficiency, however, the aberrant neutrophil nuclear morphology returns.

Down Syndrome

Up to 10% of patients with Down syndrome develop transient myeloproliferative disorder (TMD) related to peripheral blood leukocytosis with blasts in association with an accumulation of megakaryoblasts in the blood, liver, and marrow. Similar reactions have also been reported in patients with trisomy 21 mosaicism who are phenotypically normal. TMD resolves spontaneously in most patients but can progress to acute megakaryoblastic leukemia (AMKL) in 23 to 30% of affected patients. This disorder is attributable to acquisition of mutations in the *GATA1* gene, which encodes a key transcription factor for hematopoietic regulation, leading to loss of normal GATA-1 expression and expression of a truncated GATA-1 protein. Evidence supports that these mutations are acquired during fetal life, and patients present in early infancy with TMD. The pathogenesis of progression to AMKL presumably requires additional genetic events and sequential epigenetic changes, and is the focus of intense study.[3,4]

Leukocyte Adhesion Deficiency

Patients with leukocyte adhesion deficiency (LAD) (see also Chapter 169) have persistent leukocytosis, defects in stimulus-dependent activation of neutrophils, recurrent infections, and delayed separation of the umbilical cord. LAD is an abnormality of leukocyte adhesion reflecting the loss of surface adhesion molecules. LAD-1 is due to absence or marked reduction in the common β chain of β2 integrins, resulting in loss of expression of leukocyte function–associated antigen 1 (LFA-1), the C3bi receptor, and GP150;95. This results in a failure to ingest and kill microbes opsonized by C3bi. In LAD-2, neutrophils lack sialyl Lewis X, the ligand for L-selectin expressed on endothelial cells. Neutrophils appear morphologically normal but are defective in chemotaxis, adherence, and phagocytosis.[5]

Familial Cold Urticaria

Familial cold urticaria is marked by episodic fevers, leukocytosis, urticaria, rash, conjunctivitis, and muscle and skin tenderness with cold exposure. The rash is composed of infiltrating neutrophils. The syndrome appears to be related to decreased levels of C1-esterase inhibitor and is associated with mutations in the *CIAS1* gene on chromosome 1q.

Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders

Chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), and the other myeloproliferative neoplasms (namely polycythemia vera [PV] and essential thrombocythemia [ET]) are discussed in detail in Chapters 184 and 166. They are the principal acquired primary hematologic disorders associated with neutrophilia. They are marked by clonal expansion of myeloid precursors and increased release of both immature and mature myeloid cells into the peripheral blood. CML on presentation often has to be distinguished from a leukemoid reaction. In contrast to a leukemoid reaction, CML is characterized by the presence of abnormalities of other blood cell lines ("panmyelosis") and by the presence of specific abnormalities. Therefore, the peripheral blood smear in CML (but not leukemoid reaction) demonstrates increased numbers in all cells of the neutrophilic series, classically with a greater proportion of myelocytes to metamyelocytes, and may display concomitant basophilia, eosinophilia, anemia, and thrombocytosis. CNL, a rare myeloproliferative neoplasm, is characterized by hepato/splenomegaly and leukocytosis of at least 25,000/μL, with more than 80% of leukocytes being segmented neutrophil/band forms and less than 10% being immature granulocytes, in contrast to CML.[6] CML is characterized by the diagnostic presence of the Philadelphia chromosome [t(9;22)], which can be identified in the peripheral blood by the detection of the *BCR-ABL* translocation by fluorescence in situ hybridization (FISH) or reverse transcription–polymerase chain reaction (RT-PCR). At least 50% of patients with CNL, in contrast, harbor mutations in the receptor for CSF-3 (*CSF3R; GCSFR*).[6] PV and ET, on the other hand, are notable for also having a marked increase in red cell mass and a marked thrombocytosis, respectively, which is often accompanied by leukocytosis.

The leukocyte alkaline phosphatase (LAP) score was historically used in the laboratory evaluation of granulocytosis as a diagnostic marker for myeloproliferative neoplasm. The LAP score is very low (usually 0) in the setting of CML and elevated in PV. The LAP score has a very wide normal range and in practical terms was only definitively helpful in the setting of CML because "high" LAP scores can also be seen in infectious and inflammatory settings. With the availability of direct molecular genetic diagnosis of CML by assay for the *BCR-ABL* fusion gene, it can no longer be recommended as a diagnostic test.

Post-splenectomy

Patients develop leukocytosis following splenectomy, and this may be long-standing, reflecting the loss of a major site of neutrophil margination. This is of no clinical importance, except insofar as it leads to unnecessary evaluation for other pathology.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

As outlined previously, acquired leukocytosis is most commonly the result of acute or chronic infection or inflammation. When it occurs in the absence of

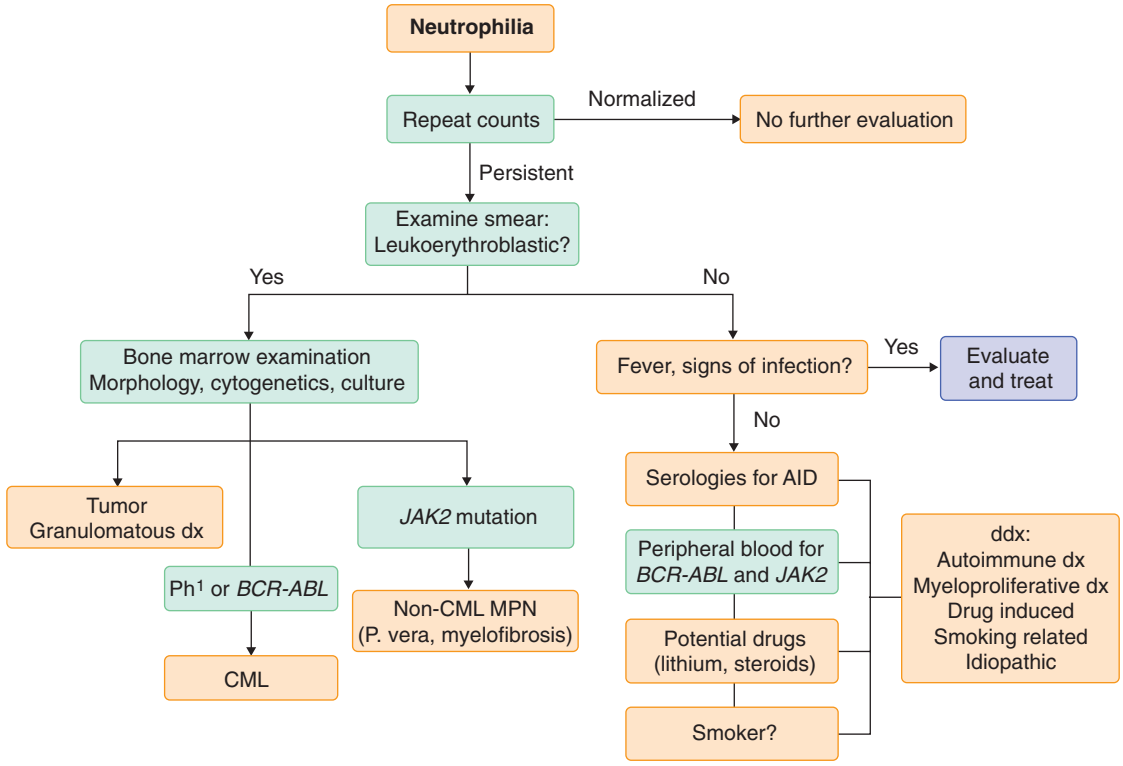

FIGURE 167-4. Diagnostic approach to neutrophilia. AID = autoimmune disease; CML = chronic myelogenous leukemia; ddx = differential diagnosis; dx = disease; MPN = myeloproliferative neoplasm; Ph[1] = Philadelphia chromosome; PV = P. vera, ET = essential thrombocytopenia.

fever, aberrations in acute phase reactants, effusions and edema, or other signs and symptoms of inflammation, it still may be secondary to drugs or an underlying nonhematologic malignancy. As such, it should be seen as the sign of a healthy hematopoietic system responding to an outside stress. Bone marrow evaluation is therefore rarely indicated. However, persistence of leukocytosis in the absence of signs and symptoms of inflammation or infection, nonhematologic malignancy, and offending drugs should prompt an evaluation for a primary myeloproliferative disease or clonal hematologic neoplasm, particularly when there is evidence of a leukoerythroblastic reaction. CML and other myeloproliferative neoplasms can be ruled out by molecular diagnosis on the peripheral blood, as described previously and in Chapter 166. In this setting, bone marrow examination is indicated to evaluate for marrow infiltration by infection, tumor, or fibrosis and should include cultures for tuberculosis and fungal infection as well as cytogenetics and flow cytometry (Fig. 167-4).

Leukocytosis Due to Expansion of Other Cell Lines

Monocytosis and lymphocytosis can also lead to elevations of the WBC. Monocytosis is defined by an absolute monocyte count of greater than 500/μL and usually occurs in the setting of chronic inflammation resulting from infections like tuberculosis, syphilis, or subacute bacterial endocarditis, autoimmune or granulomatous disease, and sarcoidosis. It can also be seen in malignancies, such as preleukemic states, nonlymphocytic leukemia including acute myelomonocytic and monocytic leukemia, histiocytosis, Hodgkin disease, non-Hodgkin lymphoma, and various carcinomas. Finally, it can be seen in the setting of chronic neutropenia, after splenectomy, and in the setting of recovery from marrow suppression (Table 167-2).

Lymphocytosis is defined by an absolute lymphocyte count of more than 5000/μL. The most common causes of an elevated lymphocyte count are viral infections such as Epstein-Barr virus and the hepatitis viruses. Although most bacterial infections cause neutrophilia, pertussis and cat-scratch disease due to *Bartonella henselae* can cause an impressive lymphocytosis. Other infections that may cause a secondary lymphocytosis include toxoplasmosis and babesiosis. Hypersensitivity reactions due to drugs or serum sickness may also be associated with lymphocytosis. Primary disorders that cause a lymphocytosis include chronic lymphocytic leukemia (CLL) and monoclonal B-cell lymphocytosis (Table 167-3; see also Table 184-2 and Chapter 184).

Eosinophilia is defined by an absolute eosinophil count of more than 400/μL. Eosinophils proliferate under the influence of IL-5 and play a role in phagocytosis and modulating toxicity due to mast cell degranulation in hypersensitivity reactions. Eosinophilia is therefore most often seen in the setting of drug reactions, allergy, atopy, and asthma. A variety of infections, particularly parasitic infections and, to a lesser degree, fungal infections, can be associated with an increased number of circulating eosinophils. Eosinophilia can also be the result of autoimmune and inflammatory conditions, as in Churg-Strauss vasculitis. Atheroembolic disease and adrenal insufficiency may also cause eosinophilia. A number of cancers have been associated with polytypic expansion of eosinophils, including lymphomas and solid tumors. There are also a number of clonal disorders of eosinophils that occur in the setting of some leukemias. Finally, there is a heterogeneous group of disorders termed *hypereosinophilic syndromes*. A *FIP1L1-PDGFRA* fusion gene has confirmed that some of these are primary clonal disorders of eosinophils; the clonality of other hypereosinophilic syndromes can be difficult to establish (see Table 170-1).

NEUTROPENIA

The risk for infection in the setting of neutropenia is highly dependent on the size of the neutrophil storage pool. Although neutropenia is defined by an absolute neutrophil count of less than 1500/μL, patients with neutrophil counts below this number may have different risks and rates of infection depending on the cause of neutropenia. For instance, patients who are neutropenic owing to chemotherapy, marrow failure, or marrow exhaustion experience infection at much higher rates than those with chronic neutropenic syndromes and immune-mediated neutropenia. Neutropenia may be congenital or acquired. The following sections first discuss congenital neutropenic disorders, the study of which has provided critical insights into normal myelopoiesis, and then the secondary causes of neutropenia (Table 167-4).

ETIOLOGY

Primary Causes of Neutropenia

Ethnic and Benign Familial (Constitutional) Neutropenia

The normal range of the neutrophil count is genetically determined and can be variable. A number of racial and ethnic groups have been observed to have a relatively large proportion of members who are neutropenic by comparison to the published normal range, usually based on young, largely white individuals. This is termed *constitutional neutropenia* and is seen among a variety of ethnic groups, including African Americans, Yemenite Jews, Falasha Jews, and African Bedouins. Single-nucleotide polymorphisms in the gene for the Duffy antigen receptor for chemokine *(DARC)* have been shown to associate with race and are a postulated candidate to explain racial and ethnic differences in neutrophil counts.[7] There is also an autosomal dominantly inherited condition called *benign familial neutropenia* that is characterized by neutrophil counts in the 800 to 1400/μL range. Neither ethnic nor benign familial neutropenia has been shown to be associated with *any* increased risk for infection.

Severe Congenital Neutropenia

First described by Rolf Kostmann in 1956, severe congenital neutropenia (SCN) is a disorder of severe neutropenia with neutrophil counts of less than 500/μL, presenting in the neonatal period with recurrent bacterial infections. These infections can occur as early as the first months of life and often include omphalitis and perirectal abscesses. There is often an increase in other myeloid cell lines, including monocytes and eosinophils. Bone marrow biopsy in SCN patients reveals a "maturation arrest" with an absence of mature neutrophil elements. SCN can follow autosomal dominant and recessive and X-linked patterns of inheritance and has been shown to be associated with mutations in a variety of genes, as summarized in Table 167-5.

Neutrophil elastase (ELA2, now ELANE) is a serine protease that is synthesized at high levels in the promyelocyte stage of neutrophil maturation and is packaged in primary granules. It was originally hypothesized that mutations in ELANE led to its defective cellular trafficking and cytoplasmic accumulation, subsequently triggering neutrophil apoptosis. Newer evidence, however, supports a mechanism by which accumulation of the mutant

Chédiak-Higashi syndrome	Autosomal recessive	*LYST*
Griscelli syndrome type 2	Autosomal recessive	*RAB27A*
Hermansky-Pudlak syndrome type 2	Autosomal recessive	*AP3B1*

ELANE = neutrophil elastase; G6PC3 = glucose-6-phosphatase catalytic subunit 3; G-6-PT = glucose-6-phosphatase translocase; G-CSFR = granulocyte colony-stimulating factor receptor; LYST = lysosomal trafficking regulatory gene; SBDS = Shwachman-Bodian-Diamond syndrome; SCN = severe congenital neutropenia; WASP = Wiskott-Aldrich syndrome protein.

neutrophil elastase in the endoplasmic reticulum activates the unfolded protein response, leading to apoptosis. SCN due to these mutations is inherited in an autosomal dominant fashion. Hax-1 is a mitochondrial protein with weak homology to bcl-2, and its absence results in mitochondrial-dependent apoptosis. It is the mutated protein implicated in the original autosomal recessive cases of SCN described by Kostmann. Although all SCN cases were originally referred to as *Kostmann syndrome*, that term is now reserved for this subgroup of autosomal recessive SCN. Wiskott-Aldrich syndrome protein (WASP) regulates actin polymerization in hematopoietic cells, and deficiency in this protein results in the Wiskott-Aldrich syndrome, characterized by small platelets in low number, sinopulmonary infections, and eczema. Another phenotype of mutated WASP, however, is X-linked thrombocytopenia and neutropenia. Mutations in the glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) are the most recently discovered cause of a subset of SCN patients; homozygous loss of this metabolic enzyme also appears to lead to activation of the unfolded protein response and increased apoptosis of neutrophil precursors.[8]

SCN was formerly a disease of infancy and early childhood because few, if any, patients survived to adulthood. However, the advent of the availability of recombinant G-CSF and the observation that G-CSF is able to raise neutrophil counts and prevent infection in most patients have allowed these children to survive. Some patients require very high doses of G-CSF, but responses are seen in 80 to 90% of individuals. Increased survival led to the emerging realization that SCN predisposes to the development of myelodysplasia and acute leukemia (MDS/AML), with the development of MDS/AML at a rate of approximately 2% per year, and a cumulative risk of about 30% over 10 years.[9] Patients refractory to, or requiring very high doses of, G-CSF appear to have a higher risk for leukemic transformation. As discussed later, development of MDS/AML is often associated with the acquisition of a mutation in the gene encoding for the G-CSF receptor. Considerable controversy exists concerning the potential contribution of G-CSF administration to the risk for malignant transformation in children with SCN who receive lifelong treatment with G-CSF (see later under Treatment).

Two classes of G-CSF receptor mutations have been associated with SCN and either hyper-responsiveness or hyporesponsiveness of the receptor. Initial studies aimed at demonstrating that SCN was caused by mutation of the G-CSF or G-CSF receptor gene did not implicate such mutations in the pathogenesis of a significant number of patients with SCN. However, a small number of patients have been shown to have mutations in the G-CSF receptor gene that block ligand binding and produce a G-CSF-resistant form of SCN. More important, however, the studies identified an acquired missense mutation that introduces a stop codon and leads to the deletion of the distal intracellular domain of the receptor known to be responsible for differentiation signaling. This has been hypothesized to cause proliferation of hematopoietic progenitors at the expense of maturation and to be associated with hypersensitivity to G-CSF, suggesting that this mutation may play an important role in the development of MDS/AML in the setting of SCN. However, whether this mutation is in fact of pathogenetic importance to the development of MDS/AML and whether G-CSF influences the risk for developing the mutation and influencing leukemic transformation remain subjects of significant controversy.

Cyclic Neutropenia

Cyclic neutropenia is defined as periods of neutropenia (≤200/μL) lasting 3 to 5 days and occurring at approximately 21-day intervals. These periods of neutropenia may be marked by recurrent fevers, mouth sores, and infections of the skin, upper respiratory tract, and ears. The disorder can be dominantly inherited or sporadic. Congenital cyclic neutropenia has also been shown to be associated with mutations in the gene for neutrophil elastase in virtually all cases tested to date.[10] The diagnosis formerly required demonstration of transient neutropenia through frequent blood counts over a course of 6 weeks but now can be established by sequencing of the neutrophil elastase gene. It is successfully treated with G-CSF and is not associated with an increased risk for leukemic transformation. Rare cases of cyclic neutropenia acquired in adulthood have been associated with systemic diseases such as large granular lymphocytosis or T-cell lymphoma.

Other Congenital Syndromes with Associated Neutropenia

A number of other congenital syndromes are associated with neutropenia as one of the constellation of disease-associated abnormalities. These include Shwachman-Diamond syndrome, Fanconi anemia, dyskeratosis congenita, glycogen storage disease Ib, myelokathexis, Chédiak-Higashi syndrome, Griscelli syndrome II, and Hermansky-Pudlak syndrome II.[11]

Shwachman-Diamond syndrome usually begins as an isolated neutropenia but progresses to marrow failure and is also associated with pancreatic dysfunction and skeletal abnormalities. The responsible gene, the Shwachman-Bodian-Diamond syndrome gene (*SBDS*), is involved in the regulation of ribosomal RNA. These patients carry an increased risk for leukemic transformation.

Fanconi anemia is due to mutations in genes involved in DNA repair, and as such, it takes more time for marrow failure to develop in these patients (median age, 7 years). Patients with Fanconi anemia often have, in addition to marrow failure, short stature with upper limb anomalies and hyperpigmented cafe au lait spots, although about one third have no physical abnormalities. Screening is done by chromosomal fragility testing following exposure to diepoxybutane or mitomycin C as well as direct assessment for known Fanconi gene mutations. Stem cell transplantation is curative but carries a high risk for morbidity and mortality owing to the toxicity of preparative regimens.[12]

Dyskeratosis congenita (DKC) is a syndrome of nail dystrophy, leukoplakia, and skin pigmentation abnormalities with associated neutropenia or aplastic anemia, or both. It can be inherited in an autosomal dominant or recessive or X-linked fashion and has been shown to be associated with mutations in several genes that are implicated in telomere maintenance. It typically does not present until the second decade of life. Recent studies have demonstrated that DKC is one of several diseases associated with telomere abnormalities, with wide-ranging manifestations including pulmonary fibrosis and hepatic cirrhosis as well as bone marrow failure.

Glycogen storage disease Ib is inherited in an autosomal recessive fashion and characterized by intermittent neutropenia due to defects in the neutrophil respiratory burst with subsequent apoptosis of circulating neutrophils. Hepatomegaly and metabolic crises are also the hallmarks of this disease and are due to mutations in the gene for the glucose-6-phosphatase translocase enzyme.

The neutropenia of *myelokathexis* is due to retention of mature neutrophils in the bone marrow despite a low peripheral neutrophil count. During infection, however, patients with myelokathexis typically have a sudden rise in their neutrophil count, which makes their clinical course relatively more benign. There is an association between this condition and hypogammaglobulinemia and warts, the WHIM syndrome (*w*arts, *h*ypogammaglobulinemia, *i*mmunodeficiency, and *m*yelokathexis). It has been shown to be caused by heterozygous mutations in the gene encoding chemokine receptor CXCR4.

Chédiak-Higashi syndrome, Griscelli syndrome II, and *Hermansky-Pudlak syndrome II* are all syndromes of albinism and neutropenia due to defects in vesicular trafficking. Chédiak-Higashi syndrome is due to mutations in a lysosomal trafficking regulatory gene (*LYST*) and is characterized by oculocutaneous albinism, bleeding, progressive neurologic disease, and increased susceptibility to hemophagocytic syndrome. Patients with Griscelli syndrome II also have an increased susceptibility to hemophagocytic syndrome as well as albinism and periodic neutropenia; Griscelli syndrome II is caused by mutations in the gene encoding the small guanosine triphosphatase RAB27A, which is involved in the release of myeloperoxidase from the primary granules of neutrophils. Hermansky-Pudlak syndrome II is due to mutations in the *AP3B1* gene, which encodes a part of a protein transport complex that is involved in vesicular trafficking in many cell types and appears to be involved in the trafficking of neutrophil elastase. It is also marked by albinism, platelet abnormalities, and pulmonary fibrosis.

Barth syndrome is an X-linked autosomal recessive disorder characterized by neutropenia, cardiomyopathy, and growth retardation, with a high mortality rate through early childhood because of the heart disease. The causative mutation is in the *TAZ* gene, which encodes tafazzin protein that is critical to remodeling cardiolipin in the mitochondrial membrane.

Secondary Causes of Neutropenia

Infection-Related Neutropenia

Several viral infections have been shown to cause a transient neutropenia that typically resolves as the viremia abates. These include varicella, measles, rubella, hepatitis A and B, Epstein-Barr virus, influenza, parvovirus, and cytomegalovirus. The mechanisms are diverse and can involve redistribution, decreased production, and immune destruction of neutrophils. Human immunodeficiency virus and acquired immunodeficiency syndrome can likewise cause mulitfactorial leukopenia and neutropenia (Chapter 393). Patients

often have splenomegaly with increased sequestration, but more commonly the neutropenia reflects immune-mediated destruction. A myriad of atypical infections like *Mycobacterium tuberculosis*, ehrlichiosis, rickettsia, tularemia, brucellosis, and some staphylococcal infections can cause a moderate neutropenia. Any infection leading to overwhelming sepsis can cause neutropenia, but this is usually through consumption of the marrow neutrophil reserve and is typically seen in newborns and elderly patients and not in individuals with an otherwise healthy and mature marrow. There is also increased margination of neutrophils during sepsis due to systemic activation of complement, exacerbating the neutropenia.

Drug-Induced Neutropenia and Neutropenia Due to Marrow Injury

Drug-induced neutropenia is the most common cause of neutropenia. Multiple drugs have been implicated in neutropenia and agranulocytosis, in both predictable and idiosyncratic patterns. Drug-induced neutropenias may reflect either suppression of marrow granulopoiesis or increased destruction or clearance of peripheral neutrophils. Many drugs cause direct dose-dependent marrow suppression, which is predictable and often mild. Others incite an idiosyncratic immune-mediated destruction that can present with profound agranulocytosis. The typical pattern of drug-induced neutropenia is a marked decline in the neutrophil count that occurs after about 1 to 2 weeks of exposure to the drug with a recovery that begins within days of stopping the drug. However, atypical cases can present long after drug initiation, and others may be associated with a longer interval before recovery of the neutrophil count (Fig. 167-5). Patients with drug-induced agranulocytosis may present with acute sepsis, and it is associated with a significant risk for acute mortality. Recovery is often preceded by the appearance of monocytes and immature neutrophil forms. The more hypercellular the marrow is at diagnosis, the earlier marrow recovery may occur. Some common drugs known to cause neutropenia, in addition to antineoplastic, antiviral, and immunosuppressive agents, include clozapine, the antithryoidal thioamides including carbimazole, methimazole and propylthiouracil, quinidine, procainamide, sulfasalazine, and Levamisole, which is widely used as a cocaine adulterant, causing cocaine-associated neutropenia. Neutrophil recovery is speeded by G-CSF, although there are no definitive data that this improves survival in this setting.

Radiation can also result in marrow injury leading to an acute or chronic marrow failure state; in high doses, it is also a risk factor for the development of myelodysplasia and leukemia. These malignant hematopoietic diseases can themselves cause marrow failure because the malignant cells proliferate within the marrow-occupying space and can cause marrow fibrosis, both of which lead to cytopenias. These diseases are discussed in greater detail in Chapters 182 and 183, respectively. Likewise, metastatic carcinoma to the bone can also cause marrow failure because the marrow becomes increasingly replaced by the metastatic cells.

Immune Neutropenia

Infection and drugs cause immune-mediated neutrophil destruction. However, immune neutropenia can also occur as an isolated phenomenon (primary immune neutropenia) or as a manifestation of an underlying systemic autoimmune disease (secondary immune neutropenia). Primary autoimmune neutropenia is primarily a disease of children younger than 4 years; median age of onset is 6 to 12 months. Although infectious risk is increased, treatment is restricted to prophylactic antibiotics, with G-CSF reserved for acute infectious episodes. Ninety-five percent of patients undergo spontaneous remissions within 2 years. Nearly all of these patients have antineutrophil antibodies directed against antigens derived from the FcγIIIb receptor; these antibodies mediate neutrophil destruction by either sequestration in the spleen or complement-mediated neutrophil lysis.

Secondary autoimmune neutropenia is a disease of adults and can be seen in association with hyperthyroidism, Wegener granulomatosis, rheumatoid arthritis, and systemic lupus erythematosus (SLE). The role of antineutrophil antibodies in these patients is less clear. More than 50% of patients with SLE, for example, have antineutrophil antibodies, but many have normal neutrophil counts, and there is a poor correlation between the presence of the antibodies and neutrophil number.[13]

Felty syndrome and *large granular lymphocyte syndrome* deserve separate mention. Felty syndrome occurs in association with long-standing rheumatoid arthritis (RA) (Chapter 264) and is characterized by splenomegaly and profound neutropenia. Large granular lymphocyte syndrome often occurs in the setting of RA but can also occur as an isolated phenomenon. Both Felty syndrome and large granular lymphocyte syndrome are associated with a proliferation of large granular lymphocytes, with a characteristic surface phenotype ($CD3^+$, $CD8^+$, $CD16^+$, and $CD57^+$). In the setting of RA, these two syndromes were originally thought to be separate diseases, with Felty syndrome being polyclonal and large granular lymphocyte syndrome representing a monoclonal proliferation of larger granular lymphocytes. However, with increasing sensitivity of detection of monoclonal populations of lymphocytes, this distinction has become blurred. It has been observed that more than 90% of RA patients with either syndrome are human leukocyte antigen (HLA)-DR4-positive, leading to the postulate that the two entities represent the extremes of a single spectrum of disease. This HLA restriction is not found among non-RA patients with large granular lymphocytes. Both syndromes cause immune-mediated neutrophil destruction by a wide array of mechanisms, including antineutrophil antibodies and cell-mediated destruction. Some patients may also have G-CSF resistance mediated by inhibitory G-CSF antibodies.[14]

There are other rare forms of immune neutropenia. Isoimmune neonatal neutropenia is a moderate to severe neutropenia of the newborn due to transplacental passage of maternal immunoglobulin G antibodies against alleles inherited from the father, resulting in neutropenia in a manner similar to the development of anemia in Rh hemolytic disease. Pure white cell aplasia is a rare disease associated with severe pyogenic infections, and also with

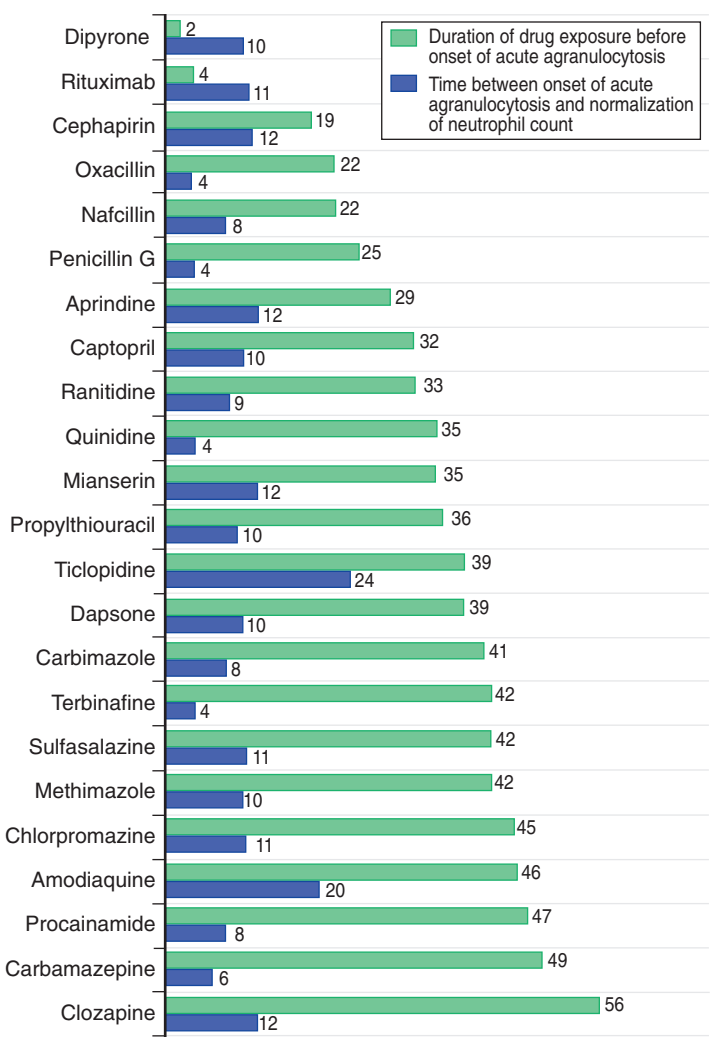

FIGURE 167-5. Median duration of treatment and neutropenia. Only drugs with more than three definite or probable reports of the time between onset of acute agranulocytosis and normalization of neutrophil count and the duration of treatment before onset of acute agranulocytosis were considered. (From Andersohn F, Konzen C, Garbe E. Systematic review: agranulocytosis induced by nonchemotherapy drugs. *Ann Intern Med.* 2007;146: 657-665.)

thymoma in more than two thirds of cases. It has also occurred following ibuprofen therapy. There is a complete absence of myeloid precursors on bone marrow examination. It is immune mediated, but removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cyclophosphamide, corticosteroids, cyclosporine, and intravenous immunoglobulin may be needed.

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation can result in both acute and chronic neutropenia as a result of increased margination of the circulating neutrophil pool. This is attributed to the fact that C5a renders neutrophils more adherent and thereby prone to aggregation within the pulmonary vasculature. This has been seen in patients suffering from burns and transfusion reactions. Complement activation may also lead to neutrophil destruction, as in paroxysmal nocturnal hemoglobinuria. The circulating neutrophil pool can also be diminished in association with hypersplenism, although this is typically less common and less pronounced than the anemia and thrombocytopenia seen in patients with an enlarged spleen.

Neutropenia Due to Nutritional Deficiency

Several vitamin and mineral deficiencies, particularly B_{12}, folate (Chapter 164), and copper, are associated with neutropenia. Copper deficiency is a particularly under-recognized cause of neutropenia (usually seen along with anemia), found especially in clinical situations like total parenteral nutrition without copper supplementation, protein-losing enteropathies, celiac disease, gastric bypass surgery and postgastrectomy, malabsorption syndromes, and zinc toxicity. In addition to low serum copper and ceruloplasmin levels, distinct morphologic findings include hypogranularity and hypolobation (PHA) on peripheral smear, and cytoplasmic vacuolization of myeloid as well as erythroid precursors and ringed sideroblasts.

Deficiencies in these vitamins and minerals result in ineffective myelopoiesis, maturation arrest, and megaloblastic changes with nuclear-cytoplasmic dyssynchrony. The characteristic finding in the setting of megaloblastic anemia is hypersegmentation of the neutrophil (Fig. 167-6).

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia in adults (CINA) has been described as an acquired disorder of granulopoiesis characterized by prolonged neutropenia in the absence of any apparent underlying etiology.[15] Patients present with chronic neutropenia that is often an incidental finding on routine blood tests, making it impossible to know how long the neutropenia has been present. They have no evidence of autoimmune disease, nutritional deficiency, or myelodysplasia. The syndrome is heterogeneous, with a wide range of neutrophil counts. A group of patients with CINA from Greece were originally found to have increased production of transforming growth factor-β (TGF-β) and consequent suppression of granulopoiesis by the bone marrow. These patients tend to have very mild neutropenia, with an absolute neutrophil count (ANC) that is rarely less than 800. They may have an ethnic predisposition to neutropenia; indeed, the neutropenia has been demonstrated to be linked to a genetic polymorphism in the TGF-β locus. It seems likely, however, that these patients should be distinguished from other CINA patients, many of whom have an ANC below 200. The etiology of neutropenia in these patients is completely unknown. However, the natural history of CINA, even in the face of very low neutrophil counts, is generally benign. Most patients require no therapy, although those with very low counts must be treated with G-CSF when they develop fever in the setting of infections. Some patients with recurrent infections or troublesome aphthous ulcers require chronic G-CSF treatment. These patients typically respond to fairly low doses of G-CSF, and there is no reported increase in the development of MDS/AML.

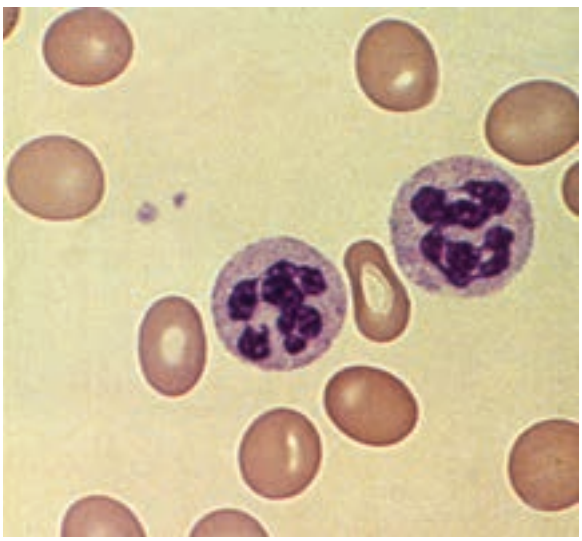

FIGURE 167-6. Peripheral blood with macrocytosis and hypersegmented neutrophils in megaloblastic anemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neutropenia by itself is not associated with many clinical signs and symptoms other than those of the condition that may be causing it. It becomes clinically evident, however, when it results in infection. Although patients with an ANC below 1000/μL do have a slightly increased risk for infection, the risk is substantially increased once the neutrophil count falls below 500/μL. Given the lack of neutrophils, the signs and symptoms of infection may be attenuated; as such, pneumonia may be present with minimal infiltrate on chest radiograph, or a urinary tract infection may yield only a very mild pyuria. Given this, fever in any neutropenic patient must be considered an emergency with prompt acquisition of cultures and administration of empirical antibiotic therapy.

When fever, infection or sepsis, and neutropenia present concomitantly for the first time, it can be difficult to determine whether the neutropenia predated the infection or, conversely, if it is the result of the infection. Examination of the peripheral blood smear can be helpful in this regard because an elevation of band forms and evidence of toxic granulation suggest the latter.

Because drug-induced neutropenia is the most common cause of acquired neutropenia, a careful inventory of all drug and toxin exposures is warranted.[16] Likewise, there should be a careful evaluation for underlying malignant and inflammatory conditions as the precipitant of neutropenia. The time course of the neutropenia and infections can provide clues to the etiology of the neutropenia (acute versus chronic, persistent versus cyclic, neonatal versus childhood versus adult onset). Attention should be paid to the skin, bones, appendages, and nails because abnormalities in these may point toward one of the congenital neutropenia syndromes. Evaluation of the complete blood count, peripheral blood smear, and vitamin B_{12} and folate levels should also be performed.

When the neutropenia is not severe and is associated with anemia and thrombocytopenia, one should consider the possibility of hypersplenism. In many cases, the diagnosis can be made by the finding of palpable splenomegaly. However, especially in obese patients, abdominal imaging should be used to evaluate spleen size. Abdominal ultrasound allows the assessment of portal venous flow with Doppler studies. If splenic enlargement is confirmed, the etiology of the splenomegaly (Chapter 168) should be determined. It may reflect congestive splenomegaly secondary to portal hypertension (as a result of cirrhosis, fatty liver, or congestive heart failure, among others) or infiltrative splenomegaly due to a benign or malignant process. Felty syndrome should be considered in the setting of RA.

In patients with chronic neutropenia in the absence of a history of infection or drug or toxin exposure or an evident B_{12} or folate deficiency, bone marrow examination should be performed to rule out myelodysplasia, with assessment of morphology, flow cytometry for large granular lymphocyte syndrome, and cytogenetics. Once a normal marrow has been obtained, further bone marrow examination is not indicated in patients with CINA (Fig. 167-7).

TREATMENT AND MANAGEMENT

Rx

The management of neutropenia is dependent on the etiology of the depressed neutrophil count as well as its severity and the presence or absence of fever or infection.[17] The approach to the patient with fever and neutropenia is discussed in more detail in Chapter 281. Neutropenia with fever is a clinical emergency because these patients are at risk for hemodynamic collapse and septic shock. Therefore, these patients should be evaluated thoroughly and cultured promptly, and antibiotics should be administered within 30 to 60 minutes of presentation before obtaining the results of the cultures. The timely empirical administration of a combination of antipseudomonal antibiotics in

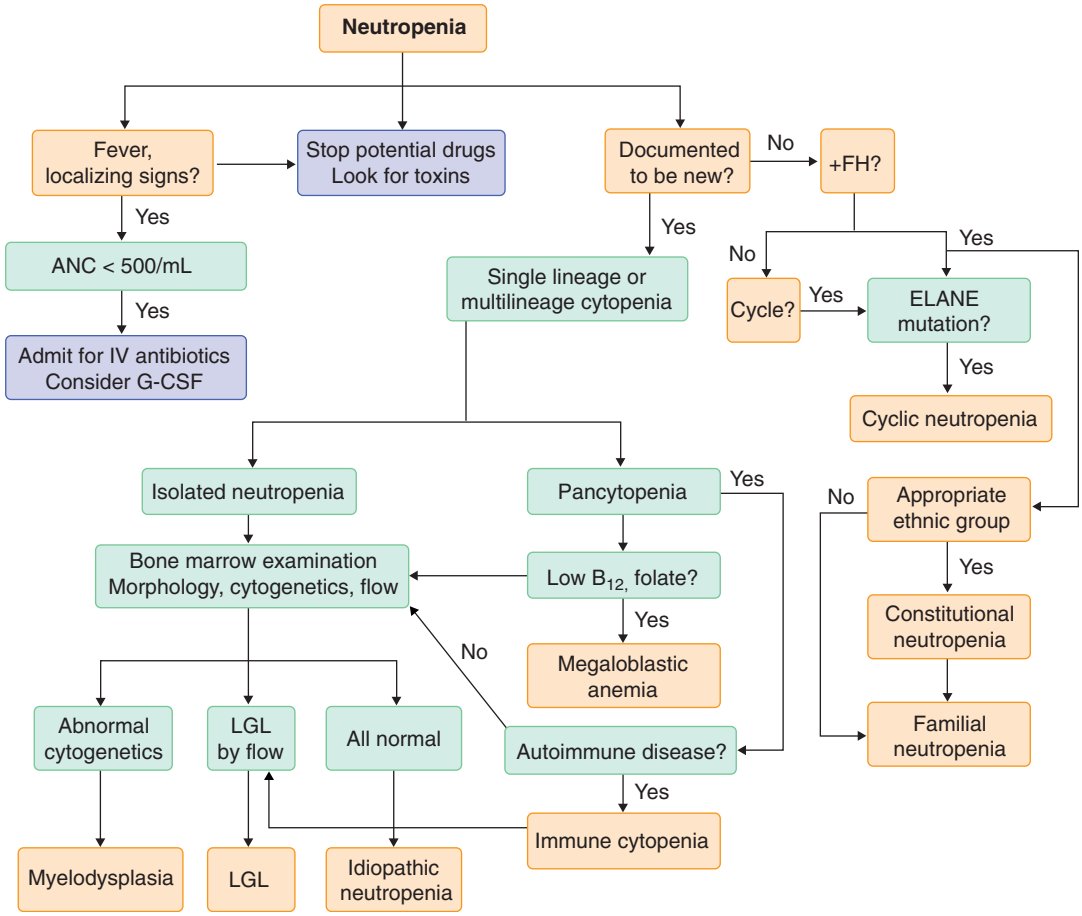

FIGURE 167-7. Diagnostic approach to neutropenia. ANC = absolute neutrophil count; ELANE = neutrophil elastase gene, FH = family history; G-CSF = granulocyte colony-stimulating factor; IV = intravenous; LGL = large granular lymphocyte syndrome.

patients with neutropenia at the onset of fever results in significant clinical benefit, with respect to both response and survival. With the advent of newer generation cephalosporins, studies have shown that monotherapy with a third- or fourth-generation cephalosporin at the onset of fever may be sufficient. A systematic review to assess the evidence for combination therapy versus monotherapy in cancer patients with febrile neutropenia in clinical trials has been recently updated.[■] It concluded that randomized controlled trials have demonstrated the survival superiority of β-lactam monotherapy compared with β-lactam-aminoglycoside combination therapy.

The addition of a second antipseudomonal agent, vancomycin, or antifungal agent is warranted in patients considered at risk for resistant pseudomonal infection, resistant gram-positive infection, or fungal infections, respectively, or in the face of a failure to defervesce within 3 to 5 days of antibiotic administration. These considerations are discussed in more detail in Chapter 281.

How to manage the uninfected and afebrile neutropenic patient is more nuanced and dependent on the etiology of the neutropenia. Patients with immune-mediated neutropenia are typically treated with immunosuppressive therapy, including steroids, antithymocyte globulin, or cyclosporine, or a combination of these, aimed primarily at treatment of the underlying autoimmune disease. Patients usually respond to G-CSF, although in the setting of RA, this may induce a flare of joint symptoms. Patients with large granular lymphocyte syndrome often respond to therapy with low-dose methotrexate (10 mg/m^2 orally once a week), cyclosporine (100 to 600 mg or 2 to 10 mg/kg orally daily), or low-dose cyclophosphamide (50 to 100 mg orally daily).[18]

Patients with congenital neutropenia, including idiopathic, severe congenital, or cyclic neutropenia, are usually successfully managed with G-CSF for years. Before the use of G-CSF, the mean age of death for patients with severe congenital neutropenia was 2 to 3 years. Since the advent of G-CSF, however, life expectancy has been extended by decades into adulthood. Therapy is daily and chronic, given by subcutaneous injection, with doses varying by the type of neutropenia and the individual responsiveness to therapy. It is usually well tolerated, although accelerated bone loss has been observed. Growth and development do not appear to be affected. Patients with SCN typically require the highest doses, whereas those with idiopathic neutropenia require the lowest, and patients with cyclic neutropenia fall somewhere in between. An increased rate of MDS/AML has been reported with the use of G-CSF in patients with SCN, but this has occurred coincidentally with improved survival. The increased incidence of MDS/AML may then be due to the fact that patients are living longer with a disease whose natural history includes a risk for developing MDS or AML. Certainly, the observation that acquired mutations in the G-CSF receptor are present in 65 to 80% of patients with SCN who develop MDS or AML suggests a potential mutagenic pathway toward leukemogenesis, but whether this is enhanced or accelerated by the administration of G-CSF has yet to be determined. Patients with idiopathic and cyclic neutropenia do not develop MDS or AML, despite therapy with G-CSF. However, recent evidence suggests that the risk for MDS/AML in SCN patients is much higher in those requiring high doses of G-CSF (>10 μg/kg/day), and patients with idiopathic and cyclic neutropenia are usually responsive to much lower G-CSF doses.

In patients with CINA, G-CSF should be reserved for acute febrile episodes unless the patient has recurrent infections. Patients with CINA treated with G-CSF may experience significant side effects, including fever, gastrointestinal symptoms, and splenomegaly. Consequently, in patients with CINA requiring chronic G-CSF administration, the cytokine should be administered at the lowest dose necessary to prevent infections; it is usually sufficient to treat to maintain the ANC in the range of 300 to 500.

For patients with an inflammatory, infectious, or drug-induced neutropenia, the recommendation is to treat the underlying condition or stop the offending agent. This, however, is not always immediately possible, as in the cases of HIV-infected patients with opportunistic infections or on antiretroviral therapy, solid organ and bone marrow transplant recipients on immunosuppression and antiviral prophylaxis and treatment, and cancer patients undergoing chemotherapy. Prophylactic use of G-CSF in these patients has been shown to be effective in improving the ANC and decreasing rates of infection and febrile neutropenia, but has not been associated with a proven or consistent survival advantage.[■] In light of these findings, many oncologic professional society guidelines recommend the use of prophylactic G-CSF in patients receiving chemotherapy who have a 20% or greater risk for developing febrile neutropenia based on age, comorbid illness, disease characteristics, and myelotoxicity of the chemotherapy regimen. In addition, it is recommended for use during hematopoietic stem cell transplantation, for patients receiving chemotherapy for non-Hodgkin lymphoma or dose-dense chemotherapy, and for patients with a history of febrile neutropenia receiving further chemotherapy.

The use of prophylactic antibiotics has also been investigated, predominantly in neutropenic patients receiving chemotherapy. Early studies in the 1980s and 1990s demonstrated an improvement in infection-related outcomes but not in infection-related or overall survival. Most recently, several randomized trials of prophylactic quinolones in patients receiving chemotherapy demonstrated an improvement in rates of infection and febrile neutropenia. A meta-analysis of studies investigating the use of prophylactic quinolones in patients receiving chemotherapy was the first to document an overall survival benefit as well, although most of these patients had hematologic as opposed to solid tumor malignancies.[A1] The current Infectious Diseases Society of America guidelines do not recommend the use of prophylactic antibiotics in cancer patients undergoing myelosuppressive chemotherapy, with the exception of trimethoprim-sulfamethoxazole in patients at risk for *Pneumocystis jirovecii* pneumonia. Antibiotic prophylaxis is not generally used outside of the stem cell transplantation setting. The use of antibiotics to prevent infection in patients with neutropenia due to other causes has not been extensively studied but is typically not recommended and should be based on clinical context.

Stem cell transplantation (Chapter 178) can be curative for a number of the congenital neutropenia and bone marrow failure syndromes. It is, however, not without risk and should therefore be reserved for patients with severe neutropenia complicated by recurrent infection definitively shown to be due to marrow failure.

Leukopenia Due to Deficiency of Other Cell Lines

Lymphocyte production takes place in a variety of anatomic sites, and lymphocyte trafficking from those sites is bidirectional, making it difficult to understand lymphocyte dynamics in the same way that we do for neutrophils. Despite this, the peripheral lymphocyte count seems to be maintained in a narrow range at 2000 to 4000/μL, 20% of which are B cells and 70% of which are T cells. Lymphocytopenia is a total lymphocyte count of less than 1500/μL. It can be the result of decreased production, defective trafficking, or increased loss or destruction. Decreased production can occur as a result of protein and calorie malnutrition; lymphocyte progenitor pool injury secondary to radiation, chemotherapy, or immunosuppressive agents; and congenital immunodeficiency states. Endogenous or exogenous glucocorticoid excess can cause lymphocytopenia by altering lymphocyte trafficking. This can also occur as the result of acute bacterial or fungal infections, certain viral infections, and granulomatous disease. Finally, many viruses can cause direct destruction of lymphocytes, as can antilymphocyte antibodies seen in patients with underlying autoimmune diseases. Lymphocytes can also be lost from intestinal lymphatics in cases of protein-losing enteropathy, primary disease of the gut or intestinal lymphatics, or gut edema secondary to severe heart failure. When lymphocytopenia is discovered, a comprehensive assessment of the immune system should be done, including lymphocyte subtyping, quantitative immunoglobulins, and skin testing to detect deficiencies of cell-mediated immunity. Treatment is typically aimed at the underlying disease, but intravenous immunoglobulin can be administered to patients who are hypogammaglobulinemic, and transplantation can be performed in patients with severe deficiencies of cell-mediated immunity due to impaired lymphocyte production and function.

Monocytopenia, eosinopenia, and basophilopenia can be seen in the setting of bone marrow failure syndromes or as a result of acute infection, malignancy, or severe injury. This is thought to be due to elevations in glucocorticoids, prostaglandins, and epinephrine. A rise in these humoral factors has the greatest impact on eosinophils such that a lack of eosinopenia in any of these settings should prompt suspicion for adrenal insufficiency, a primary myeloproliferative syndrome, parasitic infection, or primary hypereosinophilic syndrome. Monocytopenia is less frequently seen, probably owing to the diverse roles monocytes play in normal human physiology; prolonged and extreme monocytopenia may not be compatible with life.

REVIEW QUESTIONS

1. A 20-year-old African American college student receives a scholarship to spend her junior year abroad in France. She needs to have a health form completed before her departure. A complete blood count (CBC) reveals neutropenia, and her physician advises her to postpone the scholarship and to see you for evaluation. She is healthy with no history of excessive infections. Her physical examination is normal. CBC shows: white blood cell count 3400 w/ 30% neutrophils, hematocrit 41, platelets 200,000. What should you advise her?

A. She should have a bone marrow to rule out a bone marrow process causing neutropenia.
B. She should have serial blood counts to rule out cyclic neutropenia.
C. She should have chromosome analysis of her peripheral blood.
D. She should be evaluated for an elastase mutation.
E. She should go to France without any further evaluation.

Answer: E The normal neutrophil count is partially determined by ethnic background. African American males frequently have a neutrophil count of 1000 to 1500, and African American females may have counts that are even lower. Many may actually have counts below 1000. With a total neutrophil count of 1120, a normal hematocrit and platelet count, and an unremarkable history and physical examination, the patient should be diagnosed with constitutional neutropenia. This requires no further evaluation, although if DARC testing is available, confirming she is Duffy negative will confirm the diagnosis. The patient should be reassured that these counts are normal for her and present no undue risk. She should leave for France as planned. (See Ethnic and Benign Familial [Constitutional] Neutropenia.)

2. A 1-month-old baby boy presents with fever and cough and is found to have pneumonia associated with severe neutropenia. His parents have normal blood counts but had lost a baby girl at age 3 months under similar circumstances 2 years before. Which of the following statements is *not* true?

A. The patient likely has a mutation in neutrophil elastase.
B. The child should be treated with granulocyte colony-stimulating factor (G-CSF).
C. The child is at risk for developing myelodysplastic syndrome and acute myeloid leukemia (MDS/AML).
D. If the child survives, his offspring will probably have normal neutrophil counts.
E. The child's white blood cell count likely has a 21-day cycle in and out of the normal range.

Answer: A This child has a disease that is apparent in neither parent but has a sibling that died of the same disease. This is consistent with an autosomal recessive form of severe congenital neutropenia (SCN). SCN related to neutrophil elastase mutation is an autosomal dominant disorder. Cyclic neutropenia is a milder autosomal dominant disorder, also due to mutations in *ELANE;* it is clinical mild and rarely presents in infancy. Although it can appear sporadically, the occurrence in a sibling makes that virtually impossible. This case is most consistent with Kostmann syndrome, which is due to mutations in the *HAX1* gene. Because it is a very rare recessive disorder, if the child lives to adulthood and has offspring, they will be obligate heterozygotes and, like the patient's parents, will have normal counts. Like patients with dominantly inherited SCN associated with neutrophil elastase mutations, these patients respond to G-CSF and have an increased risk for developing MDS/AML. (See Severe Congenital Neutropenia.)

3. A 45-year-old man presents to the emergency department after a motor vehicle crash. He is afebrile with a blood pressure of 160/95 mm Hg and a pulse of 110 beats per minute. He has several scrapes and bruises, but no major injuries. Admission complete blood count reveals: white blood cell count 16,000, hematocrit 45, and platelets 280,000. What is the most likely explanation for his leukocytosis?

A. Acute bacterial infection
B. Undiagnosed chronic myelogenous leukemia
C. Stress-induced demargination of neutrophils
D. Cytokine release stimulating increased marrow production and release of neutrophils
E. Unsuspected splenic rupture

Answer: C Acute stress is commonly associated with leukocytosis. Acute leukocytosis in almost any setting occurs by demargination, in this case in response to the release of catecholamines during the stress of the accident, also causing his tachycardia. Cytokine-induced marrow proliferation and release of neutrophils reflect more chronic inflammation and could not have occurred in less than about a week. Unsuspected splenic rupture would likely lead to hypotension and shock. There is no reason to consider a diagnosis of chronic myeloproliferative disease or sepsis in the absence of other evidence for a secondary condition. The patient should have his counts rechecked in several days or weeks to rule out any other pathology. (See Stress.)

4. A 3-year-old child presents with recurrent infections and a diagnosis of Chédiak-Higashi syndrome (CHS) is made. Which of the following is *not* true of his disease?

A. He is likely to have associated nystagmus.
B. His sibling has a 50% chance of having the disease.
C. He is likely to have abnormal neutrophil granules.
D. He is likely to develop hemophagocytic syndrome.
E. He is likely to have a defect in skin pigmentation.

Answer: A CHS is a generalized disorder of granule formation caused by abnormalities in the *LYST* gene, which is required for the correct trafficking of proteins into granules. Consequently, patients with CHS have other defects associated with abnormal granule formation, including oculocutaneous albinism, with decreased pigmentation and nystagmus, and abnormal-appearing neutrophil granules. As the disease is an autosomal recessive disorder, the heterozygous parents are usually totally unaffected, and siblings have a 25% chance of inheriting the disease. Patients with CHS often have a terminal phase of the disease associated with the development of hemophagocytic syndrome, manifesting as fever, splenomegaly, and pancytopenia, often as a result of Epstein-Barr virus infection. (See Other Congenital Syndromes with Associated Neutropenia.)

5. A 1-month-old infant presents with a temperature of 103° F and a white blood cell count (WBC) of 90,000. He has a history of delayed umbilical cord separation, poorly healing skin lesions, recurrent otitis media, and failure to thrive. He is admitted to the hospital, where he is documented to have methicillin-resistant *Staphylococcus aureus* (MRSA). He is placed on appropriate antibiotics, but he remains febrile, and his WBC is persistently elevated in the 80,000 to 100,000 range. This patient is likely to have a mutation in which of the following?

A. *ELANE*
B. *HAX1*
C. Integrin receptor β chain
D. *LYST*
E. *G-CSFR*

Answer: C The child has a congenital disorder of neutrophils that results in leukocytosis. The diagnosis is leukocyte adhesion deficiency. This disease arises from defects in leukocyte adhesion to endothelium. It can arise from defects in the integrin receptor common β chain (LAD-1), with loss of expression of leukocyte function–associated antigen 1 (LFA-1), C3bi receptor, and gp150;95, leading to a failure to ingest and kill microbes opsonized by C3bi. It can also arise from an abnormality of selectin glycosylation (LAD-2). *ELANE* and *HAX1* mutations are causes of severe congenital neutropenia, and affected patients present with profound neutropenia. *LYST* mutations are the cause of Chédiak-Higashi syndrome, which is also associated with neutropenia. Congenital *G-CSFR* mutations are very rare, although two or three patients in the literature have been described to have such mutations as the basis for G-CSF–resistant severe congenital neutropenia. More commonly, *G-CSFR* mutations are somatic mutations that arise in patients with severe congenital neutropenia and may be a harbinger of the development of myelodysplastic syndrome or acute myeloid leukemia. (See Leukocyte Adhesion Deficiency.)

168

APPROACH TO THE PATIENT WITH LYMPHADENOPATHY AND SPLENOMEGALY

JAMES O. ARMITAGE AND PHILIP J. BIERMAN

LYMPHADENOPATHY

PHYSIOLOGY AND ANATOMY

Lymph nodes are found throughout the body along the course of the lymphatic vessels, strategically located to allow the filtering of lymphatic fluid and the interdiction of microorganisms and abnormal proteins. Lymphatic fluid enters the node in afferent lymphatic vessels that empty into the subcapsular sinus. The fluid then transverses the node and exits in a single efferent lymphatic vessel. In doing so, the lymph and its contents are exposed to immunologically active cells throughout the node. Lymph nodes are populated predominantly by macrophages, dendritic cells, B lymphocytes, and T lymphocytes. B lymphocytes are located primarily in the follicles and perifollicular areas, whereas T lymphocytes are found principally in the interfollicular or paracortical areas of the lymph node. These cells function together to provide antigen processing, antigen presentation, antigen recognition, and proliferation of effector B and T lymphocytes as part of the normal immune response to microorganisms or foreign proteins.

Because the normal immune response leads to the proliferation and expansion of one or more cellular components of lymph nodes, it often results in significant lymph node enlargement. In young children, who are continuously being exposed to new antigens, palpable lymphadenopathy is the rule. In fact, the absence of palpable lymphadenopathy in them would be considered abnormal. In adults, lymph nodes larger than 1 to 2 cm in diameter are generally considered abnormal. However, lymph nodes 1 to 2 cm in diameter in the groin are sufficiently common to be considered normal.

Lymphoid proliferation is a normal response to exposure to foreign antigens. The location of the enlarged lymph nodes often reflects the site of invasion. For example, cervical lymphadenopathy would be typical in a patient with pharyngitis. Generalized immune proliferation and lymphadenopathy can occur with a systemic disorder of the immune system, disseminated infection, or disseminated neoplasia. Malignancies of the immune system might manifest as localized or disseminated lymphadenopathy.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of lymphadenopathy (Table 168-1) is vast, and the underlying causes are responsible for either proliferation of immunologically active cells or infiltration of the lymph node by foreign cells or substances. In practice, the cause of enlarged lymph nodes is often uncertain even in retrospect; in such cases, unrecognized infectious processes are generally blamed.

Infections by bacteria, mycobacteria, fungi, chlamydia, parasites, and viruses are the major causes of lymph node enlargement. Lymph nodes in the drainage area of essentially all pyogenic infections can enlarge. In certain infections, such as bubonic plague caused by *Yersinia pestis,* dramatic regional lymph node enlargement with fluctuant lymph nodes (i.e., buboes) can be a hallmark of the disease (Chapter 312). Other bacterial infections have lymph node enlargement as a prominent feature (e.g., cat-scratch disease; Chapter 315) and can mimic lymphoproliferative disorders. Mediastinal lymphadenopathy is seen in inhalational anthrax (Chapter 294). In some parts of the world, cervical lymphadenopathy is a sufficiently frequent manifestation of tuberculosis to lead to the institution of antituberculous therapy rather than biopsy. Disseminated lymphadenopathy can be seen in cases of infection by a variety of organisms such as *Toxoplasma,* Epstein-Barr virus (i.e., infectious mononucleosis), cytomegalovirus, and human immunodeficiency virus (HIV).

TABLE 168-1 CAUSES OF LYMPHADENOPATHY

Infection
Bacterial (e.g., all pyogenic bacteria, cat-scratch disease, syphilis, tularemia)
Mycobacterial (e.g., tuberculosis, leprosy)
Fungal (e.g., histoplasmosis, coccidioidomycosis)
Chlamydial (e.g., lymphogranuloma venereum)
Parasitic (e.g., toxoplasmosis, trypanosomiasis, filariasis)
Viral (e.g., Epstein-Barr virus, cytomegalovirus, rubella, hepatitis, HIV)
Benign disorders of the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus, serum sickness, drug reactions such as to phenytoin, Castleman disease, sinus histiocytosis with massive lymphadenopathy, Langerhans cell histiocytosis, Kawasaki syndrome, Kimura disease)
Malignant disorders of the immune system (e.g., chronic and acute myeloid and lymphoid leukemia, non-Hodgkin lymphoma, Hodgkin disease, angioimmunoblastic-like T-cell lymphoma, Waldenström macroglobulinemia, multiple myeloma with amyloidosis, malignant histiocytosis)
Other malignancies (e.g., breast carcinoma, lung carcinoma, melanoma, head and neck cancer, gastrointestinal malignancies, germ cell tumors, Kaposi sarcoma)
Storage diseases (e.g., Gaucher disease, Niemann-Pick disease)
Endocrinopathies (e.g., hyperthyroidism, adrenal insufficiency, thyroiditis)
Miscellaneous (e.g., sarcoidosis, amyloidosis, dermatopathic lymphadenitis, IgG4-related disease)

TABLE 168-2 MOST FREQUENT CAUSES OF LYMPHADENOPATHY IN ADULTS IN THE UNITED STATES

Unexplained
Infection
In drainage area of infection (e.g., cervical adenopathy with pharyngitis)
Disseminated (e.g., mononucleosis, HIV infection)
Immune disorders (e.g., rheumatoid arthritis)
Neoplasms
Immune system malignancies (e.g., leukemias, lymphomas)
Metastatic carcinoma or sarcoma

TABLE 168-3 FACTORS TO CONSIDER IN THE DIAGNOSIS OF LYMPHADENOPATHY

Associated systemic symptoms
Patient's age
History of infection, trauma, medications, travel experience, previous malignancy
Location: cervical, supraclavicular, epitrochlear, axillary, intrathoracic (hilar vs. mediastinal), intra-abdominal (retroperitoneal vs. mesenteric vs. other), iliac, inguinal, femoral
Localized vs. disseminated
Presence of tenderness or inflammation
Size
Consistency

A variety of nonmalignant disorders of the immune system can lead to localized or disseminated lymphadenopathy. Autoimmune diseases such as rheumatoid arthritis (Chapter 264) and systemic lupus erythematosus (Chapter 266) often have accompanying lymphadenopathy, which can pose a diagnostic challenge because of the increased incidence of lymphoma in patients with these disorders. In the lymphadenopathy that occurs as a reaction to drugs such as phenytoin, lymph node biopsy findings can sometimes be confused with lymphoma. Benign proliferative diseases of the immune system that can also be confused with lymphoma include Castleman disease (Chapters 185 and 393; angiofollicular lymph node hyperplasia), sinus histiocytosis with massive lymphadenopathy, and disorders seen more frequently in Asia, such as Kawasaki syndrome (Chapter 439) and Kimura disease.

All the cells in the immune system can become malignant. Several of these malignancies typically manifest as lymphadenopathy, and it can be seen in all of them. Lymphadenopathy as the initial manifestation is the rule for Hodgkin disease and non-Hodgkin lymphoma, and it is common in Waldenström macroglobulinemia and B-cell chronic lymphocytic leukemia; it is seen only occasionally in the myeloid leukemias (Chapters 183 through 186) and is rare in multiple myeloma. Malignancies of all organ systems can metastasize to the lymph nodes and cause lymphadenopathy, which is usually seen in the drainage area of the primary tumor—for example, axillary lymph nodes in patients with breast cancer, hilar and mediastinal lymph nodes in patients with lung cancer, and cervical lymph nodes in patients with head and neck cancer. However, widespread lymphadenopathy can also occur. Other disorders in which lymphadenopathy may be an initial finding include storage diseases such as Gaucher disease (Chapter 208), endocrinopathies such as hyperthyroidism (Chapter 226), sarcoidosis (Chapter 95), and dermatopathic lymphadenitis. Amyloidosis (Chapter 188) can cause lymphadenopathy in patients with multiple myeloma, hereditary amyloidosis, or amyloidosis associated with chronic inflammatory states.

Among patients with lymphadenopathy actually seen in practices in the United States, diagnoses are not determined in a high proportion (Table 168-2). In such cases, the lymphadenopathy is usually blamed on infection. When the lymphadenopathy is in the drainage site of a known infection (e.g., cervical lymphadenopathy in a patient with pharyngitis) or the patient has a known infection associated with lymphadenopathy (e.g., infectious mononucleosis; Chapter 377), this infectious assumption is usually correct. Alternatively, if a patient has an immunologic disorder that is known to cause lymphadenopathy, such as rheumatoid arthritis, this disorder is usually an acceptable explanation; however, progressive lymphadenopathy in such patients should trigger a biopsy because they are at increased risk for lymphoma. Localized, progressive lymphadenopathy, particularly when associated with fever, sweats, or weight loss, requires biopsy to exclude lymphoma.

Lymph Node Evaluation

Evaluation of a patient with lymphadenopathy includes a careful history, a thorough physical examination, laboratory tests, and sometimes imaging studies to determine the extent and character of the lymphadenopathy. The age of the patient and any associated systemic symptoms might be important clues (Table 168-3). Cervical lymphadenopathy in a child is much less worrisome than equally prominent lymphadenopathy in a 60-year-old adult. The occurrence of fever, sweats, or weight loss raises the possibility of a malignancy of the immune system. The explanation for the lymphadenopathy might become apparent with the identification of a site of infection, a particular medication, a travel history, or a previous malignancy.

Physical examination allows the identification of localized versus widespread lymphadenopathy. The particular sites of involvement can be important hints to the diagnosis because infection and carcinoma are likely to cause lymphadenopathy in the lymphatic drainage of the site of the disorder. In general, tender lymph nodes are more likely to be due to an infectious process, whereas painless adenopathy raises concern for malignancy. Lymph node consistency can also aid in the diagnosis: typically, lymph nodes containing metastatic carcinoma are rock hard, lymph nodes containing lymphoma are firm and rubbery, and lymph nodes enlarged in response to an infectious process are soft.

The larger the lymph node, the more likely it is that a serious underlying cause exists; lymph nodes greater than 3 to 4 cm in diameter in an adult are very worrisome. Physical examination to assess lymph node size is only marginally accurate and reproducible, although it is by far the most widely used method. More precise methods are available with various imaging techniques.

Imaging

Imaging studies, including routine radiographs, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET), can be used to assess the extent of lymphadenopathy in the chest and abdomen (Table 168-4). Chest radiographs are the most economical and easiest way to assess mediastinal and hilar lymphadenopathy but are not as accurate as CT of the chest. CT and ultrasonography are the most useful modalities for assessing abdominal and retroperitoneal lymphadenopathy. In most patients, CT is probably the most accurate approach, but ultrasonography has the advantage of being less expensive and not requiring radiation exposure. MRI and PET are not first-line studies for the assessment of lymphadenopathy. Although few randomized controlled trials have been published to date concerning the diagnostic accuracy of PET,[1] it is applied to the assessment of patients with lymphoma both at presentation and after treatment.[2] PET is usually positive in patients with Hodgkin disease and aggressive non-Hodgkin lymphomas and can be used to assess the presence of active lymphoma in patients with lymphadenopathy and a proven diagnosis; it is especially useful for re-evaluating patients after therapy because lymph nodes do not always regress to normal size after treatment, particularly those in the mediastinum and retroperitoneum, even though the malignancy has been eradicated.

TABLE 168-5 APPROACH TO THE PATIENT WITH LYMPHADENOPATHY

Does the patient have a known illness that causes lymphadenopathy? Treat and monitor for resolution.
Is there an obvious infection to explain the lymphadenopathy (e.g., infectious mononucleosis)? Treat and monitor for resolution.
Are the nodes very large and/or very firm and thus suggestive of malignancy? Perform a biopsy.
Is the patient very concerned about malignancy and unable to be reassured that malignancy is unlikely? Perform a biopsy.
If none of the preceding is true, perform a complete blood cell count and, if unrevealing, monitor for a predetermined period (usually 2 to 8 weeks). If the nodes do not regress or if they increase in size, perform a biopsy.

TABLE 168-6 SOME DIAGNOSTIC CONSIDERATIONS FOR LOCALIZED LYMPHADENOPATHY

SITE	INFECTIONS	NEOPLASMS	OTHER
Cervical	Pharyngitis, other head and neck infections, mononucleosis, toxoplasmosis, TB	Head and neck cancers, thyroid cancer, lymphoma	
Supraclavicular		Intra-abdominal cancer (particularly left-sided nodes), lung cancer, lymphoma	
Axillary	Cat-scratch disease, distal infections, plague	Breast cancer, melanoma, lymphoma	Silicone implants
Mediastinal	TB, fungal infection, anthrax	Lymphoma, lung cancer, germ cell tumor	Sarcoidosis
Retroperitoneal	TB	Lymphoma, testicular cancer, kidney cancer, upper GI malignancy	Sarcoidosis
Mesenteric	Appendicitis, cholecystitis, diverticulitis, Whipple disease	Lymphoma, GI cancer	Inflammatory bowel disease, panniculitis
Inguinal	Distal or genital infection, plague, STDs	Lymphoma, melanoma, vulvar cancer	

GI = gastrointestinal; STD = sexually transmitted disease; TB = tuberculosis.

Interventional Evaluation

Lymph node aspiration or biopsy is often necessary for an accurate diagnosis of the cause of lymphadenopathy. Even then, morphologic findings alone may not be able to clearly distinguish between reactive changes in benign lymphadenopathies and neoplasm, particularly lymphoma; special studies on the specimens may be required to do so.[3] Fine-needle aspiration is currently popular and is an accurate means of diagnosing infection or carcinoma involving a lymph node. Although lymphomas can occasionally be diagnosed with this approach, it is inappropriate as an initial diagnostic maneuver for lymphoma. Cutting needle biopsy often provides sufficient material for an unequivocal diagnosis and subtyping of the lymphoma. However, excisional biopsy, which is most likely to provide the pathologist with adequate material to perform histologic, immunologic, and genetic studies, is also most likely to yield the correct diagnosis.

An Approach to the Patient with Lymphadenopathy

Patients with lymphadenopathy (Table 168-5) come to medical attention in several ways. Perhaps most common is a patient who feels a lymph node in the neck, axilla, or groin and seeks a physician's opinion. Lymphadenopathy might also be an unexpected finding on a routine physical examination or as part of an evaluation for another complaint. Finally, patients might be found to have unexpected lymphadenopathy on imaging studies of the chest or abdomen. When the nodes are multiple or larger than 2 to 3 cm, biopsy using mediastinoscopy, a paramediastinal incision, laparoscopy, or laparotomy is often required for diagnosis.

The approach to a patient complaining of newly discovered lymphadenopathy in the neck, axilla, or groin depends on the size, consistency, and number of enlarged lymph nodes and the patient's general health. In most cases, very large or very firm lymph nodes in the presence of systemic symptoms such as unexplained fever, sweats, or weight loss should lead to lymph node biopsy. Patients who have enlarged lymph nodes in the drainage area of a previously treated malignancy (e.g., neck nodes in a patient with a history of head and neck cancer) might be best approached by lymph node aspiration. Carcinoma can often be diagnosed in this manner, although it is a poor approach for the diagnosis of lymphoid malignancies. For cervical lymph nodes,[4] excisional biopsy should be delayed in a patient in whom head and neck cancer (Chapter 190) is a diagnostic consideration. These patients should initially undergo careful ear, nose, and throat examinations to avoid performing a biopsy that might complicate the patient's subsequent therapy. Some diagnostic possibilities for localized lymphadenopathy are presented in Table 168-6.

In the most common situation—that is, a lymph node is soft and is not larger than 2 to 3 cm and the patient has no obvious systemic illness—observation for a brief period is usually the best approach. Performance of a complete blood cell count and examination of a peripheral smear can be helpful in recognizing a systemic illness (e.g., infectious mononucleosis). These patients are often given antibiotics. If the lymph node does not regress over the course of a few weeks or if it gets bigger, a biopsy should be performed.

Part of the care of such patients involves the art of medicine and being responsive to the patient's particular needs. For example, biopsy might be performed more quickly in a patient who is very anxious about malignancy or who needs a definitive diagnosis expeditiously.

SPLENOMEGALY

DEFINITION

The spleen is the largest lymphatic organ in the body and is sometimes approached clinically as though it were a very large lymph node. Although it participates in the primary immune response to invading microorganisms and foreign proteins, the spleen has many other functions. It functions as a filter for the blood and is responsible for removing senescent red blood cells from the circulation, as well as blood cells and other cells coated with immunoglobulins. Blood enters the spleen, filters through the splenic cords, and is exposed to immunologically active cells in the spleen.

The splenic red pulp occupies more than half the volume of the spleen and is the site where senescent red cells are identified and destroyed and red blood cell inclusions are removed by a process known as *pitting*. In the absence of splenic function, basophilic inclusions known as *Howell-Jolly bodies* are seen in circulating red blood cells. The presence of Howell-Jolly bodies (Fig. 168-1) in peripheral blood indicates that the patient has undergone splenectomy or has a process that has rendered the spleen nonfunctional (e.g., sickle cell disease with repeated splenic infarcts, chronic graft-versus-host disease).

The white pulp of the spleen contains macrophages, B lymphocytes, and T lymphocytes; participates in the recognition of microorganisms and foreign proteins; and is involved in the primary immune response. Absence of this splenic function makes individuals particularly susceptible to certain

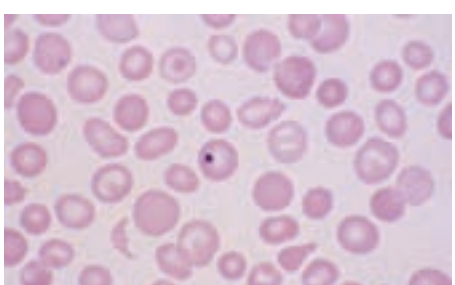

FIGURE 168-1. Howell-Jolly body in an erythrocyte. This is evidence of splenectomy or a nonfunctional spleen.

infections, including sepsis with encapsulated organisms such as *Streptococcus pneumoniae.* The risk for overwhelming sepsis is related to the age at the time of splenectomy or other cause of loss of splenic function. Children and young adults are at highest risk. If possible, all patients should undergo vaccination against *S. pneumoniae* and perhaps *Haemophilus influenzae* and *Neisseria meningitidis* before splenectomy. Some physicians have patients take oral penicillin (e.g., phenoxymethyl penicillin, 250 mg twice daily) indefinitely if splenectomy has been performed in childhood or adolescence.

PATHOBIOLOGY

As with lymphadenopathy, numerous conditions are associated with splenomegaly (Table 168-7). Certain bacterial infections such as endocarditis (Chapter 76), brucellosis (Chapter 310), and typhoid fever (Chapter 308) have splenomegaly as a frequent manifestation. Disseminated tuberculosis (Chapter 324) is often associated with splenomegaly, and splenomegaly can also be seen in cases of disseminated histoplasmosis (Chapter 332) and toxoplasmosis (Chapter 349). Splenomegaly is an almost constant accompaniment of malaria (Chapter 345). Rickettsial disorders such as Rocky Mountain spotted fever are frequently associated with splenomegaly. A wide variety of viral infections typically cause splenomegaly, including infectious mononucleosis associated with Epstein-Barr virus (Chapter 377) and viral hepatitis (Chapters 148 and 149). Splenomegaly can accompany HIV infection. Splenic abscesses, which are usually the result of hematogenous spread of pyogenic organisms, represent an unusual and difficult to diagnose cause of splenomegaly.

Splenomegaly is also seen in a variety of benign disorders of the immune system, including rheumatoid arthritis (Chapter 264); some of these patients have Felty syndrome and accompanying granulocytopenia. Splenomegaly can be detected in some patients with systemic lupus erythematosus (Chapter 266), certain drug reactions, and serum sickness.

Malignancies of the immune system and nonimmune organs can also lead to splenomegaly. Splenomegaly is usually seen in patients with chronic myeloid leukemia and is frequent in chronic lymphoid leukemia (Chapter 184). It can develop in patients with acute myeloid or lymphoid leukemia, non-Hodgkin lymphoma, Hodgkin disease, and Waldenström macroglobulinemia but is rare in multiple myeloma (Chapter 187). Isolated splenomegaly (i.e., without any enlarged lymph nodes) is characteristic of certain immune system malignancies, including hairy cell leukemia (Chapter 184), the prolymphocytic variant of chronic lymphocytic leukemia (Chapter 184), and splenic marginal zone lymphoma (Chapter 185). Metastasis of carcinomas and sarcomas to the spleen is unusual except for malignant melanoma; even with melanoma, however, palpable splenomegaly is an unusual finding.

Splenomegaly can develop as a result of increased pressure in the splenic circulation, especially in patients with portal hypertension caused by a variety of hepatic disorders, including alcoholic cirrhosis (Chapter 152). However, it also can be due to splenic or portal vein thrombosis. The first manifestation of an enlarged spleen in portal hypertension can be thrombocytopenia.

Hematologic disorders that can lead to palpable splenomegaly include autoimmune hemolytic anemia (Chapter 160), hereditary spherocytosis (Chapter 161), and a number of other anemias. The myeloproliferative neoplasms polycythemia vera (frequently), essential thrombocythemia (sometimes), and idiopathic myelofibrosis (usually) all can present with splenomegaly. In cases of idiopathic myelofibrosis, the spleen is frequently a site of extramedullary hematopoiesis (Chapter 166).

A variety of less common conditions can lead to splenomegaly. The storage disorder Gaucher disease (Chapter 208) usually manifests as splenomegaly.

TABLE 168-7 CAUSES OF SPLENOMEGALY

Infection
Bacterial (e.g., endocarditis, brucellosis, syphilis, typhoid, pyogenic abscess)
Mycobacterial (e.g., tuberculosis)
Fungal (e.g., histoplasmosis, toxoplasmosis)
Parasitic (e.g., malaria, leishmaniasis)
Rickettsial (e.g., Rocky Mountain spotted fever)
Viral (e.g., Epstein-Barr virus, cytomegalovirus, HIV, hepatitis)
Benign disorders of the immune system (e.g., rheumatoid arthritis with Felty syndrome, systemic lupus erythematosus, drug reactions such as to phenytoin, Langerhans cell histiocytosis, serum sickness)
Malignant disorders of the immune system (e.g., acute or chronic myeloid or lymphoid leukemia, non-Hodgkin lymphoma, Hodgkin disease, Waldenström macroglobulinemia, malignant histiocytosis)
Other malignancies (e.g., melanoma, sarcoma)
Congestive splenomegaly (e.g., portal hypertension secondary to liver disease, splenic or portal vein thrombosis)
Hematologic disorders (e.g., autoimmune hemolytic anemia, hereditary spherocytosis, thalassemia major, hemoglobinopathies, elliptocytosis, extramedullary hematopoiesis)
Storage diseases (e.g., Gaucher disease)
Endocrinopathies (e.g., hyperthyroidism)
Miscellaneous (e.g., sarcoidosis, amyloidosis, tropical splenomegaly, cysts)

TABLE 168-8 METHODS FOR EVALUATING THE SPLEEN

Physical examination

Liver-spleen scanning
Positron emission tomography
Biopsy
Needle aspiration
Splenectomy
Laparotomy (total or partial splenectomy)
Laparoscopy

Splenomegaly can be seen in endocrinopathies such as hyperthyroidism (Chapter 226). Sarcoidosis (Chapter 95) and amyloidosis (Chapter 188) can manifest as splenomegaly. *Tropical splenomegaly* is a term used to describe the palpable spleens found in patients who live in tropical areas, for which there may be numerous causes.

DIAGNOSIS

Evaluation of Spleen Size and Function

Physical Examination

The ability to perform an accurate physical examination and determine the presence of an enlarged spleen (Table 168-8) is an important skill, but it is not easily learned. Physical examination of the spleen can be performed with the patient supine or in the right lateral decubitus position. Inspection, percussion, auscultation, and palpation are all important parts of an accurate assessment. It is rare for a spleen to be so large that it is visible and can be seen to move with respiration. However, in patients with such a condition, it is possible to miss splenomegaly by failing to start palpation sufficiently low to find the edge. Occasionally, percussion of the left upper quadrant helps identify an area of dullness that moves with respiration and can lead to the identification of splenomegaly. Spleen size is generally recorded as the number of centimeters the spleen descends below the left costal margin in the midclavicular line on inspiration. Although auscultation is not usually a regular part of splenic examination, the existence of a splenic rub on inspiration can lead to the diagnosis of splenic infarction. The left kidney is sometimes confused with the spleen on physical examination, but its failure to move with respiration in the manner typical for the spleen usually allows its distinction.

Laboratory Evaluation

Laboratory studies are frequently valuable in assessing splenic function. In patients with an absent or nonfunctional spleen,[5,6] Howell-Jolly bodies will be seen in circulating red blood cells (see Fig. 168-1). Splenic hyperfunction (a condition often referred to as *hypersplenism*) is associated with cytopenias: the spleen is the normal reservoir for a significant proportion of platelets, and

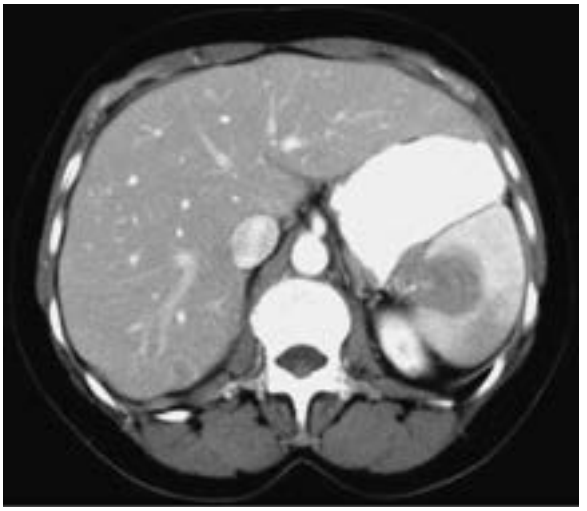

FIGURE 168-2. Enlarged spleen with metastatic adenocarcinoma.

this reservoir function can lead to thrombocytopenia in patients with splenomegaly. Patients with autoimmune hemolytic anemia usually have palpable splenomegaly, but patients with idiopathic (immune) thrombocytopenic purpura usually do not.

The spleen can be imaged with ultrasonography, CT,[7] traditional radionuclide scans, and PET (Fig. 168-2). Ultrasonography can provide an accurate determination of spleen size and is easy to repeat. CT frequently gives a better view of the consistency of the spleen and can identify splenic tumors or abscesses that would otherwise be missed. PET can aid in evaluating focal lesions in the spleen. The technetium-labeled liver-spleen scan can be important in identifying liver disease as the cause of splenomegaly; in patients with cryptogenic cirrhosis who are found to have thrombocytopenia, a technetium liver-spleen scan that shows higher activity in the spleen than in the liver might be the first hint of liver disease.

Because of the spleen's location and its propensity to bleed, needle aspiration or cutting needle biopsy of the spleen is rarely performed. In general, splenic "biopsy" involves splenectomy, which can be performed at the time of laparotomy or by laparoscopy. However, performing splenectomy laparoscopically usually leads to maceration of the organ and can reduce the diagnostic information. In very young children, in whom splenectomy leads to a high risk for serious infections such as pneumococcal septicemia, partial splenectomy can sometimes be performed. Patients who undergo splenectomy at the time of splenic trauma and rupture may have seeding of splenic cells to other sites in the abdomen (i.e., splenosis). Some patients have additional small or accessory spleens. Persistent, functional splenic tissue can be the explanation for recurrent immune thrombocytopenia after splenectomy and might be recognized by the absence of Howell-Jolly bodies in circulating red blood cells. Patients whose spleen has been removed often have thrombocytosis.

An Approach to the Patient with Splenomegaly

Patients with splenomegaly (Table 168-9) may come to medical attention for a variety of reasons. Patients may complain of left upper quadrant pain or fullness or early satiety. A splenic infarct, which typically manifests as left upper quadrant pain that sometimes radiates to the left shoulder, can be the first clue to the existence of an enlarged spleen. Rarely, splenomegaly initially manifests with the catastrophic symptoms of splenic rupture. Some patients are found to have splenomegaly as a result of evaluation for unexplained cytopenia. Splenomegaly can also be discovered incidentally on physical examination. In recent years, splenomegaly has frequently been discovered on imaging studies of the abdomen performed for other purposes.

The presence of a palpable spleen on physical examination is almost always abnormal. The one exception to this rule is a palpable spleen tip in a slender young woman. In general, the presence of a palpable spleen should be considered a serious finding, and an explanation should be sought. It is less clear whether the same rules apply to borderline splenomegaly discovered incidentally on routine imaging studies.

The approach to a patient with an enlarged spleen should focus initially on excluding a systemic illness that could explain the splenomegaly. Infectious mononucleosis, leukemia or lymphoma, rheumatoid arthritis, sarcoidosis,

TABLE 168-9 APPROACH TO THE PATIENT WITH SPLENOMEGALY

Does the patient have a known illness that causes splenomegaly (e.g., infectious mononucleosis)? Treat and monitor for resolution.
Search for an occult infection (e.g., infectious endocarditis), hematologic disorder (e.g., hereditary spherocytosis), occult liver disease (e.g., cryptogenic cirrhosis), autoimmune disease (e.g., systemic lupus erythematosus), or storage disease (e.g., Gaucher disease). If found, manage appropriately.
If systemic symptoms are present and suggest malignancy, focal replacement of the spleen is seen on imaging studies, and no other site is available for biopsy, splenectomy is indicated.
If none of the above is true, monitor closely and repeat studies until the splenomegaly resolves or a diagnosis becomes apparent.

cirrhosis of the liver, malaria, and a host of other illnesses would be reasonable explanations for the splenomegaly. The systemic condition should be treated, and then the spleen should be re-evaluated. If the systemic illness can be treated successfully, the spleen should regress to normal size over time.

Patients with no obvious explanation for an enlarged spleen present a difficult diagnostic problem. Careful follow-up of these patients sometimes reveals occult liver disease or an autoimmune process that initially defied diagnosis. Concerns about malignancy, particularly in patients with systemic symptoms such as fever, sweats, or weight loss or in whom imaging studies show a focal abnormality, are sometimes indications for splenectomy. However, in the absence of such findings, it is generally preferable to monitor patients closely with repeated attempts to establish the diagnosis by approaches other than splenectomy. It is particularly important to avoid splenectomy in a patient with occult liver disease and portal hypertension.

Splenectomy was once performed routinely as part of the staging evaluation for Hodgkin disease or other lymphomas. Today, this procedure is rarely needed to choose the correct therapy, and it should be avoided. Splenectomy[8,9] can be an effective therapy for immune thrombocytopenic purpura (Chapter 172) and autoimmune hemolytic anemia (Chapter 160), and it is occasionally an appropriate therapy to relieve cytopenias in other conditions such as advanced myelofibrosis (Chapter 166). Radiofrequency ablation is an alternative to surgical removal.■ Splenectomized patients are at increased risk for infections, especially Gram-positive infections, and require careful follow-up[10,11] (Chapter 281).

REVIEW QUESTIONS

1. Which of the following is the most likely diagnosis in a patient with a 4-cm firm, nubby, nontender right lower cervical lymph node in an otherwise well 26-year-old female?

A. Infectious mononucleosis
B. Systemic lupus erythematosus (SLE)
C. HIV infection
D. Hodgkin lymphoma
E. Cat-scratch disease

Answer: D When lymphadenopathy occurs in mononucleosis, HIV infection, or SLE, it tends to be generalized. The lymphadenopathy of cat-scratch disease can mimic that of a lymphoproliferative disorder but tends not to be as large and firm as in the case described here. Hodgkin lymphoma is the most likely diagnosis among these choices in an otherwise healthy young patient with a single prominent and firm enlarged node. (See Differential Diagnosis under Lymphadenopathy.)

2. After splenectomy, in addition to Howell-Jolly bodies, a peripheral smear is most likely to show which of the following?

A. Thrombocytosis
B. Toxic granulation of the neutrophils
C. Spherocytes
D. Dutcher bodies
E. Nucleated red blood cells

Answer: A A reactive thrombocytosis is often seen after splenectomy, and it may persist for months or years. Toxic granulations in neutrophils are unrelated to removal of the spleen; they are seen in infections and inflammatory states regardless of spleen status. The other morphologic findings in blood cells are not modified according to whether or not there is an intact spleen. (See Laboratory Evaluation under Splenomegaly; also see Figure 168-1.)

3. Lymph node enlargement would be unusual in a patient with which of the following?

A. Follicular lymphoma
B. Tuberculosis
C. Castleman disease
D. Waldenström macroglobulinemia
E. Multiple myeloma

Answer: E Localized or disseminated lymphadenopathy can be caused by malignant lymphoproliferative diseases (including follicular lymphoma and Waldenström macroglobulinemia; benign proliferative diseases of the immune system (including Castleman disease); and infections by bacteria, mycobacteria (including tuberculosis, fungi, chlamydia, parasites, and viruses). In contrast, multiple myeloma is a plasma cell dyscrasia (as opposed to Waldenström macroglobulinemia, which is actually a malignant lymphoproliferative disorder associated with a paraprotein) and is not characterized by lymphadenopathy. (See Differential Diagnosis under "Lymphadenopathy.)

4. Fine-needle aspiration (FNA) of a lymph node is a good way to diagnose which of the following?

A. Castleman disease
B. Hodgkin lymphoma
C. Sarcoidosis
D. Metastatic tonsil carcinoma
E. Post-transplantation lymphoproliferative disorder

Answer: D FNA is a popular and usually accurate means of diagnosing an infection or carcinoma involving a lymph node, like metastatic tonsil carcinoma. However, unequivocal diagnosis and histopathologic subtyping of lymphomas (including Hodgkin and non-Hodgkin lymphoma, such as post-transplantation lymphoproliferative disorder) or granulomatous disease (such as the noncaseating granulomas of sarcoidosis) require cutting needle or excisional lymph node biopsy, which preserves histologic architecture. (See Interventional Evaluation under Lymphadenopathy.)

5. Splenectomy early in life makes one particularly vulnerable to which of the following?

A. Pneumococcal sepsis
B. Bacterial endocarditis
C. Salmonella sepsis
D. Herpetic encephalitis
E. Severe influenza

Answer: A Splenectomy early in life makes individuals particularly susceptible to sepsis with encapsulated organisms such as *Streptococcus pneumoniae.* However, there is little if any strong evidence for susceptibility to overwhelming systemic infections with other types of bacteria or viruses. This is the rationale for the recommendations for vaccination against *S. pneumoniae* and possibly also *Haemophilus influenzae* and *Neisseria meningitidis* before splenectomy. (See Definition under Splenomegaly.)

169

DISORDERS OF PHAGOCYTE FUNCTION

MICHAEL GLOGAUER

Neutrophils and monocyte-macrophages are the key phagocytes of the innate immune system. Their principal innate immune role is to recognize and eliminate microorganisms that make their way past primary physical barriers, such as the epithelium and body secretions that protect the external and lining surfaces of the body. The neutrophil-pathogen interaction generates an army of antimicrobial mediators that results in efficient killing of pathogens.[1] Phagocytes identify foreign invaders through a series of pattern recognition receptors, most of which belong to the toll-like receptor family (Chapters 45 and 48). Whereas macrophages carry out sentinel duty looking for microbes in healthy tissue and act as a bridge between the innate and

adaptive immune systems, neutrophils appear only in infected or damaged tissue after being recruited by inflammatory mediators released from activated macrophages and endothelial cells or by chemical signals released by invading microorganisms themselves (Table 169-1). After accumulation of these key immune cells at sites of infection, the microbes are eliminated through the process of phagocytosis, which is defined as the engulfment, internalization, and degradation of extracellular material.

NEUTROPHILS

Neutrophils develop in the bone marrow from myeloid precursors, migrate into the circulation, and, if required, make their way into infected or damaged tissue (Fig. 169-1). Their travels are essentially one-way trips because once they leave a compartment, they do not return. After release from the bone marrow compartment, a mature neutrophil has a blood half-life of 10 hours and may survive up to an additional 48 hours within infected or damaged tissue.

The Bone Marrow Compartment: The Site of Granulopoiesis

Neutrophils are the most abundant white blood cell and account for up to 70% of circulating leukocytes. Neutrophil numbers can increase rapidly by as much as 5- to 10-fold during periods of acute infection with a rate of continuous supply by the bone marrow of $5 \times 10^{10} - 10 \times 10^{10}$ neutrophils/day. Because these cells have a very short half-life in blood, the bone marrow compartment provides a steady supply of mature neutrophils with the capability to upregulate cell production rapidly during times of infection. Neutrophils originate in the bone marrow from a common population of hematopoietic stem cells through a 10- to 14-day process of proliferation, differentiation, and maturation (Chapter 156).

Steps in Granulopoiesis

The stages of neutrophil granulopoiesis in the bone marrow (Fig. 169-2) are identified by the major transitions from the pluripotent stem cell to the mature neutrophil. The *myeloblast* is the first recognizable progenitor cell committed to granulopoiesis. This proliferating cell is characterized by its large nucleus and agranular cytoplasm. The *promyelocyte* follows and displays the initial development of primary granules. *Myelocytes* occupy the next stage of neutrophil maturation and are characterized by development of the first specific or "secondary" (peroxidase-negative) granules. *Metamyelocytes,* which follow myelocytes, are incapable of further mitosis and are readily identifiable by their now numerous cytoplasmic granules. The functional maturation of metamyelocytes results in the development of *band* cells, which are usually slightly larger than mature neutrophils and have a horseshoe-shaped nucleus and a moderate to abundant supply of specific granules. Band cells can be found in the circulation during periods of acute infection. The final mature *neutrophil,* which is released into the circulation, has a diameter of approximately 10 μm with a characteristic nucleus that is segmented and multilobed and occupies about 20% of the cell's volume; the remaining

The three major neutrophilic compartments (bone marrow, vascular, and tissue compartments) and the various steps involved in recruiting neutrophils to sites of infection are shown. ICAM = intercellular adhesion molecule; PECAM = platelet endothelial cell adhesion molecule; VCAM = vascular cell adhesion molecule.

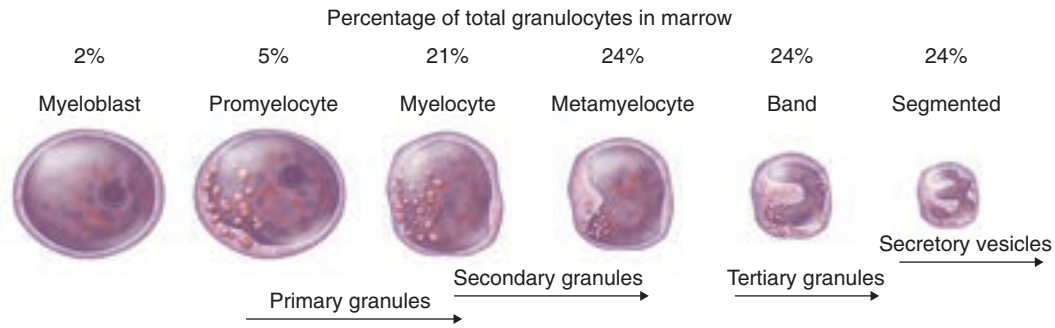

FIGURE 169-2. Cellular stages of granulopoiesis in bone marrow.

cytoplasm is taken up by granules. The distinctiveness of the granules reflects differences in content; as a result, granules formed at different stages carry specific types of matrix and membrane proteins.

Defects in granulopoiesis are manifested clinically as low circulating levels of neutrophils (neutropenia; Chapter 167). Verification of the stage at which neutrophil developmental arrest occurs can be determined by a bone marrow biopsy to assess the cellularity and characteristics of the neutrophil precursors present in the marrow space.

Regulation of Granulopoiesis

Granulopoiesis is driven by hematopoietic growth factors (Chapter 156). These factors, which are synthesized by a variety of cells, including fibroblasts and endothelial cells, are known to work together with other regulatory molecules, such as cytokines, to regulate hematopoiesis. Hematopoietic growth factors such as *interleukin-3* (IL-3), *granulocyte-macrophage colony-stimulating factor* (GM-CSF), and *granulocyte colony-stimulating factor* (G-CSF) bind to their target cells through specific receptors and are critical for the hematopoietic system to respond rapidly to infection or inflammation by dramatically increasing the production of leukocytes.

G-CSF is a potent cytokine that influences the proliferation, survival, maturation, and functional activation of cells from the neutrophil-granulocyte lineage. In normal individuals, circulating levels of G-CSF are very low (<100 pg/mL). However, in conditions of stress, G-CSF levels can rise to 20 times baseline levels, thereby resulting in a rapid increase in circulating neutrophils. G-CSF may regulate this increased granulopoiesis by increasing the mitotic pool at the promyelocyte and myelocyte stages and shortening neutrophil transit time in bone marrow.

Neutrophil Granules

One of the major mechanisms used by neutrophils to eliminate bacteria is a remarkable arsenal of antimicrobial proteins that are packed into cytoplasmic granules (Table 169-2). These antimicrobial proteins are securely contained within their respective granules and are released only when granules fuse with phagosomes or directly with the plasma membrane. Granulogenesis begins between the myeloblast and promyelocyte stages of neutrophil development and continues throughout the differentiation and maturation process of the cell. *Azurophilic* granules, which make up 30% of granules in a mature neutrophil, are the first to appear at the promyelocyte stage; they contain hydrolytic enzymes, microbicidal peptides, and myeloperoxidase. During phagocytosis, azurophil granule degranulation is restricted to internalization of phagocytic vacuoles. The *secondary,* or specific, granules appear later, beginning at the metamyelocyte stage; they are twice as abundant in the cytoplasm as azurophilic granules and contain proteins such as collagenase and lactoferrin. The *gelatinase-containing,* or *tertiary,* granules also appear at the metamyelocyte stage. A fourth group of granules, *secretory vesicles,* appears at the very final stages of neutrophil maturation, immediately before release of the cell into the circulation. All the granule types contain membrane proteins such as CR1, CR3, CD45, CD11c, and fMLP (*N*-formyl-methionyl-leucyl-phenylalanine) receptors, which are rapidly transported to the plasma membrane during activation to enhance neutrophil microbicidal activity.

A number of clinical conditions result from specific defects in granule development and formation. Initial assessment for granule defects can be made by microscopic evaluation of a peripheral blood smear (Chapter 157). Examples of obvious clinical diagnoses made with the peripheral smear include specific granule deficiency, which is characterized by bilobed nuclei in more than 80% of the neutrophils, and a significant decrease in cytoplasmic granularity. Abnormally large cytoplasmic granules are seen in individuals with Chédiak-Higashi syndrome.

The Vascular Compartment

Mature neutrophils are released from the postmitotic bone marrow compartment into the circulation, where they have an approximate lifespan of 8 to 12 hours and either circulate within the center of the blood vessel or attach to its endothelial lining, a process termed *margination*. Marginated neutrophils on the vessel walls are able to detach and reenter the circulation when required. For example, corticosteroids and epinephrine induce a rapid increase in circulating neutrophils by releasing neutrophils from the marginated pool. Neutrophils circulate until they are recruited to a site of infection. The initial phase of recruitment involves changes in the endothelial cell surface receptors lining the capillary beds closest to the site of infection or tissue damage. These critical changes in endothelial cells are mediated by immune regulators released by tissue macrophages, which initially detect the tissue damage or bacterial invasion. Emigration of circulating neutrophils from the vasculature to the site of infection or tissue damage requires three steps (see Fig. 169-1): capture and margination, firm adhesion to the endothelial wall, and diapedesis.

Margination and Capture

The marginated pool of neutrophils consists of neutrophils transiently retained against the walls of pulmonary capillaries and postcapillary venules. In the 20-μm diameter of a postcapillary venule, the smaller and faster circulating red blood cells displace the slower moving and larger neutrophils, which move to the vessel margins, where a low-affinity molecular interaction occurs between surface adhesion molecules of the neutrophil and the endothelial cells. This interaction results in neutrophil rolling and capture along the vessel walls, an event that requires the specific neutrophil receptors *leukocyte selectin* (L-selectin) and the corresponding endothelial ligand, sialyl Lewis (sLe). L-selectin is constitutively expressed in neutrophils, with highest expression in young circulating neutrophils and gradual decline with a cell's age, probably because previous margination events have depleted the receptor. The endothelial ligand for L-selectin, sLe, is a sialylated carbohydrate linked to a mucin-like molecule that can be upregulated by bacterial lipopolysaccharide or other mediators of inflammation. The selectin-ligand interactions are reversible and serve to promote and maintain accumulation of circulating neutrophils on inflamed endothelium.

TABLE 169-2 MEMBRANE AND MATRIX COMPONENTS OF NEUTROPHILIC GRANULES

COMPONENT	AZUROPHIL GRANULES (PRIMARY; PEROXIDASE POSITIVE)	SPECIFIC GRANULES (SECONDARY; PEROXIDASE NEGATIVE)	GELATINASE GRANULES (TERTIARY; PEROXIDASE NEGATIVE)	SECRETORY VESICLES
Antimicrobial proteins	Defensins Lysozyme Elastase Myeloperoxidase Cathepsin G	Lysozyme Lactoferrin	Lysozyme

Adherence to the Endothelial Wall

Low-affinity, selectin-mediated transient interactions must be replaced by high-affinity, adhesive contacts between neutrophils and endothelial cells. During an acute inflammatory event, mediators derived from bacteria, damaged host cells, complement activation, or other immune cells are released from the site of infection and diffuse to the capillary beds, where they induce an immediate and transient vascular response that results in vascular leakage, which further encourages neutrophil margination. Endothelial cells adjacent to the site of inflammation, as well as the activated neutrophils that are bound to them, express integrin receptors that lead to high-affinity attachments between the neutrophils and endothelial cells. These high-affinity connections occur between neutrophil *β2 integrins* and their endothelial counterparts, the intercellular adhesion molecules (ICAMs). Integrins, which are a receptor family of heterodimeric transmembrane glycoproteins made up of an α- and β-subunit, are integral for cell adhesion. Neutrophil β2 integrins consist of three different α-subunits (CD11a, CD11b, and CD11c) that bind to a common β-subunit (CD18). The cytoplasmic tails of these transmembrane receptors possess phosphorylation sites for attachment of signal transduction and cytoskeletal proteins. The neutrophil integrins that mediate this adhesion step are *macrophage antigen-1* (Mac-1; CD11b/CD18) and *lymphocyte-associated function antigen-1* (LFA-1; CD11a/CD18). The receptors are stored in the neutrophil granule compartments to facilitate quick transfer to the plasma membrane during cell stimulation. The integrins bind to endothelial ICAM-1 and ICAM-2 and *vascular cell adhesion molecule-1* (VCAM-1), which are upregulated on the endothelial cell membranes when a cell is exposed to inflammatory cytokines. L-selectin receptors on neutrophils are concentrated on microvillus projections of the cell membrane, whereas the integrins are restricted to the body of the neutrophil. As a result, soon after initial contact during rolling interactions, the projections retract, thereby allowing integrins to interact with their ligands.

Diapedesis

Firm adherence through the L-selectin and integrin receptors facilitates transendothelial migration, or diapedesis, which marks the "point of no return" in the process of neutrophil recruitment to the site of injury. Unlike rolling and firm adhesion, which require heterophilic interactions between one class of molecules on the neutrophil and another class of molecules on the endothelial cell, diapedesis involves homophilic interactions between the same class of molecules on both cells—the *platelet-endothelial cell adhesion molecule-1* (PECAM-1 or CD31). PECAM-1 is expressed evenly on the surface of neutrophils and is concentrated at endothelial cell junctions. When they are firmly bound to the endothelial cell surface, neutrophils migrate between the closest tricellular endothelial cell junctions through interactions with PECAM-1 receptors. The neutrophil has now entered the tissue compartment, where it is primed for its final critical role in the elimination of microorganisms and cellular debris.

Laboratory Evaluation of Margination and Firm Adhesion

A defect in neutrophil margination or adhesion to the endothelial lining of the vascular compartment results in neutrophilia (elevated circulating neutrophil levels). This condition is usually associated with leukocyte adhesion deficiency (LAD), which is the result of a lack of CD11/CD18 receptor surface expression in peripheral blood neutrophils. If LAD is suspected, surface expression of these receptors can be measured with a flow cytometer and specific antibodies to CD11, CD18, or CD15 receptors.

The Tissue Compartment

Chemotaxis

Chemotaxis is the directed movement of cells up a chemical concentration gradient of a *chemoattractant.* Chemoattractants are soluble proteins or peptides, including bacterial products, complement factors, and chemokines produced by both inflammatory and noninflammatory cells, that are released from damaged or infected tissue. A concentration difference of 1% at the opposite ends of the neutrophil is sufficient to activate neutrophil chemotaxis. After a chemoattractant binds to its corresponding neutrophil membrane receptor, a series of cytoplasmic signaling pathways leads to activation of the neutrophil cytoskeleton. This activation results in the neutrophil assuming a polarized state characterized by an actin-rich leading lamella or pseudopod that drives cell motility.

Directional cell crawling, the intrinsic basis of chemotaxis, can be broken down into smaller processes, including extension of the cell membrane, adhesion to the tissue matrix, and contraction of the cell body in an organized and reversible manner. The actin-dependent protrusion of the leading edge, which is a sheetlike structure rich in actin filaments, is critical for normal neutrophil motility. The actin filaments within these lamellar regions are assembled into highly organized structures that push the membrane forward. These structures are formed by different collections of actin-binding proteins under the regulation of specific signal transduction cascades linking chemotactic receptors with cell movement. Defects in actin assembly also result in defects in chemotaxis and recurrent infections.

Actin Assembly Biology

Actin filaments are polar structures, with each end differing in its equilibrium-binding constant for actin monomers (Fig. 169-3). Filaments grow at the high-affinity or barbed end, whereas depolymerization occurs at the low-affinity or pointed end. This difference, generated by the ability of actin to bind and hydrolyze adenosine triphosphate, provides a physical polarity that regulatory proteins use to drive filament dynamics with high temporal and spatial precision. Three classes of proteins regulate the availability of high-affinity actin filament ends: filament-nucleating proteins (e.g., ARP2/3 de novo nucleation), filament-capping proteins (e.g., gelsolin), and filament-severing proteins (e.g., cofilin). Actin-nucleating factors bind actin monomers under conditions otherwise unfavorable for assembly and generate a new filament with a free high-affinity end available for assembly. Actin filament-capping proteins bind to the high-affinity filament end and regulate the addition of monomers by their presence or absence at the end of the filament. Actin-binding proteins are regulated by various second messengers,

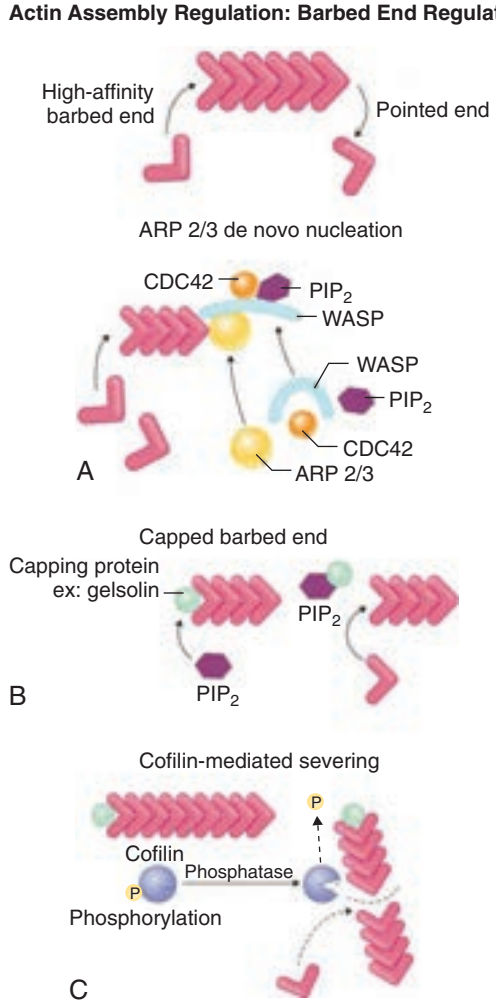

FIGURE 169-3. Regulation of actin assembly through the generation of free barbed ends by actin-binding proteins. A, The components below join together to form a nucleation complex (above). **B,** PIP_2 binds the capping protein, leading to its removal from the high-affinity end, allowing for addition and filament growth. **C,** A phosphatase removes the P from cofilin, thereby allowing it to sever the actin filament and leaving a free high-affinity end. PIP_2 = phosphatidylinositol 4,5-biphosphate; WASP = Wiskott-Aldrich syndrome protein.

including calcium. On stimulation, localized changes in the intracellular Ca^{2+} concentration lead to the rapid initiation of actin assembly and disassembly. The changes in actin filament length and the extent of cross-linkage between the filaments may account for the directional extension of actin-rich lamellae and contraction of the tail-like uropod at the other end of the cell. Movement in the neutrophil is therefore the result of lamellar protrusions resulting from the growth of actin filaments. Actin-rich lamellae will continue to be maintained as long as the neutrophil detects the chemoattractant gradient.

Laboratory Evaluation of Chemotaxis

A defect in neutrophil chemotaxis can be measured in the laboratory with a Boyden chamber, which uses a porous membrane to separate isolated neutrophils from a chemoattractant. A chemical gradient develops across the porous membrane and activates the neutrophils to crawl through the membrane toward the compartment containing the chemoattractant. Defects in chemotaxis can be determined by a lack of neutrophil transmigration through the membrane compared with control neutrophils from a healthy donor.

Phagocytosis

Phagocytosis is the process whereby neutrophils engulf and internalize invading pathogens into membrane compartments called *phagosomes*. Bacterial targets are "highlighted" or opsonized by antibodies (immunoglobulin G) or products from the classical complement pathway that coat the target and serve to mediate phagocytic adhesion. Neutrophilic phagocytosis involves two separate classes of receptors: *Fcγ receptors* (CD32 and CD16) for antibody-coated targets and *complement receptors* (CR1 and CR3) for complement-coated targets. CD32 and CR3 are functional receptors directly involved in neutrophilic phagocytosis, whereas CD16 and CR1 are coreceptors that assist their mate in completing binding and internalization. Activation of Fcγ receptors brings about phosphorylation of their cytoplasmic *immunoreceptor tyrosine-based activation motifs* (ITAMs) through activation of *Src family kinases;* the result is transduction of signals that induce extension of pseudopods, including signaling to the small Rho family of small guanosine triphosphatases (GTPases). These GTPases are responsible for the assembly of actin filaments, thereby leading to remodeling of the plasma membrane and the formation of actin-rich pseudopods, which are essential for the ingestion of particles and formation of phagosomes.

Laboratory Evaluation of Phagocytosis

Neutrophils can be incubated with fluorescently labeled bacteria after opsonization with serum from either the patient or a control. Phagocytosis is assessed by flow cytometry, which measures the increase in neutrophilic fluorescence after uptake of the fluorescently tagged bacteria.

Bacterial Killing

Phagocytes use two potent mechanisms for killing bacteria within the membrane-bound phagosome. The first involves fusion of the previously described storage granules with the phagosome to deliver microbicidal and lytic enzymes into the membrane compartment that contains the ingested microorganisms. The second mechanism uses a multiprotein enzyme complex to generate microbicidal oxidants through partial reduction of oxygen. The multiprotein enzyme complex known as reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase generates oxidants by means of oxygen consumption, hence the term *respiratory burst*.

The NADPH enzyme system is made up of four essential polypeptide subunits that are denoted by their molecular weight (kD) and the superscript phox, which denotes phagocyte oxidase. Within the cytoplasmic membrane, the subunits $p22^{phox}$ and $gp91^{phox}$ bind the electron-carrying components of the oxidase (NADPH, a flavin adenine dinucleotide, and two nonidentical hemes) and form the cytochrome b_{558} redox center of the oxidase complex. Cellular activation by inflammatory mediators results in the addition of two cytosolic components, $p47^{phox}$ and $p67^{phox}$, to the complex along with the Rac small guanosine triphosphatase (GTPase).

The membrane-bound electron transport chain NADPH oxidase catalyzes the reduction of molecular oxygen to superoxide (O_2^-). The superoxide generated by this process is in turn catalytically converted to hydrogen peroxide and serves as a cosubstrate for myeloperoxidase to oxidize halides and to produce hypochlorous acid (HOCl), a very potent antimicrobial agent. These oxidants are able to kill bacteria within the phagosomes by oxidizing their cellular constituents.

Laboratory Evaluation of the Respiratory Burst and Bacterial Killing

Flow cytometry, a rapid and effective method for quantitatively assessing the respiratory burst, measures the fluorescence generated by cytoplasmic fluorescent probes such as dihydrorhodamine, which is converted to rhodamine by H_2O_2. The nitroblue tetrazolium (NBT) test is still used for rapid assessment of the respiratory burst when flow cytometry is not available.

Bacterial killing assays using a patient's neutrophils with either the patient's or control serum and bacteria such as *Staphylococcus aureus* or *Escherichia coli* are a definitive method to determine whether a given patient's neutrophils have an intracellular killing defect. Neutrophils from a healthy control subject phagocytose and kill approximately 95% of the bacteria within 2 hours. In assays in which an intracellular killing defect is present, neutrophils kill less than 10% of bacteria over a 2-hour period. It is necessary to confirm that there is no phagocytic defect before performing the bacterial killing assay to be sure that any defect in bacterial killing is not due to an internalization defect.

Neutrophil Extracellular Traps

Neutrophils use an extracellular process to contain and kill bacteria. Neutrophil extracellular traps (NETs) are formed by the release of chromatin and antimicrobial proteins from the neutrophil cytoplasm and granules. The chromatin forms a netlike meshwork that traps the bacteria and brings them in closer proximity to the antimicrobial elements adhered to the chromatin. Activation of NET formation requires simultaneous activation by at least two different receptors, and reactive oxygen species are essential to the process. IL-8 has been shown to be a potent activator of NET formation. The importance of NETs was highlighted by work showing that DNase expressing strains of group A streptococcus (GAS) and *Streptococcus pneumoniae* are more virulent than their non-DNase-expressing counterparts because of their ability to escape NETs.

CLINICAL MANIFESTATIONS

In addition to fever and recurrent infections, the most common findings in patients with phagocytic defects are oral infections resulting in gingival inflammation, periodontal bone loss, mobile or loose teeth, and premature loss of teeth (Table 169-3). An oral examination should be performed at the initial evaluation, followed by a full dental examination, depending on the findings. The history and laboratory tests can differentiate among the various clinical causes of disordered phagocytosis (Table 169-4).

DEFECTS IN LEUKOCYTE ADHESION

A defect in neutrophil adhesion to the endothelial lining leads to neutrophilia—an accumulation of neutrophils in the circulation, with very few neutrophils at sites of infection. Defects in neutrophil adhesion can be induced by drugs or due to a genetic defect. Drugs such as corticosteroids and epinephrine result in a transient leukocyte adhesive defect that results in an apparent dramatic increase in circulating neutrophils because of release of the marginated neutrophil pool. The major genetic disease that results in an adhesion deficiency is termed *leukocyte adhesion deficiency.*

Leukocyte Adhesion Deficiency

LAD-1

PATHOBIOLOGY

LAD-1 is an autosomal recessive inherited disorder in which patients have a mutation in the gene encoding CD18. The result is a deficiency of β2 integrin

TABLE 169-3 SYMPTOMS SUGGESTIVE OF A PHAGOCYTIC DISORDER

Recurrent infections that fail to resolve with conventional treatment
Recurrent infections of unusual severity
Recurrent infections in the lung, liver, or bone
Normally nonpathogenic bacteria or fungi identified in cultures from the infection sites
Aphthous ulcers
Severe periodontal diseases, including gingivitis
Lymphadenopathy or hepatosplenomegaly
Severe recurrent cutaneous infections with *Staphylococcus aureus*
Recurrent mycobacterial infections

receptors, which are required for neutrophil migration from the vasculature into the tissues, thereby impairing the binding of neutrophils to C3bi and endothelial ICAM-1 and ICAM-2. Indications of the disorder are high resting neutrophil counts accompanied by frequent dissemination, sepsis, and recurrent infections.[2]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations in patients diagnosed with LAD-1 include delayed separation of the umbilical cord, bacterial and fungal infections, delayed wound healing, impaired pus formation, and severe destructive periodontitis with rapid tooth loss. Patients usually die during childhood. Flow cytometry is used to measure CD11/CD18 surface expression levels on neutrophils.

TREATMENT

Rx

Treatment is mainly supportive of early intervention for periodontal disease with prophylactic antibiotics in patients with recurrent infections. In severe cases, bone marrow transplantation is the treatment of choice.[3]

LAD-2 AND LAD-3

LAD-2, a variant of LAD-1, is associated with neutrophilia, the Bombay (hh) blood phenotype, dwarfism, and mental retardation. This disorder is due to a mutation in the guanosine diphosphate-fucose transporter gene, which

TABLE 169-4 DISORDERS OF PHAGOCYTIC FUNCTION

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
DEGRANULATION ABNORMALITIES			
Chédiak-Higashi syndrome	Autosomal recessive; disordered coalescence of lysosomal granules Responsible gene found at 1q42-45. The encoded protein (LYST) has structural features homologous to a vacuolar sorting protein	Decreased neutrophilic chemotaxis, degranulation, and bactericidal activity; platelet storage pool defect; impaired NK function; failure to disperse melanosomes	Neutropenia, recurrent pyogenic infections, propensity for the development of marked hepatosplenomegaly in the accelerated phase, partial albinism
Specific granule deficiency	Autosomal recessive; abnormal regulation of various myeloid granule genes by a transacting factor	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; reduced content of neutrophil defensins, gelatinase, collagenase, vitamin B_{12}–binding protein, and lactoferrin	Recurrent infections, especially sinopulmonary and skin infections
ADHESION ABNORMALITIES			
Leukocyte adhesion deficiency type 1	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoprotein (β2-integrins) on leukocyte membranes, most commonly arising from failure to express CD18 mRNA	Decreased binding of C3bi to neutrophils and impaired adhesion to ICAM-1 and ICAM-2	Neutrophilia, recurrent bacterial infection associated with lack of pus formation
Leukocyte adhesion deficiency type 2	Autosomal recessive; absence of neutrophil sialyl-$Lewis^x$	Decreased adhesion to activated endothelium expressing ELAM	Neutrophilia, recurrent bacterial infection without pus
Leukocyte adhesion deficiency type 3	Autosomal recessive; defects in activation of β1, β2, and β3 integrins	Severe leukocyte adhesion dysfunction; abnormal platelet aggregation	Neutrophilia, recurrent bacterial infection without pus, severe bleeding tendency
Neutrophil actin dysfunction	Altered polymerization of neutrophil cytoplasmic actin, perhaps arising from the presence of an inhibitor to F-actin formation	Impaired neutrophil adhesion, chemotaxis, and bacterial killing	Neutrophilia, recurrent bacterial infections without pus
DISORDERS OF CELL CHEMOTAXIS			
Hyperactive Chemotaxis			
Familial Mediterranean fever (FMF)	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called pyrin; pyrin may modify neutrophil activation	Excessive accumulation of neutrophils at inflamed sites	Recurrent fever, peritonitis, pleuritis, arthritis, amyloidosis
Depressed Chemotaxis			
Intrinsic defects of the neutrophil, e.g., leukocyte adhesion deficiency, Chédiak-Higashi syndrome, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils	In the neonatal neutrophil, there is diminished ability to express β2 integrins and a qualitative impairment in β2 integrin function	Diminished chemotaxis	Propensity for the development of pyogenic infections
Direct inhibition of neutrophil mobility, e.g., drugs	Ethanol, glucocorticoids, cyclic AMP	Impaired locomotion and ingestion, impaired adherence	Possible causes of frequent infections; neutrophilia seen with epinephrine is the result of cyclic AMP release from the endothelium
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory states	Impaired chemotaxis	Recurrent pyogenic infections
Hyperimmunoglobulin E syndrome	Disorders of cytokine signaling, most commonly due to autosomal dominant mutations in the *STAT3* gene	Impaired chemotaxis, impaired IgG opsonization of *Staphylococcus aureus*	Recurrent skin and sinopulmonary infections
DEFECTS OF MICROBICIDAL ACTIVITY			
Chronic granulomatous disease (CGD)	X-linked and autosomal recessive; failure to express functional $gp91^{phox}$ (in the phagocyte membrane) and $p22^{phox}$ (autosomal recessive). Other autosomal recessive forms of CGD arise from failure to express protein $p47^{phox}$ or $p67^{phox}$	Failure to activate neutrophil respiratory burst leading to failure to kill catalase-positive microbes	Recurrent pyogenic infections with catalase-positive microorganisms
G6PD deficiency	Less than 5% of normal activity of G6PD	Failure to activate NADPH-dependent oxidase	Infections with catalase-positive microorganisms

TABLE 169-4 DISORDERS OF PHAGOCYTIC FUNCTION—cont'd

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense mutation	H_2O_2-dependent antimicrobial activity not potentiated by myeloperoxidase	None
Deficiencies of glutathione reductase and glutathione synthetase	Failure to detoxify H_2O_2	Excessive formation of H_2O_2	Minimal problems with recurrent pyogenic infections
IMPAIRED MACROPHAGE FUNCTION			
Defects in the interferon-γ–IL-12 axis	Interferon-γ receptor ligand-binding chain, interferon-γ receptor signaling chain, IL-12 receptor β_1 chain, IL-12 p40 deficiency; the interferon-γ receptor abnormalities may be autosomal dominant or recessive; the IL-12 receptor and IL-12 abnormalities are autosomal recessive	Impaired killing of microorganisms. Fatal BCG infection secondary either to an inability to produce IL-12 by dendritic cells and macrophages or to depressed bactericidal activity of macrophages lacking normal function of the interferon receptor	Infection with atypical mycobacteria, *Salmonella*, and *Listeria*
Hemophagocytic lymphohistiocystosis (HLH) and macrophage activation syndrome (MAS)	Primary inherited form with mutations in perforin gene and genes involved in exocytosis; secondary acquired forms associated with infections, malignancies, and (in MAS) rheumatologic disorders.	Hyperinflammatory state and hypercytokinemia; impairment of NK and cytotoxic T-cell function.	Fever, hepatosplenomegaly, pancytopenia, pulmonary and neurologic complications, increased serum ferritin and triglycerides

AMP = adenosine monophosphate; BCG = bacille Calmette-Guérin; ELAM = endothelial leukocyte adhesion molecule; G6PD = glucose-6-phosphate dehydrogenase; ICAM = intracellular adhesion molecule; IL-12 = interleukin-12; NADPH = nicotinamide adenine dinucleotide phosphate; NK = natural killer; phox = phagocyte oxidase.
Modified from Boxer LA. Quantitative abnormalities of granulocytes. In: Beutler E, Lichtman MA, Coller BS, et al, eds. *Williams Hematology*, 6th ed. New York: McGraw-Hill; 2001:836.

results in impaired expression of CD15s and other selectin ligands. Symptoms are similar to those of LAD-1, and the diagnosis is confirmed by flow cytometry for CD15s.

In the most recently described LAD-3,[4] there is a primary activation defect in all three β integrins (β1, β2, and β3), and mutations have been found in kindlin-3, which binds the cytoplasmic tail of integrin. Clinical manifestations include defects in platelet activation and severe bleeding tendency. Treatment includes blood transfusion during a bleeding episode.

DEFECTS IN NEUTROPHILIC CHEMOTAXIS

After phagocytes enter the tissue compartment from the vascular pool, they migrate up the concentration gradients of various chemoattractants to the site of focal infection. A number of chemotactic defects result in severe recurrent infections.

Hyperimmunoglobin E Syndrome

PATHOBIOLOGY

Hyperimmunoglobin E syndrome, or hyper-IgE syndrome, also referred to as Job syndrome, is a group of genetically diverse, multisystem disorders of cytokine signaling. The most common form of the syndrome involves dominant mutations in the gene for signal transducer and activator of transcription-3 (*STAT3*). Hyper-IgE syndrome is prevalent among white, Asian, and African populations, with equal frequency among males and females.[5]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The neutrophilic disorder is characterized by recurrent skin abscesses, pneumonia, and periodontal diseases. After birth, patients usually have moderate to severe dermatitis, eczematous skin eruptions, nonerythematous abscesses, pneumatoceles, and severe osteoporosis that can result in bone fractures. The organisms most commonly present at infected sites are *Staphylococcus aureus, Haemophilus influenzae, Escherichia coli,* and *Candida albicans.* Patients have elevated IgE levels (typically >1000 IU/mL) and eosinophilia. The defect in neutrophilic chemotaxis is less severe than that in Chédiak-Higashi syndrome (see later). Genetic testing of the *STAT3* gene, in conjunction with characteristic manifestations, such as immunologic and infectious complications and involvement of skeletal and connective tissue, is imperative to confirm diagnosis.[6] With implementation of prophylactic measures, accompanied by IgG infusion, good long-term prognosis can be seen.

TREATMENT

Rx

Treatment includes prophylactic antibiotics, antifungal prophylaxis, IgG infusions, and aggressive treatment of infections.[7] In severe cases, hematopoietic stem cell transplantation may be considered.

Familial Mediterranean Fever

PATHOBIOLOGY

Familial Mediterranean fever, further discussed in Chapter 261, also known as recurrent polyserositis, is an autosomal recessive autoinflammatory disease that is widespread among people of Mediterranean descent, including Arabs, Armenians, and Sephardic Jews.[7] The genetic defect is a missense mutation in the *MEFV* gene, which encodes the protein pyrin. Pyrin is believed to be a transcription factor involved in downregulating inflammation, possibly through an effect on chemotaxis in neutrophils and monocytes. The *MEFV* mutation results in a hyperinflammatory response characterized by abundant neutrophilic infiltration into the peritoneal, pleural, and joint spaces.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common findings include acute, self-limited attacks of fever accompanied by pleuritis, peritonitis, arthritis, pericarditis, and erythematous skin lesions. Although first attacks may be observed during infancy, onset of clinical disease usually occurs in childhood or adolescence, with a relatively small number of adult-onset cases.

Leukocytosis has been observed during attacks, but the leukocyte count is normal between episodes. Genetic testing is available for the most common mutations. This disease can be fatal if renal failure develops as a result of amyloidosis (Chapter 188), which occurs in up to 25% of those affected.

TREATMENT

Rx

The hyperinflammatory attacks can be reduced significantly and even the complications of amyloidosis can be prevented[8] with prophylactic colchicine, 0.6 mg orally two or three times daily, up to a maximum dose of 2.0 to 2.4 mg if needed and if tolerated. The prognosis is generally good for most affected individuals maintained with colchicine. Rilonacept, an IL-1 decoy receptor, has been found to reduce frequency of attacks and is a treatment option for patients with colchicine-resistant or -intolerant disease.

DISORDERS OF NEUTROPHILIC DEGRANULATION

Granules supply key membrane proteins, including receptors required for phagocytosis. Granule-related defects result in profound abnormalities in bacterial killing.

Chédiak-Higashi Syndrome

PATHOBIOLOGY

Chédiak-Higashi syndrome is a rare autosomal recessive disorder of the *LYST* gene, which encodes a protein responsible for lysosomal trafficking. Defective targeting of granules to the membrane results in large cytoplasmic

granules that are unable to target to the plasma membrane in neutrophils, monocytes, and lymphocytes.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are recurrent bacterial infections of the skin, mouth, and respiratory tract; partial albinism; peripheral neuropathy; and mild bleeding disorders as a result of a deficiency in serotonin- and adenosine phosphate–containing granules in platelets. Defects in myelopoiesis result in neutropenia. Death usually occurs by 7 years of age because of infection. Advanced disease is characterized by lymphocytic tissue infiltrates and pancytopenia.

Giant cytoplasmic granules are seen in the peripheral blood smear. Neutrophil function testing shows defects in chemotaxis and bacterial killing.

TREATMENT Rx

Prophylactic antibiotics should be used to prevent infections. Bone marrow transplantation from an HLA-matched donor may be successful if performed before the disease becomes advanced.

Specific Granule Deficiency

PATHOBIOLOGY

Specific granule deficiency (SGD) is an autosomal recessive disorder that manifests during infancy as the recurrent appearance of deep and superficial skin infections, respiratory infections, and abscesses. Azurophilic granules in neutrophils lack lactoferrin, defensins, gelatinase, collagenase, cytochrome *b*, and vitamin B_{12}-binding protein. Neutrophils are morphologically altered and have a bilobed rather than a trilobed nucleus.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

This disorder is characterized by impaired neutrophil chemotaxis, reduced respiratory burst, and a defect in bacterial killing. Infections are commonly caused by *S. aureus, Pseudomonas aeruginosa,* and *C. albicans.* Flow cytometry is used to determine deficiency in lactoferrin and vitamin B_{12}-binding protein for diagnosis.

TREATMENT Rx

Treatment includes administration of parenteral antibiotics and drainage for infections. With aggressive treatment of infections, survival into adulthood is possible.

DISORDERS OF OXYGEN-DEPENDENT BACTERIAL KILLING

A genetic defect in any component of the respiratory burst results in delayed or ineffective bacterial killing.

Chronic Granulomatous Disease

PATHOBIOLOGY

Chronic granulomatous disease (CGD) is a genetic disease that occurs in about 1 in 200,000 live births. Neutrophils and macrophages cannot generate superoxide and are therefore unable to kill catalase-positive organisms. This condition results from mutations in one of the four structural genes of the NADPH oxidase complex. The most common genetic defect occurs in the 91-kD component of cytochrome b_{558}, which is coded on the X chromosome. The other mutations are autosomal recessive and have been detected in the 22-, 47-, and 67-kD structural proteins.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Children are prone to infections or granulomatous lesions in the lungs, skin, and liver. *S. aureus* is the most common organism, but other organisms include *Serratia marcescens, Burkholderia cepacia, Aspergillus* species, and *Nocardia* species. Staphylococcal liver abscesses are pathognomonic of CGD. Flow cytometry is used to measure the increase in fluorescence generated when dihydrorhodamine is converted to rhodamine by H_2O_2.

TREATMENT Rx

Abscesses can be removed by surgery. Trimethoprim-sulfamethoxazole prophylaxis (5 mg/kg/day divided into two equal doses) and antifungal prophylaxis with itraconazole (100 mg/day for <50 kg, 200 mg/day for >50 kg) have been shown to reduce the frequency of infections in these patients. Interferon-γ (50 μg/m^2 subcutaneously three times per week) prophylaxis is now considered "standard of care" in many centers. Bone marrow transplantation can also be considered for patients with refractory infections.[9] Gene therapy for CGD by gene-modified autologous hematopoietic stem cell transplantation has resulted in transient immune restoration but also genomic instability, monosomy 7, and clonal progression toward myelodysplasia. Future trials will be required to determine the role of gene therapy in clinical care.

Myeloperoxidase Deficiency

PATHOBIOLOGY

Myeloperoxidase (MPO) deficiency is a relatively common disorder (1 in 4000) in which the enzyme for conversion of neutrophilic hydrogen peroxide to HOCl is absent. This deficiency is not associated with increased susceptibility to infections, probably because of the accumulation of hydrogen peroxide, which is also bactericidal. Several genes have been reported to cause MPO deficiency, including *R569W*, *Y173C*, and *M251T*. The most common gene mutation related to MPO deficiency is the *R569W* gene, associated with the absence of MPO in neutrophils. Less frequently, patients with a mutation in *Y173C* gene have MPO that cannot fully mature. Differently, patients with a mutation in the *M251T* gene have fully mature MPO that are not functional.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

MPO is usually asymptomatic, although patients with diabetes mellitus may occasionally experience candidal infections. The diagnosis is made by observation of a negative peroxidase stain of the peripheral blood smear.

TREATMENT Rx

Symptomatic patients may be treated with prophylactic antibiotics with routine control of blood glucose in those who have diabetes mellitus.

Glutathione Synthetase Deficiency

PATHOBIOLOGY

Glutathione synthetase (GSS) deficiency is a autosomal recessive disorder of glutathione metabolism with approximately 70 cases reported worldwide. Glutathione, which is a potent antioxidant found in granulocytes, is required for a normal respiratory burst and bacterial killing.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

GSS deficiency can exist in mild, moderate, and severe forms. Patients with GSS deficiency typically have recurrent otitis and hemolytic anemia. Mildly affected patients typically present with hemolytic anemia; in the moderate form, metabolic acidosis occurs; and patients with the severe form in addition develop central nervous system impairment, such as seizures, mental retardation, and ataxia. The diagnosis is confirmed by verifying low or no glutathione synthetase in red blood cells, high levels of 5-oxoproline in the urine (up to 1 g/kg/day), and mutations in the glutathione synthetase (*GSS*) gene. Onset of symptoms ranges from birth to infancy and childhood.

TREATMENT Rx

Treatment goals include supplementation with antioxidants, correction of acidosis with bicarbonate, and blood transfusion.

Severe Glucose-6-Phosphate Dehydrogenase Deficiency

PATHOBIOLOGY

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked disorder (>400,000 people) distributed throughout Africa, Asia, the Mediterranean, and the Middle East. The prevalence of G6PD deficiency is associated

with the distribution of malaria and provides partial protection against malarial infection. White individuals with a severe reduction in G6PD activity are subject to recurrent infections, whereas Asians or blacks with similarly reduced G6PD levels are not. G6PD is crucial for regulating the availability of NADPH for the respiratory burst. Gene mutations associated with G6PD are located on the distal arm of the X chromosome and are frequently identified as missense mutations.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

G6PD deficiency results in recurrent bacterial infections, hemolytic anemia (Chapter 161), and jaundice. The diagnosis can be made with flow cytometry to assess the respiratory burst and to demonstrate the absence of G6PD in all blood cells. The production of NADPH from NADP is detected thorough rapid fluorescent spot testing.

TREATMENT Rx

Treatment goals include abstaining from oxidative stressors and the consumption of fava beans. In severe cases of anemia, a blood transfusion is warranted.

MACROPHAGE-RELATED ABNORMALITIES

Accumulation of monocyte-macrophages at sites of infection occurs after the major influx of neutrophils. Macrophages have a critical role in antigen presentation to lymphocytes, thereby activating the adaptive arm of the immune system. A critical defect in macrophage signaling results in susceptibility to mycobacterial infection.

Interferon-γ Receptor-1 Defects

PATHOBIOLOGY

When macrophages phagocytose mycobacteria, they produce IL-12, which in turn stimulates T cells to produce interferon-γ (IFN-γ). IFN-γ is critical to the killing of mycobacteria and other intracellular bacteria. Patients with recurrent and severe mycobacterial infections who are not infected with human immunodeficiency virus should be assessed for abnormalities in pathways that lead to the generation and utilization of IFN-γ.

Patients with autosomal recessive mutations in the IFN-γ receptors typically have a complete loss of function of the IFN-γ receptors. Autosomal dominant mutations in the IFN-γ receptors result in normal ligand binding but defective intracellular signal transduction because of a cytoplasmically truncated form of the receptor.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Recessive mutations typically manifest as severe disseminated infections and poor formation of granulomas. Multifocal mycobacterial osteomyelitis is pathognomonic of an autosomal dominant mutation in the IFN-γ receptor. Flow cytometry confirms the absence of membrane expression of IFN-γ receptor-1 in the autosomal recessive form and up to 10-fold higher membrane expression levels of the cytoplasmically truncated receptor in the autosomal dominant form.

TREATMENT Rx

For patients with autosomal dominant mutations, subcutaneous IFN-γ is effective. For autosomal recessive patients completely lacking IFN-γ receptor function, hematopoietic stem cell transplantation should be considered. Long-term antibiotic prophylaxis against mycobacterial infections with azithromycin or clarithromycin is recommended.

Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome

PATHOBIOLOGY

Hemophagocytic lymphohistiocytosis (HLH), also known as *hemophagocytic syndrome*,[10] and the related *macrophage activation syndrome* are rare, often life-threatening syndromes of diverse etiologies. Their clinical manifestations reflect a state of extreme systemic inflammation and unregulated immune activation. These disorders have been traditionally classified as either (1) primary HLH that has an inherited basis and is seen in children,[11] or (2) secondary HLH that is seen in adults and is triggered by a variety of acquired disorders like infections, malignancies, and rheumatologic diseases. Macrophage activation syndrome has been considered to represent mainly the latter group, the rheumatologic forms of secondary HLH. However, the distinction between primary and secondary HLH is becoming increasingly blurred because genetic defects are also being discovered in adults with apparently acquired disease who have presentations of the syndrome that occur later in life. Genetic defects underlying HLH (and macrophage activation syndrome) generally cause impairment of natural killer (NK) cell and cytotoxic T-cell function. Mutations tend to occur in the perforin gene or in genes important for the exocytosis of cytotoxic granules.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical manifestations of HLH result from its underlying hyperinflammatory state with hypercytokinemia. They include fever (often presenting as "fever of unknown etiology"), hepatosplenomegaly, various cutaneous manifestations, pulmonary involvement including acute respiratory failure with alveolar or interstitial infiltrates, various neurologic manifestations, bilineage or trilineage cytopenia, abnormal liver function tests, hypertriglyceridemia, and hypofibrinogenemia.

Conditions associated with secondary HLH include viral infections (herpes simplex virus, Epstein-Barr virus, cytomegalovirus, human immunodeficiency virus, parvovirus, influenza, and post vaccination); other infections (mycoplasma, bacterial, protozoal, fungal, and mycobacterial); malignancies (leukemia, Hodgkin and non-Hodgkin lymphoma, solid tumors like germ cell tumors); and immune deficiency states (including CGD and stem cell transplantation). Macrophage activation syndrome is now essentially considered to be HLH associated with rheumatic diseases, classically as a potentially lethal complication of systemic juvenile rheumatoid arthritis, but also with systemic lupus erythematosus, scleroderma, Sjögren syndrome, mixed connective tissue disorders, and Kawasaki disease.

A diagnostic hallmark of HLH, although sometimes not found early in the course of the disease, is histopathologic evidence of hemophagocytosis in the bone marrow.[12] Laboratory findings reflecting the hyperinflammatory state include extremely high serum levels of ferritin and soluble CD25 (i.e., the soluble IL-2 receptor, IL-2Rα).

TREATMENT Rx

A high index of suspicion is required to make an early diagnosis of HLH or macrophage activation syndrome so that treatment can be initiated promptly to attempt to prevent irreversible tissue damage. Most important is the identification and specific treatment of the underlying cause of the syndrome in any individual patient. Hematopoietic stem cell transplantation with reduced-intensity conditioning regimens is being increasingly considered when a genetic cause is identified. Combination therapy with (1) dexamethasone, etoposide with or without cyclosporine, or (2) corticosteroids, cyclosporine and antithymocyte globulin has been attempted, especially as a bridge to stem cell transplantation. Alemtuzumab, a monoclonal antibody to CD52-bearing lymphocytes, appears to be effective as a salvage agent for refractory HLH, leading to improvement and survival to transplantation in pediatric and adult patients.[13]

ASSESSING PHAGOCYTE FUNCTION: MAKING THE DIAGNOSIS

If a phagocyte functional disorder may be the underlying cause of recurrent infections in a patient, a complete blood count (CBC) and peripheral smear guide subsequent definitive testing (Fig. 169-4). Cultures from infected areas allow antimicrobial targeting and also provide critical diagnostic information. If the defect is a result of abnormal neutrophil development and maturation, the CBC will show neutropenia; a bone marrow biopsy might be required. Repeated CBC (twice per week for 6 weeks) is indicated if cyclic neutropenia is suspected because of a periodicity of the infections (Chapter 167).

If the CBC reveals neutrophilia, a defect in the recruitment of neutrophils into tissues is suggested. An assessment of the receptors required for transmigration by flow cytometry and specific antibodies to the surface receptors is indicated.

If circulating levels of phagocytes are normal yet the patient is experiencing recurrent infections, a phagocytic defect within the infected tissue is likely. Laboratory testing to evaluate chemotaxis, phagocytosis, and bacterial killing is indicated.

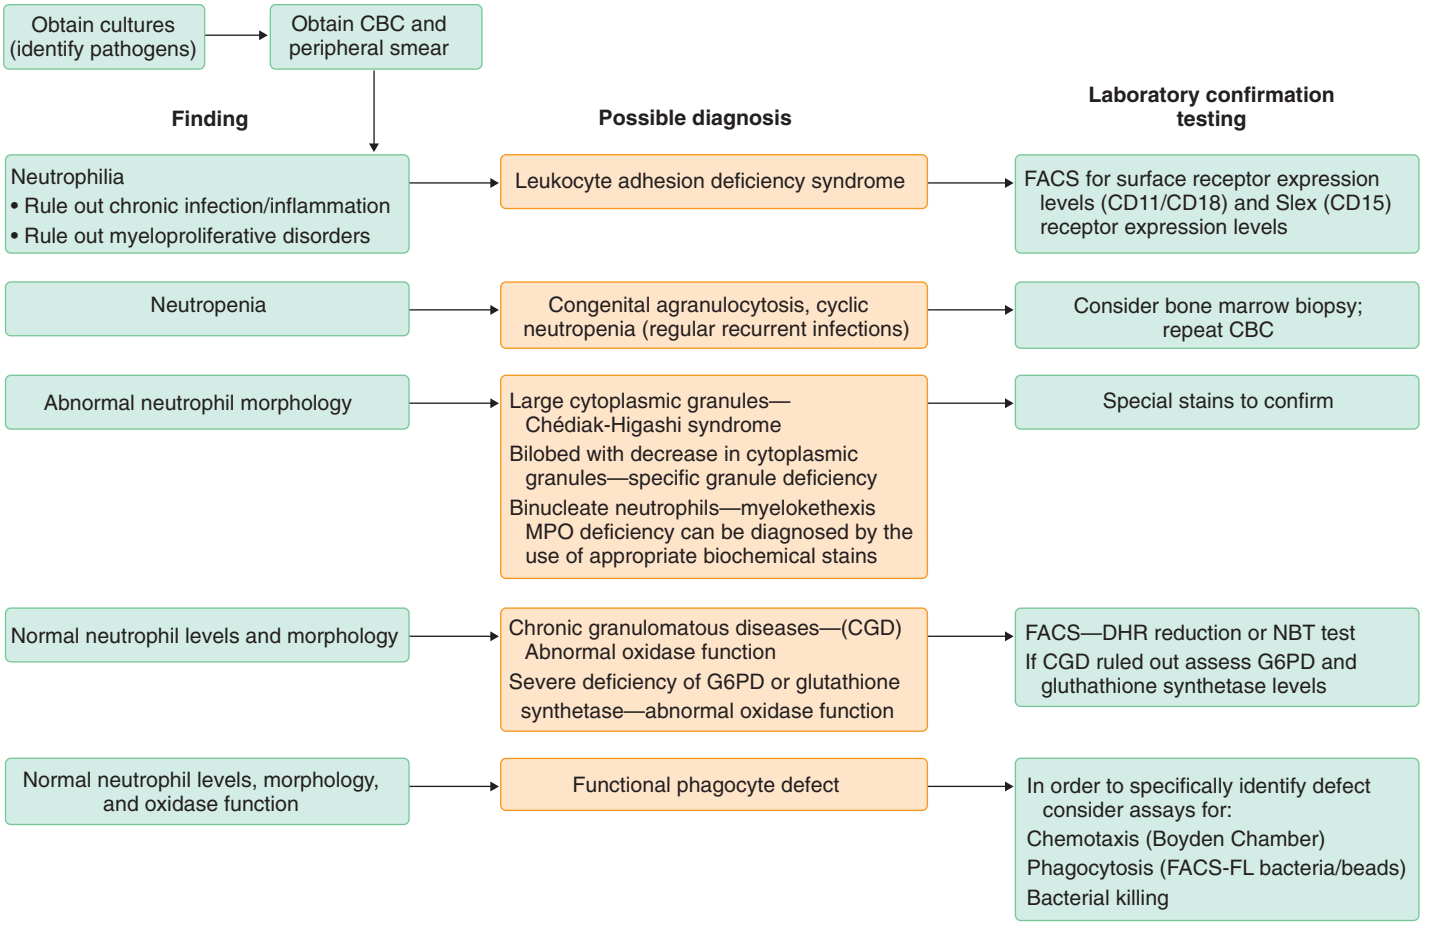

FIGURE 169-4. Approach to diagnosing a suspected phagocytic defect. CBC = complete blood count; DHR = dihydrorhodamine; FACS = flow cytometry; FL = fluorescent; G6PD = glucose-6-phosphate dehydrogenase; MPO = myeloperoxidase; NBT = nitroblue tetrazolium.

REVIEW QUESTIONS

1. What is the probable diagnosis of an 8-year-old boy with severe dermatitis, recurrent bacteria skin infections, and pneumonia for evaluation of immunodeficiency? Initial tests reveal normal complete blood count and platelets, 40,000 IU of immunoglobulin E (IgE), and normal IgA, IgM, and IgG levels.

A. Familial Mediterranean fever
B. Chédiak-Higashi syndrome
C. Hyper-IgE syndrome
D. Chronic granulomatous disease
E. Leukocyte adhesion deficiency

Answer: C This patient has recurrent bacterial infections and pneumonia, which suggest the possibility of an immunodeficiency. Significant levels of IgE present with normal complete blood count and platelets indicate hyper-IgE syndrome. Genetic testing of the *STAT3* gene can be used to confirm diagnosis. Good prognosis seen in patients with administration of antibiotics, antifungal prophylaxis, and IgG infusions.

2. A 3-year-old girl with abnormally light pigmentation of the hair and skin has a history of recurrent respiratory infection. Blood smear shows giant cytoplasmic granules and low neutrophil counts. What is the mostly likely diagnosis?

A. Chédiak -Higashi syndrome (CHS)
B. Specific granule deficiency
C. Chronic granulomatous disease
D. Interferon-γ receptor-1 defect
E. Myeloperoxidase deficiency

Answer: A The low neutrophil count is an indication of neutropenia, in addition to giant cytoplasmic granules in the blood smear, suggesting CHS. Significant indication of CHS includes partial albinism as seen in patients light pigmentation and defects in bacterial killing and chemotaxis, which can be confirmed through neutrophil function testing. Infections can be treated with prophylactic antibiotics.

3. A 6-year-old girl has a history of recurrent otitis and hemolytic anemia. Testing indicates significant excretion of 5-oxoproline in the urine and low amounts of glutathione synthetase in red blood cells. What is the mostly likely diagnosis?

A. Glutathione synthetase deficiency
B. Macrophage activation syndrome
C. Chronic granulomatous disease
D. Myeloperoxidase deficiency
E. Hyper-IgE syndrome

Answer: A This patient's low levels of glutathione synthetase suggest a mild form of glutathione synthetase deficiency. Diagnosis can be confirmed with 5-oxoproline buildup and mutations in the *GSS* gene. Antioxidant supplementations are suggested for treatment.

4. The attraction of neutrophils and other white blood cells to an inflammatory site is called which of the following?

A. Chemotaxis
B. Margination
C. Diapedesis
D. Phagocytosis
E. Extracellular trap

Answer: A Chemotaxis is the attraction and oriented movement of neutrophils to an inflammatory site after the release of chemoattractants.

5. A 15-month-old female infant is admitted for recurrent deep skin infections. Flow cytometry confirmed deficiency in vitamin B_{12}. Blood smear displays bilobed neutrophil nucleuses. What is the likeliest diagnosis?

A. Specific granule deficiency
B. Chronic granulomatous disease
C. Interferon-γ receptor-1 defect
D. Myeloperoxidase deficiency
E. Macrophage activation syndrome

Answer: A Morphologically altered neutrophils are a strong indication of specific granule deficiency. This condition usually manifests during infancy, including recurrent skin infections and vitamin B_{12} deficiency. Treatment options include parenteral antibiotics and drainage of infections.

170 EOSINOPHILIC SYNDROMES

MARC E. ROTHENBERG

DEFINITION

Eosinophilic syndromes are a heterogeneous group of disorders that involve eosinophilia, which is defined as the accumulation of eosinophils in peripheral blood and/or tissues. Circulating eosinophils normally account for only 1 to 3% of peripheral blood leukocytes, and the upper limit of the normal range is 350 cells/mm^3 of blood. Eosinophilia occurs in a variety of disorders (Table 170-1) and is usually arbitrarily classified according to the degree of blood eosinophilia: mild (351 to 1500 cells/mm^3), moderate (>1500 to 5000 cells/mm^3), or severe (>5000 cells/mm^3). Tissue eosinophilic disorders, such as eosinophil-associated gastrointestinal disorders and eosinophilic fasciitis, are not necessarily associated with blood eosinophilia, so their diagnosis is based on the microscopic identification of eosinophil-rich inflammatory infiltrates associated with tissue damage.

Historically, hypereosinophilic syndromes were generally classified as idiopathic and were defined by (1) the presence of eosinophilia (>1500 cells/mm^3 for at least 6 months) that remained unexplained despite a comprehensive evaluation for known causes of eosinophilia (such as drug reactions and infections) and (2) evidence of organ dysfunction directly attributable to the eosinophilia. Now, however, it is known that in some patients, an acquired genetic etiology is responsible. These include the (a) *FIP1L1*–platelet-derived growth factor receptor-α (*PDGFRA*) fusion gene associated with a microdeletion on 4q24; and (b) other abnormalities of 4q12 (*PDGFRA* fusion partners instead of *FIP1L1*), 5q31-33 (*PDGFRB*), 8p11-13 (*FGFR1*), 9p24 (*JAK2*), and 13q12 (*FLT3*). These are detected by conventional cytogenetics, fluorescent in situ hybridization (FISH), and reverse transcription–polymerase chain reaction (RT-PCR).[1] Identification of these diseases has important therapeutic implications because they can be treated with targeted agents like imatinib, a tyrosine kinase inhibitor.

EPIDEMIOLOGY

The most common cause of eosinophilia worldwide is helminth infections, which affect hundreds of millions of people. The most frequent cause in industrialized nations is atopic disease, which affects 10 to 30% of the population. Hypereosinophilic disorders such as *FIP1L1-PDGFRA*–associated disease and Churg-Strauss syndrome (Chapter 270) are very rare. For example, Churg-Strauss syndrome affects 4 to 6 cases per million per year, whereas true idiopathic hypereosinophilic syndromes may affect only 4000 to 5000 people worldwide. Other syndromes such as eosinophil-associated gastrointestinal disorders are more common, with a prevalence of approximately 1 in 2000 individuals.

TABLE 170-1 CAUSES OF EOSINOPHILIA

REACTIVE EOSINOPHILIA
Allergic diseases—asthma, atopic dermatitis, allergic rhinitis
Drug reactions—including cytokine infusions; drug reaction (rash) with eosinophilia and systemic symptoms (DRESS) syndrome
Infection—viral (human immunodeficiency virus) or fungal (allergic bronchopulmonary aspergillosis, coccidioidomycosis)
Parasitic infection—mostly helminths
EOSINOPHILIA ASSOCIATED WITH OTHER DISEASES
Eosinophil-associated gastrointestinal disorders—eosinophilic esophagitis, gastroenteritis
Skin—bullous pemphigoid, urticaria, eosinophilic cellulitis, episodic angioedema
Pulmonary—eosinophilic pneumonia, allergic bronchopulmonary aspergillosis
Neurologic—eosinophilic meningitis
Autoimmune—Churg-Strauss syndrome, eosinophilic fasciitis
Primary immunodeficiency—hyperimmunoglobulin E syndrome, Omenn syndrome
Post-transplantation status—liver (in association with immunosuppression)
Transplant rejection—lung, kidney, liver
Malignancy—Hodgkin disease, solid tumors
Hypoadrenalism—Addison disease, adrenal hemorrhage
Renal—drug-induced interstitial nephritis, eosinophilic cystitis, dialysis
PRIMARY AND CLONAL EOSINOPHILIAS*
Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement
Myeloid neoplasms with *PDGFRB* rearrangement
Myeloid and lymphoid neoplasms with *FGFR1* abnormalities
Chronic eosinophilia leukemia not otherwise specified (CEL-NOS)
Idiopathic hypereosinophilic syndrome (HES)
Idiopathic hypereosinophilia

*These represent the revised World Health Organization (WHO) classification (Gottlib J. World Health Organization-defined eosinophilic disorders: 2011 update on diagnosis, risk stratification, and management. *Am J Hematol* 2011;86:677-688.)

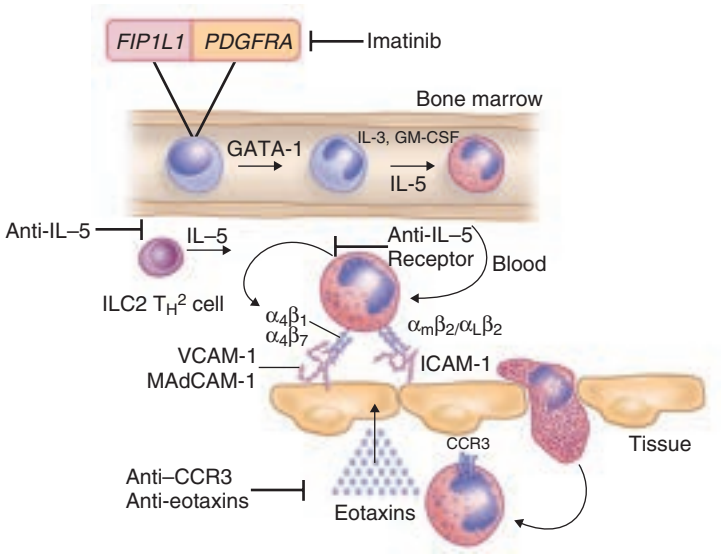

FIGURE 170-1. Schematic representation of eosinophil development, tissue recruitment, and therapeutic intervention. Eosinophil lineage development is specified by the GATA-1 transcription factor and promoted by the cytokines interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). IL-5 is most selective to the eosinophil lineage and regulates eosinophil movement from the bone marrow into the peripheral blood. Eosinophil adhesion is mediated by β1, β2, and β7 integrins and their interaction with the endothelial adhesion molecules intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), and mucosal address in cell adhesion molecule 1 (MAdCAM-1). Recruitment of eosinophils into tissue is regulated by the eotaxin chemokines that stimulate eosinophilic chemoattraction and activation through their receptor CCR3. Hypereosinophilic syndromes can develop after an 800-kilobase microdeletion on chromosome 4 results in fusion of the *FIP1L1* and *PDGFRA* genes, thereby resulting in activation of an imatinib-sensitive tyrosine kinase. Targeted therapeutic intervention for eosinophilic syndromes includes anti-IL–5 and anti–CCR3/anti-eotaxins, which are currently in clinical development.

PATHOBIOLOGY

Eosinophils are multifunctional leukocytes that are produced in the bone marrow from pluripotential hematopoietic stem cells under regulation of the transcription factor GATA-1 and the cytokines interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Fig. 170-1). They are capable of producing a wide variety of pro-inflammatory mediators and immunomodulatory molecules.[2] Eosinophils are under the regulation of helper type 2 T cells (T_H2) and type 2 innate lymphoid cells (ILC2) that secrete IL-4, IL-5, and IL-13. Notably, IL-5 is a cytokine that specifically regulates the selective differentiation of eosinophils, their release from bone marrow into the peripheral circulation, and their survival. IL-5 activity is counterbalanced by paired immunoglobulin-like receptors (PIR) expressed on eosinophils, which counterbalance cellular activation and inhibition. A humanized anti-IL–5 drug markedly lowers blood eosinophilia and reduces tissue eosinophilia more modestly. Recent preliminary studies in patients with severe asthma have shown that anti-IL–5 therapy improves asthma control, including exacerbations, and allows steroid reduction. Similarly, anti-IL–5 has a steroid-sparing effect in hypereosinophilic syndromes. Humanized anti-IL–5 therapy and cytotoxic anti-IL–5 receptor therapy are currently in clinical testing for a variety of indications, including eosinophilic esophagitis, asthma, and hypereosinophilic syndromes. IL-4 and IL-13 induce eosinophil recruitment and survival, expression of critical adhesion molecules on the endothelium that bind to the β1 and β2 integrins on eosinophils (such as intercellular adhesion molecule 1 [ICAM-1] and vascular cell adhesion molecule 1 [VCAM-1]), and eosinophil-active chemokines such as the eotaxins. The eotaxins are three structurally related eosinophil chemoattractant and activating proteins that signal exclusively through the eosinophil-selective receptor CCR3. In addition to regulating the baseline homing of eosinophils to the various tissues in which they normally predominantly reside under the regulation of ILC2, such as the gastrointestinal tract, the eotaxins are induced by T_H2-associated inflammatory triggers (e.g., IL-13) and thereby promote tissue accumulation of eosinophils. Humanized antibodies against the eotaxins and small-molecule inhibitors against CCR3 are promising new approaches for treating eosinophilic disorders that are in clinical development.

Eosinophil granules contain a crystalloid core composed of major basic protein (MBP-1 and MBP-2), as well as a matrix composed of eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO). MBP, EPO, and ECP have cytotoxic effects on a variety of tissues in concentrations similar to those found in biologic fluids from patients with eosinophilia. Additionally, ECP and EDN belong to the ribonuclease A superfamily and possess antiviral and ribonuclease activity. ECP can insert voltage-insensitive, ion-nonselective toxic pores into the membranes of target cells, and these pores may facilitate the entry of other toxic molecules. MBP directly increases smooth muscle reactivity by causing dysfunction of vagal muscarinic M_2 receptors, and this process has been postulated to contribute to the airway hyperresponsiveness associated with asthma. MBP also triggers degranulation of mast cells and basophils. Triggering of eosinophils by engagement of receptors for cytokines, immunoglobulins, and complement can lead to the generation of a wide range of inflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-13, GM-CSF, transforming growth factor α/β, tumor necrosis factor α, RANTES, macrophage inflammatory protein 1α (MIP-1α), and the eotaxins, thus indicating that eosinophils have the potential to modulate multiple aspects of the immune response. Additionally, eosinophils can directly activate T cells by antigen presentation and help polarize dendritic cells to promote a T_H2 phenotype.[3] Further eosinophil-mediated tissue damage is caused by toxic hydrogen peroxide and halide acids generated by EPO and by superoxide generated by the respiratory burst oxidase enzyme pathway in eosinophils. Eosinophils also generate large amounts of cysteinyl leukotriene C_4 (LTC_4), which is metabolized to LTD_4 and LTE_4. These three lipid mediators increase vascular permeability and mucus secretion and are potent stimulators of smooth muscle contraction. Finally, bipyramidal Charcot-Leyden crystals are derived from a nongranule lysophospholipase in eosinophils and are frequently found in sputum, feces, and tissues infiltrated by eosinophils.

CLINICAL MANIFESTATIONS

Hypereosinophilia is often recognized on a routine blood count in a patient who is asymptomatic or being evaluated for unrelated or nonspecific signs or symptoms. On other occasions, the possibility of eosinophilia may be specifically investigated in a patient with gastrointestinal or respiratory symptoms because helminthic disease or allergic causes are suspected. The clinical signs and symptoms of hypereosinophilic syndromes are heterogeneous because of the diversity of the causes and potential organ involvement. Common signs and symptoms include dermatitis, heart failure, neuropathy, and abdominal pain. One of the most serious complications of hypereosinophilia

is cardiac disease secondary to endomyocardial thrombus formation and restrictive fibrosis (Chapter 60). Mitral and tricuspid valve regurgitation may result from progressive fibrotic damage to the chordae tendineae, and resultant heart failure can develop from valvular insufficiency and endomyocardial fibrosis. Cardiac involvement can occur in association with chronic eosinophilia from diverse causes, including parasitic infections. Hypereosinophilic syndromes can result in cerebral emboli from cardiac disease, diffuse encephalopathy, and peripheral neuropathy.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of eosinophilia includes reactive eosinophilia, eosinophilia associated with other primary disorders, and eosinophilia associated with clonal hematopoiesis (see Table 170-1). Evaluation of patients is based on their history and clinical characteristics (Fig. 170-2). The initial goal is to determine whether the eosinophilia is secondary to a reactive cause (i.e., in response to another primary trigger such as allergy, infection, solid tumor, vasculitis). If reactive causes are not identified, further evaluation should determine whether the eosinophilia is secondary to a clonal hematologic disorder. If no evidence of clonality is determined, the patient is considered to have an idiopathic hypereosinophilic syndrome. The diagnosis of idiopathic hypereosinophilic *syndrome* requires an absolute eosinophil count of greater than 1500 cells/mm^3 *and* evidence of organ involvement and dysfunction.[4] These diagnostic criteria have been challenged for reasons noted in the Treatment section. Eosinophilia of an as yet unknown etiology that does not meet these criteria should be called *idiopathic hypereosinophilia*.

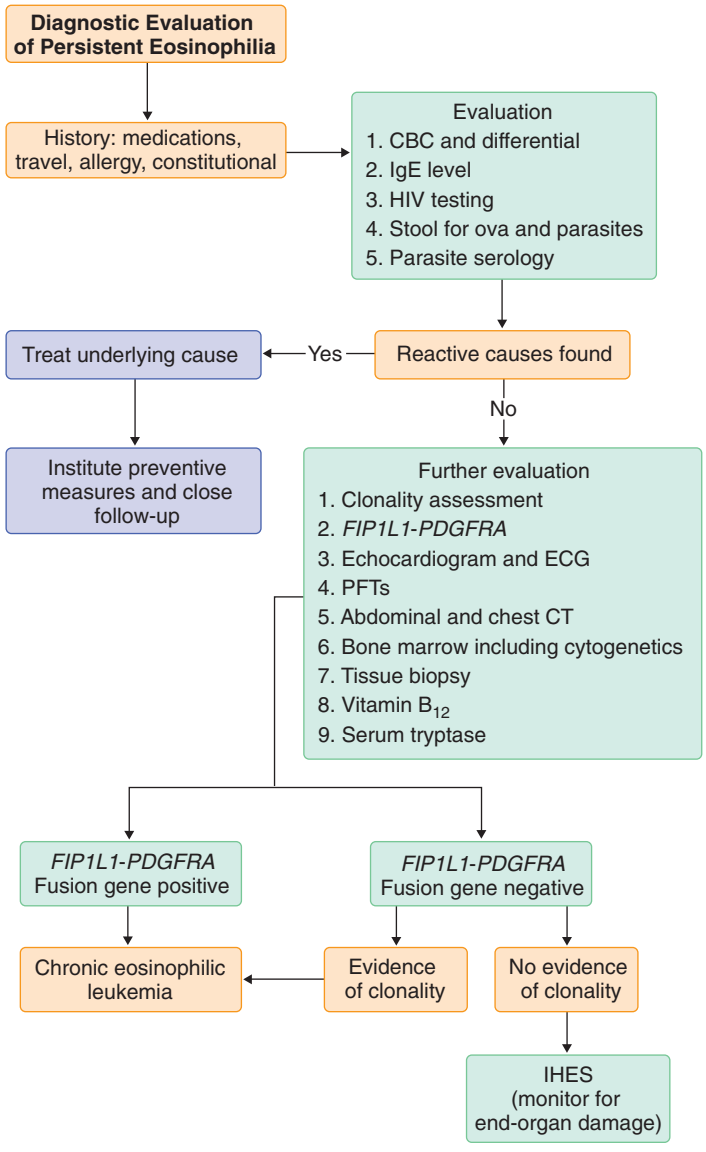

FIGURE 170-2. Diagnostic evaluation of persistent eosinophilia. CBC = complete blood count; CT = computed tomography; ECG = electrocardiogram; IgE = immunoglobulin E; IHES = idiopathic hypereosinophilic syndrome; HIV = human immunodeficiency virus; PDGFRA = platelet-derived growth factor receptor-α; PFTs = pulmonary function tests.

The differential diagnosis of eosinophilia requires a review of the patient's history, which may reveal wheezing (Chapter 87), rhinitis (Chapter 251), or eczema (indicating atopic causes); travel to areas where helminth infections (e.g., schistosomiasis [Chapter 355]) are endemic; the presence of a pet dog (indicating possible infection with *Toxocara canis* [Chapter 357]); symptoms of cancer; or drug ingestion (indicating a possible hypersensitivity reaction [Chapter 254]). Eosinophilia caused by drugs (Chapter 254) is usually benign but can sometimes be accompanied by tissue damage, as in hypersensitivity pneumonitis (Chapter 97) and in *DRESS syndrome* (drug reaction or rash with eosinophilia and systemic symptoms) (also see Chapter 440).[5] In most cases, the eosinophilia resolves when use of the drug ceases, but in some cases, such as eosinophilia-myalgia syndrome secondary to the ingestion of contaminated L-tryptophan, the disease can persist despite withdrawal of the drug.

The presence of abnormal morphologic features of eosinophils, an increase in immature and dysplastic cells in the bone marrow or blood, elevated levels of vitamin B_{12}, and splenomegaly raises suspicion of a clonal hypereosinophilic syndrome. In such cases, evidence of clonality (e.g., by analysis of X-chromosome inactivation patterns in female patients), an elevated level of mast cell tryptase (elevated in myelodysplastic variants of hypereosinophilic syndrome), the presence of aberrant lymphocyte phenotypes (elevated in lymphocytic variants of hypereosinophilic syndrome), abnormal cytogenetics, and the possible presence of specific fusion genes such as *FIP1L1-PDGFRA* should be investigated.

Other eosinophilic syndromes, such as Churg-Strauss syndrome, which is now referred to as eosinophilic granulomatosis with polyangiitis [EGPA] (Chapter 270), should be considered in patients with a history of worsening asthma, sinus disease, neuropathy, or blood eosinophilia and the presence of abnormal laboratory findings associated with inflammation and autoimmunity, such as an elevated erythrocyte sedimentation rate, C-reactive protein, and antineutrophil cytoplasmic antibodies.

An accumulation of eosinophils that is limited to specific organs is characteristic of particular diseases, such as eosinophilic cellulitis (Wells syndrome), eosinophilic esophagitis (Chapter 138), eosinophilic pneumonias (e.g., Löffler syndrome [Chapter 92]), and eosinophilic myositis (which now includes a genetic etiology caused by recessive mutations in calpain3 *[CAPN3]*).

Diagnostic Evaluation

Diagnostic studies that should be performed in patients with moderate to severe eosinophilia and considered in patients with persistent mild eosinophilia include morphologic examination of a blood smear, human immunodeficiency virus (HIV) screen, serial stool examinations for ova and parasites, parasite serology, and plasma immunoglobulin E (IgE) level.[6] Parasitic infections that cause eosinophilia are usually limited to helminthic parasites, with the exception of two enteric protozoans, *Isospora belli* (Chapter 353) and *Dientamoeba fragilis* (Chapter 353). *Strongyloides stercoralis* (Chapter 358) infection is important to diagnose because it can cause disseminated fatal disease in immunosuppressed patients; detection of such infection often requires serologic testing. Other infections to consider include trichinosis (Chapter 358), *T. canis* infection (Chapter 357), and HIV infection (Chapter 393).

Patients with sustained hypereosinophilia should be monitored closely for the subsequent development of cardiac disease. A pathologically similar disease, Löffler endomyocarditis (Chapter 60), has been noted in tropical regions, where antecedent parasite-elicited eosinophilia may be responsible for the cardiac damage. There should be a low threshold for a bone marrow analysis and testing for the presence of the *FIP1L1-PDGFRA* fusion gene in patients with hypereosinophilia. Testing for the presence of other activated tyrosine kinases (e.g., *PDGFRA* and *FGFR1*) should generally be reserved for individuals with bone marrow cytogenetic abnormalities.

TREATMENT

Reactive Hypereosinophilia and Hypereosinophilia Associated with Other Diseases

Treatment of reactive hypereosinophilia and hypereosinophilia associated with other diseases centers around identifying the cause and then treating the

underlying disease process.[7,8] For example, reactive eosinophilia typically responds by removal of the inciting triggers (e.g., allergens, parasites, and medications). Eosinophilia associated with other disease processes typically improves after treatment of the underlying disease, such as dietary manipulation in patients with allergic eosinophilic gastroenteritis.

FIP1L1-PDGFRA–Positive Disease

As noted in the next section, other hypereosinophilic syndromes, treatment should be started as soon as possible to prevent potentially serious eosinophilia-mediated organ damage. Imatinib should be considered as first-line therapy in patients in whom the *FIP1L1-PDGFRA* fusion gene has been demonstrated and in selected patients with the characteristic clinical, laboratory, and molecular features of this myeloproliferative subtype of hypereosinophilic syndrome (e.g., male gender, tissue fibrosis, elevated serum vitamin B_{12} and tryptase levels). Clinical responses to imatinib in *FIP1L1-PDGFRA*–positive patients are rapid, with normalization of eosinophil counts generally occurring within 1 week of initiation of treatment and reversal of the signs and symptoms occurring within 1 month. Doses of imatinib as low as 100 mg daily appear to be effective in controlling symptoms and eosinophilia in most patients, but some recommend beginning imatinib treatment at 400 mg daily to achieve molecular remission and then decreasing the dose slowly while monitoring the patient closely for evidence of molecular relapse. In imatinib-resistant patients, sorafenib may be effective. The utility of imatinib therapy in hypereosinophilic patients without a demonstrable *FIP1L1-PDGFRA* mutation remains controversial, although some patients have responded. Nonmyeloablative allogeneic bone marrow transplantation (Chapter 178) has also been used successfully in several patients with hypereosinophilia.

Other Hypereosinophilic Syndromes

The current diagnostic criteria for hypereosinophilic syndromes that require at least 6 months of persistent eosinophilia of more than 1500 cells/mm^3 have been challenged because prompt diagnosis and treatment are required (before 6 months have passed) to prevent potentially serious end-organ damage. New diagnostic criteria have been proposed to address this limitation.[9]

Corticosteroids, which have been used for decades in the treatment of idiopathic hypereosinophilic syndromes, remain the first-line treatment for most patients, except those with *PDGFRA*-associated hypereosinophilia. The most appropriate initial corticosteroid dose and the duration of steroid therapy have not been subjected to randomized trials, but a general recommendation is to start with a moderate to high dose (≥40 mg prednisone equivalent) and taper very slowly while monitoring the eosinophil count closely. With this approach, most patients will respond initially, and some can be maintained on low doses of corticosteroids for prolonged periods.

Monoclonal anti-IL–5 antibody therapy (e.g., mepolizumab or reslizumab) for hypereosinophilia and eosinophil-associated asthma has a number of unique advantages related to the specificity of IL-5 for the eosinophil lineage. In patients treated with this agent, eosinophil counts are twice as likely to fall below 600/μL (95% vs. 45%, $P < .001$) with significantly lower prednisone doses. Of the cytotoxic therapies that have been used for steroid-refractory hypereosinophilia, hydroxyurea has been the most extensively studied at doses of 1 to 3 g/day. Vincristine at a dose of 1 to 2 mg intravenously can rapidly lower eosinophilia in patients with extremely high eosinophil counts (>100,000/mm^3) and may be useful for the treatment of children whose aggressive disease is unresponsive to other therapies. In patients who have corticosteroid-refractory hypereosinophilic syndromes or who develop intolerable side effects of steroid treatment, immunomodulatory agents that are sometimes helpful include interferon-α, cyclosporine, and alemtuzumab. Responses can often be achieved with relatively low doses of interferon-α (1 to 2 × 10^6 U/day) and may persist for prolonged periods. Because the effects of interferon-α on eosinophil numbers in peripheral blood may not become evident for several weeks, escalation to an effective dose may require several months. Rarely, patients have remained in remission for extended periods after cessation of interferon-α therapy, suggesting that interferon-α may be curative in a small subset of individuals. Low-dose (500 mg daily) hydroxyurea appears to act synergistically with interferon-α to lower the eosinophil count without increasing side effects.

PROGNOSIS

The prognosis of hypereosinophilic syndromes depends on the primary cause. Whereas *FIP1L1-PDGFRA*–positive disease and other forms of clonal disorders have a poor prognosis (25 to 50% 5-year mortality rate if responsiveness to therapeutic intervention is not achieved), the prognosis of hypereosinophilia from reactive and other causes is usually better and continues to improve.

A recent retrospective review of 247 cases of hypereosinophilic syndrome seen at the Mayo Clinic over a period of 19 years showed that only 23 patients died during this time, with the most common causes of death being cardiac dysfunction, infection, unrelated malignancy, and thromboembolic and vascular disease.[10] It was noted that targeted monitoring of at-risk end organs, combined with early treatment, may further improve survival and reduce morbidity.

FUTURE DIRECTIONS

Treatments on the horizon for hypereosinophilic disorders include targeted therapy against the eotaxin chemokines and their receptor CCR3, as well as anti-IL–5 and anti-IL–5 receptor–based antibody therapy.[11]

REVIEW QUESTIONS

1. A 40-year-old man presents with blood eosinophilia and rash. The chest radiograph is normal, and the blood eosinophil count is 5000 cells/mm^3 on two occasions over the course of 1 month. He has no history of allergies and no risk factors for parasite infection. A bone marrow biopsy shows elevated eosinophils with no blasts. The next step would be which of the following?

A. Lymphocyte phenotyping and serum immunoglobulin levels
B. Determining the presence of the *FIP1L1-PDGFRA* fusion gene
C. Following the eosinophil count over the course of 6 months to document true hypereosinophilia
D. Determining IgE and HIV titers
E. All of the above

Answer: B The patient is presenting with classic signs of hypereosinophilic syndrome and should be evaluated for *FIP1L1-PDGFRA* because its presence would lead to imatinib therapy. Delay of 6 months exposes the patient to the potentially unnecessary risk for eosinophilia-mediated organ damage.

2. An asthmatic young man presents with progressive difficulty swallowing that is refractory to proton pump inhibitor therapy for the past 2 months. The peripheral blood count and differential are normal, specifically without eosinophilia. Which of the following is true regarding eosinophilic esophagitis?

A. It is not indicated because the patient does not have blood eosinophilia.
B. It should only be considered after repeating the blood eosinophil count over a period of time.
C. It can be assumed and treated with anti-IL–5 therapy.
D. It should be ruled out with a referral to a gastroenterologist for endoscopic evaluation.
E. It should only be considered after checking for the presence of the *FIP1L1-PDGFRA* fusion gene.

Answer: D Eosinophilic esophagitis is a tissue-specific eosinophilic disorder that can only be diagnosed by endoscopic biopsy and does not have to be accompanied by peripheral blood eosinophilia.

3. A middle-age women presents with progressive weight loss and diarrhea and is found to have blood eosinophil count of 5000 cells/mm^3. She is a nonatopic individual and has recently returned from a trip to Brazil. Which of the following would be the next step in evaluating this person?

A. Bone marrow analysis and cytogenetics
B. HIV titer
C. Stool culture and evaluation for parasites
D. Colonoscopy
E. Serologic testing for inflammatory bowel disease

Answer: C The patient has an acute presentation of eosinophilia following travel to a region likely endemic for parasites such as schistosomiasis. The next step would be a stool evaluation for parasites.

4. An 18-year-old male presents with a generalized erythematous eruption and peripheral blood eosinophilia of 2500 cells/mm^3. The history is significant for recent antibiotic use for a cellulitis in the leg. The cellulitis has not improved despite 10 days of antibiotics. The next step in evaluating this patient would include consideration of which of the following?

A. The patient likely has a simple drug allergy and should switch antibiotics.
B. The patient may have an underlying hypereosinophilic syndrome and should undergo skin biopsy, particularly at the site of the cellulitis.
C. The patient should have a chest and abdominal computed tomography scan to rule out solid tumor malignancy.
D. Referral should be made to a cardiologist to rule out cardiac involvement.
E. It is critical to rule out parasitic infection as the next step.

Answer: B The most common organ involved in hypereosinophilic syndrome is the skin. Although this patient may have a drug reaction, the persistent cellulitis is concerning for an underlying primary inflammatory process.

5. A well-appearing 60-year old women is found to have persistent blood eosinophil counts of 3500 cells/mm^3. She denies risk factors for parasite infection, is nonatopic, and has started no new medication, although she has been taking a statin and antihypertensive agent for several years. Which of the following considerations should take place?

A. Because this is a well-appearing female patient, there is little concern for hypereosinophilic syndrome.
B. Complete work-up is indicated that includes a computed tomography scan of the abdomen and bone marrow analysis.
C. Consideration of drug-induced eosinophilia is not appropriate because the patient has not started any new medications.
D. The patient should be simply followed by serial complete blood counts because she is clinically well.
E. A stool sample for ova and parasite should be the next step.

Answer: E The next logical step would be ruling out an infection. Serial complete blood counts should be performed but not in isolation because it has already been established that the patient's eosinophilia is persistent.

APPROACH TO THE PATIENT WITH BLEEDING AND THROMBOSIS

ANDREW I. SCHAFER

MECHANISMS OF HEMOSTASIS AND THROMBOSIS

Normal Hemostasis

The coagulation system is normally quiescent, and blood fluidity is maintained by the actions of a continuous monolayer of endothelial cells that line the intimal surface of the vasculature throughout the circulatory tree. At a site of vascular damage, the antithrombotic properties of endothelium are lost, and thrombogenic constituents of the subendothelial vessel wall become exposed to circulating blood. The result is rapid formation of a hemostatic clot that consists of platelets and fibrin and is localized to the area of vascular injury. Activation of platelets and formation of fibrin occur essentially simultaneously and interdependently to effect hemostasis. Subsequently, vascular repair is accomplished by thrombolysis and recanalization of the occluded site.[1]

Platelet activation at a site of vascular injury begins with the adhesion of platelets to the locally de-endothelialized intimal surface (platelet–vessel wall interaction). Platelet adhesion is mediated by von Willebrand factor, which sticks circulating platelets to the area of damaged vessel wall by binding to its receptors located in platelet membrane glycoprotein Ib. The adherent platelets then undergo a "release reaction," during which they discharge constituents of their storage granules, including adenosine diphosphate (ADP), and simultaneously elaborate thromboxane A_2 from arachidonic acid through the aspirin-inhibitable cyclooxygenase reaction. ADP, thromboxane A_2, and other components of the release reaction act in concert to recruit and activate additional platelets from the circulation to the site of vascular injury. These activated platelets expose binding sites for fibrinogen by forming the surface membrane glycoprotein IIb/IIIa complex. In the process of platelet aggregation (platelet-platelet interactions), fibrinogen (or von Willebrand factor under conditions of high shear stress) mediates the final formation of an occlusive platelet plug.

Fibrin, which anchors the hemostatic platelet plug, is formed from soluble plasma fibrinogen by the action of the potent protease enzyme thrombin (Fig. 171-1). The fibrin mesh is stabilized by covalent cross-linking mediated by factor XIII. Thrombin is formed from its inactive (zymogen) plasma

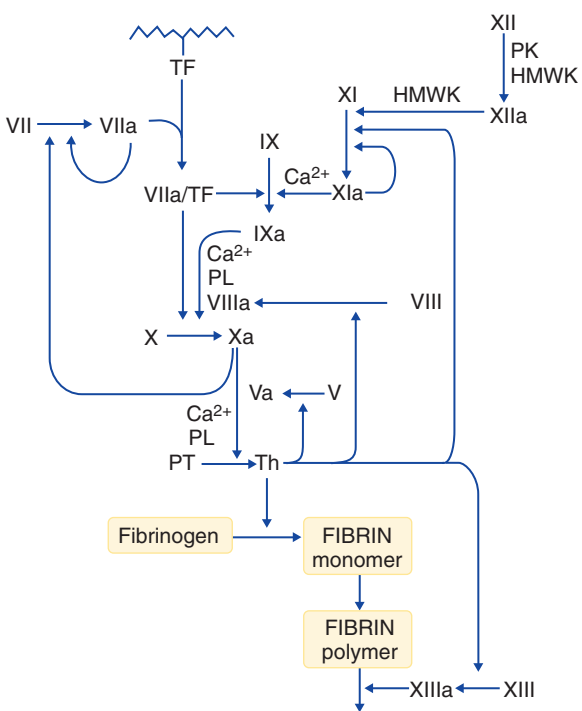

FIGURE 171-1. Coagulation cascade. This scheme emphasizes an understanding of (1) the importance of the tissue factor pathway in initiating clotting in vivo, (2) the interactions among pathways, and (3) the pivotal role of thrombin in sustaining the cascade by feedback activation of coagulation factors. HMWK = high-molecular-weight kininogen; PK = prekallikrein; PL = phospholipid; PT = prothrombin; TF = tissue factor; Th = thrombin. (From Schafer AI. Coagulation cascade: an overview. In: Loscalzo J, Schafer AI, eds. *Thrombosis and Hemorrhage.* Cambridge, MA: Blackwell Scientific Publications; 1994:3-12.)

precursor, prothrombin, by the action of activated factor X (Xa) and its cofactor, factor Va. This sequence of reactions has classically been referred to as the *common pathway* of coagulation. Factor X can be activated by either the *tissue factor (extrinsic) pathway* or the *contact activation (intrinsic) pathway* of coagulation. The tissue factor pathway is now considered to be the major physiologic initiator of coagulation activation. It is triggered by the formation of the complex of tissue factor, which is exposed on the surfaces of activated vascular and blood cells, with activated factor VII (VIIa). The contact activation pathway involves a series (or cascade) of zymogen-protease reactions that are initiated by factor XII, high-molecular-weight kininogen, and prekallikrein. Activated factor XII (XIIa) converts factor XI to XIa, which in turn activates factor IX to IXa. Factor IXa is the enzyme that converts factor X to Xa, a reaction that requires factor VIIIa as a cofactor.

Physiologic Antithrombotic Mechanisms

Intact, normal endothelium promotes blood fluidity by inhibiting platelet activation. It likewise plays a crucial role in preventing fibrin accumulation. Among the physiologic antithrombotic systems that produce this latter effect are (1) antithrombin III, (2) protein C and protein S, (3) tissue factor pathway inhibitor (TFPI), and (4) the fibrinolytic system. Antithrombin is the major protease inhibitor of the coagulation system[2]: it inactivates thrombin and other activated coagulation factors. Heparin functions as an anticoagulant by binding to antithrombin and greatly accelerating these reactions. Heparin and heparin sulfate proteoglycans are naturally present on endothelial cells, so antithrombin inactivation of thrombin and other coagulation proteases most likely occurs physiologically on vascular surfaces rather than in fluid plasma. Activated protein C, with its cofactor protein S, functions as a natural anticoagulant by destroying factors Va and VIIIa, two essential cofactors of the coagulation cascade. Thrombin itself is the activator of protein C, and this reaction occurs rapidly only on the surfaces of intact vascular endothelial cells, where thrombin binds to the glycosaminoglycan thrombomodulin. TFPI is a plasma protease inhibitor that specifically quenches tissue factor–induced coagulation. Finally, what little fibrin can be produced, despite these potent physiologic antithrombotic mechanisms, is digested rapidly by the endogenous fibrinolytic system. Fibrinolysis is mediated by the protease plasmin, which is generated from plasminogen in plasma by the action of endothelium-derived plasminogen activators.

EVALUATION OF THE PATIENT WITH A POSSIBLE BLEEDING DISORDER

History and Physical Examination

A thorough history is paramount in evaluating a patient for a possible systemic bleeding disorder. In addition to asking the patient about spontaneous bleeding episodes in the past, the responses to specific hemostatic challenges should be recorded. A bleeding tendency may be suspected if a patient previously experienced excessive hemorrhage after surgery or trauma, including common events such as circumcision, tonsillectomy, labor and delivery, menses, dental procedures, vaccinations, and injections. Conversely, a history of normal blood clotting after such specific challenges in the recent past is just as important to note. It may be a better test of the integrity of systemic hemostasis than any laboratory measurement can provide.

In a patient with a history of excessive or unexplained bleeding, the initial goal is to determine whether the cause is a systemic coagulopathy or localized anatomic or mechanical problem with a blood vessel. This situation is encountered most frequently in patients with excessive postoperative bleeding, which could be due to either local surgical trauma or a coagulation abnormality. A history of prior bleeding suggests a coagulopathy, as does the finding of bleeding from multiple sites. However, this is not always the case. Even diffuse bleeding may arise from anatomic rather than hemostatic abnormalities. An example of this is recurrent mucosal hemorrhage in patients with hereditary hemorrhagic telangiectasia (Chapter 173). Conversely, a single episode of bleeding from an isolated site may be the initial manifestation of a coagulopathy.

The history must include a survey of coexisting systemic diseases and drug ingestions that could affect hemostasis. Renal failure and the myeloproliferative disorders are associated with impaired platelet–vessel wall interactions and qualitative platelet abnormalities, connective tissue diseases and lymphomas are associated with thrombocytopenia, and liver disease causes a complex coagulopathy (Chapter 175). Ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that cause nonselective inhibition of cyclooxygenase leads to platelet dysfunction; these drugs are often contained in over-the-counter preparations that patients may neglect to report without specific questioning. Other drugs, such as antibiotics, also may be associated with a bleeding tendency by causing abnormal platelet function or thrombocytopenia. Finally, it is important to elicit a family history of bleeding problems. Although a positive history provides an important clue to a possible inherited coagulopathy, a negative history does not exclude a familial cause; for example, 20% of patients with classic hemophilia have a completely negative family history of bleeding.

Mild bleeding events are commonly reported by patients with and without subsequently laboratory-documented bleeding disorders, sometimes making it difficult for hematologists to define a "significant bleeding history." Using a web-based questionnaire, 25% of subjects in a healthy population reported epistaxis, 18% easy bruising (more commonly in women), 18% prolonged bleeding after dental extraction, and 47% of women heavy menstrual bleeding.[3] More precise quantification of bleeding symptoms is being attempted by using "bleeding score" instruments such as the Vicenza bleeding score to help discriminate, in conjunction with laboratory testing, between healthy subjects and those with mild bleeding disorders.[4]

Patterns of clinical bleeding, as revealed by the history and physical examination, may be characteristic of certain types of coagulopathy (Table 171-1). In general, patients with thrombocytopenia or qualitative platelet or vascular disorders present with bleeding from superficial sites in the skin and mucous membranes. These may involve petechiae, which are pinpoint cutaneous hemorrhages that appear particularly over dependent extremities (characteristic of severe thrombocytopenia), ecchymoses (common bruises), purpura, gastrointestinal and genitourinary tract bleeding, epistaxis, and hemoptysis. In these types of disorders, bleeding tends to occur spontaneously or immediately after trauma. In contrast, patients with inherited or acquired coagulation factor deficiencies, such as hemophilia, or those on anticoagulant therapy tend to bleed from deeper tissue sites (e.g., hemarthroses, deep hematomas, retroperitoneal hemorrhage) and in a delayed manner after trauma.

Laboratory Testing

A few simple screening tests have traditionally been used in the initial evaluation of patients with a suspected coagulopathy: platelet count, bleeding

TABLE 171-1 CHARACTERISTIC PATTERNS OF BLEEDING IN SYSTEMIC DISORDERS OF HEMOSTASIS

TYPE OF DISORDER	SITES OF BLEEDING				ONSET OF BLEEDING	CLINICAL EXAMPLES
	General	*Skin*	*Mucous Membranes*	*Other*		
Platelet-vascular disorders	Superficial surfaces	Petechiae, ecchymoses	Common: oral, nasal, gastrointestinal, genitourinary	Rare	Spontaneous or immediately after trauma	Thrombocytopenia, functional platelet disorder, vascular fragility, disseminated intravascular coagulation, liver disease
Coagulation factor deficiency	Deep tissues	Hematomas	Rare	Common: joint, muscle, retroperitoneal	Delayed after trauma	Inherited coagulation factor deficiency, acquired inhibitor, anticoagulation, disseminated intravascular coagulation, liver disease

time, prothrombin time (PT) (also reported as the international normalized ratio, or INR), activated partial thromboplastin time (aPTT), and thrombin time (TT).[5] The North American Specialized Coagulation Laboratory Association (NASCOLA) has reported that most coagulation laboratories currently perform these tests, with the exception of the bleeding time, as their "bleeding disorder panels."

Thrombocytopenia, reported by electronic particle counting, should be verified by examination of the peripheral smear. Pseudothrombocytopenia, a laboratory artifact of ex vivo platelet clumping, may be caused by the ethylenediaminetetraacetic acid (EDTA) anticoagulant used in tubes for blood cell counts, by other anticoagulants, or by nonphysiologic cold agglutinins acting at room temperature. It should be suspected whenever a very low platelet count is unexpectedly reported in a patient who does not exhibit any clinical bleeding. Pseudothrombocytopenia is indicated by the finding of platelet clumps on the peripheral smear, and the diagnosis is supported by the finding of simultaneously normal platelet counts in blood samples obtained by finger stick, in tubes containing other anticoagulants, or in a tube maintained at 37° C before platelet counting. Examination of the blood smear can also reveal clues to the cause of real thrombocytopenia, such as fragmented red blood cells in thrombotic thrombocytopenic purpura.

The bleeding time was a widely used clinical screening test for disorders of platelet–vessel wall interactions. It measures the time to cessation of bleeding after a standardized incision over the volar aspect of the forearm. However, the test is prone to problems related to quality control, reproducibility, sensitivity, and specificity. Therefore, because von Willebrand disease is the most common genetic cause of abnormal platelet–vessel wall interactions, most experts now recommend replacing the bleeding time with specific tests for von Willebrand disease (VWD screen) in the initial evaluation of patients with a suspected coagulopathy (Chapter 173). As an additional replacement for the bleeding time, especially when a functional (qualitative) abnormality of platelets is suspected by characteristic mucocutaneous bleeding or bruising, a global assay of platelet function can be appended to the panel of screening tests. This is most commonly a platelet function analyzer (PFA) closure time. The PFA and other platelet function studies (see later) must be performed after discontinuation of drugs that interfere with platelet function (e.g., aspirin and other NSAIDs).

The PT measures the integrity of the extrinsic and common pathways of coagulation (factors VII, X, and V; prothrombin; and fibrinogen) (Fig. 171-2). The aPTT measures the integrity of the intrinsic and common pathways of coagulation (high-molecular-weight kininogen; prekallikrein; factors XII, XI, IX, VIII, X, and V; prothrombin; and fibrinogen). The sensitivity of the PT and aPTT in detecting coagulation factor deficiencies may vary with the reagents used to perform these tests, and each laboratory must determine its own reference standards. The TT is a screen for quantitative deficiencies and qualitative defects of plasma fibrinogen.

With a few notable exceptions, normal results for all these screening tests of hemostasis essentially exclude any clinically significant systemic coagulopathy. However, patients with factor XIII deficiency may have a serious bleeding diathesis but normal screening tests; specific tests for factor XIII deficiency should be performed if this disease is suspected (Chapter 174). The PT and aPTT detect only the more severe deficiencies of coagulation factors, usually at levels less than 30% of normal; specific factor levels should be determined if a mild coagulation factor deficiency is suspected. Rare disorders of fibrinolysis also may be associated with normal screening tests, necessitating more specialized tests when indicated (Chapter 174).

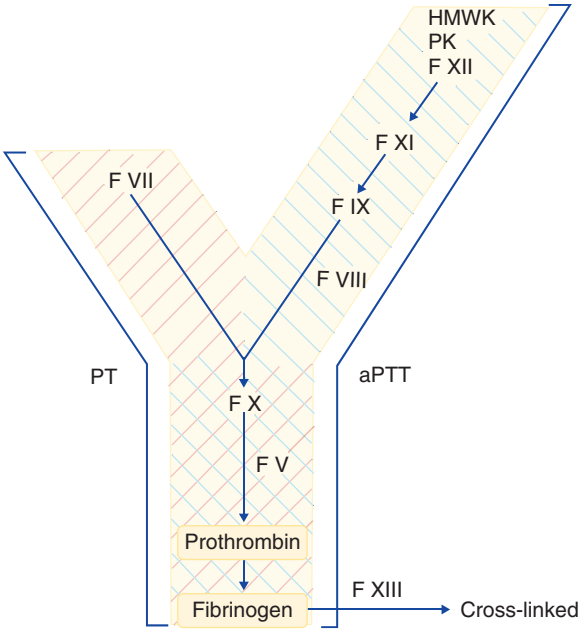

FIGURE 171-2. Classic coagulation cascade. The prothrombin time (PT) measures the integrity of the extrinsic and common pathways, whereas the activated partial thromboplastin time (aPTT) measures the integrity of the intrinsic and common pathways. Factor (F) XIII deficiency is not detected by PT or aPTT. HMWK = high-molecular-weight kininogen; PK = prekallikrein.

Abnormalities in these screening tests of hemostasis may be pursued by more specialized tests to establish a specific diagnosis (Fig. 171-3); other similar algorithms have been published.[6]

An abnormal VWD screen should be followed up with more specialized tests, including von Willebrand factor (VWF) multimer analysis, to identify the type of von Willebrand disease involved. Abnormalities in the PFA closure time should be followed by more specialized light transmission aggregometry (LTA) of platelets using a panel of agonists (ADP, epinephrine, collagen, arachidonic acid, ristocetin) that induce characteristic changes in light transmission (or optical density) in stirred suspensions of freshly isolated platelets in plasma (platelet-rich plasma, PRP). LTA is still considered the gold standard for platelet function testing[7] (see Fig. 171-3C and Chapter 173.)

The finding of a prolonged PT and/or aPTT indicates either a deficiency of one or more coagulation factors or the presence of an inhibitor (Fig. 171-4), usually an antibody, directed at one or more components of the coagulation system (see Fig. 171-3). These two possibilities can be distinguished by performing a simple inhibitor screen, which involves a 1 : 1 mix of the patient's plasma and normal plasma. The premise of the test is that even if the patient's plasma is completely deficient (0% level) in a certain factor, mixing it 1 : 1 with normal plasma (100% level) should bring the concentration of that factor to 50% in the mixture; this is sufficient to correct the prolonged PT or aPTT. If correction occurs with the inhibitor screen, individual coagulation factor levels should be assayed for a specific deficiency state. If the 1 : 1 mix fails to correct the prolonged PT and/or aPTT, an inhibitor is likely to be

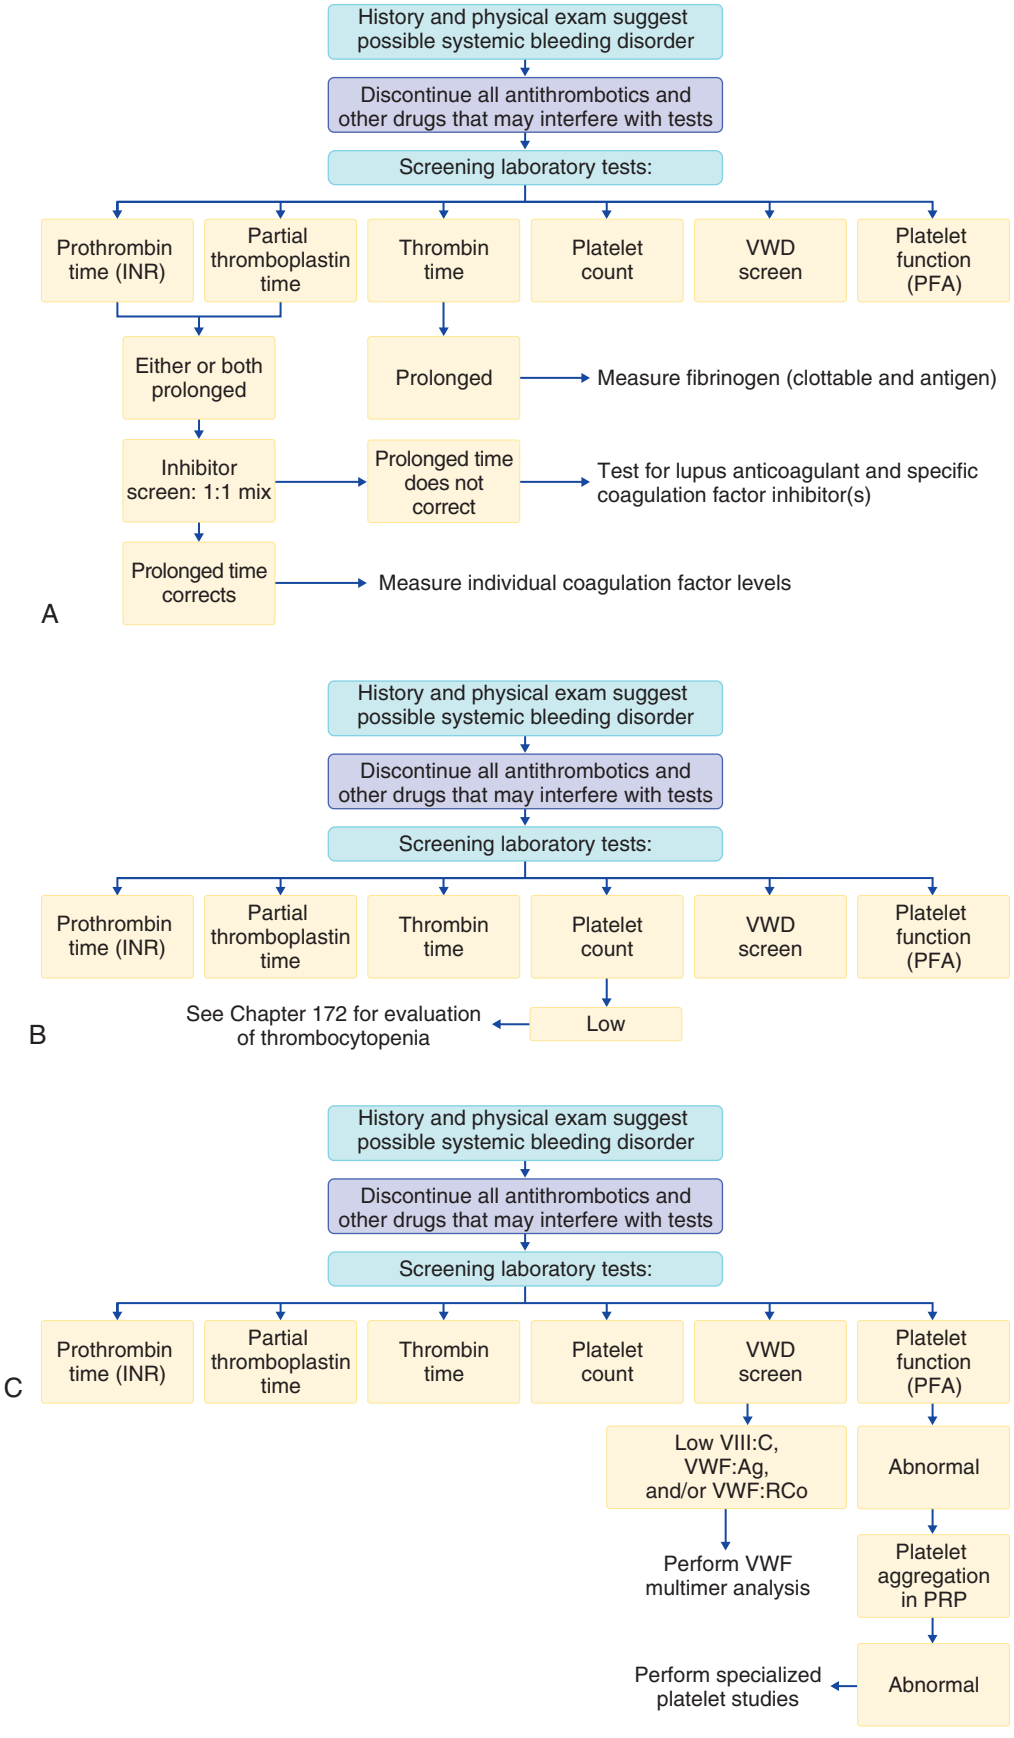

FIGURE 171-3, A to C, Algorithm for a clinical and laboratory approach to the diagnosis of a patient with a suspected systematic bleeding disorder (coagulopathy). The critical importance of a thorough personal and family history and physical examination is emphasized before initiating a laboratory work-up. INR = international normalized ratio; PFA = platelet function analyzer; VWF = von Willebrand factor; VIII:C = Factor VIII coagulant activity; VWF:Ag = von Willebrand factor antigen; VWF:RCo = von Willebrand factor: ristocetin cofactor activity; PRP = platelet-rich plasma.

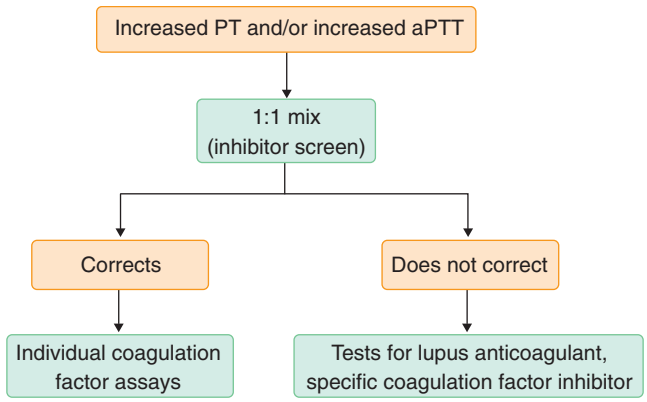

FIGURE 171-4. Approach to evaluating patients with prolonged prothrombin time (PT) or activated partial thromboplastin time (aPTT).

present, and it is interfering with coagulation in vitro in both the patient's plasma and the normal plasma. Specific assays should then be performed to determine whether there is a true inhibitor against a coagulation factor (e.g., factor VIII antibody) or whether the inhibitor is a lupus anticoagulant. A prolonged TT, with or without prolongation of the PT and/or aPTT, suggests the presence of a quantitative deficiency or a qualitative defect of fibrinogen. These can then be distinguished by following up with simultaneously performed clottable (functional) and antigenic assays of fibrinogen: a disproportionately low clottable fibrinogen points to a functional fibrinogen abnormality (dysfibrinogenemia), whereas proportionately reduced levels of clottable and antigenic fibrinogen suggest a quantitative deficiency (hypofibrinogenemia or afibrinogenemia) (see Fig. 171-3A and Chapter 174).

Newer coagulation tests, known as global assays, have the potential to offer fuller evaluation of a patient's overall clot-forming capability. These global assays, including thrombin generation tests and viscoelastic assays, have not yet advanced from experimental research to routine clinical practice.[8,9]

EVALUATION OF THE ASYMPTOMATIC PATIENT WITH ABNORMAL COAGULATION TESTS

In asymptomatic individuals who are discovered incidentally to have abnormalities in screening laboratory tests of hemostasis, the first critical question to ask is whether the findings are clinically relevant. Patients with inherited deficiencies of one of the contact activation coagulation factors (factor XII, high-molecular-weight kininogen, prekallikrein) characteristically have a markedly prolonged aPTT, yet they do not have a clinical bleeding tendency. Likewise, patients with lupus anticoagulants typically have prolongation of the aPTT and sometimes also the PT; they more often have thrombotic rather than bleeding complications. In patients with heparin-induced thrombocytopenia, a marked decrease in the platelet count is sometimes associated with arterial and venous thrombosis rather than bleeding. It is crucial to view the clinical setting, history, physical examination, and screening laboratory tests as complementary facets of the approach to patients with suspected coagulopathies.

EVALUATION OF THE PREOPERATIVE PATIENT

Routine screening of all preoperative patients with a platelet count, bleeding time, PT, and aPTT not only is uninformative but also may be counterproductive if follow-up testing causes unnecessary expense and delays in surgery (Chapter 431). Preoperative bleeding time, PT, and aPTT do not predict surgical bleeding risk in patients who are not found to be at increased risk on clinical grounds, so a thorough clinical assessment should guide the need for these preoperative screening tests. Laboratory testing and possibly further specialized tests of coagulation are indicated for patients whose bleeding histories are suspicious for a hemostatic abnormality. Preoperative screening tests of coagulation are probably warranted for patients who cannot cooperate with an adequate clinical assessment and for those who will be undergoing procedures in which even minimal postoperative hemorrhage could be hazardous. Recent guidelines for preinterventional and preoperative hemostatic evaluation have likewise concluded that bleeding risk requires a detailed personal and family history of hemorrhagic events and physical examination; but individuals with a negative history and without conditions that may interfere with systemic hemostasis should not undergo coagulation testing.[10]

TABLE 171-2 CLINICAL CHARACTERISTICS OF PATIENTS WITH INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIA)

Venous thromboembolism (>90% of cases)
Deep vein thrombosis and/or pulmonary embolism most common
Mesenteric, cerebral vein thrombosis rare but characteristic
Frequent family history of thrombosis
Typically autosomal dominant
First episode of thrombosis typically in young adulthood (<40 years)
Often apparently unprovoked (but an acquired thrombosis trigger is frequently identified with a careful history)
More common thrombophilias (factor V Leiden, prothrombin 20210G→A) are associated with a lower thrombosis risk; rarer thrombophilias (antithrombin III, protein C, protein S deficiency) are associated with a higher thrombosis risk
Warfarin-induced skin necrosis or neonatal purpura fulminans with protein C or protein S deficiency (very rare)

EVALUATION OF THE PATIENT WITH A POSSIBLE HYPERCOAGULABLE STATE

Most patients with venous thromboembolism (VTE) have an inherited basis for hypercoagulability (Chapter 176). Patients with inherited hypercoagulable states (or thrombophilia) typically present with an initial episode of VTE in early adulthood, but thrombotic manifestations may begin at any time from early childhood to old age. Patients usually have deep vein thrombosis of the lower extremities or pulmonary embolism, but other uncommon sites of venous thrombosis may be involved. Arterial thrombosis is not characteristically associated with inherited hypercoagulable states. Arterial thrombosis that occurs prematurely or in the absence of apparent risk factors should trigger a different line of investigation, possibly including evaluation for vasculitis, myeloproliferative neoplasms, hyperhomocysteinemia, antiphospholipid syndrome, and potential sources of systemic embolization.

The primary or hereditary hypercoagulable states (see Table 176-1) result from specific mutations or polymorphisms that lead to decreased levels of physiologic antithrombotic proteins or increased levels of procoagulant proteins. In contrast, the secondary or acquired hypercoagulable states (see Fig. 176-3) are a heterogeneous group of disorders that predispose to thrombosis by complex mechanisms. VTE is often precipitated by the combination of an underlying hypercoagulable genotype and an acquired prothrombotic, hypercoagulable state such as pregnancy, immobilization, or the postoperative state. Certain clinical characteristics suggest the presence of an inherited hypercoagulable state (Table 171-2). Patients with recurrent thrombosis should be tested for these disorders and, in most cases, committed to lifelong prophylactic anticoagulation. It is not clear whether it is essential to order these tests after a single episode of VTE. Counterintuitively, it has been found that most of the common inherited hypercoagulable states—which, to varying extents, clearly increase the risk for a *first* episode of VTE—are at best only weak predictors of *recurrent* VTE. It has been argued, therefore, that making a specific thrombophilia diagnosis after an initial episode of VTE will not influence the decision about the duration of prophylactic anticoagulation. However, the increased risk for recurrent VTE with the more strongly prothrombotic mutations (e.g., antithrombin III, protein C or S deficiency), combined inherited thrombophilias, or antiphospholipid syndrome may necessitate long-term anticoagulation, and therefore their diagnosis after a first episode of VTE would in fact alter decisions about the duration of anticoagulation. An algorithm for thrombophilia testing after a first episode of VTE is presented in Figure 176-2. Even if they are not maintained on long-term anticoagulation, patients with diagnosed primary hypercoagulable states should receive prophylactic anticoagulation during situations that pose a high risk for thrombosis, such as the peripartum period. There is no simple screening test for primary hypercoagulable states, and the timing of obtaining these tests is crucial to avoid erroneous diagnoses. Acute thrombosis itself can cause transient decreases in the levels of antithrombin, protein C, and protein S. Heparin therapy can cause a decrease in plasma antithrombin activity. Warfarin therapy lowers the functional levels of protein C and protein S. Inherited deficiency states can be diagnosed spuriously under these conditions. Use of one of the newer anticoagulants can also interfere with laboratory tests, especially for lupus anticoagulant.

Patients who present with VTE have an increased risk for harboring an occult malignancy. This association is increased further in patients with recurrent and unprovoked thrombosis. There are conflicting opinions on whether an evaluation for occult malignancy in these patients must be exhaustive.

Most recommend that evaluation can be limited to a thorough history, physical examination, routine complete blood cell count and chemistries, test of fecal occult blood, urinalysis, mammogram (in women), and chest radiograph, with further testing guided by any abnormalities found in this initial evaluation. Others argue for routine computed tomography scanning of the chest, abdomen, and pelvis[11,12] (see algorithm in Fig. 176-3).

In addition to classic deep vein thrombosis and pulmonary embolism, certain characteristic types of thrombosis may provide important clues to the cause and trigger a more directed evaluation. Migratory, superficial thrombophlebitis (Trousseau syndrome) or nonbacterial thrombotic endocarditis strongly suggests the presence of an occult malignancy (Chapter 179). Hepatic vein thrombosis (Budd-Chiari syndrome; Chapter 143) or portal vein thrombosis may indicate a myeloproliferative neoplasm (Chapter 166) or paroxysmal nocturnal hemoglobinuria (Chapter 160). Extensive inferior vena cava thrombosis may occur with renal cell carcinoma (Chapter 197). Warfarin-induced skin necrosis strongly suggests underlying protein C or protein S deficiency. Recurrent, spontaneous miscarriages are characteristic of the antiphospholipid syndrome (Chapter 174), although they are also associated with other thrombophilias.

REVIEW QUESTIONS

1. You are asked to clear a 48-year-old man for elective surgery for a herniated disc because he told his surgeon that he has a history of some kind of "blood problem." The patient tells you he bled heavily one day after a dental extraction 5 years ago, requiring blood transfusions in his local hospital's emergency department. He also recalls his parents telling him that he "almost died" of bleeding after a tonsillectomy in early childhood. There have been no other bleeding problems, even though he was an All-American soccer player in college and proudly says that he didn't bruise any more than his teammates. Family history is negative for bleeding except for his maternal grandfather, who had serious postoperative bleeding after coronary artery bypass graft surgery. The patient's screening coagulation test results now are normal: platelets = 380,000; prothrombin time (PT) = 11.4 (international normalized ration [INR] = 1.0); partial thromboplastin time (PTT) = 27.5. What would you do now?

A. Clear him for surgery with close postoperative observation for bleeding.
B. Order a bleeding time and platelet function tests.
C. Order factor VIII and factor IX levels.
D. Order liver function tests.
E. Order von Willebrand factor (VWF) multimer analysis.

Answer: C The type of bleeding complications this patient describes (i.e., delayed, deep bleeding, especially at oropharyngeal sites with surgery) is more characteristic of a coagulation factor defect than a platelet-vascular defect. His family history is suggestive of an X-linked inherited coagulopathy, with his mother being the silent carrier. Factor VIII deficiency (classic hemophilia) and factor IX deficiency fit that description. The PTT is not a sensitive screening test to pick up less severe forms of a coagulopathy (i.e., when the factor level is >25%), so *mild* hemophiliacs (with either factor VIII or IX deficiency) may have a normal PTT and yet still have serious bleeding complications when provoked with surgery. Therefore, factor VIII and IX levels must be obtained here to rule out the mild hemophilia, which would require prophylactic preoperative (as well intraoperative and postoperative) replacement therapy. The bleeding time, a method to test the integrity of platelet-vascular interactions, is now largely an obsolete test; and the kinds of bleeding problems this patient describes (as well as the notable absence of pathologic bruising with trauma) argues strongly against a qualitative platelet abnormality. Liver function tests could be done but are unlikely to shed additional light on this diagnostic problem; furthermore, this patient appears to have an inherited, not acquired coagulopathy. The possibility of von Willebrand disease is not unreasonable (even though it is usually autosomal dominant), although, again patients with von Willebrand disease tend to bleed superficially like patients with platelet problems. In any case, multimer analysis is not the first step to diagnosing von Willebrand disease: it should be preceded by a von Willebrand panel to assay levels of functional VWF, antigenic VWF, and factor VIII activity.

2. A 68-year-old man with coronary artery disease, diabetes mellitus, hypertension, and a history of stroke followed by seizures is now 3 days after an uncomplicated coronary artery bypass graft (CABG) surgery, and you are asked to consult for severe thrombocytopenia. The patient is on multiple medications for his chronic conditions and is now on postoperative subcutaneous heparin for thromboprophylaxis. There have been no bleeding problems postoperatively, and physical examination shows no signs of bleeding from external orifices and no ecchymoses or petechiae. The platelet count today is 5000, which triggered the STAT consult; it had been previously normal, including a count of 280,000 yesterday. Which of the following should be the first step?

A. Examine the peripheral blood smear for platelet clumping.
B. Stop heparin.
C. Stop heparin and all other medications.
D. Order STAT platelet transfusions.
E. Take a thorough history and do a comprehensive physical examination.

Answer: A The first step is to promptly determine whether the apparently sudden drop in platelet count is real or artifactual. The abrupt drop (when counts were normal as recently as 1 day ago), accompanied by the striking absence of symptoms or signs of bleeding in this patient raises a high level of suspicion for "pseudothrombocytopenia." Seeing large clumps of platelets on the peripheral smear, which should be examined by the hematologist, would confirm the suspicion, which should be then promptly documented by ordering repeat platelet counts in both the customary purple-top tube containing EDTA as the anticoagulant along with tubes containing other anticoagulants (heparin or citrate). (The platelet count in the EDTA tube should be again very low, but not in blood collected into test tubes with the other anticoagulants.) Occasionally, pseudothrombocytopenia occurs as a result of the presence of a nonphysiologic "cold agglutinin," which clumps platelets in the test tube while sitting at room temperature before counting. This can be ruled out by having the laboratory do simultaneous platelet counts on a tube kept at 37° C versus one that has been intentionally left standing at room temperature: the former should have a normal platelet count if this is the case. These findings represent pseudothrombocytopenias in which the platelet counts are artifactually low and of no clinical consequence. These tests can be all done very quickly without stopping important medications, including heparin, and before undertaking further work-up and treatment of the thrombocytopenia if they remain necessary.

3. Which of the following statements is correct regarding the relationship between cancer and thrombosis?

A. In a patient being treated for gastric cancer, secondary prevention following a first episode of venous thromboembolism is best provided by warfarin for 3 to 6 months at doses to target an international normalized ratio of 2.0 to 3.0.
B. A first episode of apparently unprovoked deep vein thrombosis in a previously healthy individual requires comprehensive search for an occult malignancy, including computed tomography of the chest, abdomen, and pelvis.
C. Pulmonary embolism in a patient being actively treated for cancer requires the placement of an inferior vena cava (IVC) filter to prevent recurrence.
D. A patient with breast cancer who completed treatment 6 months ago and is now in complete remission, with no evidence of disease, is not at increased risk for venous thromboembolism.
E. In a previously healthy individual, the spontaneous development of extensive IVC thrombosis is highly suggestive of an occult renal cell carcinoma.

Answer: E IVC thrombosis, a rare and dramatic form of venous thrombosis that can extend into the right atrium, is associated with renal cell carcinoma. Other characteristic (but not diagnostic) cancer-associated thrombosis syndromes include Budd-Chiari syndrome (hepatic vein thrombosis) or portal vein thrombosis in patients with myeloproliferative neoplasms, and superficial, migratory thrombophlebitis (Trousseau syndrome) with occult cancers of the gastrointestinal tract and pancreatic cancer. Subcutaneous low-molecular-weight heparin is superior to dose-adjusted warfarin for secondary prophylaxis after an episode of venous thromboembolism in a cancer patient, even when in remission, and it should be continued indefinitely. Although the incidence of occult malignancy in a previously healthy person who presents with unprovoked venous thromboembolism is definitely increased, most experts agree that a comprehensive history and physical examination, stool for occult blood, chest radiograph, blood counts and basic chemistries, and a mammogram in women is a sufficient initial screen for occult cancer, as long as any abnormalities picked up on that screen are more aggressively pursued. Increased risk for thrombosis in a patient with cancer continues for months or even years after complete remission has been achieved. An IVC filter is inadequate to prevent recurrent pulmonary embolism in patients with or without cancer.

172 THROMBOCYTOPENIA

CHARLES S. ABRAMS

Thrombocytopenia is defined as a platelet count of less than the normal range, typically below 140,000/μL. In the absence of qualitative platelet defects (Chapter 173), excessive bleeding does not occur in thrombocytopenic patients following trauma or surgery unless the platelet count is lower than 75,000/μL. In otherwise hemostatically normal patients, spontaneous hemorrhage typically does not occur with platelet counts above 30,000/μL. Patients with platelet counts of less than 5000/μL to 10,000/μL are at a high risk for spontaneous, life-threatening hemorrhage. However, there is no absolute threshold for spontaneous bleeding due to thrombocytopenia. Bleeding may occur at higher counts when fever, sepsis, severe anemia, and other hemostatic defects are present, or when platelet function is impaired by medication. Notably, a prolonged cutaneous bleeding time test (Chapter 171) does not accurately predict the risk for clinical bleeding. Therefore, it is critical that the physician consider the gamut of possibilities when diagnosing and managing a patient with a low platelet count.

Typically, the first step in diagnosing a patient with a low platelet count is to determine whether the thrombocytopenia is attributable to one of the three broad mechanisms for developing thrombocytopenia: (1) increased destruction of platelets, such as seen in immune-mediated causes; (2) decreased production of platelets, usually due to an underlying bone marrow disorder; or (3) sequestration of platelets within the spleen, as occurs in conditions that cause splenomegaly (hypersplenism).

Determining the cause of the patient's thrombocytopenia is essential to select the most appropriate therapy and to avoid unnecessary procedures. Because there is no easy test to differentiate among the three possibilities, clinical evaluation is critical. Therefore, a thorough history and physical examination, with attention to possible alternative explanations for thrombocytopenia, are mandatory. Particular attention should be paid to the duration of symptoms, which helps to determine whether the patient has acute or chronic thrombocytopenia. The clinician should also focus on the patient's recent exposure to new medications that might induce thrombocytopenia as a side effect.

Preliminary laboratory tests include a complete blood count (CBC) with a differential, along with an examination of the peripheral blood smear. Abnormalities in the number or morphology of the leukocytes or erythrocytes may indicate a systemic inflammatory disorder or a pathology within the bone marrow. Clumping of the platelets on the peripheral blood smear may indicate that the patient has pseudothrombocytopenia (Chapter 171). This anomaly is usually due to an antibody that binds to and thereby agglutinates platelets only in the presence of ethylenediaminetetraacetic acid (EDTA) or when the blood sample is allowed to cool to room temperature. Repeating the platelet count in a blood sample that has been anticoagulated with heparin and kept warm until it is analyzed can help exclude this spurious diagnosis. Any additional testing to determine the cause of thrombocytopenia is based solely on the available clinical information derived from the history and examination of the patient. For example, testing for human immunodeficiency virus (HIV) would be prudent in a patient with risk factors. A bone marrow aspirate and biopsy are typically not required for a patient with thrombocytopenia who has an otherwise normal CBC and peripheral blood smear. However, a bone marrow aspirate and biopsy should be considered in older patients and in patients for whom standard therapy has not been effective.

With the widespread use of the "routine CBC," asymptomatic individuals with incidentally discovered mild thrombocytopenia are being increasingly recognized. The clinical significance of mild thrombocytopenia (platelet counts between 100,000/μL and 150,000/μL) can be difficult to ascertain. Some of these individuals represent outliers of the normal distribution of platelet counts. However, others have thrombocytopenia that represents the early manifestation of an unrecognized disease. In the absence of other signs, many of these individuals are diagnosed with idiopathic (immune) thrombocytopenic purpura (ITP)—a disease that will be discussed later in this chapter. Studies of apparently healthy individuals who were incidentally discovered to have borderline thrombocytopenia have yielded some insight into their prognosis.[1] After a decade, approximately 10% will have developed ITP or another autoimmune disorder. However, approximately 90% of the subjects continued to manifest borderline thrombocytopenia without developing another disorder during this period of time. It can be concluded that most individuals with isolated and asymptomatic chronic mild thrombocytopenia simply represent the lower end of the normal platelet count distribution. Consequently, international consensus groups have set the threshold for the diagnosis of ITP at a platelet count of less than100,000/μL.

PATHOBIOLOGY

See Figure 172-1 for an approach to evaluating patients with chronic thrombocytopenia.

Increased Platelet Destruction

In the absence of splenomegaly, the presence of megakaryocytes in an otherwise normal bone marrow implies that thrombocytopenia is due to increased platelet destruction. An acute drop in a patient's platelet count also implies that a peripheral destructive process is the likely cause. For example, a patient who develops abrupt thrombocytopenia during hospitalization most likely has a low platelet count caused by an infection or by the introduction of a new medication. Both nonimmune and immune processes can lead to a shortened platelet lifespan. Nonimmune reasons for the accelerated destruction of platelets include sepsis, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), preeclampsia or eclampsia, cardiopulmonary bypass, and giant cavernous hemangioma. Thrombocytopenia that occurs in these circumstances usually resolves with treatment of the underlying disorder, and platelet transfusions are rarely necessary. Thrombocytopenia due to TTP, HUS, or heparin-induced thrombocytopenia (HIT) is more characteristically associated with microvascular occlusion or thrombosis than with bleeding (Table 172-1), so platelet transfusions are rarely necessary. In addition, reports have noted the clinical deterioration of patients with TTP or HIT following platelet transfusion, leading to the controversial suggestion that platelets should not be given to most patients with these disorders.

Immune-mediated platelet destruction can result from drugs, alloimmune sensitization, or autoimmunity. Medications should always be considered as a possible cause of acute thrombocytopenia. The list of potential offending agents is long, but drugs with strong evidence of antibody-mediated platelet destruction include quinine, quinidine, sulfonamides, and gold salts. In addition to stopping the offending medication, platelet transfusions might be required for severe thrombocytopenia.

Platelet Sequestration

Approximately 30% of the circulating platelet mass is normally sequestered within the spleen. Enlargement of the spleen due to portal hypertension or

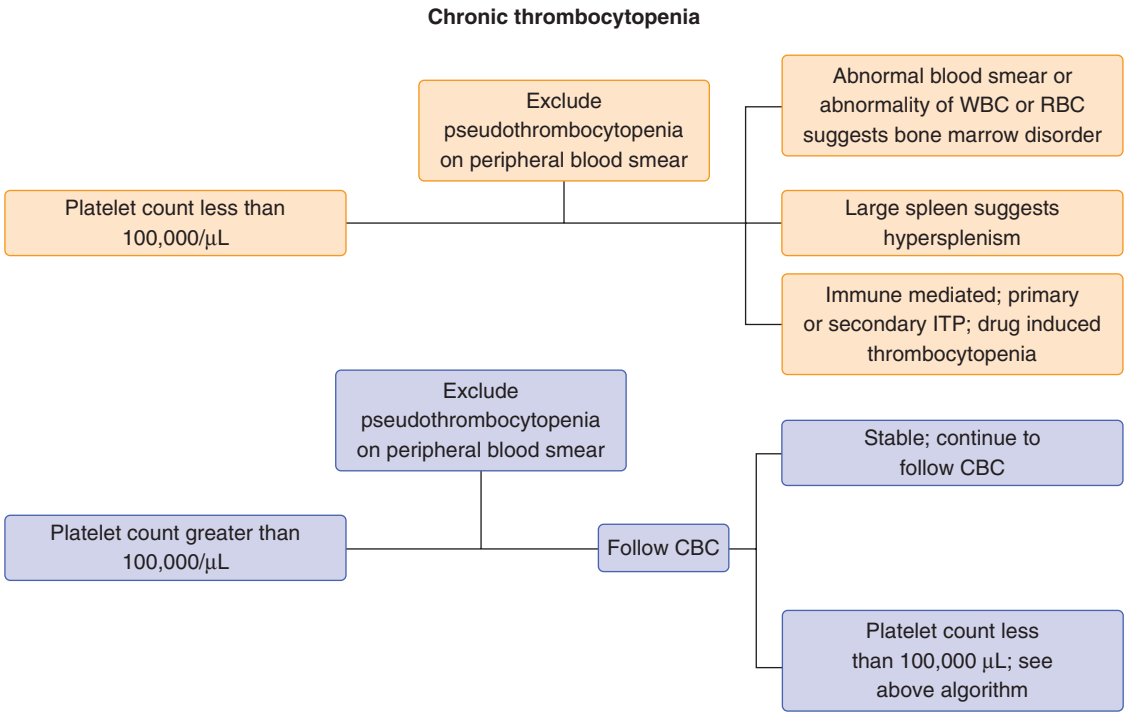

FIGURE 172-1. **Systematic approach to the evaluation of chronic thrombocytopenia.**

TABLE 172-1 DISORDERS THAT CAUSE BOTH THROMBOCYTOPENIA AND THROMBOSIS

Thrombotic thrombocytopenic purpura (TTP)
Hemolytic-uremic syndrome (HUS)
Heparin-induced thrombocytopenia (HIT)
Disseminated intravascular coagulation (DIC)
Paroxysmal nocturnal hemoglobinuria (PNH)
Vasculitis (such as systemic lupus erythematosus)
Antiphospholipid antibody syndrome (APS)

infiltration is accompanied by expansion of the splenic platelet pool. Because hypersplenism by itself rarely causes a platelet count of less than 40,000/μL to 50,000/μL, bleeding due to thrombocytopenia from hypersplenism alone is unusual. This in turn can result in moderate thrombocytopenia.

Decreased Platelet Production

Decreased platelet production occurs in primary diseases of the bone marrow, such as acute leukemia and aplastic anemia; myelophthisic processes in which bone marrow is affected by metastatic carcinoma, fibrosis, or other clonal hematopoietic disorders; following chemotherapy and/or radiation therapy; with ethanol toxicity; and during infections with viruses such as HIV, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and varicella. Thrombocytopenia also occurs when normal megakaryocyte proliferation is impaired by myelodysplasia.

Thrombocytopenia due to decreased platelet production is often accompanied by abnormalities of both the white blood cells and red blood cells. This should be readily apparent by inspection of the CBC and review of the peripheral blood smear. When thrombocytopenia in this setting is accompanied by bleeding, the bleeding usually requires treatment by platelet transfusion. Additionally, when decreased platelet production cannot be readily reversed, prophylactic platelet transfusion to prevent bleeding is often considered. However, as will be discussed in the following section, prophylactic platelet transfusion is problematic because of the short lifespan of platelets and the potential to develop alloantibodies that will limit the effectiveness of future platelet transfusions.

PLATELET TRANSFUSIONS

Clinicians usually consider "wet" bleeding to be much more ominous than "dry" bleeding. Signs of wet bleeding include epistaxis, gingival bleeding, gastrointestinal bleeding, genitourinary bleeding, and bleeding around

FIGURE 172-2. **Petechiae. Multiple pinpoint, nonblanching, erythematous macules found predominantly on skin of dependent extremities in patients with severe thrombocytopenia.**

intravenous sites. Dry bleeding is defined as ecchymosis or petechiae (Fig. 172-2). Overt wet bleeding that is clearly due to thrombocytopenia is usually treated with platelet transfusion (Chapter 177). Prophylactic platelet transfusion for patients who are not bleeding is controversial. When making the decision whether to treat a nonbleeding patient with thrombocytopenia, the practitioner must consider the short lifespan of platelets (10 days), the 5-day shelf-life of stored platelets, and the potential for the patient to develop transfusion-induced platelet alloantibodies. In patients undergoing treatment for acute leukemia, recent clinical trials have supported the clinical practice of prophylactic platelet transfusions when the platelet count is below 5000/μL or 10,000/μL, rather than waiting until bleeding occurs in the severely thrombocytopenic patient. The indications for prophylactic platelet transfusions before interventional procedures is predominantly based on clinical experience and expert opinions, rather than on clinical trials. These recommendations are summarized in Table 172-2. Platelet transfusions should continue for several days following procedures where the risk for bleeding or the complications resulting from bleeding are high. For extremely high-risk procedures that involve the nervous and ocular systems, the prophylactic platelet transfusions should be continued for at least 7 to 10 days.

TABLE 172-2 SUGGESTED MINIMUM PLATELET COUNTS BEFORE INVASIVE PROCEDURES

VERY-HIGH-RISK PROCEDURES—75,000/μL TO 100,000/μL
Neurosurgery Ocular surgery (except cataract extraction) Thyroid surgery Prostatectomy
MODERATE-RISK PROCEDURES—50,000/μL
Liver Biopsy Dental extraction Most surgical procedures
LOW-RISK PROCEDURES—30,000/μL
Endoscopy Bronchoscopy Lumbar puncture (with scrupulous technique)
VERY-LOW-RISK PROCEDURES—NO PLATELET TRANSFUSIONS NECESSARY
Bone marrow biopsy Cataract extraction

A donated unit of blood contains approximately 50 billion platelets. Infusing this number of platelets into a patient should increase his or her platelet count by 20,000/μL divided by the patient's body surface area in square meters. Therefore, transfusion into an average-sized patient should increase the recipient's platelet count by 10,000/μL to 12,000/μL. Bags of platelets used for transfusions are typically obtained by pooling platelets derived from four to eight blood donors. Therefore, a "unit" at one hospital may be derived from more donors than a "unit" obtained at another hospital.

Large quantities of platelets can be derived from a single donor by using apheresis technology (plateletpheresis) (Chapter 177). Because there is minimal loss of red blood cells with this technique, plateletpheresis allows one individual to donate very large numbers of platelets (equivalent to the number of platelets obtained from 6 to 10 units of donated blood). As discussed in the following section, the risk for platelet alloimmunization is partially dependent on the number of individuals donating platelets to a patient. Therefore, single-donor plateletpheresis can prevent or at least minimize alloimmunization.

Several trials have addressed how many platelets should be transfused into thrombocytopenic patients to maintain hemostasis and to minimize exposure to blood products (also see Chapter 177). The largest of these trials was the multicenter Platelet Dose (PLADO) Trial.■ In this study, patients with thrombocytopenia were randomized to receive transfusions of low-dose (110 billion/m^2), medium-dose (220 billion/m^2), or high-dose (440 billion/m^2) platelets while recovering from hematopoietic stem cell transplantation. Patients who received the low-dose therapy required more frequent platelet transfusions. However, overall they received fewer transfused platelets over the course of the study. Importantly, bleeding complications were identical with all platelet transfusion strategies. This study demonstrates that low doses of platelets (110 billion/m^2 of body surface area) are as safe as larger doses in patients with hypoproliferative thrombocytopenia who are receiving prophylactic platelet transfusion therapy.

Several complications of platelet transfusion therapy merit mention (also see Chapter 177). First, some patients can become alloimmunized against platelet antigens and can become refractory to future platelet transfusion therapy (discussed in detail later). Second, bacterial contamination of stored platelets is a much more common complication than the infectious risk associated with red blood cell transfusions. Unlike red blood cells, which are stored frozen after being harvested from donated blood, platelets are sensitive to cool temperatures and therefore need to be stored at room temperature. This method of storage results in more bacterial overgrowth in the transfusion bags. Transfusion-associated bacterial sepsis is one of the most frequently reported causes of transfusion-induced mortality in the United States, and platelet transfusions are the most common blood products associated with sepsis. It should also be noted that room temperature storage of platelets contributes to their short shelf life of approximately 5 to 7 days. Consequently, unlike the blood-derived products that can be frozen (such as red blood cells and plasma), there is a constant need for platelet donations year-round. In contrast to the risk for bacterial infection, the risk for viral infection from platelet transfusions is no higher than it is for red blood cell transfusions. From a single unit of platelets, the risk for being exposed to HIV is less than 1 in 2.5 million, the risk for exposure to hepatitis B virus is less than 1 in 750,000, and the risk for exposure to hepatitis C virus is less than 1 in 1 million.

Platelet transfusions have been considered contraindicated for thrombocytopenia caused by TTP or HIT. However, this recommendation is driven entirely by case reports of thrombotic events that have occurred soon after platelet transfusions have been given to such patients. This recommendation is not based on randomized trials designed to address this issue. Because thrombotic events are a known complication of both TTP and HIT, it is difficult to determine whether the thrombi that occurred in these patients were due to the platelet transfusions or merely to the intrinsic prothrombotic risk for TTP and HIT. In any case, there is usually no indication for platelet transfusions in patients with TTP and HIT because thrombosis is a much greater risk than hemorrhage in these disorders.

The Transfusion-Refractory Patient

Many patients do not have an optimal increase in their platelet count following transfusion. Although there are various definitions of platelet refractoriness, it is simplest to base this definition on the timing of platelet loss following transfusion. Patients who do not have the predicted rise in their platelet count (between 10,000/μL and 12,000/μL for every unit of donated platelets) should have their platelet count analyzed before their next platelet transfusion, 1 hour after that transfusion, and again 24 hours later. If their platelet count rises appropriately 1 hour after the transfusion but falls substantially 24 hours later, the patient has ongoing platelet consumption. This is often seen in patients with sepsis, DIC, or severe active hemorrhage, or as a result of the drug-mediated immune destruction of platelets. In these situations, the best therapy is to treat the underlying cause and to continue to support the patient with platelet transfusions as clinically indicated. Alternatively, some patients fail to have a significant increase in platelets even 1 hour after a transfusion. These patients may have (1) hypersplenism, (2) an autoantibody that eliminates not only endogenous platelets but also allogeneic platelets (as seen in patients with ITP), or (3) alloantibodies that react with antigens on the transfused platelets.

Alloantibodies develop in approximately 20% of patients who are repeatedly exposed to platelet transfusions, and these patients present some of the most challenging management issues in transfusion medicine (Chapter 177). The alloantibodies may be directed against human leukocyte antigen (HLA) class I antigens (HLA-A and HLA-B) or against platelet-specific antigens present on the surface of the platelets. Because it appears that HLA class II antigens present on the surface of leukocytes are essential for the development of antibodies directed against HLA class I antigens, efforts to remove the contamination of leukocytes in platelet transfusion preparations can minimize alloantibody formation. Therefore, filters that trap leukocytes during transfusions are useful to prevent patients from becoming refractory to future platelet transfusions. After a patient develops alloantibodies against transfused platelets, the clinician and the blood bank should attempt to identify whether the alloantibody is directed against an HLA class I antigen or against a platelet-specific antigen. If the alloantibody can be identified, platelets derived from donors matched for an HLA class I antigen or the platelet-specific antigen can be used. Corticosteroids, intravenous immunoglobulin, splenectomy, and recombinant factor VIIa are probably of no value in maintaining hemostasis in platelet-refractory patients. Antifibrinolytic agents (e.g., ε-aminocaproic acid) might be helpful for patients with bleeding that is predominantly in the oral cavity or in the genitourinary tract. However, antifibrinolytic agents are contraindicated in patients with DIC (Chapter 175) because these agents can precipitate thrombotic events.

SPECIFIC CAUSES OF THROMBOCYTOPENIA

Drug-Induced Thrombocytopenia

PATHOBIOLOGY

Drug-induced thrombocytopenia is one of the most frequent causes of cytopenias evaluated by physicians. The typical drug-induced thrombocytopenia is the result of an immune reaction elicited by either the drug or by one of its metabolites. Sometimes the drug is simply deposited on the platelet surface, and antidrug antibodies lead to accelerated platelet clearance, primarily in the spleen. More frequently, the drug binds to a protein on the platelet surface and induces a neoantigen that is ultimately recognized by the immune system.

In the absence of the drug or drug metabolites, this platelet neoantigen disappears, and the thrombocytopenia slowly resolves as new platelets are released from the bone marrow. This mechanism explains most drug-induced thrombocytopenias, but there are some exceptions. For example, chemotherapy and other bone marrow toxins can decrease platelet production and thereby induce thrombocytopenia by a mechanism independent of the immune system.

CLINICAL MANIFESTATIONS

Patients with drug-induced thrombocytopenia can have mild, moderate, or even severe forms. Almost all types of drug-induced thrombocytopenia predispose the patient to hemorrhagic but not thrombotic complications. The notable exception to this rule is heparin-induced thrombocytopenia (discussed separately in the next section). In acute or subacute cases of thrombocytopenia, it may be especially difficult to distinguish between drug-induced thrombocytopenia and the thrombocytopenia of an infection (viral or bacterial). In very ill patients, both possibilities must be considered in the management plan (see later section on Sepsis). Another difficult diagnostic dilemma is to discern drug-induced thrombocytopenia from ITP. For this distinction, the patient's medical history may be helpful. A gradually progressive thrombocytopenia is more consistent with ITP than with one induced by a medication. Conversely, the rapid onset of thrombocytopenia following the initiation of a new medication indicates that the drug is the most likely culprit. The time between the initiation of the offending drug and the development of thrombocytopenia has not been well documented for most medications. However, thrombocytopenia typically begins days to a few weeks after the administration of most medications with this type of toxicity. Presumably, this lag time represents the period required for the patient to develop an immune response against the drug-platelet complex. Medications that have been taken safely for years before the onset of thrombocytopenia are unlikely to be the offending agents. In addition to an assessment of the patient's prescribed medications, a careful and comprehensive evaluation of the patient's over-the-counter medications is necessary. Agents that contain quinine lead the list of often nonprescribed drugs that can induce life-threatening thrombocytopenia. Quinine is frequently contained in over-the-counter pills for leg cramps. Even the quinine in tonic water can induce severe thrombocytopenia ("gin and tonic purpura") when ingested by certain patients.

DIAGNOSIS

Some medications are much more likely to induce thrombocytopenia than others. Table 172-3 contains a partial list of drugs that frequently induce this type of toxicity. One particularly useful online database (www.ouhsc.edu/platelets/ditp.html) lists and periodically updates the level of evidence for specific drugs that may induce thrombocytopenia. With the exception of tests for HIT, laboratory tests for drug-induced thrombocytopenia do not have widespread applicability. Usually, drug-induced thrombocytopenia is proved only in retrospect, when the platelet count improves after the discontinuation of the suspected medication. Even then, the diagnosis is not conclusive unless thrombocytopenia recurs after rechallenging the patient with the offending drug (a practice that is almost never recommended).

TREATMENT

Rx

The most efficacious method of treating drug-induced thrombocytopenia is to stop all suspected offending medications. Usually, no additional therapy is indicated. The thrombocytopenia typically begins to resolve without further intervention within days to a week of stopping the drug. The notable exceptions involve drugs with particularly long half-lives. Sulfonamides, quinine, and quinidine are particularly notorious for inducing severe or even life-threatening thrombocytopenia. In patients with profound thrombocytopenia (<10,000/μL to 15,000/μL) or at a high risk for bleeding, platelet transfusions are indicated. If ITP cannot be confidently excluded, and the thrombocytopenia is life threatening, specific treatment for ITP can also be initiated (see later in this chapter).

Heparin-Induced Thrombocytopenia

EPIDEMIOLOGY

A special case of drug-induced immune-mediated thrombocytopenia associated with arterial and venous thrombosis, rather than bleeding, is HIT.[2] It is seen in 2 to 5% of patients exposed to unfractionated heparin, and in 0.7% of patients given low-molecular-weight heparin. HIT almost never occurs in patients who are exposed only to fondaparinux.

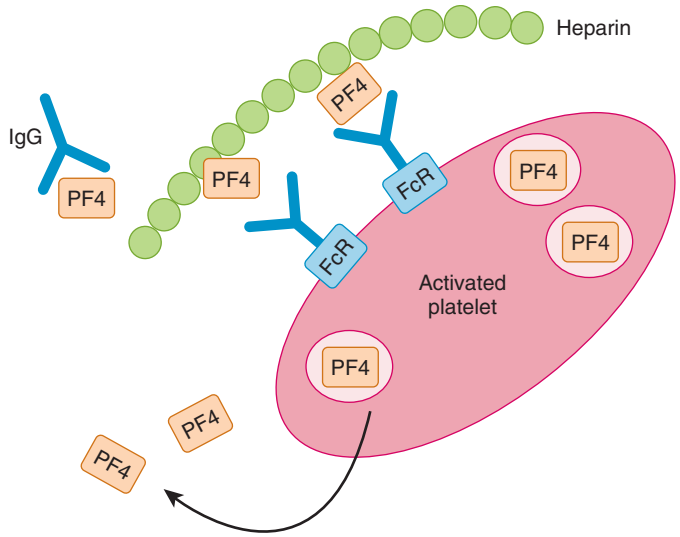

FIGURE 172-3. Pathophysiology of heparin-induced thrombocytopenia. Platelet factor 4 (PF4) is a protein that is stored in platelet granules and that is secreted from platelets upon their activation. Heparin can bind to PF4 and induce a conformational change within PF4 that in some patients produces an antibody-mediated immune response. Large complexes of immunoglobulin (Ig), heparin, and PF4 can accumulate on the platelet surface and stimulate the platelet when the Fc portion of the antibody interacts with the platelet's FcγRII receptor (FcR). Once activated, the platelets contribute to thrombosis. Additionally, the activated platelets secrete more PF4, which continues the process.

PATHOBIOLOGY

To understand this disease, one must know that platelets can secrete a protein called platelet factor 4 (PF4) that can bind to heparin. HIT is caused by an antibody that binds to this PF4-heparin complex (Fig. 172-3). Large complexes of antibodies directed against heparin-bound PF4 accumulate on the surface of platelets. At times, these anti-PF4 immunoglobulins bind to the Fc receptor that is also present on the platelet surface, leading to activation of the platelet, release of more PF4, and a cycle of events that causes the stimulation of even more platelets. Ultimately, this also leads to the activation of the

coagulation cascade. The activation of platelets and the clotting cascade leads to the formation of both thrombi and thrombocytopenia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

When thrombocytopenia is detected in a hospitalized patient, HIT must always be considered. Patients with this syndrome often have multiple potential causes of thrombocytopenia (such as other medications or infections). Therefore, it is important to exclude these other causes. Large retrospective studies of HIT have suggested that the onset of thrombocytopenia relative to the initiation of heparin therapy is useful in establishing or excluding this diagnosis. HIT typically occurs 4 to 14 days after patients are given heparin by any route (it even occurs after subcutaneous injections of "minidose" heparin or following extremely low doses by heparin flush). This lag time between heparin exposure and the appearance of HIT is due to the time it takes for the immune response to generate the requisite antibodies against the heparin-PF4 complex. Some patients who have been exposed to heparin within the past several months may already have preexisting antibodies against the heparin-PF4 complex in their circulation. Therefore, when these patients are re-exposed to heparin, they may develop an acute onset of HIT even within the first day of the reinitiation of heparin.

The unique timing of acute-onset HIT within hours of heparin re-exposure and the more typical development of HIT within 4 to 14 days of initial heparin exposure emphasize the importance of conducting a careful and critical history in establishing the diagnosis. HIT should be suspected in any patient who develops thrombocytopenia while on heparin therapy. It is important to note that the normal platelet count varies widely (140,000/μL to 450,000/μL), and some patients may have a substantial decrease in their platelet count but still remain within the normal range. Therefore, a greater than 50% decrease in the platelet count of a patient on heparin should raise the suspicion of this syndrome. HIT should also be suspected in any patient who develops a thrombotic event while on heparin therapy.

Although antibodies against the heparin-PF4 complex are almost always present in patients with HIT, these antibodies are also frequently present in heparin-treated patients who do not have this disorder (i.e., those patients with neither thrombocytopenia nor thrombosis). There are two general categories of laboratory assays for the diagnosis of HIT: functional assays and immunologic assays (Table 172-4). Functional assays analyze whether the combination of heparin and the patient's plasma can induce normal platelets to aggregate or to secrete serotonin; these assays have very high specificity but relatively low sensitivity. Immunologic assays test the patient's plasma for antibodies that bind to the heparin-PF4 complex; these assays have very high sensitivity but lack specificity. Consequently, a *negative immunologic assay* is useful in excluding this diagnosis, and a *positive functional assay* is useful in confirming the diagnosis of HIT. Several days may elapse before the test results are available. Therefore, in practice, these laboratory assays provide only confirmatory information. Urgent clinical decisions should *not* be deferred until such test results are available. The timing of the thrombocytopenia with respect to the heparin exposure and the degree of the platelet drop are the most important pieces of information needed by the physician when evaluating a patient suspected of having HIT.

Because platelets are consumed as they become activated, the clinical presentation of HIT is thrombocytopenia. However, it is unusual for the thrombocytopenia to actually cause bleeding in patients with HIT. Instead, HIT is a highly prothrombotic disorder. Both venous and arterial thromboses are common in HIT. Patients with HIT who do not have thrombosis on initial presentation still have a 20 to 30% chance of developing a thrombus within the next month. Nevertheless, the incidence of HIT-related clinical events is greatest immediately after diagnosis. More importantly, clinical studies report that the cessation of heparin alone frequently fails to prevent the development of new thrombotic events.

TABLE 172-4 LABORATORY ASSAYS FOR HEPARIN-INDUCED THROMBOCYTOPENIA

ASSAY	SENSITIVITY (%)	SPECIFICITY (%)	POSITIVE PREDICTIVE VALUE (%)	NEGATIVE PREDICTIVE VALUE (%)
Functional assay (e.g., serotonin release assay)	88	≈100	≈100	81
PF4/heparin enzyme immunoassay (ELISA)	95-98	86	93	95

ELISA = enzyme-linked immunosorbent assay; PF4 = platelet factor 4.

TREATMENT

Rx

If a patient has HIT, all heparin should be stopped immediately. This includes subcutaneous injections of "minidose" heparin, heparin flushes of intravenous lines, and low-molecular-weight heparin; even heparin-coated intravenous catheters should be withdrawn. Alternative anticoagulation, such as a direct thrombin inhibitor like argatroban (Chapter 38), should be administered, at least until the platelet count normalizes. Although not as well studied, fondaparinux appears to be a viable alternative. In contrast, low-molecular-weight heparin should not be used because this drug can react with the pathologic HIT antibodies. Warfarin should also not be used initially in cases of acute HIT because of its delayed therapeutic effect and its association with venous limb gangrene. When the platelet count has returned to a normal level after an acute episode of HIT, however, warfarin can be slowly introduced at a dose of 5 mg or less daily and gradually increased to achieve an international normalized ratio (INR) of 2 to 3 for a duration of at least 4 to 6 weeks because HIT is a risk factor for subsequent venous thromboembolism.[3] Because patients rarely become profoundly thrombocytopenic as a result of HIT alone, platelet transfusions are typically not required. In fact, some reports suggest that platelet transfusions can actually precipitate thrombotic complications, although this premise remains controversial.

Sepsis

Along with the exposure to certain drugs, bacterial and viral infections are among the most common causes of acute thrombocytopenia in hospitalized patients. Acute thrombocytopenia can be caused by the deposition of antibody-antigen complexes on the platelet surface through an "innocent bystander" phenomenon. These antibody-coated platelets are then cleared from the circulatory system by Fc receptor–expressing macrophages in the spleen. Thrombocytopenia associated with infections can also be due to DIC. The treatment of sepsis-induced thrombocytopenia is directed at treating the underlying cause, along with the administration of platelet transfusions as clinically indicated.

Idiopathic (Immune) Thrombocytopenic Purpura

DEFINITION

ITP is an autoimmune disorder caused by circulating antiplatelet autoantibodies. An ITP-like picture can also be found in patients with autoimmune diseases, such as in systemic lupus erythematosus (Chapter 266); in low-grade lymphoproliferative disorders, such as chronic lymphocytic leukemia (Chapter 184); and in HIV infection (Chapter 393).

CLINICAL MANIFESTATIONS

ITP was originally thought to be a disease of young women. Although this description is appropriate for many individuals with this disorder, more recent data indicate that ITP can occur in patients of either sex and at any age. ITP is a chronic, recurring disorder in most adults with this disease. This is in stark contrast to pediatric patients, who usually suffer from acute ITP and rarely have the chronic variant of this disorder.

In contrast to patients with coagulation factor deficiencies who present with bleeding deep within their tissues, individuals with ITP (or other platelet disorders) typically have excessive mucocutaneous bleeding. Consequently, the clinician should inquire whether the patient has noticed epistaxis, gingival bleeding, easy bruising, hematuria, melena, or hematochezia. Female patients should also be asked about inappropriate or excessive vaginal bleeding. The physical examination should pay particular attention to signs of mucocutaneous bleeding. The patient should be thoroughly examined for petechiae (see Fig. 172-2) and ecchymosis as well as for evidence of hemorrhage within the conjunctiva, retina, and central nervous system.

DIAGNOSIS

In patients with ITP, the CBC is usually normal except for the thrombocytopenia, and their peripheral blood smear is remarkable only for a decreased number of platelets, some of which may be larger than normal. Splenomegaly is absent unless the ITP is due to an underlying disorder, such as lymphoma that is associated with splenomegaly. A bone marrow examination is usually not necessary in the absence of findings that suggest a different disease such as myelodysplasia.[4] If performed, the bone marrow aspirate and biopsy of ITP patients typically show normal or increased numbers of megakaryocytes. However, the rest of their bone marrow is otherwise normal. These bone marrow findings are similar to what is observed in the bone marrows of patients who have other forms of destructive thrombocytopenia. Antiplatelet antibody assays are insufficiently sensitive or specific to be clinically useful.

TREATMENT

Rx

Because platelet production is assumed to be increased in patients with ITP as a result of the immune-mediated accelerated platelet destruction, traditional therapy has focused on moderating this immune response. For most of the latter half of the 20th century, splenectomy and corticosteroids were the sole therapies for ITP. Corticosteroids in the form of either prednisone (1 mg/kg orally daily) or high-dose dexamethasone (4-day pulses of 40 mg intravenously per day every 28 days for four to six cycles) are effective. Although corticosteroids remain first-line therapeutic modalities, immunomodulating agents, such as intravenous immunoglobulin (IVIg) and anti-D, as well as alternative immunosuppressives, have been introduced for the therapy of ITP. Alternatively, other immunosuppressives, such as cyclophosphamide, azathioprine, cyclosporine, mycophenolate mofetil, dapsone, interferon, and etanercept, might be useful.

For years, the basic mechanism of and rationale for ITP treatment revolved around altering the immune system by immunosuppressives, splenectomy, or immune modulators, such as IVIG or anti-D. A more recent addition to the ITP treatment regimen is rituximab, a "humanized" murine monoclonal antibody against CD20, which is a B-cell antigen. Although rituximab has not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of ITP, it is currently widely used off label in patients who are unresponsive to splenectomy and corticosteroids. Response rates vary significantly between studies, ranging from 28% to 44% in larger trials. In a recent study of 133 newly diagnosed adult ITP patients with follow-up of up to 4 years, the combination of rituximab (375 mg/m^2 intravenously weekly for 4 weeks) plus dexamethasone (40 mg per day orally for 4 days) induced higher response rates and longer time to relapse, although also increased the incidence of grade 3 to 4 adverse events, than monotherapy with dexamethasone alone at the same doses.

Although most ITP patients have a compensatory increase in megakaryopoiesis in response to their rapid platelet destruction, plasma derived from some ITP patients was unexpectedly found to inhibit platelet production. This prompted a re-evaluation of whether impaired megakaryopoiesis contributes to the development of thrombocytopenia in this disease. Thrombopoietin (TPO) is a potent megakaryocyte colony-stimulating factor, and along with other cytokines, it increases the size and number of megakaryocytes (Chapter 156). TPO levels are not markedly elevated in ITP, suggesting that supplemental TPO could help to increase platelet production and correct the thrombocytopenia.

Early experiments demonstrated that recombinant as well as truncated forms of TPO significantly increased the platelet count in some refractory ITP patients. However, this also induced autoimmune autoantibodies against endogenous TPO, which resulted in profound and persistent thrombocytopenia. Therefore, both recombinant TPO and its truncated form were withdrawn from clinical trials. Subsequently, peptides were developed that bear no structural resemblance to TPO but still bind to and activate the TPO receptor; these agents are called *TPO receptor agonists*. Because these recombinant drugs bear little structural similarity to native TPO, they should not trigger autoimmune anti-TPO antibodies. The FDA has approved two of these drugs, and several more are being used in clinical trials. The first of these, called romiplostim (N-plate), is composed of several copies of a TPO receptor–binding peptide spliced into a recombinant antibody. This peptide agonist competes with TPO for binding to the TPO receptor and activates the receptor in an identical fashion as would endogenous TPO. The second FDA-approved TPO receptor agonist is eltrombopag (Promacta). It is an oral drug that activates the TPO receptor by binding to the receptor's transmembrane region.

Both subcutaneously administered romiplostim and orally administered eltrombopag are capable of increasing platelet counts in approximately 70% of patients with ITP. Remarkably, these drugs can also increase the platelet count in patients with ITP that is refractory to other treatment modalities, including splenectomy. However, adverse events, including bone marrow fibrosis and thromboembolism, have been reported. It should be noted that the drugs' effects disappear soon after their discontinuation.

General Principles of ITP Therapy

Initial management of ITP is guided by both symptoms and platelet count.[4] Asymptomatic patients with platelet counts of greater than 30,000/μL can be followed without treatment. If the patient is bleeding and/or has a platelet count of less than 30,000/μL, treatment with prednisone is recommended (Table 172-5). Refractory patients may require splenectomy, other immunosuppressive medications, or one of the new thrombopoiesis-stimulating agents (Table 172-6). Splenectomy has a long history of success in this disorder, and durable complete response rates are approximately 66 to 70%. Approximately half of the remaining patients who do not have normal platelet counts following splenectomy achieve a partial response that is clinically meaningful. Unfortunately, 10 to 15% of patients derive no benefit from splenectomy, and there is no test to predict whether a particular patient will respond to this treatment.

ITP patients with severe thrombocytopenia (<5000/μL) and/or those who have internal bleeding should be promptly treated with high doses of pulse corticosteroids and IVIG. Platelet transfusions may be given concurrently with IVIG for critical bleeding. In Rh-positive patients who have not undergone a splenectomy, anti-D immune globulin may be substituted for IVIg. However, some patients develop autoimmune hemolysis from this treatment.

TABLE 172-5 THERAPY FOR THE INITIAL MANAGEMENT OF IDIOPATHIC THROMBOCYTOPENIC PURPURA

ORAL PREDNISONE	
The effect is dose dependent—approximately 80% of patients respond to 1 mg/kg/day. Toxicity also increases with the dose and duration of treatment, and side effects include glucose intolerance, immunosuppression, osteoporosis, and cataracts. Relapse is typical once therapy is discontinued.	
INTRAVENOUS IMMUNOGLOBULIN	
The effect is more rapid than daily prednisone. Administered at a dose of 1 g/kg/day for 2 consecutive days or 0.4 g/kg/day for 5 consecutive days. The response rates are approximately 80%, and the effects typically last 2 to 4 weeks. Toxicity includes headache, allergic reactions, and rarely, thrombosis.	
ANTI-D IMMUNOGLOBULIN	
It is administered at a dose of 50 to 75 μg/kg IV. The response rates are dose dependent but can approach 75 to 80%. Hemolysis is a common toxicity but is usually mild. Rarely, hemolysis can be life threatening and can be associated with disseminated intravascular coagulation, renal failure, and end-organ infarction.	

TABLE 172-6 THERAPY FOR THE MANAGEMENT OF REFRACTORY IDIOPATHIC THROMBOCYTOPENIC PURPURA

ORAL PREDNISONE	
The effect is dose dependent and rapidly dissipates after discontinuation of the medication. Some patients can be maintained on a very low and tolerable daily dose (e.g., 5 mg). Long-term use is associated with infections, diabetes, osteoporosis, avascular necrosis, weight gain, and cataracts.	
ORAL DEXAMETHASONE	
This is administered at a dose of 40 mg/day for 4 consecutive days, repeated every 2 to 4 weeks for several months. Sustained response rates of 29 to 42% have been reported, although response rates are widely believed to be lower. Toxicity is similar to that of oral prednisone.	
SPLENECTOMY	
Durable (often lifelong), significant responses are seen in 65 to 70% of patients who undergo this procedure. More modest benefits are seen in another 10 to 15% of patients. There is no useful way to predict who will respond. Splenectomy is associated with surgical morbidity and some mortality (≈1-2%). Splenectomy produces lifelong immunosuppression to encapsulated and gram-positive organisms.	
RITUXIMAB	
This is given at a dose of 375 mg/m^2/wk IV for a total of 4 weeks. Significant responses are seen in 28 to 44% of patients, and these responses typically last for months. Toxicity includes reactivation of hepatitis B, immunosuppression, and rarely, progressive multifocal leukoencephalopathy.	
THROMBOPOIETIN RECEPTOR AGONISTS	
These are administered daily (eltrombopag) or weekly (romiplostim). An effect is typically seen in 2 to 3 weeks and disappears shortly after the discontinuation of the medication. Toxicity from long-term use is not well known but may include excessive thrombosis and bone marrow fibrosis.	

Thrombotic Thrombocytopenic Purpura

DEFINITION

TTP is a consumptive thrombocytopenia associated with a mechanical hemolytic anemia.[5] The classic pentad of symptoms, which are thrombocytopenia, anemia, fever, neurologic problems, and renal abnormalities, are fully present in only a minority of patients. Many patients today have only hemolytic anemia and thrombocytopenia. The poor specificity of the clinical features of this disease and the nonspecific laboratory abnormalities makes TTP difficult to diagnose. Historically, patients with untreated TTP had a mortality rate of 90% within 3 months. With modern therapy, patients with TTP have a mortality rate of approximately 10 to 20%.

PATHOBIOLOGY

Some patients with recurrent TTP have very large multimers of von Willebrand factor (Chapter 173). Because larger multimers of von Willebrand factor are more efficient at binding and activating platelets than smaller multimers, it was speculated that TTP could be due to a deficiency of a protease that normally cleaves large multimers of von Willebrand factor into smaller, less sticky multimers. A genome-wide linkage analysis of patients with inherited and recurrent TTP (Upshaw-Schulman syndrome) demonstrated a deficiency of a metalloproteinase that has now been identified as ADAMTS13 (*a d*isintegrin-like *a*nd *m*etalloprotease with *t*hrombospondin type 1 motif, member *13*). Many patients with adult-onset TTP have an antibody against ADAMTS13 that thus causes an acquired deficiency of ADAMTS13. Inherited or acquired ADAMTS13 deficiency causes the accumulation of ultralarge multimers of von Willebrand factor in plasma, which leads to platelet activation and the microvascular thrombosis that is characteristic of this disease (Fig. 172-4). Because many patients can have a partial deficiency of ADAMTS13 without having TTP, clinical assays of ADAMTS13 enzymatic activity have not been useful in diagnosing TTP. Levels of ADAMTS13 below 5% of normal are hypothesized to be highly suggestive of TTP, but levels greater than this are not very helpful. This hypothesis still needs to be validated in large clinical trials. Consequently, analysis of ADAMTS13 enzymatic activity should not be used to diagnose TTP outside of a research setting at this time.

Some patients reportedly developed TTP soon after taking an antiplatelet drug of the thienopyridine class. Approximately 1 of 2000 patients taking ticlopidine will develop TTP. In several individuals with ticlopidine-induced TTP, an antibody against ADAMTS13 was identified. A few studies have also suggested that clopidogrel can induce TTP at an incidence as rare as 1 in 250,000. Because the incidence of TTP in the general population is approximately 1 in 100,000, it is difficult to determine whether there is a significant risk for TTP in patients who are prescribed clopidogrel. The thienopyridine-derivative prasugrel has also been implicated. It should be noted that some patients can also develop TTP after exposure to medications that directly injure the vascular endothelium (such as cyclosporin or tacrolimus). Most of these patients do not have TTP but have the related disorder HUS, discussed later in this chapter.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In TTP, patients can occasionally present with symptoms of excessive mucocutaneous bleeding, but they might present with signs of a thrombotic event (including phlebitis, myocardial infarction, or stroke). Many patients complain of abdominal pain, which is presumably due to intestinal ischemia. Signs of central nervous system disease, somnolence, and even coma can also be seen on presentation.

The two major hallmarks of TTP are microangiopathic hemolytic anemia and thrombocytopenia. Microangiopathic hemolytic anemia is a non-immune-mediated hemolytic anemia caused by red cell fragmentation. Patients with this disorder have typical laboratory findings of hemolytic anemia, including a decreasing hemoglobin concentration, a high lactate dehydrogenase (LDH) level, elevated indirect bilirubin, and an increased reticulocyte count. Examination of the peripheral blood smear (Chapter 157) shows torn red blood cells (schistocytes), and frequently also shows, early red blood cell precursor cells (nucleated red blood cells). The thrombocytopenia may be mild if the disease is diagnosed at an early stage, but advanced cases of TTP can have platelet counts of less than 10,000/μL. TTP should be considered in any patient who has evidence of hemolysis accompanied by thrombocytopenia.

Unlike most patients with typical thrombocytopenia, who tend to bleed excessively, patients with TTP have few hemorrhagic complications. Instead, they are markedly predisposed to thrombosis. In fact, a thrombotic complication in a thrombocytopenic patient is another clue that TTP might be the cause of the thrombocytopenia (see Table 172-1). Characteristically, the thrombotic occlusions are in the terminal arterioles and capillaries and are composed mainly of platelets within the damaged vascular lumen. In contrast to most blood clots, these occlusions contain very little fibrin and are referred to as *hyaline thrombi*. Before plasmapheresis was used in the treatment of this disease, TTP typically progressed and caused renal disease, neurologic symptoms, and fever. These symptoms are believed to be due to ischemia and infarction of the affected organs. Today, TTP is often diagnosed in its early stages, so patients may have only microangiopathic hemolytic anemia and thrombocytopenia.

TREATMENT Rx

The prompt initiation of plasma exchange (plasmapheresis with plasma replacement) reduces the mortality rate associated with TTP from 90% to approximately 15%. The mechanism of this benefit is not entirely known. A randomized trial demonstrated that plasma exchange is more beneficial than plasma infusion for the treatment of TTP. This implies that some of the benefit of plasmapheresis is attributable to the removal of a pathologic substance from the patient's plasma. Assuming that the pathogenesis of most acquired forms of TTP is the antibody-mediated inhibition of ADAMTS13, plasma exchange might have two benefits. First, it helps to remove the pathogenic antibody from the plasma. Second, the normal plasma infused into the patient during plasmapheresis repletes the deficiency of ADAMTS13. Both of these

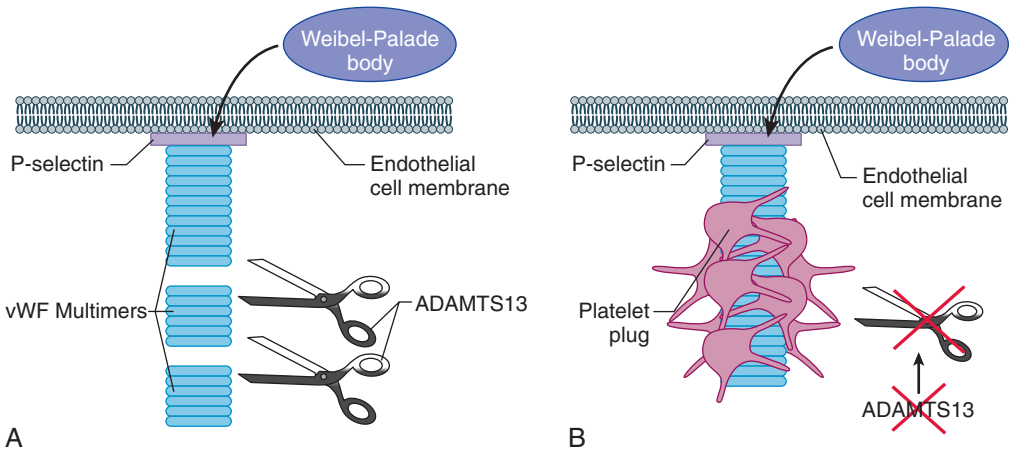

FIGURE 172-4. Pathophysiology of thrombotic thrombocytopenia purpura (TTP). A, Von Willebrand factor (vWF) is synthesized in endothelial cells and stored in Weibel-Palade bodies. The vWF is assembled into ultralarge multimers that are cleaved after they are released into the blood stream by the protease ADAMTS13. The resultant smaller multimers of vWF can bind to platelets to participate in normal hemostasis. **B,** Some patients with TTP have a deficiency of ADAMTS13. This results in the accumulation of ultralarge multimers of vWF within the circulation, which promotes the excessive adhesion of platelets. This produces large hyaline plugs of vWF and platelets that cause vascular occlusions.

benefits probably play a role in the efficacy of plasma exchange in the treatment of this disease.

Because patients with TTP can develop sudden thrombotic events (including stroke and myocardial infarction), and because patients can deteriorate quickly, it is prudent to initiate plasma exchange as rapidly as possible. Given the morbidity and mortality of untreated TTP, and given the relatively low risk of administering plasmapheresis, this therapy should be initiated even when the diagnosis is not certain. As discussed in the section on HUS (later in this chapter), plasmapheresis is not beneficial in children with Shiga toxin–induced microangiopathic hemolytic anemia or in patients who develop HUS following their exposure to endothelium-toxic drugs, such as chemotherapy.

Plasma exchange is administered to replace one entire plasma volume and is usually repeated once daily. An average-sized individual requires 20 to 30 units of fresh-frozen plasma for each plasmapheresis session. Therapy is usually administered daily, and patients are monitored for signs of improvement in their thrombocytopenia, hemolysis, neurologic symptoms, fever, and renal disease. Appropriate daily laboratory tests to monitor the patient are CBC, LDH, reticulocyte count, and creatinine. After the thrombocytopenia and hemolysis have been corrected for a few days, the daily plasmapheresis can either be discontinued or continued every other day for several more days. A typical duration of therapy is 1 to 2 weeks, although some patients require treatment far beyond this usual time course.

Approximately one third of patients relapse quickly after plasmapheresis is stopped. These patients require a reinitiation of plasma exchange and perhaps the addition of an immunosuppressive drug, such as a glucocorticoid. Some reports indicate that rituximab shows promise in reducing the incidence of relapse. However, given that this drug does not decrease antibody production for weeks to months after its administration, it is likely that if rituximab has any benefit in the treatment of TTP, it is probably only to minimize the incidence of late relapses.

Major complications of plasmapheresis do occur and are often attributable to the use of a central venous catheter. Hypotension, bacteremia, hemorrhage, and thrombosis are among the most common life-threatening complications of plasmapheresis therapy. Two specific complications deserve emphasis. First, patients taking an angiotensin-converting enzyme (ACE) inhibitor are susceptible to plasmapheresis-induced hypotension. This is due to these drugs' interference with bradykinin catabolism. Second, a patient who develops recurrent thrombocytopenia and a fever several days to a week into treatment may not be having an exacerbation of TTP but rather may be developing central line–induced sepsis. Therefore, a vigorous investigation for infection should be initiated in patients who appear to be relapsing early.

Hemolytic-Uremic Syndrome

DEFINITION

HUS is another cause of microangiopathic hemolytic anemia, and it may be difficult to distinguish from TTP. When acute renal failure is predominant, and there are no neurologic symptoms, many clinicians consider the syndrome to be HUS, not TTP.[6] In contrast to TTP, HUS is not caused by a deficiency of ADAMTS13. However, at this point, it is not clear whether ADAMTS13 levels will be clinically useful to distinguish between HUS and TTP. Because there is such overlap between the signs and symptoms of TTP and those of HUS, the distinction and diagnosis may be impossible to make in some cases.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

A toxin that directly damages endothelial cells can cause HUS. These direct endothelial toxins are either infectious or the result of a drug. Perhaps the best-characterized infectious agent that damages endothelial cells is Shiga toxin, which produces enterohemorrhagic *Escherichia coli* (Chapter 304). In Shiga toxin–induced HUS, the renal disease and microangiopathic hemolytic anemia occur after an episode of diarrhea that is often bloody. *E. coli* O157:H7 is the cause of many of the cases in the United States, and *E. coli* O104:H4 causes some of the other cases.[7] The toxin damages endothelial cells within the glomeruli and promotes the adhesion of platelets and the trapping of red blood cells in the kidneys.

Several drugs can also induce HUS by directly damaging the endothelial cells. These include calcineurin inhibitors, such as tacrolimus and cyclosporine; sometimes, lowering the dose of these drugs can reverse the microangiopathic hemolytic anemia. Cytotoxic drugs such as mitomycin C, cisplatin, and bleomycin can also induce HUS by directly damaging the endothelial cells.

Inherited forms of HUS have been described, and they usually involve the dysregulation of the complement cascade (Chapter 50). The best-described genetic mutations cause the deficiency of factor H, which is a complement regulatory protease. HUS-inducing mutations in other components of complement regulation include those found in C3, CD46, and factor I.

TREATMENT AND PREVENTION

Rx

Reducing the spread of Shiga toxin–producing *E. coli* is vital because antibiotics and antimotility drugs do not lower the risk for developing HUS symptoms. In contrast to TTP, there is little evidence that plasma exchange is beneficial. The clinical course and outcome of *E. coli* O104:H4–induced HUS are similar to infections with the more common O157:H7-induced HUS. Aggressive antibiotic therapy appears to be beneficial for reducing seizures and death. However, neither plasmapheresis nor glucocorticoids seem to be helpful. In a pilot study of 12 patients, *E. coli* O104:H4–associated HUS appeared to respond to immunoadsorption. The infusion of plasma or plasmapheresis is reportedly beneficial in the treatment of the atypical forms of HUS that are caused by the dysregulation of complement. Recent evidence suggests that some patients with atypical forms of HUS respond to eculizumab, an antibody that inhibits the terminal steps of the complement cascade.[8]

Disseminated Intravascular Coagulation

DIC is a pathologic condition that depletes components of the coagulation system, including platelets. Therefore, in contrast to TTP and HUS, the thrombocytopenia of DIC is associated with the consumption of coagulation factors and increased fibrinolysis. This often leads to prolongations of the prothrombin time (PT) and activated partial thromboplastin time (aPTT), as well as to increased levels of D-dimers. In its fully manifested state, DIC can be associated with arterial and venous thrombi, hemorrhage, microangiopathic hemolysis, thrombocytopenia, excessive fibrinolysis, and the deficiency of coagulation factors, such as fibrinogen. For a more complete review of DIC and related disorders, see Chapter 175.

Thrombocytopenia during Pregnancy

Thrombocytopenia occurs in approximately 10% of pregnant women. It may be due to a normal variant of pregnancy (gestational thrombocytopenia), a pregnancy-specific condition (preeclampsia and HELLP [*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets]) syndrome, or a condition exacerbated by pregnancy (ITP, vasculitis, TTP). A recent review estimated that thrombocytopenia occurs in approximately 7 to 10% of pregnancies, and about 75% of these cases are due to gestational thrombocytopenia, 15 to 20% are secondary to hypertensive disorders, 3 to 4% are due to an immune process, and the remaining 1 to 2% are rare constitutional thrombocytopenias, infections, and malignancies.[9] The prognosis and treatment vary tremendously based on the underlying cause.

Gestational thrombocytopenia (incidental thrombocytopenia of pregnancy) is a mild, asymptomatic thrombocytopenia that typically occurs late in pregnancy. There is no association with fetal thrombocytopenia, and this maternal thrombocytopenia resolves spontaneously after delivery. Other than thrombocytopenia during previous pregnancies, women with gestational thrombocytopenia have no prior history of a low platelet count. This lack of previous thrombocytopenia helps to distinguish gestational thrombocytopenia from ITP. Additionally, in contrast to other causes of maternal thrombocytopenia, gestational thrombocytopenia does not produce a platelet count lower than 70,000/μL. Consequently, deviation from standard obstetric care is usually not required for a patient with gestational thrombocytopenia.

Preeclampsia is a syndrome that causes the gradual development of proteinuria and hypertension during the later stages of pregnancy (Chapter 239). A minority of women with preeclampsia progress to have seizures; when this occurs, the syndrome is called *eclampsia*. Approximately 15% of women with preeclampsia have thrombocytopenia, and 5% of patients with preeclampsia have platelet counts of less than 50,000/μL. Some patients have a more severe form of preeclampsia associated with HELLP syndrome. Preeclampsia and HELLP syndrome are thought to result from a factor produced within the placenta because these syndromes usually resolve rapidly and spontaneously after delivery. These syndromes can also present postpartum, but they still resolve within a few days of delivery. If these syndromes do not resolve spontaneously within 3 days, alternative diagnoses, such as ITP and TTP, should be considered. Consequently, immediate delivery of the child is recommended, if possible, because the microangiopathic process stops soon thereafter.

Most patients with ITP or vasculitis during pregnancy have a history of thrombocytopenia before pregnancy. The antiplatelet IgG antibodies that cause this disease in the mother can cross the placenta and lead to thrombocytopenia in the fetus. However, the platelet count in the unborn child does

not correlate well with the platelet count of the mother, and attempts to sample fetal blood to monitor platelet counts are associated with significant risk. Because most children born to women with ITP have a platelet count high enough for a successful delivery, the management of ITP focuses on keeping the maternal platelet count acceptable for the mother's safety. In the early stages of pregnancy, a platelet count of 30,000/μL to 50,000/μL is considered safe. In preparation for delivery, a platelet count of 50,000/μL to 80,000/μL is more desirable. This can be managed by the use of oral glucocorticoids, and if necessary, by the administration of IVIG. The safety of rituximab and thrombopoiesis-stimulating agents during pregnancy is not known. Splenectomy performed during the first trimester has a risk for inducing miscarriage, and this operation is technically difficult during the later stages of pregnancy because of uterine enlargement. There is no evidence that a cesarean section is safer than vaginal delivery.

The diagnosis of TTP during pregnancy can be difficult to make because many of the symptoms are identical to those of preeclampsia. If the symptoms develop during the early stages of pregnancy, when preeclampsia is unlikely, the diagnosis of TTP is more certain. The presence of hyperuricemia, hypoproteinemia, elevated liver transaminases, and direct bilirubin is more consistent with preeclampsia. The development of microangiopathic hemolytic anemia and thrombocytopenia in the peripartum period is presumed to be attributable to preeclampsia, and if it is safe to do so, immediate delivery of the fetus is desirable. Typically, the thrombocytopenia starts to resolve rapidly after delivery. If no improvement is seen by the third postpartum day, standard management for TTP, including plasma exchange, is recommended.

Post-transfusion Purpura and Neonatal Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia is due to the sensitization to alloantigens, such as Pl^{A1} (HPA-1a). These alloimmune antibodies can cause thrombocytopenia approximately a week after a blood transfusion (post-transfusion purpura, or PTP).[10] A similar alloimmune antibody can cause thrombocytopenia in a fetus when it is produced by the mother (neonatal alloimmune thrombocytopenia, or NAIT). PTP causes profound thrombocytopenia 7 to 10 days after exposure to the small amount of platelets that contaminate most red blood cell transfusions. It can be treated with IVIG or by plasma exchange. NAIT can cause severe thrombocytopenia and bleeding in neonates, and it is treated with the transfusion of platelets derived from a Pl^{A1}-negative donor (most conveniently the newborn's mother), corticosteroids, and IVIg.

Vasculitis

Autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and other forms of vasculitis can also cause thrombocytopenia. This can be due to an ITP-like process that occurs in patients with a propensity for the development of autoantibodies. The treatment for these patients is immunosuppression, similar to the treatment for other patients with ITP. Some patients with active vasculitis and endothelial inflammation consume circulating platelets by promoting their adhesion to the damaged vessel wall. This creates a clinical picture that is difficult to distinguish from that of TTP without a tissue diagnosis that documents vasculitis. Because of the difficulty of discerning TTP from a flare-up of vasculitis, these patients are often treated with both plasma exchange and immunosuppression.

Dilutional Thrombocytopenia

Thrombocytopenia does not typically occur after blood loss, possibly in part owing to the release of platelets from the splenic pool. Thrombocytopenia occasionally occurs after a massive hemorrhage. However, this is only when the hemorrhage is severe enough to necessitate the replacement of 1.5 to 2 times the total blood volume, which usually requires the transfusion of at least 15 to 20 units of packed red blood cells over a short period of time. Even in this circumstance, the thrombocytopenia is usually only mild to moderate. Therefore, the clinician should remain vigilant for another cause of the thrombocytopenia (such as DIC resulting from hemorrhage-induced hypotension and shock). When indicated, dilutional thrombocytopenia can be corrected with platelet transfusions.

Congenital Thrombocytopenias

Lifelong thrombocytopenia can be due to an inherited defect that affects platelet production or survival. These disorders can be autosomal dominant (May-Hegglin anomaly and Sebastian syndrome), autosomal recessive (Bernard-Soulier disease, Fanconi's anemia, gray platelet syndrome, and thrombocytopenia with absent radius syndrome), or X-linked (Wiskott-Aldrich syndrome). Many of these disorders are associated with other abnormalities in addition to thrombocytopenia. A congenital cause of thrombocytopenia should be suspected in a patient who has long-standing moderate thrombocytopenia that was presumed to be treatment-refractory ITP.

REVIEW QUESTIONS

1. You are asked to see a patient who had coronary bypass surgery 6 days ago. The patient has abruptly developed a cold right foot, and his platelet count decreased from 350,000/μL yesterday to 155,000/μL today. He is afebrile, and his only medication is subcutaneous heparin for deep vein thrombosis (DVT) prophylaxis. You are suspicious that the patient may have heparin-induced thrombocytopenia. What should you recommend?

A. Discontinue heparin and start argatroban.
B. Discontinue heparin and observe platelet trend.
C. Discontinue heparin and start aspirin.
D. Send heparin-PF4 enzyme-linked immunosorbent assay (ELISA) and base treatment on results.
E. Change heparin to low-molecular-weight heparin.

Answer: A Stop the heparin and administer argatroban. This patient developed a probable thrombosis in his foot and had a greater than 50% decrease in his platelet count 6 days after starting to receive heparin. The time course and the magnitude of the decrease in the platelet count, along with the new thrombosis, places this patient at very high risk for the diagnosis of heparin-induced thrombocytopenia and at a very high immediate risk for a recurrent thrombotic event, even if the heparin was discontinued (ruling out answers B, C, and D). Consequently, this patient needs to be started on an alternative anticoagulant that is different enough from heparin to not be recognized by the immune response directed against heparin (ruling out answer E). Aspirin alone is not sufficient to prevent recurrent thrombi. The only acceptable approach would be to stop the heparin and to immediately start Argatroban. See Heparin-induced Thrombocytopenia, Table 172-1, Figure 172-2, and reference 2.

2. You have just met a patient with a platelet count of 115,000/μL. She has no other medical problems, and the reminder of her complete blood count (CBC) and blood smear are normal. Review of her old CBC indicates that her platelet count 1 year ago was 120,000/μL. What should you recommend?

A. Refer patient for bone marrow biopsy.
B. Repeat CBC in 1 week.
C. Repeat CBC in several months.
D. Analyze patient for antiplatelet antibodies.
E. Initiate folate and B_{12} therapy.

Answer: C Repeat CBC in several months. The patient has asymptomatic and stable mild thrombocytopenia. Her platelet count is probably at the lower end of the normal platelet count distribution, although she has a small chance of having mild idiopathic thrombocytopenic purpura (ITP) (see reference 1). Because her white and red blood cell counts are normal, and her peripheral blood smear is normal, there is no need for a bone marrow biopsy. There is no indication to repeat her CBC in a week because her platelet count is already documented as having been stable for the past year. Antiplatelet antibody assays have inadequate sensitivity and specificity to be clinically useful. In the absence of anemia and a documented deficiency of folate or B_{12}, there is no indication for the supplementation of these vitamins. See Figure 172-1 for further details on evaluating patients with chronic thrombocytopenia.

3. You are managing a patient with ITP, who typically has a platelet count of 60,000/μL to 90,000/μL. Today, she complains of symptoms consistent with an upper respiratory infection. Her CBC demonstrates that her platelet count is 42,000/μL today but is otherwise normal. Her blood smear is normal. She is on no new medications, and on physical examination her nares appear congested, but she has no ecchymosis, petechiae, or splenomegaly. What should you recommend?

A. Refer patient for bone marrow biopsy.
B. Repeat CBC in 1 week .
C. Start corticosteroid therapy.
D. Start intravenous immunoglobulin.
E. Start romiplostin.

Answer: B Repeat CBC in 1 week. The patient has an exacerbation of her ITP that is potentially a result her viral syndrome. Her otherwise normal CBC and blood smear exclude the need to consider diagnoses that would be demonstrated on a bone marrow biopsy (answer A). In the absence of excessive bleeding or a platelet count of less than 30,000/μL, there is no indication for therapy (excluding answers C, D, and E.) If her platelet count in a week continues to decrease, she might require a brief course of an ITP therapy, such as corticosteroids. See Idiopathic (Immune) Thrombocytopenic Purpura and reference 4.

4. One week ago, you prescribed trimethoprim-sulfamethoxazole for a patient with cellulitis. Her cellulitis is now resolved, but you order a CBC because her leukocyte count was 13,500/μL last week. Today's CBC demonstrates that her leukocyte count is now 9,200/μL with a normal differential, her hemoglobin is13.9 g/dL, and her platelet count is 77,000/μL. Looking back at the older laboratory results, you notice that this is the first time she has ever been thrombocytopenic. The patient has no symptoms or signs of excessive bleeding, and her spleen is not enlarged. Which of the following should you recommend?

A. Corticosteroids
B. Bone marrow biopsy
C. Hospitalization of patient for close observation
D. Discontinuing antibiotics and repeating CBC in 1 week

Answer: D Discontinue antibiotics and repeat the CBC in 1 week. The patient is asymptomatic and has an abrupt onset of moderate thrombocytopenia. Because her platelet count was normal a week ago, it makes it extremely likely that her thrombocytopenia is due to her exposure to a drug or infection (excluding answer B). Her current platelet count does not place her at a high risk for hemorrhage (excluding answers A and C.) See Drug-induced Thrombocytopenia and Table 172-3.

5. A patient is admitted with confusion and abdominal pain. She has a body temperature of 101.1° F, and her laboratory studies demonstrate the following: leukocyte count 4,400/μL, hemoglobin 10.5 g/dL, platelet count 11,000/μL, D-dimer 0.2 μg/mL, and creatinine 1.1 mg/dL. The peripheral blood smear shows nucleated red blood cells and fragmented red blood cells (schistocytes). Which of the following should you recommend?

A. Intravenous immunoglobulin
B. Platelet transfusion
C. Platelet transfusion and red blood cell transfusion
D. Plasmapheresis
E. Antibiotics

Answer: D Plasmapheresis. The patient has thrombocytopenia and anemia associated with schistocytes on her blood smear. This indicates that she has a microangiopathic hemolytic anemia. The presence of fever and neurologic symptoms suggests that the patient's diagnosis is thrombotic thrombocytopenic purpura (TTP). The normal D-dimer excludes the other likely diagnosis of disseminated intravascular coagulation. TTP requires immediate treatment with plasmapheresis. This treatment alone will correct the problem and increase the platelet count (this excludes answers A and B). Her anemia is mild, so there is no indication for red blood cell transfusion at this time (answer C). Because TTP frequently causes fever, there is no indication for antibiotics at this time (answer E). See Thrombotic Thrombocytopenic Purpura and Figure 172-4.

VON WILLEBRAND DISEASE AND HEMORRHAGIC ABNORMALITIES OF PLATELET AND VASCULAR FUNCTION

WILLIAM L. NICHOLS

VON WILLEBRAND DISEASE

DEFINITION AND EPIDEMIOLOGY

Von Willebrand disease (VWD), a usually autosomal dominantly inherited condition affecting both males and females of all ethnicities, is the most common hereditary bleeding disorder worldwide, with prevalence estimates dependent on case definition. It may also occur less frequently as an acquired disorder (acquired von Willebrand syndrome [AVWS]). Von Willebrand factor (VWF) plasma levels are variably decreased (minimally to substantially) in at least 2.5% of humans, but approximately 0.1% (one in 1000) have definite VWD with medically significant bleeding symptoms related to low VWF, and approximately 0.01% (one in 10,000) have more severe forms of VWD that often result in referral to tertiary care centers, including hemophilia centers.[1-3]

PATHOBIOLOGY

Von Willebrand disease reflects deficiency or dysfunction of VWF, a multimeric plasma glycoprotein that mediates platelet adhesion and aggregation at sites of vascular injury (Chapter 171) and that also carries and stabilizes blood coagulation factor VIII (FVIII) in the circulation. The *VWF* gene is located on chromosome 12, with a partial pseudogene on chromosome 22 that potentially complicates DNA-based mutation detection (which remains primarily a research application, with evolving clinical diagnostic potential). The protein is synthesized by vascular endothelium as approximately 270-kD subunits (protomers) that are dimerized, processed and polymerized into very large (≤~20,000 kD) hemostatically active VWF multimers, and finally secreted into the blood. Vascular endothelial cells additionally provide a storage reservoir of multimerized VWF (in intracellular Weibel-Palade

bodies) from which it can be released by stress or by drugs such as DDAVP (desmopressin). VWF is also synthesized and multimerized by bone marrow megakaryocytes and stored in circulating blood platelet α granules, from which it is secreted with platelet activation. Platelet-stored VWF represents about 10% of total blood VWF.

Multimerization of VWF is essential for its hemostatic activity that is mainly mediated by the higher-molecular-weight (larger) multimers. Circulating plasma VWF normally does not interact with platelets. However, when VWF binds to injured (deendothelialized) blood vessel walls, reflecting its collagen-binding activity, multimers can be stretched and unfolded by high intravascular shear forces, such as in the microvasculature, exposing and activating previously cryptic platelet-binding domains to promote platelet adhesion and aggregation to vessel-bound VWF. Simultaneously, activated (stretched) VWF multimers expose protomer cleavage sites for proteolysis by the circulating enzyme, ADAMTS13 (A Disintegrin And Metalloprotease domain with ThromboSpondin type 1 motifs, member 13), ultimately decreasing the size of VWF multimers and thereby downregulating VWF hemostatic function. Severe deficiency of ADAMTS13 is associated with the pathologic microangiopathy of thrombotic thrombocytopenic purpura (TTP) (Chapter 172), in which the microvascular thrombosis is mediated by ultralarge VWF multimers in the circulation.

Von Willebrand disease is classified into three major types that vary in severity and differ in clinical management, such that defining the VWD subtype is important. Type 1 VWD reflects partial quantitative deficiency of normally functioning VWF, of variable severity, and comprises 75% to 80% of individuals with symptomatic VWD. Type 2 VWD reflects qualitative VWF deficiency, with four subtypes (A, B, M, N), and comprises 20% to 25% of persons with VWD. Type 3 VWD reflects the virtual absence of VWF, with secondary near-absence of FVIII, and is rare (<1% of VWD). Inheritance of VWD is usually autosomal dominant, except that type 3 VWD is typically autosomal recessive in inheritance. Table 173-1 summarizes the classification of VWD subtypes and their basic pathophysiology.

The FVIII deficiency that often accompanies different types of VWD (see Table 173-1) is not genetically related to the disease; the gene that encodes FVIII is on the X chromosome, and its primary deficiency causes classic hemophilia (Chapter 174). FVIII deficiency in VWD is attributable to a primary deficiency or defect in the VWF molecule, which normally carries and stabilizes FVIII in the circulation. Therefore, FVIII is more rapidly cleared from the circulation, leading to its secondary deficiency in VWD.

TABLE 173-1 CLASSIFICATION OF VON WILLEBRAND DISEASE

TYPE	DESCRIPTION
1	Partial quantitative deficiency of VWF (~75%-80% of VWD)
2	Qualitative VWF defect (~20-25% of VWD)
2A	Caused by VWF mutations that decrease the proportion of large functional VWF multimers, leading to decreased VWF-dependent platelet adhesion and aggregation
2B	Caused by VWF mutations that increase platelet–VWF binding, resulting in depletion of large, functional VWF multimers. Circulating platelets are coated with mutant VWF, which may impair platelet adhesion and aggregation at sites of injury. Thrombocytopenia, persistent or intermittent, is observed in most cases. Distinguishing type 2B VWD may require RIPA to detect increased (abnormal) platelet aggregation response to low-dose ristocetin; the latter may also reflect platelet-type (pseudo) VWD caused by rare mutations in the platelet VWF receptor.
2M	Caused by VWF mutations that decrease VWF-dependent platelet adhesion and aggregation but do not deplete the large VWF multimers. Distinguishing between types 2A and 2M VWD requires VWF multimer gel electrophoretic analysis.
2N	Caused by VWF mutations that impair binding to FVIII, thereby shortening FVIII survival and lowering FVIII levels so that type 2N VWD can masquerade as an autosomal recessive form of hemophilia A. Discrimination from hemophilia A may require assays of VWF-FVIII binding.
3	Virtually complete VWF deficiency associated with markedly decreased FVIII (<1% of VWD)

FVIII = factor VIII coagulant activity; RIPA = ristocetin-induced platelet aggregation/aggregometry; VWD = von Willebrand disease; VWF = von Willebrand factor.

December 2007 (released February 29, 2008), and Yawn BP, Nichols WL, Rick ME. Diagnosis and management of von Willebrand disease: guidelines for primary care. *Am Fam Physician.* 2009;80:1261-1268, 1269-1270.

CLINICAL MANIFESTATIONS

Individuals with VWD usually experience mucocutaneous bleeding symptoms such as easy bruising, prolonged or excessive bleeding from minor cuts or other injuries, nosebleeds or other mucosal bleeding such as gastrointestinal (GI) hemorrhage, or heavy menstrual bleeding in women, and they may be at increased risk for bleeding after surgery or invasive procedures, dental extractions, traumatic injury, or childbirth. Symptoms can range from relatively mild or infrequent bleeding in type 1 VWD to severe, life-threatening bleeding in type 3 VWD. As a group, women with VWD may be more affected by bleeding symptoms than men because of hemostatic challenges of menstruation and childbirth.

DIAGNOSIS

Clinical Assessment

The diagnosis of VWD (as in other bleeding disorders [Chapter 171]) begins with clinical assessment to evaluate for a personal and possible family history of abnormal bleeding, accompanied by focused physical examination to detect signs or symptoms of bleeding (e.g., petechiae, ecchymoses, hematomas, anemia), as well as findings that may suggest other causes of increased bleeding such as liver disease (e.g., hepatosplenomegaly, jaundice), joint or skin laxity (e.g., Ehlers-Danlos syndrome), telangiectasia (e.g., hereditary hemorrhagic telangiectasia [HHT]), or anatomic lesions on gynecologic examination. Because bleeding symptoms are common in apparently normal individuals, with a prevalence of certain symptoms as high as 25% to 50%, clinical assessment for VWD or other possible bleeding disorders can be challenging (Chapter 171).

The most important parts of the medical history include (1) family history of a known or suspected bleeding disorder; (2) review of personal surgical or other hemostatic challenges throughout life and recently, including dental extractions and traumatic injuries, and whether abnormal bleeding occurred and its severity; (3) mucocutaneous bleeding symptoms (e.g., bruising, nosebleeds, ecchymoses, GI bleeding, menorrhagia), including frequency, severity, and spontaneity of events; and (4) assessment for medical conditions that can increase the risk for bleeding, such as use of certain drugs that can impede normal hemostasis, including aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs), clopidogrel, or warfarin or heparin or newer direct-acting oral anticoagulants; the presence of liver or kidney disease (e.g., cirrhosis, uremia); and a history of a low or high platelet count and blood or bone marrow disorders.[4]

Bleeding history scoring tools are being developed and applied for studying populations with VWD or other bleeding disorders but are not yet validated for routine clinical use.[5] However, in general, an increasing number of positive or abnormal clinical bleeding history items increases the likelihood that an individual has a bleeding disorder, including VWD, and may merit undergoing appropriate laboratory evaluation (Chapter 171).

Laboratory Evaluation

Because no simple, single laboratory test is available to screen for VWD, the initial laboratory evaluation requires measurements of plasma: (1) VWF antigen (VWF:Ag), (2) ristocetin cofactor activity (VWF:RCo), and (3) factor VIII coagulant activity (FVIII). All three tests are recommended for initial evaluation, and the results may not only establish the diagnosis but also suggest the type and severity of VWD if it is present.[6] These three tests are also used for monitoring therapy. Tests such as the bleeding time (BT) or platelet function analyzer (PFA-100, Siemens) assay lack sufficient sensitivity and specificity and are not recommended for routine screening.

If one or more of the three test results are abnormally low or if the ratio of VWF:RCo to VWF:Ag is below 0.5 to 0.7, additional laboratory evaluation may include selecting one or more of the following tests, based on the pattern of initial results together with clinical assessment and experience: (1) repeating the three initial VWD tests with timing and procedures optimized for conditions of the patient, the blood sample, and laboratory testing (see later discussion for additional information about these conditions); (2) VWF multimer analysis to help differentiate or exclude types 2A, 2B, or 2M VWD; (3) ristocetin-induced platelet aggregometry (RIPA), including low-dose ristocetin testing to evaluate for type 2B VWD or platelet-type (pseudo) VWD; (4) VWF-FVIII binding assay (or molecular DNA-based VWF testing) to evaluate for type 2N VWD; and (5) other tests such as VWF:CB (collagen-binding activity) or immunoassays reflecting VWF-platelet binding activity to supplement VWF:RCo testing. The latter tests (VWF:CB and VWF-platelet binding immunoassays) do not replace the VWF:RCo assay but can be useful as screening or supplementary tests.[7] Some of these tests

TABLE 173-2 PATTERNS OF LABORATORY TEST RESULTS FOR VON WILLEBRAND DISEASE DIAGNOSIS AND CLASSIFICATION*

CONDITION	VWF:RCo (IU/dL)	VWF:Ag (IU/dL)	FVIII (IU/dL)	VWF:RCo/VWF:Ag Ratio¶	RIPA	VWF MULTIMERS
Type 1 VWD	<30†	<30†‡	↓ or Normal	>0.5-0.7	Often normal	Normal
Type 2A VWD	<30†	<30-200†‡	↓ or Normal	<0.5-0.7	↓ or Normal	↓ HMW
Type 2B VWD	<30†	<30-200†‡	↓ or Normal	Usually <0.5-0.7	↑ (Low dose)	↓ HMW
Type 2M VWD	<30†	<30-200†‡	↓ or Normal	<0.5-0.7	↓ or Normal	No ↓ HMW
Type 2N VWD	30-200	30-200	↓↓	>0.5-0.7	Normal	Normal
Type 3 VWD	<3	<3	↓↓↓ (1-9)	NA	Absent	NA
"Low VWF"§	30-50§	30-50§	Normal	>0.5-0.7	Normal	Normal
Normal	50-200	50-200	Normal	>0.5-0.7	Normal	Normal

*Values in the table represent prototypical cases without additional VWF (or other disease) abnormalities. Exceptions occur, and repeat testing and clinical experience may be necessary for clarification and interpretation of laboratory test results.
†VWF values <30 IU/dL (or %) are designated as the level for definite diagnosis of VWD (especially type 1 VWD) because (1) there is a high frequency of blood type O that is associated with "low VWF" levels but not necessarily VWD; (2) bleeding symptoms are reported by a significant proportion of individuals with no disease; and (3) no abnormality in the VWF gene has been identified in many individuals who have only mildly to moderately decreased VWF levels. VWF values of 30 to 50 IU/dL include both apparently normal persons and those with mild VWD.
‡VWF:Ag is <50 IU/dL in most persons with types 2A, 2B, or 2M VWD.
§Diagnosis of VWD is not precluded for persons with VWF:RCo of 30 to 50 IU/dL if there is supporting clinical or family evidence for VWD, nor is the use of agents to increase VWF levels precluded in those who have VWF:RCo of 30 to 50 IU/dL and who may be at risk for bleeding.
¶Until more laboratories clearly define a reference range, the VWF:RCo/VWF:Ag ratio of <0.5 to 0.7 is recommended to distinguish type 1 vs. type 2 VWD variants (A, B, or M).
FVIII = factor VIII coagulant activity; HMW = high-molecular-weight VWF multimers; IU/dL = international units per deciliter (e.g., 100 IU/dL = 100% of mean normal level); NA = not applicable; RIPA = ristocetin-induced platelet aggregation/aggregometry; VWD, von Willebrand disease; VWF = von Willebrand factor; VWF:Ag = von Willebrand factor antigen; VWF:RCo = von Willebrand factor ristocetin cofactor activity; ↓, ↓↓, ↓↓↓, ↑, refer to varying degrees of decrease, or an increase, of the test result compared to the laboratory reference range.

TABLE 173-3 VARIABLE CONDITIONS OF THE PATIENT, BLOOD SAMPLING, AND LABORATORY TESTING AFFECTING LABORATORY EVALUATION FOR VON WILLEBRAND DISEASE

Phlebotomy conditions: An atraumatic blood draw limits the exposure of tissue factor from the site and the activation of clotting factors, minimizing falsely high or low values. Lipemia should be avoided because it may interfere with photo-optical testing methods, especially some used for VWF:RCo assay.
Patient stress level: Undue stress, such as struggling or crying in children or anxiety in adults, may falsely elevate VWF and FVIII levels. Very recent exercise can also elevate VWF levels.
Additional conditions in the individual: The presence of an acute or chronic inflammatory illness may elevate VWF and FVIII levels, as may pregnancy or administration of estrogen or oral contraceptives. Individuals with blood group O have VWF levels approximately 25% lower than those of other ABO blood groups. African Americans have higher VWF levels than whites.
Sample processing: To prevent cryoprecipitation of VWF and other proteins, blood samples for VWF assays should be transported to the laboratory at room temperature. Plasma should be separated from blood cells promptly at room temperature, and the plasma should be centrifuged thoroughly to remove platelets. If plasma samples will be assayed within 2 hours, they should be kept at room temperature. Frozen plasma samples should be carefully thawed at 37° C and kept at room temperature for <2 hours before assay.
Sample storage: Plasma samples that will be stored or transported to a reference laboratory must be frozen promptly at or below –40° C and remain frozen until assayed. A control sample that is drawn, processed, stored, and transported under the same conditions as the tested person's sample may be helpful in indicating problems in the handling of important test samples. Activity of FVIII typically is 10% to 20% lower in frozen-thawed plasma than in fresh (nonfrozen) plasma and can be even lower if blood processing or storage conditions are suboptimal.
Laboratory testing: Calibrators for assays of VWF:Ag, VWF:RCo, and FVIII should be referenced to the WHO plasma standard. These three tests have relatively high coefficients of variation (CVs of 10%-30%), especially the VWF:RCo assay. The quality of laboratory testing also varies considerably among laboratories (high interlaboratory CV). Test results can be reported as international units per deciliter (IU/dL) rather than as a percentage (%) of mean normal, if WHO-linked calibrators are used. Referencing VWF testing results to the population reference range, rather than to ABO-stratified reference ranges, may be clinically useful.

CV = coefficient of variation; FVIII = coagulation factor VIII; VWF = Von Willebrand factor; VWF:Ag = VWF antigen; VWF:RCo = VWF ristocetin cofactor activity; WHO = World Health Organization.

have limited availability and are mainly performed in reference laboratories. Consultation with a hemostasis specialist can help guide test selection.

Multimer analysis visualizes the distribution of plasma VWF multimers, is technically complex, is qualitatively interpreted in conjunction with results of the initial three tests and available clinical information, and is used to help determine the VWD subtype. Therefore, VWF multimer analysis is not recommended for initial VWD screening and should only be performed if initial VWD testing identifies an abnormal result (e.g., abnormally low VWF:RCo or ratio of VWF:RCo to VWF:Ag) or clinical information suggests a high likelihood of abnormal VWF multimer analysis.

Table 173-2 provides prototypical laboratory values for VWD subtypes. Diagnosis, especially for individuals with mildly decreased VWF (30%-50% IU/dL), requires correlation of clinical assessment (personal and family history of bleeding) and results of laboratory testing, the latter preferably performed or repeated in the absence of conditions associated with elevation of baseline VWF and with careful attention to blood specimen collection, processing, transportation, and storage.

The laboratory evaluation of a person with possible VWD or AVWS is relatively complex, particularly because results of the laboratory tests can be influenced by certain conditions of the patient and by variables in the blood sample and laboratory testing methodology (Table 173-3). In interpreting test results, therefore, it is important to be aware of these variabilities and the status of the patient at the time of evaluation.

TREATMENT

Management of patients with VWD is focused on treatment or prevention of bleeding episodes. Three main approaches to treatment of VWD are used individually or in combination: (1) increasing plasma concentration of VWF and FVIII by releasing endogenous VWF stores through stimulation of endothelial cells with DDAVP (desmopressin: 1-desamino-8-D-arginine vasopressin); (2) replacing or supplementing VWF and FVIII by using human plasma-derived, viral-inactivated concentrates; and (3) promoting hemostasis using hemostatic agents that work by mechanisms other than increasing VWF and FVIII. Regular prophylaxis is seldom required, and treatment is given primarily before and after planned invasive procedures or in response to episodes of bleeding. Table 173-4 outlines usual durations of treatment for a variety of surgical and other invasive procedures.

TABLE 173-4 SUGGESTED DURATIONS OF VON WILLEBRAND FACTOR REPLACEMENT FOR DIFFERENT TYPES OF SURGICAL PROCEDURES

MAJOR SURGERY 7-14 DAYS*	MINOR SURGERY 1-5 DAYS*	OTHER PROCEDURES: IF UNCOMPLICATED, SINGLE VWF TREATMENT
Cardiothoracic	Biopsy: breast, cervical	Cardiac catheterization
Cesarean section	Complicated dental extractions	Cataract surgery
Craniotomy	Gingival surgery	Endoscopy (without biopsy)
Hysterectomy	Central line placement	Liver biopsy
Open cholecystectomy	Laparoscopic procedures	Lacerations
Prostatectomy		Simple dental extractions

*Individual cases may need longer or shorter duration depending on the severity of Von Willebrand disease and the type of procedure.
VWF = Von Willebrand factor.
Adapted and modified from National Heart, Lung, and Blood Institute. *The Diagnosis, Evaluation, and Management of von Willebrand Disease.* Bethesda, MD: National Institutes of Health Publication 08-5832. December 2007 (released February 29, 2008).

TABLE 173-5 INITIAL DOSING RECOMMENDATIONS FOR VON WILLEBRAND FACTOR CONCENTRATE REPLACEMENT FOR PREVENTION OR MANAGEMENT OF BLEEDING

MAJOR SURGERY/BLEEDING
Loading dose*: 40-60 U/kg
Maintenance dose†: 20-40 U/kg every 8 to 24 hours
Monitoring: VWF:RCo and FVIII trough and peak at least daily
Therapeutic goal: trough VWF:RCo and FVIII >50 IU/dL for 7-14 days
Safety parameter: do not exceed VWF:RCo >200 IU/dL or FVIII >250-300 IU/dL
May alternate with DDAVP for latter part of treatment
MINOR SURGERY/BLEEDING
Loading dose*: 30-60 U/kg
Maintenance dose†: 20-40 U/kg every 12 to 48 hours
Monitoring: VWF:RCo and FVIII trough and peak at least once
Therapeutic goal: trough VWF:RCo and FVIII >50 IU/dL for 3-5 days
Safety parameter: do not exceed VWF:RCo >200 IU/dL or FVIII >250-300 IU/dL
May alternate with DDAVP for latter part of treatment

*Loading dose is in VWF:RCo IU/dL.
†Dosing intervals reflect approximately 12-hour average half-lives of plasma VWF and FVIII without conditions resulting in shortened survival or enhanced clearance such as bleeding or surgery.
DDAVP = desmopressin: 1-desamino-8-D-arginine vasopressin; FVIII = factor VIII; VWF = Von Willebrand factor; VWF:RCo = VWF ristocetin cofactor activity.
Adapted and modified from National Heart, Lung, and Blood Institute. *The Diagnosis, Evaluation, and Management of von Willebrand Disease.* Bethesda, MD: National Institutes of Health Publication 08-5832. December 2007 (released February 29, 2008).

Desmopressin (DDAVP)

DDAVP is a synthetic derivative of the antidiuretic hormone and causes release of preformed VWF from endothelial cells. It is mainly used in type 1 VWD; is contraindicated for type 2B VWD (because it can cause thrombocytopenia); has limited efficacy for types 2A, 2M, or 2N VWD; and has no efficacy for type 3 VWD. DDAVP is generally administered for short time periods (48-72 hours) and usually not more frequently than at 24- to 48-hour intervals, owing to tachyphylaxis and side effects. If it is required for longer periods or more frequently, the patient should be monitored for fluid and electrolyte problems because DDAVP may cause symptomatic hyponatremia. DDAVP therapy is potentially mildly thrombogenic, especially for persons who are at increased risk for atherosclerotic cardiovascular disorders such as stroke or myocardial infarction.

The hemostatic dose of DDAVP is 0.3 µg/kg body weight infused intravenously over about 30 minutes or administered subcutaneously; however, a concentrated formulation for the latter is not available in the United States. For outpatients, DDAVP can also be administered nasally using a concentrated spray (Stimate, CSL Behring) that delivers 150 µg per nostril (300 µg total dose for persons ≥50 kg body weight). Peak increments of plasma VWF and FVIII occur about 1 to 2 hours after DDAVP, typically reaching two- to fourfold higher levels than at baseline, and decline toward baseline during the next 24 hours, reflecting VWF and FVIII plasma half-lives that are about 12 hours on average. However, plasma half-lives depend on the specific VWF subtype and phenotype and also vary considerably among individuals. Because of variability in response, before therapy with DDAVP, it is important to perform a treatment trial with pharmacokinetic monitoring of VWF and FVIII, measuring baseline (pre-DDAVP) and peak (~1 hour post-DDAVP) levels, supplemented with testing about 4 to 6 hours after DDAVP if a shortened survival of endogenous VWF is a consideration. A DDAVP treatment trial with extended monitoring can also help diagnose VWD variants with intrinsically heightened VWF clearance. Because of the problem of rapid tachyphylaxis, the trial of DDAVP should be performed at least 1 to 2 weeks before an elective procedure.

Factor Replacement Therapy

Alphanate SD/HT (Grifols), Humate-P (CSL Behring), and Wilate (Octapharma) are U.S. Food and Drug Administration–approved plasma-derived VWF concentrates for treatment of VWD by intravenous infusions. They also contain FVIII but differ in VWF/FVIII ratios and in content of large (high-molecular-weight) VWF multimers. Other VWF-containing concentrates include Koate-DVI (Talecris) and Wilfactin (LFB, France), which lacks FVIII (endogenous levels of which should rise secondarily within a few hours after infusion) and is not available in the United States. Cryoprecipitate is no longer recommended for VWF (or for FVIII) replacement, and its use should be limited to urgent situations when VWF concentrates are not available.

Table 173-5 outlines dosing and laboratory monitoring recommendations for treatment or prevention of bleeding in patients with VWD. Whenever possible, particularly for individuals with more severe forms of VWD, major surgeries or bleeding events should be managed in hospitals with appropriate laboratory capability and clinical staff, including a hematologist and a surgeon skilled in the management of bleeding disorders.

Other Hemostatic Agents

Treatment with combined oral contraceptive pills can ameliorate menorrhagia in women with VWD, mediated partly by hormonal effects on uterine tissues as well as by elevating blood levels of VWF and FVIII. Contraceptive hormonal skin patches have similar effects, and either type of therapy can also increase the risk for thromboembolic events. The levonorgestrel-releasing intrauterine device is an alternative to oral or skin-patch hormonal agents. For pregnancy and delivery in women with VWD, it is important to ensure that VWF and FVIII levels are normalized at the time of delivery, either spontaneously (which often occurs) or by therapy, including before administration of epidural anesthesia and postpartum.

ACQUIRED VON WILLEBRAND SYNDROME

Acquired von Willebrand syndrome refers to deficiencies or defects in VWF concentration, structure, or function that are not inherited but are consequences of other medical disorders. AVWS is less common than congenital (hereditary) VWD and is typically associated with several different mechanisms and medical conditions (Table 173-6).

Laboratory findings in AVWS are similar to those in congenital VWD (types 1, 2A, or 3). Although VWF:RCo values are typically decreased in AVWS (with variably decreased VWF:Ag or FVIII), sometimes only VWF multimer analysis is abnormal, with mild to moderate reduction or loss of the highest-molecular-weight (largest) multimers. This latter situation is more likely for AVWS associated with enhanced VWF proteolysis reflecting shear-induced conformational changes in VWF leading to increased proteolysis of VWF by ADAMTS13, such as with severe aortic valvular stenosis and other conditions causing abnormally high shear forces somewhere in the circulation (see Table 173-6).[8] Heyde's syndrome refers to AVWS caused by severe aortic stenosis and accompanied by GI bleeding from arteriovenous malformations (AVMs).

Acquired von Willebrand syndrome and disorders causing it should be considered in individuals found to have abnormal VWF test results and bleeding symptoms without a personal or family history consistent with hereditary VWD. Conversely, when bleeding occurs in association with one of the known causative conditions listed in Table 173-6, AVWS should be considered and initial VWD testing performed if indicated.

TREATMENT

Rx

Treatment of AVWS should be focused first on elimination or amelioration of the associated causative disorder, if amenable to treatment (e.g., aortic valve replacement or repair for Heyde's syndrome). Survival of both endogenous

TABLE 173-6 CAUSES OF ACQUIRED VON WILLEBRAND SYNDROME

PATHOPHYSIOLOGIC CATEGORY*	DISEASE OR ASSOCIATION
Antibodies to VWF	Monoclonal gammopathies, lymphoproliferative disorders, or autoimmune diseases such as SLE
Shear-induced VWF conformational changes leading to increased proteolysis of VWF	Aortic valvular stenosis, VSD, hypertrophic obstructive cardiomyopathy, LVAD, or primary pulmonary hypertension
Markedly elevated blood platelet count	Essential thrombocythemia, polycythemia vera, myeloid metaplasia with myelofibrosis, or other myeloproliferative neoplasms
Removal of VWF from circulation by aberrant binding to tumor cells	Wilms' tumor and certain lymphoproliferative or plasma cell proliferative disorders
Decreased VWF synthesis	Hypothyroidism
Drugs associated with AVWS	Ciprofloxacin, valproic acid, hydroxyethyl starch, griseofulvin

*Pathophysiologic categories are listed in descending order of approximate prevalence.
AVWS = acquired von Willebrand syndrome; LVAD = left ventricular assist device; SLE = systemic lupus erythematosus; VWF, von Willebrand factor; VSD = ventricular septal defect.
Adapted and modified from Nichols WL, Rick ME, Ortel TL, et al. Clinical and laboratory diagnosis of von Willebrand disease: a synopsis of the 2008 NHLBI/NIH guidelines. *Am J Hematol.* 2009;84:366-370.

and infused VWF is often shortened in AVWS, and replacement therapy should be monitored with measurement of plasma VWF (VWF:RCo and VWF:Ag) and FVIII. For AVWS caused by monoclonal gammopathy of undetermined significance, intravenous immunoglobulin infusion may temporarily normalize plasma VWF and FVIII and stop abnormal bleeding by abrogating heightened VWF clearance. However, such treatment reflects an off-label product use.

BLEEDING CAUSED BY QUALITATIVE PLATELET DISORDERS

Hereditary Platelet Bleeding Disorders

Hereditary defects in platelet function can occur at all stages of the linked sequence of events involved in hemostatic platelet activation at sites of vascular injury, as described in Chapter 171: (1) platelet adhesion (Bernard-Soulier syndrome [BSS]), (2) platelet release reaction (storage pool disorders), and (3) platelet aggregation (Glanzmann thrombasthenia [GT]).[9,10] They lead to varying levels of severity of bleeding.

BERNARD-SOULIER SYNDROME AND GLANZMANN THROMBASTHENIA

These rare, autosomally recessive platelet hypofunctional disorders typically manifest moderately severe (minimally provoked or spontaneous) mucocutaneous bleeding symptoms during childhood and beyond as well as abnormal bleeding with hemostatic challenges such as surgery. BSS results from deficiency or dysfunction of the platelet membrane glycoprotein (GP) Ib-IX-V complex that is the principal receptor for binding VWF, mediating platelet adhesion to injured blood vessels. (In some ways, therefore, BSS is the platelet counterpart of VWD as an adhesion defect, the latter being caused by an abnormality in the plasma VWF rather than the platelets.) GT reflects deficiency or dysfunction of the platelet GPIIb-IIIa complex that is the principal receptor for binding plasma fibrinogen, mediating platelet aggregation. The platelet count and morphology are normal in GT, but BSS demonstrates moderate thrombocytopenia and enlarged (giant) platelets. BT or PFA-100 test results are typically markedly abnormal in both disorders but are nonspecific. Platelet aggregometry findings are usually diagnostic. BSS demonstrates an absence of aggregation response to ristocetin, but responses to other agonists are relatively normal. Conversely, GT demonstrates relatively normal response to ristocetin, contrasting with complete absence of aggregation response to other agonists, such as adenosine diphosphate, collagen, arachidonic acid, and epinephrine. Quantitative analysis of platelet membrane GPs by flow cytometry is evolving as a supplemental diagnostic tool for BSS and GT. Mutational DNA-based testing is primarily a research tool.

PLATELET STORAGE POOL DISORDERS

Platelet dense (δ) granule storage pool deficiency (DG-SPD) is more common than BSS and GT. Inheritance is typically autosomal recessive or occasionally dominant, with evolving understanding of different mutational causes. Bleeding symptoms are usually mild but may be clinically significant. Hermansky-Pudlak syndrome (HPS) is oculocutaneous albinism associated with platelet DG-SPD, with a propensity to develop pulmonary fibrosis or granulomatous colitis. DG-SPD can accompany some other hereditary disorders such as the X-linked Wiskott-Aldrich syndrome, in which it is associated with microthrombocytopenia, or Chédiak-Higashi syndrome with partial albinism and leukocyte inclusions. Isolated DG-SPD, including HPS, demonstrates normal platelet count and morphology by peripheral blood smear review. Results of BT, PFA-100, or platelet aggregometry testing may or may not be abnormal. Platelet content and secretion of adenosine triphosphate are decreased in DG-SPD, and platelet electron microscopy can diagnostically confirm absence or marked decrease of dense granules; however, these tests have limited availability.

Platelet α-granule deficiency manifests as the gray platelet syndrome, which is typically autosomal recessive in inheritance and may result in mild bleeding symptoms. Moderate thrombocytopenia is present, and peripheral blood smear review is usually diagnostic, demonstrating enlarged platelets that are "gray" (absence of granulomere staining, reflecting absence of α granules and their contents that include VWF). X chromosome–linked mutations of *GATA1*, the gene encoding a transcription factor essential for erythropoiesis and megakaryocytopoiesis, can cause a gray platelet syndrome–like disorder affecting males.

OTHER HEREDITARY PLATELET HYPOFUNCTIONAL DISORDERS

Hereditary platelet secretion disorders (defective release of α- and δ-granule contents without granule deficiency) comprise a variety of abnormalities affecting different platelet receptors or mechanisms of signal transduction and platelet activation, including defective platelet procoagulant activity, with or without thrombocytopenia or other syndromic features, and with variable bleeding propensity and symptoms. Some of these disorders are reviewed in Chapter 172.

TREATMENT Rx

For treating or preventing major bleeding events (e.g., certain surgical challenges), judicious use of platelet transfusion may be indicated for patients with more severe hereditary platelet bleeding disorders such as BSS and GT. To reduce the risk for platelet alloimmunization, single-donor apheresis platelet concentrates are preferred when available, and HLA-matched transfusions may sometimes be indicated. DDAVP administration has been reported to improve hemostasis in patients with DG-SPD, BSS, and some other hereditary platelet disorders. Treatment with recombinant activated coagulation factor VII (NovoSeven, NovoNordisk) has been reported as an alternative or salvage therapy for bleeding in GT and certain other platelet hypofunctional disorders. Antifibrinolytic therapy with epsilon-aminocaproic acid or tranexamic acid can be useful for dental extractions or for surgical procedures involving other tissues with high intrinsic fibrinolytic activity (e.g., nose, mouth and throat, extraocular tissues).[11]

Acquired Platelet Bleeding Disorders

DRUGS

Drugs are a relatively common cause of platelet hypofunction that can result in mild bleeding symptoms, particularly if other bleeding propensities are present, such as thrombocytopenia.[12] Aspirin, thienopyridines (e.g., clopidogrel, prasugrel, ticagrelor), dipyridamole, and inhibitors of platelet GPIIb/IIIa function are used therapeutically or prophylactically for atherosclerotic cardiovascular disorders such as coronary artery or cerebrovascular disease. In addition to aspirin, other NSAIDs can inhibit platelet arachidonic acid metabolism (Chapter 37) and contribute to bleeding. Other agents that may sometimes impair platelet function include certain selective serotonin reuptake inhibitors or antibiotics and some herbal or nutritional supplements. Laboratory testing for platelet hypofunction is not often indicated and may not yield diagnostic findings.

OTHER ACQUIRED PLATELET BLEEDING DISORDERS

Myelodysplastic and myeloproliferative disorders can sometimes manifest intrinsic platelet hypofunction disproportionate to thrombocytopenia or

thrombocytosis when they are present. Cirrhosis or liver failure can cause platelet hypofunction as well as thrombocytopenia. Uremia may induce platelet hypofunction that can be ameliorated by dialysis and erythropoietin therapy. Antibodies causing autoimmune thrombocytopenia (Chapter 172) can sometimes cause acquired platelet hypofunction (e.g., acquired GT or BSS) in addition to the low platelet count.

TREATMENT

Rx

Review of patient medications and medical conditions and modifications of them when feasible and indicated can often suffice for recognition and management of acquired platelet hypofunctional disorders.

VASCULAR HEMORRHAGIC DISORDERS

Hereditary Vascular Hemorrhagic Disorders

Hereditary hemorrhagic telangiectasia, also called Osler-Weber-Rendu syndrome, is an autosomal dominant vascular disorder characterized by development of telangiectases and AVMs in the skin, mucous membranes, and certain viscera (especially the central nervous system, lung, and liver), with a propensity for severe recurring nosebleeds and GI bleeds resulting in chronic anemia and iron deficiency.[13] The diagnosis primarily relies on physical examination (Fig. 173-1). Several mutations in two genes have been described: endoglin in HHT type 1 and activin receptor-like kinase-1 (*ALK1*) in HHT type 2. These genes encode proteins that modulate transforming growth factor-β signaling in vascular endothelial cells, and mutations in them in HHT lead to the development of fragile telangiectatic vessels and AVMs. Molecular DNA-based testing has limited availability. Supportive treatment includes supplemental iron therapy for iron deficiency anemia. Among 24 patients with HHT, severe hepatic vascular malformations, and high cardiac output, bevacizumab (5 mg/kg every 14 days for a total of six injections) normalized the cardiac index in 20 of 24 patients (complete response in three; partial response in 17), with concomitant reductions in epistaxis and improvements in quality of life.[14] Tranexamic acid (1 gram three times daily) is effective for reducing recurrent epistaxis, and intranasal administration is also being studied. In a small randomized trial, tamoxifen (20 mg per day for 6 months) also significantly reduced bleeding in patients with recurrent epistaxis.

FIGURE 173-1. Hereditary hemorrhagic telangiectasia (HHT). Telangiectasias commonly occur on the fingers (**A**); face, lips, and tongue (**B**); and in other areas, including the nasal and gastrointestinal mucosa, and may develop in certain other internal organs. Skin or mucous membrane lesions typically blanch with pressure in contrast to petechiae, which do not. (**A,** Copyrighted and used with permission of the Mayo Foundation for Medical Education and Research, all rights reserved. **B,** Courtesy of Dr. Andrew Schafer.)

Ehlers-Danlos syndrome (Chapter 260) is caused by mutations in genes encoding fibrillar collagen or related genes and includes at least six subtypes that vary in clinical manifestations, severity, and prognosis.[15] Inheritance is primarily autosomal dominant. Principal manifestations of Ehlers-Danlos syndrome include skin or joint hyperextensibility, with an associated bleeding tendency including easy bruisability (purpura), surgical bleeding, poor wound healing, and menorrhagia in women. Diagnosis depends mainly on physical examination, supplemented with molecular DNA-based testing that currently has limited availability.

Acquired Vascular Hemorrhagic Disorders

Systemic amyloidosis, Waldenström macroglobulinemia, and cryoglobulinemia are dysproteinemic disorders reflecting monoclonal gammopathies or hyperglobulinemias (Chapters 187 and 188) that can manifest purpuric or other bleeding symptoms caused by either vascular deposition of immunoglobulin fragments (amyloidosis) or inhibition of platelet-vessel hemostatic functions by immunoglobulins.[16] Henoch-Schönlein purpura (Chapter 270) is primarily a transient disease of children that typically presents with a palpable purpuric rash of the lower extremities, arthralgias, abdominal pain and renal symptoms (hematuria, proteinuria) in some cases, manifestations of a systemic vasculitis characterized by deposition of immunoglobulin A–containing immune complexes in the skin, GI tract, and kidneys. Palpable purpura can also result from systemic sepsis or disseminated intravascular coagulation. Scurvy (Chapter 218) is caused by the effects of vitamin C deficiency on collagen structure and often presents with bruising or petechiae, including tiny perifollicular hemorrhages. Senile purpura or purpura simplex is thought to reflect partly the age-related changes of skin vascular structure and is typified by easy bruisability of the dorsa of the hands, forearms, and lower legs. Psychogenic purpuras are controversial entities that include Gardner-Diamond syndrome, which is characterized by recurring focal pain preceding development of ecchymoses, believed to reflect poorly understood psychosomatic mechanisms. It can be difficult to differentiate this rare syndrome from factitious or self-induced purpura and bleeding.

REVIEW QUESTIONS

1. A 40-year-old woman complains of easy bruising and menorrhagia present for a few years. Bruises have mainly occurred on the lower extremities, often after recollected minor trauma, and typically have been small (<1-3 cm in diameter) and without induration (hematomas). Her menses have been heavier in recent years but without passage of blood clots, and there is no history of anemia. A previous pregnancy and full-term vaginal delivery were uncomplicated by bleeding with delivery or postpartum. During childhood, she had occasional nosebleeds that did not require medical attention. She has not undergone surgical challenges nor had dental extractions or significant injuries. Currently, she is not using oral contraceptive or iron supplementation, nor taking aspirin or other nonsteroidal antiinflammatory drug (NSAIDs). Family history review is negative for bleeding disorder. Physical examination discloses two small superficial bruises (1-2 cm diameter) on the lower extremities but is otherwise unremarkable, including no evidence of oronasal or skin telangiectasias nor unusual skin or joint laxity. Recent laboratory testing demonstrates normal complete blood count (CBC) results, including platelet and erythrocyte measurements, and normal prothrombin time (PT) and activated partial thromboplastin time (aPTT). From previous ABO blood group testing, she is known to have blood group O. Concerning additional evaluation for possible von Willebrand disease (VWD), which *one* of the following is the most appropriate recommendation for initial laboratory blood sample testing?

A. Platelet function analyzer (PFA-100) closure time
B. Von Willebrand factor (VWF) antigen (VWF:Ag)
C. VWF:Ag and VWF ristocetin cofactor activity (VWF:RCo)
D. VWF:Ag, VWF:RCo, and coagulation factor VIII activity (FVIII)
E. VWF:Ag, VWF:RCo, FVIII, and VWF multimer analysis

Answer: D The medical and bleeding history review raises the possibility of a mild bleeding disorder such as VWD (that would not be excluded by normal CBC, PT, and aPTT test results). PFA-100 or bleeding time (BT) testing are not recommended for initial screening to detect or exclude VWD because they lack sufficient sensitivity and are nonspecific tests. The three recommended tests to screen for or exclude VWD are VWF:Ag, VWF:RCo, and coagulation FVIII. Abnormal results on one or more of these three tests may also help identify the subtype of VWD if present and its severity, and supplemental or follow-up VWD tests may be indicated for clarification. VWF multimer analysis is not recommended for initial screening for VWD unless there is high clinical suspicion of abnormal VWF multimers such as can occur in association with acquired Von Willebrand syndrome (AVWS).

2. The following blood plasma test results are obtained for the 40-year-old woman described in question 1.

VWF:Ag = 42% (reference range, 50%-200%)
VWF:RCo = 42% (reference range, 50%-200%)
FVIII = 60% (reference range, 55%-200%)
What is the most appropriate interpretation of these test results in the context of the clinical information?

A. Type 1 VWD
B. Possible type 1 VWD
C. "Low VWF"
D. Type 2A VWD
E. B and C

Answer: E The mildly decreased levels of VWF:Ag and VWF:RCo (with low normal FVIII) suggest the possibility of mild type 1 VWD vs. "low VWF" such as can occur in apparently normal individuals with blood group O. The latter can have VWF levels as low as approximately 40% of mean normal. The patient's mild bleeding history (childhood nosebleeds not requiring medical interventions, ease of bruising with small bruises only, menorrhagia that apparently has not caused anemia or iron deficiency, absence of other bleeding symptoms or events) is not definitive for VWD or another bleeding disorder at this time, although raising possibility of such. The concordant VWF:RCo and VWF:Ag levels (ratio, 1.0; reference range, ≥0.5-0.7) are not suggestive of type 2A VWD. If clinical suspicion of VWD remains, it could be appropriate to repeat the VWD panel testing in the absence of conditions associated with elevation of baseline VWF and FVIII levels (see Table 173-3).

American Society of Hematology. *2012 Clinical Practice Guideline on the Evaluation and Management of von Willebrand Disease (VWD).* www.hematology.org/policy/resources/guidelines/vwd.

3. A 47-year-old woman is establishing medical care, having recently relocated, and has a history of von Willebrand disease (VWD) but is otherwise apparently in good health. She is unsure of the specific diagnosis such as VWD subtype and is in the process of obtaining her previous medical records. She reports a lifelong bleeding tendency, including recurring nosebleeds that have sometimes required nasal packing or cautery, excessive bleeding with cuts or other minor trauma, and troublesome bleeding after a dental extraction (prolonged oozing managed with packing). Since menarche, she has had menorrhagia that was initially managed by oral contraceptive therapy beginning at age 15 years in association with the diagnosis of VWD. Her only successful pregnancy at age 38 years was managed by cesarean section supplemented with infusions of VWF-FVIII concentrate, and she did not have bleeding complications. Family history discloses that neither of her parents had a history of abnormal bleeding, nor did two brothers or one sister nor their progeny. Her son has had troublesome nosebleeds and tonsillar bleeding and has been diagnosed as having VWD; however, no additional details or laboratory test results are currently available. Her physical examination is essentially unremarkable, including no pallor.

Initial laboratory testing results include a normal complete blood count (CBC), prothrombin time (PT) and activated partial thromboplastin time (aPTT). A VWD test profile with reflexive supplemental VWF testing of plasma yielded these results:
VWF:Ag = 24% (reference range, 50%-200%)
VWF:RCo = <12% (reference range, 50%-200%)
FVIII = 34% (reference range, 55%-200%)
VWF-platelet binding activity (latex immunoassay screen) = 7% (reference range, 50%-200%)
VWF multimer analysis = abnormal, with absence of higher molecular weight multimers and increased abundance of lower-molecular-weight multimers (normal = "normal multimer distribution")
What is the most appropriate interpretation of the VWD profile test results in the context of the clinical information?

A. Type 1 VWD
B. "Low VWF"
C. Type 2A VWD
D. Type 2B VWD
E. Type 3 VWD

Answer: C The clinical history identifies a variety of mucocutaneous bleeding episodes lifelong and altogether yields an elevated bleeding history assessment "score" that is highly suggestive of hereditary or congenital VWD or a similar bleeding disorder. The family history of VWD (son) provides additional probability that the woman has VWD. Values for plasma VWF:Ag and FVIII are substantially decreased, and VWF:RCo is undetectably low, altogether consistent with VWD. The unmeasurably low value for VWF:RCo was reflexively evaluated using an automated immunoassay based on a latex-coupled monoclonal antibody to the VWF-platelet glycoprotein (GP) Ib binding domain to indirectly measure VWF-platelet binding activity and confirms a very low but measureable value (7%). The discordantly lower values for VWF:RCo activity and VWF "immunoactivity," relative to the higher value for VWF:Ag, yield decreased activity to antigen ratios (<0.5; reference range, ≥0.7-0.8) and are indicative of a qualitative defect of VWF-platelet binding, consistent with types 2A, 2B, or 2M VWD. Supplemental VWF multimer analysis demonstrates absence of higher-molecular-weight multimers consistent with types 2A or 2B VWD and not consistent with type 2M VWD (nor types 1 or 3 VWD). The blood platelet count (CBC) is normal, providing no suggestion of type 2B VWD (or platelet-type "pseudo-VWD"), conditions that typically manifest persisting or intermittent thrombocytopenia. However, supplemental testing would be indicated to definitively exclude these rare VWD subtypes: ristocetin-induced platelet aggregation (RIPA), including demonstration of no abnormal response to low-dose ristocetin.

Nichols WL, Hultin MB, James AH, et al. Von Willebrand disease (VWD): evidence-based diagnosis and management guidelines, the National Heart, Lung, and Blood Institute (NHLBI) Expert Panel report (USA). *Haemophilia.* 2008;14(2):171-232.

American Society of Hematology. 2012 Clinical Practice Guideline on the Evaluation and Management of von Willebrand Disease (VWD). http://www.hematology.org/policy/resources/guidelines/vwd.

4. A 64-year-old man has had intermittent gastrointestinal (GI) bleeding episodes (melena or hematochezia) for about 7 years, sometimes requiring red blood cell transfusions. Repeated upper and lower GI endoscopies and capsule imaging studies have failed to identify a source of bleeding. However, recently a capsule study and subsequent extended GI endoscopy identified several focal vascular ectasias (arteriovenous malformations) in the duodenum and proximal jejunum which were photoablated. He has not had other types or episodes of bleeding, including having undergone several surgical procedures (lithotripsy for nephrolithiasis, partial parathyroidectomy for hyperparathyroidism, dental extraction) before onset of the recurrent GI bleeding. There is no family history of a bleeding disorder. Additionally, the patient has a 13-year history of exertional dyspnea with occasional syncopal episodes and 5 years ago was diagnosed as having hypertrophic obstructive cardiomyopathy (HOCM) with aortic stenosis–like left ventricular outflow obstruction that has gradually worsened by clinical and echocardiographic assessments.

Recent hematologic testing included a normal complete blood count (CBC) and platelet count and normal prothrombin time (PT) and activated partial thromboplastin time (aPTT). A von Willebrand disease (VWD) test profile with reflexive supplemental von Willebrand factor (VWF) multimer analysis yielded these plasma test results:

VWF:Ag = 159% (reference range, 50%-200%)
VWF:RCo = 116% (reference range, 50%-200%)
FVIII = 119% (reference range, 55%-200%)
VWF multimer analysis = abnormal, with absence of the highest-molecular-weight multimers and no increased abundance of lower molecular weight multimers (normal = "normal multimer distribution")

What is the most appropriate clinical diagnosis, considering the clinical and laboratory test results, including the VWD profile test results?

A. No evidence of VWD
B. Acquired Von Willebrand syndrome (AVWS)
C. Heyde's syndrome
D. B and C
E. Type 2M VWD

Answer: D The clinical history identifies recurring GI bleeding for several years but no antecedent abnormal bleeding history nor family history of such, and suggests the possibility of focal (GI) anatomic abnormalities or an acquired bleeding diathesis. Recent GI endoscopy has identified small bowel vascular ectasias or angiodysplasias (arteriovenous malformations) as the probable anatomic source of GI bleeding. The association of GI bleeding and severe aortic stenosis is known as Heyde's syndrome. Many patients with Heyde's syndrome have GI angiodysplasias (AVMs), as well as acquired abnormalities of VWF (selective absence of the highest-molecular-weight VWF multimers) that reflects effects of the abnormally high blood shear flow stress associated with severe aortic stenosis. It is thought that the VWF abnormality predisposes to bleeding from GI AVMs and may also contribute to AVM formation (dysregulated angiogenesis) and results in AVWS, which is a bleeding propensity reflecting acquired VWF changes.

In this context, answer D (Heyde's syndrome + AVWS) is the most appropriate diagnosis. However, because the patient has HOCM rather than classic aortic valvular stenosis, one might consider the diagnosis to be "Heyde's syndrome variant" or a similar appellation. Although the patient's levels of VWF:RCo and VWF:Ag are normal and adequately concordant (ratio, 0.73; reference range, ≥0.7), it is only the VWF multimer analysis that allows detection of the VWF abnormality. Alternative evolving methods for measuring VWF activity may have greater sensitivity for detecting subtle VWF multimeric abnormalities (abnormal VWF activity to antigen ratio) compared with the VWF:RCo assay. This vignette is based on a published case; the patient underwent cardiac septal myectomy and has remained free of GI bleeding for more than 7 years of follow-up.

Blackshear JL, Schaff HV, Ommen SR, et al. Hypertrophic obstructive cardiomyopathy, bleeding history and acquired von Willebrand syndrome: response to septal myectomy. *Mayo Clin Proc.* 2011:86:219-224.

5. A 75-year-old man is referred for evaluation of an 18-month history of recurring severe nosebleeds and an earlier episode of gastrointestinal (GI) bleeding. He had three episodes of severe and prolonged nosebleeds requiring nasal packing or cautery, and red blood cell transfusions were given on one occasion. One year before the onset of nosebleeds, he had melena that was evaluated with upper and lower endoscopies that identified arteriovenous malformations (AVMs) in the stomach and duodenum that were cauterized, and later a GI capsule imaging study identified a possible jejunal AVM. He had also noted some increased bruising that improved after stopping prophylactic aspirin. The patient has not previously experienced abnormal bleeding and had several surgical challenges, including bilateral knee replacements, radical prostatectomy, inguinal hernia repair, and childhood tonsillectomy and adenoidectomy. His general health has otherwise been relatively good (treated hypertension and hyperlipidemia). Family history is not suggestive of a hereditary or congenital bleeding diathesis. Physical examination is unremarkable for age.

Initial laboratory evaluation identified borderline low blood hemoglobin (12.2 g/dL) with normocytic erythroid indices, and normal blood platelets and leukocyte count and differential. Serum ferritin was decreased (12 mcg/L; reference range, 24-336 mcg/L). Hemostatic testing included normal prothrombin time (PT), thrombin time, and fibrinogen level, however the activated partial thromboplastin time (aPTT) was mildly prolonged (48 sec; reference range, 26-36 sec), and a 1 : 1 mixing study with normal plasma (nonincubated) demonstrated correction. Coagulation factor activity assays demonstrated substantially decreased factor VIII (FVIII, 8%; reference range, 55%-200%), but factors IX, XI and XII were normal, as was a factor XIII screening assay. Supplemental testing was negative for a time-dependent FVIII inhibitor. Von Willebrand disease (VWD) testing demonstrated markedly decreased plasma VWF:Ag (9%; reference range, 50%-200%) and undetectably low VWF:RCo (<12%; reference range, 50%-200%), with supplemental VWF immunoactivity assay confirming low value (11%; reference range, 50%-200%). VWF multimer analysis revealed barely detectable VWF multimers, however, all multimeric species appeared to be present with no reduction of higher–molecular-weight multimers.

Considering a preliminary diagnosis of probable acquired Von Willebrand syndrome (AVWS), which *one* of the following investigations would be most likely to uncover the etiologic cause of AVWS?

A. VWF inhibitor testing
B. Transthoracic echocardiography (TTE)
C. Serum thyroid stimulating hormone (TSH) assay
D. Serum protein electrophoresis and immunoelectrophoresis
E. Bone marrow biopsy

Answer: D The broad differential diagnostic categories of disorders pathophysiologically associated with AVWS include (1) antibodies to VWF, especially monoclonal gammopathies (e.g., monoclonal gammopathy of undetermined significance [MGUS], myeloma, macroglobulinemia) and less commonly autoimmune disorders such as (systemic lupus erythematosus [SLE]); (2) lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL) and lymphoma; (3) myeloproliferative disorders associated with marked thrombocytosis (e.g., essential thrombocythemia, polycythemia vera); (4) aberrant VWF binding to tumor cells (e.g., certain lymphoproliferative disorders or rarely other tumors); (5) cardiovascular disorders associated with shear-induced proteolysis of VWF, including aortic valvular stenosis, hypertrophic obstructive cardiomyopathy (HOCM), ventricular septal defect, ventricular assist devices (VADs), and so on; (6) decreased VWF synthesis such as in association with hypothyroidism; and (7) certain drugs (e.g., ciprofloxacin, valproic acid, hydroxyethyl starch). Considering the patient's age, essentially normal CBC findings, overall medical history, and the physical examination without evidence of hepatosplenomegaly or lymphadenopathy, nor aortic stenosis or similar conditions, MGUS would be high on the list of conditions to consider and evaluate. In this case, the patient was found by serum protein electrophoresis and immunoelectrophoresis to have a monoclonal IgG kappa monoclonal protein along with increased free

kappa light chain in the serum, but total serum IgG level was normal, all consistent with MGUS in the overall clinical context (Chapter 187). Monoclonal immunoglobulins can have specificity for VWF and cause clearance of immune complexes, typically without inhibiting VWF function, and causing very low VWF levels with secondary deficiency of FVIII. Inhibitors of VWF activity (VWF:RCo), either paraproteins or autoantibodies, are rarely detected by currently available testing, and VWF inhibitor test results were negative. Essentially normal CBC findings (except for mild anemia reflecting iron deficiency), together with physical examination, effectively excluded other causes of AVWS, including myeloproliferative or other lymphoproliferative or malignant disorders. The patient was not receiving drugs that can cause AVWS.

This patient received a trial infusion of VWF-FVIII concentrate (50 VWF:RCo units/kg body weight), and testing of blood samples showed transient normalization of VWF and FVIII levels that returned to baseline values within 24 hours, suggesting shortened survival. A trial infusion of intravenous immunoglobulin (IVIG, 1 g/kg body weight) was given, and serial testing of blood samples documented normalization of VWF and FVIII levels within 24 hours, with sustained normal levels for more than 5 days. It was recommended that either the former or the latter of these treatments be considered for future episodes of serious bleeding. There have been several case reports and small case series describing that infusion of IVIG can transiently normalize decreased VWF and FVIII levels in persons with IgG isotype monoclonal gammopathies.

HEMORRHAGIC DISORDERS: COAGULATION FACTOR DEFICIENCIES

MARGARET V. RAGNI

COAGULATION DEFICIENCIES

Severe coagulation factor deficiencies, or coagulopathies, are typically characterized by spontaneous or traumatic bleeding, such as during surgery or trauma, and may result in life- or limb-threatening complications. By contrast, moderate and mild coagulopathies may remain clinically silent until they are detected coincidentally on routine laboratory screening tests (e.g.,

prothrombin time [PT], activated partial thromboplastin time [aPTT]) or when these tests are ordered to evaluate the cause of abnormal bleeding or bruising. Much of the morbidity of coagulopathies can be minimized or avoided altogether by prophylactic replacement of the deficient clotting factor proteins. In contrast to the lifelong clinical manifestations of hereditary or congenital coagulopathies, acquired coagulation deficiencies usually appear acutely in previously asymptomatic individuals; they may not be suspected and often remit spontaneously or after eradication of an inciting disease state or withdrawal of an offending medication. Acquired coagulation deficiencies may be associated with more severe bleeding than congenital deficiencies, in part because of the delay in diagnosis. In general, coagulation factor deficiencies may result from inadequate synthesis of coagulation factor proteins or from inhibition of activated clotting factor proteins by acquired antibodies or anticoagulant medications. Finally, qualitative defects of coagulation factors, either congenital or acquired, may also result in bleeding.

Hereditary Hemophilias

DEFINITION

The hemophilias include hemophilia A and hemophilia B, caused by deficiencies or defects in clotting factor VIII (antihemophilic factor) and factor IX (antihemophilic factor B, or Christmas factor), respectively. A deficiency of either of these intrinsic coagulation pathway proteins results in inadequate formation of thrombin at sites of vascular injury.

EPIDEMIOLOGY

Hemophilia A and B are sex-linked recessive disorders estimated to occur in 1 in 5000 and 1 in 30,000 male births, respectively. The higher incidence of hemophilia A may be due to the greater amount of DNA "at risk" for mutation in the factor VIII gene (186,000 base pairs) compared with the factor IX gene (34,000 base pairs). Hemophilia A and B are observed in all racial and ethnic groups, and in the United States, more than 20,000 individuals are affected. Although carrier testing, genetic counseling, and prenatal diagnosis are widely available in the United States through the network of federally funded hemophilia treatment centers (HTCs), fecundity rates remain high, and few confirmed carriers elect to terminate their pregnancies, even if an affected fetus is detected in utero. These decisions are likely influenced by the wide availability of safe and effective coagulation factor replacement concentrates and by the prospect of an eventual cure for the hemophilias through gene transfer. A substantial proportion (30%) of hemophilia cases arise as new, spontaneous mutations. Overall, the hemophilias are much more common than the autosomal recessive coagulation factor deficiencies (see later), which often affect progeny from consanguineous relationships and require the inheritance of two defective alleles for the bleeding manifestations to become evident.

PATHOBIOLOGY

Genetics

As with other sex-linked recessive diseases, the genes for factor VIII and factor IX are located on the long arm of the X chromosome. Males with a defective allele on their single X chromosome transmit this gene to all their daughters, who are obligate carriers, but to none of their sons. Because the offspring of female carriers inherit one affected X chromosome, half of their sons develop the coagulation disorder, and half of their daughters are obligate carriers. Female carriers may manifest bleeding symptoms, particularly postpartum bleeding, if the alleles on the X chromosome are unequally inactivated (lyonization); the defective hemophilic allele is expressed in preference to the normal allele, plasma factor VIII levels are below 50%, and phenotypic hemophilia results. Female hemophilia may arise as a result of mating between a hemophilic male and a female carrier (homozygous for the defective factor VIII or IX gene) or in carrier females who have the 45,XO karyotype (Turner syndrome) and are hemizygous for the defective hemophilia gene.

No single mutation is responsible for the hemophilias. Many missense and nonsense point mutations, deletions, and inversions have been described. Severe molecular defects predominate, with 40 to 50% of all cases of severe hemophilia A evolving from a unique inversion of intron 22 (the largest of the factor VIII introns). This inversion results from the recombination and translocation of DNA within intron 22 of the factor VIII gene, with areas of extragenic but homologous "nonfunctional" DNA located at a distance from intron 22. Other less common severe molecular defects include large gene deletions (5 to 10% of cases) and nonsense mutations (10 to 15% of cases). The encoded proteins resulting from these mutations are defective and do not express any factor VIII activity. Mild or moderate hemophilia A is commonly associated with point mutations and deletions. In contrast, factor IX mutations are more diverse, and severe hemophilia B is more likely caused by large deletions. Mutated clotting factor genes responsible for the hemophilias may also encode for the production of defective nonfunctional proteins that circulate in the plasma and are detected at normal quantitative levels by immunoassays but not by functional assays. A listing of the mutations that cause the hemophilias can be accessed through the Human Gene Mutation Database (www.hgmd.org).

CLINICAL MANIFESTATIONS

Hemophilia A and hemophilia B are said to be clinically indistinguishable, with clinical severity corresponding inversely to the circulating levels of plasma coagulant factor VIII or IX activity, respectively. However, several studies have found a higher bleeding frequency, greater factor use, and more frequent hospitalizations in hemophilia A, suggesting greater clinical severity than hemophilia B. Individuals with less than 1% of normal factor VIII or IX activity are classified as having "severe" disease, characterized by frequent spontaneous bleeding events in joints (hemarthrosis) and soft tissues and by profuse hemorrhage with trauma or surgery. Although spontaneous bleeding is uncommon in mild deficiencies (>5% normal activity), excess bleeding typically occurs with trauma or surgery. A moderate clinical course is associated with factor VIII or IX levels between 1 and 5%. Approximately 60% of all cases of hemophilia A are clinically severe, whereas only 20 to 45% of cases of hemophilia B are severe.

Severe hemophilia is typically suspected and diagnosed during infancy in the absence of a family history. Among newborns, intracranial hemorrhage is the leading cause of morbidity and mortality, with a cumulative incidence of 3.8%, according to data collected by the Centers for Disease Control and Prevention. Intracranial hemorrhage does not appear to be related to the mode of delivery, although half of such hemorrhages occur in the newborn period. Current guidelines suggest cesarean section delivery be considered for any known male infants with severe hemophilia A. Vacuum extraction may increase cephalohematoma formation and is discouraged. Circumcision within days after birth is accompanied by excessive bleeding in less than half of severely affected boys. The first spontaneous hemarthrosis in severely affected hemophiliacs usually occurs between 9 and 18 months of age, when ambulation begins; in moderately affected individuals, it generally does not occur until 2 to 5 years of age. The knees are the most prominent sites of spontaneous bleeds, followed by the elbows, ankles, shoulders, and hips; wrists are less commonly involved.

Acute hemarthroses (Fig. 174-1) originate from the subsynovial venous plexus underlying the joint capsule and produce a tingling or burning sensation, followed by the onset of intense pain and swelling. On physical examination, the joint is swollen, hot, and tender to palpation, with erythema of the overlying skin. Joint mobility is compromised by pain and stiffness, and the joint is usually maintained in a flexed position. Immediate or early replacement of the deficient clotting factor to normal hemostatic levels rapidly reverses the pain. Delayed treatment results in excess pain, morbidity, and joint damage. Optimal management includes *r*est, *i*ce, factor *c*oncentrate, and *e*levation (RICE). Swelling and joint immobility improve as the intra-articular hematoma resolves. Intra-articular needle aspiration of fresh blood is not recommended because of the risk for introducing infection. Short courses of oral corticosteroids may be helpful to reduce the acute joint symptoms in children but are rarely used in adults.

FIGURE 174-1. Acute hemarthrosis of the knee is a common complication of hemophilia. It may be confused with acute infection unless the patient's coagulation disorder is known because the knee is hot, red, swollen, and painful. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

FIGURE 174-2. Severe chronic arthritis in hemophilia. The knee is the most commonly affected joint. Both knees are severely deranged in this patient. Note that he is unable to stand with both feet flat on the floor. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

Recurrent or untreated bleeds result in chronic synovial hypertrophy and, eventually, damage to the underlying cartilage, with subsequent subchondral bone cyst formation, bony erosion, and flexion contractures. Abnormal mechanical forces from weight bearing can produce subluxation, misalignment, loss of mobility, and permanent deformities of the lower extremities (Fig. 174-2). These changes are accompanied by chronic pain, swelling, arthritis, and disability. Plain radiographs and clinical examination of chronic hemarthroses often underestimate the extent of bone and joint damage; serial magnetic resonance imaging is superior to radiography or computed tomography and is the most sensitive and specific means of detecting and monitoring early and progressive disease.

Intramuscular hematomas account for about 30% of hemophilia-related bleeding events and are rarely life threatening. They are usually precipitated by physical or iatrogenic trauma (e.g., after intramuscular injections) and may compromise sensory and motor function or arterial circulation if they entrap and compress vital structures in closed fascial compartments. The latter occurrence, termed *compartment syndrome*, presents with the rapid onset of swelling and severe pain in an extremity, unrelieved by factor infusion and standard analgesics. This is considered a medical emergency and may require fasciotomy to preserve tissue and provide pain relief. Retroperitoneal hematomas may be confused clinically with appendicitis or hip bleeds but should be suspected in a patient who is hunched over and unable to stand erect owing to the pain of muscle extension in the presence of hematoma. Unless these bleeding episodes are treated immediately and aggressively, permanent anatomic deformity, such as flexion contracture, nerve damage, or pseudotumor formation (expanding hematomas that erode and destroy adjacent skeletal structures), may occur. Bleeding from mucous membranes is very common and may be exaggerated by the degradation of fibrin clots by fibrinolytic enzymes contained in secretions. Bleeding involving the tongue or the retropharyngeal space may rapidly produce life-threatening compromise of the airway. Gastrointestinal hemorrhage typically originates from anatomic lesions proximal to the ligament of Treitz and may be exacerbated by esophageal varices secondary to cirrhosis and portal hypertension or by the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for the treatment of hemarthroses. Spontaneous bleeding in the genitourinary tract secondary to hemophilia is a diagnosis of exclusion after ruling out renal stones and infection. Ureteral blood clots produce renal colic, which may be confused with nephrolithiasis and may be worsened by the use of antifibrinolytic agents. A short course of steroids may be helpful, especially in children, to hasten their resolution. Ninety percent of hemophiliacs experience at least one episode of gross hematuria or hemospermia.

Intracranial bleeds occur in 10% of patients, are usually induced by trauma, and may be fatal in 30% of cases. The risk for developing an intracranial hemorrhage is approximately 2% per year. Neuromuscular defects, seizure disorders, and intellectual deficits may ensue.

Individuals with hemophilia cared for at HTCs have lower mortality and reduced costs of care compared with those receiving treatment elsewhere. The chronic care model practiced at HTCs emphasizes prevention to reduce joint disease and complications, optimization of factor dosing, and counseling regarding safe sports and the avoidance of aspirin and other drugs that inhibit platelet function.

DIAGNOSIS

The diagnosis of hemophilia[1] is suspected on the basis of a family and personal bleeding history and laboratory detection of prolongation of the aPTT (with normal PT). It is confirmed by significantly reduced plasma factor VIII or IX activity. As noted in Chapter 171, the aPTT is not a sufficiently sensitive screening test to be prolonged in mild hemophiliacs, in whom the factor VIII level is sometimes greater than 30% of normal. Severe hemophilia is usually recognized in infancy, with circumcision bleeding; by contrast, moderate or mild disease is recognized later in life after trauma or surgery. Hemophilia can be distinguished from von Willebrand disease (VWD; Chapter 173) by normal ristocetin cofactor and von Willebrand factor (VWF) antigen levels. In type 2N VWD, factor VIII is significantly lower than ristocetin cofactor and VWF antigen levels because of reduced factor VIII binding; this variant of VWD may require genotyping to distinguish it from hemophilia A. Other congenital intrinsic factor deficiencies (e.g., factor XI and XII) can be determined by coagulation factor–specific assays. Vitamin K deficiency (see later and Chapter 175) can be detected by the associated PT prolongation; deficiencies of factors II, VII, IX, and X; and resolution of the coagulation defect with vitamin K. The presence of heparin can be confirmed by correction of the aPTT after running the sample over a heparin absorption column. Failure of the aPTT to correct in a 1 : 1 mix with normal plasma suggests the presence of an inhibitor; specific inhibitors are associated with a single decreased factor level (usually factor VIII; see Alloantibody Inhibitors to Factors VIII and IX under Treatment), whereas blocking inhibitors cause nonspecific factor level changes associated with a positive hexagonal lipid assay (see Antiphospholipid Syndrome and Lupus Anticoagulant later).

Although existing laboratory tests quantify the amount of factor in plasma, which is useful diagnostically and prognostically, these assays are limited in their ability to fully evaluate a patient's clot-forming capability. Newer, so-called global assays have the potential to more objectively measure the hemophilic phenotype as well as the response to treatment, especially in patients who develop inhibitors and in those for whom traditional coagulation tests cannot fully measure laboratory response to bypassing agents (see later); global assays such as thrombin-generation tests and viscoelastic assays await full validation in clinical practice.[2]

TREATMENT

Rx

Treatment and prevention of acute bleeding events in hemophilia A and B are based on replacement of the missing or deficient clotting factor protein to restore adequate hemostasis (Table 174-1). The morbidity, mortality, and overall cost of care for individuals with hemophilia are reduced significantly if care is provided by comprehensive HTCs that have the multispecialty expertise and laboratory capabilities to coordinate and monitor specific patient needs.

The goal of replacement therapy (Table 174-1) is to achieve plasma factor VIII and IX activity levels of 25 to 30% for minor spontaneous or traumatic bleeds (e.g., hemarthroses, persistent hematuria), at least 50% clotting factor activity for the treatment or prevention of severe bleeds (e.g., major dental surgery, maintenance replacement therapy after major surgery or trauma), and 80 to 100% activity for any life-threatening or limb-threatening hemorrhagic event (e.g., major surgery, trauma). After major trauma or if visceral or intracranial bleeding is suspected, replacement therapy adequate to achieve 100% clotting factor activity should be administered *before* diagnostic procedures are initiated. To calculate the initial dose, plasma factor VIII activity generally increases about 2% (0.02 IU/mL) for each unit of factor VIII administered per kilogram of body weight, and factor IX activity increases about 1% (0.01 IU/mL) for each unit of factor IX administered per kilogram of body weight. Therefore, a 70-kg individual with severe hemophilia A or B (factor VIII or IX activity <1% of normal) who requires replacement to 100% activity for major surgery should initially receive 3500 IU of factor VIII or 7000 IU of factor IX concentrate. The circulating half-lives of factors VIII and IX require subsequent dosing at half the initial dose every 8 to 12 hours and every 18 to 24 hours, respectively. However, this empirical dosing (based on calculations) should be individualized according to the peak recovery increment within 10 to 15 minutes after bolus infusion, as well as trough activity levels. The frequency of repeat dosing is also determined by the rapidity of pain relief, recovery of joint function, and resolution of active bleeding. Replacement is usually maintained

TABLE 174-1 FDA-APPROVED COAGULATION PROTEINS AND REPLACEMENT THERAPIES AVAILABLE IN THE UNITED STATES

COAGULATION PROTEIN DEFICIENCY	INHERITANCE PATTERN	PREVALENCE	MINIMUM HEMOSTATIC LEVEL	REPLACEMENT SOURCES
Factor I (fibrinogen) Afibrinogenemia Dysfibrinogenemia	 Autosomal recessive Autosomal dominant or recessive	 Rare (<300 families) Rare (>300 variants)	50-100 mg/dL	Cryoprecipitate, FFP, fibrinogen concentrate
Factor II (prothrombin)	Autosomal dominant or recessive	1 in 2 million births	30% of normal	FFP, factor IX complex concentrates
Factor V (labile factor)	Autosomal recessive	1 in 1 million births	25% of normal	FFP
Factor VII	Autosomal recessive	1 in 500,000 births	25% of normal	Recombinant factor VIIa (15-20 μg/kg), FFP, factor IX complex concentrates
Factor VIII (antihemophilic factor)	X-linked recessive	1 in 5000 male births	80-100% for surgery/life-threatening bleeds, 50% for serious bleeds, 25-30% for minor bleeds	Factor VIII concentrates (recombinant preferred)
Von Willebrand disease (also see Chapter 173) Type 1 and 2 variants Type 3	 Usually autosomal dominant Autosomal recessive	 1% prevalence 1 in 1 million births	>50% VWF antigen and ristocetin cofactor activity	DDAVP for mild to moderate disease (except type 2B; variable response to 2A); cryoprecipitate and FFP (not preferred, except in emergencies); factor VIII/VWF concentrates, viral attenuated, intermediate purity (preferred for surgery, for disease unresponsive to DDAVP, and for type 3
Factor IX (Christmas factor)	X-linked recessive	1 in 30,000 male births	25-50% of normal, depending on extent of bleeding, surgery	Factor IX concentrates (recombinant preferred); FFP not preferred except in dire emergencies
Factor X (Stuart-Prower factor)	Autosomal recessive	1 in 500,000 births	10-25% of normal	FFP or factor IX complex concentrates
Factor XI (hemophilia C)	Autosomal dominant; severe type is recessive	4% of Ashkenazi Jews; 1 in 1 million general population	20-40% of normal	FFP or factor XI concentrate
Factor XII (Hageman factor), prekallikrein, high-molecular-weight kininogen	Autosomal recessive	Not available	No treatment necessary	—
Factor XIII (fibrin stabilizing factor)	Autosomal recessive	1 in 3 million births	5% of normal	FFP, cryoprecipitate, or viral-attenuated factor XIII concentrate

DDAVP = desmopressin; FDA = U.S. Food and Drug Administration; FFP = fresh-frozen plasma; VWF = von Willebrand factor.

for 10 to 14 days after major surgery to allow proper wound healing. Bolus dosing typically results in wide fluctuations in clotting factor activity levels and requires frequent laboratory monitoring to avoid suboptimal troughs. A continuous infusion regimen, consisting of 1 to 2 IU of factor VIII or IX concentrate per kilogram per hour after a bolus dose, maintains a plateau level without the need for frequent laboratory testing. Continuous infusion also reduces total concentrate consumption by 30 to 75% in surgical settings. Ongoing and completed phase I/II/III clinical trials of long recombinant factors VIII and IX, pegylated or fused to albumin or to the Fc domain of immunoglobulin G1 (IgG1), indicate these proteins are safe, effective, and prolong half-life 1.5- to 2-fold for factor VIII and 2- to 4-fold for factor IX, suggesting they may allow simpler dosing schedules and fewer intravenous factor infusions. A completed phase III clinical trial of recombinant factor IX-Fc fusion protein (rFIXFc) in adults with severe hemophilia B has demonstrated safety, efficacy, and a 3-fold longer circulating half-life than recombinant factor IX, such that some patients were able to dose every 10 to 14 days.[3] Similarly, recombinant factor VIII-Fc (rFVIIIFc) is safe, effective, and has a 1.5-fold longer half-life than recombinant factor VIII, resulting in dosing every 3 to 5 days.

Because of the potential thrombogenicity associated with the repeated administration of prothrombin complex concentrates to replace factor IX deficiency, high-purity, plasma-derived, or genetically engineered factor IX concentrates, which lack activated vitamin K–dependent clotting factors, are preferred in hemophilia B.

Cryoprecipitate (a cold precipitate of fresh-frozen plasma [FFP] after thawing at 4°C) and FFP contain factor VIII, but only FFP contains factor IX. However, neither cryoprecipitate nor FFP is an optimal replacement product for either hemophilia A or hemophilia B because these agents may transmit blood-borne pathogens and require large-volume infusion. All clotting factor concentrates available in the United States (see Table 174-1), whether plasma derived or genetically engineered, are equally efficacious and are considered extremely safe; none has been implicated in the transmission of blood-borne viral pathogens or prions. The second- and third-generation recombinant factor VIII and IX concentrates are manufactured free of added human or animal proteins in the culture medium or in the final formulation, eliminating the theoretical risks for transmission of prions or murine viruses.

Hemarthroses

The moderate or severe pain that accompanies acute hemarthroses responds to immediate analgesic relief, temporary immobilization, restraint from weight bearing, and clotting factor replacement. Narcotic analgesics, such as codeine or synthetic derivatives of codeine, should be prescribed alone or combined with doses of acetaminophen that are low enough to avoid hepatic toxicity in patients with chronic hepatitis. Although these medications do not possess significant anti-inflammatory activity, they are preferable to NSAIDs or aspirin, which can exacerbate bleeding complications through their inhibition of platelet aggregation.

Strategies intended to prevent end-stage joint destruction should be initiated at an early age. Although prophylaxis beginning soon after the first bleed is the recommended approach (see later), most adults have not had the benefit of early prophylaxis and thus have advanced arthropathy with reduced motion, disability, and pain, for which surgery may be recommended. Synovectomy through open surgery or arthroscopy removes the inflamed tissue and should result in substantially decreased pain and less recurrent bleeding. Nonsurgical synovectomy (synoviorthosis), which involves the intra-articular administration of a radioisotope, is particularly useful for high-risk patients and for those with alloantibody inhibitors to factor VIII or IX (see later). The occurrence of leukemia in several hemophilic children undergoing radioisotopic synoviorthosis has raised concerns about potential leukemogenesis, especially given the low background rate of cancers in individuals with hemophilia. Neither synovectomy nor synoviorthosis reverses joint damage, but both procedures may delay its progression. Non-weight-bearing exercises, such as swimming and isometrics, are important to periarticular muscle development and maintenance of joint stability for ambulation. Intractable pain and severe joint destruction secondary to repeated hemorrhage require prosthetic replacement. Chronic ankle pain responds best to open surgical or arthroscopic fixation and fusion (arthrodesis).

The ultimate strategy to minimize or eliminate progressive joint destruction by recurrent hemarthroses is predicated on the concept of prophylaxis—the scheduled administration of clotting factor concentrates several times weekly (twice a week for factor IX, three times a week for factor VIII) at doses to maintain trough factor activity levels greater than 1 to 2% of normal. In a

prospective, randomized clinical trial, the Joint Outcomes Trial, prophylaxis with factor VIII (25 IU/kg every other day) was superior to episodic therapy (on demand) in young children with severe hemophilia in reducing joint bleeding and joint damage as shown by magnetic resonance imaging and radiography.[3] These findings were confirmed in older children in the ESPRIT trial,[3] with the best outcomes when prophylaxis was initiated before 3 years of age. In several adult studies of two- or three-times-weekly prophylaxis at 20 to 80 IU/kg, there were significantly fewer joint bleeds and pain and better quality of life than in those on on-demand therapy.[3] Although prophylaxis uses more factor product at greater expense, the benefits of long-term prophylaxis to promote joint health and avert disability have led to the recommendation that it be initiated in young children with severe disease at the time of the first bleed. Compliance with prophylaxis is not easy because it requires intravenous factor, which is invasive, burdensome, and in small children may require central venous access devices, which may be complicated by infection.

With the development of long-acting factor VIII and IX,[4] currently in clinical trials, infusion frequency and bleeds may decrease and access devices may be avoided entirely. Some unanswered questions include the minimal effective dose for prophylaxis in children, and the role of generic versus personal pharmacokinetic studies to optimize dosing. The risk for bleeding is thought to be related to the time spent at nadir factor levels less than 1% (0.01 IU/mL) between dosing. It is generally agreed that spontaneous bleeding may be averted by maintaining factor levels at 1% (0.01 U/mL) or greater.

Factor Concentrate–Transmitted Viral Infections

In contrast to other at-risk groups, individuals with hemophilia were exposed at a young age to transmissible agents through clotting factors. These include hepatitis C virus (HCV), leading to infection in 90% of those transfused from the late 1970s through the mid-1980s, and human immunodeficiency virus (HIV) infection in 80% of those transfused with factor VIII products and 50% of those transfused with factor IX products from 1978 through the mid-1980s. Overall, of those with HCV infection (Chapter 148), 40% have coinfection with HIV, and hepatitis C remains the leading cause of death in hemophilia. With the implementation of viral inactivation and recombinant technologies, viral transmission has been virtually eliminated in hemophiliacs born since the 1990s. Nevertheless, among those exposed to HCV, 25% have liver fibrosis, and those with HIV coinfection have a 1.4-fold greater fibrosis rate. Combined antiretroviral therapy (cART) has slowed the rate of HCV progression in coinfected patients to rates observed in HCV-monoinfected hemophilic men.

GB virus C (GBV-C), formerly known as hepatitis G virus, observed in 15 to 25% of hemophiliacs, is susceptible to current viral attenuation procedures. Hepatitis A and B vaccination have rendered viral infections with these agents rare in those with hemophilia, and although parvovirus B19 (Chapter 371) seroprevalence approaches 80% in older adult hemophiliacs exposed to plasma-derived products, the long-term clinical consequences remain unclear. Cadaver and living-donor liver transplantation (Chapter 154) has improved the survival of hemophilic men with chronic hepatitis-induced liver failure and has also resulted in the phenotypic cure of hemophilia, confirming that the liver is the predominant source of normal synthesis of factors VIII and IX. Liver transplantation is also performed successfully in HIV/HCV-coinfected patients on cART therapy, although HCV recurrence remains a universal problem.

Ancillary and Other Therapies

Ancillary treatment strategies for the hemophilias include antifibrinolytic agents, such as ε-aminocaproic acid (50 mg/kg 3 to 4 times daily) or tranexamic acid (3 or 4 g given orally daily in divided doses), to minimize mucous membrane bleeding, and the application of fibrin glue to bleeding sites. Desmopressin (DDAVP), which is also used in VWD (Chapter 173), can be administered by nasal insufflation 2 hours before a scheduled surgical procedure (one spray per nostril, to provide a total dose of 300 µg; or, in patients weighing less than 50 kg, 150 µg administered as a single spray); alternatively, DDAVP can be administered intravenously (dissolved in 50 mL normal saline) over 30 minutes at a dose of 0.3 µg/kg. DDAVP is useful in patients with mild hemophilia A because an adequate incremental rise in factor VIII activity can circumvent the use of clotting factor concentrates. Repeated administration of DDAVP (intravenously or by intranasal spray) may be complicated by facial flushing, tachyphylaxis, hyponatremic seizures (primarily in children), and, rarely, angina.

Alloantibody Inhibitors to Factors VIII and IX

Alloantibodies—that is, antibodies to "foreign" infused factor VIII or, less frequently, factor IX—are usually detected in childhood after a median of 9 to 12 days of exposure to clotting factor. These inhibitors occur preferentially in those with a family history of inhibitors; those with large, multidomain factor VIII and factor IX gene deletions; blacks; and Hispanics. Among blacks, gene sequence data suggest that mismatched factor VIII transfusions may account for the high inhibitor risk. Although hemophiliacs with major deletions of the factor VIII gene have a very high (up to 90%) prevalence of inhibitors, its prevalence in those with factor VIII gene missense mutations is low (<10%), as it is in those with intron 22 inversion (20%) even though the latter have severe hemophilia. Algorithms have been developed to stratify inhibitor risk for individuals and subpopulations. The incidence of factor VIII alloantibodies among hemophilia A patients is 15 to 25%, whereas the incidence of factor IX alloantibodies among hemophilia B patients is 1.5 to 3%. The latter is most common in Scandinavians and is also associated with anaphylaxis and nephrotic syndrome. Increasing evidence from the RODIN study suggests that although inhibitor risk appears to be unrelated to factor type (e.g., recombinant vs. plasma-derived), it is significantly associated with early high-intensity factor exposure (i.e., >3 to 5 days), especially in those with a family history or an at-risk mutation (e.g., a large deletion mutation).[5,6]

The development of an alloantibody inhibitor is suspected when replacement therapy is ineffective in controlling bleeding symptoms. These antibodies, typically of the IgG4 subclass, completely neutralize clotting factor activity and prevent or reduce any increment in factor VIII or IX levels following bolus infusions of concentrate. Characterized as time and temperature dependent, inhibitors are quantitated in Bethesda units (BU): by definition, 1 BU is the amount of inhibitor that neutralizes 50% of the specific clotting factor activity in normal plasma. "High responders," or patients with high-titer inhibitors (>5 BU), mount an anamnestic antibody response to factor VIII clotting factor protein, usually within 5 to 7 days after subsequent exposure, and are no longer responsive to infused factor VIII. By contrast, "low responders," or patients with low-titer inhibitors (≤5 BU), do not manifest anamnesis, and such low-titer inhibitors can easily be overwhelmed by large amounts of human factor VIII or factor IX concentrate and can be successfully treated with three to four times the usual factor dose.

Management of patients with high-titer inhibitors against factor VIII or IX is difficult, and no single approach is uniformly successful.[7] There are two components: first, assurance of hemostasis using "bypass therapy," and second, eradication of inhibitor formation. Hemostasis can be provided by "bypass" agents that are used to treat bleeding episodes (see Table 174-1); specifically, the activated prothrombin complex concentrate FEIBA VH (75 to 100 IU/kg initially, then 50 to 100 IU/kg every 6 to 8 hours) and recombinant factor VIIa (90 µ/kg every 2 to 3 hours) can be administered until bleeding is controlled. In studies of congenital hemophilia A patients with alloantibody inhibitors, one dose of FEIBA VH or two doses of recombinant factor VIIa controlled hemarthrosis episodes 81 and 79% of the time, respectively. The activated and unactivated prothrombin complex concentrates contain activated vitamin K–dependent clotting factors that "bypass" the intrinsic pathway (factor VIII or IX) inhibitor. As a result, repeated administration over a short time may be complicated by potential thrombogenicity: the aPTT and clotting factor assays are not helpful in monitoring hemostasis in these cases. In patients with high-titer inhibitors to factor VIII or IX, recombinant factor VIIa may achieve effective hemostasis, but its use is limited by the need for frequent intravenous dosing, usually every 2 hours to start. Although continuous dosing has been used in some patients, general experience dictates that for surgery or procedures in which significant bleeding is likely, bolus dosing is required to achieve optimal hemostasis—a so-called "thrombin burst." The product has also been effective in patients who experience anaphylactic reactions or nephrotic syndrome after exposure to factor IX–containing replacement products or fresh-frozen plasma (FFP). Several studies have shown that prophylactic treatment in adult inhibitor patients with either rFVIIa, 90 µg/kg daily or 270 µg/kg daily, or FEIBA, 85 IU/kg weekly, can significantly reduce bleeding rates compared with on-demand treatment.[3]

Eradication of inhibitors is usually attempted with "immune tolerance induction" regimens,[8] which are generally effective if initiated within 12 months of the inhibitor's detection. Tolerance regimens consist of daily doses of factor concentrates to accomplish desensitization to infused factor, a process associated with a 68% success rate. In an international randomized trial of high-dose factor VIII (200 IU/kg daily) vs. low dose (50 IU/kg three times weekly) for immune tolerance induction (ITI) in young inhibitor patients, there was no difference in inhibitor eradication, but there was greater bleeding (mostly hematomas) in the low-dose arm.[3] These findings suggest improved hemostasis may be possible in the high-dose arm, despite inhibitor detection. The authors also initiated ITI only after waiting for the inhibitor titer to drop below 10 BU because tolerance took longer to achieve the higher the inhibitor titer.[3] After tolerance was achieved, prophylaxis with factor VIII or IX concentrate two or three times weekly (at 20 to 30 IU/kg) appears necessary to maintain tolerance. Individuals with inhibitors since childhood for whom immune tolerance was not possible before adulthood are unlikely to respond to ITI. Alternative single or combination immunosuppressive agents (e.g., rituximab, mycophenolate, or cyclosporine) may be used as alternative therapies but appear to be variably effective.[9]

PREVENTION

Carrier Detection and Prenatal Diagnosis

Carrier detection and prenatal diagnosis have become technically feasible, very sensitive, and widely available. Noninvasive prenatal diagnosis by use of

microfluidic digital PCR of maternal plasma DNA is an emerging technique that is based on relative mutation dosage from a blood sample of a pregnant carrier with or without an affected fetus, which may detect hemophilia as early as the 11th week of gestation. The application of these diagnostic tools, however, is influenced by ethical, cultural, religious, economic, educational, and personal considerations. For instance, carrier detection is particularly useful in identifying women who may be at risk for hemorrhagic complications during the delivery process and male offspring who are particularly vulnerable to intracerebral bleeds at birth. Alternatively, these techniques can provide important information used to make difficult reproductive decisions. Genetic testing should be performed only following genetic counseling and with no patient coercion to accept such testing.

PROGNOSIS

The life expectancy of individuals with severe hemophilia is approaching that of the normal population. The age-matched death rate in hemophilia is 2.7-fold greater than that in the general population, although ischemic heart disease mortality is nearly 60% lower than in the general population. Life expectancy is related to the severity of hemophilia: the mortality rate of severely affected patients is 4- to 6-fold greater than that of patients with mild deficiency. Among those with alloantibody inhibitors, mortality rates are significantly higher than in noninhibitor patients. The three leading causes of death are hepatitis C, HIV/AIDS, and central nervous system bleeding. Hepatitis C, the leading cause of death, accounts for more than half of the deaths, whereas deaths from HIV have declined with the availability of cART therapy (Chapter 388). Among those with HIV/HCV coinfection, cART also slows the progression of HCV-related liver disease. Predictors of hepatitis C disease progression in hemophilia include alcohol use, the use of acetaminophen for pain relief of hemophilic arthropathy, hepatitis B surface antigenemia, and HIV coinfection. Bleeding also accounts for causes of death: the lifetime risk for intracranial hemorrhage is 2 to 8%, and although it is the leading cause of morbidity and mortality in the newborn period, prospective monitoring of central nervous system function continues to be a priority as the population ages. Finally, with the essential elimination of disease transmission through blood products in this population, the usual problems of aging are increasingly being recognized in those with hemophilia, including atherosclerosis, hypertension, hyperlipidemia, obesity, and diabetes. The impact of these conditions on the natural history of hemophilia, given the recognized lower mortality from ischemic heart disease, remains to be seen. More data are needed to help guide clinical management of these patients.

FUTURE DIRECTIONS

Gene Therapy for Hemophilia a and B

The hereditary hemophilias are model diseases for gene therapy because they are caused by specific, well-defined gene mutations; a small, incremental rise in clotting factor synthesis can lead to substantially improved treatment and quality of life; and inadvertent overexpression by successful gene transfer would not be detrimental. Successful gene transfer techniques have been developed to provide long-term therapeutic benefits in hemophilic mice and dog models, and early success is now being reported in humans. In one study of gene transfer using serotype-8 pseudotyped adeno-associated virus vector (AAV8) carrying a codon-optimized factor IX transgene, factor IX expression of 1 to 6% was achieved in hemophilia B patients, persisting up to the present, up to 2 years later.[10] An immune response to the AAV capsid, associated with increases in alanine transaminase (ALT) and aspartate transaminase (AST) in some of the subjects, resolved with a 4-week course of oral steroids, but approaches to avert this immune response are underway, including modification to neutralize excess AAV. Other approaches include design of less immunogenic vectors and use of innovative delivery systems, such as platelets. Novel therapeutic approaches to enhance clotting factor replacement therapy include RNAi silencing of antithrombin III, a thrombin inhibitor, to promote hemostasis through thrombin generation; oral delivery systems using bioencapsulated proteins; and molecular modifications to enhance the desirable properties of clotting factor.

Acquired Hemophilias

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoantibody inhibitors occur spontaneously in individuals with previously normal hemostasis (nonhemophiliacs). In contrast to alloantibody inhibitors in hemophilic men, which are directed against foreign infused clotting factor, autoantibody inhibitors are directed against a "self" clotting factor, most commonly factor VIII. These autoantibodies typically arise in individuals with no past bleeding history; thus the diagnosis may be missed until a prolonged aPTT and aPTT mix tests are obtained (Chapter 171). Although half of those with autoantibody inhibitors have no obvious underlying cause, autoimmune diseases, lymphoproliferative disorders, idiosyncratic drug reactions, pregnancy, and advanced age are associated in the other half.[11]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Massive hemorrhagic events, even more severe than in hemophilia patients with alloantibodies, and more commonly in soft tissues, may occur in those with autoantibodies because of a delay in diagnosis and treatment. The laboratory expression of autoantibodies is similar to that of alloantibodies, except that clotting factor activity is not completely neutralized. Residual clotting factor activities between 3 and 20% of normal are frequently observed in patients with autoantibodies.

TREATMENT

Rx

The same principles of replacement therapy for alloantibodies apply to these acquired autoantibody inhibitors.[12] There are two goals of treatment: (1) stop the bleeding and assure hemostasis, and (2) eradicate the inhibitor. For hemostasis, recombinant factor VIIa, activated prothrombin complex concentrate (aPCC), or factor VIII bypass activity is commonly used, in similar doses used to achieve hemostasis with alloantibody. Data from the EACH2 registry (European Acquired Haemophilia Registry) indicate that optimal bleeding control is with bypass treatment (rFVIIa or aPCC), which was effective in 93%, compared with FVIII or DDAVP, 68%. Thrombotic events were reported in only 3.6% for all of these hemostatic agents combined. Eradication of the inhibitor was significantly better in those treated with steroids and cyclophosphamide (80%), than those treated with steroids alone (58%); and the combination is more effective in autoantibody patients than in alloantibody patients; this includes corticosteroids (prednisone 1 mg/kg/day orally), cytotoxic agents (e.g., cyclophosphamide 150 mg/day orally or 500 to 750 mg/m^2 intravenous bolus every 3 to 4 weeks), or a combination, with dose titration based on inhibitor levels and complicating cytopenias. Rituximab (anti-CD20 antibody)-based regimens (375 mg/m^2 intravenously weekly for 4 weeks) are also effective in 61%. High-dose intravenous gamma globulin (IVIG)-based regimens may be effective in 45%. These agents are tapered and discontinued after the autoantibody has disappeared. The time to complete remission is about 5 weeks for steroids with or without cyclophosphamide, whereas rituximab-based regimens require twice as long to achieve remission.

PROGNOSIS

Several large series of patients with acquired hemophilia reveal a substantial mortality rate of 15 to 25%, which is considerably higher than that observed with alloantibody factor VIII inhibitors. A large meta-analysis found that overall survival in acquired hemophilia was influenced primarily by the achievement of a complete remission, age younger than 65 years at diagnosis, and related diseases (malignancy vs. postpartum vs. others). As many as 17% of the deaths were associated with sepsis, and 71% of those arose as a complication of cyclophosphamide-induced neutropenia. Hemorrhagic complications were the primary cause of death, but these could be reduced if the inhibitor could be eradicated.

Von Willebrand Disease

The most common congenital bleeding disorder is von Willebrand disease (VWD). This disorder is inherited in an autosomal dominant fashion and affects both sexes, with a prevalence of 1 to 3% and no ethnic predominance. Homozygous patients are rare and carry a recessive mutant gene. VWF, the protein that is decreased or defective in VWD, is a large, multimeric glycoprotein encoded by the *VWF* gene, located on chromosome 12. A personal history of mucocutaneous bleeding, a family history, and decreased functional VWF constitute a diagnostic triad. Treatment is accomplished with DDAVP or VWF concentrates. Detailed discussion of VWD is provided in Chapter 173.

Factor XI Deficiency

EPIDEMIOLOGY

Factor XI deficiency has a prevalence of 1 in 1 million in the general population and 1 in 500 births in Ashkenazi Jewish families.[13] Factor XI is the only component of the contact phase (factor XII, prekallikrein, and high-molecular-weight kininogen) of the intrinsic pathway of coagulation

that is associated with excessive bleeding complications when a deficiency exists.

PATHOBIOLOGY

Factor XI deficiency is predominantly an autosomal recessive trait, although some mutations may have a dominant transmission pattern. The factor XI gene (*FXI*) is located on chromosome 4, and the protein circulates as a homodimer, with each FXI monomer composed of 4 apple domains encoded by exons 3 through 10 and a protease domain encoded by exons 11 through 15. The Glu117 stop mutation in *FXI* is the most common cause of factor XI deficiency; it is secondary to poor secretion or stability of the truncated protein or decreased levels of messenger RNA. To date, more than 170 mutations of *FXI* have been identified in factor XI–deficient patients (see www.factorxi.org), but close correlation between hemorrhagic phenotype and genotype is lacking. Most are missense or nonsense mutations and are located across all 4 apple domains and the serine protease region. In Ashkenazi Jewish individuals, factor XI deficiency is common, with a heterozygote frequency of 8 to 10%; two predominant gene mutations occur with equal frequency and are designated type II (a stop codon in exon 5) and type III (a single base defect in exon 9). The most severe clinical disease is observed in patients homozygous for type II, who usually have less than 1% factor XI activity. Homozygous type III individuals also manifest severe symptoms, but typically less severe than those of type II patients; they have slightly higher factor XI levels of about 10 to 20%. Compound heterozygotes, type II/III, make up the bulk of factor XI–deficient patients; they have clinically mild disease, with factor XI levels between 30 and 50%. In non-Jewish individuals, the mutations are more variable, although Cys128 stop has been described in several kindreds, and Cys38Arg has been found in several French Basque families. One third of those who develop inhibitors are homozygous for Glu117 stop, which results in an absent *FXI*. Genotypic identification of affected patients is determined by measuring factor XI levels rather than by defining the specific gene defect.

CLINICAL MANIFESTATIONS

The clinical bleeding tendency in factor XI deficiency is less severe than that observed in severe hemophilia A or B and, in contrast to the hemophilias, does not correlate with the severity of the deficiency. Most individuals with less than 20% of normal factor XI activity experience excessive bleeding after trauma or surgery; however, a few do not bleed. In contrast, bleeding has been observed in approximately 35 to 50% of mildly affected patients with factor XI levels between 20 and 50% of normal. Spontaneous hemorrhagic episodes, hemarthroses, and intramuscular and intracerebral bleeds are unusual; traumatic and surgical bleeds typically involve the mucous membranes. Patients undergoing tonsillectomy, prostatectomy, or dental extraction are at highest risk for bleeding unless replacement therapy is administered. Women may experience significant menorrhagia, and it has been recommended that women with menorrhagia be screened for both VWD and factor XI deficiency. Patients with mild factor XI deficiency and coincident mild VWD have an increased risk for bleeding.

DIAGNOSIS

Factor XI deficiency is diagnosed in the laboratory by a prolonged aPTT, normal PT, and decreased factor XI activity ascertained in a specific quantitative clotting assay (normal range, 60 to 130%).

TREATMENT Rx

Not all individuals with factor XI deficiency bleed, so it may be reasonable to monitor with no treatment, especially if there is no family history of bleeding. For surgical or other major bleeding, FFP 15 to 20 mL/kg may be given, although potential complications include fluid overload and infection risk, which can be reduced with the use of pathogen-inactivated FFP, if available. Use of factor XI concentrate, which is available in Europe but not the United States, may be complicated by thrombosis, which occurs in approximately 10% of patients, particularly in older individuals with preexisting cardiovascular disease or malignancy. Replacement dosing levels should not exceed 70% of factor XI activity. Repeat dosing with FFP or factor XI concentrate should take into consideration the long (60- to 80-hour) biologic half-life of factor XI in vivo.

The decision to treat heterozygotes with factor XI at levels greater than 20% is empirical and should be based on individual history of bleeding after trauma or surgery. There is no clear evidence of benefit with the use of DDAVP. Because hemorrhagic complications originate most commonly from mucous membrane surfaces, antifibrinolytic agents such as ε-aminocaproic acid or tranexamic acid are frequently helpful as adjunctive therapy. In women with menorrhagia or postpartum hemorrhage, testing for VWD is recommended because both diseases may be present.

Alloantibody inhibitors, which neutralize the hemostatic effects of exogenously administered factor XI replacement, can develop in patients with severe factor XI deficiency who have been exposed to plasma or factor XI concentrate. Recombinant factor VIIa can prevent bleeding during or after surgery in these patients.

Deficiencies of Contact Activation Factors

Although factor XI plays an important role in the activation of factor IX in the intrinsic pathway generation of thrombin, it is only one of the four components of the contact phase of coagulation. Deficiencies in any of the other three factors (factor XII, prekallikrein, and high-molecular-weight kininogen) produce in vitro laboratory abnormalities. Even among those with severe factor XII deficiency (<1% activity), there is no clinical bleeding; however, up to 8 to 10% with severe factor XII deficiency actually experience venous thromboembolic events, which are occasionally fatal. This finding has led to speculation that factor XII deficiency may lead to hypercoagulability through defective participation of the contact phase proteins in the activation of fibrinolysis.

DIAGNOSIS

Deficiencies of each of these factors prolong the aPTT, often markedly, which may normalize after prolonged incubation of the patient's plasma at 37° C with a negatively charged activator of the aPTT assay (i.e., kaolin or celite). Specific assays are also available to quantitate each of the contact factors.

TREATMENT Rx

Deficiencies of the contact activation factors, however severe they are and however prolonged the associated aPTT may be, do not cause clinical bleeding problems, even in response to surgery or trauma. Therefore, no therapy is indicated for factor XII deficiency, prekallikrein deficiency, or high-molecular-weight kininogen deficiency. Routine anticoagulation regimens are used to treat thrombogenic events.

Factor XIII (Fibrin-Stabilizing Factor) Deficiency

Factor XIII is a transglutaminase that is activated by thrombin and functions to cross-link fibrin to protect it from lysis by plasmin. It is also involved in wound healing and tissue repair and seems to be crucial for maintaining a viable pregnancy. Homozygous severe deficiency states are rare and are inherited in an autosomal recessive manner, with a prevalence of 1 per 3 million births. Consanguinity is common. Most patients are deficient in the A subunit (FXIII-A). Half of the molecular defects that account for A-subunit deficiency are missense mutations.

CLINICAL MANIFESTATIONS

Heterozygous carriers are usually asymptomatic, but homozygotes have lifelong bleeding that typically starts shortly after birth with persistent bleeding around the umbilical stump. Intracranial bleeding events, usually precipitated by minimal trauma, occur commonly enough in infants (25%) to justify the initiation of a primary prophylaxis regimen of replacement therapy. Delayed bleeding after surgery and trauma is the hallmark of the disease; however, easy bruising, poor wound healing with defective scar formation and dehiscence, and hemarthroses are characteristic. Spontaneous abortions are increased in severely affected women.

DIAGNOSIS

The diagnosis is usually suspected on clinical grounds, given that factor XIII deficiency is not detected by conventional screening coagulation assays (i.e., aPTT, PT). Most laboratories use a rapid screening assay that assesses the ability of a fibrin clot to remain intact with incubation in 5 mol/L of urea or 1% monochloroacetic acid. With factor XIII levels less than 1% of normal, the clot dissolves within 2 to 3 hours.

TREATMENT Rx

Replacement therapy for prophylaxis or the treatment of acute bleeds in factor XIII deficiency can be accomplished by administering cryoprecipitate, FFP, or, preferably, plasma-derived factor XIII concentrate (Corifact, CSL Behring), which is pasteurized for viral safety. Normal hemostasis is achieved with a factor XIII level of only 5% of normal. The dose is 10 to 20 U/kg intravenously, and because it has a long half-life (10 days), prophylactic replacement can be given every 3 to 4 weeks. Acquired alloantibody inhibitors can develop in severely affected individuals. Autoantibodies also occur, usually in association with systemic lupus erythematosus. Preliminary data from an ongoing clinical trial of recombinant factor XIII indicates it is safe and effective in preventing bleeds in factor XIII–deficient patients.[14]

Dysfibrinogenemia and Afibrinogenemia

Approximately 300 abnormal fibrinogens have been described, but few cause hemostatic symptoms. Abnormal fibrinogens are rare autosomally inherited proteins. Quantitative fibrinogen deficiencies (afibrinogenemia and hypofibrinogenemia) may result from mutations affecting fibrinogen synthesis or processing, whereas qualitative defects (dysfibrinogenemia) are caused by mutations that lead to abnormal polymerization, defective cross-linking, or defective assembly of the fibrinolytic system.

CLINICAL MANIFESTATIONS

More than 50% of the dysfibrinogenemias are asymptomatic, 25% are associated with a mild hemorrhagic tendency (commonly caused by defective release of fibrinopeptide A), and 20% predispose individuals to thrombophilia (usually caused by impaired fibrinolysis) (Chapter 176). Concurrent bleeding and thrombosis also may occur. The prevalence of dysfibrinogenemia in patients with a history of thromboembolic episodes approaches 0.8%. A high prevalence of dysfibrinogenemia has been reported among patients with chronic thromboembolic pulmonary hypertension, implicating changes in the molecular structure of fibrin in the development of this disorder (Chapter 68). Women experience a high incidence of pregnancy-related complications, such as spontaneous abortion and postpartum thromboembolic events. Thrombin times and reptilase times (plasma-based clotting times with the substitution of reptilase snake venom for thrombin) are not helpful in predicting whether an abnormal fibrinogen will be prothrombotic, prohemorrhagic, or asymptomatic. However, clinical history, fibrinopeptide release studies, and fibrin polymerization studies may be useful. Clinically insignificant dysfibrinogenemias may be acquired in association with hepatocellular carcinoma (Chapter 196).

In contrast to the hepatic synthesis of a qualitatively abnormal protein in dysfibrinogenemia, congenital afibrinogenemia, an autosomal recessive disorder, represents the markedly deficient production of a normal protein. Severe life-threatening hemorrhagic complications can occur at any site, beginning at birth with umbilical bleeding. Intracranial hemorrhage is a frequent cause of death. Poor wound healing is characteristic. All coagulation-based assays that depend on the detection of a fibrin clot end point are markedly prolonged. Afibrinogenemia is usually detectable by specific functional or immunologic assays. Platelet dysfunction may accompany afibrinogenemia and exacerbate bleeding.

DIAGNOSIS

Abnormalities are usually detected incidentally when routine coagulation screening assays reveal decreased fibrinogen concentrations and prolonged thrombin clotting times. On further evaluation, discordance between functional and immunologic fibrinogen levels (>50 mg/dL more antigenic than functional) is observed; clotting times using snake venom (reptilase or ancrod) are variably prolonged.

TREATMENT Rx

Deficiencies of fibrinogen can be corrected by the administration of FFP, cryoprecipitate, or a viral-attenuated (pasteurized), plasma-derived fibrinogen concentrate (Riastap, CSL Behring). The target replacement goal is a plasma level of 100 mg/dL, and given a circulating biologic half-life of at least 96 hours, treatment every 3 to 4 days is adequate. Primary prophylaxis regimens may be useful in afibrinogenemia, with on-demand or prophylactic replacement for trauma or surgery. Individuals with thrombophilic manifestations should receive anticoagulation long term, depending on risk-benefit assessment (Chapter 176). Riastap is not recommended for use in dysfibrinogenemia. Solvent/detergent plasma (Octaplas, Octapharma), a pooled human plasma that reduces allergic reactions and transfusion-related acute lung injury (TRALI), or psoralen-treated FFP (when licensed by the U.S. Food and Drug Administration [FDA]) may provide an alternative therapy.

Factor V Deficiency

Factor V is a component of the prothrombinase complex that assembles factors Va and Xa on the phospholipid membrane of the platelet for prothrombin (factor II) activation to thrombin (Chapter 171).

CONGENITAL FACTOR V DEFICIENCY

Deficiency of factor V is a rare, autosomal recessive disorder (1 in 1 million births). The factor V Leiden protein, which is responsible for resistance to activated protein C and thrombophilia, does not affect factor V coagulant activity (Chapter 176). The severity of plasma factor V deficiency correlates less well with the risk for clinical bleeding than does the factor V content in platelet α-granules (which cannot be measured in the clinical laboratory). This observation illustrates the critical role of the platelet in promoting adequate hemostasis at bleeding sites and explains why transfusions of normal platelets may be preferred over FFP for the treatment of hemorrhagic episodes secondary to congenital or acquired factor V deficiency. Hemostasis can be maintained without correcting plasma factor V activity (to >25% of normal).

COMBINED DEFICIENCIES OF FACTORS V AND VIII

Factors V and VIII are structurally homologous proteins, and combined deficiencies of these factors occur as an autosomal recessive disorder with a prevalence of 1 in 100,000 births among Jews of Sephardic origin. The severity of bleeding is determined by the levels of these factors, which usually range from 5 to 30% of normal. Replacement therapy should be aimed at normalizing both clotting protein activities.

ACQUIRED FACTOR V DEFICIENCY

Acquired factor V deficiency has been described in individuals exposed to bovine factor V, which contaminates the thrombin preparations used topically to control bleeding during cardiovascular surgery. This abnormality probably represents the development of anti–bovine factor V antibodies that cross-react with the human factor V protein. Profuse bleeding accompanies this complication.

Deficiencies of Vitamin K–Dependent Coagulation DEFICIENCIES OF FACTORS II, VII, AND X

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The coagulopathies of vitamin K deficiency and liver failure are discussed in Chapter 175. Congenital deficiencies of factors II (prothrombin), VII, and X are rare autosomally inherited disorders. Heterozygotes (with factor levels approximately 20% of normal) are typically asymptomatic except in the immediate newborn period, when physiologic vitamin K deficiency exacerbates the underlying clotting factor deficiency. Homozygotes with clotting factor levels less than 10% of normal manifest variable symptoms. As with other coagulopathies, these deficiencies are usually suspected after neonatal umbilical stump bleeding. Thereafter, unless replacement or prophylactic therapy is provided, these patients are subject to mucosal bleeding from epistaxis, menorrhagia, and dental extractions; hemarthroses and intramuscular hematomas; and bleeding after surgery or trauma.

Acquired factor VII deficiency has been associated with Dubin-Johnson and Gilbert syndromes (Chapter 147). Acquired factor IX deficiency has been associated with Gaucher disease because factor IX binds to glucocerebroside (Chapter 208). Acquired factor X deficiency and amyloidosis are discussed later.

DIAGNOSIS

In the coagulation laboratory, factor VII deficiency is associated with a prolonged PT and a normal aPTT. This pattern localizes the deficiency to the extrinsic pathway. In contrast, deficiencies of factors II (prothrombin) and X prolong both the PT and the aPTT, with the defects localized to the common pathway of coagulation. A Russell viper venom–based clotting assay can

differentiate between these two deficiencies; as a direct activator of factor X, the assay is prolonged with factor X deficiency but not with factor II deficiency. Mixing patient plasma with normal plasma results in a correction of these assays, and specific clotting assays using plasma deficient in the coagulation protein to be studied can confirm the diagnosis.

TREATMENT Rx

Replacement therapy is indicated for acute symptomatic bleeds and for prophylaxis before surgery. In addition to FFP, which has the potential to transmit blood-borne viruses, factor IX complex concentrates can be administered to achieve hemostatic levels of any of these vitamin K–dependent factors (to >25 to 30% of normal).

Bleeding complications caused by acquired IgG autoantibodies directed against any coagulation factor protein can be reversed rapidly, albeit temporarily, by extracorporeal immunoadsorption over a Sepharose-bound polyclonal antihuman IgG or staphylococcal A column, with concomitant replacement therapy and initiation of immunosuppression. Recombinant factor VIIa is increasingly used for surgery in those with rare congenital coagulation deficiencies but typically at lower doses than with hemophilia inhibitors—generally 10 to 15 µg/kg/day or less, for up to several days.

FACTOR DEFICIENCY IN AMYLOIDOSIS

Severe acquired deficiency of factor X, often accompanied by deficiencies of other vitamin K–dependent factors, occasionally occurs in individuals with systemic amyloidosis (Chapter 188). Because amyloid fibrils in the reticuloendothelial system bind endogenous and exogenous sources of factor X, replacement therapy with FFP or factor IX complex concentrates, even in large quantities, may not be sufficient. Recombinant factor VIIa concentrate has been used to reverse acute bleeding. Splenectomy may ameliorate recurrent bleeding complications.

Other Acquired Coagulation Abnormalities

ANTIPHOSPHOLIPID SYNDROME AND LUPUS ANTICOAGULANT

EPIDEMIOLOGY

The antiphospholipid antibody syndrome (APS) is associated with recurrent thrombosis or recurrent pregnancy loss with autoantibodies directed against phospholipids. Antiphospholipid antibodies (APAs) may include lupus anticoagulant (LA), anticardiolipin antibody (CL), or anti-β2-glycoprotein-I (anti-β2-GPI). Thrombocytopenia is also a common finding in this prothrombotic disorder. Rarely, multiorgan failure may arise from widespread thrombosis, termed *catastrophic APS*.

PATHOBIOLOGY

Our understanding of the role of individual antibodies in diagnosing APS continues to be enhanced with clinical studies, which may also contribute to the development of better diagnostic assays.[15] It has been suggested that the prothrombotic effects of APAs may derive from their ability to complex with β2-GPI in vivo (thereby negating their modulatory phospholipid-binding function) or through APA inhibition of protein C activation, interference with antithrombin III activity, and/or disruption of the annexin V "shield," thereby preventing normal clot breakdown (fibrinolysis). Although complement and inflammation play a role in fetal loss in a murine model of APS, the pathogenic mechanism of APS-associated pregnancy loss remains unclear. Although non-β2-GPI antibodies detected by CL enzyme-linked immunosorbent assay (ELISA) may play a role in early obstetric APS, and anti-β2-GPI antibodies with LA activity play a role in late miscarriage, additional studies are needed to better classify, understand, and manage this syndrome.

CLINICAL MANIFESTATIONS

APAs prolong coagulation in in vitro assays but are not generally associated with clinical bleeding. Rarely, clinical bleeding may occur when APA interacts with factor II (prothrombin), producing an acquired prothrombin (factor II) deficiency associated with accelerated clearance of LA-prothrombin complexes from the circulation. Bleeding tendencies also may arise when LA targets platelet membranes and produces quantitative and/or qualitative platelet abnormalities. Other clinical findings in APS include livedo reticularis (Chapter 80), valvular heart lesions, and nephropathy. Clinically, although both arterial and venous thrombosis (Chapter 176) may occur in APS, the most relevant is venous thrombosis and stroke in young adults. A diagnostic work-up in those with arterial thrombosis should include transesophageal echocardiography to exclude a cardiac source for arterial clots. In obstetric patients, other causes of miscarriage should be excluded. A case-control study has indicated that a history of recurrent spontaneous abortion associated with antiphospholipid syndrome is a risk factor for subsequent venous thromboembolism in the long term.[16] Nonpregnant individuals with APS-associated thrombotic manifestations have a 50% risk for experiencing recurrent events over a 5-year period. Typically, recurrent thrombotic and vascular episodes occur in a pattern consistent with the initial findings (e.g., venous recurrence following an initial deep vein thrombosis).

DIAGNOSIS

By international consensus, a diagnosis of APS is based on both clinical and laboratory criteria.[17] Clinical criteria include (1) arterial, venous, or small vessel thrombosis in any tissue or organ and (2) pregnancy morbidity. The latter includes one or more pregnancy losses before 10 weeks' gestation; one or more pregnancy losses before 34 weeks due to eclampsia, preeclampsia, or placental insufficiency; or three or more spontaneous abortions before 10 weeks. APS may be suspected in the setting of recurrent spontaneous miscarriages or pregnancy-related thromboembolic events; with the detection of cerebral arterial thromboses in young adults; in those with systemic lupus erythematosus (20 to 40%; Chapter 266) or other autoimmune diseases or lymphoproliferative malignancies; in those receiving psychotropic medications (e.g., chlorpromazine); or when incidental coagulation assays reveal aPTT prolongation.

Laboratory criteria[18] include one or more high-titer APAs (LA, CL, anti-β2-GPI) on at least two occasions at least 12 weeks apart. APAs can be detected by three assays: the LA assay, the CL ELISA assay, and the β2-GPI ELISA assay. The LA assay includes a screening test, based on a prolonged phospholipid-dependent clotting time; a mixing test that distinguishes the inhibitor (fails to correct in a 1 : 1 mix) from a deficiency state (corrects in a 1 : 1 mix); and a confirmatory test based on platelet neutralization to demonstrate that the inhibitor is phospholipid dependent (clotting time corrects) or a modified aPTT reagent based on the binding of hexagonal phase phospholipids to LA. The CL ELISA measures antibodies in dilute sera that bind to CL-coated plates, including those that bind to CL alone or bind to bovine β2-GPI and both IgG and IgM, but it may miss CL bound to human β2-GPI. The β2-GPI ELISA detects antibodies that bind to β2-GPI–coated irradiated plates, but it has reduced specificity owing to binding by nonpathogenic antibodies. Positivity in multiple assays is strongly associated with thrombosis and miscarriage: the risk for first thrombosis among asymptomatic individuals positive for LA, CL, and β2-GPI antibodies, so-called triple-positive patients, is 5.3% per year. Of the three assays, the β2-GPI ELISA is most strongly associated with thrombosis and early recurrent miscarriage; the LA assay is associated with venous thrombosis, stroke, and late miscarriage. The greatest weight is given to a positive LA test. From a practical standpoint, testing for all three antibodies at diagnosis is recommended to guide follow-up because oral anticoagulants may interfere with the LA test.

TREATMENT Rx

Because of the high risk for recurrent thromboembolism, patients with APS should receive antithrombotic therapy. The approach is based on achieving a balance between thrombosis risk and bleeding complications, especially in those with thrombocytopenia. Because of the limited information from randomized clinical trials, the recommendations for APS are similar to those for patients without APS—that is, to use unfractionated heparin or low-molecular-weight heparin (LMWH), with a 4- to 5-day overlap with warfarin, for acute venous thromboembolism (VTE), followed by long-term warfarin to a target international normalized ratio (INR) of 2.0 to 3.0. This recommendation is based on a randomized trial indicating no difference in bleeding rates with high-intensity (INR >3.0) versus low-intensity (INR 2.0 to 3.0) anticoagulation. In individuals with thrombocytopenia, more frequent monitoring of the INR may be warranted to avoid bleeding complications. The duration of anticoagulation in those both with and without APS is based on a balance between VTE recurrence and bleeding.

For women with APS and pregnancy loss but no past thrombosis, the goal is to prevent recurrent pregnancy loss. Based on prospective studies indicating higher birth rates with aspirin plus heparin, recommendations include low-dose aspirin (81 mg) in combination with prophylactic heparin or LMWH in the antepartum period.

Among those with APS-associated thrombocytopenia and a platelet count below 20 to 30 $\times 10^9$/L, in the setting of bleeding or when bleeding potential exceeds the risk for bleeding with VTE treatment, management is similar to

that for idiopathic thrombocytopenic purpura (Chapter 172). This includes steroids, intravenous immunoglobulin, and immunosuppressive agents (e.g., cyclophosphamide, azathioprine, off-label rituximab). Case reports indicate that danazol, dapsone, aspirin, and chloroquine may be helpful adjuncts. In pregnant women with APS-associated thrombocytopenia, treatment is advised before epidural anesthesia or cesarean delivery. In the latter case, early delivery under cover of intravenous immunoglobulin is recommended.

Treatment of APS-associated bleeding is dependent on the site and severity of bleeding. For anticoagulation bleeding, the anticoagulant should be withheld and an antidote (e.g., protamine) given, if available. For thrombocytopenia bleeding, platelet transfusions should be given, along with red blood cell transfusions, if necessary. If both thrombosis and bleeding occur, treatment should be directed at the component that is most life threatening. In those with a high bleeding risk, anticoagulants should be withheld or given at a lower dosage; those with a high thrombotic risk, despite thrombocytopenia, should be anticoagulated and given agents to boost platelet count simultaneously. For those who receive prolonged heparin, supplemental calcium and vitamin D should be administered to minimize the risks for osteoporosis.

In the life-threatening multisystem complication of catastrophic antiphospholipid syndrome, which is characterized by histopathologic evidence of small vessel thrombosis and dysfunction of multiple organs (e.g., lung, brain, heart, kidneys, skin, and/or gastrointestinal tract) over a short period of time, maximal anticoagulation, plasma exchange, and immunosuppressive therapy have been used. A recent report showed that eculizumab, an inhibitor of terminal complement, was effective in a patient with recurrent catastrophic antiphospholipid syndrome.[19]

REVIEW QUESTIONS

1. A 7-month-old boy with severe hemophilia A, who is receiving daily postoperative factor replacement for major surgery 10 days ago, has developed several large painful hematomas over his extremities. Despite factor replacement, his hematomas have not improved. Which of the following approaches is most appropriate for this child?

A. Draw trough factor VIII (before next dose), activated partial thromboplastin time (aPTT) mix, and anti–factor VIII.
B. Draw peak factor VIII (after the next dose), aPTT mix, and anti–factor VIII.
C. Draw aPTT, aPTT mix, and anti–factor VIII.
D. Draw random factor VIII.
E. Dose with 100% factor VIII and apply ice to hematomas.

Answer: B This child likely has developed an inhibitor because there was long duration factor early in life, and despite ongoing factor treatment, hematoma formation has occurred, indicating lack of response. To determine whether an inhibitor is present, the simplest approach is to draw a factor VIII level just after a 100% dose (i.e., peak); in the case of an inhibitor, the factor VIII level will be neutralized and lower than expected. A random factor VIII could also be drawn, but because children have a large volume of distribution, it is not as helpful as a peak factor VIII. Prolongation of both the aPTT and aPTT mix confirms the presence of an inhibitor, and the anti–factor VIII quantitates how high it is in Bethesda units. Given that the hematomas occurred while on treatment, it is unlikely that increasing the dose will improve the hematomas. Ice is a good approach, but determining whether the inhibitor is present is the most pressing need because, if present, a bypass agent may be needed, that is, recombinant factor VIIa (rFVIIa) or prothrombin complex concentrate (PCC).

2. A 26-year-old woman who is 20 weeks pregnant is referred for management recommendations at delivery. She has had menorrhagia in the past and oozing with dental extractions. A maternal uncle has hemarthroses. What is the most appropriate next step in the evaluation of this patient?

A. Screen for von Willebrand disease.
B. Screen for hemophilia carrier status and von Willebrand disease.
C. Screening is not helpful because von Willebrand factor (VWF) and factor VIII increase during pregnancy.
D. Obtain VWF and factor VIII in the 8th month of pregnancy.
E. Plan DDAVP (desmopressin) for delivery and neuranesthesia.

Answer: D This woman may have a congenital bleeding disorder, with both a personal and a family bleeding history. Menorrhagia is a common symptom of von Willebrand disease, but it could also indicate hemophilia A or B carrier status. The history of a hemarthrosis (bleeding in a joint) in her uncle suggests he may have the X-linked congenital bleeding disorder, hemophilia, either A or B, and if inherited, gives her a 50-50 chance of being a carrier. Hemarthrosis is uncommon in other bleeding disorders but may occur in severe type 3 von Willebrand disease. Testing for von Willebrand disease or hemophilia carrier status is complicated by the well-known increase in VWF and factor VIII (but not factor IX) during pregnancy, potentially masking diagnosis of VWD or hemophilia carrier, but it is critical to screen VWF, factor VIII, and factor IX at the 8th month of pregnancy to plan for peripartum and neuranesthesia management. DDAVP is contraindicated at delivery because of major fluid loss and intravenous replacement, which could precipitate hyponatremia and seizures; VWF concentrate is the drug of choice for VWD, and recombinant factor VIII or IX is indicated for symptomatic factor VIII (or IX) for carriers.

3. A 47-year-old woman weighing 150 kg with factor VII deficiency is planning to undergo gastric bypass surgery. She is referred to you for hemostatic management of her surgery. What is the most appropriate management for her surgery?

A. Fresh-frozen plasma (FFP) 15-20 U/kg before and for up to 1-2 days postoperatively
B. PCC 50 IU/kg before and every 6 hours for 2 days postoperatively
C. PCC 25 IU/kg before and every 6 hours for 2 days postoperatively
D. Recombinant VIIa 90 μg/kg before and every 3-4 hours for 2 days postoperatively
E. Recombinant VIIa 15 μg/kg before and on day 1 and 2 postoperatively

Answer: E The current treatment for congenital factor VII deficiency is low-dose factor VIIa: for surgery, it is given preoperatively and for several days postoperatively. After the tissue factor VIIa–triggered extrinsic coagulation pathway is activated, several days of treatment are usually sufficient to maintain the clot. Because obesity and surgery are both associated with risk for thromboembolism, the patient should be mobilized early in the postoperative course. FFP and PCC are alternative treatments, but levels of VII are low in FFP and in three-factor PCC, and the latter may increase thrombosis risk. rFVIIa in this patient would be less likely to increase thrombosis risk, given the patient's congenital deficiency (associated with lack of thrombin burst).

4. A 17-year-old high school senior with congenital factor XI deficiency is referred for management of his upcoming wisdom teeth extraction. His family history is negative for bleeding, and the patient has no bleeding history but has not had surgery. What is the most appropriate surgical management for this patient?

A. FFP 15-20 U/kg preoperatively
B. Amicar 50 mg/kg PO every 6 hours preoperatively
C. DDAVP 0.3 μg/kg IV over 30 minutes preoperatively, and days 1 and 2 postoperatively
D. Stimate 300 μg by nasal spray, given as 150 μg in each nostril preoperatively
E. No preoperative treatment, but FFP 14-20 U/kg for postoperative bleeding

Answer: E At least half of those with factor XI deficiency have no personal or family history of bleeding, even with factor XI levels below 1%. Bleeding tendency is consistent within families. In the absence of family history, no treatment is given preoperatively, but if postoperative bleeding occurs, FFP is recommended. In Europe, a factor XI concentrate is available, but it not approved in the United States. Although Amicar, DDAVP, and Stimate may provide hemostasis, they are not specific for factor XI deficiency. For mucosal bleeding postoperatively, Amicar is a reasonable alternative.

5. A 50-year-old man with the lupus anticoagulant test (LAC) and positive β2-glycoprotein I (β2-GPI) antibody, as well as a recent lower extremity deep vein thrombosis, comes for a second opinion regarding need for long-term anticoagulation. In 2 weeks, he will complete a 6-month course of Coumadin 7.5 mg alternating with 5 mg to maintain an international normalized ratio (INR) of 2 to 3. What is the optimal management of this patient?

A. Coumadin to maintain INR of 2.0 to 3.0 as long as benefits outweigh risks
B. Coumadin to maintain INR of 2.0 to 3.0 plus low-dose acetylsalicylic acid (ASA; 81 mg) as long as benefits outweigh risks
C. Coumadin to maintain INR of >3.0 as long as benefits outweigh risks
D. Coumadin to maintain INR of >3.0 plus low-dose ASA (81 mg) as long as benefits outweigh risks.
E. Stop Coumadin after 6 months, with careful monitoring for venous thromboembolism (VTE) recurrence.

Answer: A The occurrence of β2-GPI antibody and LAC with deep vein thrombosis is consistent with the antiphospholipid syndrome (APS). Individuals with APS are at increased risk for recurrent VTE, and thus anticoagulation should be continued as long as the benefits of anticoagulation outweigh bleeding risk. Several studies have demonstrated that standard Coumadin to an INR of 2.0 to 3.0 is adequate VTE prophylaxis for individuals with APS, with no added benefit to maintain INR above 3 for patients with antiphospholipid syndrome. ASA, other than in the setting of pregnancy, appears to provide no added benefit in clot protection in individuals with APS.

HEMORRHAGIC DISORDERS: DISSEMINATED INTRAVASCULAR COAGULATION, LIVER FAILURE, AND VITAMIN K DEFICIENCY

ANDREW I. SCHAFER

DISSEMINATED INTRAVASCULAR COAGULATION

DEFINITION

Disseminated intravascular coagulation (DIC), also referred to as consumptive coagulopathy or defibrination, is caused by a wide variety of serious disorders (Table 175-1). In most patients, the underlying process dominates the clinical picture, but in some cases (e.g., occult malignant neoplasm, envenomation), DIC may be the initial or predominant manifestation of the disorder. DIC never occurs in isolation, without an inciting cause.

TABLE 175-1 MAJOR CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

INFECTIONS
Gram-negative bacterial sepsis
Other bacteria, fungi, viruses, Rocky Mountain spotted fever, malaria
IMMUNOLOGIC REACTIONS
Transfusion reactions (ABO incompatibility)
Transplant rejection
OBSTETRIC COMPLICATIONS
Amniotic fluid embolism
Retained dead fetus
Abruptio placentae
Toxemia, preeclampsia
Septic abortion
MALIGNANT NEOPLASMS
Pancreatic carcinoma
Adenocarcinomas
Acute promyelocytic leukemia
Other neoplasms
LIVER FAILURE
ACUTE PANCREATITIS
ENVENOMATION
RESPIRATORY DISTRESS SYNDROME
TRAUMA, SHOCK
Brain injury
Crush injury
Burns
Hypothermia or hyperthermia
Fat embolism
Hypoxia, ischemia
Surgery
VASCULAR DISORDERS
Giant hemangioma (Kasabach-Merritt syndrome)
Aortic aneurysm
Vascular tumors

PATHOBIOLOGY

DIC is pathophysiologically a thrombotic process. However, its clinical manifestation may be widespread hemorrhage in acute cases. The basic pathophysiologic mechanism (Fig. 175-1), regardless of cause, is entry into the circulation of procoagulant substances that trigger systemic activation of the coagulation system and platelets. This results in disseminated deposition of fibrin-platelet thrombi within the microvasculature.[1] In most cases, the procoagulant stimulus is tissue factor, a lipoprotein that is not normally exposed to blood. In DIC, tissue factor gains access to blood by tissue injury, its elaboration by malignant cells, or its expression on the surface of monocytes and endothelial cells by inflammatory mediators. Components of the inflammatory response and the coagulation system are reciprocally activated in some forms of DIC, such as sepsis. Tissue factor triggers generation of the coagulation protease thrombin, which induces fibrin formation and platelet activation. In some specific cases of DIC, procoagulants other than tissue factor (e.g., a cysteine protease or mucin in certain malignant neoplasms) and proteases other than thrombin (e.g., trypsin in pancreatitis, exogenous enzymes in envenomation) provide the procoagulant stimulus.

In acute, uncompensated DIC, coagulation factors are consumed at a rate in excess of the capacity of the liver to synthesize them, and platelets are consumed in excess of the capacity of bone marrow megakaryocytes to release them. The resulting laboratory manifestations under these circumstances are a prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT) and thrombocytopenia. Increased fibrin formation in DIC stimulates a heightened process of secondary fibrinolysis, in which plasminogen activators generate plasmin to digest fibrin (and fibrinogen) into fibrin(ogen) degradation products (FDPs). FDPs are potent circulating anticoagulants that further contribute to the bleeding manifestations of DIC. Intravascular fibrin deposition can cause fragmentation of red blood cells and lead to the appearance of schistocytes in blood smears; however, frank microangiopathic hemolytic anemia is unusual in DIC. Occlusive microvascular thrombosis in DIC can compromise the blood supply to some organs and

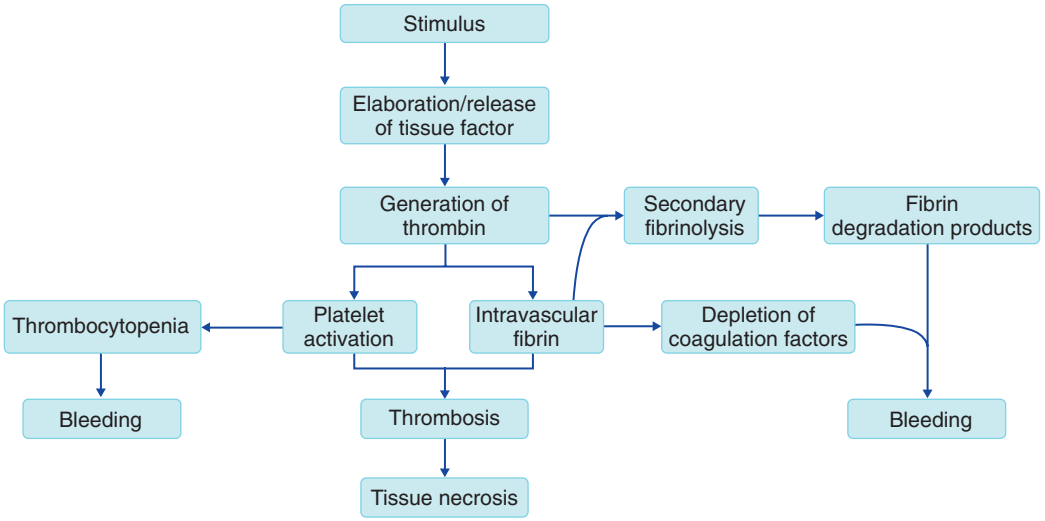

FIGURE 175-1. **Pathophysiologic process of bleeding, thrombosis, and ischemic manifestations in patients with disseminated intravascular coagulation.**

lead to multiorgan failure, particularly when it is accompanied by systemic hemodynamic and metabolic derangements.

Underlying Causes

DIC always has an underlying cause that generally must be identified and eliminated if the coagulopathy is to be managed successfully. The development of DIC in many of these disorders is associated with an unfavorable outcome. Infection is the most common cause of DIC. The syndrome is particularly associated with gram-negative or gram-positive sepsis (Chapter 108), although it can be triggered by a variety of other bacterial, fungal, viral, rickettsial, and protozoal microorganisms.

The placenta and uterine contents are rich sources of tissue factor and other procoagulants that are normally excluded from the maternal circulation; a spectrum of clinical manifestations of DIC may accompany obstetric complications when this barrier is breached, especially in the third trimester. These syndromes range from acute, fulminant, and often fatal DIC in amniotic fluid embolism to chronic or subacute DIC with a retained dead fetus. Other obstetric problems associated with DIC include abruptio placentae, toxemia, and septic abortion.

Chronic forms of DIC are caused by a variety of malignant neoplasms, particularly pancreatic cancer (Chapter 194) and mucin-secreting adenocarcinomas of the gastrointestinal tract (Chapter 193), in which thrombotic rather than bleeding manifestations predominate. Treatment with all-*trans*-retinoic acid has greatly reduced the incidence of severe DIC in patients with acute promyelocytic leukemia (Chapter 183). It is not known whether liver failure (see later) can cause DIC or whether its coexistence merely exacerbates intravascular coagulation because of impaired clearance of activated clotting factors, plasmin, and FDPs. Snake venom contains a variety of substances that can affect coagulation and endothelial permeability. Bites from rattlesnakes and other vipers can induce profound DIC by introduction of these exogenous toxins and release of endogenous tissue factor through tissue necrosis.

The likelihood and degree of DIC caused by trauma, surgery, and shock (Chapter 106) are related to the extent of tissue damage and the organs involved. The brain is a particularly rich source of tissue factor, so traumatic brain injury (Chapter 399) can precipitate acute DIC. Large aortic aneurysms (Chapter 78), giant hemangiomas, and other vascular malformations can cause subclinical or clinical DIC that is initiated locally within the abnormal vasculature but can "spill" into the systemic circulation.

CLINICAL MANIFESTATIONS

The clinical manifestations of DIC are determined by the nature, intensity, and duration of the underlying stimulus. The coexistence of liver disease exacerbates DIC of any cause. Low-grade DIC is often asymptomatic and diagnosed only by laboratory abnormalities. Thrombotic complications of DIC occur most often with chronic underlying diseases, as exemplified by Trousseau's syndrome in cancer (Chapter 176). DIC can be manifested as acrocyanosis and gangrene of the digits in critically ill, hemodynamically compromised patients receiving vasopressors. Hemorrhagic necrosis of the skin (Fig. 175-2) and purpura fulminans may also be manifestations of DIC.

FIGURE 175-2. **Disseminated intravascular coagulation resulting from staphylococcal septicemia.** Note the characteristic skin hemorrhage ranging from small purpuric lesions to larger ecchymoses. (From Forbes CD, Jackson WF. Color Atlas and Text of Clinical Medicine. 3rd ed. London: Mosby; 2003.)

Bleeding is the most common clinical finding in acute, uncompensated DIC. Bleeding can be limited to sites of intervention or anatomic abnormalities, but it tends to be generalized in more severe cases, including widespread ecchymoses and diffuse oozing from mucosal surfaces and orifices.

DIAGNOSIS

The laboratory diagnosis of severe, acute DIC is not usually difficult. Consumption and inhibition of the function of clotting factors cause prolongation of the PT, aPTT, and thrombin time. Consumption of platelets causes thrombocytopenia. Secondary fibrinolysis generates increased titers of FDPs, which can be measured by latex agglutination or D-dimer assays. Some schistocytes may be seen in the peripheral blood smear, but this finding is neither sensitive nor specific for DIC. Chronic or compensated forms of DIC are more difficult to diagnose, with highly variable patterns of abnormalities in "DIC screen" coagulation tests.[2,3] Increased D-dimers and a prolonged PT are generally more sensitive measures than are abnormalities of the aPTT and platelet count. Overcompensated synthesis of consumed clotting factors and platelets in some chronic forms of DIC may actually cause shortening of the PT and aPTT or thrombocytosis (or both), even though elevated levels of D-dimers indicate secondary fibrinolysis in such cases.

The most difficult differential diagnosis of DIC occurs in patients who have coexisting liver disease. The coagulopathy of liver failure (see later section on liver failure) is often indistinguishable from that of DIC, partly because advanced hepatic dysfunction is in fact accompanied by a state of DIC. In liver failure, the combination of decreased synthesis of clotting factors, impaired clearance of activated clotting factors, secondary fibrinolysis, and thrombocytopenia from portal hypertension and hypersplenism may make the coagulopathy virtually impossible to differentiate from DIC. Thrombotic microangiopathies including thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome, the syndrome of "hemolysis, elevated liver enzymes, and low platelet count" (HELLP) in obstetric patients,[4] and other

forms of platelet consumption and thrombocytopenia (Chapter 172) are not accompanied by activation of clotting factors or secondary fibrinolysis; therefore, the PT, aPTT, thrombin time, and D-dimers are generally normal in these disorders. Schistocytes, often with frank hemolysis, are much more prominent in the peripheral smear in thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (Chapter 172) than in DIC.

Primary hyperfibrinolysis is disputed as a distinct entity.[5] Some patients with a serious clinical bleeding diathesis, however, have laboratory evidence of predominantly fibrinolysis, including high levels of FDPs (D-dimers) and severe hypofibrinogenemia, with relatively little consumption of coagulation factors and normal or nearly normal platelet counts. These unusual findings, which approximate the findings expected with fibrinolytic therapy, are encountered occasionally, particularly in patients with prostate cancer.

TREATMENT

Successful treatment of DIC (Table 175-2) requires that the underlying cause be identified and eliminated. All other therapies, including hemodynamic support, replacement of coagulation factors and platelets, and pharmacologic inhibitors of coagulation and fibrinolysis, are just temporizing measures. Because of the difficulty of testing this complex syndrome with multiple causes by controlled, randomized clinical trials, current guidelines for treatment are generally not based on high-grade evidence.[6]

In many patients with asymptomatic, self-limited DIC who have only laboratory manifestations of the coagulopathy, no treatment may be necessary. In patients with DIC who are actively bleeding or who are at high risk for bleeding, the blood component treatments of choice are transfusions of platelets to improve the thrombocytopenia and fresh-frozen plasma to replace all consumed coagulation factors and to correct the prolonged PT and aPTT. Large volumes of plasma (e.g., >6 U/24 hours) may be required to ameliorate bleeding in severe cases. In some patients who have particularly profound hypofibrinogenemia, the additional transfusion of cryoprecipitate, a plasma concentrate that is enriched in fibrinogen, may be useful. The theoretical concern that these blood products could "fuel the fire" and exacerbate the DIC has not been supported by clinical experience.

The use of pharmacologic inhibitors of coagulation and fibrinolysis in DIC is controversial. Heparin is of theoretical benefit because it blocks thrombin activity and quenches intravascular coagulation and the resultant secondary fibrinolysis. In practice, heparin might exacerbate the bleeding tendency in acute DIC. Heparin is usually reserved for special forms of DIC, including those manifested by thrombosis or acrocyanosis and forms that accompany cancer, vascular malformations, retained dead fetus, and possibly acute promyelocytic leukemia, in which active bleeding is not present. In cases of DIC in which thrombosis or acral ischemia predominates, unfractionated heparin should be used by continuous infusion because of its short half-life and reversibility in the event of increased bleeding. Monitoring of the aPTT in the presence of DIC may be problematic, so heparin infusion in this setting should be followed mainly by clinical response and improvement in results of other tests of coagulation (e.g., thrombocytopenia). Antifibrinolytic agents, including ε-aminocaproic acid and tranexamic acid, are generally contraindicated in DIC. By blocking the secondary fibrinolytic response to DIC, these drugs cause unopposed fibrin deposition and may precipitate thrombosis. Antifibrinolytic agents may be effective in decreasing life-threatening bleeding in DIC, however, particularly in extreme cases in which aggressive blood component replacement fails to control the hemorrhage; in such situations, simultaneous infusion of low doses of heparin may reduce the risk for thrombosis. Bleeding and DIC laboratory parameters may also be improved with recombinant activated factor VII (rFVIIa) in patients whose bleeding is not controlled by standard measures.

TABLE 175-2 TREATMENT OF DISSEMINATED INTRAVASCULAR COAGULATION

Identify and eliminate the underlying cause
No treatment if mild, asymptomatic, and self-limited
Hemodynamic support, as indicated, in severe cases
Blood component therapy
Indications: active bleeding or high risk for bleeding
Fresh-frozen plasma
Platelets
In some cases, consider cryoprecipitate, antithrombin III
Drug therapy
Indications: heparin for DIC manifested by thrombosis or acrocyanosis and without active bleeding; antifibrinolytic agents are generally contraindicated except with life-threatening bleeding and failure of blood component therapy

DIC = disseminated intravascular coagulation.

Recombinant human activated protein C (rhAPC) was approved in 2001 for use in severe sepsis or septic shock, which is often accompanied by DIC. The mechanisms by which rhAPC is thought to modify disease course are through its actions on dysregulated coagulation and subsequent microvascular thrombosis as well as by its possible anti-inflammatory effects. However, subsequent trials failed to confirm the mortality reduction benefit of rhAPC in patients with septic shock or any of its prescribed subgroups or in groups that were less acutely ill, with lower risk of death from sepsis (Acute Physiology and Chronic Health Evaluation or APACHE II scores <25 or single-organ failure), and with extended infusions or in pediatric patients. Therefore, rhAPC was withdrawn by its manufacturer in 2011. Nevertheless, controversy has persisted with the subsequent publication of favorable meta-analyses and observational trials.[7] Although recombinant tissue factor pathway inhibitor, antithrombin III concentrates, and human soluble thrombomodulin may have some efficacy in improving laboratory parameters of DIC, the overall survival benefit with these agents in patients with DIC has not been demonstrated.

LIVER FAILURE

Bleeding complications in patients with advanced liver disease (Chapters 153 and 154) can be severe and even fatal and directly account for about 20% of the deaths associated with hepatic failure. The extent of the bleeding tendency depends on the severity and type of liver disease involved. About one third of deaths in patients undergoing liver transplantation are attributable to perioperative hemorrhage.

PATHOBIOLOGY

The pathophysiologic mechanism of bleeding in liver failure is complex and multifactorial.[8] Anatomic abnormalities resulting from portal hypertension are frequently the major cause of gastrointestinal bleeding in patients with liver disease. Upper gastrointestinal bleeding can be caused by esophageal varices or hemorrhagic gastritis (congestive gastropathy), whereas lower gastrointestinal bleeding, although seldom life-threatening, can be due to hemorrhoids.

The complexity of the systemic coagulopathy of liver failure is not surprising inasmuch as the liver is the principal organ site for the synthesis of coagulation and fibrinolytic factors as well as their protein inhibitors (Table 175-3). Therefore, the impaired hemostasis of liver failure is accompanied by opposing prothrombotic alterations. Hepatocytes produce all of the clotting factors except von Willebrand factor, and advanced parenchymal liver disease results in impaired synthesis of these proteins. Liver disease can also cause impairment in vitamin K–dependent γ-carboxylation of the procoagulant factors II, VII, IX, and X as well as the anticoagulant proteins C and S. Functional abnormalities of fibrinogen, termed dysfibrinogenemias, are frequently found in various forms of liver disease, particularly in hepatocellular carcinoma. Most forms of advanced liver disease are accompanied by some degree of DIC caused by impaired synthesis of inhibitors of blood coagulation and defective hepatocellular clearance of activated coagulation factors. DIC and bleeding risk are exacerbated by the enhanced fibrinolytic activity (hyperfibrinolysis) of liver disease caused by increased levels of tissue plasminogen activator accompanied by decreased synthesis of inhibitors of plasminogen activator and plasmin.

Quantitative and qualitative abnormalities of platelets also contribute to the bleeding diathesis of liver failure. Congestive splenomegaly secondary to portal hypertension causes increased pooling of platelets in the spleen (hypersplenism). The resultant thrombocytopenia, the degree of which generally correlates with spleen size, rarely causes a reduction in the platelet count to less than 30,000/mm^3. In alcoholic patients, suppression of bone marrow thrombopoiesis by the acute toxic effects of alcohol or folate deficiency may contribute to the thrombocytopenia. Qualitative platelet abnormalities have also been described in patients with liver disease.

Liver transplantation (Chapter 154) poses special problems to the coagulation system. During the anhepatic stage of surgery, which lasts about 2 hours, the complete cessation of synthesis of coagulation factors causes further prolongation of the PT and aPTT. Release of tissue plasminogen activator from the newly grafted liver leads to increased fibrinolysis and transient exacerbation of bleeding risk in the postoperative period.

CLINICAL MANIFESTATIONS

The most common hemorrhagic complication of liver disease is gastrointestinal bleeding, which is usually caused by anatomic abnormalities and exacerbated by the systemic coagulopathy of liver failure. Bleeding from other

TABLE 175-3 COAGULATION ABNORMALITIES IN LIVER DISEASE

ABNORMALITIES IN COAGULATION
Decreased synthesis of coagulation factors
Impaired vitamin K–dependent γ-carboxylation
Dysfibrinogenemia
Disseminated intravascular coagulation
Increased fibrinolytic activity
ABNORMALITIES IN PLATELETS
Thrombocytopenia (hypersplenism)
Abnormal platelet function

mucosal sites, extensive ecchymoses, or more serious hemorrhage into the retroperitoneum or central nervous system generally indicates more significant derangements of the coagulation system.

The severe coagulopathy in patients with liver disease makes liver biopsy a potentially hazardous procedure. The PT and platelet count may be the best guides to bleeding risk, but they too lack reliability as predictors of risk of bleeding with liver biopsy. In general, liver biopsy can be performed safely if the PT and aPTT do not exceed 1.5 times control values and the platelet count is higher than 50,000/mm^3. The American Association for the Study of Liver Diseases has concluded that the bleeding risk-benefit ratio of liver biopsy must be carefully considered on a case-by-case basis.[9]

DIAGNOSIS

Although the PT and aPTT are often prolonged in patients with advanced liver disease, the PT tends to be a more sensitive assay early in the course; a disproportionate prolongation of the aPTT should raise suspicion of a coexisting coagulation abnormality, such as a lupus anticoagulant or clotting factor inhibitor. A prolonged PT is also a useful prognostic indicator of poor outcome in patients with cirrhosis, acute acetaminophen hepatotoxicity, and acute viral hepatitis; in acute viral hepatitis, it is a better index of prognosis than are serum albumin and transaminases. A disproportionate prolongation of the thrombin time should suggest the presence of dysfibrinogenemia. Hypersplenism (Chapter 168), possibly associated with nutritional folate deficiency or the acute toxic effects of alcohol on bone marrow, often causes mild to moderate thrombocytopenia in patients with liver disease; however, consideration should be given to other coexisting causes of thrombocytopenia if the platelet count is significantly less than 30,000/mm^3.

The coagulopathy of liver failure is often indistinguishable from that of DIC, in part because some degree of DIC is in fact a necessary accompaniment of advanced liver disease. In general, patients with DIC have more marked decreases in levels of factor VIII and increases in D-dimer than do patients with liver failure. The simplistic notion that a prolonged PT (and sometimes also aPTT) as well as a thrombocytopenia creates a state of natural "auto-anticoagulation" in patients with liver failure ignores the complex pathophysiologic mechanism of the coagulopathy in this setting, which involves a delicate balance of not only antihemostatic abnormalities (leading to a bleeding tendency) but also prohemostatic abnormalities (leading to a simultaneous thrombotic tendency).[10] In fact, the risk of venous thromboembolism is two-fold higher in patients with liver failure than in controls, even in the presence of a prolonged international normalized ratio. The thrombotic risk is not just a localized one, involving portal vein and other abdominal venous thrombosis, but also a systemic one, involving lower extremity deep venous thrombosis and pulmonary embolism.

TREATMENT

Rx

Therapy for the coagulopathy of liver disease may be directed at preventing the hemorrhagic complications of invasive procedures or treating active bleeding. The most effective treatment is blood component therapy with fresh-frozen plasma (which contains all the coagulation factors) and platelet transfusions (Chapter 177). Some patients require large volumes of fresh-frozen plasma (15 to 20 mL/kg) to lower the prolonged PT; rarely, plasmapheresis with plasma exchange is required to avoid fluid overload in these situations. Because of the short half-lives of some clotting factors, fresh-frozen plasma may have to be administered every 8 to 12 hours to maintain acceptable coagulation test parameters. In some patients, especially those with cholestasis, parenteral administration of vitamin K can at least partially reverse the coagulation abnormalities; however, in patients with advanced hepatocellular failure, vitamin K is largely ineffective. Prothrombin complex concentrates are relatively contraindicated in patients with liver failure, as in those with DIC, because of the risk of thrombotic complications. Because of immediate pooling of transfused platelets in the enlarged spleen of patients with hypersplenism, a higher than calculated dose of platelet concentrates is usually required to increase circulating platelet counts significantly. The oral thrombopoietin receptor agonist eltrombopag (25 to 100 mg daily) has been shown to increase platelet numbers in thrombocytopenic patients with hepatitis C virus infection complicated by advanced fibrosis and cirrhosis, allowing otherwise ineligible patients to use antiviral therapy, leading to increases in sustained virologic responses.[A2]

A Cochrane database meta-analysis of randomized clinical trials of recombinant human activated factor VII (rFVIIa) found no evidence to support or to reject its administration to patients with liver disease and upper gastrointestinal bleeding.[A3] Routine use of rFVIIa for the coagulopathy of liver disease cannot be recommended at this time. Desmopressin (DDAVP), which can shorten the bleeding time of patients with cirrhosis, may be considered as ancillary therapy in patients undergoing invasive procedures.

VITAMIN K DEFICIENCY

Vitamin K is required for γ-carboxylation of glutamic acid residues of the procoagulant factors II (prothrombin), VII, IX, and X and the anticoagulant factors protein C and protein S. This post-translational modification normally renders these proteins functionally active in coagulation. The PT is more sensitive than the aPTT in detecting vitamin K deficiency states because factor VII, the only vitamin K–dependent factor that is in the extrinsic pathway of coagulation, is the most labile of these proteins.

The two major sources of vitamin K are dietary intake and synthesis by the bacterial flora of the intestine. In the absence of malabsorption, nutritional deficiency alone rarely causes clinically significant vitamin K deficiency. The condition can arise, however, when eradication of gut flora is combined with inadequate dietary intake. This situation typically occurs in critically ill patients in intensive care units who have no oral intake and are receiving broad-spectrum antibiotics for prolonged periods. Vitamin K deficiency can also develop in patients receiving total parenteral nutrition unless the infusions are supplemented with vitamin K.

Vitamin K is absorbed predominantly in the ileum and requires the presence of bile salts. Clinically significant vitamin K deficiency occurs with malabsorption of fat-soluble vitamins secondary to obstructive jaundice (Chapter 155) or with malabsorption caused by intrinsic small bowel diseases, including celiac sprue, short-bowel syndrome, and inflammatory bowel disease (Chapters 140 and 141).

Warfarin (Chapter 38) acts as an anticoagulant by competitive antagonism of vitamin K. Rare cases of hereditary deficiency of the vitamin K–dependent coagulation factors may cause a lifelong bleeding tendency.

Correction of vitamin K deficiency, when it is clinically significant, can be achieved with oral supplementation, unless malabsorption is present, in which case parenteral vitamin K (10 mg subcutaneously daily) should be administered. Emergency treatment of bleeding caused by vitamin K deficiency is transfusion of fresh-frozen plasma.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding disseminated intravascular coagulation (DIC)?

A. There is always an underlying cause for DIC.
B. Laboratory screening test results showing normal to increased platelet counts or normal to shortened (not prolonged) prothrombin time (PT) and activated partial thromboplastin time (aPTT) essentially rule out DIC.
C. The primary pathophysiologic mechanism of DIC is bleeding; thrombosis can sometimes occur as a secondary event.
D. Large numbers of schistocytes (fragmented red cells) are characteristic blood smear findings in DIC.
E. The prolongation of PT and aPTT in DIC is a function of depletion of coagulation factors.

Answer: A DIC is a syndrome with many possible causes and never occurs in isolation as a primary event without an underlying cause. The results of laboratory screening tests of DIC (PT, aPTT, platelet count, D-dimers) can be highly variable; in fact, in chronic forms of so-called overcompensated DIC, most commonly due to malignant disease, the PT and aPTT can be actually shortened and the platelet count can even be elevated. The primary pathophysiologic mechanism of DIC, regardless of cause, is activation of the coagulation cascade leading to increased fibrin generation and microvascular fibrin deposition; therefore, DIC is a primarily thrombotic process. The systemic bleeding that is more often seen in acute DIC is due to a combination of depleted ("consumed") coagulation factors and platelets as well as the circulating anticoagulant effect generated by increased levels of D-dimers. Schistocytes (fragmented red cells) are nowhere nearly as prominent in the peripheral smear of a patient with DIC as they are in thrombotic thrombocytopenic purpura. As noted before, the prolongation of PT and aPTT in DIC is caused not just by the depletion of clotting factors ("consumption") but also by the powerful circulating anticoagulant effects of fibrin(ogen) degradation products.

2. Which of the following statements is correct regarding the coagulopathy of liver failure?

A. In considering anticoagulation in a patient with liver failure, it should be taken into account that the already prolonged PT (and sometimes also aPTT) intrinsic to liver failure has already made the patient at least partially "auto-anticoagulated."
B. The degree of decrease in serum albumin is a better prognostic marker than the PT (or international normalized ratio [INR]) in a patient with acute viral hepatitis who has fulminant liver failure.
C. Patients with the coagulopathy of liver failure (prolonged PT and sometimes aPTT, with thrombocytopenia) have a serious bleeding risk but not thromboembolic risk.
D. In general, liver biopsy can be safely performed in a patient with liver failure when the PT and aPTT do not exceed 1.5 times control values and the platelet count is above 50,000.
E. In case of bleeding in a liver failure patient, prothrombin complex concentrates and recombinant human activated factor VII (rFVIIa) are first-line hemostatic agents.

Answer: D The American Association for the Study of Liver Diseases has stated that the bleeding risk-benefit ratio of liver biopsy must be carefully considered on a case-by-case basis. Nevertheless, most experts think that in general, biopsy can be performed without excessive risk of bleeding with the PT and aPTT both being less than 1.5 times control and the platelet count above 50,000. The notion that a patient in liver failure who already has a prolonged PT and thrombocytopenia is auto-anticoagulated is misleading. It ignores the complex pathophysiologic process of the coagulopathy of liver failure, which also involves important prothrombotic abnormalities. Patients with liver failure have a two-fold increase in the risk of venous thromboembolism compared with control individuals, even when the PT (INR) is prolonged. Prothrombin complex concentrates and rVIIa are effective "general" hemostatic agents but carry a risk of thrombosis, especially in liver failure patients, who may have an impaired ability to clear those activated clotting factors. A prolonged PT is a useful prognostic indicator in various forms of liver disease and is actually a better index of prognosis than the serum albumin in acute viral hepatitis.

3. A 62-year-old man with known cirrhosis with portal hypertension and splenomegaly as well as alcoholic cardiomyopathy with poorly controlled heart failure is admitted to the intensive care unit with septic shock secondary to gram-negative sepsis. He is still intubated on hospital day 6. A hematology consultation is requested now because it is noted that his INR (PT) has been progressively rising since admission, from a baseline of 1.2 to 1.9. Which of the following is *not* likely to be contributing to this patient's rising INR?

A. Cirrhosis
B. Splenomegaly with hypersplenism
C. Sepsis
D. Heart failure
E. Vitamin K deficiency

Answer: B Worsening liver function could be contributing to the rising INR in this setting but not the associated portal hypertension, splenomegaly, and hypersplenism. Sepsis could be causing DIC, and worsening right-sided heart failure could be causing passive hepatic congestion, both of which might be likewise contributing. The two major sources of vitamin K are its dietary intake and its synthesis by bacterial flora in the intestine. Both of these sources of vitamin K have been essentially eliminated in this patient because he has not been eating and his gut flora has been largely sterilized with the use of broad-spectrum antibiotics for sepsis; this is a prototypical setting for vitamin K deficiency. (Elimination of only one source of vitamin K, that is, poor nutrition or use of antibiotics, is usually not sufficient to cause clinically significant vitamin K deficiency.)

4. Which of the following is *not* a coagulation abnormality in advanced liver disease?

A. Dysfibrinogenemia
B. Disseminated intravascular coagulation
C. Acquired factor VIII inhibitor
D. Increased fibrinolytic activity
E. Decreased synthesis of coagulation factors

Answer: C The pathophysiologic mechanism of bleeding in liver failure is complex and multifactorial. Impaired liver function reduces the synthesis of all coagulation factors because that organ is the major site of their synthesis. Because the liver is also the major site of clearance of trace amounts of circulating activated clotting factors, liver failure is associated with increased levels of these, leading to essentially a state of DIC. (It is why it is so difficult and sometimes impossible to distinguish the coagulopathy of liver failure from the coagulopathy of DIC; they may in fact often coexist in liver failure.) Enhanced fibrinolytic activity, partly secondary to DIC, is part of the picture in liver disease, as is the development of dysfibrinogenemia (functional abnormality of fibrinogen).

176 THROMBOTIC DISORDERS: HYPERCOAGULABLE STATES

ANDREW I. SCHAFER

The hypercoagulable states, also referred to as thrombophilias, encompass a group of inherited or acquired conditions that are associated with an increased risk for thrombosis.

The primary hypercoagulable states are quantitative or qualitative abnormalities in specific coagulation proteins that induce a prothrombotic state. Most of these disorders involve inherited mutations and polymorphisms that lead to either a deficiency of a physiologic antithrombotic factor (typically associated with a loss-of-function mutation) or an increased level of a prothrombotic factor (typically associated with a gain-of-function mutation) (Table 176-1). Particularly when they are combined with other inherited prothrombotic mutations (multigene interactions), these primary hypercoagulable states are associated with a lifelong predisposition to thrombosis. The secondary hypercoagulable states, a diverse group of mostly acquired conditions, cause a thrombotic tendency by more complex, often multifactorial mechanisms. The trigger for a discrete, clinical thrombotic event is often the development of one of the acquired, secondary hypercoagulable states superimposed on an inherited state of hypercoagulability (Fig. 176-1).

PRIMARY HYPERCOAGULABLE STATES

Antithrombin III Deficiency

EPIDEMIOLOGY AND PATHOBIOLOGY

Inherited quantitative or qualitative deficiency of antithrombin III leads to increased fibrin accumulation and a lifelong propensity to thrombosis (Chapter 171). Antithrombin is the major physiologic inhibitor of thrombin and other activated coagulation factors; therefore, its deficiency leads to unregulated protease activity and fibrin formation.[1]

The frequency of asymptomatic heterozygous antithrombin deficiency in the general population may be 1 in 350. Most of these individuals have clinically silent mutations and never have thrombotic manifestations. The frequency of symptomatic antithrombin deficiency in the general population has been estimated to be between 1 in 2000 and 1 in 3000. Among all patients seen with venous thromboembolism (VTE), antithrombin deficiency is detected in only about 1 to 2%, but it is found in approximately 2.5% of selected patients with recurrent thrombosis or onset of thrombosis at a younger age (<45 years old).

Patients with type I antithrombin deficiency have proportionately reduced plasma levels of antigenic and functional antithrombin that result from a quantitative deficiency of the normal protein. Impaired synthesis, defective secretion, or instability of antithrombin in type I antithrombin-deficient individuals is caused by major gene deletions, single nucleotide changes, or short insertions or deletions in the antithrombin gene. Patients with type II antithrombin deficiency have normal or nearly normal plasma antigen accompanied by low activity levels, indicating a functionally defective molecule. Type II deficiency is usually caused by specific point mutations leading to single amino acid substitutions that produce a dysfunctional protein. More than 250 different mutations causing type I or type II antithrombin deficiency have been recognized to date.

The pattern of inheritance of antithrombin deficiency is autosomal dominant. Most affected individuals are heterozygotes whose antithrombin levels are typically about 40 to 60% of normal. These individuals may have the full clinical manifestations of lifelong hypercoagulability. Rare homozygous antithrombin-deficient patients generally have type II deficiency with reduced heparin affinity, a variant that is associated with a low risk for thrombosis in its heterozygous form; other forms of homozygous antithrombin deficiency are probably incompatible with life.

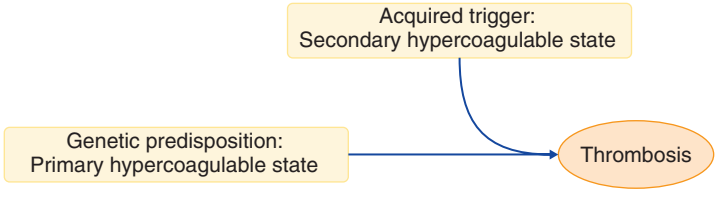

FIGURE 176-1. General scheme of thrombosis pathogenesis. A clinical episode of thrombosis is triggered by an acquired trigger, often one of the secondary hypercoagulable states, superimposed on a genetic predisposition caused by a primary hypercoagulable state. The magnitude of the acquired trigger varies from major (e.g., knee or hip surgery) to minor (e.g., lengthy air travel) to subclinical (not overt and identifiable). Likewise, the magnitude of the lifelong genetic predisposition varies from major (e.g., heterozygous antithrombin III, protein C, or protein S deficiency; homozygous factor V Leiden or prothrombin gene mutation; or two or more primary hypercoagulable states) to minor (e.g., heterozygous factor V Leiden or prothrombin gene mutation).

Protein C Deficiency

Protein C deficiency leads to unregulated fibrin generation because of impaired inactivation of factors VIIIa and Va, two essential cofactors in the coagulation cascade.

EPIDEMIOLOGY

The prevalence of heterozygous protein C deficiency in the general population is about 1 per 200 to 500. Protein C deficiency is found in 2 to 5% of all patients with VTE.

PATHOBIOLOGY

As with antithrombin deficiency, two general forms of protein C deficiency are recognized: type I, in which quantitative deficiency of the protein is associated with a proportionate decrease in protein C antigen and activity; and type II, in which qualitative defects in protein C are associated with disproportionately reduced protein C activity relative to antigen. More than 270 mutations are known to cause protein C deficiency. In the more common type I deficiency, frameshift, nonsense, or missense mutations cause premature termination of synthesis or loss of protein C stability. In type II deficiency, different mutations can cause abnormalities in protein C activation or function. The mode of inheritance of protein C deficiency is autosomal dominant. As in antithrombin deficiency, most affected individuals are heterozygotes. Neonatal purpura fulminans, a very rare complication involving widespread and sometimes fatal thrombosis, occurs in homozygous protein C– or protein S–deficient individuals.

Protein S Deficiency

Protein S is the principal cofactor of activated protein C (APC), and its deficiency mimics that of protein C in causing loss of regulation of fibrin generation by impaired inactivation of factors VIIIa and Va. A population-based study showed that low levels of free protein S and total protein S could only marginally identify subjects at risk for venous thrombosis. Only when cutoff levels for free protein S were far below the normal range, or when unprovoked venous thrombosis was considered an outcome event, was even just a two-fold to five-fold increased risk found.[2]

EPIDEMIOLOGY

Protein S deficiency is estimated to occur in about 1 in 500 in the general population. Its frequency in all patients evaluated for VTE (1 to 3%) is comparable to that of protein C deficiency.

PATHOBIOLOGY

Protein S circulates in plasma partly in complex with C4b-binding protein; only free protein S, which normally constitutes about 35 to 40% of total protein S, can function as a cofactor of APC. As in antithrombin and protein

C deficiencies, quantitative (type I) and qualitative (type II) forms of inherited protein S deficiency are known. In addition, type III protein S deficiency is characterized by normal plasma levels of total protein S but low levels of free protein S.

More than 220 mutations of the protein S gene have been found to cause a deficiency state to date. Most involve frameshift, nonsense, or missense point mutations.

Activated Protein C Resistance (Factor V Leiden)

EPIDEMIOLOGY

The factor V Leiden mutation is remarkably frequent (3 to 8%) in healthy white populations of European ancestry but is far less prevalent in certain black and Asian populations. It causes APC resistance. In various studies, APC resistance was found in a wide range of frequencies (10 to 64%) in patients with VTE.

PATHOBIOLOGY

Almost all subjects with functional APC resistance have a single, specific point mutation in the gene for factor V, which is a critical target of the physiologic anticoagulant action of APC. In this mutation, termed factor V Leiden, guanine is replaced with adenine at nucleotide 1691 (G1691A), which leads to the amino acid substitution of Arg504 by Gln and renders factor Va incapable of being inactivated by APC. Heterozygosity for the autosomally transmitted factor V Leiden mutation increases the risk for thrombosis by a factor of 5 to 10, whereas homozygosity increases the risk by a factor of 50 to 100.

Prothrombin Gene Mutation (Prothrombin G20210A)

The substitution of G for A at nucleotide 20210 of the prothrombin gene has been associated with elevated plasma levels of prothrombin and an increased risk for venous thrombosis. The allele frequency for this gain-of-function mutation is 1 to 6% in white populations, but it is much less prevalent in other racial groups. The prothrombin G20210A mutation is found in 3 to 8% of all patients with VTE.

Other Primary Hypercoagulable States

The first X-linked thrombophilia was reported in a family with a gain-of-function mutation in the gene for coagulation factor IX (factor IX Padua). Juvenile thrombophilia in this family was associated with a five- to ten-fold increase in factor IX clotting activity (with normal quantitative protein levels). Hereditary thrombosis in a Japanese family was associated with a missense mutation in the prothrombin gene (prothrombin Yukuhashi) that causes impaired inhibition of its mutant thrombin product by antithrombin. Elevated levels of factor VIII coagulant activity are a significant risk factor for venous thrombosis and its recurrence, and family studies suggest that high factor VIII levels are often genetically determined.[3] Increased levels of factor VII, factor IX, factor XI, fibrinogen, von Willebrand factor, and thrombin-activatable fibrinolysis inhibitor as well as very low levels of tissue factor pathway inhibitor may also confer increased risk. Many other inherited abnormalities of specific physiologic antithrombotic systems may be associated with a thrombotic tendency. Most of these conditions are limited to case reports or family studies, their molecular genetic bases are less well defined, and their prevalence rates are unknown but are probably much lower than those of the disorders described earlier. The other primary hypercoagulable states include heparin cofactor II deficiency, dysfunctional thrombomodulin, and many fibrinolytic disorders that lead to impaired fibrin degradation, including hypoplasminogenemia, dysplasminogenemia, plasminogen activator deficiency, and certain dysfibrinogenemias that cause a thrombotic rather than a bleeding diathesis.

CLINICAL MANIFESTATIONS

The primary hypercoagulable states are associated with predominantly venous thromboembolic complications (see Table 171-2). Deep venous thrombosis (DVT) of the lower extremities and pulmonary embolism (PE) are the most frequent clinical manifestations. Venous thromboses occurring in more unusual sites include superficial thrombophlebitis and mesenteric and cerebral venous thrombosis (see Table 171-2). Arterial thrombosis involving the coronary, cerebrovascular, and peripheral circulations is not generally linked to any of the primary hypercoagulable states. However, venous thrombosis can result in arterial occlusion by paradoxical embolism across a patent foramen ovale. Also, epidemiologic studies have revealed increased overall risk of arterial thrombotic and atherosclerotic vascular disease in patients with a history of VTE and vice versa.[4] Recurrent pregnancy loss is probably increased in primary hypercoagulable states, but this association is not as strongly established as it is in antiphospholipid syndrome (see later under Secondary Hypercoagulable States).

The initial episode of VTE can occur at any age in patients with primary hypercoagulable states, but it typically takes place in early adulthood. Positive family histories of thrombosis can frequently be elicited. The risk for thrombosis varies among the individual primary hypercoagulable states and is highest in patients with deficiencies of antithrombotic factors (Table 176-2); it is markedly increased with the coexistence of multiple prothrombotic mutations. Patients with homozygous deficiency states tend to have more severe thrombotic complications. Warfarin-induced skin necrosis (Fig. 176-2) infrequently complicates the initiation of oral anticoagulant therapy in patients with heterozygous protein C or protein S deficiency. Because both these proteins depend on vitamin K for normal function, their plasma levels in patients with inherited deficiency states may drop to nearly zero within a few days of starting therapy with warfarin, a vitamin K antagonist, and lead to a transient prothrombotic imbalance and skin necrosis caused by dermal vascular thrombosis. Nevertheless, oral anticoagulation does provide effective long-term antithrombotic prophylaxis in these individuals.

In most patients with primary hypercoagulable states, discrete clinical thrombotic complications appear to be precipitated by acquired prothrombotic events (e.g., pregnancy, use of oral contraceptives, surgery, trauma, immobilization), many of which are the secondary hypercoagulable states discussed subsequently (see Fig. 176-1). For example, thrombosis complicates pregnancy, especially during the puerperium, in about 30 to 60% of women with antithrombin deficiency, 10 to 20% with protein C or protein S deficiency, and almost 30% with APC resistance (factor V Leiden) unless prophylactic anticoagulation is administered during this period.

TABLE 176-2 INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIAS): EPIDEMIOLOGY AND RISK OF VENOUS THROMBOEMBOLISM (VTE)

	PREVALENCE (%)		RELATIVE RISK	
THROMBOPHILIA	*General Population**	*Unselected VTE*	*First VTE*	*Recurrent VTE*
Antithrombin deficiency	0.02-0.3	1-2	5-8	2.5
Protein C deficiency	0.2-0.5	2-5	5-8	2.5
Protein S deficiency	0.5	1-3	1.7-8	2.5
Factor V Leiden	3-8	10-65	5-10†	1.3
Factor II G20210A	1-6	3-8	1.5-3.8	1.4
Factor V Leiden and factor II G20210A	0.01	—	20-60	2.5

*Data refer to white populations. The prevalence of factor V Leiden and factor II G20210A is less than 0.1% in African, African American, and Asian populations.
†Relative risk of first VTE with homozygous factor V Leiden is up to 10-fold higher (50-100).Modified from Coppola A, Tufano A, Cerbone AM, et al. Inherited thrombophilia: implications for prevention and treatment of venous thromboembolism. *Semin Thromb Hemost.* 2009;35:683-694.

FIGURE 176-2. Acute skin necrosis in a patient with protein C deficiency who was treated with heparin and warfarin for deep venous thrombosis that occurred after elective hip surgery. Warfarin treatment was withdrawn and anticoagulation continued with heparin. Skin grafting of the affected area was required. (From Forbes CD, Jackson WF. Color Atlas and Text of Clinical Medicine. 3rd ed. London: Mosby; 2003.)

Although DVT and PE have been considered to simply reflect the clinical spectrum of manifestations of the same single entity (i.e., VTE), some distinct patterns for the two clinical events have become evident. When patients initially present with PE, regardless of cause, they are more likely to have PE again if VTE recurs, and likewise for DVT if VTE recurs.[5] In addition, certain hypercoagulable states have been noted to preferentially be manifested with either DVT or PE. Factor V Leiden poses a clearly higher risk for DVT than for PE (the so-called factor V Leiden paradox); conversely, individuals with underlying pulmonary disease (e.g., chronic obstructive pulmonary disease, pneumonia, or sickle cell disease) have a disproportionately higher likelihood of presenting with PE than with DVT as the primary manifestation of VTE.[6] The reasons that some individuals with VTE appear to be more embolism prone than others are not known.

DIAGNOSIS

Laboratory diagnosis (Chapter 171) of the primary hypercoagulable states requires testing for each of the disorders individually because no general screening test is currently available to determine whether a patient may have such a condition.[7] Factor V Leiden can be diagnosed by a DNA-based assay or by a functional test for APC resistance; the DNA-based assay is required to distinguish between heterozygous and homozygous states. DNA-based assay is required to identify the prothrombin G20210A mutation. In contrast, many different mutations have been found in the genes for antithrombin, protein C, and protein S, so DNA-based tests are not practical for the diagnosis of these inherited deficiency states. Therefore, they are detected by functional and immunologic tests. Because type II (qualitative) deficiencies of antithrombin, protein C, and protein S exhibit normal immunologic levels, functional assays for these proteins are better screening tests.

The diagnostic approach to a patient with a documented episode of VTE includes a thorough history, physical examination, and basic laboratory tests to search for possible precipitating conditions or triggers for the acute event and to rule out underlying acquired causes of hypercoagulability, including occult malignant disease, as discussed later in the section on secondary hypercoagulable states.

As noted in Chapter 171 (section under Evaluation of the Patient with a Possible Hypercoagulable State), the lack of evidence of clearly increased risk of thrombosis *recurrence* in patients with a history of VTE associated with most of the primary hypercoagulable states (thrombophilias) has made thrombophilia testing after a first episode debatable. This controversy is reflected by current practice guidelines.[8-11] An algorithm for thrombophilia testing is shown in Figure 176-3.

A reasonable diagnostic approach at this time is to screen at least all "strongly thrombophilic" patients after an initial episode of VTE: individuals with a documented event before 40 years of age, a positive family history, or unprovoked or recurrent VTE. Thrombophilia testing is not routinely recommended, however, indiscriminately in all patients after a first VTE episode or in those with overt provoking factors. Analysis of results from a randomized trial showed that recurrent VTE was not increased, at least during warfarin therapy, in the presence of factor V Leiden, prothrombin G20210A mutation, antithrombin deficiency, or elevated levels of factor VIII, factor XI, or homocysteine.[■] However, there have been no controlled clinical trials to date that have assessed the benefit of testing for thrombophilia on the risk of recurrent VTE. Although indefinite anticoagulation is recommended for patients who have had two or more VTE events, regardless of whether a primary hypercoagulable state is found, testing of these individuals for thrombophilia is still useful to guide family screening strategies (see Fig. 176-3). Individuals with arterial thrombosis generally should not be tested for any of these disorders because primary hypercoagulable states (see Table 176-1) are not clearly associated with an increased risk for arterial thrombosis. In contrast, some of the secondary hypercoagulable states, including hyperhomocysteinemia and the antiphospholipid syndrome (see later), are associated with an increased risk for arterial as well as venous thrombosis.

In general, testing for primary hypercoagulable states is not recommended immediately after a major thrombotic event. Optimally, it should be performed in clinically stable patients at least 2 weeks after completion of oral anticoagulation following a thrombotic episode. This is because active thrombosis may transiently consume and deplete some of the antithrombotic proteins in plasma and lead to the erroneous diagnosis of inherited antithrombin, protein C, or protein S deficiency. In addition to acute thrombosis, pregnancy, estrogen use, liver disease, and disseminated intravascular coagulation may cause acquired deficiencies of antithrombin, protein C, or protein S. Anticoagulation may also interfere with some of the functional tests for primary hypercoagulable states. Heparin treatment can cause a decline in antithrombin levels to the deficiency range even in normal individuals. In contrast, warfarin can elevate antithrombin levels into the normal range in patients who do have an inherited deficiency state. Warfarin therapy, by its very mode of action, also predictably reduces the functional levels and, less prominently, the immunologic levels of protein C and protein S. This warfarin action thereby potentially leads to a misdiagnosis of inherited deficiency. When testing is indicated in patients in whom interruption of prophylactic oral anticoagulation is considered to be too risky, protein C and protein S levels can be determined after warfarin therapy has been discontinued under heparin coverage for at least 2 weeks.

As noted previously, functional assays are the best screening tests for antithrombin, protein C, and protein S deficiencies because they detect both quantitative and qualitative defects; antigenic (immunologic) assays detect only quantitative deficiencies of these proteins. Functional coagulation assays for protein C and protein S may yield spuriously low values, however, if APC resistance is present. APC resistance can be diagnosed by newer high-sensitivity and high-specificity coagulation assays or by DNA analysis of peripheral blood mononuclear cells for the factor V Leiden mutation.

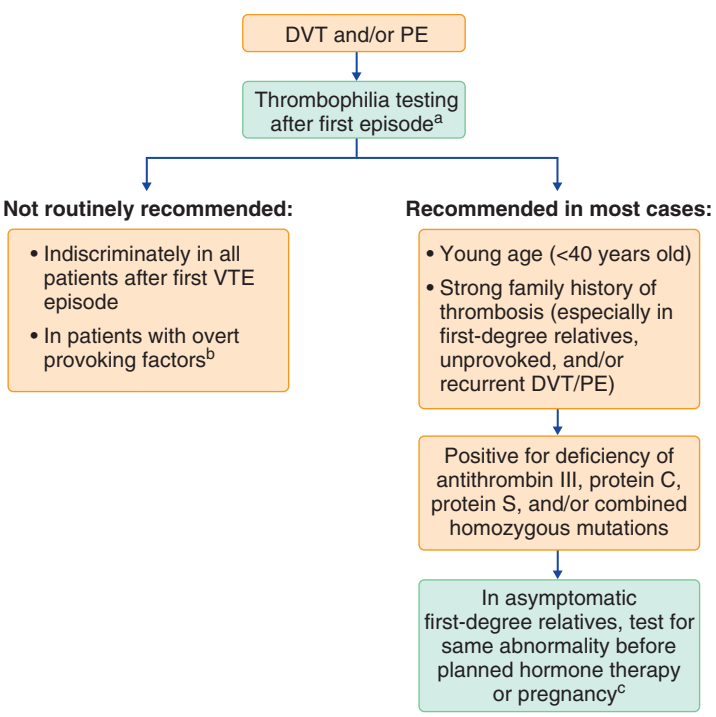

FIGURE 176-3. Algorithm for thrombophilia testing after a first episode of deep venous thrombosis (DVT) or pulmonary embolism (PE) and in asymptomatic, first-degree relatives. In the absence of strong evidence-based guidelines (see text), decisions about thrombophilia testing should be individualized, ranging from "not routinely recommended" to "recommended in most cases." VTE = venous thromboembolism. [a]Thrombophilia testing to include antithrombin III, protein C, protein S, factor V Leiden, prothrombin 20210A gene mutation, and lupus anticoagulant/antiphospholipid antibodies. [b]Provoking factors include active malignant disease, postoperative state, immobilization, trauma, active chronic inflammatory disease (e.g., extensive psoriasis), myeloproliferative neoplasm, pregnancy, oral contraceptives, and hormone replacement therapy. [c]In asymptomatic first-degree relatives of such individuals, avoidance is an alternative to testing.

TREATMENT

The initial treatment of acute venous thrombosis or PE in patients with primary hypercoagulable states is not different from that in patients without genetic defects (Chapters 38 and 81). As in patients without known thrombophilia, thrombolytic therapy should be considered after massive venous thrombosis or PE. Acute management is initiated with at least 5 days of unfractionated or low-molecular-weight heparin or fondaparinux. Oral anticoagulation with warfarin can be started on the first day of parenteral anticoagulation use and continued for at least 6 months in patients with VTE in the absence of triggering factors (e.g., postoperative state), with regulation of the dose to maintain an international normalized ratio of the prothrombin time between 2.0 and 3.0.

TABLE 176-3 LONG-TERM MANAGEMENT OF PATIENTS WITH PRIMARY HYPERCOAGULABLE STATES*

RISK CLASSIFICATION	MANAGEMENT
High risk ≥2 spontaneous thromboses 1 spontaneous life-threatening thrombosis 1 spontaneous thrombosis at an unusual site (e.g., mesenteric, cerebral venous) 1 spontaneous thrombosis in the presence of antiphospholipid syndrome, antithrombin deficiency, or more than a single hypercoagulable state	Indefinite or lifelong anticoagulation
Moderate risk 1 thrombosis with an acquired prothrombotic stimulus	Vigorous prophylaxis during high-risk situations
Asymptomatic	

*Beyond initial period of thromboprophylaxis.
Modified from Bauer K. Approach to thrombosis. In: Loscalzo J, Schafer AI, eds. Thrombosis and Hemorrhage. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:330-342.

Continuing oral anticoagulant prophylaxis beyond the initial 6 to 12 months after an acute episode of VTE must be weighed against continued exposure of the individual patient to the significant risk for bleeding complications. Patients with primary hypercoagulable states who have had two or more thrombotic events should receive indefinite or lifelong prophylactic oral anticoagulation (Chapter 38). Indefinite or lifelong anticoagulation is probably indicated for individuals with recurrent thrombosis even in the absence of identifiable primary hypercoagulable states.

The decision to continue prophylactic oral anticoagulation beyond the initial period after the first episode of thrombosis is more difficult (Table 176-3). After a single episode of thrombosis, patients with inherited hypercoagulable states should probably receive indefinite or lifelong anticoagulation if their initial episodes were life-threatening or occurred in unusual sites (e.g., mesenteric or cerebral venous thrombosis) or if they have more than one prothrombotic genetic abnormality. Some authorities also recommend indefinite or lifelong anticoagulation after an initial venous thromboembolic event in patients whose risk of recurrence likewise appears to be increased: those with isolated heterozygous deficiencies of antithrombin, protein C, or protein S and patients with homozygous factor V Leiden. In the absence of these characteristics, particularly if the initial episode was precipitated by a transient acquired prothrombotic situation (e.g., pregnancy, postoperative state, immobilization), it is reasonable at this time to discontinue warfarin therapy after 3 months and to administer subsequent prophylactic anticoagulation only during high-risk periods.

Asymptomatic individuals with known thrombophilia who have not had previous thrombotic complications do not require prophylactic anticoagulation except during periods of high risk for thrombosis. Because about half of the first-degree relatives of a patient with a primary hypercoagulable state should be affected, these individuals should be counseled about the implications of testing them and potentially making a diagnosis.

Management of pregnancy in women with primary hypercoagulable states requires special consideration because of the high risk for thrombosis, particularly during the puerperium.[12] Women with thrombophilia who have previously had thrombosis—and probably also asymptomatic women with thrombophilia—should receive prophylactic anticoagulation throughout pregnancy and for at least 6 weeks post partum, a particularly high-risk period. Coumarin derivatives cross the placenta and have the potential to cause both bleeding and teratogenic effects in the fetus; therefore, oral anticoagulants should not be used during pregnancy. Heparin does not cross the placenta and does not cause these fetal complications. Fixed-dose, low-molecular-weight heparin (instead of unfractionated heparin) is the anticoagulant of choice during pregnancy. Neither warfarin nor heparin induces an anticoagulant effect in a breast-fed infant when the drug is given to a nursing mother, so either can be given safely when indicated in the postpartum period.

Because warfarin-induced skin necrosis (see Fig. 176-2) is a rare problem, screening of all patients for inherited protein C or protein S deficiency, conditions that are known to predispose to this complication, is not indicated before starting warfarin therapy. Most cases can be avoided by not initiating warfarin therapy with high loading doses and by concomitant coverage with heparin. When the complication does occur, as manifested by painful red and subsequently dark, necrotic skin lesions (see Fig. 176-2) within a few days of starting warfarin, such therapy must be discontinued immediately, vitamin K administered, and heparin started (Chapter 38). The use of fresh-frozen plasma or purified protein C concentrate to normalize protein C levels rapidly can improve results. Despite this rare complication, warfarin is an effective, long-term prophylactic anticoagulant in patients with inherited protein C or protein S deficiency.

Antithrombin concentrate purified from normal human plasma or human recombinant antithrombin may be a useful adjunct to anticoagulation in "heparin-resistant" patients, who represent unusual cases of type II antithrombin deficiency, and in antithrombin-deficient patients with recurrent thrombosis despite adequate anticoagulation. Infusion of antithrombin concentrate can also be considered in some perioperative or obstetric settings in which anticoagulation poses an unacceptable bleeding risk.

SECONDARY HYPERCOAGULABLE STATES

DEFINITION

The secondary hypercoagulable states are diverse, mostly acquired disorders that predispose patients to thrombosis by complex, multifactorial pathophysiologic mechanisms. Many of these conditions also represent the acquired precipitating stimuli for clinical thrombotic events in individuals with a genetic predisposition (primary hypercoagulable states). Although each disorder causes thrombosis primarily through abnormalities in blood flow (rheology), the composition of blood (coagulation factors and platelet function), or the vessel wall, multiple overlapping mechanisms are operative in many of them.

Hyperhomocysteinemia

Hyperhomocysteinemia is an elevated blood level of homocysteine, a sulfhydryl amino acid derived from methionine by a transmethylation pathway (E-Fig. 176-1). Homocysteine is remethylated to methionine or catabolized to cystathionine. The major remethylation pathway requires folate and cobalamin (vitamin B_{12}) and involves the action of methylenetetrahydrofolate reductase (MTHFR); a minor remethylation pathway is mediated by betaine–homocysteine methyltransferase. Alternatively, homocysteine is converted to cystathionine in a trans-sulfuration pathway catalyzed by cystathionine β-synthase (CBS), with pyridoxine used as a cofactor.

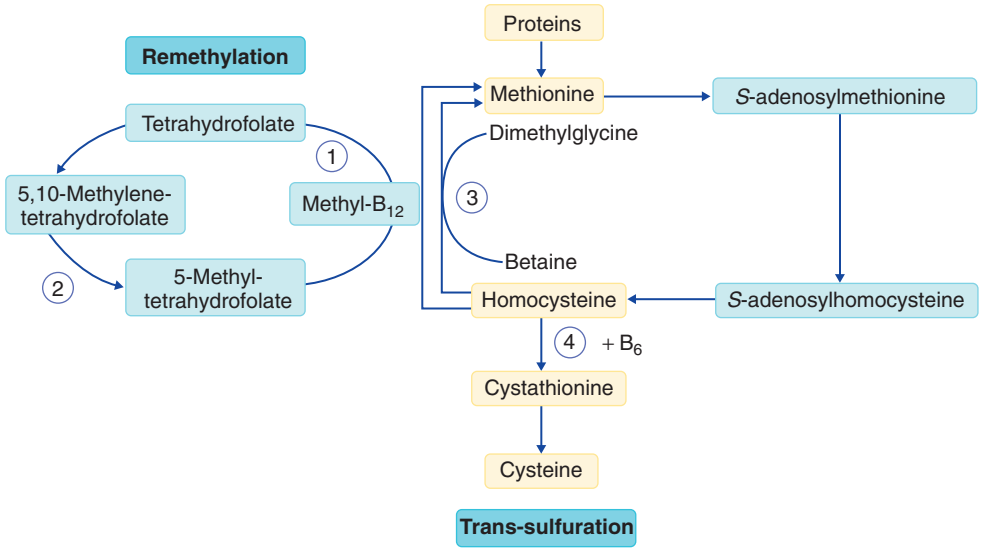
Homozygous CBS deficiency states that lead to severe hyperhomocysteinemia (homocystinuria) (Chapter 209) cause premature arterial atherosclerotic disease and VTE as well as mental retardation, neurologic defects, lens ectopy, and skeletal abnormalities. By comparison, adults with heterozygous CBS deficiency, with resultant mild to moderate hyperhomocysteinemia, may have only venous or arterial thrombotic manifestations. Hyperhomocysteinemia resulting from inherited remethylation pathway defects usually involves reduced activity of MTHFR. In homozygous individuals with the autosomal recessive C677T mutation of the *MTHFR* gene, which occurs in 15% of certain populations, moderate hyperhomocysteinemia may occur and is correctable with folic acid, but it does not appear to be related to risk of venous thrombosis.[13] Acquired causes of hyperhomocysteinemia in adults most commonly involve nutritional deficiencies of the cofactors required for homocysteine metabolism, including pyridoxine, cobalamin, and folate.

Acquired and inherited hyperhomocysteinemia is a probable risk factor for both arterial and venous thrombosis. The mechanism of homocysteine-induced thrombosis and atherogenesis involves complex, probably multifactorial effects on the vessel wall. Homocysteine can cause vascular endothelial injury, conversion of the endothelial surface of blood vessels from an antithrombotic to a prothrombotic state, and smooth muscle cell proliferation. These toxic effects of homocysteine on the vessel wall may be mediated by oxidant stress.

Vitamin supplementation with folate, pyridoxine, and cobalamin can normalize elevated blood levels of homocysteine. However, several prospective clinical trials of homocysteine-lowering therapy have failed to show reduced rates of vascular events in patients with established vascular disease. It remains to be determined whether this disappointing lack of clinical benefit with homocysteine-lowering vitamin therapy indicates that homocysteine is not a direct atherogenic factor, or that vitamin therapy in this setting might have other, offsetting deleterious effects, or that possibly other mechanisms are operative.

Malignant Disease

Multiple abnormalities of hemostasis are involved in the hypercoagulable state in cancer patients, many of which initiate a systemic process of chronic disseminated intravascular coagulation (Chapter 175). The thrombotic tendency of patients with cancer may also be related to mechanical factors, such as immobility, indwelling central venous catheters, or a bulky tumor mass compressing vessels, and to comorbid conditions, such as sepsis, surgery,



E-FIGURE 176-1. Intracellular metabolism of homocysteine occurs through remethylation to methionine or trans-sulfuration to cysteine. Numbered circles indicate the principal enzymes involved: (1) methionine synthase; (2) 5,10-methylenetetrahydrofolate reductase; (3) betaine–homocysteine methyltransferase; (4) cystathionine β-synthase. (Modified from De Stefano V, Finazzi G, Mannucci PM. Inherited thrombophilia: pathogenesis, clinical syndromes, and management. *Blood.* 1996;87:3531-3544.)

liver dysfunction secondary to metastases, and the prothrombotic effects of certain antineoplastic agents.

The incidence of thrombotic complications in cancer patients depends in part on the type of malignant disease. Hypercoagulability is most prominent in patients with pancreatic cancer (Chapter 194), adenocarcinoma of the gastrointestinal tract (Chapters 192 and 193), lung (Chapter 191), ovarian cancer (Chapter 199), and hematologic malignant neoplasms. The presence of underlying malignant disease compounds the independent risk for thrombosis in the postoperative state. There is a two-fold increase in risk of postoperative thrombosis (see later section, Postoperative State, Immobilization, and Trauma) in cancer patients compared with noncancer patients. Thrombosis most commonly occurs in patients with established or concurrently diagnosed malignant disease. In these patients, the risk of venous thrombosis has been found to be highest in the first few months after the diagnosis of malignant disease, then decreases progressively during the subsequent 15 years. The same large case-control study showed that the risk of venous thrombosis in cancer patients is approximately 12- to 17-fold increased in those who also have the factor V Leiden or the prothrombin G20210A mutation.

The increased risk of harboring an undiagnosed, usually occult malignant neoplasm in patients who present with VTE is now well established. The overall prevalence of undiagnosed cancer in patients with unprovoked VTE is approximately 6% at the time of thrombosis and 10% within the first year after thrombosis. Beyond thorough history, physical examination, and routine laboratory tests and radiography, the benefit of extensive evaluation for occult cancer including advanced imaging studies is not established, however.[14] An algorithm for evaluating a patient for occult malignant neoplasm after an episode of VTE is shown in Figure 176-4.

The most frequent thrombotic manifestations in patients with neoplasms are DVT and PE, but more unusual and distinctive thrombotic complications are also found. Trousseau's syndrome, characterized by migratory superficial thrombophlebitis of the upper or lower extremities, is strongly linked to cancer. Nonbacterial thrombotic endocarditis involves fibrin-platelet vegetations on heart valves, which produce clinical manifestations by systemic embolization (Chapter 60). Of patients with nonbacterial thrombotic endocarditis, 75% have underlying malignant neoplasms at autopsy. Trousseau's syndrome and nonbacterial thrombotic endocarditis are highly associated with adenocarcinomas. The occurrence of either syndrome in patients without known cancer demands a more vigorous search for occult malignant disease than in patients with DVT or PE. Thrombotic microangiopathy (Chapter 172), characterized by hemolysis with red blood cell fragmentation, thrombocytopenia, and microvascular thrombosis with involvement of target organs, occurs in about 5% of patients with metastatic carcinomas, most commonly those with gastric (Chapter 192), lung (Chapter 191), and breast (Chapter 198) primary sites.

Some antineoplastic agents themselves increase the risk of thrombosis in cancer patients. These include antiangiogenic agents (VTE with thalidomide and lenalidomide; arterial thrombosis with bevacizumab, sunitinib, sorafenib). In multiple myeloma (Chapter 187), the thrombotic risk of thalidomide is increased 10-fold when the drug is combined with high-dose dexamethasone and an anthracycline. Other thrombogenic chemotherapeutic agents include all-*trans*-retinoic acid and arsenic trioxide, particularly when used as induction chemotherapy for acute promyelocytic leukemia (Chapter 183); cisplatinum (causing both venous and arterial thrombosis); L-asparaginase (which can also cause bleeding); and methotrexate.[15]

TREATMENT

Rx

Treatment of acute VTE in cancer patients should be initiated as in other patients, but subsequent prophylactic anticoagulation generally should be continued while active malignant disease is present.[16] In some patients, however, complete resolution of the VTE may allow treatment to be stopped safely. Anticoagulation can be difficult in many cancer patients; these patients may be resistant to warfarin prophylaxis. Anticoagulation can also be complicated by bleeding into tumors. Long-term treatment of cancer patients with low-molecular-weight heparin (LMWH) after VTE (Chapter 38) reduces recurrences and possibly decreases bleeding complications compared with treatment with warfarin. LMWH also reduces the risk of a first VTE in patients with cancer and is more effective than warfarin in doing so, although it has not been shown to increase overall survival in this setting. Evidence-based practice guidelines have been published for the prevention and treatment of VTE in cancer patients.

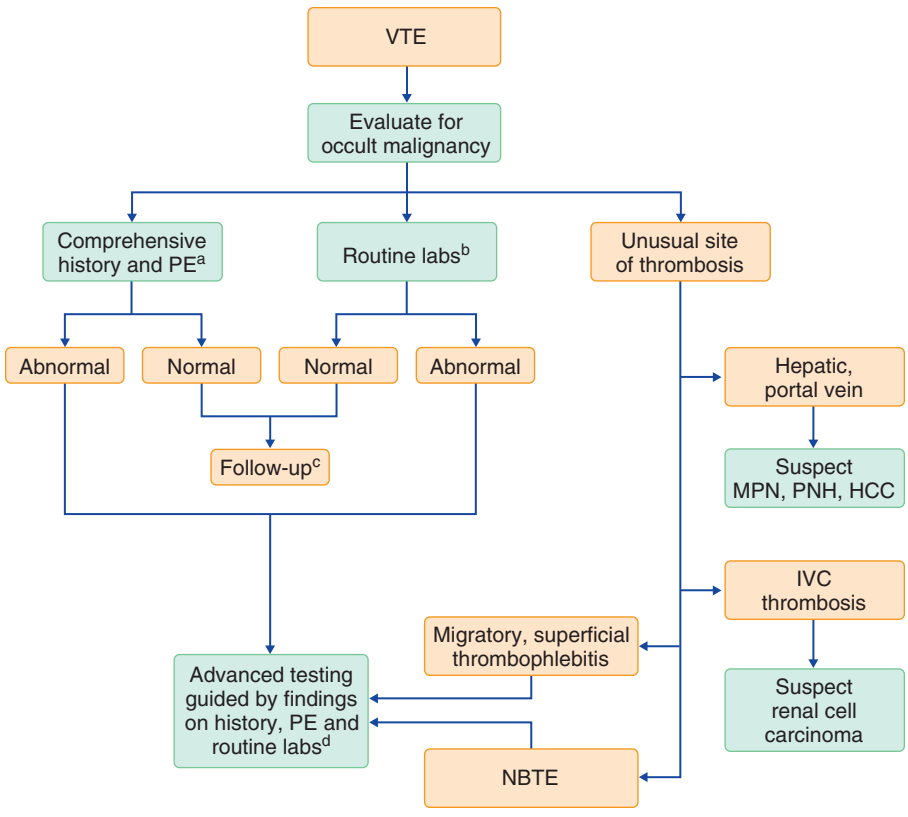


FIGURE 176-4. Algorithm for evaluating a patient for occult malignant neoplasm after an unprovoked episode of deep venous thrombosis or pulmonary embolism or thrombosis at an unusual site. HCC = hepatocellular carcinoma; IVC = inferior vena cava; MPN = myeloproliferative neoplasm; NBTE = nonbacterial thrombotic endocarditis; PE = physical examination; PNH = paroxysmal nocturnal hemoglobinuria; VTE = venous thromboembolism. [a]Physical examination to include rectal (with stool sample for occult blood) and breast and pelvic examinations for women. [b]Routine laboratory evaluations to include chest radiography, complete blood count, basic chemistries, and calcium concentration. [c]Follow-up suggested at 6 to 12 months. [d]Advanced testing could include advanced imaging, endoscopies, cytologies, and the like.

Myeloproliferative Neoplasms and Paroxysmal Nocturnal Hemoglobinuria

Thrombosis and, apparently paradoxically, bleeding are major causes of morbidity and mortality in patients with chronic myeloproliferative neoplasms (Chapter 166) and the related bone marrow stem cell disorder paroxysmal nocturnal hemoglobinuria (Chapter 160). In uncontrolled polycythemia vera (Chapter 166), increased whole blood viscosity contributes to the thrombotic tendency. Thrombocytosis, abnormal platelet function, and other less well understood factors are also probably involved in the hemostatic defect of the myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria.

In addition to DVT and PE, some distinctive thrombotic manifestations are seen. Hepatic vein thrombosis (Budd-Chiari syndrome) and portal and other intra-abdominal venous thromboses (Chapter 143) are associated with myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria (Chapter 160) and may be the initial manifestations of the disease. Myeloproliferative neoplasms, particularly polycythemia vera (Chapter 166) and essential thrombocythemia (Chapter 166), may cause erythromelalgia, a syndrome of microvascular thrombosis manifested by intense pain accompanied by warmth, duskiness, and mottled erythema, sometimes resembling livedo reticularis, in a patchy distribution in the extremities, most prominently in the feet; digital microvascular ischemia progressing to vascular insufficiency and gangrene may ensue (Chapter 80). A wide spectrum of neurologic manifestations may be caused by cerebrovascular ischemia, especially in patients with essential thrombocythemia.

TREATMENT

Rx

Treatment of VTE in patients with the myeloproliferative neoplasms and paroxysmal nocturnal hemoglobinuria should be initiated as in patients without these hematologic disorders. In patients with thrombosis associated with polycythemia vera, the hematocrit should be maintained in the normal range with phlebotomies or chemotherapy, or with both (Chapter 166). Patients maintained at a hematocrit target of less than 45% have a significantly lower rate of cardiovascular death and major thrombosis than do those with hematocrit targets of 45 to 50%. Low-dose aspirin (100 mg daily) can prevent thrombotic complications without increasing the incidence of major bleeding in patients with polycythemia vera who have no contraindications to such treatment. In patients with essential thrombocythemia, cytoreduction of the elevated platelet count should be achieved with chemotherapy (Chapter 166).

Antiphospholipid Syndrome

Antiphospholipid syndrome (Chapter 174) is characterized by venous and arterial thrombosis, recurrent spontaneous pregnancy loss (which may also be due to thrombosis), thrombocytopenia, and a variety of neuropsychiatric manifestations.[17] The syndrome is associated with a heterogeneous group of autoantibodies that bind to anionic phospholipid-protein complexes, a protein cofactor of which is β_2-glycoprotein I. Patients with this syndrome have any combination of positive responses to tests to detect different plasma antiphospholipid-protein antibodies (e.g., anticardiolipin antibodies) and phospholipid-based clotting tests (lupus anticoagulants) (Chapter 257). The predominant prothrombotic effects of these antibodies are probably directed to the vessel wall.

DVT and PE are the most frequent venous thrombotic events in these patients. Cerebrovascular events are the most common arterial thrombotic complications and are manifested as stroke, transient ischemic attacks (Chapter 407), multi-infarct dementia (Chapter 402), or retinal artery occlusion. Peripheral and intra-abdominal vascular occlusion is encountered more rarely. About one third of these patients have nonbacterial heart valve vegetations (Libman-Sacks endocarditis). The most prominent obstetric complications are recurrent spontaneous pregnancy loss and fetal growth retardation, which are probably due to thrombosis of placental vessels. Patients are occasionally seen with "catastrophic" antiphospholipid syndrome involving a series of acute and sometimes fatal vascular occlusive events, or "thrombotic storm." Thrombotic complications are limited largely to patients with primary antiphospholipid syndrome and patients in whom the antibodies are associated with collagen vascular disease, not with drugs or infections.

TREATMENT AND PREVENTION

Rx

Acute management of thrombosis in these patients is essentially the same as in other individuals. Monitoring of heparin anticoagulation is difficult in patients with a lupus anticoagulant because they already have a prolonged activated partial thromboplastin time at baseline; the use of low-molecular-weight heparin, which does not require monitoring, can circumvent this problem. Warfarin is effective in preventing recurrent thrombosis but usually requires prolonged or indefinite therapy with doses to achieve an international normalized ratio of 2.0 to 3.0. Whereas laboratory evidence of antiphospholipid antibodies in patients with a first episode of VTE is still usually considered an indication for indefinite anticoagulant therapy, a systematic review showed that the strength of this association is uncertain because of low-quality evidence supporting it.[18] No established treatment of women with antiphospholipid syndrome has been shown to prevent recurrent fetal loss. Treatment with prednisone and aspirin during pregnancy is not effective in promoting live birth and may increase the risk for prematurity.

Asymptomatic carriers of a "high-risk profile" of antiphospholipid antibodies (confirmed triple positive for anticardiolipin, lupus anticoagulant, and anti–β_2-glycoprotein I) are at considerable risk for a first thromboembolic event; some such individuals should even be considered for primary thromboprophylaxis.[19]

Pregnancy, Oral Contraceptives, and Hormone Replacement Therapy

Activation of the coagulation system is initiated locally in the maternal uteroplacental circulation, where the placenta is the source of increased thrombin generation. Platelet activation and increased platelet turnover also occur during normal pregnancy, and about 8% of healthy women have mild thrombocytopenia at term. Simultaneously, the fibrinolytic system is progressively blunted throughout pregnancy because of the action of placental plasminogen activator inhibitor type 2. The net effect of these coagulation changes is creation of a state of hypercoagulability that makes pregnant women vulnerable to thrombosis, particularly in the puerperium. These systemic alterations are compounded by prothrombotic mechanical and rheologic factors in pregnancy, including venous stasis in the legs caused by the gravid uterus, pelvic vein injury during labor, and the trauma of cesarean section. Oral contraceptives induce a prothrombotic state by increasing procoagulant effects and decreasing physiologic anticoagulant effects.

The use of oral contraceptives is associated with an increased risk for venous thrombosis, myocardial infarction, stroke, and peripheral arterial disease, particularly during the first year of use (Chapter 238). Unexpectedly, third-generation oral contraceptives, which contain less estrogen and a different progestin, double the risk for VTE in comparison to second-generation preparations. Postmenopausal hormone replacement increases the risk for deep VTE by a factor of 2 to 3.5, at least during the first year. Hormone replacement therapy has no beneficial effect and possibly even a detrimental effect on the risk for arterial disease (Chapter 240).

DVT and PE are the most common thrombotic complications of pregnancy and the use of oral contraceptives or hormone replacement therapy. Coexisting primary hypercoagulable states are an at least additive risk factor in all these settings. In the absence of a clear family history of clinical VTE or a strongly thrombophilic mutation in a first-degree relative, there is little justification, however, to screen for prothrombotic mutations with pregnancy or before starting hormone replacement therapy or oral contraceptives. Increasing age, increasing parity, cesarean delivery, prolonged bedrest or immobilization, obesity, and previous thromboembolism are additional prothrombotic risk factors in pregnant women. Most thrombotic events associated with pregnancy occur in the peripartum period, especially after delivery. Special considerations for anticoagulation in the setting of pregnancy are noted in the section on treatment of primary hypercoagulable states.

Systemic Inflammation

Systemic inflammation may be involved in the pathogenesis of VTE through vessel wall inflammation and damage as well as systemic hypercoagulability. Patients with autoimmune connective tissue diseases, particularly rheumatoid arthritis,[20] juvenile rheumatoid arthritis, and systemic lupus erythematosus, are at increased risk of VTE. Psoriasis, an immunoinflammatory disease that is associated with cardiovascular risk and atherothrombotic

events, has also been shown in a cohort study to carry an increased risk of VTE; the risk was found to be highest in younger patients with severe psoriasis. Other skin diseases that are autoimmune in etiology were not associated with VTE risk in another population-based case-control study.

Postoperative State, Immobilization, and Trauma

Postoperative thrombosis (Chapter 433) is caused by a combination of local mechanical factors, including decreased venous blood flow in the lower extremities, and systemic changes in coagulation. The level of risk for postoperative thrombosis depends largely on the type of surgery performed. It is compounded by coexisting risk factors, such as an underlying inherited primary hypercoagulable state or malignant disease (see earlier sections), advanced age, and prolonged procedures. Postoperative DVT and PE, the most common thrombotic complications, are often asymptomatic and detectable only by noninvasive studies. The incidence of DVT after general surgical procedures is about 20 to 25%, with almost 2% of these patients having clinically significant PE. Without prophylaxis, the risk for DVT after hip surgery and knee reconstruction ranges from 45 to 70%, and clinically significant PE occurs in 20% of patients undergoing hip surgery. Although the process of thrombosis generally begins intraoperatively or within a few days of surgery, the risk for this complication can be protracted beyond the time of discharge from the hospital, particularly in hip replacement patients.

Patients who are bedridden or experiencing prolonged air travel are at increased risk for VTE. VTE is also one of the most common causes of morbidity and mortality in survivors of major trauma, and asymptomatic DVT of the lower extremities has been detected by venography in more than 50% of hospitalized trauma patients. The risk for venous thrombosis after trauma is increased by advanced age, need for surgery or transfusions, and presence of lower extremity fractures or spinal cord injury.

Mechanical methods of prophylaxis against VTE should be considered in high-risk postoperative patients and bedridden patients with medical conditions, either in combination with anticoagulant prophylaxis or instead of it in patients who have an unusually high risk for bleeding with anticoagulation. Such methods include graduated compression stockings, intermittent pneumatic compression devices, and venous foot pumps.

For long-distance travelers at increased risk of VTE, including those with previous VTE or hypercoagulable states, current recommendations include frequent ambulation, nonalcoholic hydration, calf muscle exercises, and the use of properly fitted, below-knee graduated compression stockings providing 15 to 30 mm Hg of pressure at the ankle during travel; compression stockings are not recommended for other long-distance travelers. The use of aspirin or anticoagulants to prevent VTE is not recommended for long-distance travelers at increased risk of VTE.[21]

REVIEW QUESTIONS

1. A 45-year-old man was diagnosed 3 days ago to have a left lower extremity deep venous thrombosis (DVT) by ultrasound. No provoking factors were identified. He was discharged from the emergency department without further work-up but with instructions to begin subcutaneous injections of therapeutic doses of a low-molecular-weight heparin together with daily warfarin at a dose of 7.5 mg/day, to be followed up by you in your primary care office. Which of the following would you do on this visit?

A. Initiate imaging work-up for diagnosis of occult malignant disease.
B. Obtain a prothrombin time (international normalized ratio).
C. Repeat the lower extremity ultrasound.
D. Obtain pulmonary embolism protocol chest computed tomography.
E. Test for most common primary hypercoagulable states (thrombophilias).

Answer: B The emergency department physicians correctly initiated therapeutic heparin while at the same time beginning longer term warfarin oral anticoagulation to prevent recurrent venous thromboembolism (VTE). It is now time to begin regulating the warfarin dose on the basis of the prothrombin time, with a target international normalized ratio of 2.0 to 3.0. Although several studies have shown some increased risk of otherwise healthy individuals with VTE harboring an occult malignant neoplasm, a thorough history and physical examination, including stool samples for occult blood and basic studies like chest radiography and mammography in women, are considered to be sufficient. Advanced imaging studies to look for cancer are indicated only if abnormalities are found in this basic work-up. Another lower extremity ultrasound examination at this point is not indicated unless there is some uncertainty about the original diagnosis. The finding of a simultaneous, silent pulmonary embolism will not make any difference in your diagnostic and therapeutic plan. In fact, a large percentage (up to 50%) of patients with symptomatic lower extremity DVT would be found to have silent pulmonary emboli on imaging. Whatever might be found on blood tests for a primary hypercoagulable state at this point would not alter therapy, and the test results may be misleading right after an acute thrombotic event.

2. You are the primary care physician of a 50-year-old woman with a history of pregnancy-associated DVT 20 years ago. She has had no work-up for hypercoagulable states (thrombophilias). The patient has had no recurrent VTE and is not taking anticoagulants, but she is planning a nonstop flight from New York to Hong Kong. Which of the following would you recommend?

A. Start aspirin 325 mg daily until return from Hong Kong.
B. Prescribe a single dose of subcutaneous injection of low-molecular-weight heparin immediately before embarking on flights to and from Hong Kong.
C. Recommend nothing except frequent ambulation and hydration on flights.
D. Do thrombophilia testing before flights.
E. Strongly recommend interrupting flights with layovers.

Answer: C A single episode of DVT in the past that was clearly related to a provoking event (i.e., pregnancy) does not require any special preventive measures before a long-haul flight in addition to the recommendation for ample hydration (with nonalcoholic beverages), frequent ambulation, and leg exercises. There is no evidence that prophylactic aspirin or low-molecular-weight heparin coverage for the flights would significantly reduce risk of flight-related VTE, even if a thrombophilia is found on testing in this situation. There is a very rough relationship between duration of long-haul air travel and risk of VTE, but the risk in any case is very small, and there is no evidence to suggest that it requires interruption of nonstop flights.

3. Which of the following statements is incorrect with regard to cancer-associated venous thromboembolism (VTE)?

A. VTE may precede detection of an occult malignant neoplasm by months or years.
B. Risk of cancer-associated VTE is further increased by surgery.
C. Risk of cancer-associated VTE is further increased by some chemotherapies.
D. VTE risk is increased with localized as well as with advanced metastatic cancers.
E. Risk of recurrent VTE is best prevented by use of warfarin for as long as the cancer is active.

Answer: E Although prophylactic anticoagulation is recommended in most cancer patients after one or more thrombotic events, low-molecular-weight heparin has been demonstrated to be superior to warfarin in this particular setting. VTE may be an indicator of an occult malignant neoplasm months or even years before its discovery (see algorithm in Figure 176-4). Major surgery clearly increases the risk of thrombosis in a patient with cancer. The same is true for certain antineoplastic agents, including antiangiogenic agents (thalidomide, lenalidomide, bevacizumab, sunitinib, sorafenib), all-*trans*-retinoic acid and arsenic trioxide (used for treatment of acute promyelocytic leukemia), L-asparaginase, cisplatinum, and methotrexate. Thrombotic complications are more frequent in cancer patients with advanced disease but can certainly also develop in those with localized tumors.

TRANSFUSION MEDICINE

LAWRENCE T. GOODNOUGH

DEVELOPMENT OF TRANSFUSION MEDICINE

Concepts in blood transfusion and blood conservation include blood safety, blood inventory, and blood costs. The formation of clinical practice guidelines in patient blood management is based on effective blood utilization, new strategies in blood conservation, including pharmacologic alternatives to blood transfusion, and patients' informed consent for transfusion. The broad-based multidisciplinary constituency of transfusion medicine includes blood collection facilities, hospital-based transfusion services, research laboratories, and the commercial sector.

Patient-focused blood management is described in the Circular of Information[1] as "a professional judgment based on clinical evaluation that determines the selection of components, dosage, rate of administration. ..." Patient blood management therefore encompasses an evidence-based medical and surgical approach with preventive strategies that are emphasized to identify, evaluate, and manage anemia (e.g., pharmacologic therapy and reduced iatrogenic blood losses from diagnostic testing); to optimize hemostasis (e.g., pharmacologic therapy and point-of-care testing); and to establish decision thresholds (e.g., guidelines) for the appropriate administration of blood therapy.[2,3]

The medical director of the blood bank is responsible for issues related to blood inventory and safety, through the oversight of laboratory policies and procedures and quality management (Fig. 177-1). Management of the transfusion service includes coordinating blood transfusion and blood conservation activities and serving as a consultant to clinicians whose patients are undergoing massive transfusions, apheresis, or transplantation or who are having difficulty finding compatible blood products. Finally, the transfusion medicine specialist supervises quality assurance to satisfy regulatory and accreditation requirements.[4]

Blood Availability

Blood centers must be able to supply blood in response to acute crises. Sporadic shortages of blood and blood products (e.g., packed red cells, platelet products, albumin, intravenous immunoglobulin, and clotting factor concentrates) are potentially life threatening. Such shortages have been attributed to disruptions in production, increasingly strict criteria for accepting donors, product recalls, increased use (including off-label use), and stockpiling or other market issues.

In the United States, the Department of Health and Human Services monitors sentinel community blood services and hospital transfusion services to track blood collection and transfusion activity. Blood transfusion and collection activities peaked in 1986 and then declined until 1994. However, blood transfusion and collection subsequently increased 8.0% in 1997, 10.2% in 1999, and an estimated 4% to 5% annually thereafter.

Within the American Red Cross, which supplies about half of all blood products in the United States, a 3- to 4-day supply of red blood cell products is typical, but some independent centers have higher reserves. Use of frozen red cells as a hedge against inventory shortages has generally not been practical because the shelf life of thawed units is only 24 hours; however, an automated, functionally closed system for the glycerolization and deglycerolization processes allows a 2-week post-thaw shelf life. With such a system, many blood centers and transfusion services can expand their available red cell inventories as reserves. After disasters—human or natural—on-hand blood supplies are adequate in the short term and can be rapidly mobilized over great distances. Because of the need to maintain reserves, blood collection must routinely surpass the anticipated need for blood transfusion.[5]

Red Blood Cell Transfusion

Worldwide, more than 75 million units of whole blood are estimated to be donated every year, with yearly transfusion of 24 million blood units in the United States.

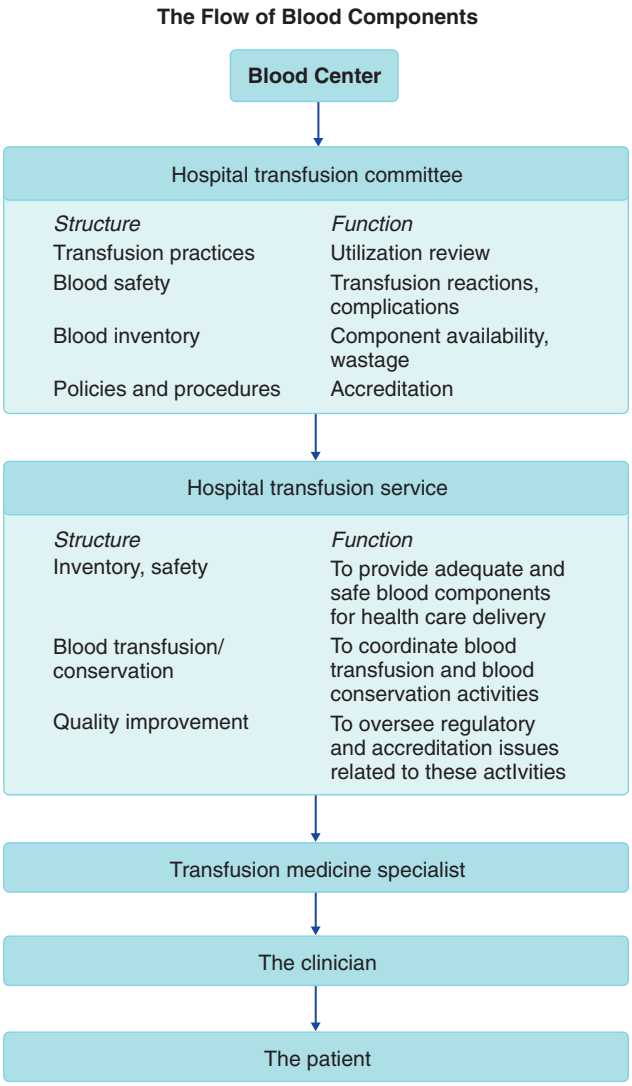

FIGURE 177-1. **A hospital's transfusion committee and transfusion service can help treating physicians manage the availability, safety, and use of blood products. (From Goodnough LT. What is a transfusion medicine specialist? *Transfusion.* 1999;39: 1031-1033.)**

Whole Blood

A unit of blood is collected as a donation of 450 mL ± 10% into a citrate anticoagulant that also contains phosphate and dextrose. The red cell and hemoglobin content is variable and dependent on the donor's hematocrit and the precise volume bled.

Whole blood is stored at 4 ± 2°C to diminish red cells' utilization of adenosine triphosphate and to preserve their viability, which should be at least 70% at the end of a shelf life of 35 days. After 10 days of storage, all predonation 2,3-diphosphoglycerate content in red cells is lost, but up to 50% is regenerated within 8 hours after transfusion.

In Western countries, whole blood is rarely used because within a few hours or days, some coagulation factors (especially factors V and VIII) and platelets decrease in quantity or lose viability. After a 7-day hold at 4°C, factor VIII levels fall to 0.32 ± 0.09 IU/mL, and factor V levels fall to 0.78 ± 0.15 IU/mL. At 4°C, platelets undergo a shape change from discoid to spherical that is irreversible after 8 hours, and their in vivo survival is reduced to 2 days.

Red Cell Components

Red cells are provided in various formats that differ with respect to the presence of additive solutions and the extent to which white cells are removed. Solutions that contain combinations of saline, adenine, phosphate, bicarbonate, glucose, and mannitol provide better red cell viability during storage and allow up to a 42-day shelf life. Red cells and red cells in additive solution can be used interchangeably, with the exception that red cells in additive solution are not recommended for exchange or massive transfusions in neonates.

Red cells should be refrigerated until the time of the transfusion because of the risk for bacterial proliferation within the pack at room temperature. Red cells that have been out of refrigeration for 30 minutes or longer cannot be returned to stock. A unit of red cells should be infused over a maximum period of 4 hours.

Irradiated Cellular Blood Components

Gamma-irradiated cellular blood components are used to prevent the occurrence of transfusion-associated graft-versus-host disease (see later).

Leukocyte-Reduced Blood Components

Blood components are depleted of leukocytes by means of filtration. A leukocyte-reduced component is defined as one with less than 5×10^6 residual white cells per liter, and 100% of tested units should meet this standard. Leukocyte removal should be performed while the cells are still intact by filtering the blood as soon as possible after collection.

Leukocyte reduction reduces the incidence of human leukocyte antigen (HLA) alloimmunization in multitransfused recipients, but immunization rates of 10 to 25% are still seen in women who have already been exposed to HLA alloantigens through previous pregnancy. Leukocyte reduction has less impact on refractoriness to random platelet donations because of the importance of nonimmune factors in the poor response to transfused platelets.

Leukocyte reduction also lowers the risk for nonhemolytic febrile reactions after the transfusion of red cells or platelets. Several studies suggest that leukocyte reduction has a beneficial impact on the rate of postoperative infection. The impact of leukocyte reduction on the incidence of transfusion-associated graft-versus-host disease is unknown.

Preventing Transmission of Cytomegalovirus

A small number of studies of prestorage leukocyte reduction have suggested its efficacy in preventing transfusion-transmitted cytomegalovirus (CMV) infection (Chapter 377), which occurs in 4% of cases, even with seronegative components. Prestorage leukocyte depletion reduces the infection rate to less than 1%, suggesting that this technology may be at least equivalent to serologic testing for CMV antibodies for the prevention of CMV transmission; however, CMV testing of leukocyte-reduced components continues to be performed by most transfusion services. Indications for CMV-seronegative components include transfusion in pregnancy, intrauterine transfusion, transfusions to neonates less than 37 weeks' gestation, transfusions to CMV-seronegative patients who are potential or actual recipients of allogeneic bone marrow or peripheral blood progenitor transplants when the donor is also CMV seronegative, and patients infected with human immunodeficiency virus (HIV).

Immunomodulatory Effects

Previous transfusion has an immunomodulatory benefit for the survival of renal allografts, even with the use of potent immunosuppressive drugs, although the exact mechanism of this benefit remains unknown. Retrospective studies suggest an adverse effect of transfusion on the rate of perioperative infections or recurrent cancers.

Typing and Crossmatching

Blood and blood components for transfusion must be compatible with the same blood type as the patient. Obtaining an accurate ABO/Rh grouping for a patient is the most significant serologic test performed before transfusion. When type-specific blood and components are unavailable or emergency circumstances do not allow their identification or use, type O-negative red cells should be used. Group O is the only choice for group O recipients and is the alternative choice for groups A, B, and AB.

Red cell antigens other than ABO and D are not routinely considered when selecting *donor* blood products for transfusion; the exception is when unexpected, clinically significant red cell antibodies are present in the patient, as determined by an antibody screen or previous identification. Red cell alloantibodies are produced by exposure to foreign red cell antigens through previous transfusion, pregnancy, or both. For an antibody to be considered clinically significant, it must be associated with a hemolytic transfusion reaction or decreased survival of transfused incompatible red cells. Most of the clinically significant antibodies are optimally reactive at 37°C or are detected by the antiglobulin test. If an antibody screen is negative in the *recipient,* the probability is greater than 99% that an ABO and Rh crossmatch will also be compatible. If no unexpected, clinically significant antibodies are detected and there is no record of their previous detection, only serologic testing for

ABO incompatibility is required (i.e., antiglobulin testing is not required when the crossmatch is performed).

Red Blood Cell Transfusion

If a transfusion is appropriate, a benefit should occur. In a large study of Jehovah's Witnesses (whose religious beliefs preclude the use of blood transfusion), the risk for death was higher in surgical patients with cardiovascular disease than in those without. A follow-up analysis of a subset of these patients reported that the odds of death in patients with a postoperative hemoglobin level less than 7 g/dL increased 2.5 times for each 1 gram decrease in the hemoglobin level; although no deaths occurred in 98 patients with postoperative levels of 7.1 to 8.0 g/dL, 34.4% of 32 patients with postoperative levels of 4.1 to 5.0 g/dL died. These data suggest that in surgery-induced anemia, survival is improved if blood transfusion is administered to maintain the hemoglobin concentration at greater than 7 g/dL. Data from randomized trials consistently support more restrictive policies for the transfusion of red blood cells and platelets (Table 177-1).

In a large, randomized trial of elderly patients undergoing repair of hip fracture, transfusion at a hemoglobin threshold of 10 g/dL was no better than transfusion for symptoms of anemia or at physician discretion for a hemoglobin level of less than 8 g/dL. In a multi-institutional study, 418 critical care patients received red cell transfusions when their hemoglobin levels dropped below 7 g/dL and had their levels maintained between 7 and 9 g/dL, whereas another 420 patients received transfusions when their hemoglobin levels dropped below 10 g/dL and had their levels maintained between 10 and 12 g/dL. Thirty-day mortality rates were not significantly different in the two groups, suggesting that a transfusion threshold as low as 7 g/dL may be as safe as a higher threshold of 10 g/dL in critically ill patients. A follow-up analysis found that the more restrictive strategy of red blood cell transfusion also appeared to be safe in most patients with cardiovascular disease.

A retrospective study analyzed the relationships among anemia, blood transfusion, and mortality in nearly 80,000 patients older than 65 years hospitalized for acute myocardial infarction. Anemia, defined as a hematocrit below 39%, was present on hospital admission in 44% of patients and was 33% or less in 10% of patients; blood transfusion in patients with hematocrit levels lower than 33% at admission was associated with a significantly lower 30-day mortality. On the basis of this study, transfusion to maintain hematocrit levels above 30% has been recommended in patients with acute myocardial infarction. In patients with heart failure, transfusion to maintain a hemoglobin level above 10 g/dL appears to improve outcomes. Among patients undergoing cardiac surgery, a restrictive perioperative transfusion strategy is as good as a more liberal strategy.

Clinical Practice Guidelines

The number of published clinical practice guidelines for red blood cell, platelet, and plasma transfusions attests to the increasing interest and importance of appropriate blood utilization by professional societies and health care institutions (Table 177-2). The guidelines acknowledge the necessity of considering patient covariables or other patient-specific criteria for making transfusion decisions. Among published guidelines, it is generally agreed that transfusion is not of benefit when the hemoglobin is greater than 10 g/dL but may be beneficial when the hemoglobin is less than 6 to 7 g/dL.[6] The selection of a discrete hemoglobin as a trigger for transfusion has been controversial. For example, the initial guidelines by the American Society of Anesthesiology (ASA) in 1996 identified a hemoglobin level of less than 6 g/dL as a transfusion trigger for acute blood loss, whereas the updated ASA guidelines in 2006 noted that "although multiple trials have evaluated transfusion thresholds on patient outcome, the literature is insufficient to define a transfusion trigger in surgical patients with substantial blood loss." Three guidelines have specified a hemoglobin threshold for patients with acute bleeding only, whereas the concept of an empirical hemoglobin concentration as a transfusion trigger has been refuted by a number of other published clinical practice guidelines. Arbitrary laboratory values are inadequate to define when red blood cell transfusions are appropriate, so that each patient must be evaluated individually and patient-specific anemia management strategies employed. Implementing real-time clinical decision support and best practice alerts into physician order entry for blood transfusions has resulted in improved blood utilization and improved patients outcomes.

Platelet Transfusion

The use of intensive chemotherapy regimens and bone marrow or stem cell transplantation has increased the demand for platelet products, particularly in patients with severe thrombocytopenia or bleeding complications. The use of apheresis platelet transfusions (i.e., a platelet unit collected from a dedicated donor through an apheresis procedure) has increased substantially, driven by the need for platelet inventories to support cardiac surgery, oncology, and stem cell transplantation programs. Emerging issues in platelet transfusion therapy include re-evaluation of the platelet threshold for prophylactic transfusion and modification of the dose of platelet transfusions. The problem

of platelet alloimmunization and the platelet transfusion–refractory patient is discussed in detail in Chapter 177.

Threshold for Platelet Transfusion

The appropriate threshold for prophylactic platelet transfusion depends on the clinical situation (Fig. 177-2). Prospective, randomized studies indicate that a platelet transfusion threshold of 10,000 cells/μL is as safe and effective as higher thresholds in patients undergoing chemotherapy or stem cell transplantation.

For consumptive thrombocytopenias such as disseminated intravascular coagulation (Chapter 175), platelet therapy is supportive but not effective until the underlying cause is treated. Platelet transfusions are generally not indicated in patients with idiopathic thrombocytopenic purpura or the thrombotic microangiopathies, including thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (Chapter 172).

Platelet Dose

The AABB standards require that 75% of apheresis platelet products contain more than 3×10^{11} platelets; however, no consensus exists for a standardized platelet dose, and clinical trials have used a broad range of doses. In general, higher platelet doses result in greater incremental increases in the platelet count and prolonged time to the next transfusion; however, the estimated platelet half-life is similar, and there are no other differences in outcomes.

Low-dose platelet therapy (i.e., <1 platelet unit) may be more beneficial in thrombocytopenic patients who are receiving prophylactic platelet transfusions. The fixed platelet requirement for hemostasis is estimated at 7100/μL^3/day, and platelet needs above this threshold are mainly a result of platelet consumption. For patients who become thrombocytopenic as a result of myeloablative therapy, platelet survival decreases with increasing severity of thrombocytopenia. A trial of prophylactic platelet transfusions in patients with hypoproliferative thrombocytopenia found that low doses (1.1×10^{11} per square meter) of platelets led to a decreased number of transfusions but an increased number of platelets transfused (and donor exposures). At doses between 1.1×10^{11} and 4.4×10^4 platelets per square meter, no effect on the incidence of bleeding was demonstrated.

Plasma Transfusion

Plasma therapy provides a source of clotting factors for patients with inherited or acquired coagulation disorders. Patients with inherited disorders such as hemophilia (Chapter 174) or von Willebrand disease (Chapter 173) are now treated primarily with clotting factor concentrates, which are blood derivatives from processed and treated commercial lots from pooled donors. For patients with acquired coagulopathies, there is little systematically derived, evidence-based guidance to inform plasma transfusion decisions. For patients with mild prolongation of coagulation assays such as prothrombin time and partial thromboplastin time (Chapter 171), plasma therapy has little or no value in prophylaxis for invasive procedures. Plasma therapy is indicated in patients undergoing massive hemorrhage (trauma, postpartum hemorrhage, or gastrointestinal bleeding) or for emergent reversal of warfarin-associated coagulopathy (Chapter 38), such as in patients with intracranial hemorrhage.[7] Recommended dosage in these settings is 15 to 30 mL/kg.

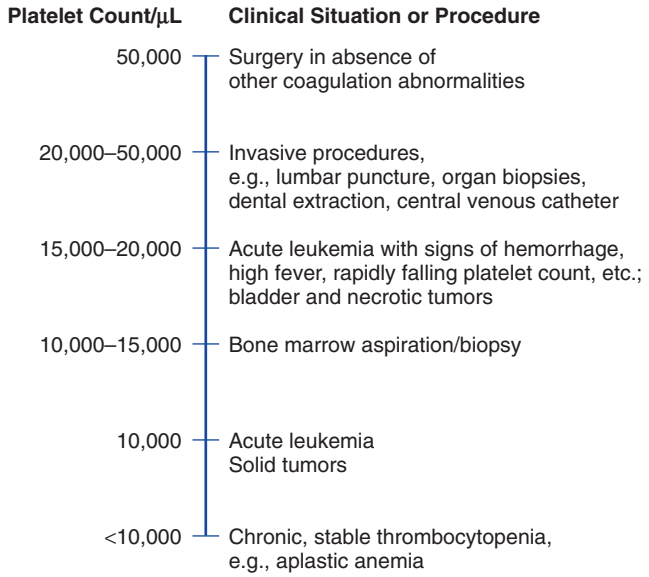

FIGURE 177-2. Threshold for providing platelet transfusions in thrombocytopenic patients.

BLOOD SAFETY

Adverse reactions associated with transfusion are listed in Table 177-3.

Errors in Transfusion Medicine

The mistransfusion rate (blood transfused to other than the intended recipient) is about 1 in 14,000 to 28,000 units. About two thirds of the errors occur in the clinical arena (patient misidentification and/or specimen mislabeling at the time of drawing blood for type and screen/crossmatch, incorrect identification of the recipient of the blood unit, and failure to recognize a transfusion reaction). Implementing a two-blood-specimen requirement to verify a patient's blood type before transfusion can minimize the issuing of mismatched blood products owing to wrong blood in the tube specimens. About

half of mistransfusions are ABO incompatible, and about 10% of these are fatal. The frequency of death as a result of ABO error can therefore be estimated at approximately 1 per 600,000 blood units, a risk that is higher than the current risks for transmitting HIV or hepatitis C virus (see later).

Transfusion Reactions

Acute Hemolytic Transfusion Reaction

An acute hemolytic transfusion reaction is most commonly defined as hemolysis of donor red cells within 25 hours of transfusion by preformed alloantibodies in the recipient's circulation. Life-threatening acute hemolytic transfusion reactions are most commonly due to ABO-incompatible blood being transfused to a recipient with naturally occurring ABO alloantibodies (anti-A, anti-B, anti-A, B). Clerical errors (mislabeling blood or misidentifying patients) account for 80% of such reactions.

Signs and symptoms of an acute intravascular hemolytic transfusion reaction may develop when as little as 10 to 15 mL of ABO-incompatible blood has been infused. Fever, which is the most common initial manifestation, is frequently accompanied by chills. The patient may complain of a general sense of anxiety or uneasiness or pain at the infusion site or in the back or chest (or both). The most serious sequela is acute renal failure. In an unconscious or anesthetized patient, diffuse bleeding at the surgical site may be the first indication of intravascular hemolysis and may be accompanied by hemoglobinuria and hypotension.

Treatment begins with immediate cessation of the transfusion. The risk for renal failure may be reduced by the administration of crystalloid fluids, including sodium bicarbonate (250 to 500 mg intravenously over a 1- to 4-hour period), to maintain urine pH at 7.0 and by diuresis with 20% mannitol (100 mL/m^2 in 30 to 60 minutes, followed by 30 mL/m^2/hour for 12 hours) or furosemide (40 to 120 mg intravenously).

Febrile Nonhemolytic Transfusion Reactions

Febrile nonhemolytic transfusion reactions are common and are estimated to occur in 0.5% of all red cell transfusions and up to 15% of platelet transfusions. A febrile transfusion reaction is defined as a rise in temperature greater than 1°C, which may be accompanied by chills, rigor, or both.

These reactions are thought to be due to a reaction of HLA or leukocyte-specific antigens on transfused lymphocytes, granulocytes, or platelets in the donor unit with antibodies in previously alloimmunized recipients. Multiply transfused individuals and multiparous women are most likely to experience this type of transfusion reaction. Febrile nonhemolytic transfusion reactions, especially those associated with platelet transfusions, may be caused by the infusion of biologic response modifiers, such as cytokines, that have accumulated in the platelet concentrate during storage.

Symptoms may occur during the transfusion or may not manifest until 1 to 2 hours after its completion. The diagnosis of a febrile nonhemolytic transfusion reaction is generally made by excluding other causes of fever (e.g., underlying patient condition, bacterial contamination of the unit, acute hemolytic transfusion reaction).

Febrile nonhemolytic transfusion reactions in susceptible populations can often be prevented by administering antipyretics before the transfusion of blood components. Prestorage leukocyte reduction is recommended to prevent reactions resulting from the accumulation of cytokines during storage.

Allergic Reactions

Allergic reactions can be mild, moderate, or life threatening and are associated with the amount of plasma transfused. From 1 to 5% of all blood transfusion recipients experience mild allergic reactions.

Anaphylactic transfusion reactions are sometimes associated with antibodies to immunoglobulin (Ig) A, which are common and have an incidence of approximately 1 in 700 individuals. However, the incidence of anaphylactic transfusion reactions is much lower—1 in 20,000 to 50,000.

Urticarial reactions are not well understood but are believed to be an interaction between antibodies in the recipient's plasma and plasma proteins in the donor blood. There is usually no specific identifiable antigen to which the patient is reacting. Symptoms are generally mild and include localized urticaria, erythema, and itching.

Anaphylactic or anaphylactoid reactions, which can occur after the transfusion of only a few milliliters of blood or plasma, include skin flushing, nausea, abdominal cramps, vomiting, diarrhea, laryngeal edema, hypotension, shock, cardiac arrhythmia, cardiac arrest, and loss of consciousness. Fever is notably absent. In some cases, there may be symptoms indicative of airway involvement, such as hoarseness, wheezing, dyspnea, and substernal pain. Management begins with discontinuation of the transfusion. Treatment is diphenhydramine (25 to 50 mg intravenously), but more severe episodes may require aggressive therapy (Chapters 252 and 253).

Patients who experience recurrent allergic or urticarial reactions can be treated with antihistamines and/or histamine-2 receptor antagonists (H_2 blockers) before transfusion. Washed red blood cells may be indicated for patients who experience repeated severe urticarial reactions. Severe allergic or urticarial reactions may require treatment with corticosteroids.[8]

Bacterial Contamination

Bacterial contamination may be introduced into a unit of blood through skin contaminants during venipuncture or from donors with asymptomatic bacteremia. Multiplication of bacteria can occur in blood and blood components stored at refrigerated temperatures but is more likely to occur in platelets stored at room temperature.

Bacterial contamination of red cells is most often due to *Yersinia enterocolitica,* followed by *Serratia liquefaciens,* whereas platelets are most often contaminated with *Staphylococcus* and Enterobacteriaceae. The incidence of bacterial contamination of red cells has been estimated to be 1 in 60,000, with an overall fatality rate of 1 in 1 million. The incidence of bacterial contamination of platelets was estimated to be 1 in 5000 before the initiation of bacterial detection systems in 2004, but it is now estimated to be 50% lower (1 in 10,000).

Recipients of units with low bacterial counts may have relatively mild symptoms such as fever and chills, but those receiving units with high bacterial counts may have severe or fatal reactions. Clinically, the patient may experience high fever, shock, hemoglobinuria, renal failure, and disseminated intravascular coagulation. The blood transfusion must be stopped immediately, the patient's blood and any untransfused blood must be cultured, and broad-spectrum antibiotics (Chapter 108) should be started.

Circulatory Overload

Acute pulmonary edema, caused by the circulatory system's inability to handle an increased fluid volume, can occur in any patient who is transfused too rapidly. Although the true frequency of this type of transfusion reaction is unknown, prospective surveillance studies estimate that 8% of patients have transfusion-associated circulatory overload (TACO). Susceptible populations are primarily very young patients, elderly patients, and patients with a small total blood volume or cardiopulmonary disease.[9,10] Treatment is the same as for heart failure (Chapter 59).

Delayed Reactions

A delayed hemolytic transfusion reaction generally occurs 3 to 7 days after transfusion of the implicated unit. Hemolysis is usually extravascular, and red cells are destroyed in the recipient's circulation by antibody produced as a result of an immune response to the transfusion. These reactions are most commonly due to an anamnestic response (secondary exposure to a red cell antigen) in a patient with a negative antibody screen despite a low level of antibody as a result of previous exposure to a foreign red cell antigen through

either pregnancy or transfusion. Exposure to the same antigen a second time may cause IgG antibody to reappear within hours or days of the transfusion. This subsequent exposure to the antigen produces an anamnestic antibody response, resulting in increased production of IgG antibodies that are capable of reacting with any transfused cells present.

In most cases, anamnestic production of antibody does not result in acute hemolysis, but red cell destruction does occur between 3 days and 2 weeks after the transfusion. Patients are generally asymptomatic, and hemolysis may be noted only by a more rapid decline than usual in the patient's hemoglobin level or by an absence of the expected rise in hemoglobin. Fever, the most common initial symptom, is occasionally noted, along with jaundice; renal failure is rare. Prednisone (1 to 2 mg/kg/day) is indicated for more severe reactions.

Transfusion-Associated Graft-versus-Host Disease

Transfusion-associated graft-versus-host disease results from the transfusion of immunologically competent lymphocytes into an immunologically incompetent host. An individual's risk depends on whether the recipient is immunocompromised (and to what degree), the degree of HLA similarity between the transfusion donor and recipient, and the number of transfused T lymphocytes capable of multiplying and engrafting. The engrafted lymphocytes mount an immunologic response against the recipient's tissue, resulting in pancytopenia with bleeding and infectious complications. Symptoms usually appear within 12 days of transfusion. Transfusion-associated graft-versus-host disease is rare, but it is fatal in approximately 90% of affected patients.[11]

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI; Chapter 94) is an acute respiratory distress syndrome (Chapter 104) that occurs within 6 hours after transfusion and is characterized by dyspnea and hypoxia secondary to noncardiogenic pulmonary edema.[12,13] Although the actual incidence is almost certainly underreported, the estimated frequency is approximately 1 in 8000 transfusions. In a prospective nested case-control study, 16 of 668 (2.4%) of cardiac surgery patients developed TRALI, suggesting that the incidence of TRALI is particularly high in this population. In approximately 50% of cases, blood donor antibodies with HLA or neutrophil antigenic specificity can be shown to react with the recipient's leukocytes, leading to increased permeability of the pulmonary microcirculation.

Most recently, reactive lipid products from donor blood cell membranes that arise during the storage of blood products have been implicated in the pathophysiology of TRALI. Such substances are capable of neutrophil priming, with subsequent damage to the pulmonary-capillary endothelium of the recipient, particularly in patients who receive massive transfusions during cardiac surgery or for trauma or in patients receiving chemotherapy for malignancy. In each of these settings, the true incidence of TRALI may be underreported because the findings may be blamed on the underlying disease process or the surgical procedure. Similar to other causes of acute respiratory distress syndrome, therapy is supportive, and 90% of patients recover. Ongoing initiatives to reduce TRALI risks include recruiting male plasma donors or female donors with no prior history of pregnancy and screening female apheresis platelet donors for HLA antibodies and limiting donation to those who are HLA antibody negative.

Transmission of Blood Pathogens

Categories of transfusion-transmitted agents,[14] as well as those currently screened, are listed in Table 177-4. The implementation of nucleic acid testing of multiple minipools (donation samples, test well) from blood donations has markedly reduced the transmission of HIV and hepatitis C virus during the infectious window period. Current estimates of the risk per unit of blood are 1 in 1.4 million to 2.4 million for HIV and 1 in 872,000 to 1.7 million for hepatitis C virus (Fig 177-3). Restrictive transfusion strategies also reduce health care-associated infections.

Only 43% of the World Health Organization's 191 member states test blood for HIV, hepatitis C virus, and hepatitis B virus, so at least 13 million units of blood donated every year are not tested for these transmissible viruses. In the poorest countries, the cost of testing ($40 to $50 per blood

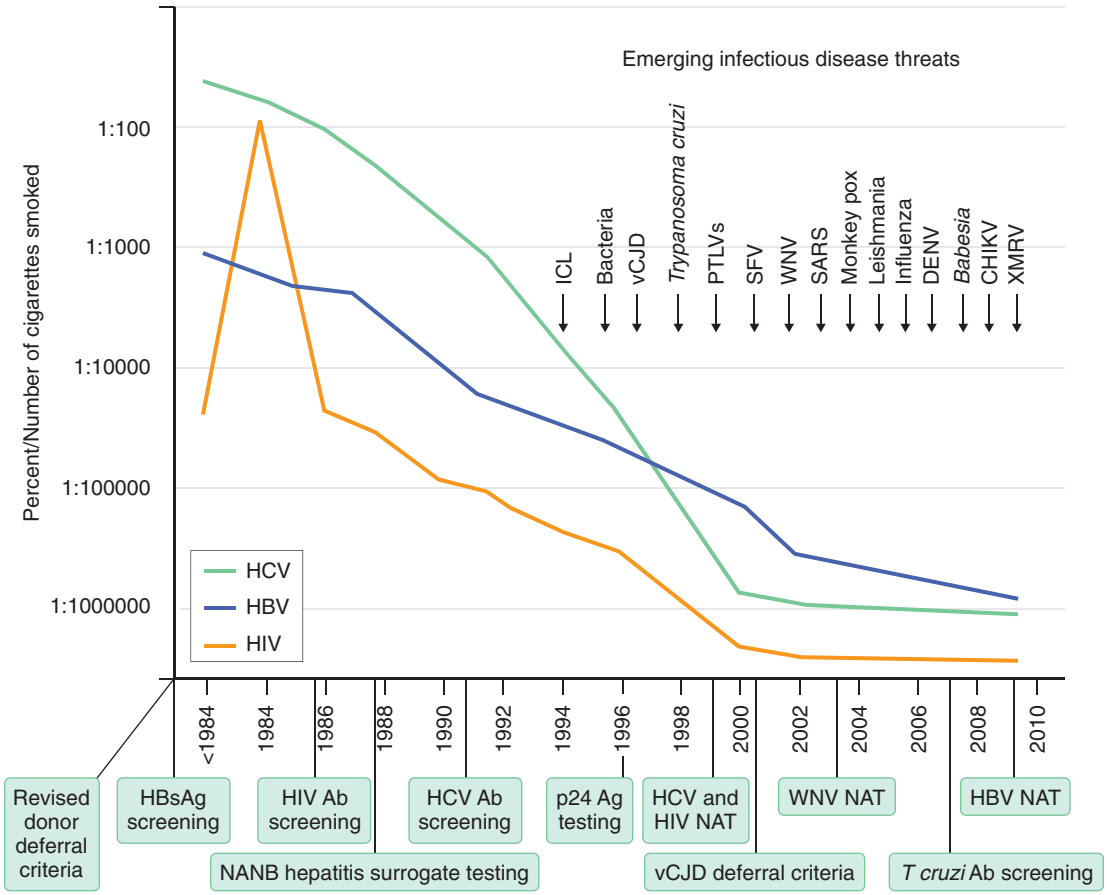

FIGURE 177-3. Risks for major transfusion-transmitted viruses (TTVs) linked to interventions, and accelerating rate of emerging infectious diseases (EIDs) of concern to blood safety. Evolution of the risks for transmission by blood transfusion of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). Major interventions to reduce risks are indicated below the time line on the *x*-axis. donation) is prohibitive. Every year, unsafe transfusions are estimated to account for 8 million to 16 million hepatitis B infections, 2.3 million to 4.7 million hepatitis C infections, and 80,000 to 160,000 HIV infections.

EMERGING ISSUES AND EVOLVING TECHNOLOGIES

Problems related to blood component storage have long been known, such as depletion of 2,3-diphosphoglycerate in red cell units during storage at 4°C for longer than 35 to 42 days. Some evidence suggests that in patients undergoing coronary artery bypass surgery, transfusion of older red cells is associated with a significantly increased risk for postoperative complications, as well as reduced survival. A prospective, randomized multicenter trial comparing the transfusion of blood less than 10 days old versus blood 21 days or older in adult patients undergoing coronary artery bypass surgery is currently underway in the United States. Erythropoiesis-stimulating agents, including recombinant human erythropoietin, modified erythropoietin molecules, and erythropoietin receptor agonists, along with artificial oxygen carriers, can potentially decrease the need for red cell transfusion.[15] It is important that oversight of these biotechnology products and other specialized blood products (e.g., solvent- or detergent-treated plasma, leukoreduced blood products, irradiated blood components, cytomegalovirus-negative blood components) be placed under the auspices the transfusion medicine committee. Otherwise, promotion of such products by the commercial sector directly to consumers undermines both institutional oversight and evidence-based rationales for their use.

REVIEW QUESTIONS

1. A 65-year-old, generally healthy man is transfused with 2 units of packed red cells in the recovery room after uncomplicated hip replacement surgery. Two hours later, he complains of acute onset of shortness of breath, and he is found to be hypertensive, cyanotic, and hypoxic. He is afebrile. Blood counts are normal. Chest radiograph shows bilateral opacities. A bedside echocardiogram is normal, as is the serum brain natriuretic peptide level. He is quickly transferred to the intensive care unit for imminent intubation and ventilatory support. Which of the following is the most likely diagnosis?

A. Transfusion-associated graft-versus-host disease
B. Bacterial contamination of the blood products
C. Delayed transfusion reaction
D. Transfusion-associated circulatory overload (TACO)
E. Transfusion-related acute lung injury (TRALI)

Answer: E TRALI is now the leading cause of transfusion-related mortality. It typically presents as this case, with the patient becoming acutely symptomatic after having been transfused with any blood product within the previous 3 to 6 hours. Transfusion-associated graft-versus-host disease results from the transfusion of immunologically competent lymphocytes into an immunocompromised host, which this patient is not, and leads mainly to pancytopenia. A delayed transfusion reaction occurs much later, usually 3 to 7 days after the transfusion, and leads to hemolysis of red cells in the recipient by antibody produced as a result of the immune response to the transfusion. TACO can be difficult to distinguish from TRALI, but in this case, the normal echocardiogram and serum brain natriuretic peptide would argue against that (though not rule it out). Finally, septic transfusions are typically accompanied by hypotension and fever, which this patient did not have. Bacterial contamination of blood products occurs much more frequently with the transfusion of platelets, which are stored at room temperature: this patient received packed red cells. Very importantly, however, septic transfusions can mimic or even coexist with TRALI and, whenever there is any doubt, should be aggressively diagnosed and treated as such. The management of TRALI by itself is largely supportive.

2. Each of the following patients needs transfusion of 2 units of pack red cells for various reasons. Which one of them requires cytomegalovirus (CMV)-negative blood?

A. 30-year-old woman in the third trimester of an uncomplicated pregnancy
B. 50-year-old man in remission from acute myelogenous leukemia
C. 87-year-old woman hospitalized for exacerbation of chronic heart failure
D. 45-year-old woman with systemic lupus erythematosus, maintained on prednisone
E. 55-year-old man, homeless and alcoholic, admitted with upper gastrointestinal bleed

Answer: A Blood product recipients who are CMV naïve (anti–CMV antibody negative) and have profoundly impaired immune systems are at increased risk for primary CMV infection when they receive CMV-positive blood products. CMV-negative blood products are required for pregnant mothers to prevent congenital CMV infection in the fetus. Profoundly immunocompromised individuals would include those receiving allogeneic or peripheral stem cell transplantations and untreated AIDS patients. In general, most institutions do not screen for CMV-negative blood products for patients needing transfusion who are receiving steroids or chemotherapy. Other indications in recipients for having CMV-seronegative blood transfused are intrauterine transfusion and neonates less than 37 weeks' gestation. Prestorage leukocyte depletion of blood products (red cells, platelets) significantly reduces the infection risk, but even for those products, most blood banks will still do CMV testing. (See Preventing Transmission of Cytomegalovirus.)

3. Which of the following statements regarding delayed transfusion reactions is correct?

A. Delayed hemolytic transfusion reactions typically occur 48 to 72 hours after transfusion of the implicated unit.
B. Delayed transfusion reactions mostly occur in patients who have very low titers of preexisting antibodies from previous transfusions or through pregnancy and therefore had a negative antibody screen before transfusion; they are thus anamnestic responses.
C. Most patients present with fevers, chills, and back and flank pain.
D. Steroids should be avoided in the management of delayed transfusion reactions.
E. The hemolysis of delayed transfusion reactions is mostly intravascular.

Answer: B Delayed hemolytic transfusions (1) characteristically occur 3 to 7 days after transfusion of the implicated unit; (2) typically present without symptoms, with just a more rapid decline than usual in the recipient's hemoglobin (or failure to increase the hemoglobin after transfusion) accompanied by hemolytic chemistries including hyperbilirubinemia; and (3) should be treated with prednisone (1 to 2 mg/k/day) in more severe reactions. The hemolysis in delayed transfusion reactions is mostly extravascular and results from an anamnestic response in recipients previously exposed to the antigen(s) through blood transfusions or pregnancy but having sufficiently low baseline titers of antibody to escape detection by routine screening. (See Delayed Reactions.)

HEMATOPOIETIC STEM CELL TRANSPLANTATION

ARMAND KEATING AND MICHAEL R. BISHOP

INTRODUCTION

Hematopoietic stem cell transplantation (HSCT) is a procedure by which hematopoietic stem cells (HSCs) are infused intravenously to restore hematopoiesis and immune function after high-dose chemotherapy with or without radiation therapy. Stem cells used for HSCT are of hematopoietic origin, in contrast to the more primitive pluripotent stem cells (embryonic stem cells), which are of growing interest for use in regenerative therapy because of their ability to differentiate into virtually any somatic cell. The term *HSCT* has replaced the term *bone marrow transplantation* because HSCs can be derived from a variety of sources, including bone marrow, the peripheral blood, and umbilical cord blood. In addition to treating blood cancers and other malignancies, HSCT can also provide clinically significant enzyme replacement. HSCs can give rise to all blood elements and may be genetically modified to enhance their function. Furthermore, HSCs may be manipulated ex vivo and used in the burgeoning field of regenerative medicine. Taken together, HSCT is a major component and foundation of the broader field of cellular therapy, which many believe forms the "third pillar" of medicine, complementing small molecule drugs and biologic agents.

The clinical development and application of HSCT originated in the observations of the severe myelosuppressive effects of radiation among survivors of the Hiroshima and Nagasaki nuclear bombings. There were intensive research efforts over the subsequent decade to develop methods to protect against and reverse the myelosuppressive effects of radiation, including the infusion of bone marrow. These efforts were primarily hindered by graft rejection. Among animals that did not reject their marrow grafts, a syndrome of weight loss, alopecia, diarrhea, and eventually death, referred to as "runting" disease, was commonly observed. This syndrome is now referred to clinically as graft-versus-host disease (GVHD) and is discussed in more detail later in this chapter. The subsequent determination and understanding of the major histocompatibility complex (MHC) and human leukocyte antigens (HLA), the major determinants of graft rejection, and of GVHD, enabled HSCT to be clinically applied. The first successful reports of clinical bone marrow transplantation, used for patients with severe combined immunodeficiency disorders, severe aplastic anemia, and advanced acute leukemias, occurred in the late 1960s and early 1970s. Subsequently in the 1980s, it was demonstrated that the administration of high-dose chemotherapy followed by HSCs obtained from the bone marrow or peripheral blood of the patients themselves improved outcomes and survival of patients with a

variety of hematologic and solid tumors. HSCT is a standard treatment option for many malignancies, immunodeficiency states, metabolic disorders (e.g., Hurler syndrome), and defective hematopoietic states (e.g., severe aplastic anemia, thalassemia).

The three types of HSCT are allogeneic, autologous, and syngeneic. HSCs obtained from someone other than the patient are referred to as allogeneic, while HSCs obtained from the patient are referred to as autologous. In syngeneic HSCT, patients receive HSCs from an identical twin, a relatively rare event (<1%). The determination of the type of HSCT that a patient receives (i.e., allogeneic vs. syngeneic vs. autologous) is based on the disease to be treated, disease state (e.g., initial treatment vs. treatment of recurrent disease), the urgency to treat with HSCT, availability of a donor, and urgency in obtaining a donor.

As previously mentioned, HSCs may be obtained from the bone marrow, the peripheral blood, and umbilical cord blood. HSCs can be obtained directly from bone marrow by serial aspirations from the posterior iliac crests while the patient is under general anesthesia. Alternatively, HSCs can be obtained from peripheral blood after stimulation of the donor with hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and plerixafor followed by leukapheresis. HSCs from bone marrow are used in both autologous and allogeneic HSCT, although less frequently than in the past. Peripheral blood HSCs are currently used in approximately 90% of autologous HSCT and in approximately 70% of allogeneic HSCT. The greater use of peripheral blood HSCs is related to their relative ease of procurement and moderate advantage in the rate of hematopoietic recovery after infusion compared with HSCs derived from bone marrow, but the outcomes of the two approaches are similar. The HSCs may be infused fresh or cryopreserved. Cryopreservation involves processing the cells in culture medium containing dimethyl sulfoxide (DMSO), placing them in specialized plastic bags, and then storing the cells indefinitely in the vapor phase of liquid nitrogen until needed. Cord blood HSCs are collected at the time of delivery, cryopreserved, and stored. For allogeneic donation, HSCs may also be infused on the day of collection. For autologous donation, HSCs are always cryopreserved.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

The distinctive characteristics of allogeneic HSCT are that the stem cell graft is free of contamination by malignant cells and contains lymphocytes, primarily T and natural killer (NK) cells that are capable of mediating an immunologic reaction against foreign antigens.[1] This latter characteristic can be a major advantage if the immunologic response is directed against malignant cells, referred to as the graft-versus-leukemia or graft-versus-tumor effect, which can potentially eradicate disease and reduce the chance of disease relapse. However, if the immunologic response is directed against antigens present on normal tissues, the graft-versus-host response, the destruction of normal organs can result and is described clinically as GVHD. The risk of both graft rejection (host-versus-graft reaction) and GVHD rises with the degree of HLA disparity between the donor and the recipient.

The graft-versus-leukemia effect first was recognized in animal models and subsequently was noted among patients undergoing allogeneic HSCT for acute and chronic leukemias. The clinical importance of the role that immunocompetent donor T cells play in mediating a graft-versus-leukemia effect was provided by initial observations of increased rates of relapse in patients who received allogeneic stem cell grafts from which T cells had been removed (T-cell depletion), an inverse correlation between relapse and severity of GVHD, and increased rates of relapse after syngeneic or autologous HSCT using the same myeloablative conditioning regimen. These data suggested that T cells within the allograft were involved directly in eradicating leukemia. Finally, the most compelling evidence for the importance of T cells mediating the graft-versus-leukemia effect arose from the clinical observation that infusion of allogeneic T cells alone, termed a donor lymphocyte infusion (DLI), at a time remote from the transplant conditioning regimen, successfully eradicated leukemia which had persisted or recurred after allogeneic HSCT. However, there is wide variability in the clinical effectiveness of the graft-versus-leukemia effect against different malignancies after allogeneic HSCT.

Sources of Donor Hematopoietic Stem Cells

As previously emphasized, HSCs are obtained from a donor other than the recipient or an identical twin in allogeneic HSCT. Because of the immunologic barriers that can result in graft rejection and GVHD, allogeneic HSCT requires that the donor and the recipient share key genes. The most important of these are HLA, which are derived from the MHC located on chromosome 6. The most important HLAs include HLA-DR, HLA-DP, and HLA-DQ loci. A single set of MHC alleles, described as a haplotype, is inherited from each parent, resulting in HLA pairs. A clinical "match" means that HLA in the donor match perfectly with those in the patient.

The choice of donor for an allogeneic HSCT takes into account several factors, including the patient's disease, disease state, and urgency in obtaining a donor. A fully HLA-matched sibling is the preferred donor source because of the sibling's availability and the observation that the risks of graft rejection and GVHD are lowest with these allogeneic HSCs. The probability of having a HLA match from a sibling is approximately 25% and increases with the number of siblings within a specific family. The probability can be estimated using the following formula: chance of having an HLA-matched sibling = $1 - (0.75)^n$, where n is the number of potential sibling donors. There is approximately a 1% chance of a crossover event (i.e., genetic material switched between chromosomes during meiosis), primarily between the HLA-A and the HLA-B loci. The clinical outcomes for allogeneic HSCT using a sibling with a single HLA mismatch are similar to those with a fully HLA-matched sibling.

For patients who lack an HLA-identical sibling donor, the alternative sources for allogeneic HSCs include a fully HLA-matched volunteer unrelated donor, a fully or partially HLA-matched cord blood unit, or a partially HLA-matched first-degree family member. The genes encoding HLAs are numerous, and the odds that any two unrelated individuals are HLA identical for main loci are less than one in 10,000. More than 22 million volunteer donors are available worldwide; a donor can be found for about 50% of patients for whom a search is initiated. The probability of identifying a suitable volunteer is highly dependent upon race because of varying degrees of HLA diversity. For example, for persons of northern European extraction, the probability of a match can be as high as 90%. It usually takes about 2 to 4 months to locate an unrelated donor, which may be too long for some patients with rapidly progressive malignancies. When a suitable volunteer is not available or a donor is needed more urgently, HSCs from alternative donors can be considered, including partially HLA-matched ("haploidentical") relatives or umbilical cord blood. Haploidentical HSCs are readily available but have increased risks of graft rejection and GVHD. These risks can be reduced by T-cell depletion methods but lead to delayed immune reconstitution and competency posttransplant, leading to increased risks of infection and disease recurrence. Umbilical cord blood HSCs are taken at the time of delivery, stored in cord blood banks, and are readily available when needed.[2] Because of the unique immature biology of lymphocytes in umbilical cord blood, these transplants are associated with less GVHD; consequently, the HLA matching requirements are less strict, and two or three HLA mismatches may be acceptable. However, the small volume (50-150 mL) of cord blood that can be collected results in a limited number of HSCs, which often prohibits their use in adults because successful engraftment correlates with the number of HSCs per patient body weight. The limitation of cell dose can be overcome by the use of more than one cord blood unit. Cord blood HSCs are associated with delayed times to engraftment and immune reconstitution leading to an increased rate of infection. The other significant disadvantage is that after the cord blood unit is used, there is no possibility to obtain additional cells in the event of graft failure or if a DLI is required.

Conditioning and Preparation of Recipient

After an allogeneic stem cell source has been identified, the recipient patients then receive regimens with the intent of "conditioning" or "preparing" them for the infusion of HSCs (Fig. 178-1). These conditioning regimens are designed to be adequately immunosuppressive to overcome the host-versus-graft reaction and permit engraftment. They also are designed for tumor eradication in patients with an underlying malignancy. Most conditioning regimens use a combination of radiation and chemotherapy. Doses of total body and total lymphoid irradiation vary between 200 and 1440 cGy. The most commonly used chemotherapy agents in conditioning regimens are alkylating agents (e.g., cyclophosphamide). Conditioning regimens also may contain monoclonal antibodies that target T cells (e.g., alemtuzumab). The choice of a specific conditioning regimen depends on the disease that is being treated. The doses of chemotherapy and radiation used in these regimens are highly variable. When the doses result in a degree of myelosuppression and immunosuppression that is nearly universally fatal without the infusion of HSCs as a rescue product, they are referred to as "myeloablative." Allogeneic HSCT with myeloablative conditioning regimens has been performed successfully in patients older than 60 years of age; however, survival after these

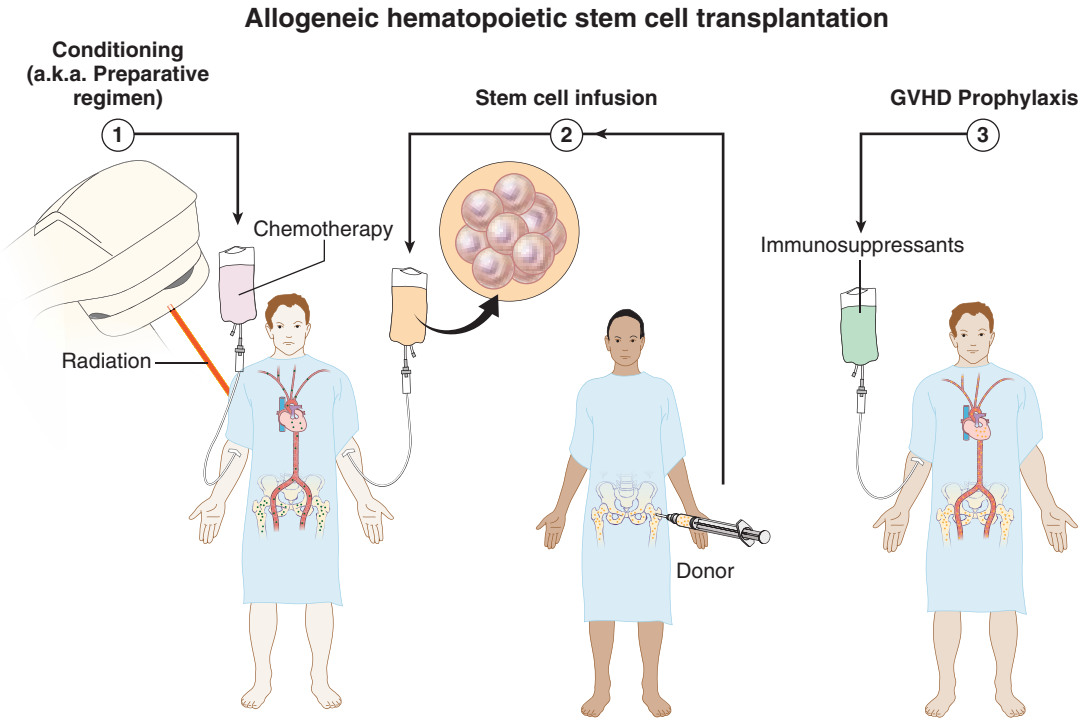

FIGURE 178-1. The process of allogeneic hematopoietic stem cell (HSC) transplantation. (1) The patient receives a conditioning regimen of chemotherapy or radiation therapy (or both) that is used to both eliminate the underlying malignancy and suppress the immune system to prevent rejection of the allogeneic HSCs. (2) Allogeneic HSCs are then collected directly from the bone marrow or from the blood of a related or unrelated stem cell donor and infused intravenously into the donor. (3) After the infusion of the HSCs, the patient receives immunosuppressant drugs to help prevent the development of graft-versus-host disease (GVHD).

transplants declines with increasing age, limiting the application of allogeneic transplantation to a minority of patients who potentially could benefit from this procedure. However, the demonstration that an immune-mediated graft-versus-leukemia effect plays a central role in the therapeutic efficacy of allogeneic HSCT led to the hypothesis that myeloablative conditioning regimens were not essential for tumor eradication. This idea subsequently led investigators to develop less intensive conditioning regimens, which were adequately immunosuppressive to permit the engraftment of donor HSCs but were associated with decreased toxicities compared with myeloablative regimens. These "nonmyeloablative" and "reduced-intensity" conditioning regimens increase the potential option of allogeneic HSCT for older patients and patients with preexisting comorbidities. However, the reduced doses in radiation and chemotherapy result in decreased antitumor activity and are associated with higher rates of disease recurrence after transplant.

Graft-Versus-Host Disease

After engraftment has occurred, patients are at risk for the development of GVHD, which represents the most important clinical challenge with allogeneic HSCT. GVHD is described as either acute, generally presenting within the first 100 days after transplant, or chronic, generally presenting after the first 100 days after transplant. However, clinical features of both acute and chronic GVHD may be observed at any time point after allogeneic HSCT. Current opinion holds that clinical manifestations rather than time after transplantation determine whether the clinical GVHD syndrome is considered acute or chronic. The broad category of acute GVHD includes "classic" acute GVHD, occurring within 100 days after transplantation or DLI and "persistent," "recurrent," or "late" acute GVHD, occurring beyond 100 days after transplantation or DLI. Risk factors for acute GVHD include HLA mismatch, a female donor (particularly a multiparous donor), more advanced age in the patient and the donor, and cytomegalovirus (CMV) seropositivity of the donor or patient, use of an unrelated donor or the use of a T cell–replete versus T cell–depleted graft.

Acute GVHD can often be diagnosed on the basis of clinical findings and is manifest by symptoms in several organ systems, but it primarily affects the skin, gastrointestinal tract, and liver. The skin manifestations range from a maculopapular rash to generalized erythroderma or desquamation. The severity of gastrointestinal GVHD is based on the quantity of diarrhea per day, and the severity of liver GVHD is scored on the basis of the bilirubin level. Organs may be involved in isolation or simultaneously. Histologic confirmation can be valuable in excluding other possibilities such as infection. Mild GVHD of the skin may demonstrate vacuolar degeneration and infiltration of the basal layer by lymphocytes. With more advanced disease, histologic findings of necrotic dyskeratotic cells with acantholysis may progress to frank epidermolysis. In the liver, early GVHD may be difficult to distinguish from hepatitis of other causes. A clinical grading system (Table 178-1) correlates with clinical outcome. Severity is described as grade I (mild) to grade IV (severe).

TABLE 178-1 CLASSIFICATION OF PATIENTS WITH ACUTE GRAFT-VERSUS-HOST DISEASE

	CLINICAL STAGING		
STAGE	**SKIN**	**LIVER**	**GUT**
+	Rash <25% BSA	Total bilirubin, 2-3 mg/dL	Diarrhea, 500-1000 mL/day
++	Rash 25%-50% BSA	Total bilirubin, 3-6 mg/dL	Diarrhea, 1000-1500 mL/day
+++	Generalized erythroderma	Total bilirubin, 6-15 mg/dL	Diarrhea >1500 mL/day
++++	Desquamation and bullae	Total bilirubin >15 mg/dL	Pain with or without ileus

	CLINICAL GRADING STAGE			
GRADE	**SKIN**	**LIVER**	**GUT**	**PS**
0 (none)	0	0	0	0
I	+ to ++	0	0	0
II	+ to +++	+	+	+
III	++ to +++	++ to +++	++ to +++	++
IV	++ to ++++	++ to ++++	++ to ++++	+++

BSA = body surface area; PS = performance status.

The best therapy for GVHD is prophylaxis.[3] The prophylactic use of a calcineurin inhibitor (e.g., cyclosporine, tacrolimus) in combination with methotrexate is effective in reducing the incidence of acute GVHD as well as improving the survival of transplant patients and is the most commonly used

form of GVHD prophylaxis. Cyclosporine is a cyclic polypeptide that prevents T-cell activation by inhibiting interleukin-2 (IL-2) production and IL-2 receptor expression. Although effective as GVHD prophylaxis, cyclosporine imparts significant toxicities, including hypertension, nephrotoxicity, hypomagnesemia, a risk for seizures, hypertrichosis, gingival hyperplasia, tremors, and anorexia. Tacrolimus is a macrolide lactone that closely resembles cyclosporine in mechanism of action, spectrum of toxicities, and pharmacologic interactions. The combination of tacrolimus and methotrexate was demonstrated to be superior to cyclosporine and methotrexate in reducing grade II to IV acute GVHD when used as prophylaxis. For allogeneic HSCT, prophylactic immunosuppression is not lifelong; when immunologic tolerance is established, immunosuppressive agents can be slowly withdrawn and discontinued. The incidence of clinically significant GVHD (grades II-IV) in recipients of HLA-matched sibling grafts (T-cell replete) using tacrolimus and methotrexate for GVHD prophylaxis is approximately 30% to 40%. The incidence of grade II to IV GVHD in recipients of HLA-matched unrelated donor grafts is approximately 50% to 80%. Another strategy to prevent GVHD is to deplete the donor's T cells from the graft; the disadvantage of this approach is its association with increased rates of disease relapse and infection, and overall survival does not seem to be improved.

Moderate to severe GVHD (grades II-IV) requires treatment; the mainstay of therapy is corticosteroids. Methylprednisolone at a dose of 1 to 2 mg/kg/day achieves responses in 40% to 60% of patients. Higher doses of steroids are not of greater benefit. Steroid-refractory GVHD responds poorly to second line therapies such as antithymocyte globulin or various monoclonal antibodies (e.g., daclizumab, infliximab) and are associated with increased mortality rates. In general, whereas acute GVHD of the skin is most responsive to treatment, GVHD of the liver is least responsive. The fatality rate for acute GVHD may be as high as 50%.

Chronic GVHD occurs in 20% to 50% of long-term survivors. Chronic GVHD occurs most commonly between 100 days and 2 years from the transplant and has polymorphic features similar to a number of autoimmune diseases. Chronic GVHD is classified as either classic chronic GVHD, which consists only of manifestations that can be ascribed to chronic GVHD or acute and chronic GVDH overlap syndrome, in which features of both acute and chronic GVHD appear together. These distinctions are clinically relevant as "late-onset" acute GVHD and overlap syndrome subsets have been associated with poor survival rates in some studies. Chronic GVHD is most likely to develop in older patients who also had acute GVHD or received peripheral blood rather than bone marrow grafts. In 20% of cases, there is no history of prior acute GVHD. Adverse prognostic factors include thrombocytopenia, a progressive clinical presentation, extensive skin involvement, and an elevated bilirubin. Common manifestations include the sicca syndrome, lichen planus–like skin rash, scleroderma-like skin changes, esophageal and intestinal fibrosis, obstructive lung disease with or without pneumonitis, and elevated alkaline phosphatase with or without hyperbilirubinemia. Underlying immunologic deficiencies, including hypogammaglobulinemia, are common, placing patients at increased risk for infectious events.

Historically, chronic GVHD has been considered as limited or extensive. Whereas limited disease implies localized skin involvement with minimal or no liver involvement, extensive disease suggests generalized skin involvement with or without other organ involvement. This classification is relatively poorly reproducible and does not always provide useful prognostic information. A new chronic GVHD clinical staging system is now recommended for scoring of individual organs (scale, 0-3) that describes the severity for each affected organ or site at any given time and also measures functional impact. Treatment for chronic GVHD is guided by the extent of disease. Initiation of therapy before functional impairment is of critical importance. Treatments for chronic GVHD include corticosteroids, cyclosporine, thalidomide, ultraviolet light treatments, monoclonal antibodies, or other immunosuppressive agents. Alternative treatments include azathioprine, psoralen ultraviolet A, and extracorporeal photopheresis. Given that the most common cause of death in patients with chronic GVHD remains infection, all patients with GVHD should receive prophylactic antibiotics with or without intravenous immunoglobulin depending on levels.

SYNGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Syngeneic HSCT uses stem cells from an identical twin. Because the HSCs are genetically identical with the recipient, the major advantage of a syngeneic HSCT is that it is not associated with GVHD or graft rejection, resulting in a relatively low risk of treatment-related morbidity and mortality. Another advantage of syngeneic HSCT, shared with allogeneic HSCT, is a lack of contamination of the graft by malignant cells. The major disadvantage of syngeneic HSCT is that it does not provide the graft-versus-leukemia effect associated with allogeneic HSCT. However, fewer than 1% of patients have an identical twin, and consequently, this is not an option for most patients.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

The major rationale for autologous HSCT, using the patient's own HSCs, is that certain malignancies, such as leukemias and lymphomas, have a steep dose-response curve to chemotherapy and, to a relative degree, radiation.[4] However, the major limitation to the administration of higher doses of chemotherapy or radiation is the myelosuppressive effects of these therapies. Autologous HSCs (and for that matter, allogeneic and syngeneic HSCs) permit the administration of high-dose chemotherapy with or without radiation by restoring hematopoiesis. The major advantages of autologous HSCT compared with allogeneic HSCT are that (1) the patient can serve as his or her own donor, and (2) it may be performed in older patients with significantly lower morbidity and mortality because of the absence of GVHD as a major complication. However, autologous HSCT can be associated with more morbidity than conventional doses of chemotherapy. Although patients undergoing autologous transplantation have higher relapse rates than those undergoing allogeneic transplantation, the lower rate of other complications seems to translate into similar long-term outcomes.

INDICATIONS FOR TRANSPLANTATION

An estimated 60,000 HSC transplants are performed annually worldwide. They are used primarily for the treatment of hematologic malignancies, bone marrow failure states, and immune and enzyme deficiencies (Fig. 178-2).

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) (Chapter 183) was one of the first malignancies in which all forms of HSCT were demonstrated to be effective. Allogeneic HSCT is capable of resulting in the long-term survival of 10% of patients with refractory AML. Long-term survival and an apparent cure rate of 20% to 40% have been achieved in patients treated in second or subsequent complete remission, and cure rates of 40% to 70% have been reported in patients given transplants in first complete remission.[5] Randomized controlled trials comparing autologous and allogeneic HSCT with conventional chemotherapy in patients with AML in first complete remission have demonstrated improved leukemia-free survival with both forms of HSCT. However, the data vary regarding an improvement in overall survival. Several meta-analyses demonstrate improved overall survival with allogeneic HSCT for AML in first complete remission, compared with nonallogeneic treatments in patients with intermediate- and high-risk cytogenetics but not for good-risk AML.[6] More recent studies indicate the importance of the presence of molecular mutations. For example, intermediate-risk AML with a normal karyotype represents a highly heterogeneous group with respect to prognosis based on molecular mutation status. Approximately one third of patients with normal karyotype AML harbor the *FLT3*-internal tandem mutation, which carries a poor prognosis, and may benefit from HLA-matched related HSCT transplantation, regardless of the presence of other mutations.

Acute Lymphocytic Leukemia

The results of conventional chemotherapy for acute lymphocytic leukemia (ALL) in children are excellent, except for ALL associated with the Philadelphia chromosome (Ph). In adults, however, although remission is frequently attained after intensive induction therapy, the probability of relapse is high is this disease, and some form of consolidation therapy is recommended, including allogeneic HSCT. Adverse prognostic factors include the presence of Ph, high white blood cell count, advancing age, and the presence of minimal residual disease. Studies suggest that HSCT improves overall survival compared with conventional chemotherapy alone, particularly for those who are Ph positive. The overall prognosis for both pediatric and adult patients with relapsed ALL is relatively poor, and the general treatment strategy is to obtain a second complete remission and then proceed to an allogeneic HSCT.

Myelodysplastic Syndrome

The only known curative treatment for myelodysplastic syndrome (MDS) (Chapter 182) is allogeneic HSCT. Unfortunately, the vast majority of patients are not considered candidates for this therapy for many reasons, including advanced age, comorbidities, donor availability, access to relatively

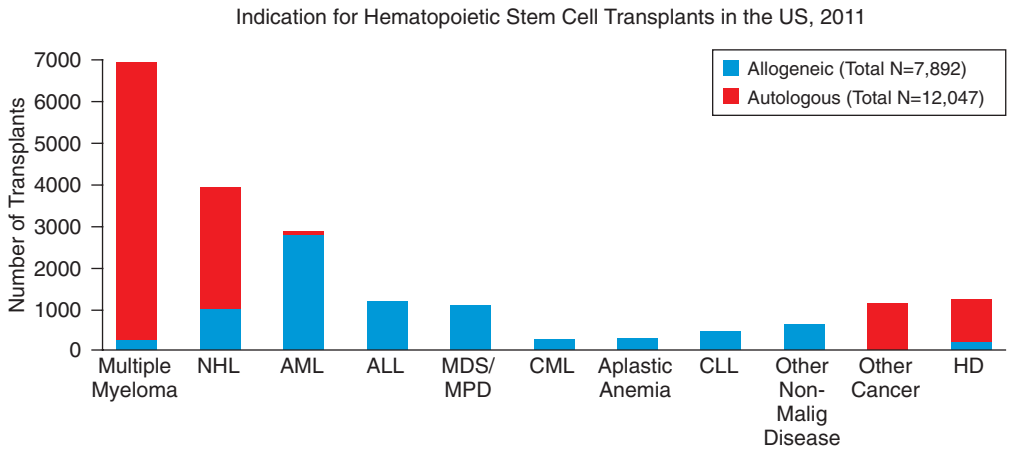

FIGURE 178-2. Indications for hematopoietic stem cell transplantation in the United States as Reported to the Center for International Blood & Marrow Research. AA = aplastic anemia; ALL = acute lymphocytic leukemia; AML = acute myeloid leukemia; CLL = chronic lymphocytic leukemia; HD = Hodgkin disease; MDS/MPD = myelodysplastic syndrome/ myeloproliferative disorders; MM = multiple myeloma; NHL = non-Hodgkin lymphoma. (From Dunn, R. Current Uses and Outcomes of Hematopoietic Stem Cell Transplantation 2013: Summary Slides. Center for International Blood & Marrow Transplant Research. http://www.cibmtr.org/referencecenter/slidesreports/summaryslides/documents/2013 summary slides- final web version v2 4.14.2014.pptx)

well tolerated agents such as azacytidine or lenalidomide, and clinician or patient preferences. The best results have been obtained in relatively younger patients, who are earlier in their disease course and have not received any prior therapy. There is increasing evidence that reduced-intensity allogeneic HSCT may benefit even considerably older patients with MDS, and this is of importance given that the median age at diagnosis is in the seventh to eighth decades of life. The use of autologous HSCT for MDS remains investigational.

Chronic Myeloid Leukemia

Previously, allogeneic HSCT was the treatment of choice for chronic myeloid leukemia (CML) (Chapter 184); however, currently most CML patients are successfully treated with a tyrosine kinase inhibitor (TKI), such as imatinib. Consequently, in most cases, allogeneic HSCT is not performed in patients with CML in chronic phase, but it is reserved for patients in accelerated phase (AP) or blast crisis (BC) CML, those who are intolerant of or fail TKIs, and those with TKI-resistant mutations of *BCR-ABL*. Although the results of allogeneic HSCT in AP or BC CML are poor, results of posttransplant treatment with TKIs appear promising. In the TKI era, autologous stem cell collections, even in patients with hematopoiesis shown to be *BCR-ABL* negative by reverse transcription polymerase chain reaction, are rarely performed.

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (Chapter 166), such as primary myelofibrosis, polycythemia vera, and essential thrombocythemia, usually are chronic in nature but can progress to a "spent" phase and develop myeloid metaplasia, which is characterized by bone marrow fibrosis and a generally poor prognosis with transformation into acute leukemia and a median survival time of less than 3 years. Conventional treatment options in this disease state are limited, and an accepted standard of care for myeloid metaplasia/myelofibrosis is allogeneic HSCT with increasing reports of the efficacy of nonmyeloablative allogeneic HSCT for these disorders in this older age population.

Non-Hodgkin Lymphoma

Although allogeneic, syngeneic, and autologous HSCT have all been reported to yield long-term, disease-free survival and an apparent cure for patients with advanced non-Hodgkin lymphomas (NHL) (Chapter 185), the current standard of care for patients with primary refractory or chemotherapy-sensitive relapsed NHL of specific histologies, including diffuse large B-cell lymphoma, remains autologous HSCT.

Autologous HSCT also has been used to treat patients with indolent follicular NHL resulting in disease-free survival rates as high as 60%. However, late relapses and the long overall survival period observed with conventional therapy make long-term follow-up necessary to document the efficacy of this approach. The demonstration of a potent graft-versus-leukemia effect against NHL is less clear. Consensus is currently lacking regarding the most appropriate role of HSCT (whether autologous or allogeneic) for patients with follicular lymphoma. Recent studies, however, suggest the potential value of nonmyeloablative allogeneic HSCT regimens in the context of clinical trials that incorporate rituximab or radioimmunoconjugates.

In the case of mantle cell lymphoma (MCL), further prospective trials are required, although autologous HSCT appears to improve progression-free and possibly overall survival in patients when used as part of front-line therapy. Patients with high-risk MCL are candidates for trials investigating the role of nonmyeloablative allogeneic HSCT.

Hodgkin Lymphoma

Based on a small prospective randomized trial conducted in the early 1990s, autologous HSCT has become the standard of care for patients with primary refractory and relapsed Hodgkin lymphoma (Chapter 186). The usual approach is to first treat these patients with second-line chemotherapy followed by the high-dose therapy and autologous HSCT. Allogeneic HSCT has had a limited role because of the efficacy of autologous HSCT and the significant treatment-related toxicities associated with myeloablative allogeneic HSCT. Data are accumulating on the efficacy of reduced-intensity allogeneic HSCT, especially in patients who relapse after autologous HSCT.

Multiple Myeloma

Although the advent of new agents, such as immunomodulatory derivatives and proteasome inhibitors, for the treatment of multiple myeloma (MM) (Chapter 187) is leading to a reappraisal of the role of autologous HSCT in the early treatment of the disease, current opinion indicates that standard of care remains induction therapy with novel agents followed by autologous HSCT.[7] Prospective comparisons of single versus tandem autologous transplants give conflicting results, although overall survival rates appear similar. Comparisons of tandem autologous versus autologous followed by allogeneic HSCT indicate improved complete remission rates and event-free survival but no increased overall survival and significantly worse nonrelapse mortality rates with the latter. Consensus appears to be to reserve a second transplant for patients who relapse after the first autologous HSCT, provided the duration of response was more than 1 year after the initial transplant.

Solid Tumors

High-dose chemotherapy plus transplantation has had success in the treatment of some chemotherapy-sensitive solid tumors, including germ cell tumors and childhood cancers such as neuroblastoma and Wilms tumor. In patients with germ cell tumors for whom platinum-based chemotherapy regimens fail to result in a cure, the use of high-dose chemotherapy and autologous HSCT has resulted in prolonged disease-free survival time, including patients with refractory disease. After initial promising results of autologous HSCT for advanced and metastatic breast cancer, several randomized trials failed to demonstrate an overall survival benefit, and the procedure is no longer performed for these indications.

Nonmalignant Conditions

Hematopoietic stem cell transplantation is also effective for treatment of nonmalignant disorders, including aplastic anemia, thalassemias, sickle cell disease[8], immunodeficiency disorders, and enzyme deficiency states. These latter indications are primarily for children and young adults. Allogeneic

HSCT can lead to long-term, disease-free survival times in more than 50% of patients with severe aplastic anemia (Chapter 165). When compared with standard immunosuppressive therapy, allogeneic transplantation is more likely to produce a complete and durable reversal of the hematologic abnormalities. Patients with aplastic anemia who are less heavily transfused have better outcomes with allogeneic transplantation. For patients with less severe aplastic anemia, patients older than 40 years, and those without a matched sibling donor, a trial of immunosuppression therapy is usually appropriate before consideration of allogeneic transplantation.

The hemoglobinopathies can be cured only by allogeneic HSCT, and the most extensive experience is with β-thalassemia (Chapter 162). Best results are obtained with HLA-identical sibling donor transplantations and in pediatric patients. Adults tend to have more advanced disease with greater iron overload and more organ dysfunction; hence, they have high treatment-related mortality rates. Studies with nonmyeloablative regimens are ongoing. There is considerably less experience with sickle cell disease (Chapter 163), partly because of reluctance to contemplate allogeneic HSCT in patients with an unpredictably variable clinical course.

Autologous HSCT has been investigated for almost 20 years for the treatment of severe autoimmune disease, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis. Results have been promising in nonrandomized trials with approximately one third of patients exhibiting clinically significant responses, including medication-free remissions. The strategy has been to reconstitute the immune system without the presence of autoreactive T-cell clones. There has been a reluctance to consider allogeneic HSCT, with its attendant morbidity and mortality, because in general patients with autoimmune diseases have a low probability of death from their underlying disorder, but HSCT can confer a long-term survival benefit in patients with diffuse cutaneous systemic sclerosis.

COMPLICATIONS AFTER HEMATOPOIETIC STEM CELL TRANSPLANTATION

Early complications associated with all forms of HSCT include direct organ toxicities from the conditioning regimen (e.g., mucositis) and prolonged cytopenias (7-14 days) resulting in infections and bleeding. As described earlier in this chapter, allogeneic HSCT can be associated with acute and chronic GVHD. Long-term complications, particularly secondary malignancies, require that patients continue to be monitored for the remainder of their lives. Through improved supportive measures, there has been steady improvement in survival after HSCT over time.[9] A simple index, based on pretransplant comorbidities, has been developed that reliably predicts nonrelapse mortality and survival.[10] This comorbidity index is useful for patient counseling before HSCT. The late toxicities of HSCT must always be kept in mind when considering the option of HSCT for patients.

Graft Rejection

Graft rejection occurs when immunologically competent cells of host origin destroy the transplanted cells of donor origin. This complication occurs more commonly in patients who receive transplants from alternative or HLA-mismatched donors, in T cell–depleted transplants, and in patients with aplastic anemia. Graft rejection is rarely, if ever, observed in patients undergoing autologous or syngeneic HSCT.

Infections

Infections are a major cause of morbidity and mortality after all forms of HSCT, but especially after allogeneic transplantation because of prolonged use of immunosuppression for the prevention or treatment of GVHD. Bacterial infections are frequently related to central venous catheters. Prophylactic antibiotics significantly reduce the incidence of infection but not mortality. *Aspergillus* infections typically occur in patients receiving prolonged high-dose steroids for the treatment of GVHD.[11] Viral infections include reactivation of CMV, human herpes virus 6, and Epstein-Barr virus (EBV) infections. Brincidofovir, an investigational oral nucleotide analog, and letermovir, a novel antiviral agent, reduce CMV events in recipients of HSCT. Post-HSCT patients are also susceptible to seasonal respiratory viruses. Revaccinations for common childhood infections are required after transplantation.

Cardiac Toxicity

Most transplant centers screen potential patients for underlying cardiac abnormalities that would place them at a potentially increased risk during the procedure. Despite this screening, however, a small number of patients experience cardiotoxicity, either acutely during the transplant or at a later time, manifest as a cardiac arrhythmia, congestive heart failure, or cardiac ischemia because of the large volumes of fluids administered during the procedure or from the added physiological stress. Complications associated with a pericardial effusion can be seen in some patients during or after transplant and are more common in patients with disease near that area and those receiving radiation therapy in that field. An idiosyncratic cardiomyopathy, associated with the administration of high doses of cyclophosphamide, has been documented in a small number of patients. Viral cardiomyopathies also can be seen.

Engraftment Syndrome

Engraftment syndrome occurs during neutrophil recovery after both autologous and allogeneic HSCT. It consists of a constellation of symptoms and signs that may include fever, erythrodermatous skin rash, and noncardiogenic pulmonary edema, and, in its most extreme forms, acute renal failure and diffuse alveolar hemorrhage. These clinical findings reflect the manifestations of increased capillary permeability and extensive endogenous cytokine. Corticosteroid therapy is often dramatically effective for engraftment syndrome, particularly for the treatment of the pulmonary manifestations.

Pulmonary Toxicities

Pulmonary toxicities are common during and after transplantation. Patients who receive certain chemotherapeutic agents, such as 1,3-bis (2-chloroethyl)-1-nitrosourea (BCNU; carmustine) have an increased incidence of chemotherapy-induced lung tissue damage after transplant, which usually can occur several weeks after transplantation and can be treated successfully with the prompt initiation of corticosteroid therapy. In addition to these complications, patients who are undergoing allogeneic HSCT are at increased risk for pneumonitis caused by CMV and fungal infections due to the patient's increased immunosuppression, and adult respiratory distress syndrome or interstitial pneumonia of unknown etiology. Chronic GVHD also can manifest as bronchiolitis obliterans in the lung.

Liver Toxicity

The most common liver complication associated with transplantation is veno-occlusive disease (VOD)/sinusoidal obstruction syndrome (SOS) of the liver. Symptoms associated with VOD/SOS include jaundice, tender hepatomegaly, ascites, and weight gain. Progressive hepatic failure and multiorgan system failure can develop in the most severe cases. Predisposing factors appear to be previous hepatic injury, use of estrogens, and high-dose intensity conditioning.

Renal Toxicity

Acute renal failure requiring dialysis during the transplant occurs infrequently, although patients with underlying renal dysfunction are at risk for this complication. An idiopathic or cyclosporine-induced hemolytic-uremic syndrome can be a serious complication after allogeneic HSCT and poses a high mortality risk or can result in end-stage renal disease. Recently, nephrotic syndrome and membranous nephropathy have been described in long-term survivors; these complications seem to be associated more commonly with chronic GVHD and nonmyeloablative conditioning.

Secondary Malignancies

One complication of the chemotherapy or radiation therapy (or both) used to treat malignancy is the development of a secondary malignancy. There have been several reports of the development of secondary AML or MDS after autologous transplantation. Some studies have suggested that total-body irradiation may increase the risk for these complications. After allogeneic transplantation, the overall incidence of secondary malignancies is 2.2% at 10 years and 6.7% at 15 years after transplantation. Within the first 1 to 2 years, the most common malignancies are EBV-related lymphoproliferative disorders; solid tumors are more likely to occur more than 3 years after transplantation. Risk factors include the use of antithymocyte globulin to treat GVHD, the use of a T cell–depleted allogeneic graft, HLA incompatibility, and perhaps total-body irradiation.

Infertility and Hypogonadism

Many of the preparative regimens used for transplant are associated with a high incidence of permanent sterility, particularly regimens containing total-body irradiation. However, successful pregnancies have occurred in some patients after other regimens, particularly in younger patients. Gynecomastia

occasionally occurs in males. A reproductive endocrinologist should be consulted before transplantation in patients for whom future fertility is important.

Endocrine Dysfunction

Iatrogenic Cushing syndrome and diabetes can occur and are commonly caused by long-term steroid therapy for chronic GVHD. Particularly disabling are steroid-induced myopathy, avascular necrosis of the hip, and osteoporosis. Because many patients take steroids for many months, tapering can be associated with malaise, nausea, hypotension, and musculoskeletal pains. In these situations, slower tapering over several months or reintroduction of physiological replacement doses (e.g., 5 to 7.5 mg/day of prednisone) is appropriate. Hypothyroidism is typically related to the use of total-body irradiation or local irradiation of the head and neck for lymphoma or other cancers. Osteoporosis occurs in 50% to 60% of patients after HSCT. The major contributing causes include hypogonadism, secondary hyperparathyroidism caused by low serum calcium, and posttransplant steroid therapy. Bone mineral density should be evaluated before and after transplantation; osteopenia should be treated as appropriate with bisphosphonates, calcium, vitamin D, estrogen, and testosterone (Chapter 243).

CONCLUSION

There has been much progress in increasing the safety of HSCT and in expanding the application of this treatment to more patients. Areas currently under development that may further improve the use and efficacy of transplantation include continuous improvements in supportive care for transplant patients and the broadened use of alternative donors. Better treatments are necessary for the treatment of GVHD, and innovative studies are ongoing. Future progress depends on the ability to identify safer and better-targeted antitumor therapies that can be incorporated in transplantation regimens without increasing toxicity or attenuating graft-versus-tumor responses. However, novel cellular therapies, including genetic modification of lymphocytes to enhance cancer-killing activity, hold considerable promise.

REVIEW QUESTIONS

1. The distinctive characteristic(s) of allogeneic hematopoietic stem cell transplantation include(s):

A. The stem cell graft is free of contamination by malignant cells
B. Associated with decreased complications compared with autologous and syngeneic hematopoietic stem cell transplantation
C. Contains lymphocytes that are capable of mediating an immunologic reaction against foreign antigens
D. Both A and C
E. A, B, and C

Answer: D Both allogeneic and syngeneic grafts are free of tumor cell contamination. Allogeneic hematopoietic stem cell transplantation (HSCT) is associated with higher rates of treatment-related morbidity and mortality because of the potential for the development of graft-versus-host disease and need for immunosuppressive agents leading to higher risks of infection. Allogeneic transplantation contains lymphocytes that can mediate immunologic reactions against foreign antigens, including those on tumors leading to lower rates of relapse compared with either autologous or allogeneic HSCT.

2. The cells that contribute most to the graft-versus-tumor effects observed with allogeneic stem cell transplantation are

A. neutrophils.
B. monocytes.
C. dendritic cells.
D. T lymphocytes.
E. B lymphocytes.

Answer: D Although neutrophils and monocytes play important roles in eliminating infections, they contribute little to observed graft-versus-tumor effect. B lymphocytes and dendritic cells have been demonstrated to play roles in the graft-versus-tumor effects observed with allogeneic hematopoietic stem cell transplantation ; however, T lymphocytes play the most important role. This has been most clearly evident clinically by the observation that infusion of donor T lymphocytes (i.e., donor lymphocyte infusion) after recurrence of cancer following allogeneic stem cell transplantation can alone result in sustained complete remissions.

3. All of the following are disadvantages for the clinical use of cord blood hematopoietic stem cells (HSCs) except

A. clinical outcomes are in general inferior to fully HLA-matched sibling and volunteer unrelated donors.
B. because of the unique immature biology of lymphocytes in umbilical cord blood, these transplants are associated with more GVHD.
C. because of the small volume (50-150 mL) of cord blood, only a limited number of HSCs can be collected, which often prohibits their use in adults because successful engraftment correlates with the number of HSCs per patient body weight.
D. cord blood HSCs are associated with delayed times to engraftment and immune reconstitution, leading to an increased rate of infection.
E. after a cord blood unit is used, there is no possibility to obtain additional cells in the event of graft failure or if a donor lymphocyte infusion is required.

Answer: B Cord blood transplantation is generally associated with less graft-versus-host disease even when the donor and recipient are human leukocyte antigen (HLA) disparate. This is the major advantage of cord blood stem cells and permits the application of hematopoietic stem cell transplantation to a broader group of patients. Outcomes, however, are generally not as good as those observed with either fully HLA-matched sibling or volunteer donors in similar patients. The limited number of HSCs, delayed hematopoietic recovery and immune reconstitution, and availability of only a single unit for each patient are major clinical disadvantages.

4. Risk factors for the development of acute graft-versus-host disease (GVHD) include all except which of the following?

A. HLA mismatch
B. Cytomegalovirus seronegativity of the donor or patient
C. More advanced age in the patient and the donor
D. Female donor (particularly a multiparous donor)
E. Use of an unrelated donor

Answer: B Seropositivity, not negativity, in either the recipient or the donor is associated with a greater risk of developing acute GVHD. All of the other factors have also been associated with higher risks of developing acute GHVD. When a patient has more than one potential human leukocyte antigen–matched donors, these factors are used in the donor selection.

5. All of the following are considered standard indications for hematopoietic stem cell transplantation (HSCT) except

A. allogeneic HSCT from HLA-matched donors for patients with intermediate- and high-risk acute myeloid leukemia in first remission.
B. high-dose chemotherapy and autologous HSCT for patients with primary refractory and relapsed diffuse large B-cell lymphoma that remains chemotherapy sensitive.
C. allogeneic HSCT from HLA-matched sibling in adult patients with advanced sickle cell disease.
D. high-dose chemotherapy and autologous HSCT for patients with newly diagnosed multiple myeloma after induction therapy.
E. allogeneic HSCT for patients with therapy-related acute myeloid leukemia.

Answer: C In all of the other clinical scenarios, either allogeneic or autologous HSCT has been demonstrated to significantly improve progression-free or overall survival. Several meta-analyses have demonstrated the benefit of allogeneic HSCT from human leukocyte antigen–matched donors for patients with intermediate- and high-risk acute myeloid leukemia in first remission. The benefit in patients with normal cytogenetics is being further delineated by molecular studies (e.g., FLT3-ITD). In relapsed, chemotherapy-sensitive diffuse large B-cell lymphoma, autologous HSCT has been demonstrated to result in improved progression-free and overall survival in randomized trials compared with conventional therapy. Although the continuing introduction of novel agents is changing clinical practice, autologous transplantation remains a standard component in the initial management of multiple myeloma patients. In the case of therapy-related acute myeloid leukemia, allogeneic stem cell transplantation is the only option that can provide long-term survival and possibly cure. Although there have been promising results with allogeneic HSCT in adults with advanced sickle cell disease, it still is considered investigational because ongoing trials attempt to identify the most appropriate patients in which to use this treatment.

179 APPROACH TO THE PATIENT WITH CANCER

JAMES H. DOROSHOW

INTRODUCTION TO THE CANCER PATIENT

Conveying or receiving an initial diagnosis of cancer, or the knowledge that cancer has recurred, are among the most difficult of human enterprises, and no amount of either specialized training or forewarning can adequately assuage the intensity of the emotions associated with these encounters. Patients often experience a storm of feelings that may limit useful discussion immediately following the receipt of a diagnosis of cancer. Unquestionably, it is difficult for even the most well-informed patient to process the complexities of his or her individual situation, including the range of additional diagnostic tests that may be required and the potentially vast array of treatment options and potential outcomes that lie ahead. And yet, at some point prior to the initiation of treatment, the physician and the patient must discuss the diagnosis, its implications, and therapeutic alternatives. Because of the wide range of potential prognoses (from curable disseminated testicular cancer to the limited lifespan of patients with locally advanced gastric or pancreatic cancer), it is often useful for family members or close friends to be present in the consulting room when detailed discussions of the complexities of either disease or therapy are conducted, both to provide emotional support and to be another "set of ears" during the visit. It is helpful to ask patients directly: "What do you understand about your diagnosis and treatment?" Family members or close associates of the patient may also be especially helpful in developing a written or digital record of the questions posed to and answered by health care providers; many patients find such a record to be especially helpful for later reference.

If the physician is not familiar with the latest treatment options, prompt referral to a specialist, whether a surgical oncologist, radiation oncologist, or medical oncologist, is imperative. The generalist should not be a therapeutic nihilist unless he or she is intimately involved in the field and is well versed in the potential risks and benefits of currently available therapies and clinical trials.

DIAGNOSIS

Diagnostic possibilities are protean for the wide range of human malignancies that may be discovered either in the presence of nonspecific but foreboding symptoms or signs (severe weight loss, hematuria, jaundice) or in asymptomatic individuals (e.g., during a routine physical examination). The importance of the medical history and physical examination, however, must be emphasized *whether or not* a pathologic diagnosis of cancer has already been confirmed. One of the most important considerations that underlies the approach to both the diagnostic work-up and choice of cancer treatment (surgical, radiation, or systemic therapy) is the patient's basic physiologic condition or "performance status" (Table 179-1). For example, a past medical history of prolonged tobacco smoking is not only relevant to a possible diagnosis of lung cancer but to the ability of a patient to tolerate potentially curable multimodality treatment. Underlying evidence of excessive alcohol consumption may play a role in both the tolerance for and metabolism of systemic chemotherapeutic agents. Family histories of cancer can provide prognostic indicators as well as suggest molecularly guided treatment approaches in, for example, women with possible *BRCA1*-related breast or ovarian cancer. It is also critical to assess the environment of care, including all of the patient's support systems, that may be sorely tested by the experience of a cancer diagnosis and the interventions that ensue therefrom. Finally, the physical examination will define the extent of certain sites of measurable malignancy—lymph node, splenic, or hepatic enlargement, for example—as well as the patient's muscle strength, the presence of possible malignant effusions, and potential central or peripheral neuropathies reflective of metastatic disease or paraneoplastic syndromes. But most importantly, it provides the treating physician with an initial sense of the patient's well-being, or lack thereof, prior to the initiation of therapy.

Diagnostic Procedures

A lesion that has been found on physical examination, or following radiographic studies prompted by abnormal laboratory results, will often undergo a percutaneous biopsy for pathologic evaluation. It is critical that the biopsy be representative of the entire tumor and be robust enough in size that appropriate investigations (e.g., special immunohistologic stains, flow cytometry, cytogenetics, hormone assays) can be performed before treatment is initiated. If there is a question whether the lesion is benign or malignant or about its proper classification, consideration should be given to additional biopsies, and consultation with a reference pathologist may be indicated. The recent emergence of a wide range of molecularly targeted systemic therapeutic agents active in solid tumors (see Table 179-4) has focused renewed attention on obtaining sufficient tissue from patients for performance of the essential molecular studies (DNA sequencing, RNA expression analyses, FISH [fluorescence in situ hybridization]) necessary to determine treatment choice. Although tumors removed by surgical resection are routinely of sufficient size to permit the full range of diagnostic examinations, active involvement of a skilled interventional radiologist or endoscopist is often required to produce both the size and number of tumor biopsies required for modern cancer therapeutic decision making. Finally, there is seldom a need for such rapid therapy that appropriate pretreatment evaluations cannot be performed. For some tumor sites such as the colon (Chapter 193), there is one predominant histology but critical molecular features of the tumor (presence or absence of a mutant *Ras* oncogene) that can define therapy; in others, such as the lung (Chapter 191), the distinction between small cell lung cancer and non–small cell lung cancer is critical for treatment. For breast cancer (Chapter 198), the treating physician is interested in a variety of factors, such as histology, tumor grade, the presence (and its degree) or absence of estrogen and progesterone receptor proteins, and the presence of HER2/neu overexpression. The rapidly increasing sophistication of molecular diagnostics has, furthermore, begun to improve the potential to localize cancers of unknown primary origin (Chapter 204).

Staging and Multidisciplinary Evaluation

After a tissue diagnosis has been established, staging follows to determine the extent of disease. The American Joint Committee on Cancer staging system is considered the standard in the United States and is based on the TNM (tumor, node, metastasis) system that is anatomically and pathologically based. The approach to staging from a clinical perspective depends on the type of cancer, but it commonly includes computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scans, and, increasingly, positron emission tomography (PET). These studies are supplemented by routine hematologic and chemistry profiles, tumor markers (when appropriate), and in some cases, bone marrow aspiration and biopsy.
