However, the development and increasingly widespread availability of ready-to-use therapeutic food (RUTF), most often a fortified peanut paste, makes it preferable to treat children in community-based outpatient feeding programs instead, assuming that the child demonstrates a mental status and appetite conducive to feeding at home (see E-Fig. 215-1).[10] After ensuring that the child has an appetite and is not suffering from complications such as hypoglycemia, severe dehydration, respiratory distress, severe anemia, and high fevers, a test feeding of approximately 30 g RUTF is given under directly observed therapy. Most children will successfully complete this test feeding and can be discharged home with 1 to 2 weeks of 175 kcal/kg/day of RUTF. Anthropometry and clinical assessments are repeated at 1- to 2-week intervals; children are treated until their edema resolves and either their WHZ is no more than 2 SD below the mean or their MUAC reaches 125 mm (depending on whether they were diagnosed based on WHZ or MUAC criteria). Almost all children will recover within 8 to 12 weeks, with approximately half recovering by 4 to 6 weeks if the child is receiving all of the intended food and there are no interim complications. Any child not improving as expected should have a thorough social and medical assessment to evaluate whether they are being fed appropriately and whether any acute infectious complications have developed; inpatient care may be necessary in those situations.

Mortality and nutritional recovery outcomes from community-based programs are generally superior to those achieved by inpatient care, making this the current international standard of care[11] and relegating inpatient care only to those children with anorexia or medical complications or who are in an area where RUTF is not available. Outpatient care can be improved further with empirical antibiotic therapy for all patients because of the high risk for overwhelming sepsis and death. Integration of outpatient nutritional care into a complete package of routine health interventions, including linkage to HIV testing and treatment, will likely only improve outcomes further.

Patients with secondary protein-energy malnutrition should, first and foremost, have their underlying illness addressed because this is most likely to lead to long-term recovery of their nutritional status. Concomitantly, nutritional rehabilitation should be undertaken to prevent further energy losses and allow for recovery of damaged organic pathways. Fluid, electrolyte, and acid-base status should be corrected cautiously in the usual fashion. In general, enteral nutrition (Chapter 216) is preferred over parenteral, assuming the gastrointestinal tract is functioning adequately. Frequent small feedings or slow drip feedings may be necessary. Aggressive tube feeding or parenteral nutrition should be avoided in the early stages of rehabilitation because the

% of total energy from fat	36	53	45-60

RUTF = ready-to-use therapeutic food.

refeeding syndrome is a real danger in patients who are malnourished. Hypophosphatemia, hypokalemia, hypomagnesemia, hyperglycemia, fluid overload, muscular weakness, cardiac arrhythmias, and diarrhea are all possible with aggressive refeeding. Fluid status, glycemic status, and electrolyte levels should be monitored closely throughout the refeeding process.[12]

PREVENTION

Prevention of stunting and acute malnutrition remains one of the most challenging and elusive goals in global health, especially given the intergenerational effects of maternal malnutrition. Providing pregnant women with nutritional supplementation, intermittent malaria treatment, timely care for sexually transmitted infections, and comprehensive prenatal care shows some success in improving birth weights and decreasing premature delivery. Adherence to recommendations for exclusive breast-feeding for the first 6 months and continued breast-feeding for at least the first 2 years also shows profound benefit.[13] Early diagnosis and treatment of HIV in mothers and their infants is also beneficial.[14] Nevertheless, children in the developing world remain at high risk for stunting and acute malnutrition because of the relative lack of sanitation, high rates of food insecurity, spotty vaccination coverage, and limited access to medical care. Addressing these underlying societal factors may provide the most benefit to decreasing environmental enteric dysfunction, stunting, and acute malnutrition.

Close attention to the nutritional status of medical and surgical patients, with risk stratification based on BMI and weight trajectory, is necessary to limit the risk for protein-energy malnutrition in these patients as they are treated for their underlying illnesses. Optimizing nutritional status will aid in recovery from their primary conditions, and similarly recovery from the primary condition will improve benefit to overall nutritional status. Efforts to empirically provide extra protein, calories, and micronutrients during times of particular oxidative stress and catabolism will help limit weight loss and its adverse effects.

PROGNOSIS

The prognosis for stunted children generally remains poor because the physical and cognitive deficits they suffer are mostly carried with them throughout life,[15] despite some catch-up growth in later childhood and adolescence. Children who recover from an episode of severe acute malnutrition are somewhat more susceptible to further episodes over the next several months than their peers, although those with underlying illnesses such as HIV or tuberculosis remain at significantly elevated risk. The highest recovery rates in severe acute malnutrition treatment programs are approximately 90%, with about 4 to 5% mortality. Untreated, episodes of severe wasting carry an estimated 10%-20% mortality risk per month. Although many children will recover spontaneously, most will never return to their baseline nutritional status and fully thrive. Early childhood growth faltering may be linked to an increased risk for the metabolic syndrome as adults, contributing to the double epidemic of childhood undernutrition and adult obesity being increasingly observed throughout the developing world.

REVIEW QUESTIONS

1. Which one of the following is *not* considered a form of protein-energy malnutrition?

A. Stunting
B. Beriberi
C. Marasmus
E. Kwashiorkor
E. HIV wasting

Answer: B Beriberi occurs as a result of vitamin B_1 (thiamine) deficiency and may be due to inadequate intake, malabsorption in the gastrointestinal tract, alcoholism, dialysis, genetic disorders, and other causes (Chapter 218). Although beriberi may be present in patients with protein-energy malnutrition, it is a micronutrient deficiency and would be part of a more global malnutrition syndrome in these patients.

2. Which of the following is the most common underlying factor in childhood mortality worldwide?

A. Malaria
B. HIV
C. Intestinal parasites
D. Malnutrition
E. Premature birth

Answer: D Malnutrition, in all of its various forms, is an underlying factor in about 45% of all deaths in children younger than 5 years worldwide.[2] Although malaria, HIV, intestinal parasites, and prematurity remain extremely common and are a cause of significant mortality and morbidity, malnutrition continues to exceed all of these as a contributing factor to childhood mortality. Malaria accounts for approximately 7% of all childhood deaths, HIV 2%, and prematurity 14%, although each of these numbers would be lower if not for the malnutrition suffered by the mothers and children in question. Intestinal parasites rarely lead directly to mortality, but instead contribute greatly to morbidity, including malabsorptive syndromes and iron deficiency anemia.

3. Which of the following interventions is most likely to be effective in reducing the burden of environmental enteric dysfunction (EED)?

A. Ensuring all children receive their routine immunizations
B. Antibiotic prophylaxis
C. Routine probiotic administration
D. Zinc supplementation
E. Albendazole for deworming
F. Improved sanitation

Answer: F EED is most likely a result of repeated pernicious insults to the intestinal tract that are found most often in developing settings, influenced to a large degree by the lack of sanitation present there in impoverished areas (Korpe PS, Petri WA Jr. Environmental enteropathy: critical implications of a poorly understood condition. *Trends Mol Med.* 2012;18:328-336). Immunizations are unlikely to have an effect on EED because most do not target enteric pathogens, and none target intestinal bacterial or parasitic pathogens. Antibiotics and probiotics have not shown benefit in rigorous clinical prospective clinical trials (Trehan I, Shulman RJ, Ou CN, et al. A randomized, double-blind, placebo-controlled trial of rifaximin, a nonabsorbable antibiotic, in the treatment of tropical enteropathy. *Am J Gastroenterol.* 2009;104:2326-2333). Zinc and albendazole have recently shown modest benefits (Ryan KN, Stephenson KB, Trehan I, et al. Oral zinc or albendazole ameliorates environmental enteropathy in Malawian children: a randomized controlled trial. *Clin Gastroenterol Hepatol.* 2014;12:1507-1513), but these are relatively minimal compared with the degree of benefit that would be expected from modern sanitation systems.

4. Nutritional supply and function of which of the following organs are preserved the longest and most in protein-energy malnutrition?

A. Brain
B. Heart
C. Intestine
D. Liver
E. Lung
F. Skin

Answer: A Nutrient supply to the brain is preserved the longest in patients with protein-energy malnutrition, whereas the other organs must adapt to the decreased nutrients available to them. Nevertheless, some degree of cerebral atrophy is seen, with often permanent irreversible cognitive stunting and developmental delay for children who suffer protein-energy malnutrition.

5. Which of the following is the most useful anthropometric measure for diagnosing acute wasting in a 3-year-old child?

A. Height
B. Height-for-age Z-score
C. Mid-upper arm circumference
D. Weight
E. Weight-for-age Z-score
F. Weight-for-height Z-score

Answer: C The two parameters that are used for diagnosing wasting in all patients are mid-upper arm circumference (MUAC) and weight-for-height Z-score (WHZ). Although WHZ has traditionally been the preferred method for diagnosing acute wasting, MUAC has in recent years proved to be a better predictor of future mortality than WHZ and is now the preferred anthropometric criterion for diagnosing acute wasting. If resources are available to assess both criteria in any given health system, then both should be performed, but this may be tedious, time-consuming, and more expensive (Briend A, Maire B, Fontaine O, Garenne M. Mid-upper arm circumference and weight-for-height to identify high-risk malnourished under-five children. *Matern Child Nutr.* 2012;8:130-133). Height-for-age Z-score and weight-for-age Z-score are useful for diagnosing stunting and underweight, respectively, which are both markers of chronic malnutrition. Height and weight alone do not provide any specific information because there is wide genetic variability in each individual's potential height and weight, and because this is also a function of gender and age.

216 ENTERAL NUTRITION

STEPHEN A. MCCLAVE

The benefit of nutrition therapy in the hospitalized patient is clearly related to the provision of early enteral nutrition (EN).[1] Outside the setting of intestinal failure or short bowel syndrome, a true benefit over providing parenteral nutrition (PN) is not clear, and its use should be determined on a case-by-case basis. Providing early EN to the critically ill patient in the intensive care unit (ICU), on the other hand, exerts a beneficial physiologic effect that downregulates inflammation and improves patient outcome.[2] Because the gut is the largest immune organ in the body, the timing, volume, and content of nutrient that is infused into the lumen of the gut have a major impact on the level of oxidative stress, the tone of systemic immune responses, and the likelihood for complications. A window of opportunity exists shortly after admission to the ICU, during which placement of enteral access and initiation of feeding will improve patient outcome by reducing rates of infection, overall complications, organ failure, length of hospital stay, and, in some disease processes, even mortality.[3] Failure to utilize the gut in critical illness results in a different physiologic response, whereby the gut becomes a pro-inflammatory organ and outcome is worsened. Depending on the patient population, the window of opportunity for such modulation may be very narrow. Burns are considered "nutritional emergencies," in which the window of opportunity may be as short as 3 to 6 hours before increased permeability occurs. In other disease processes, such as pancreatitis or major elective operations, the window may be longer (i.e., 48 to 72 hours). At some point, the ability to modulate the immune system and contain gut barrier function begins to diminish. Preventing increases in permeability of the gut is easier than containment after barrier function is compromised. The main purpose of early EN in the hospitalized critically ill patient then is to maintain gut integrity and modulate systemic immunity. With time, provision of nutrients to prevent the deterioration of nutritional status and the development of malnutrition becomes increasingly important. Therefore, EN is indicated in any critically ill patient who is unable to eat and should be initiated as soon as the patient receives full volume resuscitation. If the patient is not critically ill, EN is indicated if the patient is anticipated to be unable to eat for more than 7 days. The only true contraindications to feeding are bowel ischemia, mechanical obstruction of the gut, and peritonitis. It is important for the clinician to realize that although ileus, pancreatitis, nausea, vomiting, and other such factors may make enteral feeding difficult, none is an absolute contraindication to providing EN.

PHYSIOLOGIC BENEFIT OF ENTERAL NUTRITION

The provision of EN maintains both the functional and structural integrity of the intestinal epithelium. Early EN stimulates intestinal contractility and

TABLE 216-1 COMPARISON OF PHYSIOLOGIC EFFECTS OF FEEDING VERSUS STARVATION

	ENTERAL FEEDING	STARVATION
Intestinal contractility	Increased	Decreased
Release of secretory IgA from gut	Increased	Decreased
Release of trophic agents (bile salts, gastrin)	Increased	Decreased
Splanchnic intestinal blood flow	Increased	Decreased
Luminal microbiota Organisms Population	 Commensal Normal	 Pathogenic Overgrowth
Gut integrity and epithelial cell tight junctions	Intact	Permeable
Mass of GALT	Maintained	Diminished
Support of MALT at distant sites	Maintained	Diminished
Population of CD_4 helper lymphocytes emerging from gut into systemic circulation	T_H2 (anti-inflammatory)	T_H1 (pro-inflammatory)
Expression of adhesion molecules	MAdCAM	E-selectin
Cell line affected (pass out of vascular space)	GALT cells	Neutrophils

GALT = gut-associated lymphoid tissue; IgA = immunoglobulin A; MALT = mucosal-associated lymphoid tissue; MAdCAM = mucosal addressin adhesion molecule.

causes release of trophic substances such as bile salts, gastrin, bombesin, and motilin. Good contractility controls the overall number of bacteria within the lumen of the gut by peristaltic movement of organisms downstream. EN stimulates the release of secretory immunoglobulin A (IgA), which helps coat luminal bacteria and prevents their adherence to the epithelial wall (Table 216-1). EN stimulates blood flow to the gut and supports the mass of gut-associated lymphoid tissue (GALT). EN stimulates the production of T_H2 anti-inflammatory CD4 helper lymphocytes, which enter the systemic circulation and support immune function. Secretory immunoglobulin A (IgA)-producing immunocytes form mucosal-associated lymphoid tissue (MALT), which generates further production of secretory IgA. EN promotes the role of commensal bacteria, which provide *direct protection* by degrading bacterial toxins and *indirect protection* by preventing colonization of pathogenic organisms (such as *Pseudomonas aeruginosa*). By fermenting prebiotic fiber to short-chain fatty acids, commensal bacteria stimulate butyrate receptors in the colon, which further downregulates inflammation. EN also simulates the immune process of oral tolerance, which further supports the anti-inflammatory functions of T_H1 and T_H3 lymphocytes and the production of the anti-inflammatory agent transforming growth factor-β (TGF-β). The T_H2 cytokines that are produced in this process suppress the adhesion molecule E-selectin, which functions to trap neutrophils within the vasculature. T_H2 cytokines also stimulate the release of mucosal addressin cell adhesion molecule-1 (MAdCAM), which allows GALT cells to mobilize from the splanchnic circulation and return to the lamina propria of the gut.

In specific patient populations, the addition of certain pharmaconutrient agents to an enteral formula exerts a synergistic effect to the benefit already induced by standard enteral formula alone. The addition of arginine has a direct stimulant effect on immune function and thus may further support the T_H2 response, proliferation of lymphocytes, and secretory IgA-producing immunocytes created by the delivery of enteral feeding. The addition of antioxidants, particularly selenium, serves to decrease oxidative stress. Providing fat in the form of fish oil reduces stimulation of the inflammatory ligand toll-like receptor-4 (TLR-4) on macrophages, neutrophils, and adipocytes, reducing the production and generation of NFκ-B and tumor necrosis factor-β. Provision of fish oil generates alternative prostaglandins (PGE_3), leukotrienes (LTB_5), and thromboxane (TXA_3), which have a downregulatory effect on inflammatory mediators compared with the corresponding products of omega-6 fatty acids (PGE_2, LTB_4, TXA_2). Glutamine added to an enteral formula serves as an antioxidant and helps maintain gut integrity. Zinc has a direct effect on the zona occludens, maintaining tight junctions between the gut epithelial cells.

CONSEQUENCES OF NOT PROVIDING ENTERAL NUTRITION

For the critically ill patient, failure to provide enteral feeding generates a different physiologic response that is pro-inflammatory and is associated with worsened outcome. Increases in gut permeability allow activation of macrophages and neutrophils and upregulation of the innate immune responses. Engagement of the luminal bacteria by adherence to the gut epithelium with loss of barrier function adversely affects the acquired immune response, with stimulation and proliferation of T_H1 lymphocytes. Reduced contractility of the gut promotes bacterial overgrowth. Bacteria express virulence genes, which allow them to adhere to the epithelium. A contact-dependent activation of the epithelial cells results in the release of cytokines into the lymphatic channels. A gut-lung axis of inflammation is initiated, in which cytokines pass through the lymphatic channels and the thoracic duct to the systemic circulation and the capillary system of the lungs, promoting acute respiratory distress syndrome (ARDS) (Chapter 104) and pneumonia. The production of T_H1 cytokines stimulates the adhesion molecule E-selectin, which allows extravasation of activated neutrophils out of the vascular space and into the pulmonary alveoli. The same cytokines suppress the release of MAdCAM, which effectively traps GALT cells in the vascular space, preventing their return to the intestinal lamina propria. With the increases in gut permeability and the upregulation of immune responses, the gut becomes a pro-inflammatory organ and contributes its own component to the systemic inflammatory response syndrome (SIRS).

INITIATING ENTERAL FEEDING

In most cases, enteral access may be achieved quickly and easily by placing a nasogastric tube and initiating EN immediately after full volume resuscitation and attainment of hemodynamic stability. Although orogastric feeding may reduce the incidence of sinusitis compared with nasogastric feeding, it may be more difficult to secure a tube adequately that is protruding from the patient's mouth. Surprisingly, more than 95% of critically ill patients will tolerate gastric feeding despite risk for ileus and aspiration. Compared with small bowel feeding, gastric feeding tends to be initiated almost one full day sooner. Small bowel (postpyloric enteral) feeding quickly "catches up" such that the overall mean provision of calories and time to advancement to goal calories are the same between the two levels of feeding. Small bowel feeding does reduce the risk for aspiration but may not significantly reduce the incidence of pneumonia. Small bowel feeds are perceived to be tolerated better because residual volumes are lower compared with gastric feeding. Percutaneous access is required only in those patients anticipated to require tube feeding for longer than 4 weeks.

With initiation of feeding, it often is important to advance to goal as quickly as possible (within 24 to 36 hours).[4] For most patients, the goal of feeding is set by protein and calorie requirements. Accurate determination of caloric requirements helps avoid the danger of overfeeding. The caloric goal can be determined by weight-based equations, such as 25 kcal/kg/day, or by measuring requirements with indirect calorimetry. Protein requirements are best estimated again by weight-based equations, such as 1.2 to 1.5 g/kg/day, or by calculating nitrogen balance using measurement of urinary urea nitrogen excreted in 24 hours (protein requirement = 1 g urine urea nitrogen × 6.25 g protein/1 g N).

There are three clinical scenarios in which it may be appropriate to "permissively" underfeed the hospitalized patient. In obese critically ill patients, meeting protein requirements (estimated at 2.0 to 2.5 g/kg ideal body weight per day) while providing only 60 to 70% of caloric requirements may help mobilize fat stores while maintaining lean body mass.[5] In any patient placed on PN, providing 80% of caloric requirements over the first week of hospitalization helps avoid overfeeding, improves insulin sensitivity, and may increase the chance for an outcome benefit from the PN. In patient with ARDS, trophic feeds providing only 25% of caloric requirements over the first 6 days of hospitalization has been shown to have similar outcomes as full feeds.

However, patients at high nutritional risk should receive feeds as close to goal as possible. Nutrition risk is determined both by evidence of malnutrition (low body mass index, weight loss, or reduced nutrient intake before admission) and disease severity. Nutrition risk may be determined objectively by assessment tools such as the Nutrition Risk Score (NRS) 2002 and the Nutric Score.[6] Patients at high nutritional risk (NRS 2002 score ≥5 or Nutric Score ≥6) should receive at least 80% of goal feeds to obtain optimal benefit (and lowest mortality) from nutrition therapy (E-Table 216-1).

E-TABLE 216-1 NUTRITION ASSESSMENT SCORING SYSTEMS USED TO DETERMINE NUTRITION RISK

NRS 2002: FACTORS USED TO DETERMINE SCORE

IMPAIRED NUTRITIONAL STATUS		SEVERITY OF DISEASE	
Absent score 0	Normal nutritional status	Absent Score 0	Normal nutritional requirements
Mild score 1	Wt loss > 5% in 3 mo *Or* Food intake below 50-75% of normal requirement in preceding week	Mild Score 1	Hip fracture Chronic patients in particular with acute complications: cirrhosis, COPD *Chronic hemodialysis, diabetes, oncology*
Moderate score 2	Wt loss >5% in 2 mo *Or* BMI 18.5-20.5 + impaired general condition *Or* Food intake 25-50% of normal requirement in preceding week	Moderate Score 2	Major abdominal surgery, stroke *Severe pneumonia, hematologic malignancy*
Severe score 3	Wt loss >5% in 1 mo (15% in 3 mo) *Or* BMI <18.5 + impaired general condition *Or* Food intake <25% of normal requirement in preceding week	Severe Score 3	Head injury Bone marrow transplantation *Intensive care patients (APACHE II ≥10)*

Note: If age ≥70 years, add 1 point.
Total score = (points for nutritional status) + (points for disease severity) + (points for age).

NUTRIC SCORE: FACTORS USED TO DETERMINE SCORE

	NUTRIC POINTS			
FACTORS	***0***	***1***	***2***	***3***
Age (yr)	<50	50-74	≥75	—
APACHE II score	<15	15-19	20-27	≥28
Baseline SOFA score	<6	6-9	≥10	—
No. of comorbidities	0-1	≥2	—	—
Days in hospital to ICU admit	0	≥1	—	—
Interleukin-6 (μ/mL)	0-399	≥400	—	—

Total score = (total from six separate factors).

APACHE = Acute Physiologic and Chronic Health Evaluation; BMI = body mass index; COPD = chronic obstructive pulmonary disease; LOS = length of stay; SOFA = simplified organ failure assessment; Wt = weight.

Formula selection has been simplified with the advent of pharmaconutrient formulas. The initial decision in any critically ill patient concerns whether the individual is a candidate for an immune-modulating formula. Patients expected to benefit from an arginine-containing pharmaconutrient formula (compared with a standard formula) are those who require major elective gastrointestinal surgery (esophagectomy, gastrectomy, or pancreatectomy), patients who have experienced major trauma (with an Abdominal Trauma Index Score >20, especially with head injury), burn patients (total body surface area >30%), and patients with head and neck cancer.[■] Critically ill patients who are septic or on mechanical ventilation have not been shown to benefit from use of an arginine-containing pharmaconutrient formula or from supplemental glutamine, omega-3 fatty acids, selenium, or antioxidants.[■] As a result, a standard enteral formula providing 1.0 to 1.5 kcal/mL should be selected for most patients. The only other type of clinical scenario in which a specialty formula is required is when the patient demonstrates evidence of malassimilation (either maldigestion from pancreatic disease or malabsorption from compromise of small bowel absorption). In these patients, a formula composed of small peptides and medium-chain triglyceride oil or a fiber-containing formula should be initiated. Specialty formulas designed for specific organ failure are rarely indicated, owing to their increased expense and the fact that their use has not been shown to alter patient outcome.

After feeds are initiated, the clinician must assess tolerance of EN (Table 216-2). Patients should be assessed to make sure they have achieved adequate volume resuscitation before initiation. Evaluating gut motility is important in selecting the proper tube, the level of feeding within the gastrointestinal tract, and whether there is need for simultaneous gastric decompression while feeding into the small bowel. Adequate gastric contractility is indicated by a nasogastric output of less than 1200 mL/day. Small bowel contractility may be assessed by bowel distention, bowel sounds on physical examination, and air-fluid levels on abdominal radiograph. Colonic contractility is evaluated by passage of stool and flatus. In the absence of risk for ischemia (such as a patient who is hypotensive on pressor agents), ileus is not a contraindication to feeding. In fact, feeding will stimulate promotility agents such as bombesin and motilin. Clinicians should be encouraged to "feed an ileus." Rapid ramp-up in the rate of feeding is tolerated better than slow ramp-up, and enteral feeding protocols should be in place to prevent inappropriate cessation of feeding. The head of the patient's bed should be elevated 35 to 45 degrees, and oral hygiene with chlorhexidine mouthwash twice a day should be used to decrease the bacterial count in oropharyngeal secretions.

TABLE 216-2 ENTERAL NUTRITION (PROTOCOL FOR NASOGASTRIC FEEDING

1. Elevate head of bed 30 to 45 degrees at all times.
2. Scrutinize and correct electrolyte abnormalities (esp. K^+, Ca^{2+}, Mg^{2+}, and phosphorus).
3. Initiate proton pump inhibitor intravenously every 8 hours.
4. Place nasal bridle.
   - Place 12-French nasogastric tube into stomach.
   - Secure tube to bridle.
   - Confirm position by abdominal radiograph.
5. Initiate enteral nutrition (EN) feeds with small peptide/medium-chain triglycerides (MCT) oil formula full strength at 25 mL/hr.
   - Advance by 25 mL/hr every 12 hours as tolerated to goal.
   - State goal feeds: _____ kcal/day, infused at final rate _____ mL/hr.
6. Administer chlorhexidine mouthwash with good oral hygiene nursing care twice daily.
7. Check gastric residual volume (GRV) every 4 hours.
   - Return all contents <500 mL to the patient.
8. If GRV > 400 mL, initiate the following:
   - Continue EN at the current rate.
   - Turn patient to right lateral decubitus position if possible for 30 minutes.
   - Begin metoclopramide 10 mg IV every 6 hours (if patient is receiving opioid narcotics).
   - Begin naloxone, 8 mg in 10 mL saline per tube every 6 hours.
   - Recheck GRV in 4 hours.
9. Only if second GRV 4 hours later is >400 mL, hold EN.
   - Recheck GRV every 2 hours and restart EN when GRV is <400 mL.
   - If no other signs of intolerance, restart at same rate.
   - If other evidence of intolerance is present, consider reducing rate by 25 mL/hr when GRV <400 mL (or to baseline 25 mL/hr).
10. If tube in small bowel and GRV > 50 mL, recheck position of tube by abdominal radiograph. Consider switching to aspirate/feed nasojejunal tube.

Physicians should have a low threshold for initiating prokinetic agents, should monitor laboratory tests to avoid the adverse effect of electrolyte abnormalities on motility, and in the future may use narcotic antagonists (a nonabsorbable methylnaltrexone or an intravenous μ-receptor antagonist, alvimopam) infused through the feeding tube to reverse the effects of any opioid narcotic in order to promote intestinal contractility. Promotility agents such as metoclopramide or erythromycin should be used with caution because they prolong QT intervals and thus may precipitate dysrhythmias.

Gastric residual volume (GRV) is a poor marker of gastric emptying and risk for aspiration. Raising the GRV cutoff level for cessation of feeds does not lead to increased aspiration, and lowering the number does not protect the patient from aspiration or pneumonia. Enteral feeding protocols should set the cutoff value for GRV somewhere between 400 and 500 mL, and feeds should not be stopped for the first GRV above this set point. After the first elevated GRV, the head of the bed should be elevated, the patient should be rolled over if possible into the right lateral decubitus position to promote gastric emptying, promotility agents should be considered, and the EN may be continued. In the absence of other signs of intolerance, the feedings should not be stopped for a single GRV above this cutoff point alone. Only after a second GRV is obtained above the cutoff level 4 hours later should feeds be stopped and the patient assessed further for evidence of intolerance. Eliminating use of GRV as a monitor has been shown surprisingly to increase delivery of EN without increases in aspiration, pneumonia, or any other adverse outcome.[■]

COMPLICATIONS OF ENTERAL FEEDING

Aspiration is the most feared complication arising from provision of EN, but the ability of the clinician to monitor such events is limited. Studies using a very specific and very sensitive laboratory marker for aspiration (tracheal pepsin levels) have shown that most critically ill patients (>75%) show signs of aspiration, occurring at a frequency of 22 to 36% of bedside assessments done every 4 hours. These aspiration events are unwitnessed and unmeasurable by clinical parameters, but an increase in their frequency does correlate with increased risk for pneumonia.[7] Ironically, aspiration of bacteria-laden oropharyngeal secretions is more likely than aspiration of bacteria-laden gastric contents to cause pneumonia. Likelihood for developing pneumonia may be reduced in the high-risk patient by elevating the head of the bed, switching from bolus to continuous infusion, displacing the levels of feeds lower in the gastrointestinal tract below the ligament of Treitz, adding a prokinetic agent, initiating oral hygiene twice daily with chlorhexidine mouthwash, and adding simultaneous gastric decompression.

Tube occlusion occurs when acid from the stomach comes in contact with the formula in the tube and forms a clot. The best declogging agent is a Viokase pancreatic enzyme preparation combined with sodium bicarbonate tablets mixed in warm water. This combination is more than twice as effective as soft drinks or papain meat tenderizer. Failure to declog the tube with these agents may necessitate mechanical declogging with some kind of cytology brush, stylette, or commercial corkscrew device.

Although diarrhea is a frequent complaint in the ICU for patients on tube feeding, most cases represent low-volume incontinence. Although diarrhea in the ICU certainly creates a nursing problem, feeding does not need to be stopped. The most frequent cause of diarrhea in the ICU is the addition of sorbitol as a mixing agent for drugs infused through the feeding tube. Pseudomembranous colitis from *Clostridium difficile* occurs in less than 20% of patients (Chapter 296). Rarely, diarrhea is related to the osmolarity of the formula. Switching to a small peptide formula with medium-chain triglyceride oil or adding fiber to a formula often corrects the problem.

Bowel ischemia (Chapter 143) is a rare and unpredictable complication of enteral feeding. This complication is more often described in patients undergoing surgical placement of a small bowel feeding tube, but cases nonetheless have been shown to occur with nasoenteric feeding tubes. In the patient on EN who becomes hypotensive, feeds should be held if pressor therapy is being initiated, the dose of pressors are being increased, or a second or third agent is being added to the first. Feeds may be restarted in the hypotensive patient on pressor agents if they have been stable for 24 to 36 hours or the doses have already been reduced, or both. It is important to confirm adequate volume resuscitation, fiber should be avoided in these situations, and it may be safer to feed into the stomach than into the small bowel. Enteral feeding in the patient on pressor agents should be held for any sign of intolerance, such as increases in nasogastric output, sudden abdominal distention, new abdominal pain, or cessation of flatus and stool, because these may be the first signs of intestinal ischemia.

One other complication that is seen even today in modern urban university-based hospitals is the *refeeding* syndrome,[8] a syndrome of sudden death associated with abrupt initiation of nutrition therapy. Potential candidates for refeeding syndrome are patients who have not been fed for more than 7 to 10 days, are already severely malnourished, require mechanical ventilation and are prone to hypercapnia, or have congestive heart failure. The mechanism of the refeeding syndrome is related to underlying cardiomyopathy and congestive heart failure, electrolyte shifts when the patient becomes anabolic, or volume overload from the feeding itself. Refeeding syndrome may be prevented by closely monitoring fluid volume, electrolytes, and caloric requirements, starting at a low rate of infusion with a mixed fuel substrate and advancing to goal slowly over 3 to 4 days.

CONCLUSION

The provision of early enteral feeding is one of the most important proactive therapeutic strategies that can favorably alter the outcome of critically ill patients through their course of hospitalization. A fairly narrow window of opportunity in time exists during which to initiate feeds in order to achieve attenuation of oxidative stress and modulate systemic immune responses. The timing, dose, and aspects of delivery of EN determine whether the patient receives the full benefit. The physiologic response seen from enteral feeding cannot be duplicated with parenteral nutrition or starvation. Instituting infusion protocols, improving clinician education (regarding issues such as ileus, GRVs, and perceived tolerance), and having the skills for deep jejunal placement of feeding tubes are all factors that promote the delivery of early EN in the ICU setting.

REVIEW QUESTIONS

1. When performing nutritional assessment on a patient in the ICU, the least important factor in the critical care setting is which of the following?

A. Disease severity
B. Nutritional intake before admission
C. Weight as a percentage of ideal body weight
D. Body mass index
E. Anthropometric measures

Answer: E Nutritional risk is determined by both evidence of malnutrition and disease severity. Evidence of malnutrition is determined by evaluating body mass index, weight as a percentage of ideal body weight, and nutrition intake before admission. These markers of nutritional status and disease severity then can be combined through an assessment tool such as the NRS 2002 or the Nutric Score to determine overall nutrition risk (see E-Table 216-1). Anthropometric measures such as arm muscle circumference and skinfold thickness have little application in the hospitalized setting.

2. In a critically ill patient with acute sepsis, serum albumin levels are low due to which of the following?

A. Increased intestinal permeability
B. Increased vascular permeability
C. Increased hepatic production of albumin
D. Shift to greater protein synthesis of skeletal muscle
E. Increased mobilization of albumin from tissue stores

Answer: B Low albumin levels that follow an acute insult, injury, or admission to an intensive care unit occur because of increased vascular permeability, change in prioritization of hepatic protein synthesis (from proteins of homeostasis to acute phase proteins), and use of albumin as a source of cysteine by the body for antioxidant defense. Serum albumin levels thus represent a negative acute phase response and do not really reflect nutritional status.

3. Which of the following regarding use of the gut in nutrition therapy is true?

A. The gut contains less than 25% of the immune tissue in the body.
B. Antigen processing at the level of the gut supports immune tissue localized only within the gut wall.
C. Bacteria that translocate from the gut migrate out to distant organ sites through the systemic circulation and cause direct infection to that organ.
D. Maintaining gut integrity suppresses a gut-lung axis of inflammation that would otherwise lead to respiratory failure.
E. Opening of the paracellular channels between the epithelial cells stimulates blood flow to the mucosa.

Answer: D The gut contains 65% of overall immune tissue of the body and is responsible for 80% of immunoglobulin production. Antigen processing occurs at the level of the gut but supports and delivers immune tissue to distant sites of mucosal-associated lymphoid tissue (MALT), such as the lungs, genitourinary system, and lacrimal glands. Although bacteria and their products may translocate across the gut wall, they rarely make it past mesenteric lymph nodes or the liver. On the rare occasion that bacteria do make it to the systemic circulation, the inoculum is low, and clinical sequelae are minimal. Maintaining gut integrity through provision of enteral nutrition suppresses the gut-lung axis of inflammation, preventing inflammatory cytokines from passing from the gut up through lymphatics to the lung and causing subsequent respiratory failure. Opening the pericellular channels between the epithelial cells is what accounts for increased permeability and allows bacteria within the gut to engage the immune system.

4. Which of the following is true regarding gastric residual volumes as a monitor for aspiration?

A. Gastric residual volumes correlate well with gastric emptying and risk for aspiration pneumonia.
B. Decreasing gastric residual volume from 400 to 200 mL protects the patient from aspiration.
C. Gastric residual volumes in the range 200 to 500 mL indicate a major risk factor for aspiration and should prompt a change in strategy to reduce risk.
D. Eliminating gastric residual volumes as a monitor of enteral nutrition in the intensive care unit is associated with increased risk for aspiration pneumonia.
E. Raising gastric residual volumes from 200 to 400 mL will result in fewer occasions for cessation of formula infusion, but the incidence of aspiration may be expected to increase dramatically.

Answer: C Gastric residual volumes correlate poorly with gastric emptying and risk for aspiration pneumonia. Changing the cutoff value for residual volume (up or down) does not change the incidence of aspiration or gastroesophageal reflux. Lowering the cutoff value for gastric residual volumes leads simply to cessation of nutrition therapy. Elevated gastric residual volumes in the range of 200 to 500 mL have been identified as a major risk factor for aspiration and should prompt a change in strategy to reduce risk, such as elevating the head of the bed, initiating prokinetic therapy, and placing the patient in the right lateral decubitus position. Surprisingly, eliminating the use of gastric residual volume as a monitor of enteral nutrition in the intensive care unit is associated with increased delivery of enteral nutrition and no additional adverse sequelae.

5. Ileus during enteral nutrition represents which of the following?

A. Decreased splanchnic blood flow
B. Occult infection
C. Reduced intestinal contractility
D. Loss of GALT tissue
E. Reduced gastrointestinal absorptive capacity

Answer: C Ileus represents reduced intestinal contractility in response to acute injury, insult, or critical illness. Early provision of enteral nutrition helps preserve contractility and minimize ileus. Although failure to provide enteral nutrition in the critical care setting does result in reduced splanchnic blood flow, loss of GALT tissue, and reduced absorptive capacity with loss of intestinal villi, ileus relates solely to issues of contractility.

MALNUTRITION, NUTRITIONAL ASSESSMENT, AND NUTRITIONAL SUPPORT IN ADULT HOSPITALIZED PATIENTS

THOMAS R. ZIEGLER

MALNUTRITION IN HOSPITALIZED PATIENTS

Numerous surveys conducted in developed countries in the 21st century continue to demonstrate the frequent rate of protein-energy malnutrition or depletion of specific micronutrients in patients with chronic illnesses and in those requiring elective or emergent hospital admission. Hospitalized patients commonly receive inadequate amounts of calories, protein, vitamins, and minerals during their stay, and ad libitum intake of prescribed diets is typically inadequate. Studies have shown that worsening of malnutrition during the hospital admission is common. This is a problem because adequate intake of essential macronutrients (energy, carbohydrate, protein/amino acids, and fats) and micronutrients (vitamins, minerals, and electrolytes) is critical for optimal cellular and organ structure and function, muscle mass, tissue repair, immune function, ambulatory capacity, and recovery of the patient. Significant erosion of lean body mass (predominantly derived from skeletal muscle) or deficiency of specific vitamins and minerals is variously associated with weakness and fatigue, increased rates of infection, impaired wound healing, and delayed convalescence. This relationship is especially apparent in those with chronic protein-energy malnutrition and body weight loss associated with illness (Chapters 215 and 216).

Patients with acute and chronic illnesses typically have experienced several days to several weeks or months of continuous or intermittent decreased food intake because of anorexia, gastrointestinal symptoms, depression or anxiety, and other medical factors. They may also have had food intake restricted because of surgical operations or diagnostic or therapeutic procedures and recovery from these. Some patients have abnormal nutrient losses due to diarrhea (e.g., with chronic malabsorptive and maldigestive disorders or infectious diarrhea), vomiting, polyuria (as in uncontrolled diabetes mellitus), wound drainage, dialysis, and other causes. Certain drugs, including corticosteroids, chemotherapeutic agents, antirejection drugs, and diuretics, are associated with skeletal muscle breakdown, gastrointestinal injury, and electrolyte or water-soluble vitamin losses, respectively. Bedrest or markedly decreased ambulation is common in outpatient and inpatient settings and in turn associated with skeletal muscle wasting and impaired protein synthesis. Catabolic and critical illnesses are associated with concomitantly increased blood concentrations of "counter-regulatory" hormones derived from the adrenal glands and pancreas (e.g., cortisol, catecholamines, glucagon); release of proinflammatory cytokines from stimulated immune, endothelial, and epithelial cells (interleukins 1, 6, and 8 and tumor necrosis factor-α); and peripheral tissue resistance to anabolic hormones (insulin and insulin-like growth factor-I). These hormonal and cytokine alterations serve to increase the availability of endogenous metabolic substrates critical for cellular and organ function, wound healing, and host survival (e.g., glucose through glycogenolysis and gluconeogenesis, amino acids through skeletal muscle breakdown, and free fatty acids through lipolysis). This combination of decreased nutrient intake and increased tissue nutrient losses, coupled with increased energy (calorie), protein, and micronutrient needs due to inflammation, infection, and cytokinemia, is responsible for the wasting and micronutrient depletion common in medical patients with acute and chronic illness. Common causes of protein-energy malnutrition and micronutrient depletion in medical patients are shown in Table 217-1. Obesity has become a widespread medical problem and is a form of malnutrition but is considered in detail elsewhere (Chapter 220).

NUTRITIONAL ASSESSMENT

Serial assessment of nutritional status is a critically important component of routine medical care (Chapter 214). The major objectives are to detect preexisting depletion of body protein, energy reserves, and micronutrients; to identify risk factors for malnutrition (see Table 217-1); and to take steps to prevent nutrient deficiencies, depletion of lean body mass, and loss of skeletal muscle. Unfortunately, there are still no practical "gold standard" tests that can be used as an index of general nutritional status. Blood concentrations of specific micronutrients (e.g., copper, zinc, thiamine, 25-hydroxyvitamin D, vitamin B_6, folate, vitamin B_{12}) and electrolytes (e.g., magnesium, potassium, phosphorus) are important to guide needs and repletion responses. Nutritional assessment (Chapter 214) involves an integration of multiple factors: medical and surgical history; type and severity of the acute or chronic underlying illness and anticipated medical and surgical course; fluid drainage sites and amounts; physical examination findings; history of body weight change (degree and temporal aspects); dietary intake pattern; use of nutritional supplements, including prior administration of specialized enteral nutrition (EN) or parenteral nutrition (PN); evaluation of current organ function and fluid status; and determination of selected vitamin, mineral, and electrolyte concentrations in blood (E-Table 217-1). In the intensive care unit (ICU) setting, measured body weight typically reflects recent intravenous fluid administration and is typically much higher than recent "dry" or preoperative body weight, which is the best parameter to use.

E-TABLE 217-1 COMPREHENSIVE NUTRITIONAL ASSESSMENT OF MEDICAL AND SURGICAL PATIENTS

REVIEW PAST MEDICAL AND SURGICAL HISTORY AND CURRENT ILLNESS

Degree of catabolic stress (e.g., fever, infections, sepsis, surgeries, lung failure)
Organ function (e.g., liver, kidneys, lung, heart/vascular, gastrointestinal)
Use of medications that may decrease nutrient absorption (e.g., phenytoin, sulfasalazine, elixir-based medications), alter metabolism/utilization (e.g., warfarin, isoniazid, methotrexate), or increase excretion (e.g., gentamicin, loop diuretics)
Recent intravenous fluid and electrolyte therapy
Medical and surgical procedures that are likely in the near term
Hemodynamic status and requirements for pressor agents to maintain blood pressure

OBTAIN BODY WEIGHT HISTORY

Current body weight: dry weight, if available (e.g., preoperative, recent clinic visit), and usual body weight when healthy or clinically stable; calculate percentage body weight loss from usual body weight during the past several weeks and months
Calculate current weight as percentage of ideal body weight*
Determine body mass index (BMI = weight (kg)/height $(m)^2$; BMI < 18.5 is considered underweight)

DETERMINE DIETARY INTAKE PATTERN IN RELATION TO NUTRIENT NEEDS

General food and beverage intake pattern; percentage of usual dietary intake consumed in recent weeks and months (e.g., percentage of usual); unusual or excessive consumption of specific foods or beverages, including alcoholic beverage consumption
Previous use and type of enteral tube feedings or parenteral nutritional support
Previous use of liquid or solid nutritional supplements, multivitamin-mineral preparations, specific vitamins or minerals
Consult registered dietitian for more detailed nutrient intake assessment

PERFORM DETAILED PHYSICAL EXAMINATION

Skeletal muscle wasting (cannot be assessed accurately in overweight or obese patients)
Loss of body fat stores
Presence and qualities of wounds
Skin, hair, tongue, or conjunctival lesions suggestive of micronutrient deficiency (see Table 217-2)
Evidence of organ dysfunction (gastrointestinal, liver, renal, cardiopulmonary)
Fluid status (e.g., normal, dehydrated, fluid overload, capillary leak); fluid requirements are typically ≈ 30-40 mL/kg body weight

EVALUATE GASTROINTESTINAL TRACT FUNCTION

Swallowing or chewing difficulties, nausea, emesis, abdominal pain
Intestinal ileus, motility disorders, partial or complete obstruction
Diarrhea history (frequency, amount, other characteristics)
Acute or chronic gastrointestinal bleeding
Presence of fistulas; history of recent abdominal surgery
Drainage tube losses (e.g., gastric, biliary, intestinal, peritoneal)

DETERMINE FUNCTIONAL STATUS

Ability to perform daily activities, ambulatory capacity, bedrest, chemical paralysis
History or physical examination evidence of muscle weakness and fatigue
Mental capacity, history of psychiatric disorders that may preclude oral food intake

SERIAL EVALUATION OF SELECTED BIOCHEMICAL TESTS

Concentrations of standard blood measures of organ function
Electrolyte concentrations (e.g., calcium, magnesium, phosphorus, and potassium)
Blood pH (in ICU patients on mechanical ventilation)
Blood triglyceride concentrations (in patients receiving intravenous lipid emulsion)
Blood concentrations of selected vitamins and minerals if suggested by medical or dietary history, physical examination, or underlying illness (e.g., blood levels of zinc, selenium, copper, thiamine, vitamin B_6, vitamin B_{12}, folate, 25-hydroxyvitamin D)
Serum prealbumin (in stable outpatients)†

ESTIMATE CALORIE, PROTEIN, AND MICRONUTRIENT NEEDS

Calorie needs by Harris-Benedict equation,‡ guidelines on kilocalories per kilogram of body weight,§ or indirect calorimetry results (use serially in ICU patients and in initial assessment of very underweight or obese hospitalized patients requiring prolonged nutritional support)
Protein needs vary as a function of recognized clinical situations (see Table 217-3)
Vitamin and mineral needs are based on conventional requirements, serial blood levels, and clinical judgment regarding intake and estimated losses from comprehensive nutritional assessment
Nitrogen balance studies are not useful in non-research settings because of their variability and inaccuracy
Serial body composition measurements for lean body mass and body fat estimates may be useful in the outpatient setting (by BIA or DEXA) but are not practical or reliable in inpatient non-research settings because of fluid shifts and other factors

EVALUATE ENTERAL AND PARENTERAL ACCESS FOR NUTRIENT DELIVERY

Ability to take oral diet or liquid supplements
Central venous or PICC line access; peripheral line access
Nasogastric, nasoenteric, or percutaneous feeding tube availability or feasibility

CONSULTATION WITH MULTIDISCIPLINARY NUTRITION SUPPORT TEAM

BIA= bioelectrical impedance analysis; DEXA = dual-energy x-ray absorptiometry; ICU = intensive care unit; PICC = peripherally inserted central venous catheter.
*Ideal body weight can be estimated in men as 48 kg (106 pounds) per 5 feet of height + 2.7 kg (6 pounds) for each inch of height above 5 feet and in women as 45 kg (100 pounds) per 5 feet of height + 2.3 kg (5 pounds) for each inch of height above 5 feet.
†Blood concentrations of albumin and prealbumin in hospitalized patients, especially in the ICU setting, are markedly affected by non-nutritional factors (inflammation, infection, fluid status, capillary leak, decreased hepatic synthesis, and increased clearance from blood).
‡Harris-Benedict equation to estimate basal energy expenditure (BEE) for males and females:

$$\text{Males (kcal per 24 hours)} = 66.5 + (13.8 \times \text{kg body weight}) + (5.0 \times \text{height in cm}) - (6.8 \times \text{age in years})$$

$$\text{Females (kcal per 24 hours)} = 655 + (9.6 \times \text{kg body weight}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$$

§Calorie needs can also be estimated as kcal/kg/day (using dry weight or ideal body weight in ICU patients with fluid overload): ICU settings = 20 to 25 kcal/kg/day (some studies suggest that 15 to 20 kcal/kg/day or lower may be appropriate); non-ICU settings = 25 to 35 kcal/kg/day.

TABLE 217-1 COMMON CAUSES OF PROTEIN-ENERGY MALNUTRITION AND MICRONUTRIENT DEPLETION IN MEDICAL PATIENTS WITH ACUTE OR CHRONIC ILLNESSES

- Decreased spontaneous food intake due to anorexia from chronic or acute illness, gastrointestinal symptoms (e.g., nausea, vomiting, abdominal pain), depression/anxiety
- Restricted food intake required for surgical operations or diagnostic/therapeutic procedures and gastrointestinal dysfunction that follows these
- Abnormal macronutrient and micronutrient losses from the body due to malabsorption (e.g., celiac sprue, short-gut syndrome, inflammatory bowel disease, cystic fibrosis, diarrhea), maldigestion (e.g., pancreatitis), emesis, polyuria (e.g., in diabetes), wound drainage, or renal replacement therapy
- Periods of increased energy expenditure (calorie needs), protein requirements, and micronutrient needs (e.g., critical illness, increased inflammation)
- Catabolic effects of counter-regulatory hormones (e.g., cortisol, catecholamines, glucagon), release of proinflammatory cytokines from stimulated immune cells and endothelial and epithelial cells (interleukins 1, 6, and 8 and tumor necrosis factor-α), and peripheral tissue resistance to the anabolic hormones insulin and insulin-like growth factor-I
- Bedrest, decreased ambulation, and chemical paralysis during mechanical ventilation (skeletal muscle wasting due to impaired protein synthesis)
- Administration of drugs that induce skeletal muscle breakdown, gastrointestinal injury, or electrolyte and water-soluble vitamin losses (e.g., corticosteroids, chemotherapeutic agents, diuretics, and antirejection regimens)
- Socioeconomic deprivation, inadequate caregivers, ambulation difficulties in the home setting
- Inadequate provision of calories, protein, and essential micronutrients (vitamins, minerals, and trace elements) during hospitalization

TABLE 217-2 CLINICAL MANIFESTATIONS OF SPECIFIC NUTRIENT DEFICIENCIES

PHYSICAL EXAMINATION SIGN OR SYMPTOM OF NUTRIENT DEPLETION	SPECIFIC NUTRIENT DEPLETED
Muscle and fat wasting, weakness	Calories, protein, combined calories and protein
Anorexia	Calories, protein
Glossitis (discolored, smooth, painful tongue)	Folate, vitamin B_{12}, niacin, riboflavin, thiamine, iron
Cheilosis, angular stomatitis	Riboflavin, niacin, folate, vitamin B_{12}
Symmetrical motor or sensory dysfunction, ataxia, nystagmus, heart failure, mental status changes or confusion	Thiamine (beriberi)
Peripheral edema	Thiamine (heart failure), protein (low oncotic pressure)
Loss of vibratory or position sense, fatigue	Vitamin B_{12}
Dermatitis (sun-exposed skin), diarrhea, dementia	Niacin (pellagra)
Bleeding gums, petechiae, ecchymosis	Vitamins C and K
Poor wound healing	Calories, protein, calories and protein, vitamin C, vitamin A, zinc, others
Bone pain	Vitamin D (osteomalacia)
Follicular hyperkeratosis, night blindness, Bitot's spots	Vitamin A
Flaky, whitish dermatitis	Essential fatty acid (linoleic, α-linolenic)
Hair sparse or easily pluckable	Zinc, protein
Pale skin, nail spooning (koilonychia)	Iron
Loss of taste; reddish dermatitis around nose, mouth, groin; hair loss	Zinc
Peripheral neuropathies, gait abnormalities, weakness, fatigue	Copper
Muscle pain, heart failure	Selenium
Paresthesias, carpal pedal spasm	Calcium, magnesium, phosphorus, or potassium

Note: Typically severe deficiency of specific nutrients (with depletion of initially tissue and later blood concentrations) has occurred before physical manifestations of deficiency.

Integration of the factors outlined in E-Table 217-1 provides important information on whether patients are likely to be adequately nourished; to have mild, moderate, or severe protein-energy malnutrition; or to have depletion or deficiency of specific vitamins, minerals, or electrolytes. Patients with an involuntary body weight loss of 5 to 10% or more of their usual body weight in the previous few weeks or months, those weighing less than 90% of their ideal body weight, or those who have a body mass index less than 18.5 kg/m^2 should be carefully evaluated as these individuals are likely to be malnourished.

In hospitalized patients, especially those in the ICU, circulating concentrations of proteins (e.g., albumin, prealbumin) are generally low and not useful as protein nutritional status biomarkers, given their lack of specificity. Plasma concentrations of albumin and prealbumin typically fall during active inflammation or infection, in critical illness, and after traumatic injury (deceased synthesis by liver, catabolism of blood proteins) and are markedly affected by non-nutritional factors, including fluid status, capillary leak, decreased hepatic synthesis, and increased clearance from blood. Because of the long circulating half-life of albumin (18 to 21 days), concentrations in blood remain low despite adequate feeding and are slow to respond to nutritional repletion, irrespective of the other confounding factors noted before. Prealbumin has a much shorter circulating half-life than albumin (several days), and serial blood levels can be used as a general indicator of protein status in clinically stable outpatients. Table 217-2 illustrates physical examination findings that may be observed in association with depletion of specific nutrients.

Energy requirements can be estimated by standard equations, such as the Harris-Benedict equation, which incorporate the patient's age, gender, weight, and height to determine basal energy expenditure (BEE; see E-Table 217-1). Physical activity and the thermic effect of macronutrient administration can be added to the BEE to arrive at the energy prescription to maintain current body weight; this is estimated for most hospital patients and outpatients as 1.2 to 1.3 times BEE, unless the patient is sedated or at bedrest (common in the ICU), which decreases energy needs. The estimated maintenance energy requirement is approximately 1.3 times BEE in ambulatory subjects. Lower amounts of calories are now typically given in ICU patients (see later). Data obtained from a bedside metabolic cart machine (indirect calorimeter), which measures expired breath to determine oxygen consumption and carbon dioxide production, provide accurate actual energy expenditure in most settings and can be useful (see E-Table 217-1). A simple and relatively accurate method to estimate energy needs is simply to use 20 to 25 kcal/kg/day actual dry or ideal body weight in most patients. This assumes that the body weight used does not reflect intravenous fluid administration or capillary leak syndromes (see earlier). In ICU patients, even lower calorie doses (equivalent to 15 to 20 kcal/kg dry weight/day) have been advocated by some on the basis of known complications of overfeeding (see later) and limited clinical outcome data as a function of energy dose. In clinically stable, malnourished, non-ICU patients who require nutritional repletion, higher doses of calories (up to 35 kcal/kg/day) appear to be generally well tolerated, as long as refeeding syndrome is avoided (see later). In obese subjects (defined for these calculations as >20 to 25% above ideal body weight), adjusted body weight should be used in the calculation of energy and protein needs by the following equation:

$$\text{Adjusted body weight} = \text{current weight} - \text{ideal body weight}\ (\text{from standard tables or equations}) \times 0.25 + \text{ideal body weight}$$

Guidelines for protein/amino acid administration are given in Table 217-3. Studies in nonburned ICU patients indicate that protein loads of more than 2.0 g/kg/day are not efficiently used for protein synthesis and the excess may be oxidized and contribute to azotemia. In most catabolic patients requiring specialized feeding, a generally recommended protein dose is 1.5 g/kg/day in individuals with normal renal function. This is about twice the recommended dietary allowance for healthy adults of 0.8 g/kg/day. The administered protein dose should be adjusted downward as a function of the degree and tempo of azotemia (in the absence of dialysis therapy) and hyperbilirubinemia (see Table 217-3). This strategy takes into account the relative inability of catabolic patients to efficiently use exogenous nutrients and the knowledge that most protein and lean tissue repletion occurs in a period of several weeks to months during post-hospital convalescence. Adequate

TABLE 217-3 ESTIMATION OF PROTEIN/AMINO ACID REQUIREMENTS IN ADULT PATIENTS

CLINICAL CONDITION	PROTEIN/AMINO ACID DOSE (g/kg/day)*,†
Well nourished with acute illness	1.2-1.5
Malnourished or severe catabolic stress	1.5-2.0
Postoperative	1.2-1.5
Acute hepatic failure	0.6-1.2
Encephalopathy	0-0.6
Acute renal failure, not receiving renal replacement therapy	0.6-1.0
Renal failure, receiving renal replacement therapy	1.2-2.5

*Oral/enteral nutrient supplements and tube feedings contain either intact or partially hydrolyzed high-quality protein (typically casein, soy, or whey). Parenteral nutrition solutions for peripheral or central vein administration provide known essential L-amino acids combined with several nonessential amino acids. These may be limiting in certain conditionally essential amino acids (e.g., cysteine, taurine) in some clinical conditions.
†Limited data from randomized controlled trials on optimal protein/amino acid dosing in hospitalized patients are available.

TABLE 217-4 SOME CLINICAL INDICATIONS FOR SPECIALIZED ORAL/ENTERAL OR PARENTERAL NUTRITION SUPPORT

- Patient currently exhibits moderate to severe protein or protein-energy malnutrition or has evidence of specific deficiency of one or more essential micronutrients
- Patient with involuntary body weight loss of 5-10% or more of usual body weight in the previous few weeks or months, who weighs <90% of ideal body weight, or who has BMI <18.5 kg/m^2.
- Dietary food intake in hospital or outpatient setting likely to be <50% of needs for more than 5-10 days because of underlying illness
- Patient with severe catabolic stress (e.g., ICU care, serious infection) and adequate nutrient intake unlikely for >3-5 days
- After major gastrointestinal surgery or other major operations (e.g., hip replacement, partial organ resection)
- Medical illness associated with prolonged (>5-10 days) gastrointestinal dysfunction (diarrhea, nausea/vomiting, gastrointestinal bleeding, severe ileus, partial obstruction) or short-bowel syndrome, chronic/severe diarrhea, or other malabsorptive disorders
- Clinical settings in which adequate oral food intake may be contraindicated or otherwise significantly decreased, such as respiratory or other acute or severe organ failure, dementia, dysphagia, chemotherapy/irradiation, inflammatory bowel disease, pancreatitis, high-output enterocutaneous fistula, alcoholism, drug addiction
- Chronic obstructive lung disease, chronic infection, and other chronic inflammatory or catabolic disorders with documented poor nutrient intake or recent weight loss

BMI = body mass index; ICU = intensive care unit.

nonprotein energy is essential to allow amino acids to be effectively used for protein synthesis and to not be oxidized for energy (adenosine triphosphate) production. The nonprotein calorie-to-nitrogen ratio used in most centers now typically ranges from 75 : 1 to 125 : 1 (nitrogen = protein/6.25; thus, 75 to 125 nonprotein kilocalories for each 6.25 g of protein or amino acid administered). Highly catabolic patients in the ICU are typically given protein loads at the lower end of this range, assuming near-normal renal and hepatic function.

NUTRITIONAL SUPPORT

Table 217-4 lists common clinical scenarios in which specialized oral/EN or PN support may be indicated. In these settings, consultation with a multidisciplinary nutrition support team, if one is available, has been shown to reduce complications and costs and to increase the appropriate use of EN and PN in both academic and community medical centers.[1]

Oral nutrition supplementation includes provision of balanced oral diets of usual foods supplemented with complete liquid (or solid) nutrient products, protein supplements (e.g., hydrolyzed whey or casein powder that can be mixed with dietary beverages), high-potency multivitamin-mineral supplements, and specific micronutrients required to treat a diagnosed deficiency (e.g., zinc, copper, vitamin B_6, vitamin B_{12}, and vitamin D). Special supplements designed for patients with chronic renal failure featuring concentrated calories and low amounts of protein and electrolytes are available, as are a variety of formulations designed for other specific disease categories (see later). Several studies show that convalescence is enhanced with addition of one or two cans per day of complete liquid nutrient supplements to meals after stresses such as total hip replacement and gastrointestinal surgery. These provide calories, carbohydrate, high-quality protein, fat, and micronutrients; they are lactose and gluten free and may contain small peptides and medium-chain triglycerides to facilitate amino acid and fat absorption, respectively. Some formulations also contain soluble fiber or prebiotics (e.g., fructo-oligosaccharides) designed to decrease diarrhea. For patients who can tolerate oral medications, it is probably prudent to prescribe a potent oral multivitamin-mineral preparation, at least for several months, especially for those who either exhibit or are at risk for micronutrient depletion (see E-Table 217-1 and Table 217-2).

Administration of Enteral Tube Feeding

Patients with conditions outlined in Table 217-4 may have a functional gastrointestinal tract but may be unable to consume an adequate diet orally because of medical or surgical conditions (e.g., mechanically ventilated patients; those with pancreatitis, dementia, or dysphagia; and after trauma or burns). Although PN is commonly administered in these settings, this practice is not evidence based; academic guidelines strongly suggest that oral nutritional supplements or enteral tube feedings be used if specialized nutrition support is indicated in patients with a functional gastrointestinal tract ("if the gut works, use it"). On an individualized basis, aggressive nutrition support, including placement of feeding tubes, may not be desired by a competent patient or legally authorized representatives, such as in premorbid states or terminal illness. In these cases, full discussion with the patient and family or representatives is required with regard to the plan for EN.

Detailed discussion of EN and enteral tube feeding is provided in Chapter 216.

Administration of Parenteral Nutrition

PN support includes administration of standard complete nutrient mixtures, which contain dextrose, L-amino acids, lipid emulsion, electrolytes, vitamins, and minerals (and certain medications as indicated, such as insulin or octreotide), given through either a peripheral or central vein. PN technically also includes parenteral administration of specific micronutrients or micronutrient combinations to replete a deficiency (e.g., thiamine, copper, electrolytes). Administration of complete PN therapy in patients with gastrointestinal tract dysfunction has become a standard of care in most hospitals and ICUs throughout the world, although use in individual institutions varies widely.[2,3] PN is life-saving in patients with intestinal failure (e.g., short-bowel syndrome); unfortunately, in patient subgroups with lesser degrees of intestinal failure, few objective data from properly designed, large, randomized controlled studies are available to determine the true efficacy of and optimal indications for PN.[4] The use of PN in ICUs in the United States declined during the past decade, with EN increasing coincidentally during the same time.[5]

Existing data indicate that PN does benefit patients with preexisting moderate to severe malnutrition or with critical illness by decreasing overall morbidity and possibly mortality compared with patients receiving inadequate EN or hydration (intravenous dextrose) therapy alone. An earlier meta-analysis of well-designed, intent-to-treat, randomized controlled trials in adult ICU patients showed that early PN and early EN (each started within 24 hours of ICU admission) were equivalent in terms of mortality, but PN was associated with decreased mortality compared with ICU patients who received delayed enteral feeding (begun >24 hours after admission).■ In this and earlier trials, however, PN use was associated with a higher rate of infection compared with enterally fed patients. Randomized controlled trials suggest that patient subtype and ability to tolerate EN can influence the clinical effects of different strategies for the timing of initiation of PN in critical illness. A consensus based on recent rigorous studies in critical illness is emerging that early PN is no better than early EN.■ PN should probably not be initiated until day 3 or 4 after ICU admission in patients unable to tolerate adequate EN.■■ The provision of early PN to critically ill adults with relative contraindications to early EN, compared with standard care, was recently found not to result in a difference in mortality at 60 days, fewer days of ventilation, or significantly shorter ICU stay or hospital days.■

The basic principle in considering PN therapy is that the patient must be unable to achieve adequate nutrient intake by the enteral route. Compared with PN, EN is less expensive, probably maintains intestinal mucosal structure and function to a greater extent, is safer in terms of mechanical and metabolic complications (see later), and is associated with reduced rates of nosocomial infections. Thus, the enteral route of feeding should be used and advanced whenever possible and the amount of administered PN correspondingly reduced. Generally recognized indications for PN include the following:

- Patients with short-bowel syndrome or other conditions causing intestinal failure that prohibit adequate intake or absorption of enteral nutrients (e.g., motility disorders, obstruction, severe ileus, severe inflammatory bowel disease), especially in those with preexisting malnutrition
- Clinically stable patients in whom adequate enteral feeding (e.g., >50% of needs) is unlikely for 7 to 10 days because of any underlying illness
- Patients with severe catabolic stress requiring ICU care in whom adequate enteral nutrient intake is unlikely for more than 3 to 5 days

There is no reason to withhold PN in hospital patients for any time if they exhibit preexisting moderate to severe malnutrition and are deemed to be unlikely to meet their needs by the oral or enteral route.

Generally accepted contraindications to PN (that are largely not evidence based) include the following:

- The gastrointestinal tract is functional and access for enteral feeding is available
- PN is thought to be required for 5 days or less
- The patient cannot tolerate the extra intravenous fluid required for PN or has severe hyperglycemia or electrolyte abnormalities on the planned day of PN initiation
- The patient has uncontrolled blood stream infection or severe hemodynamic instability
- New placement of an intravenous line solely for PN poses undue risks on the basis of clinical judgment
- On an individualized basis when aggressive nutrition support is not desired by the competent patient or legally authorized representatives, such as in premorbid patients or those with terminal illness (full discussion with the patient and family or representatives is required)

PN can be delivered as either peripheral vein solutions or central vein solutions through percutaneous subclavian vein or internal jugular vein catheters for infusion into the superior vena cava (nontunneled in the hospital setting), subcutaneously tunneled central venous catheters (e.g., Hickman catheters) or central venous ports (for chronic home PN therapy), or peripherally inserted central venous catheters (PICC). Although data are limited, it is clearly preferable to manage patients requiring long-term central venous PN at home with a tunneled central venous catheter compared with a PICC line because of the higher rate of local complications (e.g., phlebitis, catheter breakage) and possibly catheter-associated infections with PICC lines.

A comparison of typical fluid, macronutrient, and micronutrient content of peripheral and central vein PN is shown in Table 217-5. To diminish the risk of phlebitis, typical peripheral vein PN solutions provide low concentrations of dextrose (5%; provides 3.4 kcal/g) and amino acids (<3.5 %; provides 4 kcal/g), with a large proportion of energy administration as fat emulsion (50 to 60% of total calories). Because fluid restriction or organ dysfunction often precludes use of large fluid volumes for PN, peripheral vein PN is generally not indicated in ICU patients or in patients with fluid overload or renal, hepatic, or cardiac failure. These solutions are most useful in stable patients who can tolerate the large fluid volumes required to meet amino acid and energy goals (usually 2.5 to 3 L/day) without providing excessive lipid.

Intravenous lipid emulsions (typically added to PN as a 20% soybean oil–based solution in the United States) provide both essential linoleic and α-linolenic fatty acids and energy (10 kcal/g); these are generally infused during a 24-hour period in the complete PN administration bag. The maximal recommended rate of fat emulsion infusion is approximately 1.0 g/kg/day. Most patients clear triglyceride from intravenous fat emulsion well from plasma. In some studies, larger doses of soybean oil–based fat emulsion were associated with proinflammatory and pro-oxidative effects and possibly immune suppression, presumably due to the high amount of omega-6 fatty acids derived from the linoleic fatty acid component. This has led to the approval and clinical availability of intravenous fish oil, olive oil/soybean oil, medium-chain triglyceride/soybean oil, and combinations of these formulations in Europe and other non-U.S. countries. An intravenous lipid emulsion of 80% olive oil/20% soybean oil was recently approved for use in adult PN in the United States. It is important to monitor blood triglyceride levels at baseline and then approximately weekly and as indicated to assess clearance of intravenous fat. Triglyceride levels should be maintained below 400 mg/dL to decrease the risk of pancreatitis or diminished pulmonary diffusion capacity in patients with severe chronic obstructive lung disease.

TABLE 217-5 COMPOSITION OF TYPICAL PARENTERAL NUTRITION SOLUTIONS

COMPONENT*	PERIPHERAL PN	CENTRAL PN
Volume (L/day)	2-3	1-1.5
Dextrose (%)	5	10-25
Amino acids (%)†	2.5-3.5	3-8
Lipid (%)‡	3.5-5.0	2.5-5.0
Sodium (mEq/L)	50-150	50-150
Potassium (mEq/L)	20-35	30-50
Phosphorus (mmol/L)	5-10	10-30
Magnesium (mEq/L)	8-10	10-20
Calcium (mEq/L)	2.5-5	2.5-5
Trace elements§		
Vitamins¶		

*Electrolytes in parenteral nutrition (PN) are adjusted as indicated to maintain serially measured serum levels within the normal range. The percentage of sodium and potassium salts as chloride is increased to correct metabolic alkalosis, and the percentage of salts as acetate is increased to correct metabolic acidosis. Regular insulin is added to PN as needed to achieve blood glucose goals (separate intravenous insulin infusions are commonly required with hyperglycemia in intensive care unit settings).
†Provides all essential amino acids and several nonessential amino acids. Dose of amino acids is adjusted downward or upward to goal as a function of the degree of azotemia or hyperbilirubinemia in patients with renal and hepatic failure, respectively.
‡Lipid is given as soybean oil– or olive oil/soybean oil–based fat emulsion in the United States, Europe, and other non-U.S. countries; intravenous fish oil, olive oil, medium-chain triglycerides, and combinations of these are available for use in PN. Lipid is typically mixed with dextrose and amino acids in the same PN infusion bag ("all-in-one" solution).
§Trace elements added on a daily basis to peripheral vein and central vein PN are mixtures of chromium, copper, manganese, selenium, and zinc (can also be supplemented individually).
¶Vitamins added on a daily basis to peripheral vein and central vein PN are mixtures of vitamins A, B_1 (thiamine), B_2 (riboflavin), B_3 (niacinamide), B_6 (pyridoxine), B_{12}, C, D, and E and biotin, folate, and pantothenic acid. Vitamin K is added on an individual basis (e.g., in patients with cirrhosis). Specific vitamins can also be supplemented individually.

Central venous administration of PN allows higher concentrations of dextrose (3.4 kcal/g) and amino acids (4 kcal/g) to be delivered as hypertonic solutions, and thus lower amounts of fat emulsion are needed to reach calorie goals (see Table 217-5). Requirements for potassium, magnesium, and phosphorus are typically higher with central vein PN compared with peripheral vein PN because of the increased dextrose provided by insulin-mediated intracellular electrolyte shifts, use in anabolic pathways, glucose metabolism, and adenosine triphosphate production. The higher concentrations of dextrose and amino acids possible allow most patients to achieve calorie and amino acid goals with only 1 to 1.5 L/day of PN. In central vein PN, initial orders typically provide 60 to 70% of non–amino acid calories as dextrose and 30 to 40% of non–amino acid calories as fat emulsion. These percentages are adjusted as indicated on the basis of blood glucose and triglyceride levels, respectively. The dextrose amount in central vein PN should be reduced or regular insulin added to the PN bag to maintain blood glucose concentration within the desired range. Separate intravenous insulin infusions should usually be used in the ICU when patients receiving central vein PN develop hyperglycemia.[6]

Specific requirements for intravenous trace elements and vitamins have not been rigorously defined for patient subgroups, and therapy is directed at meeting published recommended doses that maintain blood levels in the normal range in most stable patients with standardized intravenous preparations (see Table 217-5). Several studies have shown that a significant proportion of ICU patients have low zinc, selenium, vitamin C, vitamin E, and vitamin D levels despite receiving specialized PN (or EN). Depletion of these essential nutrients may in turn impair antioxidant capacity, immunity, wound healing, and other important body functions. For example, zinc is known to be important for immune function, wound healing, protein synthesis, and gastrointestinal mucosal regeneration. Zinc (and other micronutrients, such as copper) should probably be increased in the PN of patients with burns, large wounds, significant gastrointestinal fluid losses, and other conditions if

serum concentrations indicate low levels. This practical recommendation is not evidence based, however, because recent rigorous randomized trials in ICU patients administered large doses of selenium could not reproduce the positive clinical benefits observed in earlier smaller studies, and studies of zinc supplementation in the ICU setting have been inconclusive. Recent data suggest that thiamine depletion is not uncommon in patients receiving chronic diuretic therapy or in those with severe malabsorption.

Complications of Parenteral Nutrition

The most common complication of peripheral vein PN is local phlebitis due to the catheter. Alterations in blood electrolytes can be treated with adjustment of concentration in the peripheral PN prescription. Hypertriglyceridemia typically responds well to lowering of the total PN lipid dose. Central vein PN is associated with a much higher rate of mechanical, metabolic, and infectious complications than peripheral vein PN. Mechanical complications include those related to insertion of the central venous catheter (e.g., pneumothorax, hemothorax, malposition of the catheter, and thrombosis). Infectious complications include catheter-related blood stream infections and non–catheter-related infections by bacteria and fungal species that may in some cases be due to endogenous bacterial translocation from the gut lumen. The risk for these infections appears to be increased with use of non–subclavian vein central venous access (e.g., jugular, femoral veins) and multiple-use catheters with non-dedicated PN infusion ports used for additional purposes, such as blood drawing or medication administration. Poorly controlled blood glucose concentration (>140-180 mg/dL) is not uncommon in patients requiring central vein PN and is associated with an increased risk of nosocomial infection. Risk factors for hyperglycemia include poorly controlled blood glucose concentration at PN initiation; use of high dextrose concentrations (>10%) in the initial few days of PN administration or too rapid an increase in total dextrose load; insufficient exogenous insulin administration; inadequate monitoring of blood glucose responses to central vein PN administration; and administration of corticosteroids and vasopressor agents such as norepinephrine, which stimulate gluconeogenesis and cause insulin resistance.

Recent data also suggest that inadequate or no provision of the amino acid glutamine may increase infection risk in patients requiring PN. This amino acid appears to be conditionally essential in catabolic states and serves as an important fuel for immune cells and cells of the gut mucosa, among other potentially beneficial functions. A large number of animal studies and several human trials show that supplementation of glutamine in EN and PN enhances immunity, decreases hospital infections, and maintains indices of gut barrier function. Several expert panels now recommend that glutamine be routinely added to the PN in ICU patients, but this practice remains controversial because some studies show no benefit (or even harm) in certain patient subgroups, and an improvement in hospital mortality has not been documented.■

Studies of nutrient use efficiency and metabolic complications in severely catabolic patients suggest that lower amounts of total energy and amino acid/protein should be administered than were routinely given in the past, particularly in unstable and ICU patients. High calorie, carbohydrate, amino acid, and fat loads (hyperalimentation) are easily administered by central vein PN but, if ordered by physicians, can induce severe metabolic complications, including carbon dioxide overproduction, azotemia, hyperglycemia, electrolyte alterations, and hepatic steatosis and injury (Table 217-6). Dextrose and lipid doses in PN should be advanced during several days after initiation; blood glucose concentration, electrolyte values, triglyceride levels, organ function test results, intake and output measurements, and the clinical course must be closely monitored.

Refeeding syndrome[7] with central vein PN administration is relatively common in patients at risk, including those with preexisting malnutrition, electrolyte depletion, or alcoholism, and after prolonged periods of intravenous hydration therapy (e.g., 5% dextrose) without nutrition support, all of which are common in hospitalized patients. Refeeding syndrome is mediated by administration of excessive intravenous dextrose (>150-250 g, such as given in 1 L of PN with 15-25% dextrose). This, in turn, markedly stimulates insulin release, which rapidly lowers blood potassium, magnesium, and especially phosphorus concentrations because of intracellular shift and use in carbohydrate metabolic pathways. Administration of high doses of carbohydrate also consumes thiamine, which is required as a cofactor for carbohydrate metabolism and can precipitate symptoms of thiamine deficiency (see Table 217-2), especially in patients with poor thiamine nutrition at baseline. Hyperinsulinemia also tends to cause sodium and fluid retention at the level of the kidney. Together, fluid and sodium retention, the drop in blood electrolyte levels (which can cause arrhythmias), and hypermetabolism due to excessive calorie provision can result in heart failure, especially in patients with preexisting heart disease, as well as cardiac muscle atrophy due to prolonged protein-energy malnutrition. Prevention of refeeding syndrome requires vigilance to identify patients at risk; use of initially low PN dextrose concentrations; and empirical provision of higher doses of potassium, magnesium, and phosphorus based on current blood levels and renal function and supplemental thiamine (100 mg/day for 3 to 5 days).

For patients in whom home PN is indicated, primary physicians should consult with social service professionals to identify appropriate home care companies and nutrition support professionals to assess intravenous line access, metabolic status, and the home PN order and to arrange for follow-up care and monitoring of PN. It is important not to arrange for hasty hospital discharge in patients newly started on PN; obtaining appropriate venous access and monitoring of fluid and electrolyte status during a 2- to 3-day period are important aspects of care for most patients started on PN and imperative in those with severe malnutrition and those at risk for refeeding syndrome.

TABLE 217-6 SOME COMMON METABOLIC COMPLICATIONS OF PARENTERAL NUTRITION

PN ORDER PROBLEM	METABOLIC OR CLINICAL CONSEQUENCE
Excess kcal, CHO, fat	Abnormal liver function test results, hepatic steatosis
Excess CHO	Hypercapnia
Excess fluid, kcal, CHO, fat	Respiratory insufficiency
Excess amino acids	Azotemia
Excess sodium and fluid	Sodium and fluid retention
Excess CHO; inadequate insulin	Hyperglycemia-mediated immune cell dysfunction, infection
Inadequate or excessive electrolytes	Abnormal blood electrolyte levels
Excess fluid, kcal, sodium, CHO; inadequate electrolytes	Cardiac failure, arrhythmias
Excess CHO; inadequate electrolytes, thiamine	Refeeding syndrome

CHO = carbohydrate; kcal = calories; PN = parenteral nutrition.

REVIEW QUESTIONS

1. A 73-year-old woman with type 2 diabetes mellitus is admitted to the medical intensive care unit (ICU) with abdominal pain on eating on occasion and a 10% weight loss from her usual weight during the past 2 months due to decreased food intake. The patient is obese on physical examination, and skeletal muscle mass cannot be assessed. Which of the following is the most appropriate regarding nutritional assessment?

A. Malnutrition cannot be assessed.
B. An involuntary weight loss of less than 15% during 2 months is not yet a signal for malnutrition.
C. The patient is likely to be malnourished.
D. Begin parenteral nutrition within 7 days.
E. Insert a feeding tube for tube feeds within 2 days of admission.

Answer: C An involuntary weight loss of 10% or more is a classic sign of nutritional inadequacy. Muscle mass cannot be assessed in obese patients accurately in most cases. Use of parenteral or enteral tube feeds for nutrition is indicated only after further evaluation of gut function and oral food tolerance. (Ziegler TR. Parenteral nutrition in the critically ill patient. *N Engl J Med*. 2009;361:1088-1097.)

2. A 23-year-old man with Crohn's disease and chronic, intermittent flares with bloody diarrhea is dependent on oral prednisone (10 mg/day) and is seen in the clinic. He exhibits evidence of skeletal muscle wasting on physical examination. Which of the following is likely to be true?

A. A combination of protein loss through stool and muscle breakdown from corticosteroids has probably contributed to muscle wasting.
B. Use of prednisone at doses of 10 mg/day is unlikely to influence catabolism.
C. Inflammation contributes to the patient's muscle loss.
D. Iron depletion is unlikely.
E. Parenteral nutrition should be started immediately.

Answer: A Protein loss in stool and steroid-induced muscle catabolism probably contributed to muscle loss in this patient. Inflammation also contributes to net body protein catabolism. Iron depletion from stool blood loss is likely. No evidence exists for immediate institution of parenteral nutrition in this setting. (Brown RO, Minard G, Ziegler TR. Parenteral nutrition. In: Ross AC, Caballero B, Cousins RJ, et al, eds. *Modern Nutrition in Health and Disease*. 11th ed. Philadelphia: Lippincott Williams & Wilkins; 2012:1136-1161.)

3. A 65-year-old man with a history of chronic obstructive pulmonary disease exhibits clinical evidence of sepsis and respiratory failure in the emergency department and is admitted to the medical ICU. He is placed on ventilator support. Gut dysfunction is present due to apparent ileus and emesis. The patient's body mass index is very low at 17 kg/m^2. Which of the following is true?

A. Parenteral nutrition should be held for at least 8 to 10 days.
B. Severely malnourished patients, as in this case, have been shown to be harmed by early parenteral nutrition begun after 4 days of ICU admission.
C. A large clinical trial suggests that some patients may have worse clinical outcomes with early (within 2 days) use of parenteral nutrition in ICU settings.
D. Tube feedings should be started, regardless of gut function.
E. Parenteral micronutrients should be initiated.

Answer: C No clinical practice guideline recommends withholding of parenteral nutrition in patients with gut dysfunction for more than 7 days. A large study showed possible harm from early parenteral nutrition in the ICU (but severely malnourished patients were excluded). Another recent trial showed no difference in mortality at 60 days or length of ICU stay or total hospital days when early parenteral nutrition is started in critically ill patients with relative contraindications to early enteral nutrition. Tube feeds should not be started with clinical evidence of gut dysfunction. Micronutrient requirements and timing for initiation in the ICU are unclear. (Casaer MP, Mesotten D, Hermans G, et al. Early versus late parenteral nutrition in critically ill adults. *N Engl J Med*. 2011;365:506-517. Doig GS, Simpson F, Sweetman EA, et al. Early parenteral nutrition in critically ill patients with short-term relative contraindications to early enteral nutrition: a randomized controlled trial. *JAMA*. 2013;309:2130-2138.)

4. A 55-year-old woman with partial small bowel obstruction precluding any food intake for 10 to 12 days presents to the emergency department and is admitted for failure to thrive. Parenteral nutrition is deemed to be needed for nutritional repletion. Which of the following is true?

A. Parenteral nutrition with a high dextrose content may cause hypophosphatemia due to insulin-induced movement of phosphorus intracellularly.
B. Enteral feeding should be instituted as it may prevent bacterial translocation from the gut.
C. Extra vitamin C should be added to parenteral nutrition as an antioxidant.
D. Parenteral nutrition should improve gut function in this patient.
E. Parenteral nutrition containing micronutrients can be initiated after 5 days.

Answer: A High dextrose parenteral nutrition can drive phosphorus intracellularly. Enteral feeds are contraindicated clinically, and there are no data that extra vitamin C or parenteral nutrition would be beneficial. Micronutrient needs in hospital patients are unknown, as is the timing of administration. (Brown RO, Minard G, Ziegler TR. Parenteral nutrition. In: Ross AC, Caballero B, Cousins RJ, et al, eds. *Modern Nutrition in Health and Disease*. 11th ed. Philadelphia: Lippincott Williams & Wilkins; 2012:1136-1161.)

5. A 20-year-old woman is admitted to the trauma ICU after a motor vehicle accident with multiple large bone fractures but no sign of gut dysfunction. She is mechanically ventilated to protect her airway and in anticipation of orthopedic surgery within several days. Which of the following is true?

A. Parenteral nutrition should be instituted.
B. Energy needs of the patient probably exceed 300% of normal.
C. An enteral feeding tube should be placed and enteral feeds initiated within the first 1 or 2 days of ICU admission.
D. Parenteral nutrition should be used to complement enteral feeds in this patient.
E. Enteral tube feeds containing adequate energy, protein, and micronutrients can be initiated after 6 days of parenteral nutrition.

Answer: A Most trauma patients can tolerate enteral nutrition, and there is no evidence of gut dysfunction in this patient. Energy needs go up with trauma, but not to 300% of normal. A feeding tube should be placed for institution of early enteral nutrition (within 2 days of admission), but use in such a non-malnourished patient early on is unclear. Optimal timing of enteral nutrition in the ICU remains unclear. (Doig GS, Simpson F, Sweetman EA, et al; Early PN Investigators of the ANZICS Clinical Trials Group. Early parenteral nutrition in critically ill patients with short-term relative contraindications to early enteral nutrition: a randomized controlled trial. *JAMA*. 2013;309:2130-2138.)

218 VITAMINS, TRACE MINERALS, AND OTHER MICRONUTRIENTS

JOEL B. MASON

MICRONUTRIENTS IN NUTRITIONAL SCIENCE

Dietary Requirements

Micronutrients are a diverse array of dietary components necessary to sustain health. The physiologic roles of micronutrients are as varied as their composition. Some micronutrients are used in enzymes as either coenzymes or prosthetic groups, others as biochemical substrates or hormones; in some instances, the functions are not well defined. Under normal circumstances, the average daily dietary intake for each micronutrient that is required to sustain normal physiologic functions is measured in milligrams or smaller quantities. In this manner, micronutrients are distinguished from macronutrients, which encompass carbohydrates, fats, and proteins as well as the macrominerals calcium, magnesium, and phosphorus.

Optimal Intake

For orderly homeostasis to proceed, most dietary nutrients must be ingested in quantities that are neither too small nor too great. Disorders may arise, therefore, when intake regularly falls outside of this physiologic window. The size of this physiologic window varies for each micronutrient and should be kept in mind, particularly in this era when the administration of large quantities of certain micronutrients is increasingly explored for possible therapeutic implications. The dietary requirement for a particular micronutrient is determined by many factors, only one of which is the amount needed to sustain those physiologic functions for which it is used (Table 218-1). The U.S. Institute of Medicine Food and Nutrition Board regularly updates dietary guidelines that define the quantity of each micronutrient that is "adequate to meet the known nutrient needs of practically all healthy persons." These *recommended dietary allowances* (RDAs) were most recently revised between 1998 and 2001, and the values for adults appear in Tables 218-2 and 218-3. Also established for the first time for each micronutrient were *tolerable upper limits* (TULs), which are the "maximal daily levels of oral intake likely to pose no adverse health risks." *Adequate intake*, the amount necessary to prevent a deficiency state, is not necessarily synonymous with *optimal intake*.

TYPES AND FUNCTION OF MICRONUTRIENTS

Vitamins

Vitamins are categorized as either fat soluble (A, D, E, K) or water soluble (all the others), as shown in Table 218-2. This categorization remains physiologically meaningful. None of the fat-soluble vitamins appears to serve as a coenzyme. Intestinal absorption of the fat-soluble vitamins is primarily through a micellar phase, and pathophysiologic conditions associated with fat malabsorption frequently are associated with selective deficiencies of the fat-soluble vitamins. In contrast, most of the functions of the water-soluble vitamins are as coenzymes, and they are not absorbed through the lipophilic phase in the intestine.

TABLE 218-1 FACTORS THAT DETERMINE DIETARY REQUIREMENT OF A MICRONUTRIENT

PHYSIOLOGIC FACTORS
Bioavailability: the proportion of a micronutrient that is ingested and is capable of being assimilated and used for physiologic purposes
Quantity required to fulfill physiologic roles
Extent to which the body can reuse the micronutrient
Distribution of nutrient in the body: storage compartments
Gender
Stage of life cycle: intrauterine development, childhood, adulthood, elder adulthood, pregnancy, lactation
PATHOPHYSIOLOGIC AND PHARMACOLOGIC FACTORS
Inborn errors of metabolism: variously affect assimilation, utilization, or excretion of micronutrients
Acquired disease states that alter the amounts required to sustain homeostasis (e.g., malabsorption, maldigestion, states that increase use)
Lifestyle habits: smoking, ethanol consumption
Drugs: may alter bioavailability or utilization

Trace Elements

Fifteen trace elements have been identified as essential for health: iron, zinc, copper, chromium, selenium, iodine, fluorine, manganese, molybdenum, cobalt, nickel, tin, silicon, vanadium, and arsenic (see Table 218-3), but only for the first 10 of these has compelling evidence indicated that they are essential nutrients in humans. Cobalt appears to be essential solely as a component of vitamin B_{12}, but an isolated deficiency state has never been described. Deficiency syndromes for several of the essential trace elements were not recognized until recently because of their exceedingly small requirements and because of the ubiquitous nature of these elements in foodstuffs. Only under exceptional circumstances, such as long-term reliance on total parenteral nutrition lacking these elements, have some of the deficiency syndromes been observed.

The biochemical functions of trace elements appear to be as components of prosthetic groups or as cofactors for enzymes. Determination of essential trace element status is problematic with the exception of iron. The low concentrations of these elements in body fluids and tissues, the finding that blood levels frequently do not correlate well with levels in the target tissues, and the fact that functional tests cannot be devised until their biochemical functions are better understood preclude an accurate laboratory method of assessing the adequacy of most trace elements.

Additional Compounds with Nutritional Relevance

Evidence indicates that humans also have an absolute requirement for the dietary component choline, which is a necessary precursor for acetylcholine and phospholipids and is needed to sustain normal levels of biologic methylation. To date, the most significant adverse effect of dietary inadequacy has been hepatic inflammation. Deficiency is nevertheless thought to be extremely rare, although pregnancy, and particularly lactation, increases the apparent requirement. Individuals whose long-term nutritional requirements are solely derived from total parenteral nutrition appear to be susceptible to choline deficiency. Both an RDA (425 mg, women; 550 mg, men) and a TUL (3.5 g) have now been established.

L-Carnitine is a dietary component that facilitates the transport of fatty acids into mitochondria, and a deficit therefore limits the fatty acid β-oxidation that occurs in those organelles.[1] Although no evidence exists for a dietary requirement in healthy children or adults, premature infants have very low stores of skeletal muscle carnitine. Therefore, preterm infants receiving parenteral nutrition without carnitine supplements appear to be a group at risk for deficiency. In clinical trials, parenteral supplementation of carnitine in such infants increases serum carnitine concentration, although it has not improved clinical end points in most studies. Similarly, it has been suggested that individuals on long-term hemodialysis and those dependent on total parenteral nutrition may also be susceptible to the clinical consequences of L-carnitine depletion, but convincing evidence is lacking.

CONDITIONS THAT INCREASE REQUIRED DIETARY INTAKE

Many physiologic, pathophysiologic, and pharmacologic factors increase the dietary requirements for micronutrients (see Table 218-1), thereby enhancing the risk for development of a deficiency state.

Physiologic Factors

Stages of the life cycle frequently have a significant impact on the requirements of nutrients. Phases of rapid growth and development, such as in utero development, infancy, adolescence, and pregnancy, are associated with increases in the utilization of certain micronutrients on a per-kilogram basis.

Pregnancy

Requirements for most micronutrients are increased in pregnancy, but, proportionately, the observed increases in the maternal requirements for iron and folate are particularly great and are related to the rapid proliferation of the placental and fetal tissues. Periods of lactation are similarly associated with remarkable increases in requirements; a lactating woman experiences disproportionately large increases in her requirements for zinc and vitamins

TABLE 218-2 VITAMINS AND THEIR FUNCTIONS

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
FAT-SOLUBLE VITAMINS				
Vitamin A	A family of the retinoid compounds, each member having biologic activity qualitatively similar to retinol. Carotenoids are structurally related to retinoids. Some carotenoids, most notably β-carotene, are metabolized into compounds with vitamin A activity and are therefore considered to be provitamin A compounds. Vitamin A is an integral component of rhodopsin and iodopsins, light-sensitive proteins in rod and cone cells in the retina. *Additional functions:* induction and maintenance of cellular differentiation in certain tissues; signal for appropriate morphogenesis in the developing embryo; maintenance of cell-mediated immunity. 1 μg of retinol = 3.33 IU of vitamin A.	Follicular hyperkeratosis and night blindness are early indicators. Conjunctival xerosis, degeneration of the cornea (keratomalacia), and dedifferentiation of rapidly proliferating epithelia are later indications of deficiency. *Bitot spots* (focal areas of the conjunctiva or cornea with foamy appearance) are an indication of xerosis. Blindness, due to corneal destruction and retinal dysfunction, ensues if left uncorrected. Increased susceptibility to infection is also a consequence. [F: 700 μg; M: 900 μg]	In adults, >150,000 μg may cause *acute* toxicity: fatal intracranial hypertension, skin exfoliation, and hepatocellular necrosis. *Chronic* toxicity may occur with habitual daily intake of >10,000 μg: alopecia, ataxia, bone and muscle pain, dermatitis, cheilitis, conjunctivitis, pseudotumor cerebri, hepatocellular necrosis, hyperlipidemia, and hyperostosis are common. Single, large doses of vitamin A (30,000 μg) or habitual intake of >4500 μg/day in early pregnancy can be teratogenic. Excessive intake of carotenoids causes a benign condition characterized by yellowish discoloration of the skin. Habitually large doses of canthaxanthin, a carotenoid, have the additional capability of inducing a retinopathy. [3000 μg]	Retinol concentration in the plasma and vitamin A concentrations in the milk and tears are reasonably accurate measures of adequate status. Toxicity is best assessed by elevated levels of retinyl esters in plasma. A quantitative measure of dark adaptation for night vision and electroretinography are useful functional tests.
Vitamin D	A group of sterol compounds whose parent structure is cholecalciferol (vitamin D_3) Cholecalciferol is formed in the skin from 7-dehydrocholesterol (provitamin D_3) by exposure to UVB radiation. A plant sterol, ergocalciferol (provitamin D_2), can be similarly converted into vitamin D_2 and has similar vitamin D activity. The vitamin undergoes sequential hydroxylations in the liver and kidney at the 25 and 1 positions, respectively, producing the most bioactive form of the vitamin, 1,25-dihydroxy vitamin D. Vitamin D maintains intracellular and extracellular concentrations of calcium and phosphate by enhancing intestinal absorption of the two ions and, in conjunction with PTH, promoting their mobilization from bone mineral. It retards proliferation and promotes differentiation in certain epithelia. Purported actions of vitamin D as an anti-diabetes, anti-inflammatory, and cancer preventive agent remain controversial and are under investigation. 1 μg = 40 IU.	Deficiency results in decreased mineralization of newly formed bone called *rickets* in childhood and *osteomalacia* in adults. Expansion of the epiphyseal growth plates and replacement of normal bone with unmineralized bone matrix are the cardinal features of rickets; the latter feature also characterizes osteomalacia. Deformity of bone and pathologic fractures occur. Decreased serum concentrations of calcium and phosphate may occur. [15 μg, ages 19-70 yr; 20 μg, age >70 yr]	Excess amounts result in abnormally high concentrations of calcium and phosphate in the serum; metastatic calcifications, renal damage, and altered mentation may occur. [100 μg for ages ≥9 yr]	The serum concentration of the major circulating metabolite, 25-hydroxyvitamin D, is the best indicator of systemic status except in advanced kidney disease (stages 4 and 5), in which the impairment of renal 1-hydroxylation results in disassociation of the mono- and dihydroxyvitamin concentrations. Measurement of the serum concentration of 1,25-dihydroxyvitamin D is then necessary.
Vitamin E	A group of at least 8 naturally occurring compounds, some of which are tocopherols and some of which are tocotrienols At present, the only dietary form that is thought to be biologically active in humans is α-tocopherol. Vitamin E acts as an antioxidant and free radical scavenger in lipophilic environments, most notably in cell membranes. It acts in conjunction with other antioxidants, such as selenium.	Deficiency due to dietary inadequacy is rare. It is usually seen in premature infants, individuals with fat malabsorption, and individuals with abetalipoproteinemia. Red blood cell fragility occurs and can produce a hemolytic anemia. Neuronal degeneration produces peripheral neuropathies, ophthalmoplegia, and destruction of posterior columns of spinal cord. Neurologic disease is frequently irreversible if deficiency is not corrected early enough. May contribute to the hemolytic anemia and retrolental fibroplasia seen in premature infants. Reported to suppress cell-mediated immunity [15 mg]	Depressed levels of vitamin K–dependent procoagulants and potentiation of oral anticoagulants have been reported, as has impaired WBC function. Doses of 800 mg/day have been reported to increase slightly the incidence of hemorrhagic stroke. [1000 mg]	Plasma or serum concentration of α-tocopherol is most commonly used. Additional accuracy is obtained by expressing this value per milligram of total plasma lipid. RBC peroxide hemolysis test is not entirely specific but is a useful functional measure of the antioxidant potential of cell membranes.

TABLE 218-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin K	A family of naphthoquinone compounds with similar biologic activity. Phylloquinone (vitamin K_1) is derived from plants; a variety of menaquinones (vitamin K_2) are derived from bacterial and animal sources. Vitamin K serves as an essential cofactor in the post-translational γ-carboxylation of glutamic acid residues in many proteins. These proteins include several circulating procoagulants and anticoagulants as well as proteins in a variety of tissues.	Deficiency syndrome is uncommon except in breast-fed newborns, in whom it may cause "hemorrhagic disease of the newborn"; in adults with fat malabsorption or who are taking drugs that interfere with vitamin K metabolism (e.g., coumarin, phenytoin, broad-spectrum antibiotics); and in individuals taking large doses of vitamin E and anticoagulant drugs. Excessive hemorrhage is the usual manifestation. [F: 90 µg; M: 120 µg]	Rapid intravenous infusion of K_1 has been rarely associated with dyspnea, flushing, and cardiovascular collapse; this is likely related to the dispersing agents in the solution. Supplementation may interfere with coumarin-based anticoagulation. Pregnant women taking large amounts of the provitamin menadione may deliver infants with hemolytic anemia, hyperbilirubinemia, and kernicterus. [no TUL established]	Prothrombin time is typically used as a measure of functional K status; it is neither sensitive nor specific for vitamin K deficiency. Determination of fasting plasma vitamin K is an accurate indicator of status. Undercarboxylated plasma prothrombin is also an accurate metric, but only for detecting the deficient state, and is less widely available than plasma vitamin K.
WATER-SOLUBLE VITAMINS				
Thiamin (vitamin B_1)	A water-soluble compound containing substituted pyrimidine and thiazole rings and a hydroxyethyl side chain. The coenzyme form is thiamin pyrophosphate (TPP). Thiamin serves as a coenzyme in many α-ketoacid decarboxylation and transketolation reactions. Inadequate thiamin availability leads to impairments of these reactions, resulting in inadequate adenosine triphosphate synthesis and abnormal carbohydrate metabolism, respectively. It may have an additional role in neuronal conduction independent of the aforementioned actions.	Classic deficiency syndrome (beriberi) is described in Asian populations consuming a polished rice diet. Alcoholism, chronic renal dialysis, and persistent nausea and vomiting after bariatric surgery are also common precipitants. High carbohydrate intake increases need for B_1. *Mild deficiency*: irritability, fatigue, and headaches *More severe deficiency*: combinations of peripheral neuropathy, cardiovascular dysfunction, and cerebral dysfunction. Cardiovascular involvement (wet beriberi): congestive heart failure and low peripheral vascular resistance. Cerebral disease: nystagmus, ophthalmoplegia, and ataxia (Wernicke's encephalopathy); hallucinations, impaired short-term memory, and confabulation (Korsakoff's psychosis) Deficiency syndrome responds within 24 hr to parenteral thiamin but is partially or wholly irreversible after a certain stage. [F: 1.1 mg; M: 1.2 mg]	Excess intake is largely excreted in the urine, although parenteral doses of >400 mg/day are reported to cause lethargy, ataxia, and reduced tone of the gastrointestinal tract. [TUL not established]	The most effective measure of B_1 status is the erythrocyte transketolase activity coefficient, which measures enzyme activity before and after addition of exogenous TPP; RBCs from a deficient individual express a substantial increase in enzyme activity with addition of TPP. Thiamin concentrations in blood or urine are also used.
Riboflavin (vitamin B_2)	Consists of a substituted isoalloxazine ring with a ribitol side chain Riboflavin serves as a coenzyme for a diverse array of biochemical reactions. The primary coenzymatic forms are flavin mononucleotide and flavin adenine dinucleotide. Riboflavin holoenzymes participate in oxidation-reduction reactions in myriad metabolic pathways.	Deficiency is usually seen in conjunction with deficiencies of other B vitamins. Isolated deficiency of riboflavin produces hyperemia and edema of nasopharyngeal mucosa, cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, and a normochromic, normocytic anemia. [F: 1.1; M: 1.3]	Toxicity is not reported in humans. [TUL not established]	The most common method of assessment is to determine the activity coefficient of glutathione reductase in RBCs (the test is invalid for individuals with glucose-6-phosphate dehydrogenase deficiency). Measurements of blood and urine concentrations are less desirable methods.

TABLE 218-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Niacin (vitamin B_3)	Refers to nicotinic acid and the corresponding amide, nicotinamide The active coenzymatic forms are composed of nicotinamide affixed to adenine dinucleotide, forming NAD or NADP. More than 200 apoenzymes use these compounds as electron acceptors or hydrogen donors, either as a coenzyme or as a co-substrate. The essential amino acid tryptophan is a precursor of niacin; 60 mg of dietary tryptophan yields approximately 1 mg of niacin. Dietary requirements thus depend partly on tryptophan intake. Requirement is often determined on basis of calorie intake (i.e., niacin equivalents/1000 kcal). Large doses of nicotinic acid (1.5-3 g/day) effectively lower low-density lipoprotein cholesterol and elevate high-density lipoprotein cholesterol.	*Pellagra* is the classic deficiency syndrome and is often seen in populations in which corn is the major source of energy; it is still endemic in parts of China, Africa, and India. Diarrhea, dementia (or associated symptoms of anxiety or insomnia), and a pigmented dermatitis that develops in sun-exposed areas are typical features. Glossitis, stomatitis, vaginitis, vertigo, and burning dysesthesias are early signs. It is reported occasionally to occur in carcinoid syndrome because tryptophan is diverted to other synthetic pathways. [F: 14 mg; M: 16 mg]	Human toxicity is known largely through studies examining hypolipidemic effects. Includes vasomotor phenomenon (flushing), hyperglycemia, parenchymal liver damage, and hyperuricemia. [35 mg]	Assessment of status is problematic; blood levels of the vitamin are not reliable. Measurement of urinary excretion of the niacin metabolites *N*-methylnicotinamide and 2-pyridone is thought to be the most effective means of assessment at present.
Vitamin B_6	Refers to several derivatives of pyridine, including pyridoxine, pyridoxal, and pyridoxamine, which are interconvertible in the body. The coenzymatic forms are pyridoxal-5-phosphate (PLP) and pyridoxamine-5-phosphate. As a coenzyme, B_6 is involved in many transamination reactions (and thereby in gluconeogenesis), in the synthesis of niacin from tryptophan, in the synthesis of several neurotransmitters, and in the synthesis of δ-aminolevulinic acid (and therefore in heme synthesis). It also has functions unrelated to coenzymatic activity: pyridoxal and PLP bind to hemoglobin and alter oxygen affinity; PLP also binds to steroid receptors, inhibiting receptor affinity to DNA and thereby modulating steroid activity.	Deficiency is usually seen in conjunction with other water-soluble vitamin deficiencies. Stomatitis, angular cheilosis, glossitis, irritability, depression, and confusion occur in moderate to severe depletion; normochromic, normocytic anemia has been reported in severe deficiency. Abnormalities on electroencephalography and, in infants, convulsions have also been observed. Some sideroblastic anemias respond to B_6 administration. Isoniazid, cycloserine, penicillamine, ethanol, and theophylline can inhibit B_6 metabolism. [Ages 19-50 yr: 1.3 mg; >50 yr: 1.5 mg for women, 1.7 mg for men]	Long-term use with doses exceeding 200 mg/day (in adults) may cause peripheral neuropathies and photosensitivity. [100 mg]	Many useful laboratory methods of assessment exist. The plasma or erythrocyte PLP levels are most common. Urinary excretion of xanthurenic acid after an oral tryptophan load and activity indices of RBC alanine or aspartate transaminase are functional measures of B_6-dependent enzyme activity.
Folate	A group of related pterin compounds More than 35 forms of the vitamin are found naturally. The fully oxidized form, folic acid, is not found in nature but is the pharmacologic form of the vitamin. All folate functions relate to its ability to transfer one-carbon groups. It is essential in the de novo synthesis of nucleotides and in the metabolism of several amino acids; it is an integral component for the regeneration of the "universal" methyl donor, *S*-adenosylmethionine. Inhibition of bacterial and cancer cell folate metabolism is the basis for the sulfonamide antibiotics and chemotherapeutic agents, such as methotrexate and 5-fluorouracil, respectively.	Women of childbearing age are most likely to be deficient. *Classic deficiency syndrome*: megaloblastic anemia, diarrhea. The hematopoietic cells in bone marrow become enlarged and have immature nuclei, reflecting ineffective DNA synthesis. The peripheral blood smear demonstrates macro-ovalocytes and polymorphonuclear leukocytes with an average of more than 3.5 nuclear lobes. Megaloblastic changes also occur in other epithelia that proliferate rapidly (e.g., oral mucosa and gastrointestinal tract, producing glossitis and diarrhea, respectively). Sulfasalazine and diphenytoin inhibit absorption and predispose to deficiency. [400 μg of dietary folate equivalents (DFE); 1 DFE = 1 μg food folate = 0.6 μg folic acid]	Doses >1000 μg/day may partially correct the anemia of B_{12} deficiency and may therefore mask (and perhaps exacerbate) the associated neuropathy. Large doses are also reported to lower seizure threshold in individuals prone to seizures. Parenteral administration is rarely reported to cause allergic phenomena, which is probably due to dispersion agents. [1000 μg]	Serum folate measures short-term folate balance, whereas RBC folate is a better reflection of tissue status. Serum homocysteine rises early in deficiency but is nonspecific because B_{12} or B_6 deficiency, renal insufficiency, and older age may also cause elevations.

TABLE 218-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Vitamin C (ascorbic and dehydroascorbic acid)	Ascorbic acid readily oxidizes to dehydroascorbic acid in aqueous solution. Dehydroascorbic acid can be reduced in vivo, so it possesses vitamin C activity. Total vitamin C is therefore the sum of ascorbic and dehydroascorbic acid content. Vitamin C serves primarily as a biologic antioxidant in aqueous environments. Biosyntheses of collagen, carnitine, bile acids, and norepinephrine as well as proper functioning of the hepatic mixed-function oxygenase system depends on this property. Vitamin C in foodstuffs increases the intestinal absorption of nonheme iron.	Overt deficiency is uncommon in developed countries. The classic deficiency syndrome is *scurvy:* fatigue, depression, and widespread abnormalities in connective tissues, such as inflamed gingivae, petechiae, perifollicular hemorrhages, impaired wound healing, coiled hairs, hyperkeratosis, and bleeding into body cavities. In infants, defects in ossification and bone growth may occur. Tobacco smoking lowers plasma and leukocyte vitamin C levels. [F: 75 mg; M: 90 mg; increase requirement for cigarette smokers by 35 mg/day]	≥500 mg/day (in adults) may cause nausea and diarrhea. >1 g/day modestly increases risk for oxalate kidney stones. Supplementation may interfere with laboratory tests based on redox potential (e.g., fecal occult blood testing, serum cholesterol, and glucose). Withdrawal from chronic ingestion of high doses of vitamin C supplements should be done gradually because accommodation appears to occur, raising a concern of "rebound scurvy." [2 g]	Plasma ascorbic acid concentration reflects recent dietary intake, whereas WBC levels more closely reflect tissue stores. Women's plasma levels are approximately 20% higher than men's for any given dietary intake.
Vitamin B_{12}	A group of closely related cobalamin compounds composed of a corrin ring (with a cobalt atom in its center) connected to a ribonucleotide through an aminopropanol bridge. Microorganisms are the ultimate source of all naturally occurring B_{12}. The two active coenzyme forms are deoxyadenosylcobalamin and methylcobalamin. These coenzymes are needed for the synthesis of succinyl CoA, which is essential in lipid and carbohydrate metabolism, and for the synthesis of methionine. The synthesis of methionine is essential for amino acid metabolism, for purine and pyrimidine synthesis, for many methylation reactions, and for the intracellular retention of folates.	Dietary inadequacy is a rare cause of deficiency except in strict vegetarians. Most deficiencies arise from loss of intestinal absorption, which may occur with pernicious anemia, pancreatic insufficiency, atrophic gastritis, small bowel bacterial overgrowth, or ileal disease. Megaloblastic anemia and megaloblastic changes in other epithelia (see Folate) are the result of sustained depletion. Demyelination of peripheral nerves, posterior and lateral columns of spinal cord, and nerves within the brain may occur. Altered mentation, depression, and psychoses occur. Hematologic and neurologic complications may occur independently. Folate supplementation, in doses of 1000 μg/day, may partly correct the anemia, thereby masking (or perhaps exacerbating) the neuropathic complication. [2.4 μg]	A few allergic reactions have been reported to crystalline B_{12} preparations and are probably due to impurities, not the vitamin. [TUL not established]	Serum or plasma concentrations are generally accurate. Subtle deficiency with neurologic complications, as described in the Deficiency column, can best be established by concurrently measuring the concentration of plasma B_{12} and serum methylmalonic acid, which is a sensitive indicator of cellular deficiency.
Biotin	A bi-cyclic compound consisting of a ureido ring fused to a substituted tetrahydrothiophene ring. Endogenous synthesis by intestinal flora may contribute significantly to biotin nutriture. Most dietary biotin is linked to lysine, a compound called biotinyl lysine, or biocytin. The lysine must be hydrolyzed by an intestinal enzyme called biotinidase before intestinal absorption occurs. Biotin acts primarily as a coenzyme for several carboxylases; each holoenzyme catalyzes an adenosine triphosphate–dependent carbon dioxide transfer. The carboxylases are critical enzymes in carbohydrate and lipid metabolism.	Isolated deficiency is rare. Deficiency in humans has been produced by prolonged total parenteral nutrition lacking the vitamin and by ingestion of large quantities of raw egg white, which contains avidin, a protein that binds biotin with such high affinity that it renders it biounavailable. Alterations in mental status, myalgias, hyperesthesias, and anorexia occur. Later, a seborrheic dermatitis and alopecia develop. Deficiency is usually accompanied by lactic acidosis and organic aciduria. [30 μg]	Toxicity has not been reported in humans with doses as high as 60 mg/day in children. [TUL not established]	Plasma and urine concentrations of biotin are diminished in the deficient state. Elevated urine concentrations of methyl citrate, 3-methylcrotonylglycine, and 3-hydroxyisovalerate are also observed in deficiency.

TABLE 218-2 VITAMINS AND THEIR FUNCTIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Pantothenic acid	Consists of pantoic acid linked to β-alanine through an amide bond Pantothenic acid is an essential component of CoA and phosphopantetheine, which are essential for synthesis and β-oxidation of fatty acids as well as for synthesis of cholesterol, steroid hormones, vitamins A and D, and other isoprenoid derivatives. CoA is also involved in the synthesis of several amino acids and δ-aminolevulinic acid, a precursor for the corrin ring of vitamin B_{12}, the porphyrin ring of heme, and of cytochromes. CoA is also necessary for the acetylation and fatty acid acylation of a variety of proteins.	Deficiency is rare; it has been reported only as a result of feeding of semisynthetic diets or an antagonist to the vitamin. Experimental, isolated deficiency in humans produces fatigue, abdominal pain, vomiting, insomnia, and paresthesias of the extremities. [5 mg]	In doses of 10 g/day, diarrhea is reported to occur. [TUL not established]	Whole blood and urine concentrations of pantothenate are indicators of status; serum levels are not thought to be accurate.

CoA = coenzyme A; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate; PTH = parathyroid hormone; RBC = red blood cell; UVB = ultraviolet B; WBC = white blood cell.
*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001. In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.
†Tolerable upper limit (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.

TABLE 218-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Chromium	Dietary chromium consists of both inorganic and organic forms. Its primary function in humans is to potentiate insulin action. It accomplishes this function as a circulating complex called *glucose tolerance factor*, thereby affecting carbohydrate, fat, and protein metabolism.	Deficiency in humans has been described only in long-term total parenteral nutrition (TPN) patients receiving insufficient chromium. Hyperglycemia or impaired glucose tolerance occurs. Elevated plasma free fatty acid concentrations, neuropathy, encephalopathy, and abnormalities in nitrogen metabolism are also reported. Whether supplemental chromium may improve glucose tolerance in glucose-intolerant individuals remains controversial. [F: 25 μg; M: 35 μg]	Toxicity after oral ingestion is uncommon and seems confined to gastric irritation. Airborne exposure may cause contact dermatitis, eczema, skin ulcers, and bronchogenic carcinoma. [no TUL established]	Plasma or serum concentration of chromium is a crude indicator of chromium status; it appears to be meaningful when the value is markedly above or below the normal range.
Copper	Copper is absorbed by a specific intestinal transport mechanism. It is carried to the liver, where it is bound to ceruloplasmin, which circulates systemically and delivers copper to target tissues in the body. Excretion of copper is largely through bile and then into the feces. Absorptive and excretory processes vary with the levels of dietary copper, providing a means of copper homeostasis. Copper serves as a component of many enzymes, including amine oxidases, ferroxidases, cytochrome *c* oxidase, dopamine β-hydroxylase, superoxide dismutase, and tyrosinase.	Dietary deficiency is rare; it has been observed in premature and low-birthweight infants fed exclusively a cow's milk diet and in individuals on long-term TPN lacking copper. It has also been described after gastric bypass surgery and with chronic zinc supplementation. Clinical manifestations include depigmentation of skin and hair, myelopathy and other neurologic lesions, leukopenia, anemia, and skeletal abnormalities. Anemia arises from impaired utilization of iron and therefore often is manifested as a sideroblastic anemia. The peripheral smear and bone marrow may mimic myelodysplasia. A deficiency syndrome is also observed in Menkes' disease, a rare inherited condition associated with impaired copper utilization. [900 μg]	Acute copper toxicity has been described after excessive oral intake and with absorption of copper salts applied to burned skin. Milder manifestations include nausea, vomiting, epigastric pain, and diarrhea; coma and hepatic necrosis may ensue in severe cases. Toxicity may be seen with doses as low as 70 μg/kg/day. Chronic toxicity is also described. Wilson's disease is a rare, inherited disease associated with abnormally low ceruloplasmin levels and accumulation of copper in the liver and brain, eventually leading to damage to these two organs. [10 mg]	Practical methods to detect marginal deficiency are not available. Marked deficiency is reliably detected by diminished serum copper and ceruloplasmin concentrations as well as by low red blood cell superoxide dismutase activity.

TABLE 218-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Fluorine	Known more commonly by its ionic form, fluoride. Fluorine is incorporated into the crystalline structure of bone, thereby altering its physical characteristics.	Intake of <0.1 mg/day in infants and <0.5 mg/day in children is associated with an increased incidence of dental caries. Optimal intake in adults is between 1.5 and 4 mg/day. [F: 3 mg; M: 4 mg]	Acute ingestion of >30 mg/kg body weight is likely to cause death. Excessive chronic intake (0.1 mg/kg/day) leads to mottling of teeth (dental fluorosis), calcification of tendons and ligaments, and exostoses and may increase the brittleness of bones. [10 mg]	Estimates of intake and clinical assessment are used because no good laboratory test exists.
Iodine	Iodine is readily absorbed from the diet, concentrated in the thyroid, and integrated into the thyroid hormones thyroxine and triiodothyronine. These hormones circulate largely bound to thyroxine-binding globulin. They modulate resting energy expenditure and, in the developing human, growth and development.	In the absence of supplementation, populations relying primarily on food from soils with low iodine content have endemic iodine deficiency. Maternal iodine deficiency leads to fetal deficiency, which produces spontaneous abortions, stillbirths, hypothyroidism, cretinism, and dwarfism. Permanent cognitive deficits may result from iodine deficiency during the first 2 years of life. In the adult, compensatory hypertrophy of the thyroid (goiter) occurs along with varying degrees of hypothyroidism. [150 μg]	Large doses (>2 mg/day in adults) may induce hypothyroidism by blocking thyroid hormone synthesis. Supplementation with >100 mg/day to an individual who was formerly deficient occasionally induces hyperthyroidism. [1.1 mg]	Iodine status of a population can be estimated by the prevalence of goiter. Urinary excretion of iodine is an effective laboratory means of assessment. Thyroid-stimulating hormone blood level is an indirect and therefore not entirely specific means of assessment.
Iron	Conveys the capacity to participate in redox reactions to a number of metalloproteins, such as hemoglobin, myoglobin, cytochrome enzymes, and many oxidases and oxygenases. The primary storage form of iron is ferritin and, to a lesser degree, hemosiderin. Intestinal absorption is 15-20% for "heme" iron and 1-8% for iron contained in vegetables. Absorption of the latter form is enhanced by the ascorbic acid in foodstuffs; by poultry, fish, or beef; and by an iron-deficient state. It is decreased by phytate and tannins.	Iron deficiency is the most common micronutrient deficiency in the world. Women of childbearing age are the group at highest risk because of menstrual blood losses, pregnancy, and lactation. The classic deficiency syndrome is hypochromic, microcytic anemia. Glossitis and koilonychia ("spoon" nails) are also observed. Easy fatigability often is an early symptom, before anemia appears. In children, mild deficiency of insufficient severity to cause anemia is associated with behavioral disturbances and poor school performance. [postmenopausal F and M: 8 mg; premenopausal F: 18 mg]	Iron overload typically occurs when habitual dietary intake is extremely high, intestinal absorption is excessive, repeated parenteral administration occurs, or a combination of these factors exists. Excessive iron stores usually accumulate in the reticuloendothelial tissues and cause little damage (hemosiderosis). If overload continues, iron eventually begins to accumulate in tissues such as the hepatic parenchyma, pancreas, heart, and synovium, causing hemochromatosis (Chapter 212) Hereditary hemochromatosis results from homozygosity of a common recessive trait. Excessive intestinal absorption of iron is seen in homozygotes. [45 mg]	Negative iron balance initially leads to depletion of iron stores in the bone marrow; a bone marrow biopsy and the concentration of serum ferritin are accurate indicators of early depletion. As the severity of deficiency proceeds, serum iron (SI) decreases and total iron-binding capacity (TIBC) increases; an iron saturation (SI/TIBC) of <16% suggests iron deficiency. Microcytosis, hypochromia, and anemia ensue. Elevated levels of serum ferritin or an iron saturation of >60% suggest iron overload, although systemic inflammation elevates serum ferritin regardless of iron status.
Manganese	A component of several metalloenzymes. Most manganese is in mitochondria, where it is a component of manganese superoxide dismutase.	Manganese deficiency in the human has not been conclusively demonstrated. It is said to cause hypocholesterolemia, weight loss, hair and nail changes, dermatitis, and impaired synthesis of vitamin K–dependent proteins. [F: 1.8 mg; M: 2.3 mg]	Toxicity by oral ingestion is unknown in humans. Toxic inhalation causes hallucinations, other alterations in mentation, and extrapyramidal movement disorders. [11 mg]	Until the deficiency syndrome is better defined, an appropriate measure of status will be difficult to develop.
Molybdenum	A cofactor in several enzymes, most prominently xanthine oxidase and sulfite oxidase	A probable case of human deficiency is described as being secondary to parenteral administration of sulfite and resulted in hyperoxypurinemia, hypouricemia, and low sulfate excretion. [45 μg]	Toxicity not well described in humans, although it may interfere with copper metabolism at high doses. [2 mg]	Laboratory means of assessment are not meaningful until the deficiency syndrome is better described.

TABLE 218-3 NUTRITIONAL TRACE ELEMENTS AND THEIR CLINICAL IMPLICATIONS—cont'd

	BIOCHEMISTRY AND PHYSIOLOGY	DEFICIENCY [RDA*]	TOXICITY [TUL†]	ASSESSMENT OF STATUS
Selenium	Most dietary selenium is in the form of an amino acid complex. Nearly complete absorption of such forms occurs. Homeostasis is largely performed by the kidney, which regulates urinary excretion as a function of selenium status. Selenium is a component of several enzymes, most notably glutathione peroxidase and superoxide dismutase. These enzymes protect against oxidative and free radical damage of various cell structures. The antioxidant protection conveyed by selenium apparently operates in conjunction with vitamin E because deficiency of one seems to potentiate damage induced by a deficiency of the other. Selenium also participates in the enzymatic conversion of thyroxine to its more active metabolite, triiodothyronine.	Deficiency is rare in North America but has been observed in individuals on long-term TPN lacking selenium. Such individuals have myalgias or cardiomyopathies. Populations in some regions of the world, most notably some parts of China, have marginal intake of selenium. In these regions *Keshan's disease*, a condition characterized by cardiomyopathy, is endemic; it can be prevented (but not treated) by selenium supplementation. [55 µg]	Toxicity is associated with nausea, diarrhea, alterations in mental status, peripheral neuropathy, and loss of hair and nails; such symptoms were observed in adults who inadvertently consumed 27-2400 mg. [400 µg]	Erythrocyte glutathione peroxidase activity and plasma or whole blood selenium concentrations are the most commonly used methods of assessment. They are moderately accurate indicators of status.
Zinc	Intestinal absorption occurs by a specific process that is enhanced by pregnancy and corticosteroids and diminished by coingestion of phytates, phosphates, iron, copper, lead, or calcium. Diminished intake of zinc leads to an increased efficiency of absorption and decreased fecal excretion, providing a means of zinc homeostasis. Zinc is a component of more than 100 enzymes, among which are DNA polymerase, RNA polymerase, and transfer RNA synthetase.	Zinc deficiency has its most profound effect on rapidly proliferating tissues. *Mild deficiency:* growth retardation in children. *More severe deficiency:* growth arrest, teratogenicity, hypogonadism and infertility, dysgeusia, poor wound healing, diarrhea, dermatitis on the extremities and around orifices, glossitis, alopecia, corneal clouding, loss of dark adaptation, and behavioral changes. Impaired cellular immunity is observed. Excessive loss of gastrointestinal secretions through chronic diarrhea and fistulas may precipitate deficiency. *Acrodermatitis enteropathica* is a rare, recessively inherited disease in which intestinal absorption of zinc is impaired. [F: 8 mg; M: 11 mg]	Acute zinc toxicity can usually be induced by ingestion of >200 mg of zinc in a single day (in adults). It is manifested by epigastric pain, nausea, vomiting, and diarrhea. Hyperpnea, diaphoresis, and weakness may follow inhalation of zinc fumes. Copper and zinc compete for intestinal absorption: long-term ingestion of >25 mg/day of zinc may lead to copper deficiency. Long-term ingestion of >150 mg/day has been reported to cause gastric erosions, low high-density lipoprotein cholesterol levels, and impaired cellular immunity. [40 mg]	No accurate indicators of zinc status exist for routine clinical use. Plasma, red blood cell, and hair zinc concentrations are often misleading. Acute illness, in particular, is known to diminish plasma zinc levels, in part by inducing a shift of zinc out of the plasma compartment and into the liver. Functional tests that determine dark adaptation, taste acuity, and rate of wound healing lack specificity.

*Recommended daily allowance (RDA) established for female (F) and male (M) adults by the U.S. Food and Nutrition Board, 1999-2001. In some instances, insufficient data exist to establish an RDA, in which case the adequate intake (AI) established by the board is listed.
†Tolerable upper limit (TUL) established for adults by the U.S. Food and Nutrition Board, 1999-2001.

A, E, and C to meet the metabolic demands incurred by milk production in addition to the aforementioned needs observed in pregnancy.

Aside from its general role in supporting the rapid proliferation of placental and fetal tissues, folate plays a specific role in the prevention of particular birth defects. A 20 to 85% reduction in births complicated by neural tube defects (NTDs, i.e., spina bifida and anencephaly) has been realized by providing women with a daily supplement of folic acid in the form of supplements or fortified foods. The optimal dose is not well defined, but 200 to 400 µg/day clearly affords a substantial degree of protection. Populations with a high background rate of NTD births attain the largest reductions in NTDs from supplemental folate. However, because the nascent neural tube closes about day 20 after conception, the additional folate must be provided before this time to be effective.

Infancy

Infancy carries particular vulnerabilities to specific micronutrient inadequacies. Healthy infants in the United States are typically supplemented with vitamin K at birth and with iron and vitamin D during the course of the first year because of their particular susceptibility to deficiencies of these nutrients.

Women of Childbearing Age

The ability to maintain adequate iron status from menarche through menopause is compromised in women by the additional losses incurred by menstruation, pregnancy, and lactation. Therefore, it is not surprising that the population subset that almost invariably displays the highest rate of iron deficiency is women of childbearing age.

Elderly Persons

Specific dietary recommendations for elderly people have been formally incorporated into the recommended dietary allowances (RDA) because aging has an impact on the need for certain micronutrients. Vitamin B_{12} status declines significantly with aging, in large part because of the high prevalence of atrophic gastritis and its associated impairment in protein-bound vitamin B_{12} absorption.[2] Estimates suggest that 10 to 20% of the elderly population is at risk for clinically significant vitamin B_{12} deficiency. Consequently, elderly persons should consume some of their vitamin B_{12} requirement in the crystalline form rather than solely from the naturally occurring protein-bound forms found in food because absorption of the crystalline form is not impaired by atrophic gastritis. Elderly people also require greater quantities of vitamins B_6 and D to maintain health compared with younger adults, as reflected in

the new RDAs (see Table 218-2). For instance, the RDA of vitamin D in persons older than 70 years is now set at 20 μg/day (800 IU), as opposed to adults who are 70 years of age or younger, whose RDA is 15 μg/day.[3,4] This increased need appears to result from diminished cutaneous synthesis of vitamin D by senile skin and from decreased sun exposure, which appears to be particularly important in elders residing in institutional facilities. The need for crystalline vitamin B_{12} and for a quantity of vitamin D that is difficult to achieve without resorting to a supplement suggests that universal use of a daily supplement pill containing these nutrients would benefit elderly people. Widespread use of a multivitamin that contains a broad spectrum of micronutrients is more controversial, in part because of concerns about subtle toxicity. For example, elders with chronic renal failure appear to have a vulnerability to vitamin A toxicity, suggesting that use of supplements containing this vitamin is contraindicated.

PATHOPHYSIOLOGIC AND PHARMACOLOGIC FACTORS

Diseases of the Gastrointestinal Tract

Malabsorption and maldigestion predispose to multiple micronutrient deficiencies. Both fat- and water-soluble micronutrients (except vitamin B_{12}) are absorbed predominantly in the proximal small intestine. Therefore, diffuse mucosal diseases affecting the proximal portion of the gastrointestinal tract are likely to result in deficiencies. Even in the absence of mucosal disease of the proximal small intestine, extensive ileal disease, small bowel bacterial overgrowth, and chronic cholestasis can each interfere with the maintenance of adequate intraluminal conjugated bile acid concentrations and thereby impair absorption of fat-soluble vitamins. Maldigestion is usually the result of chronic pancreatitis. Untreated, it frequently causes malabsorption and deficiencies of fat-soluble vitamins. Vitamin B_{12} malabsorption can often be demonstrated in this setting, a result of inadequate R-protein digestion, but clinical vitamin B_{12} deficiency is rarely reported.

Inborn Errors of Metabolism

Myriad rare inborn errors of metabolism have been described for vitamins and minerals that impair an individual's ability to assimilate, to use, or to retain a particular micronutrient (Chapter 205). Such defects are usually partial and can often be overcome, to a certain extent, by administering doses of the nutrient that are several orders of magnitude greater than usually required. Suspicion for such defects should be entertained if a known defect exists in the family, a deficiency syndrome arises at birth or during infancy, or the deficiency syndrome is present despite adequate dietary intake and the absence of any disease that would impair the ability to assimilate the nutrient.

Medications

Long-term administration of many drugs may adversely affect micronutrient status. The manner in which drug-nutrient interactions occur varies; some of the more common mechanisms are outlined in Table 218-4. Some drugs exert their therapeutic effects by specifically inhibiting the actions of a micronutrient. Examples include coumarin, which inhibits γ-carboxylation reactions mediated by vitamin K, and methotrexate, which binds tightly to dihydrofolate reductase, thereby inhibiting folate metabolism.

TABLE 218-4 DRUG-MEDIATED EFFECTS ON MICRONUTRIENT STATUS: EXAMPLES

DRUG	NUTRIENT	MECHANISM OF INTERACTION
Dextroamphetamine, fenfluramine, levodopa	Potentially all micronutrients	Induces anorexia
Cholestyramine	Vitamin D, folate	Adsorbs nutrient, decreases absorption
Omeprazole	Vitamin B_{12}	Modest bacterial overgrowth, decreases gastric acid, impairs absorption
Sulfasalazine	Folate	Impairs absorption and inhibits folate-dependent enzymes
Isoniazid	Pyridoxine	Impairs utilization of B_6
Nonsteroidal anti-inflammatory drugs	Iron	Gastrointestinal blood loss
Penicillamine	Zinc	Increases renal excretion

Toxins

Tobacco smoking alters the metabolism of several vitamins, including folate and vitamins C and E. In large surveys, diminished plasma levels of folate and ascorbic acid have been observed in chronic smokers. Smoking is also associated with diminished levels of folate in cells of the oral mucosa, diminished ascorbic acid levels in leukocytes, and decreased concentrations of vitamin E in the alveolar fluid, findings providing evidence that many tissues can be affected by smoking and that the effect does not simply represent a shift of these micronutrients out of the plasma compartment.

ADVANCES IN NUTRITIONAL SCIENCE

New Frontiers in Marginal Deficiency States of Micronutrients

Does Optimal Intake of Micronutrients Optimize Health?

Updating the definition of a micronutrient deficiency and establishing recommended daily intakes that are consistent with the most recent evidence have proved difficult for several reasons. In some instances, a novel biochemical or physiologic role for a nutrient has been identified but the question that arises is whether optimization of such functions translates into optimization of health. For example, providing supplemental vitamin E to elderly individuals whose vitamin E status falls within normative standards enhances T-lymphocyte responsiveness; nevertheless, it is unclear whether this translates into diminished infection rates. Another difficult problem pertains to the use of micronutrients in supraphysiologic quantities that exceed all conventional concepts of what is necessary for health. Some micronutrients, when they are taken in large quantities, have effects on physiologic functions that impart apparent health benefits. The ingestion of gram quantities of niacin to reduce low-density lipoprotein (LDL) cholesterol is an example. Such physiologic effects are not observed at more conventional levels of intake and are therefore usually considered pharmacologic effects of the nutrient. Thus, the determination of optimal nutrient intake is highly dependent on which physiologic effect is sought. Furthermore, if only a segment of the population will benefit from supraphysiologic quantities of a nutrient, should dietary guidelines for the remainder of the population be established according to this effect?

Determining an adequate level of intake implies the existence of a means of measuring nutrient status. In seeking an appropriate measure of nutrient status, the diversity of function often makes it difficult to decide which measurement is the most germane. Tobacco smoking, for example, diminishes vitamin E levels in alveolar fluid but not in the serum. Thus, the concepts of localized nutrient deficiencies and tissue-specific requirements add an additional level of complexity to the determination of nutrient status.

Redefinition of Nutritional Requirements

Folate

An example of the complexities that have arisen in redefining the criteria for vitamin deficiencies and vitamin requirements is the water-soluble vitamin folate. In the past, guidelines regarding its necessary intake were straightforward because they were based solely on the prevention of megaloblastic anemia. Measurement of serum and erythrocyte folate concentrations was the most common means of assessing status, and maintaining these levels within accepted normative ranges provided assurance that folate status was adequate to prevent anemia. However, degrees of deficiency that are insufficient to cause anemia may still disturb normal biochemical and physiologic homeostasis and, in some instances, cause clinical disease. Clinical trials have demonstrated that women taking folic acid supplements at the time of conception have a markedly lower chance of delivering a baby with an NTD compared with women who are not folate supplemented but whose folate status falls within a conventionally accepted range. This observation compelled the U.S. government to mandate the fortification of flour, beginning in 1998. Present recommendations are that women of childbearing age consume 400 μg/day of folic acid in the form of supplements or fortified foods, although the dose-response curve of this effect is ill-defined.

Less than optimal intake of folate is also evidenced by an increase in serum homocysteine, an amino acid that is normally metabolized by a folate-dependent pathway. Before the federally mandated fortification of flour, the median intake of folate among adults was half of the present RDA, and a substantial minority of Americans had significantly elevated serum homocysteine levels. Elevated homocysteine is associated with the development of

occlusive vascular disease and accelerated cognitive decline. In randomized clinical trials, however, supplementation with folate, vitamin B_{12}, and vitamin B_6 has shown no benefit against cardiovascular disease despite its ability to lower homocysteine levels. Such supplementation also has no clear benefit for cognitive function, except perhaps in patients with low baseline folate levels.

A compelling body of observations in both humans and animals has demonstrated that habitually low consumption of folate substantially increases the risk of colorectal cancer[5] and perhaps cancers of other organs, such as those of the breast and pancreas. This inverse relationship is observed even when folate status (or dietary intake) falls within the range of conventionally accepted normative values. This relationship has further complicated the determination of what constitutes an optimal intake of folate because the recent epidemiologic data suggest that about 500 μg constitutes the optimal daily intake for suppressing the risk of colon cancer. The issue is further confounded by observations, albeit controversial, suggesting that exceptionally high doses of supplemental folic acid among those who unknowingly harbor precancerous or cancerous lesions may paradoxically enhance the progression of these neoplasms,[6] thereby underscoring the potential for harm produced by taking a nutrient outside of its physiologic window.

The most recent update of the U.S. RDA for folate raised the value from 200 to 400 μg/day, citing both the prevention of anemia and optimization of serum homocysteine as criteria, and recommended that women capable of becoming pregnant consume an additional 400 μg/day in the form of supplements or fortified food. The issues surrounding the prevention of cardiovascular disease, cancer, and cognitive decline were not incorporated into that 1998 determination because the existing data at the time were inconclusive. However, future revisions of the RDAs may integrate some of this new knowledge. The potential for toxicity, the criterion for which was primarily linked to its ability to mask vitamin B_{12} deficiency, was dealt with by setting the TUL at 1000 μg/day of folic acid obtained from supplements and fortified foods in addition to that obtained from natural food sources (see Table 218-2).

Table 218-5 lists several examples of biochemical functions of vitamins that were not formerly recognized. As the clinical significance of each of these new roles is defined and as quantities of each vitamin needed to optimize such functions are determined, redefinition of the desirable range of vitamin status is likely to occur. Future efforts to refine appropriate dietary goals for each micronutrient will, however, need to take into consideration an important theme that is underscored by the previous discussion: the level of consumption of a particular micronutrient that conveys health benefits to one segment of the population is not necessarily beneficial, or even appropriate, for all segments of society.

Antioxidant and Free Radical Scavenging Vitamins and Provitamins

Vitamins A, C, and E as well as many of the carotenoids are effective antioxidants. In addition, vitamins C and E and some of the carotenoids can scavenge free radicals when these nutrients are taken in adequate quantities. Oxidation and free radical damage have been implicated as important contributors to common degenerative illnesses, such as atherosclerosis, cancer, cataracts, and retinal degeneration. Clinical trials to test the efficacy of antioxidant supplements have generally shown no benefit and in some instances harm,[7] although growing evidence indicates that health benefits of such supplements can be realized in populations with marginal antioxidant status. Two large-scale clinical intervention trials with β-carotene supplements conducted in the 1990s reported increased rates of lung cancer among the recipients of the carotenoid. Subsequent mechanistic studies indicated that the large doses administered (20 to 30 mg/day) result in asymmetrical cleavage of the carotenoid into unnatural products that antagonize normal signaling pathways in the lung epithelium, whereas lower supplemental doses undergo symmetrical cleavage into two molecules of vitamin A, thereby protecting against neoplastic transformation.

LDL oxidized in vivo is atherogenic. Prevention of LDL oxidation, at least in animal models, retards the process of atherogenesis. Supplementation of human subjects with several times the RDA of α-tocopherol, and perhaps some of the other antioxidant micronutrients, is an effective means of preventing LDL oxidation. Human intervention trials with vitamin E or other antioxidant nutrients, however, have generally been unable to demonstrate clinical benefits in the reduction of cardiovascular events. There nevertheless has been a sizable reduction in cardiovascular events observed with vitamin E supplementation among populations of patients who are under exceptional oxidative stress, such as those with chronic renal failure and certain classes of diabetics, suggesting that it is only among select groups of individuals that a clinical benefit may be realized.

Epidemiologic studies indicate that occurrence of cancers of the oral cavity, lung, esophagus, and stomach (and perhaps the colorectum) is inversely related to dietary intake of fresh vegetables and fruits. Careful dissection of dietary data suggests that β-carotene and vitamin E content are strongly predictive components of these foodstuffs. High doses of vitamin A and some of its synthetic analogues (e.g., 13-*cis*-retinoic acid) can effectively reduce the recurrence of head and neck cancers, although hepatic toxicity is sometimes a limiting factor in such cancer preventive therapy. Similarly, these agents, as well as β-carotene or vitamin E, taken in large doses have been shown significantly to promote the regression of oral leukoplakia, a premalignant lesion. Daily supplementation with one to three times the U.S. RDA of β-carotene, selenium, and vitamin E has been shown to reduce the incidence of adenocarcinoma of the stomach in a region of China where the disease as well as marginal vitamin status is particularly prevalent. However, as mentioned earlier, trials conducted in developed Western countries have observed no diminution of lung cancer among smokers with daily supplementation of β-carotene and vitamin E.

Epidemiologic associations also suggest an inverse relationship between lens cataract or macular degeneration and the intake of vitamin C, vitamin E, and β-carotene. These common degenerative conditions of the eye are caused, at least in part, by photo-oxidation. Some evidence in animal models indicates that they can be retarded by supraphysiologic supplementation with vitamin C or E. When tested under the conditions of a rigorously conducted multicenter, controlled trial, daily supplementation with a combination of vitamin C, vitamin E, and β-carotene (with or without zinc) had no effects compared with placebo on the likelihood for development of cataracts. However, the combination that included zinc produced an approximately 30% decline in the progression of early macular degeneration to an advanced stage and the likelihood of moderate visual acuity loss.

Further investigation is necessary to define the circumstances more clearly under which antioxidant nutrients can be used to prevent or to treat chronic degenerative diseases.

TABLE 218-5 NEWLY IDENTIFIED ROLES FOR VITAMINS

VITAMIN OR PROVITAMIN	CLASSIC ROLE	NEW ROLE
β-Carotene	Pro-vitamin A	Antioxidant, free radical
Niacin	NAD/NADP coenzyme	Reduction of LDL, elevation of HDL cholesterol
Folate	Hematopoietic factor	Diminishes homocysteinemia
Vitamin A	Transduction of visual input in retina	Induction and maintenance of epithelial differentiation, signal in embryogenesis
Vitamin D	Regulator of calcium	Retards epithelial proliferation; promotes differentiation
Vitamin B_6	Coenzyme for transamination	Modulation of steroid activity

HDL = high-density lipoprotein; LDL = low-density lipoprotein; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate.

Vitamin B_{12} and Neuropsychiatric Disease

Plasma vitamin B_{12} concentrations are considered to be an accurate indication of vitamin B_{12} status. Values greater than 150 pg/mL were thought, until recently, to exclude vitamin B_{12} deficiency as a cause of neurologic or psychiatric syndromes.[8] Recent observations now indicate that 7 to 10% of individuals who have plasma vitamin B_{12} values between 150 and 400 pg/mL may develop neuropsychiatric complications of vitamin B_{12} deficiency in the absence of any indications of megaloblastic anemia. Such individuals can be identified by the demonstration of an elevated level of methylmalonic acid in the blood that decreases to normal levels with parenteral vitamin B_{12} administration. An elevation in serum methylmalonic acid is both a sensitive and a specific indication of cellular vitamin B_{12} deficiency. An alternative approach is to administer several parenteral injections of vitamin B_{12} to an individual who has an otherwise unexplained neuropsychiatric syndrome and whose plasma vitamin B_{12} level falls in the range of 150 to 400 pg/mL. Awareness of this phenomenon is particularly important because it has become clear that atrophic gastritis, an asymptomatic condition that affects approximately

30% of the elderly population, frequently produces a modest decrease in vitamin B_{12} status; similarly, long-term use of proton pump inhibitor drugs inhibits absorption and also increases the risk of clinically significant deficiency.[9]

Is Routine Multivitamin and Multimineral Supplementation Beneficial?

A common query by patients is whether regular use of a multivitamin or multimineral supplement is safe and efficacious in the maintenance of health. Although there is not a unanimous consensus about the "correct" answer to this question, the weight of available evidence indicates that for the general adult North American population, supplementation offers little or no benefit in regard to the prevention of the common chronic degenerative diseases, such as vascular disease, cancer, and dementia.[A1–A5] Although this apparent lack of efficacy has been notably contradicted by two clinical trials conducted in Western industrialized countries in which men taking multivitamins realized modest decreases in the incidence of cancer,[10] such benefits have not been substantiated by other investigations.

Although daily supplementation at the levels found in most multivitamin preparations probably presents no risk of harm, adverse health effects have been observed in several rigorously performed clinical trials in which long-term supplementation with micronutrients at levels that exceed the RDA (or conventional levels of dietary intake) by several-fold was examined. For example, an increased incidence of prostate cancer was observed in the SELECT trial, in which vitamin E was administered at a dose of 400 IU/day, and β-carotene supplementation resulted in an increased incidence of lung cancer among heavy smokers in the ATBC and CARET trials at doses of 20 to 30 mg/day.

This is not to say that health benefits cannot be realized from supplementation in select groups of individuals, although some thought needs to be exercised to determine which segments of the population should be targeted and what specific nutrients should be administered. Certainly, health benefits are likely in individuals whose dietary intake is chronically inadequate or in patients whose medical conditions are often complicated by micronutrient deficiencies, such as those on chronic renal dialysis or among individuals with marginally controlled intestinal malabsorption. The elderly frequently cannot achieve recommended intakes of vitamin D and calcium with diet alone, and therefore targeted supplementation with these nutrients is often indicated. Similarly, the high prevalence of atrophic gastritis among the elderly as well as the frequent use of proton pump inhibitor drugs each conspire to impair adequate vitamin B_{12} status.[11] Moreover, in many regions of the world, there continues to be a high prevalence of marginal micronutrient status among the general adult population, and in such areas widespread supplementation may be indicated; the Linxian trial in China, in which supplementation with a mixture of several antioxidant micronutrients led to a sizable decrease in gastric cancer, is one such example.

EATING DISORDERS

MARIAN TANOFSKY-KRAFF

DEFINITION

Feeding and eating disorders are defined as syndromes "characterized by a persistent disturbance of eating or eating-related behavior that results in the altered consumption or absorption of food and that significantly impairs physical health or psychosocial functioning." The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) defines anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED) as primary diagnoses in adolescents and adults. All other diagnoses are identified as Unspecified Feeding or Eating Disorder and represent presentations that do not meet the criteria for the primary eating disorders but nonetheless cause significant distress and impairment. The severity of each disorder is also specified as mild, moderate, severe, or extreme. Given the recent publication of the DSM-5, most empirical data available to date involve the criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR, published in 2000).

ANOREXIA NERVOSA

AN involves a restriction of "energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health."[1] Individuals with AN experience an intense fear of gaining weight or becoming fat, are overly concerned with weight or shape, and often may not recognize the seriousness of their low body weight. AN has two subtypes: restricting and binge-eating/purging. DSM-5 criteria for AN are listed in Table 219-1.

BULIMIA NERVOSA

A diagnosis of BN requires recurrent episodes of binge eating (i.e., the consumption of an unambiguously large amount of food given the context, accompanied by a sense of loss of control over eating). Episodes of binge eating co-occur with behaviors intended to compensate for energy consumed and to prevent weight gain, such as self-induced vomiting and fasting. Binge eating and compensatory behaviors must occur, on average, at least once a week for 3 months. The self-esteem of individuals with BN is excessively influenced by their body weight and shape. DSM-5 criteria for BN are outlined in Table 219-2.

BINGE EATING DISORDER

BED is characterized by recurrent episodes of binge eating in the absence of regular compensatory behaviors that are present in BN. The binge

TABLE 219-1 DSM-5 DIAGNOSTIC CRITERIA FOR ANOREXIA NERVOSA

A. Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. *Significantly low weight* is defined as a weight that is less than minimally normal or, for children and adolescents, less than minimally expected.
B. Intense fear of gaining weight or becoming fat, or persistent behavior that interferes with weight gain, even though at a significantly low weight.
C. Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight.

Specify whether:

Restricting type: During the last 3 months, the individual has not engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas). This subtype describes presentations in which weight loss is accomplished primarily through dieting, fasting, and/or excessive exercise.

Binge-eating/purging type: During the last 3 months, the individual has engaged in recurrent episodes of binge eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

From Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

TABLE 219-2 DSM-5 DIAGNOSTIC CRITERIA FOR BULIMIA NERVOSA

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
   2. A sense of lack of control over eating during the episodes (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.

C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.

D. Self-evaluation is unduly influenced by body shape and weight.

E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

From Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

TABLE 219-3 DSM-5 DIAGNOSTIC CRITERIA FOR BINGE EATING DISORDER

A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   1. Eating, in a discrete period of time (e.g., within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
   2. A sense of lack of control over eating during the episodes (e.g., a feeling that one cannot stop eating or control what or how much one is eating).

B. The binge eating episodes are associated with three (or more) of the following:
   1. Eating much more rapidly than normal.
   2. Eating until feeling uncomfortably full.
   3. Eating large amounts of food when not feeling physically hungry.
   4. Eating alone because of feeling embarrassed by how much one is eating.
   5. Feeling disgusted with oneself, depressed, or very guilty afterward.

C. Marked distress regarding binge eating is present.

D. The binge eating occurs, on average, at least once a week for 3 months.

E. The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

From Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

episodes are distinguished by at least three associated characteristics, such as eating rapidly, eating until feeling uncomfortably full, and feeling disgust and guilt regarding the episodes. Individuals experience marked distress surrounding the binge episodes, and the binge eating episodes must occur, on average, at least once a week for 3 months. DSM-5 criteria for BED are listed in Table 219-3.

EPIDEMIOLOGY

Data suggest a lifetime prevalence of AN of approximately 0.6%, with higher rates among women (0.9%) compared with men (0.3%).[2] The lifetime prevalence of BN appears to be about 1%, with higher rates among women (1.5%) than among men (0.5%). The lifetime prevalence of BED is estimated at 3.5% for women and 2.0% for men. Among adolescents, lifetime prevalence estimates of AN, BN, and BED have been reported at 0.3%, 0.9%, and 1.6%, respectively.[3] Contrary to the view that eating disorders afflict only non-Hispanic white, affluent women, individuals of all races, ethnicities, and cultures are affected by these diagnoses.[4]

PATHOBIOLOGY

Research regarding the neuropathology of eating disorders is in nascent stages. Data suggest that several brain regions may be involved in and potentially interact in the manifestation of all eating disorders. Individuals with eating disorders appear to have brain function alterations in emotional/limbic, reward, and cognitive control circuits.[5] Fear circuitry networks involving the amygdala, anterior cingulate cortex, hippocampus, insula, striatum, and prefrontal cortex have demonstrated differential activation among individuals with eating disorders (with the majority of research in AN) compared with controls. Specifically, there tends to be a hyper-responsiveness in the limbic circuitry in response to potentially threatening cues, such as food and body weight/shape.

There also appear to be alterations in reward function in patients with AN, but the direction is unclear. By contrast, individuals with BN and BED consistently demonstrate hyper-responsivity in reward and somatosensory regions on exposure to food images. Data also suggest that individuals with eating disorders may have dysregulated frontal cortical cognitive neural networks acting in concert with regional reward systems.[6] Individuals with eating disorders have demonstrated impaired cognitive flexibility. Specific to BN, impulsivity and poor inhibitory control have also been reported.

Given the brain regions implicated in eating disorders, current studies have focused on the role of dopamine and serotonin in the manifestation of eating disorders. Individuals with AN appear to have impaired dopaminergic signaling, particularly in striatal circuits, that might contribute to altered reward and affect, decision making, and executive control as well as compulsivity and decreased food ingestion. Moreover, emerging clinical research suggests that striatal dopamine abnormalities exist in individuals with BN and BED. Because serotonin (5-hydroxytryptamine) 1A and 2A receptors and the serotonin transporter may play a part in symptoms of eating disorders, such as impulse control and associated mood symptoms, it is likely that interactions between the serotonin and dopaminergic systems contribute to eating disorders.

Risk Factors

Eating disorders develop as the result of multiple biological, psychological, and sociocultural factors. AN, BN, and BED aggregate in families, with estimates from twin studies suggesting that 40 to 60% of vulnerability for eating disorders is genetic. Studies have reported links between eating disorders and polymorphisms in the serotonin transporter gene (*SLC6A4*), the dopamine D_2 receptor (*DRD2*) gene, the μ_1 opioid receptor (*OPRM1*) gene, the fat mass and obesity-associated (*FTO*) gene, and the brain-derived neurotrophic factor (*BDNF*) gene. Although genetic linkage and association studies have implicated several susceptibility loci for AN, BN, and BED, specific genes that consistently lend vulnerability to eating disorders are less conclusive.[7]

Female sex, pediatric overweight, elevated shape and weight concerns, sexual abuse, trauma, and mood disorders have been identified as risk factors for all eating disorders. Personality-related variables, such as impulsivity and perfectionism, appear to be linked to eating disorders.[8] Importantly, internalization to the "thin ideal" (a sociocultural emphasis on shape and weight and a marked preference for a thin body type) with resulting weight and shape concerns has been proposed to contribute to eating disorder development, particularly among adolescents who are under strong influence from their peer and family environments. For example, parental overconcern about eating, shape, and weight as well as weight-related teasing by family members confers risk for eating disorders. Specific to BED, maltreatment, including teasing and bullying, and perceived stress are risk factors for the disorder.[9]

CLINICAL MANIFESTATIONS

Symptoms and Signs

For AN, physical symptoms and signs may include amenorrhea, constipation, cold intolerance, anemia, and lanugo hair. Reduced bone density is believed to predict the onset of premature osteopenia and osteoporosis. Health problems associated with malnutrition affect cardiovascular, gastrointestinal, reproductive, and endocrine systems. Individuals with AN frequently present with comorbid psychiatric disorders, including mood and anxiety disorders (e.g., social phobia, specific phobia, post-traumatic stress disorder), and high rates of suicidal ideation and behavior.

Individuals with BN present with signs and symptoms most commonly associated with purging behavior. These include dental enamel erosion secondary to vomiting, gastrointestinal symptoms, salivary gland hypertrophy, and electrolyte disturbances. Electrolyte abnormalities can have deleterious effects on the renal and cardiovascular systems. BN patients are at risk for cardiometabolic conditions (e.g., diabetes, stroke) as well as chronic pain. Metabolic acidosis can also occur in patients who are abusing laxatives as a result of the loss of bicarbonate from the bowel. Noninflammatory swelling of the salivary glands is a common clinical manifestation of BN. The most common psychiatric comorbidities in BN are major depressive disorder, anxiety disorders, substance use disorders, and disruptive behavioral disorders.

Individuals with BED are frequently overweight or obese. However, adults with BED are likely to report the development of diagnoses of metabolic syndrome components (e.g., dyslipidemia, hypertension, type 2 diabetes) after accounting for the contribution of body weight. The presence of BED may affect bariatric surgery outcome, resulting in less weight loss or more weight regain, but this is not a consistent finding. However, the presence of "loss of control" eating after surgery consistently predicts less weight loss or greater weight regain. Compared with obese adults without BED, those with the disorder experience significant impairment in a number of domains of

psychosocial functioning, including a poorer quality of life and more impaired functioning in their home and social lives. Individuals with BED often have higher levels of disability, health problems, and work productivity impairment compared with obese and healthy controls without binge eating. With regard to comorbid psychiatric diagnoses, adults with BED experience Axis I psychiatric disorders at a rate comparable to (or higher than) that of individuals with AN or BN, including major depressive disorder, anxiety disorders, substance use disorders, and disruptive behavioral disorders.

Natural History

AN is typically manifested during adolescence, although the disorder can develop before puberty. BN frequently develops during later adolescence or early adulthood. BED is often manifested in adulthood, but adolescents also present with the disorder. Several retrospective and prospective studies report that binge and "out of control" eating occur as early as middle childhood.

Data on the natural course of eating disorders in the clear absence of treatment are limited. Eating disorders tend to exhibit a remitting and relapsing natural course across the lifespan, and there appear to be high rates of diagnostic crossover.[10] Treatment outcome data indicate that AN tends to transition to BN or an Unspecified Eating Disorder, and those with BN and BED tend to migrate from one to the other.

DIAGNOSIS

A number of structured, well-validated assessments for the diagnosis of eating disorders exist. These include but are not limited to the Structured Clinical Interview for the DSM and the Eating Disorder Examination. However, eating disorders are typically diagnosed by review of the patient's history, symptoms, and behaviors in an interview format. Evaluation of comorbid psychiatric problems, most notably mood, anxiety, substance use disorders, and disruptive behavioral disorders, is also required. Information should be gathered on interpersonal relationships, history of sexual and physical abuse, self-harm, and suicidal ideation or behavior. Family involvement is crucial, particularly for pediatric patients. A complete physical examination to assess body composition, vital signs, cardiovascular function, and hematologic and blood chemistry parameters is recommended for all patients.

TREATMENT Rx

Anorexia Nervosa

There is limited evidence on effective treatments for AN. For severely underweight patients, inpatient medical monitoring and supervised nutrition rehabilitation are required. The optimal setting (inpatient versus outpatient treatment) remains a subject of debate, and the evaluation of treatment costs in AN plays an important role in determining treatment. However, for pediatric patients, family-based psychotherapy, particularly during the early phases of the disorder, has demonstrated effectiveness.[11] Maudsley's family-based therapy involves both joint family sessions and simultaneous but independent patient/family intervention. Antidepressants (e.g., selective serotonin reuptake inhibitors) are associated with high rates of noncompliance, and compelling evidence of beneficial effects has not been found. The use of antipsychotic drugs has been explored, but results regarding their effectiveness remain nondefinitive.

Bulimia Nervosa

Cognitive-behavioral therapy (CBT) has been recognized as the treatment of choice for BN. Interpersonal psychotherapy (IPT) is also effective for the treatment of BN, particularly for those who are nonresponsive to CBT. There is growing support that pharmacotherapy may be helpful for some patients with BN. Antidepressants, especially selective serotonin reuptake inhibitors, are modestly effective for reducing binge eating in BN over the short and long term. Topiramate has consistently been shown to decrease binge eating in BN, but side effects may limit its usefulness. It is unclear whether combination therapy may be required for optimal outcomes.

Binge Eating Disorder

Psychological treatment for BED aims to reduce binge eating, weight and shape concerns, and prevent excess weight gain and/or induce modest weight loss. The psychotherapies most evaluated in clinical trials include CBT, IPT, behavioral weight loss, and CBT guided self-help (CBTgsh) approaches. CBT and IPT are first-line treatments. Given its cost-effectiveness, CBTgsh may be an optimal treatment option when specialist care is not available. With regard to pharmacologic treatment in BED, three medications or classes of medications have been studied in two or more placebo-controlled trials. Selective serotonin reuptake inhibitors, sibutramine, and topiramate all produce reductions in frequency of binge eating relative to placebo in short-term trials.[12] However, sibutramine has been withdrawn from the market, and topiramate is frequently associated with problematic cognitive effects, thus limiting its clinical utility.

PREVENTION

Whereas an increasing number of macro-level environmental public health initiatives have emerged (i.e., anti-dieting media campaigns and sanctions on advertising practices propagating an ideal of extreme thinness), few empirical data exist evaluating their efficacy. However, there are more data on individual, micro-level interventions aimed at reducing proximal eating disorder risk factors as well as current and distal eating pathology. Selected, interactive, multisession programs with adolescent girls may be more effective than universal, didactic, heterogeneous-sampled and single-session programs in reducing risk factors for eating disorder symptoms. For example, a dissonance-based program aimed at reducing eating disorder risk factors in adolescent girls has demonstrated effectiveness.

PROGNOSIS

Anorexia Nervosa

Remission rates vary widely for AN. Lower remission rates (29%) have been observed, particularly in studies with the shortest follow-up duration. However, most individuals with AN (approximately 76%) treated in outpatient settings will remit within 5 years after the initiation of treatment. Most individuals who do not achieve remission from AN during follow-up periods transition to a diagnosis of BN or an Unspecified Eating Disorder, which likely captures partial syndrome AN. Among psychiatric diagnoses, AN consistently has one of the highest mortality rates due to suicide, nutritional deficits, cardiac complications, and substance abuse.[13] The crude cumulative mortality rate is 2.8%, with longer duration of illness before receiving treatment and the need for inpatient treatment as negative prognostic indicators for AN.[14] Predictors of relapse include desiring a lower weight at the end of treatment and receiving treatment in a general (versus specialty) clinic.

Bulimia Nervosa

Similar to AN, most individuals with BN (70% or more) who receive treatment fully remit when assessed 5 to 20 years later, with remission rates being much lower (27 to 28%) at 1-year follow-up. If individuals with BN do not achieve remission within 5 years, however, they are likely to exhibit a chronic course of the illness. Mortality rates for BN range between 0 and 2%. Diagnostic crossover from BN to AN is relatively rare; yet, there is frequent diagnostic crossover between BN and BED, which may suggest a possible common psychological and/or biologic maintaining process. Negative prognostic indicators for BN include endorsement of greater psychiatric comorbidity, multiple impulsive behaviors (e.g., self-harm, substance use disorder), and a family history of alcohol abuse. Individuals who receive inpatient treatment or have a low motivation for engaging in treatment are more likely to relapse.

Binge Eating Disorder

A paucity of data exists on the long-term outcomes for BED patients. There are data to suggest that at 1 year after outpatient treatment, upwards of 80% of patients remit. In one clinical trial that examined 4-year outcomes, between 52 and 76% of individuals receiving psychological treatment for BED demonstrated remission from binge eating.[15] These preliminary data suggest that the prognostic trajectory may be similar to that of BN. Diagnostic crossover from BED to BN is high, whereas crossover to AN is relatively rare. Although examination of prognostic indicators for BED is in its early stages, patients reporting an undue influence of their body shape or weight on self-evaluation are less likely to have remission from binge eating at 12-month follow-up.[16] Rapid remission of binge eating has also been shown to be a positive prognostic indicator for binge remission.[17]

REVIEW QUESTIONS

1. A 21-year-old woman presents with scarred knuckles, faded wrist scarring, electrolyte imbalance, and low weight (body mass index [BMI] = 20). The menstrual cycle is reported as abnormal and infrequent. The patient denies current abnormal or restrictive eating patterns and self-injurious and compensatory behaviors. The patient expresses clear discomfort during collection of weight and avoids eye contact with clinical staff. No binge eating is reported. What is the most likely diagnosis for this individual?

A. Anorexia nervosa, general diagnosis: patient exhibits low body weight, potential self-harming behaviors, amenorrhea, and clear discomfort with body weight.
B. Bulimia nervosa, general diagnosis: low weight, knuckle scarring, and electrolyte imbalance are consistent with bulimia nervosa.
C. Anorexia nervosa, purging subtype: low weight, potential self-harming behaviors, and amenorrhea are consistent with anorexia nervosa; knuckle scarring and electrolyte imbalance are consistent with anorexia nervosa purging subtype.
D. No current eating disorder diagnosis: patient's BMI is not *significantly* low within the context of age and sex to indicate a clinical diagnosis of anorexia nervosa, and binge eating and compensatory behaviors are not present.
E. Bulimia nervosa, restricting subtype: presence of menstrual cycle, discomfort with body weight, knuckle scarring, and electrolyte imbalance are consistent with bulimia nervosa; low body weight is consistent with bulimia nervosa restricting subtype.

Answer: D The patient's body weight is within a normal range, and denial of abnormal or restrictive eating patterns excludes a diagnosis of anorexia nervosa. Although knuckle scarring and electrolyte imbalance are suggestive of self-induced vomiting, a diagnosis of bulimia nervosa cannot be made without clear indication of the regular use of compensatory behaviors. Although amenorrhea is often a symptom, it is currently neither a necessary nor conclusive criterion for the diagnosis of anorexia nervosa. Although the patient cannot be given a conclusive eating diagnosis, further psychological and physical examination is warranted.

2. A 19-year-old female college student presents with current bulimia nervosa. The patient reports feeling very dissatisfied with her body shape and weight and engaging in binge eating while watching reality television. What is the best *initial* course of treatment action for you to suggest to the patient?

A. Instruct the patient to modify television preferences to reduce episodes of binge eating while opening up a dialogue with friends about healthy eating habits.
B. Refer the patient to a therapist for cognitive-behavioral therapy.
C. Prescribe topiramate to help the patient reduce episodes of binge eating.
D. Instruct the patient to keep a journal documenting emotions surrounding binge episodes for personal reflection.
E. Refer the patient to a therapist for dialectical behavioral therapy.

Answer: B Cognitive-behavioral therapy remains the "gold standard" for the treatment of bulimia nervosa. Although other interventions, such as interpersonal psychotherapy and dialectical behavioral therapy, have shown efficacy in treatment of bulimia nervosa, cognitive-behavioral therapy shows the greatest efficacy across studies and subjects. Although discussing or expressing emotions regarding food and body shape and weight can be helpful for individuals with bulimia nervosa, constructive guidance is generally necessary for symptom reduction and cessation. Although topiramate has been shown to help individuals reduce binge eating, it has a number of cognitive side effects that may make its use impractical.

3. Which of the following is *not* a criterion for the diagnosis of binge eating disorder?

A. BMI ≥ 30 (body mass index obesity threshold)
B. Marked distress surrounding binge episodes
C. Binge eating
D. Lack of regular compensatory behaviors
E. Weekly episodes of binge eating for at least 3 months

Answer: A There is no weight requirement for a diagnosis of binge eating disorder. Although individuals with binge eating disorder are often overweight or obese, BMI is not a required criterion for the diagnosis.

4. Which of the following statements regarding the genetics of disordered eating is true?

A. Identical twins are 100% concordant for anorexia nervosa.
B. Several genes have been conclusively linked to increased vulnerability for eating disorders.
C. Of the neurotransmitters, dopamine and norepinephrine are the most likely candidates for eating disorder maintenance.
D. Media generally play a bigger role than genetics in the onset of eating disorders.
E. Children of individuals with binge eating disorder are more likely to experience out of control eating episodes than anorexia nervosa.

Answer: E Studies show that disordered eating behaviors, such as binge or loss of control eating, are often highly heritable. Offspring of mothers with binge eating have a higher genetic propensity to develop binge eating than do children of mothers who do not exhibit the behavior. Although monozygous twins share equal genetic predisposition for the development of disordered eating behaviors, no eating disorder shows 100% concordance between monozygous twins. Furthermore, although several gene loci have been indicated in the development and maintenance of eating disorders, evidence does not conclusively point to specific genes as responsible for disordered eating. Although studies have indicated the role of norepinephrine in the onset and maintenance of eating disorders, dopamine and serotonin are currently generally considered to be the most likely neurotransmitters to influence disordered eating behaviors. Findings regarding the effect of media on increasing risk for disordered eating are mixed; genetics, however, are strongly implicated.

5. Which of the following is *not* a finding regarding the neuropathology of eating disorders?

A. Individuals with bulimia nervosa and binge eating disorders are hyperresponsive to food images in reward and somatosensory regions.
B. Individuals with bulimia nervosa exhibit decreased impulsivity and enhanced inhibitory control relative to control subjects.
C. Individuals with anorexia nervosa exhibit impaired dopaminergic signaling in striatal circuits.
D. Individuals with anorexia nervosa exhibit differential activation of fear circuits relative to control subjects.
E. Findings indicate that dysregulation in the limbic system may be influential in the development of eating disorders.

Answer: B Data suggest that individuals with bulimia nervosa exhibit *increased* impulsivity and *decreased* inhibitory control relative to control subjects.

220 OBESITY

MICHAEL D. JENSEN

Obesity is the most common nutritional disorder in the United States and directly or indirectly accounts for a significant portion of health-related expenses. The safest treatment approaches (lifestyle change and behavior modification) are not those commonly employed by physicians and require considerable time to implement. The recently released Guideline for the Management of Overweight and Obesity in Adults provides direction for clinicians for the treatment of obesity.

DEFINITION

The Guideline for the Management of Overweight and Obesity in Adults produced by the National Institutes of Health and the National Heart, Lung, and Blood Institute (NHLBI) and disseminated by the American College of Cardiology (ACC), the American Heart Association (AHA), and The Obesity Society (TOS) provides evidence-informed, scientifically based recommendations on evaluation and management of overweight and obesity.

Body mass index (BMI) continues to be the recommended approach to categorize weight relative to height for adults. BMI is calculated as weight (in kilograms) divided by height squared (in meters):

$$BMI = \frac{weight\ (kg)}{height^2\ (m^2)}$$

To calculate BMI with pounds and inches, the formula is modified as follows:

$$BMI = \frac{weight\ (lb)}{height^2\ (in^2)} \times 703$$

The guideline suggested that no changes are indicated in the weight classifications by BMI, which are summarized in Table 220-1. Individuals who are overweight (BMI of 25.0 to 29.9) may or may not be overfat. Some adults may be overweight because of increased muscle mass, which is a straightforward clinical observation. Although, in general, the risk for development of adiposity-related health problems increases continuously as the BMI exceeds 25, the new guideline continues to recommend the use of waist circumference measurements to discriminate among patients who may require more testing. Overweight and class I obese patients with a waist circumference in the high-risk category deserve a discussion of lifestyle issues as they relate to health and weight loss. Some individuals with a BMI of 27 to 29.9 develop serious metabolic complications that improve with weight loss and are candidates for more aggressive treatment, including pharmacotherapy if it is needed. Asian populations, in particular, are at risk for the typical metabolic complications of obesity at lower BMI and waist circumferences than those for whites, Hispanics, blacks, and Polynesians; the guideline for at-risk BMI in Asian populations is 23 to 24.

TABLE 220-1 CLASSIFICATION OF OVERWEIGHT AND OBESITY BY BODY MASS INDEX (BMI)

	OBESITY CLASS	BMI (kg/m^2)
Underweight		<18.5
Normal		18.5-24.9
Overweight		25.0-29.9
Obesity	I	30.0-34.9
Obesity	II	35.0-39.9
Extreme obesity	III	≥40

Jensen MD, Ryan DH, Apovian CM, et al. 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society. *J Am Coll Cardiol.* 2014;63:2985-3023.

The prevalence of comorbidities and risk of future morbidities increase considerably at a BMI of more than 30, the cut point for obesity. Obesity is divided into three classes, also depending on BMI (see Table 220-1). Treatment approaches may differ for those who are overweight and for different classes of obesity. For example, current U.S. Food and Drug Administration guidelines indicate that pharmacotherapy can be adjunct treatment for any class of obesity, even if medical complications are not present. Familiarity with the guidelines is important. Supervisory agencies and third-party payers use them to determine who is eligible for treatment benefits. Extreme obesity (BMI > 40) is one of the key features that would prompt consideration of a patient for bariatric surgery when medical treatments have failed. Patients with class II obesity (BMI of 35.0 to 39.9) may be considered for bariatric surgery if medical treatments have failed and if severe, life-threatening complications are present.

As noted, the new NHLBI/ACC/AHA/TOS guidelines continue to recommend waist circumference as an office assessment tool to help with the treatment decision-making process. The new guidelines suggest that the previous waist circumference cut points of more than 102 cm (40 inches) for men and more than 88 cm (35 inches) for women are indicators of increased metabolic risk. However, the report stated that the relationships between disease risk and waist circumference are continuous and progressive, with no obvious cut points. The recommendation is to measure waist circumference in overweight and class I obesity adults. Those adults with waist circumferences above the cut points deserve further evaluation to detect other cardiovascular disease risk factors. Adults with class II or class III obesity are at sufficiently high risk that waist circumference information does not appear to add valuable information. These definitions of overweight and obesity and of high-risk waist circumference are generally applicable to those of European and African descent, but lower values are recommended for those of Asian descent. The risks of metabolic abnormalities occur at lower BMI and lower waist circumference in these populations.

EPIDEMIOLOGY

Prevalence of Obesity

Although the number of overweight and obese adults in the United States has increased dramatically during the past 30 years, the increase in the prevalence is now slowing or leveling off.[1] In 2009-2010, the prevalence of obesity was 35.5% among adult men and 35.8% among adult women, with no significant change compared with 2003-2008. Approximately 60% of U.S. men and 51% of U.S. women are overweight or obese, although a greater percentage of women than men are obese. There are substantial differences in the prevalence of obesity by age, race, and socioeconomic status. The prevalence of obesity in adults tends to rise steadily from the ages of 20 to 60 years, decreasing in later years. It has been estimated that almost 75% of men aged 60 to 69 years in the United States have a BMI of more than 25. The increase in mean BMI with age is not as much of a threat to population health as is a similar increase in the BMI of younger populations. The lowest mortality rates for young adults are for a BMI in the lower part of the normal range (20.0 to 24.9), whereas the BMI associated with the lowest mortality rates is somewhat above 25 kg/m^2 for those in the 60s and 70s. Physicians should base their weight recommendations for individual patients on whether adverse health consequences associated with obesity are present.

The differences in overweight and obesity among African Americans, Mexican Americans, and European Americans are not subtle. African American women and Mexican Americans of both sexes have the highest rates of overweight and obesity in the United States. In interpreting these data, however, it is important to keep in mind that there is an inverse relationship between socioeconomic status and obesity, especially among women (Chapter 5). Women in lower socioeconomic classes are much more likely than those in higher socioeconomic classes to be obese. This association reduces but does not eliminate the racial differences in the prevalence of obesity. Whether the remaining racial differences in the prevalence of obesity are due to genetic, constitutional, or social factors is not yet known.

PATHOBIOLOGY

Etiology

Genetic and constitutional susceptibility to obesity are heavily influenced by the environment. Evidence from studies of twins adopted into different families indicates that within a given environment, a significant portion of the variation in weight is genetic.[2] That said, the remarkable increase in the prevalence of obesity in the United States during the past 3 decades is unlikely to be due to wholesale changes in the genetic makeup of Americans.

Genetic Aspects of Human Obesity

Although obesity susceptibility is a classic polygenic condition, there are also a number of syndromic and monogenic obesity syndromes. The long-recognized genetic defects resulting in obesity include Prader-Willi and Laurence-Moon-Biedl syndromes. More recently, rare monogenic forms of human obesity due to mutations in the leptin gene, the leptin receptor gene, and the melanocortin signaling system genes have been described. These gene mutations are most often associated with increased appetite rather than with reduced energy expenditure. Genome-wide association studies have reported a number of genes associated with higher BMI. Those that appear to predict the greatest amount of variance in BMI include the fat mass and obesity-associated (*FTO*) gene and the melanocortin-4 receptor (*MC4R*) gene. Other genes that have been reliably associated with obesity include *TMEM18*, *KCTD15*, *GNPDA2*, *SH2B1*, *MTCH2*, and *NEGR1*. Together, however, the combined effects of all the identified genetic contributions account for less than 1% of the variance in BMI. This emphasizes both the huge environmental effects and the polygenic nature of susceptibility to obesity.

Constitutional Influences on Obesity

A number of environmental factors can result in long-term, epigenetic effects on body weight regulation and the susceptibility to obesity-related health problems. These epigenetic effects are ascribed to processes that include changes in DNA methylation, acetylation, and chromatin remodeling. The effect of the intrauterine environment and the perinatal period on subsequent weight and health is best studied. Undernutrition in the last trimester of pregnancy and in the early postnatal period decreases the risk of adult obesity, although the low birthweight associated with undernutrition (or smoking) in late pregnancy also increases the risk of adulthood hypertension, abnormal glucose tolerance, and cardiovascular disease. In contrast, undernutrition limited to the first two trimesters of pregnancy is associated with an increased probability of adult obesity. The infants of diabetic mothers tend to be fatter than those of nondiabetic mothers, and children of diabetic mothers have a greater prevalence of obesity when they are 5 to 19 years old, independent of whether their mother is obese. Finally, intrauterine exposure to the diabetic environment results in an increased risk of diabetes mellitus and obesity in the offspring. Thus, the issue of the genes versus the environment in regard to obesity and metabolic complications of obesity is blurred in the intrauterine and perinatal time intervals. One of the striking and worrisome aspects of these metabolic effects is not only the long-term effects on the individual's weight regulation and health but also the suggestion that these traits can be passed on to future generations.

Environmental Contributors to Human Obesity

Dramatic changes in the environment of Western countries have occurred during the past 50 years, including reduced demands for physical activity and alterations in the food supply. These food supply changes appear to have either increased or prevented the expected decrease in energy intake that would be needed to match the reduced energy expenditure from physical activity.[3]

Food

A number of environmental factors can influence food intake (Table 220-2). Consuming energy-dense foods results in greater energy intake because adults tend to respond to food volume rather than to the energy content. This factor likely accounts for the association between high-fat diets and excess body weight; many high-fat foods are also energy dense. When humans consume diets that are high in fat but low in energy density, energy intake is not greater than would be expected on the basis of the energy density of the foods. Larger food portion size has also been shown to increase food intake. Given the trend in the United States to serve larger portions of food and beverage, this could contribute to greater obesity risk. Food variety can also affect energy intake. An increased variety of entrees, sweets, snacks, and carbohydrates in the diet is associated with an increase in body fatness and food intake. In contrast, an increase in the variety of vegetables available does not appear to increase energy intake and is not associated with increased body fatness. Other factors that may have broad population effects in the United States include the reduced costs of food, increased availability, and palatability. Finally, there is evidence that consumption of sugar-sweetened beverages, such as soft drinks and fruit juices, is not accompanied by a decrease in food intake to offset the extra energy intake. The implication is that some types of beverages will add to the energy intake during the day and promote weight gain.

A number of psychological factors also influence how the properties of food affect energy intake. Individuals vary with respect to their dietary restraint (the tendency to consciously limit food intake to control weight), their feelings of hunger, or their disinhibition (the tendency to overeat opportunistically). It has been proposed that interindividual differences in these factors modify how food variety and portion size affect the eating profile. The social context in which food is consumed and the emotional state of the individual also modulate food intake.

TABLE 220-2 ENVIRONMENTAL FACTORS PROMOTING OBESITY

DIETARY	ACTIVITY
↑ Energy density of foods	↑ Sedentary behavior
↑ Portion size	↓ Activities of daily living
↑ Variety*	↓ Employment physical activity
↑ Palatability	
↑ Availability	
↓ Cost	
↑ Caloric beverages (sugar-sweetened beverages)	

*Variety of sweets, snacks, and entrees.

Physical Activity

Physical activity can be divided into three categories: (1) exercise (fitness- and sports-related activities); (2) work-related physical activity; and (3) non-exercise, nonemployment (spontaneous) activity. Tables are widely available that allow one to calculate energy expenditure on the basis of an individual's weight as well as the type and duration of exercise. Only about 20 to 30% of Americans engage in exercise at the recommended frequency, intensity, or duration that could be expected to have a protective effect on the development of obesity and other health problems, but this does not seem to have changed in recent decades. Recent data suggest that the amount of time spent in sedentary activities (e.g., watching television, using the computer) is an independent predictor of metabolic abnormalities associated with obesity over and above the effects of exercise. Thus, to the extent that reduced physical activity is contributing to the epidemic of obesity, it is likely that it is reduced employment-related and spontaneous physical activity that is changing.

Although it is becoming easier for individuals to measure the energy expended in nonexercise activity with step counters and electronic motion detection devices, there are insufficient longitudinal, population-based data to define the extent to which changes in this activity parameter have occurred. Certainly, employment-related physical activity has decreased with the advent of more automated systems in the workplace. One estimate suggests that between 1982 and 1992, energy expenditure at work decreased by about 50 kcal/day. The additional workplace changes since that time have probably reduced employment physical activity further.

The other component of nonexercise physical activity, the activities of daily living, has probably been reduced by the plethora of labor-saving conveniences (e.g., drive-through food and banking, escalators, remote controls, e-mail, online shopping) now available. Again, there are few hard data to assess how much of a change has actually occurred, although a reduction in daily walking trips and an increase in daily automobile trips have been documented.

There is a large amount of information on how differences in sedentary activity (television watching, video games, and computer use) relate to obesity and obesity complications. The evidence indicates that more time spent in sedentary pursuits is associated with an increased risk of overweight and obesity. The striking aspect to these studies is that the adverse effect of sedentary activities is independent of participation in traditional exercise activities.

Understanding the contributions of decreased work-related physical activity, decreases in activity of daily living, and increases in sedentary behavior can help the physician working with the patient to uncover patterns that may relate to weight gain. Physicians who are aware of these environmental factors are in a better position to help their obese patients identify which of these

environmental factors are contributing to the problem and to develop plans for intervention. In this regard, patients who regularly use step counters or other types of activity-monitoring devices will be better able to self-identify and modify their behavior to obtain sufficient physical activity.

Regulation of Body Weight and Energy Balance

The regulation of adult body weight is a well-balanced process. For example, the typical U.S. adult will take in and expend approximately 2000 to 3000 kcal/day. If there were a consistent error of even 1% in overconsumption of food, this would result in the gain of approximately 25 to 30 pounds of fat every 10 years, assuming no change in energy expenditure. It follows that most adults regulate their average energy balance with greater than 1% precision. There appears to be regulation of both energy intake and energy expenditure through conscious and unconscious processes.

The excess energy consumed by adults is generally stored as triglycerides in adipocytes. Humans continuously recruit new adipocytes from a large preadipocyte pool to replace dying adipocytes. Although the primary means by which abdominal adipose tissue mass expands is through increased fat cell size (adipocyte hypertrophy), this process can store only a limited amount of fat. Adults who gain leg fat accumulate more rather than larger adipocytes on average, resulting in a net increase in adipocyte number as more new adipocytes are created than needed to replace dying cells. Some adults recruit new adipocytes more readily than others do and thus gain weight more so from adipocyte hyperplasia (increased fat cell number) than from hypertrophy. Those who gain fat with large adipocytes, especially in association with an adipose tissue inflammatory response (greater numbers of classically activated macrophages and other immune cells), are more likely to be insulin resistant and to have signs of low-grade systemic inflammation (increased C-reactive protein, mildly elevated interleukin-6 and tumor necrosis factor).

Leptin, a cytokine family protein that is secreted almost exclusively by adipocytes, was the first identified adipose tissue hormone; it has been shown to have potent central nervous system effects on food intake in humans. Leptin also has other hypothalamic-pituitary functions and is proposed to have diverse peripheral physiologic actions. The leptin-deficient animal model of obesity, the *ob/ob* mouse, is severely obese, hyperphagic, hypometabolic, and sexually immature and has low levels of spontaneous activity. Administration of leptin to this animal corrects all of these defects. A few leptin-deficient humans (due to mutations in the leptin gene) have been identified. These children had very low plasma leptin concentrations, were hyperphagic and severely obese, and responded to exogenous leptin administration with dramatic weight loss, reduced food intake, and accelerated maturation of the pituitary-gonadal axis. Overwhelmingly, however, obese humans are not leptin deficient and in fact have high plasma leptin concentrations unless they are in a major negative energy balance circumstance. Because leptin is secreted as a function of percentage body fat, and because women have more body fat than men for any given BMI, they also have higher plasma leptin concentrations. Thus, screening for leptin deficiency is not warranted except in severe, hyperphagic obesity that begins in early childhood, is accompanied by sexual immaturity, and exists in the absence of other known causes (e.g., Prader-Willi syndrome).

Some animal models of genetic obesity (the *db/db* mouse and *fa/fa* rat) have defective leptin receptors, making them unresponsive to leptin. Although rare cases of obese humans with defective leptin receptor genes have been reported, again it appears that leptin resistance due to leptin receptor defects (or genetic post-receptor signaling abnormalities) is extremely uncommon. Clinical screening for leptin receptor mutations is not warranted, given that no treatment exists.

Energy Intake

Much of what has been learned about the biologic regulation of food intake has been from the study of animal models. These signals may affect different aspects of eating behavior. They can affect *hunger*, the compelling need or desire for food; *satiation*, the state of being satisfactorily full and unable to take on more; or *satiety*, the sense of no longer being hungry, a complex set of postprandial events that affect the interval to the next meal or the amount consumed at the next meal. Some of the signals that alter eating behavior affect one aspect and others affect multiple aspects. For example, ghrelin, a peptide produced by the stomach, increases hunger but does not appear to affect satiation or satiety. Cholecystokinin causes satiation but has no effect on satiety. Leptin appears to act on multiple pathways; leptin deficiency is associated with increased hunger and reduced satiation and satiety.

TABLE 220-3 SUGGESTED BIOLOGIC MODULATORS OF FOOD INTAKE

PERIPHERAL SIGNAL	PROPOSED EFFECT ON FOOD INTAKE
Vagal	–
Cholecystokinin	–
Apolipoprotein A-IV	–
Insulin	–
Peptide YY_{3-36}	–
Glucagon-like peptide 1	–
Other glucagon-related peptides	–
Leptin	+ when leptin ↓↓
Ghrelin	+
Tumor necrosis factor-α	–
Obestatin	–

TABLE 220-4 CENTRAL NERVOUS SYSTEM MODULATORS OF ENERGY BALANCE

CENTRAL ANABOLIC (↑ INTAKE)	CENTRAL CATABOLIC (↓ INTAKE)
Neuropeptide Y	α-Melanocyte-stimulating hormone
Agouti-related protein	Corticotropin-releasing hormone
Melanin-concentrating hormone	Thyrotropin-releasing hormone
Hypocretins and orexins	Cocaine- and amphetamine-regulated transcript
Galanin	Interleukin-1β
Norepinephrine	Urocortin
Endogenous endocannabinoids (anandamide and 2-arachidonoylglycerol)	Oxytocin
	Neurotensin
	Serotonin

Peripheral satiety signals act to inhibit further food intake at some point during meal consumption. Some of the signals reach the brain through the vagus nerve and some through the systemic circulation. Examples of the proposed factors modulating appetite are listed in Table 220-3. The compounds range from gut-derived (ghrelin, cholecystokinin, glucagon-like peptide 1) and pancreas-derived (insulin) hormones to peptides such as apolipoprotein A-IV, which is secreted with chylomicrons. The signals are thought to be triggered both by mechanical stimuli (e.g., the fullness of the stomach) and by the presence of nutrients in the jejunum and ileum.

The central nervous system regulation of food intake is becoming better understood. A number of neuropeptides, lipid derivatives, and monoamines have either anabolic (increased food intake with or without decreased energy expenditure) or catabolic (decreased food intake with or without increased energy expenditure) properties. A list of these molecules is provided in Table 220-4. Many of these compounds serve more than one function, such as regulation of hormone secretion (thyrotropin-releasing hormone and corticotropin-releasing hormone), wakefulness (norepinephrine), and behavior-reinforcing systems (endocannabinoids).

Energy Expenditure

There is a wide range of daily energy expenditure in adults, from less than 1400 kcal/day to more than 5000 kcal/day, with larger, more physically active individuals having the greatest energy needs. Typically, daily energy expenditure is divided into resting (or basal) metabolic rate, the thermic effect of food, and physical activity energy expenditure.

Basal Metabolic Rate

The basal metabolic rate (BMR) is the energy expenditure of lying still at rest, awake, in the overnight postabsorptive state. The resting metabolic rate (RMR) is similarly defined but is not necessarily measured before arising from bed. For most sedentary adult Americans, the RMR represents the

major portion of energy expended during the day and may range from less than 1200 to more than 3000 kcal/day. Most (~80%) of the BMR can be explained by the amount of lean tissue an individual has. There are a number of formulas that can be used to estimate BMR. The Harris-Benedict formula (available through numerous online calculators) predicts BMR on the basis of height, weight, age, and sex and is accurate to within 10% in approximately 90% of adults with BMIs of 18.5 to 45 kg/m^2.

Not all components of lean tissue consume oxygen at the same relative rates. Visceral or splanchnic bed tissues account for about 25% of RMR but a much smaller proportion of body weight. The brain, which is only a small percentage of body weight, accounts for almost 15% of RMR. Likewise, the heart (~7%) and kidneys (~5 to 10%) account for greater portions of resting energy needs than their relative contribution to body mass. In contrast, resting muscle makes up 40 to 50% of lean tissue mass but accounts for only 25% of RMR. This contribution changes dramatically with exercise, however, at which time muscle can account for 80 to 90% of energy expenditure. Adipose tissue is a minor contributor to daily energy expenditure, consuming only approximately 3 kcal/kg of body fat per day.

Brown fat is adipose tissue that expresses large amounts of uncoupling protein-1, a protein that allows a mitochondrial membrane proton leak, resulting in heat release as opposed to chemical work from adenosine triphosphate—"uncoupling" of substrate oxidation from chemical or mechanical work. This thermogenic tissue was thought to be present only in human infants but has recently been shown to exist in adults.[4] Methods used to detect brown fat largely rely on ^{18}F-fluorodeoxyglucose positron emission tomography scanning of humans exposed to cold. Lean adults are more likely than obese adults to have brown fat, and brown fat is more readily detectable after obese adults lose weight. Whether brown fat plays any meaningful role in thermogenesis is currently a matter of debate.

Although most of the RMR can be accounted for by the mass of lean tissue, there are also other, more subtle influences on RMR. Age, sex (women have slightly lower BMR even corrected for fat-free mass), and fat mass affect RMR. Small changes in BMR occur during the menstrual cycle (luteal phase > follicular phase). There is also evidence that heritable or family factors influence BMR, accounting for as much as 10% of the interindividual differences.

There are both obligatory and facultative components to RMR. With an energy-restricted diet, significant reductions in BMR relative to the amount of fat-free mass occur. Reductions in the production of triiodothyronine from thyroxine and the sympathetic nervous system drive are thought to contribute to this phenomenon. Likewise, during brief periods of overfeeding, RMR increases slightly above that which would be expected for the amount of lean tissue present.

It has been proposed that individuals with BMRs lower than predicted are at increased risk of future weight gain. Published data suggest that the relative risk is small, and clinical effort to identify such patients is not warranted. Measurement of BMR is sometimes helpful in the evaluation of patients who insist that they are unable to lose weight while following diets containing less than 1000 kcal/day. Almost without fail, if BMR is measured with a reliable instrument, it is substantially greater than the reported food intake. This underscores the fact that most adults are unreliable in assessing their own food intake.

The Thermic Effect of Food

An average of 10% of the energy content of food is expended in the process of digestion, absorption, and metabolism of nutrients. There is a significant interindividual variability in this value, however, ranging from a low of about 3% to a high of about 15% of meal calories that are "wasted" in the postprandial interval. The thermic effect of a meal is related to its carbohydrate and protein calorie content; the fat content has little stimulatory effect. Both obligatory (60 to 70%) and facultative (30 to 40%) components of the thermic effect of food have been identified. The obligatory components no doubt reflect the energy costs of digestion, absorption, and storage of nutrients. The two factors thought to play a role in the facultative component of the thermic effect of food are the postprandial insulin response and activation of the sympathetic nervous system. The thermic effect of food is somewhat lower in insulin-resistant and obese humans, but this has not been linked to future obesity.

Physical Activity Energy Expenditure

The energy expenditure of physical activity is a product of the amount of work done and the work efficiency of the individual. Tracking the total amount of physical activity that humans perform throughout the day is becoming easier with a variety of relatively inexpensive devices. By doing so, it is also possible to calculate the energy expended with published values for estimating the energy costs of work performed. Work units are expressed as metabolic equivalents (METs), a multiple of the RMR. If an individual's RMR is 1 kcal/minute (1440 kcal/day), a workload of 5 METs would be 5 kcal/minute. Although most sedentary individuals can work for only a limited amount of time at relatively low workloads, highly trained athletes can work at extremely high METs (>16) for extended periods. This is because athletes have both a greater peak work capacity (or maximal amount of calories or oxygen that can be consumed) and a higher lactate threshold. The lactate threshold is closely related to the level at which exercise begins to become so uncomfortable that it cannot be maintained much longer. The biochemical definition of lactate threshold describes the progressive rise in blood lactate concentrations observed during sufficiently high-intensity exercise. The lactate threshold may range from 50 to 90% of an individual's peak work capacity. Training raises the lactate threshold closer to the maximal workload and thus allows individuals to work at higher rates for longer periods. Thus, highly fit individuals can expend much greater amounts of energy per minute of exercise with less sense of discomfort than can obese, sedentary individuals who typically have low aerobic fitness and low lactate thresholds (sometimes on the order of 4 to 5 METs). The lactate threshold can be even lower in obese patients with type 2 diabetes, such that walking a mere 3 miles per hour can exceed their lactate threshold. Appreciation of the physical limitations of patients, which can usually be overcome with a carefully designed training program, is necessary to provide realistic activity recommendations.

Exercise (fitness- and sports-related activities) is commonly considered the main component of physical activity thermogenesis. Because most adults do not exercise at high levels or for a sufficient duration to expend a large amount of energy, focusing solely on "exercise" as the main component of physical activity will miss significant opportunities for improving energy balance. The benefits of and energy expended in nonexercise activity can be far greater than with exercise, given the limited amount of time and effort that most patients can commit to exercise.

Nonexercise activity thermogenesis (NEAT) is the calorie expense of performing all activities other than exercise- or employment-related and spontaneous activity. The range of observed NEAT under controlled (metabolic chamber) conditions has been less than 100 to more than 800 kcal/day. The energy expended from a physically demanding job or volitional exercise may or may not be offset by reductions in spontaneous (nonemployment) activity. For example, young adult men and women respond differently to 1 year of extra exercise; men lose weight and women do not, despite the absence of detectable change in food intake. Women must either reduce spontaneous activity in response to exercise or have subtle increases in food intake. It has also been shown that the variations in unconscious increases in NEAT relate strongly to the amount of fat gained in response to overeating. Low levels of NEAT have been reported to predict future weight gain in some populations, and there may be differences between lean and obese persons in the daily amount of NEAT, which could relate to differential tendencies to regulate weight.

Secondary Causes of Obesity

Medications

A number of medications cause weight gain in some or most of the patients for whom they are prescribed. Awareness of the medications that have this potential can facilitate weight loss treatment in some patients. Table 220-5 lists a number of medications that are associated with weight gain as well as alternative treatment approaches, if any, for the underlying condition.

Diseases

Less than 1% of obese patients have an underlying disease that can explain the development of their obesity. Endocrinopathies are the most common secondary cause of obesity. These include Cushing's syndrome (Chapter 227), hypothalamic damage resulting in overeating (most commonly after pituitary surgery), insulinoma (Chapter 230), and hypothyroidism (Chapter 226). A Cushing syndrome–like fat distribution is common; therefore, other physical or laboratory findings are the best clues to whether to test for this condition. These include the classic purple striae, thinning skin, easy bruising, proximal muscle weakness, and electrolyte abnormalities. Correction of Cushing's syndrome commonly results in substantial loss of excess body fat. Insulinoma is a rare tumor, and only a small portion of patients with

TABLE 220-5 PHARMACOLOGIC INFLUENCES IN WEIGHT GAIN AND ALTERNATIVE THERAPIES

DRUGS THAT MAY PROMOTE WEIGHT GAIN	ALTERNATIVE TREATMENTS: WEIGHT NEUTRAL OR WEIGHT LOSS
PSYCHIATRIC AND NEUROLOGIC MEDICATIONS Antipsychotics: olanzapine, clozapine, risperidone, quetiapine, aripiprazole Antidepressants Tricyclics: imipramine, amitriptyline Triazolopyridines: trazodone Serotonin reuptake inhibitors: paroxetine, fluoxetine, citalopram Tetracyclics: mirtazapine Monamine oxidase inhibitors Antiepileptic drugs: gabapentin (higher doses), valproic acid, carbamazepine, divalproex Mood stabilizers: lithium, carbamazepine, lamotrigine, gabapentin (higher doses)	**ALTERNATIVE PSYCHIATRIC AND NEUROLOGIC MEDICATIONS** Ziprasidone Nortriptyline, bupropion, nefazodone, fluvoxamine, sertraline, duloxetine Topiramate, zonisamide (weight loss), lamotrigine (less weight gain)
STEROID HORMONES Progestational steroids Corticosteroids Hormonal contraceptives	**ALTERNATIVES TO STEROID HORMONES** Barrier methods, intrauterine device Nonsteroidal anti-inflammatory drugs
ANTIDIABETES AGENTS Insulin (most forms) Sulfonylureas Thiazolidinediones	**ALTERNATIVE ANTIDIABETES AGENTS** Metformin Acarbose, miglitol Exenatide Dipeptidyl peptidase 4 inhibitors Liraglutide Sodium-glucose co-transporter 2 inhibitors
ANTIHISTAMINES Commonly reported with older agents; also oxatomide, loratadine, and azelastine	**ALTERNATIVE TO ANTIHISTAMINES** Decongestants, mast cell stabilizers, antagonists of endogenous mediators of inflammation
ANTIHYPERTENSIVE AGENTS α-Adrenergic and β-adrenergic receptor blockers Calcium channel blockers: nisoldipine	**ALTERNATIVE ANTIHYPERTENSIVE AGENTS** Angiotensin-converting enzyme inhibitors Calcium channel blockers: most other agents Angiotensin receptor blockers Diuretics
HIGHLY ACTIVE ANTIRETROVIRAL THERAPY	

insulinoma develop obesity. The weight gain associated with hypothyroidism is largely due to fluid retention and resolves with thyroid hormone replacement. Unfortunately, successful treatment is not available for hyperphagia due to hypothalamic damage. Adult patients with growth hormone deficiency, most commonly after hypophysectomy, may lose excess body fat with growth hormone replacement therapy.

Psychosocial Aspects of Obesity

Sexual, physical, and emotional abuse, especially in women, can result in long-term adverse consequences, including obesity. The effects of the abuse tend to be most profound if it occurs in childhood and adolescence. These women may be severely obese, suffer from chronic depression, and experience a number of psychosomatic symptoms, particularly chronic gastrointestinal distress. Identifying these issues before initiation of weight loss programs is important because successful weight loss may actually aggravate the distress experienced by these women. In addition, appropriate referral for psychiatric help may be needed before initiation of treatment for obesity.

PATHOPHYSIOLOGY

Metabolic Complications of Obesity

A central or upper body fat distribution is more predictive than total fat mass of the metabolic complications of obesity. Adipose tissue release of free fatty acids (FFAs) and glycerol into the circulation through lipolysis provides 50 to 100% of daily energy needs. Adipose tissue lipolysis is regulated primarily by insulin (inhibition) and catecholamines (stimulation), although growth hormone, cortisol, and atrial natriuretic peptide also stimulate lipolysis. Upper body obesity is associated with several abnormalities of adipose tissue lipolysis, most remarkably with higher postprandial FFA release and concentrations; this abnormality is particularly evident in type 2 diabetes mellitus. Abnormally high FFA concentrations can contribute to a number of the metabolic complications of obesity.

Insulin Resistance

The term *insulin resistance* is typically used in referring to the ability of insulin to promote glucose uptake and to inhibit the release of glucose into the circulation. The primary site of insulin-stimulated glucose uptake, oxidation, and storage is skeletal muscle. The principal site of glucose production is the liver. Insulin resistance initially leads to hyperinsulinemia and may eventually lead to the development of type 2 diabetes mellitus (Chapter 229).

The ability of insulin to promote glucose uptake, oxidation, and storage in muscle and to suppress plasma FFA concentrations is reduced in upper body obesity. High plasma FFA concentrations can induce a state of insulin resistance both in the muscle (glucose uptake) and in the liver (glucose release), independent of obesity. Thus, abnormal regulation of adipose tissue FFA export is a significant component of the development of insulin resistance. It is hypothesized that excess FFAs induce muscle insulin resistance by promoting increased synthesis of diacylglycerols and ceramides, both of which can interfere with the normal insulin signaling pathway.

Dysregulated production of a number of adipose-derived hormones, also called adipokines, is hypothesized to contribute to insulin resistance and the metabolic complications of obesity. Adiponectin, an adipocyte-derived hormone that improves insulin action, is secreted at reduced rates in obesity and diabetes. Increased production of resistin, interleukin-6, tumor necrosis factor, and retinol-binding protein-4 by adipose tissue has been linked to insulin resistance in animal models. We currently lack the experimental evidence from human studies to know what role adipokines play in the metabolic complications of obesity.

Islet Cell Failure and Type 2 Diabetes Mellitus

Type 2 diabetes usually results from defects in both insulin secretion and insulin action (Chapter 229). Many obese individuals are insulin resistant, yet only a subset will develop diabetes mellitus. It follows that those who develop type 2 diabetes develop pancreatic β-cell decompensation with subsequent hyperglycemia. Animal (rodent) studies have suggested that a process referred to as lipotoxicity is involved in pancreatic β-cell failure. In this model, increased FFAs are proposed to contribute to the insulin secretory abnormalities seen in obesity and ultimately to lead to β-cell failure. There is some evidence that elevated FFAs have adverse effects on islet β-cell function in humans. Another potential contributor to β-cell failure in obesity is the overproduction of islet amyloid polypeptide. This protein is co-secreted with insulin and, because of its tertiary structure, can form toxic amyloid deposits in β cells. Amyloid deposits have been found in the pancreatic islets obtained at autopsy from patients with type 2 diabetes mellitus.

Hypertension

Blood pressure can be increased by a number of mechanisms (Chapter 67). Increased circulating blood volume, abnormal vasoconstriction, decreased vascular relaxation, and increased cardiac output may all contribute to hypertension in obesity. The effect of hyperinsulinemia to increase renal sodium absorption may contribute to hypertension through increased circulating blood volume. Abnormalities of vascular resistance also contribute to the pathophysiologic process of obesity-related hypertension. Under some experimental conditions, elevated FFAs have been found to cause increased vasoconstriction and reduced nitric oxide–mediated vasorelaxation, similar to that seen in the metabolic syndrome. Some obese adults have increased sympathetic nervous system activity, which could contribute to obesity-associated hypertension. Finally, angiotensinogen (also produced by adipocytes) is a precursor of the vasoconstrictor angiotensin II and is proposed to contribute to elevated blood pressure.

Dyslipidemia

Upper body obesity and type 2 diabetes mellitus are associated with increased triglycerides, decreased high-density lipoprotein (HDL) cholesterol, and a high proportion of small, dense low-density lipoprotein (LDL) particles (Chapter 206). This dyslipidemia contributes to the increased cardiovascular risk observed in the metabolic syndrome. Fasting hypertriglyceridemia is caused by increased hepatic very low density lipoprotein (VLDL) secretion, which may be driven by increased delivery of FFAs to the liver coming from both visceral fat and upper body subcutaneous fat. The reduced HDL cholesterol concentrations and the increased small, dense LDL particle concentrations associated with upper body obesity are likely an indirect consequence of elevated triglyceride-rich VLDL. Increased cholesterol ester transfer protein activity and hepatic lipase activity can theoretically account for the atherogenic shifts in triglycerides and cholesterol between lipoproteins. Genetic influences play a significant role in the expression of these lipid abnormalities. Polymorphisms in the genes for apolipoprotein E, lipoprotein lipase, apolipoprotein B-100, and apolipoprotein A-II are correlated with increased triglycerides and decreased HDL.

Endocrine Manifestations of Obesity

Obesity is associated with abnormalities of the endocrine system, one of the most common being polycystic ovary syndrome. This syndrome (Chapter 236) is characterized by mild hirsutism and irregular menses or amenorrhea with anovulatory cycles. It is most commonly linked with obesity and often improves with weight loss and other treatments that improve insulin resistance. The insulin resistance associated with obesity may trigger the development of polycystic ovary syndrome in susceptible individuals. Whereas mild to moderate androgen overproduction is a feature of upper body obesity in women, obese men may suffer from mild to severe hypothalamic hypogonadism. This androgen deficiency improves with weight loss, and attempts to treat this condition with testosterone replacement offer little clinical benefit. There has been some concern that testosterone treatment of obese men may increase the risk of obstructive sleep apnea and perhaps even cardiovascular events. Although estrogens are not elevated in obese premenopausal women, they remain somewhat above postmenopausal levels in obese postmenopausal women. Serum growth hormone concentrations are commonly low in obese adults, but insulin-like growth factor-I concentrations are often normal, and growth hormone concentrations increase with weight loss. Treatment of these patients with growth hormone has been reported to worsen insulin resistance and glucose intolerance and cannot be justified, considering the costs and poor risk-to-benefit ratio.

Mechanical Complications of Obesity

The excess body weight associated with obesity is thought to be responsible for the increased prevalence of lower extremity degenerative joint disease. Extreme obesity can result in premature degenerative joint disease, and this may be especially difficult to treat surgically, given the greater stress on joint replacements. Severely obese individuals may also have problems with venous stasis, which is occasionally aggravated by right-sided heart failure (see later).

Obstructive Sleep Apnea and Sleep Restriction

Sleep apnea (Chapter 100) is common in severely obese patients, tending to be more prevalent in men and in women with an upper body/visceral obesity. Sleep apnea is most likely explained by enlargement of upper airway soft tissue, resulting in collapse of the upper airways with inspiration during sleep. The obstruction leads to apneas, with hypoxemia, hypercarbia, and high catecholamine and endothelin levels. The frequent arousals to restore breathing result in poor sleep quality. Sleep apnea is associated with an increased risk of hypertension, and if sleep apnea is severe, it can lead to right-sided heart failure and sudden death. A history of daytime hypersomnolence, loud snoring, restless sleep, or morning headaches is suggestive of obstructive sleep apnea. Treatment of sleep apnea is important to improve cardiovascular risk, and the failure to recognize and to treat this complication may make weight loss intervention strategies much less successful.

Epidemiologic studies have linked short sleep duration and disruptions of circadian rhythm with increased risk of metabolic syndrome and diabetes. Experimentally induced sleep restriction combined with circadian disruption in humans led to decreased RMR and increased postprandial plasma glucose levels due to inadequate insulin secretion.

Cancer

The risk of breast cancer and endometrial cancer is increased in obese women (Chapter 180). It is thought that this may be due to the increased estrogen levels associated with obesity in the postmenopausal woman. Obese men also have a higher mortality of cancers of the prostate and colon. The reasons for this association are unknown.

Gastrointestinal Disorders

Gastroesophageal reflux disease and gallstones are more prevalent in obese patients. Likewise, fatty liver and nonalcoholic steatohepatitis (Chapter 152) are more common in obesity. Nonalcoholic steatohepatitis can eventually progress to life-threatening hepatic cirrhosis. Weight loss and interventions that improve insulin sensitivity have been shown to improve fatty liver and nonalcoholic steatohepatitis.

DIAGNOSIS

Evaluation of Obesity

In the office practice, obtaining height and weight allows calculation of BMI. For patients with a BMI above 25 and below 35, a second piece of information—the waist circumference—provides an added indicator as to whether the patient is at greater risk for adverse consequences (see earlier). Measurement of blood pressure (which may require a large blood pressure cuff) then provides a third item of health information at almost no cost. The presence or absence of dyslipidemia (HDL cholesterol < 45 mg/dL for women, HDL cholesterol < 35 mg/dL for men, or triglycerides > 150 mg/dL), hypertension, glucose intolerance and diabetes, and hyperuricemia should be documented. A history suggestive of sleep apnea should prompt a referral for overnight oximetry or a sleep disorder evaluation.

A review of the patient's lifestyle, including an assessment of physical activity level and eating habits, may help provide information about why the patient is obese. A family history of obesity, or long-standing obesity, provides evidence against a secondary cause of obesity. A careful medication history and social history may help the clinician identify precipitating factors that can be modified. By emphasizing the role of modifiable lifestyle factors that predispose to disease risk, as opposed to focusing solely on the patient's weight, it may be possible to initiate a conversation about weight/disease management in a less threatening manner from the patient's perspective.

Before a patient enters a weight management program, it is helpful to ensure that the patient is interested and ready to make lifestyle changes and has realistic goals and expectations. Patients who expect to lose large amounts of weight in a short time are virtually doomed to disappointment. Medical treatment programs, even if they include pharmacotherapy, struggle to routinely achieve sustained weight loss of more than 10%. Although this amount of weight loss is sufficient to markedly reduce the medical complications of obesity, disappointment with "only" 10% weight loss may cause patients to abandon a medically successful program. Helping the patient to understand that lifestyle changes resulting in achievable (10%) weight loss is a reasonable, initial goal can be one of the more challenging aspects for a physician.

It is sometimes necessary to delay entry into treatment programs if a patient is not ready to make lifestyle changes. In this case, a reasonable strategy is to remind the patient periodically of the potential health benefits of improved activity and eating habits. Once a willingness to make changes is apparent, treatment is more likely to succeed.

TREATMENT

Obesity represents an individual's response to the environment based on genetics and learned behavior and is best viewed as a chronic disease. Therefore, treatment must be considered a long-term issue, much like diabetes, hypertension, or dyslipidemia. Substantial weight loss can be induced through severe calorie restriction, but without approaches to ensure behavioral changes, body fat is invariably regained. To the extent that environmental factors contribute to a patient's overweight status, and to the extent that the macroenvironment is unlikely to change, patients must learn how to make permanent lifestyle changes (eating and activity behavior) to hope for permanent weight loss. Behavior modification approaches,[5] which can help patients recognize and circumvent environmental cues for sedentary behavior and overeating, can increase the likelihood that patients will accomplish these lifestyle changes. A randomized study has shown that intensive lifestyle intervention (as compared to only support and education) is associated with fewer hospitalizations, fewer medications, and lower health care costs in overweight or obese adults with type 2 diabetes.

Reducing energy intake is the most efficient and effective means to lose weight. For example, creating a 500 kcal/day deficit by reduced food intake will theoretically result in the loss of 1 pound of fat per week. Although possible, it is much more difficult to increase energy expenditure by 500 kcal/week through exercise. Higher levels of physical activity can prevent weight gain (or weight regain after weight loss). Some patients are able to change eating and activity habits on their own, given the proper information, whereas others require formal or informal behavior modification interventions (see later) to help make these changes. In some instances, pharmacotherapy or surgery may be needed for treatment of obesity. A flow diagram on how to evaluate and to manage patients with overweight and obesity is presented in Figure 220-1.

Diet

Changes in eating habits must be permanent if weight loss is to be maintained. An experienced registered dietitian can be helpful in the evaluation of a patient's eating habits and will be able to provide the needed education. The diet history may identify eating behaviors that result in excess energy intake. Although it is important to address specific adverse eating behaviors, patients need to understand some general principles regarding diet. Reducing the energy density of food (most commonly accomplished by reducing dietary fat) can allow patients to feel satiated while consuming fewer calories. The NHLBI/AHA/ACC/TOS obesity guideline[6] recommends that providers prescribe 1200 to 1500 kcal/day for women and 1500 to 1800 kcal/day for men. Alternatively, diets that produce an energy deficit of 500 to 750 kcal/day can be recommended. Because there appears to be no clear superiority of one diet over another with regard to weight loss, it is recommended that providers prescribe one of the evidence-based diets that restricts selected food types (e.g.,

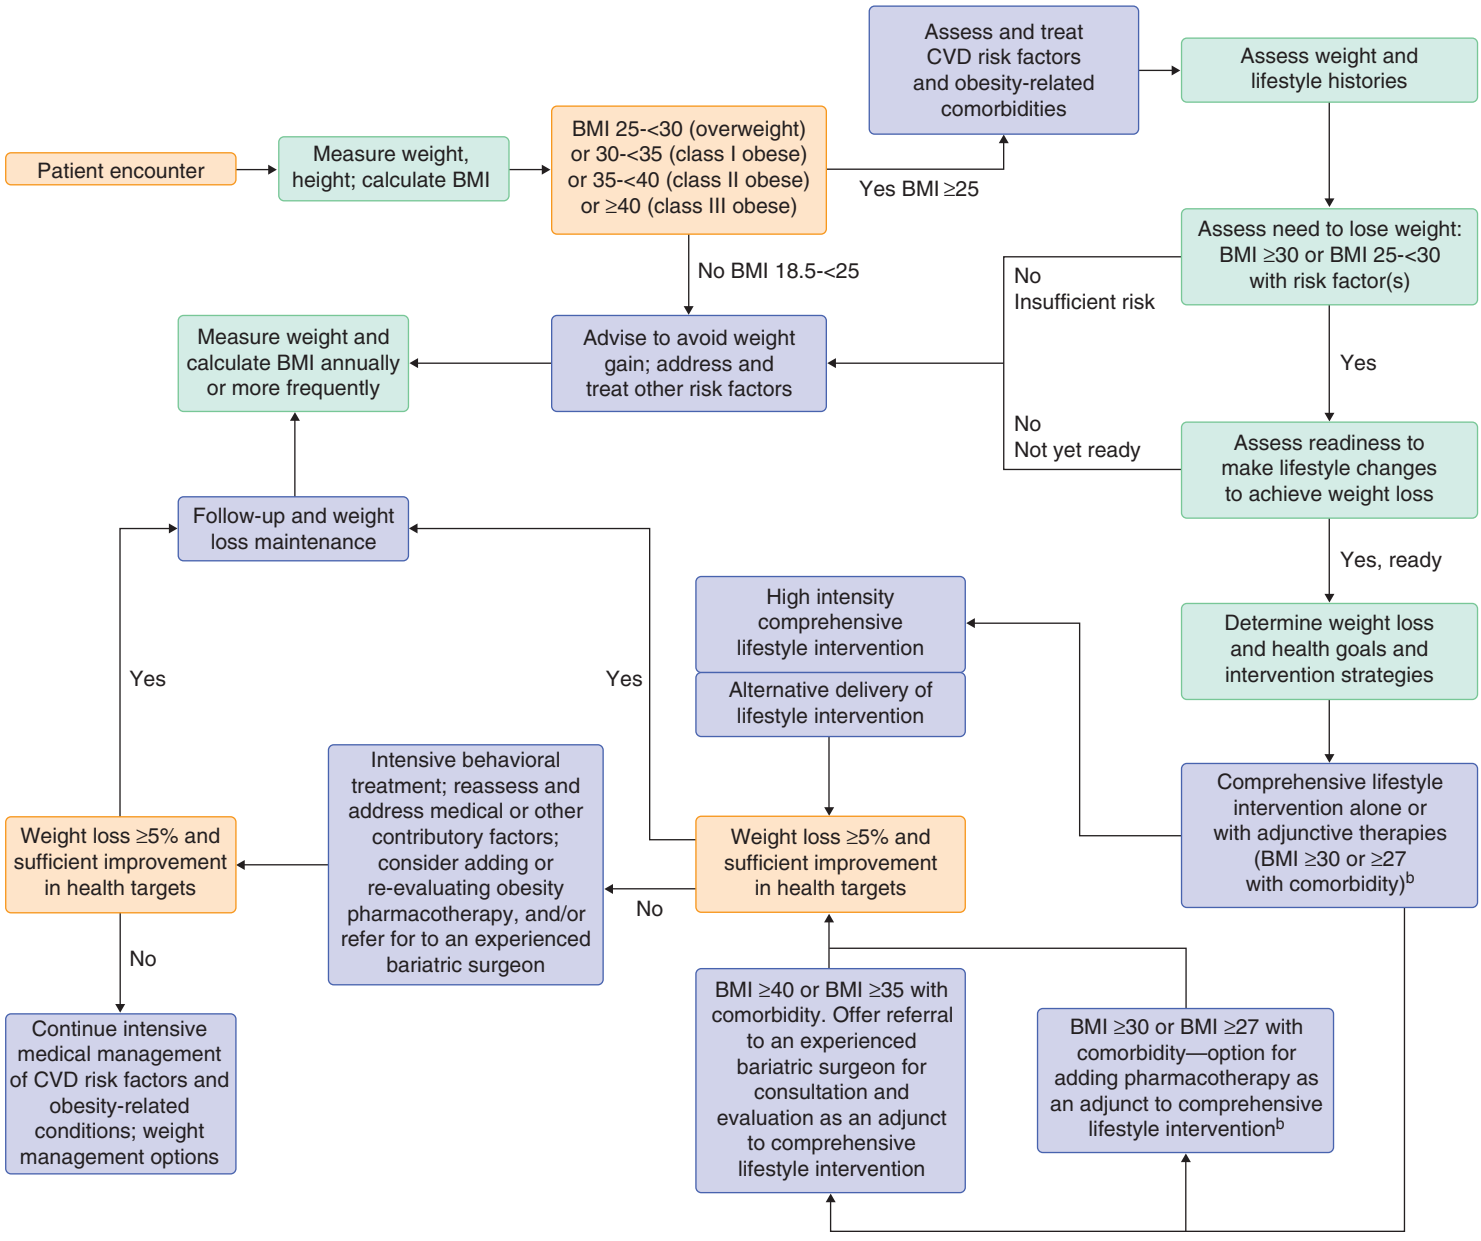

FIGURE 220-1. Flow diagram for the evaluation and management of overweight and obesity. BMI = body mass index; CVD = cardiovascular disease. [b]BMI cutpoint determined by the U.S. Food and Drug Administration (FDA) and listed on the package inserts of FDA-approved obesity medications. (Modified from Jensen MD, Ryan DH, Apovian CM, et al. 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society. *J Am Coll Cardiol*. 2014;63:2985-3023.)

high-carbohydrate foods, low-fiber foods, or high-fat foods) to create an energy deficit by reduced food intake as well as to address issues such as dyslipidemia, diabetes, and hypertension. Patients should be informed that consuming foods high in water and fiber (fruits, vegetables, legumes, and soups) can provide satiety without excess calories. Patients should be counseled to reduce the intake of beverages containing substantial calories, most often sugar-sweetened beverages. Finally, a regular pattern of eating should be encouraged.

New diets are continually being promoted with the promise of easy weight loss. A common feature of these diets is the claim that special properties of certain foods help people lose weight or are the cause of obesity. If followed, most of these diets result in weight loss because of a reduced energy intake. The reduced intake can be related to the monotony of the diet, and there have been no diets identified that cause persons to lose weight not in accordance with physiologic principles. Although a number of dietary approaches can be successful in promoting weight loss, if there is no peer-reviewed evidence for safety and success of new diets, a review by a dietitian for nutritional safety is warranted. The NHLBI/AHA/ACC/TOS obesity guideline concluded that many types of diets are able to help patients achieve long-term, medically significant weight loss. Thus, it may be less important what specific type of diet (DASH diet, Mediterranean diet, high-carbohydrate/low-fat or high-fat/low-carbohydrate diet) is recommended than for the patient to find dietary adherence to be relatively easy.[7] A comprehensive lifestyle intervention that includes a high-intensity, on-site behavioral intervention provides the best results.

Very low calorie diets (<800 calories per day) are still used to achieve accelerated weight loss. Because the long-term results of these diets are no better and sometimes worse than the results from the standard low-calorie diet combined with behavior modification, these diets are no longer commonly used. The expensive laboratory monitoring required for very low calorie diets without an improved long-term outcome raises questions about the costs versus benefits of this approach.

Physical Activity

A long-term increase in physical activity, either through the activities of daily living or through regular exercise, is key to preventing weight regain, thereby increasing the amount of successful, long-term weight loss. Unfortunately, many overweight and obese patients are unfit, being unable to walk even 1 mile continuously. It is not possible for most adults to expend a great deal of energy through exercise. For example, only about 100 kcal are expended by a 70-kg adult walking one mile. Losing weight solely by increasing exercise is impractical for most patients. However, increasing physical activity as a means of maintaining weight loss is an attainable goal for most patients.

Successful maintenance of weight loss requires that daily energy expenditure be an average of 80 to 90% above RMR. This is a considerable increase for most patients. For example, someone with an RMR of 1500 kcal/day would need to expend about 1000 kcal/day in physical activity to meet this target. Activities other than exercise are important means to achieve this goal. The most commonly applicable approach is by increasing the amount of walking done throughout the day.

The health benefits from regular physical activity over and above the effects on weight include lower cardiovascular and all-cause mortality as well as improved mood and cognition. The options for increasing physical activity include exercise (sports or fitness pursuits) and use of lifestyle approaches. Both methods can improve fitness and allow weight stability; however, persuading obese patients to become more active is not easy. Physicians can begin by asking patients about their current and past activity habits as well as what barriers they see to increasing physical activity. This accomplishes the goal of stimulating patients to think about the issue in a tactful manner. It can help to ask the patient what personal benefits are envisioned as a result of increasing the level of activity. If patients agree to begin an exercise or physical activity program, they will need to monitor their activity and set realistic goals for the amount of exercise they are going to achieve. The ready availability of step counters and electronic activity monitoring devices offers practical means for patients to track physical activity throughout the day and to assess the effects of changes in lifestyle on their activity level. Patients should be advised to acquire devices that have been shown to accurately count steps. Self-monitoring of how many steps are taken each day for 1 to 2 weeks can give patients a good sense of their baseline activity level. Many Americans take as few as 4000 to 5000 steps per day, whereas it may take as many as 15,000 to 17,000 steps per day to help those who have lost significant amounts of weight to maintain that lower weight. Gradually increasing the number of steps regularly taken during the day through a series of changes in habits (e.g., parking farther away, walking during work breaks) is more likely to result in long-term success for most persons than setting aside 2 hours or more for continuous walking.

Behavior Modification

Patients who are unable to make changes in eating activity habits on their own or with informal office counseling may benefit from referral to an interventionist trained in behavior therapy. The goals are to help patients modify their eating, activity, and thinking habits that predispose to obesity and focus on specific pathways to achieve the goals. These pathways may include identifying and removing barriers to development of better eating or activity habits. Small, incremental, and consistent changes in behavior are encouraged. Self-monitoring of food and activity is considered a key feature to success because most obese patients underestimate food intake and overestimate exercise. Cognitive restructuring has been introduced as a way to help overcome the thought processes that can lead to failure of a weight management program. Patients are taught to identify, to challenge, and to correct self-defeating thoughts.

The best weight loss results are provided by in-person, high-intensity (≥14 sessions in 6 months) comprehensive behavioral interventions, which average an 8-kg (5 to 10% of body weight) loss in 6 months. Approaches that provide electronically delivered counseling (telephone or Internet), including some commercial programs, can also achieve weight loss, but generally less than with in-person delivery approaches. Commercial programs that have published their results in peer-reviewed journals are preferred. Physicians who refer patients to programs that offer intensive, comprehensive lifestyle interventions are encouraged to obtain outcomes data from those programs.

TABLE 220-6 INDICATIONS FOR PHARMACOLOGIC TREATMENT OF OBESITY

Body mass index > 27 kg/m^2
One or more complications or conditions that are likely to improve with weight loss
Previous failure of conservative treatment with behavioral intervention, diet, and exercise
Agree to 2- to 4-wk trial of making initial changes in diet and exercise before starting pharmacotherapy
Agree to continued treatment with diet, exercise, and behavioral modification while receiving pharmacologic treatment
Agree to periodic follow-up
Premenopausal women (able to have children) must use some form of contraception
Consider a pregnancy test on initiation of treatment if there is any possibility of pregnancy
No contraindications to the specific drug used for pharmacologic treatment

Pharmacotherapy

A limited number of drugs are currently available to help patients with weight loss.[8] Optimally, any medication for obesity treatment will be prescribed in the context of a comprehensive lifestyle intervention by providers knowledgeable in its use. Not all overweight or obese patients are candidates for pharmacologic treatment of obesity. Table 220-6 provides criteria that should help select patients for pharmacologic treatment. Because pharmacologic treatment of obesity exposes patients to some risks and expense, it is reasonable to require an objective benefit. A rational argument can be made that prioritization should be given to those with one or more medical complications or conditions that are likely to improve with weight loss. In prescribing antiobesity medications, it is important to set clear goals with respect to both weight loss and health benefits.

Currently Available Medications

The medications currently available for long-term use act through either appetite reduction or inhibition of pancreatic lipase, which results in fat maldigestion. Phentermine is approved only for short-term (3 months) use. Recent additions to the medications approved by the Food and Drug Administration for chronic treatment of obesity include lorcaserin, a selective serotonin 2C receptor agonist,[9] the combination of topiramate and phentermine (see later), and a combination of bupropion with naltrexone.[10] Because weight that is lost with pharmacotherapy (especially when it is used without a comprehensive program) is regained once the medication is discontinued, agents that are approved for long-term use are better therapeutic choices.

Orlistat at the typical dose of 120 mg three times daily with meals causes about 30% of dietary fat to be malabsorbed. As expected, adverse gastrointestinal side effects, such as oily spotting, abdominal pain, excess flatus, fecal urgency, and fatty or oily stools, are not uncommon. These side effects decrease over time, and the concomitant use of bulk-forming laxatives (e.g., psyllium, methylcellulose) can reduce these symptoms. A daily multivitamin is recommended for those receiving long-term orlistat therapy. It is not necessary to take orlistat if a nonfat meal is being consumed. Orlistat is now available as an over-the-counter medication. Orlistat improves the results of medical treatment programs that include diet, exercise, and behavior modification, resulting in almost twice as many patients achieving goal weight loss (10% of body weight).

The combination of phentermine and topiramate in an extended-release capsule is approved for chronic treatment of obesity. The highest dose (15 mg phentermine/92 mg controlled-release topiramate) resulted in an average of about 10% weight loss at 2 years (8% more than with placebo), with slightly

more than half of patients achieving 10% weight loss and 15% of patients achieving 20% weight loss.[A] As both components of this medication were previously approved (topiramate for seizures and migraine prevention), the side effects were most commonly upper respiratory tract infection, constipation, paresthesia, sinusitis, and dry mouth; the incidence of individual adverse effects diminishes significantly after the first year.

Lorcaserin inhibits the serotonin pathway in a manner similar to fenfluramine, but without the cardiac valvulopathy effects. Patients taking lorcaserin 10 mg/day for 1 year lost an average of 5.8 kg compared with 2.2 kg with placebo. At 1 year, 47% of patients treated with lorcaserin lost 5% or more of their body weight compared with 20% of the placebo group.[A]

Combined bupropion and naltrexone addresses the issues of dopamine-induced gratification and addictive behavior. The drug results in an average weight loss comparable to other approved drugs, with few side effects and no abuse potential.

Success of Medical Therapy

It has been estimated that more than 95% of those embarking on self-diets or fad diets fail to maintain a significant weight loss for a time that would have meaningful health benefits. The published results from two commercial programs have shown better results. These commercial weight loss interventions provided a comprehensive intervention that was delivered in person and resulted in an average weight loss of 4.8 to 6.6 kg at 6 months in trials in which conventional foods were consumed and 6.6 to 10.1 kg at 12 months in trials in which prepared food was provided. Comprehensive weight management programs delivered at academic medical centers that employ behavior modification, dietary instruction, and physical activity can achieve equally or more impressive results. Average 1-year weight losses of about 10% can be achieved and maintained for 1 to 2 years, depending on the intensity of follow-up. The addition of medications, when indicated (see earlier), can produce even greater amounts of weight loss.

Bariatric Surgery

Surgical treatment can provide more weight loss than medications for class II and class III (see Table 220-1) obese patients with medical complications that could be expected to improve with successful weight loss, such as uncontrolled type 2 diabetes,[11] assuming past attempts at medical treatment have failed.[A] Patients with a BMI of 35 to 40 with life-threatening complications can be considered, but more typically patients with a BMI higher than 40 and several complications are candidates for surgery. Because the risks and costs of surgical treatment are greater than for medical treatment, selection of patients who stand to obtain more potential benefit from surgery should optimize the risk-to-benefit ratio. Contraindications to surgery include active substance abuse, defined noncompliance or inability to comply with medical care, and schizophrenia, borderline personality disorder, or uncontrolled depression.

A multidisciplinary team, including a physician, dietitian, psychologist or psychiatrist with expertise in this area, and surgeon experienced in bariatric procedures, is important for optimal outcome. Defining realistic expectations is an important part of the evaluation process. Patients undergoing bariatric surgery are not likely to be reduced to their ideal body weight. Successful weight loss is typically defined as losing an average of 50 to 60% of excess body weight, which is a difficult criterion to explain to patients. An easier explanation is that most successful patients will achieve weight losses of 25 to 35% of body weight. Follow-up to support the necessary changes in long-term behavior is recommended to optimize weight loss outcomes.

A variety of bariatric surgical procedures have been used. The jejunoileal bypass, long abandoned because of complications that include liver failure, renal failure, and arthropathy, is typically encountered only in those who underwent bariatric surgery more than 3 decades ago and who present with these complications. Procedures that modify the capacity of the stomach (laparoscopic gastric banding and sleeve gastrectomy) but do not create malabsorption of nutrients are employed, but these are generally less effective than the Roux-en-Y gastric bypass in terms of long-term weight loss and outright surgical success. The partial pancreaticobiliary bypass, the very long limb Roux-en-Y gastric bypass, and the duodenal switch procedures create malabsorption that results in greater weight loss than with the standard Roux-en-Y gastric bypass. Unfortunately, the incidence of severe, even fatal vitamin and mineral deficiencies (Chapter 218) is much higher with these procedures. Laparoscopic approaches are now routinely employed for bariatric surgery as they have allowed the time of hospitalization to be reduced considerably and with lesser rates of incisional hernias compared with open procedures.

After surgery, almost all of the weight loss that occurs will happen during the first 1 to 2 years. Long-term (>5 year) success rates are outstanding in good programs. Virtually all patients with successful weight loss will have a dramatic improvement in the medical complications of obesity. For these reasons, bariatric surgery has become an important tool in the treatment of severe, medically complicated obesity.

The results of the Roux-en-Y gastric bypass for treatment of morbid obesity have been favorable. Approximately 70% of patients achieve success as defined previously with this procedure. The mortality and morbidity (e.g., infection, anastomotic leak, wound dehiscence) of this procedure are low in centers with expertise, despite the high-risk population. Laparoscopic gastric banding, once popular because of the reduced short-term risk, is becoming less so as the inferior long-term weight loss results and late complications of band slippage, erosion, and weight regain become more apparent. Whether the sleeve gastrectomy results will more closely mimic gastric bypass or laparoscopic banding is not yet known. After any of the malabsorptive procedures, the patients require permanent follow-up specifically for adverse nutritional consequences.

The long-term follow-up of patients who have undergone gastric bypass surgery is needed to ensure adequate protein, calorie, vitamin, and mineral nutrition. Supplemental vitamin B_{12}, iron, and calcium are routinely added to standard multivitamins. The most common nutritional consequences of malabsorptive procedures are disorders of calcium and vitamin D metabolism, although many severely obese patients have low vitamin D levels even before surgery (Chapter 244). An increase in bone alkaline phosphatase may signal calcium or vitamin D deficiency. Low plasma vitamin D levels and low urinary calcium excretion should prompt aggressive replacement therapy. Iron deficiency, other fat-soluble vitamin deficiencies, and cases of copper deficiency occurring more than 5 to 10 years after surgery have been described. There have also been cases of pancreatogenous hypoglycemia that develop after bariatric surgical procedures. The symptoms are primarily postprandial and are occasionally severe enough to warrant partial pancreatectomy.

PREVENTION

The dramatic increase in the prevalence of obesity during the past few decades strongly suggests that preventive strategies are needed. Public health approaches that emphasize education have been almost uniformly unsuccessful at preventing weight gain or producing weight loss. Public health strategies that virtually impose behavior change are more successful in this regard. Unless widespread efforts are made to address the problem of obesity, it is likely that its prevalence and complications will become an ever-increasing health burden.

REVIEW QUESTIONS

1. A 52-year-old woman with type 2 diabetes, normal renal function, and a body mass index (BMI) of 36 asks for a referral to a surgeon for evaluation of possible bariatric surgery. Her glycemic control is adequate with a hemoglobin A_{1c} value of 7.2% on 500 mg/day of metformin, 30 U/day of intermediate-acting insulin, and 30 mg/day of pioglitazone. She also has well-managed depression treated with fluoxetine. She has seen a dietitian in the past and has been unable to lose weight. Which of the following is the most appropriate recommendation?

A. Advise the patient to begin a walking program and refer her to a surgeon with experience in laparoscopic banding procedures.
B. Advise the patient to begin a walking program and refer her to a surgeon with experience in laparoscopic gastric bypass procedures
C. Advise the patient to begin a walking program and refer her to a commercial weight loss program that has good outcome results based on peer-reviewed, published data and change the fluoxetine to bupropion.
D. Advise the patient to begin a walking program, gradually increase the metformin to 2500 mg/day, substitute liraglutide for pioglitazone, and request the dietitian to re-evaluate the patient.
E. Refer the patient to an academic weight management program that includes cognitive-behavioral therapy and dietary and exercise intervention components.

Answer: D Although the patient's BMI and medical condition technically meet the criteria for bariatric surgery, her previous weight loss attempts have not included a comprehensive program, and she is taking three medications that have weight gain as a side effect. Failure to address iatrogenic causes of weight gain will predispose to medical treatment failure. Surgery should be an option for those who fail to respond to optimal medical management. Pioglitazone and insulin promote weight gain to a greater extent than fluoxetine does, and the decision to change from fluoxetine to bupropion is best made by a clinician responsible for managing her depression. Increasing the metformin to maximum doses and substituting liraglutide for pioglitazone may reduce the need for insulin while maintaining glycemic control. Revisiting dietary strategies is likely to be more effective in the absence of medications that promote weight gain.

2. A 33-year-old woman presents for treatment of obesity. She has been overweight since her teens and experienced net weight gain with each of two pregnancies such that her BMI is now 32.5 kg/m^2. She had normal glucose tolerance during both pregnancies. Her waist circumference is 29 inches, and her blood pressure in the office is 110/70. Which of the following approaches best matches evaluation/treatment risks and costs with the potential health benefits of weight loss interventions?

A. Recommend over-the-counter orlistat, advise the patient to begin a walking program, and refer her to a dietitian for instruction in a 1200 kcal/day diet.
B. Measure thyroid-stimulating hormone, fasting triglycerides, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, aspartate transaminase, alanine transaminase, and alkaline phosphatase and perform an oral glucose tolerance test to look for hormonal causes of obesity and to screen for metabolic complications. Refer the patient to a dietitian for specific dietary advice based on test results.
C. Advise the patient to begin a walking program, prescribe phentermine/topiramate in an extended-release capsule, and refer her to a dietitian for a 1200 kcal/day diet.
D. Advise the patient to begin a walking program and refer her to a commercial weight loss program that has good outcome results based on peer-reviewed publications.

Answer: D This patient is at low risk for metabolic complications of obesity. She has a low waist circumference for a woman in her BMI range and had no pregnancy-associated glucose abnormalities. Weight gain with pregnancy is common, and in the absence of symptoms of hypothyroidism, laboratory screening is unlikely to be revealing. Costly laboratory testing looking for metabolic abnormalities is likewise a low-yield strategy in this patient. Although this patient is technically a candidate for pharmacotherapy, in practice, the out-of-pocket expense is such that the majority of patients will not continue with treatment because the amount of weight lost is insufficient. In addition, the side effects and risks of some medications make the risk-to-benefit ratio unappealing. Proven commercial weight loss programs can offer support and education not commonly available in a primary care provider's office. However, providers may wish to confirm that local programs maintain the integrity of the program's published results.

3. A 23-year-old man with a BMI of 56 kg/m^2 presents in the office after a work screening examination revealed a fasting blood glucose concentration of 180 mg/dL. The patient admits to nocturia for the past 6 months. He has been severely obese since early childhood and reports being frequently hungry and eating large amounts of food. All members of his immediate family are obese. On examination, he has acanthosis nigricans, large amounts of subcutaneous fat, no cushingoid striae, and normal chest and pubic hair. Which of the following further evaluations is most helpful in making disease management decisions?

A. Administer the Berlin Questionnaire, perform overnight oximetry, and measure hemoglobin A_{1c}, lipids, and liver function.
B. Measure serum leptin concentration to test for leptin deficiency and refer the patient to a center with a leptin treatment IND if indicated.
C. Perform genetic screening for leptin receptor and melanocortin-4 receptor gene mutations.
D. Measure serum testosterone, cortisol, thyroid-stimulating hormone, and growth hormone to screen for endocrine causes of obesity

Answer: A The patient has evidence of sexual maturation, which would not be expected with either leptin deficiency or leptin receptor mutations. Furthermore, there are currently no therapies for patients with leptin or melanocortin-4 receptor gene mutations. Endocrine causes of obesity that begin in childhood would prevent normal adult development (Cushing's syndrome, growth hormone deficiency, hypothyroidism), and testosterone may be low because of obesity. If the patient has sleep apnea, treatment with continuous positive airway pressure is urgently needed, and knowing whether the patient has dyslipidemia or fatty liver disease will inform the urgency of medical or surgical treatment of obesity.

4. A 42-year-old premenopausal woman with type 2 diabetes, dyslipidemia, and a BMI of 44 kg/m^2 failed to lose a clinically meaningful amount of weight during a comprehensive lifestyle program and is now scheduled for gastric bypass surgery in 1 week's time. In the process of evaluating microcytic anemia and elevated alkaline phosphatase, she is found to have severe iron and vitamin D deficiency. Gastrointestinal studies are negative for bleeding or malabsorption. Which of the following approaches best balances the risks and benefits of treatment?

A. Prescribe the patient oral vitamin D 50,000 U three times weekly and ferrous sulfate 325 mg, one tablet three times daily, in preparation for surgery.
B. Prescribe the patient oral vitamin D 2000 U daily and ferrous sulfate 325 mg, one tablet three times daily, in preparation for surgery. Inform the patient that she will likely need parenteral supplements after surgery.
C. Prescribe the patient oral vitamin D 50,000 U three times weekly and ferrous sulfate 325 mg, one tablet three times daily, and defer surgery until her blood levels are replete.
D. After surgery, prescribe the patient oral vitamin D 50,000 U three times weekly and ferrous sulfate 325 mg, one tablet three times daily, and monitor blood levels.

Answer: C Bariatric surgery is never an emergency, although many patients are impatient to have this procedure. Absorption of iron, vitamin D, and calcium is often reduced after gastric bypass, making correction of preexisting deficiencies even more difficult. It is highly unlikely that it will be possible to correct this patient's iron and vitamin D deficiencies in 1 week. Aggressive replacement therapy and deferment of surgery until her deficiencies have been corrected will make it easier to manage this patient after bariatric surgery and may improve the surgical risks.

5. A 48-year-old woman, height 175 cm, weight 104 kg, requests treatment for obesity. She states that she has not lost weight following a 1200 kcal/day diet prescribed by a dietitian despite walking 5 miles/day. Her serum thyroid-stimulating hormone level is normal with no thyroid hormone replacement, and her only medication is an angiotensin-converting enzyme inhibitor for hypertension. She requests instruction in a very low calorie (800 kcal/day) diet and a prescription for a medication to help her lose weight. This patient is most likely to benefit from which of the following approaches?

A. Refer the patient for measurement of a basal metabolic rate to assess whether she is hypometabolic.
B. Ask the patient to use a pedometer to ensure that she is walking 5 miles per day.
C. Prescribe an 800 kcal/day high-protein diet and monitor electrolytes carefully.
D. Request that the patient complete a real-time diet diary for 2 weeks and weigh the patient when she returns.

Answer: D The patient's basal metabolic rate calculated by the Harris-Benedict formula is 1750 kcal/day, which is likely to be within 10% of her actual metabolic rate if it were measured. It is virtually physiologically impossible for her metabolic rate, let alone total daily energy expenditure, to be less than 1200 kcal/day even if she is not walking at all. Even a very sedentary woman at this height, weight, and age would be expected to expend at least 2000 kcal/day. If she is walking 5 miles, her daily energy expenditure will exceed 2500 kcal/day. The patient must not be following a 1200 kcal/day diet. Self-monitoring of food intake is a proven approach to improve awareness of the types and amounts of food consumed. Many patients will lose weight while self-monitoring, and this approach can help identify problem eating habits. On occasion, patients will record perfect eating habits of unbelievably low energy intake and still not lose weight. Under these circumstances, measurement of a basal metabolic rate may help the physician and patient understand that inaccurate perception of food intake is the issue.

221

APPROACH TO THE PATIENT WITH ENDOCRINE DISEASE

DAVID R. CLEMMONS AND LYNNETTE K. NIEMAN

Most endocrine disorders are due to either an excess or a deficiency of a hormone that is transported in the systemic circulation and therefore result in multiorgan manifestations. It is unusual for patients to present with a single isolated set of symptoms that are referable to only one organ system. Additionally, generalized nonspecific symptoms such as weakness, difficulty concentrating, lack of energy, and change in appetite occur commonly in patients with endocrine disorders. Often, a constellation of symptoms is required to point the clinician in the direction of the correct diagnosis, and single symptoms evaluated in isolation are rarely helpful even if one considers an exhaustive differential diagnosis (Table 221-1). Another important feature of the evaluation of patients presenting with endocrinologic disease is obtaining a good longitudinal history. The duration of exposure to a hormone excess or deficiency often dictates the severity of symptoms, and characterizing the symptomatic changes that occur over time can be very helpful in both selecting the tests to confirm the diagnosis and either substantiating the need for treatment or selecting the correct mode of treatment. Physical examination is helpful for confirming the likelihood of a diagnosis; for example, the presence of a symmetrically enlarged thyroid gland indicates that Graves disease is the most likely cause of hyperthyroidism. However, because of the accuracy and precision of modern endocrinologic testing, endocrine disorders sometimes are diagnosed in the absence of symptoms or signs of overt disease (e.g., hyperparathyroidism). In such instances, a thorough history and physical examination are still important because they establish that the patient is truly in the asymptomatic phase of the disease, and this is often helpful in determining whether therapy or observation is required. A careful temporal history of a symptomatic change may also be helpful in the differential diagnosis—for example, in ascertaining whether a thyroid mass is likely due to a hemorrhagic cyst (i.e., occurring suddenly) or is a thyroid adenoma that might have evolved over an extended period. A thorough general history and physical examination may help to establish the diagnosis of diseases that are associated with endocrinologic abnormalities, such as cancers that ectopically secrete hormones, or may help to exclude the likelihood of an endocrinologic etiology of a specific disease manifestation.

Precise genetic testing to establish the etiology of endocrinologic syndromes is becoming more prevalent; therefore, an accurate family history can be useful in determining the need for genetic testing and familial screening. A thorough evaluation of medication use is also mandatory. Some medications can clearly mask the symptoms of overt endocrine disease, such as β-blockers in hyperthyroidism, and others can exacerbate the findings, such as hydrochlorothiazide use in hyperparathyroidism. Often, specific medications will confound laboratory evaluation, such as diuretics in patients with hyperaldosteronism or antihypertensive drugs in patients being screened for pheochromocytoma. Appropriate withdrawal of the medication may be required to establish a firm diagnosis. Medications may also directly alter a laboratory test, such as use of oral contraceptives in attempting to diagnose hyperthyroidism or hypothyroidism. Finally, an accurate history of the specific complaint may be challenging. For example, in evaluating male sexual dysfunction, a corroborating history from the patient's partner is often necessary for verification.

COMMON SYMPTOMS OF ENDOCRINOLOGIC DISEASE

Generalized symptoms such as weakness and fatigue are prominent features of adrenal insufficiency, hyperthyroidism and hypothyroidism, hypopituitarism, and poorly controlled diabetes mellitus. Pain is an uncommon complaint in endocrinologic disorders and is usually only seen with acute endocrinologic emergencies, such as diabetic ketoacidosis or acute adrenal insufficiency (abdominal pain). Chronic pain seen in primary or secondary hyperparathyroidism due to bone reabsorption and in osteomalacia (Chapter 244) can occur in the shafts of the long bones. Symptoms of menstrual dysfunction are common in women with adrenal insufficiency, hypopituitarism, Cushing's syndrome, hyperprolactinemia, hyperthyroidism, hypothyroidism, polycystic ovarian disease, and primary ovarian failure. Weakness and easy fatigability can be secondary to anemia, which is common in adrenal insufficiency, androgen deficiency, hypothyroidism, hyperparathyroidism, and panhypopituitarism.

The most common endocrine-related symptom of intestinal dysfunction is constipation. This occurs frequently in patients with diabetic autonomic neuropathy and in hypercalcemia, hypothyroidism, or pheochromocytoma. Diarrhea can be an early and prominent symptom in hyperthyroidism and metastatic carcinoid tumors. Fever, like abdominal pain, usually only occurs in endocrine emergencies, typically in severe adrenal insufficiency and very severe hyperthyroidism. Generalized hair loss not related to androgen excess occurs in hypothyroidism, hypopituitarism, and thyrotoxicosis. Typical male-pattern baldness can be a feature of hirsutism in women as well as Cushing's syndrome and acromegaly. Persistent recurrent headaches are a feature of expanding pituitary tumors, whereas episodic headaches occur frequently in patients with pheochromocytoma and hypoglycemia. Changes in libido are often present in patients with hyperthyroidism, hypopituitarism, hypogonadism, Cushing's syndrome, and poorly controlled diabetes mellitus. Polyuria and nocturia are features of both diabetes insipidus and diabetes mellitus and can also occur in severe hypercalcemia.

Weight gain is an early symptom of Cushing's syndrome and hypothyroidism. Weight loss accompanied by anorexia is common in adrenal insufficiency, metastatic hormone-producing tumors such as ectopic adrenocorticotropic (ACTH) hormone syndrome, type 1 diabetes mellitus, and panhypopituitarism. Weight loss with no change or an increase in appetite is common in hyperthyroidism (see Table 221-1). An important differential diagnostic issue in patients with weight loss is depression. Depression can occur concomitantly in patients with adrenal insufficiency, Cushing's syndrome, hypercalcemia, and hypothyroidism.

An important neuropsychiatric symptom is widening of mood swings—that is, an exaggeration of normal cyclothymic changes. This occurs in hyperthyroidism and Cushing's syndrome. A history of skin changes occurs with several endocrine disorders. Acanthosis nigricans occurs with severe obesity, polycystic ovarian disease, severe insulin resistance syndromes, Cushing's syndrome, and acromegaly. Acne is a symptom of androgen excess and occurs with androgen-producing tumors, polycystic ovarian disease, and Cushing's syndrome. Generalized hyperpigmentation occurs in Addison's disease and Nelson's syndrome. Dry skin is present in almost all patients with hypothyroidism. It also occurs in panhypopituitarism. In Cushing's syndrome, skin changes such as striae, plethora, and easy bruisability are common. Vitiligo occurs in association with several endocrine autoimmune diseases, most prominently with autoimmune thyroid disease and Addison's disease.

Assessment of any of these symptoms in isolation is unlikely to lead a clinician to the correct diagnosis. However, assessment of combinations of these symptoms (e.g., the combination of weight gain, constipation, cold intolerance, and dry skin in hypothyroidism) is likely to lead to the correct set of diagnostic decisions.

PHYSICAL EXAMINATION

Physical examination of a patient with a suspected endocrine disorder is extremely helpful in terms of confirming the significance of findings that were ascertained by a careful medical history (Table 221-2). Examination of the skin is important because endocrinopathies lead to skin changes that progress over time. These often occur early in the course of the illness and can be a major aid in making the correct diagnosis. Primary adrenal failure is usually accompanied by increased skin pigmentation, particularly over the creases of the palms and extensor surfaces. The oral mucosa is often hyperpigmented, which can be helpful in African Americans. Patients with Cushing's syndrome present with persistent facial plethora, acne, and characteristic striae, which are generally larger than 1 cm and exhibit a dark red to purplish hue. These are most common over the abdomen. The presence of axillary purpura is also suggestive of Cushing's syndrome and results from increased capillary fragility. Patients with acromegaly often present with excessive skin tags that increase in number over time and multiple types of benign skin tumors such as dermatofibromas and lipomas. The skin is also much thicker over the dorsum of the hand, and the amount of subcutaneous tissue in the palms is prominent. Patients with Cushing's syndrome have thinning of the skin over the forehead and around the eyes. Patients with hypothyroidism often present with evidence of hyperkeratosis, particularly over the extensor surfaces. Severe long-standing thyroid disease is also accompanied by myxedema of

TABLE 221-1 SYMPTOM CONSTELLATIONS SUGGESTING SPECIFIC ENDOCRINE DISORDERS

SYMPTOM CONSTELLATION	DIAGNOSIS
Weakness, fatigue, anorexia, loss of appetite, postural blood pressure changes	Adrenal insufficiency
Cold intolerance, dry skin, constipation, weight gain	Hypothyroidism
Fatigue, easy bruising, striae, proximal muscle weakness, central obesity, hypertension, acne	Cushing's syndrome
Weight loss, increased appetite, palpitations, tremor, emotional lability, diffuse hair thinning	Hyperthyroidism
Galactorrhea, amenorrhea, headaches	Prolactin-producing pituitary tumor
Weight loss, anorexia, loss of pubic and axillary hair	Hypopituitarism
Episodic palpitations, tremor, anxiety, headaches, sweating, weight loss	Pheochromocytoma
Episodic flushing, palpitations, abdominal cramping, and diarrhea	Carcinoid syndrome

TABLE 221-2 PHYSICAL SIGNS THAT SUGGEST SPECIFIC ENDOCRINE DISORDERS

Hyperpigmentation of palms, extensor surfaces, and buccal mucosa	Adrenal insufficiency
Facial plethora, moon facies, striae, purpura	Cushing's syndrome
Skin tags, acral enlargement, prognathism, orthodontia	Acromegaly
Proptosis, lid lag, symmetrically diffuse thyroid enlargement, hyperreflexia	Graves disease
Retinal microaneurysms, macular edema	Diabetic retinopathy
Short stature, web neck, loss of tears	Turner's syndrome
Shield-like chest, short fourth vertebra	Primary ovarian failure

the extremities, a specific skin finding of thickening of both the dermis and epidermis due to mucopolysaccharide accumulation. In contrast, patients with Graves disease present with thinning of the skin, but more prominently with skin that is moist and warm. Both adrenal insufficiency and hyperthyroidism or hypothyroidism can be associated with vitiligo. The nails in hyperthyroidism reveal onycholysis in cases of longer duration. Hair changes occur commonly with several endocrinopathies. In hypothyroidism, the hair becomes coarse, whereas in hyperthyroidism, diffuse thinning occurs. Long-standing hypothyroidism can be accompanied by loss of the lateral third of the eyebrow hair. Hirsutism with hair growth over the areolae and along the linea alba is present in patients with gonadal dysfunction or with hyperandrogenism due to polycystic ovarian disease or androgen-producing tumors. In contrast, patients with hypopituitarism or hypogonadism often present with loss of pubic and axillary hair.

The eye examination can be helpful in establishing the diagnosis of hyperthyroidism. Graves ophthalmopathy occurs in 40% of patients and presents with exophthalmos that can be unilateral. Extraocular movement assessment is important in patients with pituitary tumors because local expansion of these tumors can lead to third, fourth, or sixth nerve palsies, whereas compression of the optic tracts can cause the distinctive visual field defect of bitemporal hemianopsia. On neck examination, ascertainment of whether a goiter is smooth, symmetrical, and multinodular or a single nodule can be helpful in guiding further work-up in the evaluation of hyperthyroidism.

Cardiovascular evaluation is helpful for evaluating the severity and duration of endocrine illness. Patients with hyperthyroidism have evidence of increased sympathomimetic activity, including tachycardia, a widened pulse pressure, and prominent precordial activity. Flow murmurs may be heard as a result of increased cardiac output, and occasionally a bruit is easily heard on auscultation of the thyroid. In patients with hypothyroidism and Addison's disease, these findings are reversed. Specific cardiac abnormalities, such as coarctation of the aorta, may be present in patients with primary ovarian failure due to Turner's syndrome. Patients with pheochromocytoma often have a postural blood pressure change of greater than 20 mm Hg. Cardiomyopathy can be a feature of acromegaly. Hypertension is common in many endocrine disorders, including hypercalcemia, hyperparathyroidism, acromegaly, diabetes mellitus, obesity, Cushing's syndrome, primary aldosteronism, and pheochromocytoma.

Nearly all patients with acromegaly demonstrate evidence of hand and foot enlargement, a very unusual occurrence in adulthood. This often manifests as a history of changing ring size or shoe size and is easily demonstrable on physical examination. Patients with hyperthyroidism often have a significant hand tremor and evidence of peripheral bruits on auscultation. Evaluation of the extremities is also helpful in the differential diagnosis of metabolic bone disease. The presence of bowing of the legs can be found in either dietary or X-linked hypophosphatemic rickets. The presence of edema is usually an early sign of disorders of hormone-producing tumors that result in salt retention, including Cushing's syndrome and hyperaldosteronism. Measurement of upper to lower segment ratios and arm span is helpful in establishing the timing and onset of puberty in primary gonadal disorders.

Pelvic examination is a major aid to the differential diagnosis of ovarian disorders. Palpation may identify polycystic ovaries and suggest the absence of ovarian tissue. The absence of a uterus is important in the differential diagnosis of pseudohermaphroditism, and the evaluation of external genitalia can be important in establishing the presence of congenital adrenal hyperplasia. Vaginal dryness is a sign of severe estrogen deficiency, as is breast atrophy. Hyperprolactinemia often first manifests as the presence of expressible galactorrhea.

Neurologic changes can occur in a variety of diseases. Evaluation of the ability to detect monofilament or vibratory sensation is an important tool for evaluating the presence of diabetic neuropathy. The presence of peripheral motor nerve defects in diabetes is also an important presenting sign, as is the presence of a cranial nerve palsy, such as third nerve palsy. Funduscopic examination can reveal microaneurysms even in patients with undiagnosed type 2 diabetes, and this can be helpful for estimating antecedent duration of illness. Hyporeflexia with a delayed relaxation phase is one of the earliest physical changes in hypothyroidism and is prominent in most patients with clinically significant disease; hyperreflexia occurs in hyperthyroidism. Patients with Cushing's syndrome often have extreme proximal muscle weakness, and this occurs in severe long-standing hyperthyroidism. Midgut carcinoids frequently present with severe flushing and diarrhea. The skin characteristically has an unusual purplish hue, and this change typically lasts for the duration of the episode, about 20 to 30 minutes. Mental status changes occur frequently in patients with Cushing's syndrome, hyperthyroidism, and extreme hypercalcemia.

LABORATORY EVALUATION

Patients with endocrinologic diseases are frequently diagnosed in an asymptomatic state as a result of abnormal radiologic evaluation or hormonal testing abnormalities.

The most common radiologic conundrums occur in patients who are noted incidentally to have small pituitary, thyroid, or adrenal masses. Although most of these patients generally do not have a hormonal dysfunction syndrome, proper evaluation to exclude the presence of a functionally active tumor is usually necessary. For pituitary tumors, the minimal evaluation would include measurements of a baseline serum prolactin level and, in cases with suggestive symptoms, of 24-hour urine free cortisol and of growth hormone after glucose suppression. In patients with incidentally found adrenal masses ("incidentalomas"),[1] important findings are a large tumor mass (i.e., >4 cm), hypertension or hypokalemia, and symptoms and signs of Cushing's syndrome. If any of these are present, appropriate evaluation to exclude hyperaldosteronism, Cushing's syndrome, and pheochromocytoma should be undertaken.

The sensitivity and specificity of hormonal testing have reached levels that have significantly changed the initial evaluation of patients for endocrine disorders. For example, screening of asymptomatic patients for thyroid disease, disorders of lipoprotein metabolism, and disorders of gonadal dysfunction are common and widespread.

Hormones are often measured using immunologic detection methods. Most measurements use blood or urine samples to detect the active hormone.

Occasionally, measurement of a metabolite of the active hormone, such as 25-hydroxycholecalciferol (a vitamin D metabolite), is more reliable than that of the parent hormone. Some hormones (e.g., thyroxine) have a very long half-life in plasma, and therefore a measurement at any time of day reflects the ability of the gland to produce that hormone. However, other hormones (e.g., growth hormone) are secreted episodically, and therefore a static measurement may or may not be indicative of hormone excess or deficiency. In these cases, suppression or stimulation testing is used to confirm the diagnosis. Usually, an exogenous substance (e.g., ACTH) is administered either orally or intravenously, and the production of the hormone (e.g., cortisol) by the gland is either stimulated or suppressed.

Many hormones are present in the circulation bound to binding proteins. With the exception of peptide hormones that circulate in the free (unbound) form, this can cause problems in interpretation: medications or concomitant illnesses can result in a major change in the concentration of the binding protein, which in turn alters the total hormone concentration. This problem can be obviated either by measuring the binding protein itself or by direct measurement of the free hormone, such as measurement of free thyroxine.[2] Free hormone measurements, however, can be less reliable than total hormone measurements; therefore, a decision sometimes needs to be made wherein the reliability of the assay is compared with the quality of the information that will be provided.

Often, static hormone measurements are used for screening—for example, morning cortisol in screening for the presence of hypoadrenalism. Subsequently, stimulation or suppression testing is used for confirmation of the diagnosis.[3] In some cases, plasma measurements are much less reliable than urinary testing (e.g., a single morning cortisol level to rule in or out the presence of Cushing's syndrome). In these cases, 24-hour urinary measurement of hormone is often required to document overproduction. Urinary assays have the advantage of providing integrative assessment over 24 hours and thus are less likely to be susceptible to errors due to episodic hormonal secretion over time. Occasionally, measurements of other substances, such as electrolytes or metabolites, are also informative for confirming the diagnosis. For example, measurement of 24-hour urinary calcium can be important in the differential diagnosis of hypercalcemia. Metabolites in the urine may be extremely important in the evaluation of adrenal disorders and in documentation of pheochromocytoma and carcinoid syndrome. Simultaneous measurements of two substances is extremely helpful in the diagnosis of some disorders. Measurement of simultaneous serum calcium and parathyroid hormone (PTH) is important for confirming the presence of hyperparathyroidism. Likewise, simultaneous measurement of blood glucose and insulin can be important in screening for the presence of an insulin-producing tumor. Indirect measurement of hormonal status can also be important; for example, measurement of insulin-like growth factor (IGF)-I, which is inducible by growth hormone (GH), provides an integrative measure of GH secretion. Similarly, measurement of hemoglobin A_{1c} provides an integrative measurement of long-term blood sugar control in diabetes.

Imaging studies are commonly used in endocrine diagnosis. Magnetic resonance imaging and computed tomography are helpful in evaluating pituitary and adrenal masses. Scanning of the thyroid gland using radioactive iodine is useful for evaluation of the functional status of thyroid nodules and the functional activity of the thyroid gland as a whole.[4] Bone mineral density testing is now commonplace in screening of patients for osteoporosis and in the evaluation of patients with established fracture syndromes. Imaging can also be combined with hormonal measurements. Specifically, cannulation of the adrenal veins can be helpful in confirming the presence of functioning adrenal tumors such as aldosteronomas. Likewise, determining the location of tumors such as those producing PTH can often be confirmed by venous sampling procedures. Similarly, intraoperative measurements of hormones that change rapidly, such as intraoperative PTH, can help determine whether surgical removal of the hormone-secreting tumor has been adequate. The primary use of biopsy in endocrinologic diagnosis is fine-needle aspiration of the thyroid gland. This procedure can be done safely in the outpatient setting, often aided by ultrasound guidance. It is a highly accurate method for determining whether further diagnostic evaluation or therapeutic intervention is necessary.

GENETIC EVALUATION

Use of genetic testing in endocrinologic diagnosis has become much more commonplace. Polymerase chain reaction amplification of DNA obtained from peripheral blood cells is often used to determine the presence of a specific disorder. This has been extremely useful in differential diagnosis, for determining prognosis, and for deciding whether family screening is required (e.g., in the presence of multiple endocrine neoplasia). Whether genetic testing is required is often dictated by whether this information is necessary to solve a differential diagnostic problem (e.g., disorders of vitamin D metabolism) or to decide whether more extensive surgery should be required (e.g., in pheochromocytoma) or whether family screening is necessary (e.g., in multiple endocrine neoplasia 2 syndrome).

EVALUATION OF THE RESPONSE OF AN ENDOCRINE DISEASE TO TREATMENT

Most hormone excess syndromes are treated surgically by removal of the particular endocrine gland or tumor that is oversecreting the hormone.[5] However, follow-up of these patients mandates that (1) it be established that the disease has truly been cured by the resection or (2) if residual disease is present, and (3) determining whether repeat operation is likely to be of benefit to the patient or some other means of treating the patient should be undertaken. These decisions generally need to be made in consultation with surgeons and radiotherapists. If an endocrine deficiency is present, hormone replacement therapy is most often used to correct the disorder. In some cases, the efficacy of substitution therapy can be measured directly by laboratory testing, such as measurement of thyroid-stimulating hormone during thyroxine replacement. In other cases (e.g., measurement of ACTH suppression during substitution therapy for adrenal insufficiency), testing could lead to misleading information and overtreatment of patients; therefore, a combination of return of symptoms and signs to normal, laboratory testing, and indirect tests (e.g., potassium, blood urea nitrogen, and creatinine in the case of adrenal insufficiency) is required to determine the adequacy of replacement therapy. Understanding the pharmacology of the particular synthetic hormone used is important for proper replacement therapy. For example, synthetic glucocorticoids vary greatly in their half-life, and therefore dosage and timing of administration are important issues for patients receiving these hormones. Some patients, such as those with hypopituitarism, require substitution with multiple hormones, and often these need to be coordinated (e.g., glucocorticoid dosage in a patient with panhypopituitarism is dependent on the dosage of thyroid hormone that is administered). Because monitoring thyroid-stimulating hormone is not useful in such patients, empirical substitution with both hormones is required to establish that the therapeutic regimen results in return of functional activity to normal. At times, the signs of hormone excesses may have to be treated with ancillary medications; for example, β-blockade may be useful in patients with hyperthyroidism, and both α- and β-blockade are often necessary in patients with pheochromocytoma. The etiology of osteoporosis is often unknown. In most cases, this disease is generally treated by administration of agents that inhibit bone reabsorption by a variety of mechanisms, including the bisphosphonates, estrogen replacement therapy, and calcitonin.

Hormones are also used throughout medicine for treatment of other disorders, and sometimes these treatments result in a hormone excess syndrome. The most common example is administration of high-dose glucocorticoid therapy for immune suppression resulting in Cushing's syndrome. Similarly, growth hormone may be administered to children with short stature who do not have GH deficiency. PTH is the only agent available for stimulation of an anabolic effect in bone; therefore, it is administered to patients with osteoporosis even though they do not have hypoparathyroidism. Octreotide acetate, a long-acting derivative of somatostatin, can be useful for controlling gastrointestinal symptoms in patients with neuroendocrine tumors. Supraphysiologic doses of progesterone are commonly used as contraceptives. Hormone antagonists are also used in both endocrine and nonendocrine disorders. Estrogen receptor antagonists are commonly used in breast cancer therapy, as are androgen receptor antagonists in prostate cancer therapy. Similarly, gonadotropin-releasing hormone agonists have been found to be useful in patients with prostate cancer that is metastatic to bone. Prostaglandin antagonists are commonly used in acute and chronic inflammatory disorders, and angiotensin receptor antagonists as well as renin antagonists are used in the treatment of hypertension, whether it is due to an endocrine or nonendocrine etiology. A comprehensive knowledge of the actions of these hormones can intelligently guide the proper use of these agents in treating nonendocrine disorders.

PRINCIPLES OF ENDOCRINOLOGY

ALLEN M. SPIEGEL

INTRODUCTION

The principal manifestation of most endocrine diseases is over- or undersecretion of one or more hormones, but the causes of endocrine disease are not unique to endocrinology as a subspecialty of medicine. Benign or malignant proliferation of endocrine cells, destruction of endocrine cells by autoimmune, infectious, or other infiltrative processes, mutations in genes expressed by endocrine cells, and alterations in endocrine cell function caused by metabolic abnormalities or drugs are major causes of endocrine disease shared with diseases of other organ systems. If the causes of endocrine disease are not unique, there are nonetheless some general principles of endocrinology that define it as a medical subspecialty. These principles all derive from the study of hormones. Endocrinology was born with the recognition that certain cells secrete specific chemical entities—hormones—directly into the blood stream to act on specific distant targets. This immediately posed a series of questions: how are hormone synthesis and secretion regulated, how are hormones transported and metabolized, and how do hormones exert their actions on target tissues? This chapter will provide an overview of the answers to each of these questions and how they inform our current approach to the diagnosis and treatment of endocrine diseases.

WHAT IS A HORMONE?

The initial definition of a hormone was based on physiology rather than chemistry. Action on target cells reached via the blood stream was the operative principle. Secretin, now known to be a peptide hormone secreted by enteroendocrine cells in the gastrointestinal lining and acting on pancreatic exocrine cells, was the first example.[1] In contrast to enteroendocrine cells dispersed in the gut lining with other cell types, discrete collections of hormone-secreting cells, endocrine glands such as the adrenals, gonads, thyroid, and parathyroids, were soon recognized and their hormonal secretions chemically characterized. We now know that peptides, steroids, and many other chemical substances fit the definition of a hormone.

Endocrine action, a hormone secreted into the blood stream acting at a distance, has been contrasted with *paracrine action*, a growth factor or other signaling molecule secreted from one cell and acting on adjacent cells, and *autocrine action*, a cell secreting a signaling molecule that acts on the same cell. The distinction between endocrine, paracrine, and autocrine actions is not sharp. In some cases, a factor such as parathyroid hormone–related peptide (PTHrP) that acts physiologically in paracrine fashion during normal bone development may act as an endocrine factor in the syndrome of humoral hypercalcemia of malignancy. The definition of what constitutes an endocrine gland has also blurred. First came the discovery that specialized neurons could synthesize and secrete hormones directly into the blood stream, so-called neuroendocrine action, exemplified by vasopressin secretion by posterior pituitary cells. This contrasts with classic neuronal secretion of neurotransmitters into the synaptic cleft. With increasing recognition that many tissues secrete hormones (e.g., erythropoietin by the kidney and leptin and other adipokines by fat cells), the role of endocrine glands as the exclusive purveyors of hormonal secretions has diminished. This blurring of the boundaries between endocrinology and other medical specialties is a general phenomenon in which study of hormones has informed seemingly disparate fields. Radioimmunoassay, the concept of receptors, and other principles of signal transduction first elucidated in studying hormone action are now broadly applied in all fields of medicine.

REGULATION OF HORMONE SYNTHESIS AND SECRETION

There are two broad categories of hormone synthesis: (1) that responsible for synthesis of peptide hormones and (2) that responsible for synthesis of steroids, including the active form of vitamin D, thyroid hormones, catecholamines, and other nonpeptide hormones. In the former category, hormone structure is encoded genetically. mRNA translation yields a protein precursor (pre-pro-hormone) that is generally cleaved through successive steps to yield the mature secreted product. Some protein precursors such as proopiomelanocortin contain within them multiple hormonal products, adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (MSH), and endorphins in that example. In certain pathologic conditions, inappropriate immature hormone secretion occurs (e.g., excessive proinsulin secretion by insulinomas). Post-translational modifications occur for some hormones, such as disulfide bond formation for vasopressin and insulin, C-peptide cleavage for insulin, and glycosylation of the pituitary glycoprotein hormones, thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Mutations in genes encoding peptide hormones can lead to disruption of normal hormone synthesis or secretion, a rare cause of hormone deficiency. Peptide hormones are typically stored in secretory granules, and they are secreted by exocytosis, a process regulated by Ca^{++} and other factors. For steroids and other nonpeptide hormones, hormone synthesis is accomplished by a series of enzymatic steps acting on precursors (cholesterol for steroid hormones; aromatic amino acids for thyroid hormones, catecholamines, and related compounds). Mutations in genes encoding enzymes responsible for one or more steps in hormone synthesis can lead to hormone deficiency.

Negative feedback regulation is the general principle that governs normal hormone synthesis and secretion. For endocrine glands whose growth and hormone secretion is stimulated by pituitary trophic hormones (gonads, adrenal cortex, thyroid), the hormone secreted by the gland acts directly on cognate pituitary trophic cells (e.g., cortisol acting on ACTH-secreting pituitary corticotrophs) to suppress hormone secretion (Fig. 222-1). Conversely, a physiologically meaningful reduction in target gland hormone secretion leads to increased pituitary trophic hormone secretion. In many other cases, negative feedback regulation operates without the pituitary as an intermediate (e.g., PTH secretion from the parathyroid glands regulates extracellular Ca^{++} homeostasis, and Ca^{++} feeds back directly on parathyroid cells to regulate PTH secretion). Chronic hormone deficiency with resultant loss of negative feedback can lead to hypersecretion of the cognate trophic hormone and even to neoplastic proliferation of trophic hormone–secreting cells. Examples include Nelson's syndrome in which corticotroph tumors form secondary to adrenalectomy, and tertiary hyperparathyroidism in which parathyroid adenomas occur in the setting of chronic hypocalcemia. In some adrenal cortical disorders, hormone deficiency leading to loss of negative feedback of trophic hormone secretion causes pathologic hypersecretion of alternative steroid hormones. The various forms of congenital adrenal hyperplasia are caused by mutations in one of the several enzymes in the cortisol biosynthetic pathway. 21-Hydroxylase deficiency, the most common, can lead to virilization in female infants, with excessive adrenal androgen secretion caused by ACTH stimulation in the face of inability to synthesize cortisol. Inhibition of enzymatic steps in hormone synthesis, such as aromatase inhibitors to decrease estrogen formation in estrogen receptor–positive forms of breast cancer, may be an important therapeutic target.

Hormone hypersecretion syndromes in which excessive hormone secretion occurs in the face of "normal" levels of the factor that ordinarily suppresses the cognate hormone are by definition caused by some intrinsic defect in negative feedback suppression. This may occur secondary to a neoplastic proliferation of hormone-secreting cells, so that "basal" hormone secretion from the increased mass of cells exceeds physiologic levels. This may also be due to alterations in the intrinsic "set-point" for negative feedback suppression of hormone secretion. In practice, it may be impossible to differentiate these two mechanisms, and they are not mutually exclusive.

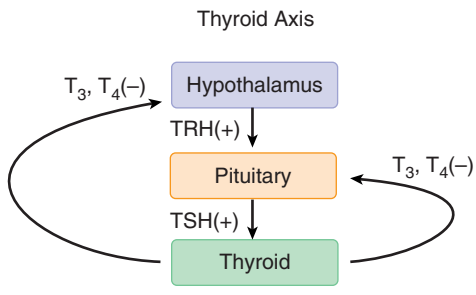

FIGURE 222-1 Hypothalamic-pituitary-thyroid axis illustrating negative feedback regulation. Following thyroid-stimulating hormone (TSH) secretion by the pituitary, the thyroid gland secretes T_3 and T_4, which feed back on the hypothalamus and pituitary to suppress further increases in thyrotropin-releasing hormone (TRH) and TSH secretion.

Hormone secretion is subject to many additional forms of regulation beyond simple negative feedback suppression. These include metabolic, neural, and other internal and environmental inputs. The temporal pattern of hormone secretion is often related to diurnal rhythms, as classically seen for cortisol, and also pulsatility. Changes in gonadotropin secretion during the menstrual cycle and during the course of puberty are striking examples of complex regulation of temporal patterns of hormone secretion.

HORMONE TRANSPORT AND METABOLISM

Most peptide hormones circulate as the free peptide, but insulin-like growth factor 1 (IGF-1) uniquely binds to a number of specialized binding proteins. Steroid and thyroid hormones are lipophilic molecules that circulate largely in protein-bound form. Specialized binding proteins for cortisol, androgens, estrogens, and thyroid hormones are selective for their cognate hormone. The free circulating hormone concentration is only a small fraction of the total hormone measured by routine analytic methods. Binding protein abnormalities can occur in liver disease, because most are synthesized by the liver. Thus, the determination of free as opposed to total plasma hormone concentration may be critical to accurate diagnosis in certain clinical conditions.

Hormone metabolism is another critical determinant of action for some hormones. For testosterone, thyroxine, and vitamin D, enzymatic conversion to more potent hormones—dihydrotestosterone formation in target tissues such as skin by 5-α reductase, thyroxine conversion to triiodothyronine by deiodinases, and 1,25 dihydroxyvitamin D formation by sequential hydroxylations in the liver and kidney—are all critical to normal hormone action. Defects in these metabolic steps leads to impaired hormone action. Even some peptide hormones such as angiotensin must undergo enzymatic conversion from secreted precursor form to generate the active hormone.

MECHANISM OF HORMONE ACTION

The central question in hormone action is how a hormone circulating in the blood stream in minute concentrations recognizes its specific target cells and regulates physiologic processes within them. Research addressing this question over the past four decades defined receptors, previously a purely theoretical concept, in molecular terms. Receptors are highly selective molecules that bind their cognate hormones with high affinity and specificity. Two broad classes of receptors were identified: (1) cell surface receptors that typically span the plasma membrane one or more times (Fig. 222-2) and (2) so-called nuclear receptors that reside either in the nucleus or in the cytoplasm, with subsequent translocation to the nucleus[2] (Fig. 222-3).

Hormones regulate cellular physiologic processes such as secretion of hormones, enzymes, and other compounds, muscle contraction, growth, and proliferation. *Signal transduction* is the general term for the biochemical steps between hormone binding to receptor and alterations in cell physiology. Most peptide and protein hormones (e.g., insulin, growth hormone, ACTH) bind to cell surface receptors that can be classified according to the

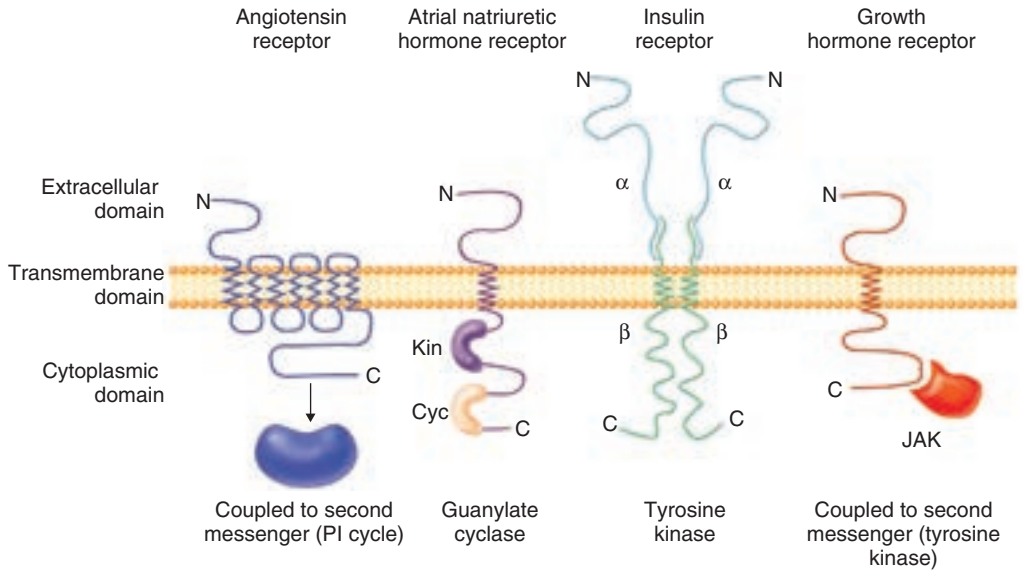

FIGURE 222-2. **Structures of different types of peptide hormone receptors.**

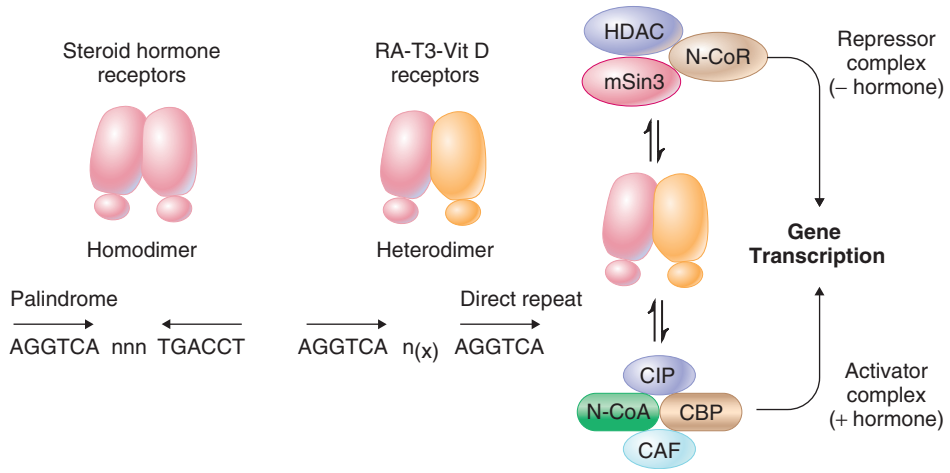

FIGURE 222-3. **How steroid hormone receptors function.** *Left,* Glucocorticoid receptor family members bind as homodimers to palindromic DNA sites. Thyroid hormone receptor family members bind primarily as heterodimers with retinoid X receptor to direct repeat DNA sites separated by varying numbers of base pairs. *Right,* As a result of hormone binding, repressor complexes dissociate and activator complexes bind to nuclear receptors. Repressor complexes contain histone deacetylase (HDAC), and activator complexes contain histone acetylase (CAF).

mechanism of signal transduction to which they are coupled (e.g., G protein–coupled[3] receptor tyrosine or serine kinase, JAK/STAT coupled; see Fig. 222-2). Cell surface receptors may generate "second messengers," which in turn regulate a kinase cascade. Receptor activation may have rapid effects such as exocytosis of secretory granules, but longer-term actions involving gene regulation may also be a consequence of second messenger and kinase cascade activation. Steroid and thyroid hormones and vitamin D bind to members of the nuclear receptor family. The latter act as "ligand-regulated" transcription factors to regulate gene expression (see Fig. 222-3).

Selectivity of hormone binding by receptors is not absolute. "Specificity spillover" is a clinically important phenomenon in which supraphysiologic concentrations of a hormone leads to binding and activation of a non-cognate receptor for a closely related hormone. Examples include: hypoglycemia seen with non–islet cell tumors secreting IGF-2, which binds to the insulin receptor[4]; skin hyperpigmentation in subjects with Addison's disease in whom excessive ACTH secretion activates the melanocortin receptor in melanocytes normally regulated by MSH; and hyperthyroidism in pregnant women with high human chorionic gonadotropin (HCG) concentrations activating the TSH receptor.

Genetic endocrine diseases include those caused by mutations in one component of a signal transduction pathway leading either to hormone "resistance" or hormone-independent activation (Tables 222-1 and 222-2). In the former, subjects present with apparent hormone deficiency, but direct hormone measurement reveals high concentrations of bioactive hormone that fails to act owing to target organ resistance. In the latter, patients present with apparent endocrine hyperfunction, but direct measurement reveals suppressed hormone concentration due to intact negative feedback. Loss-of-function mutations in receptors and in signaling intermediates such as G proteins have been identified in patients with hormone resistance. The converse, mutations that constitutively activate receptors or downstream signaling components,[5] have been identified in endocrine hyperactivity diseases such as familial male precocious puberty and familial nonautoimmune hyperthyroidism. Receptor inactivating mutations that lead to hormone-resistance diseases have been identified for both the cell surface and nuclear classes of receptors.

TABLE 222-1 DISEASES CAUSED BY G PROTEIN–COUPLED RECEPTOR LOSS-OF-FUNCTION MUTATIONS

RECEPTOR	DISEASE	INHERITANCE
V2 vasopressin	Nephrogenic diabetes insipidus	X-linked
ACTH	Familial ACTH resistance	Autosomal recessive
GHRH	Familial GH deficiency	Autosomal recessive
GnRH	Hypogonadotropic hypogonadism	Autosomal recessive
GPR54	Hypogonadotropic hypogonadism	Autosomal recessive
Prokineticin receptor 2	Hypogonadotropic hypogonadism	Autosomal dominant*
FSH	Hypergonadotropic ovarian dysgenesis	Autosomal recessive
LH	Male pseudohermaphroditism	Autosomal recessive
TSH	Familial hypothyroidism	Autosomal recessive
Ca^{2+} sensing	Familial hypocalciuric hypercalcemia, neonatal severe primary hyperparathyroidism	Autosomal dominant Autosomal recessive
Melanocortin 4	Obesity	Autosomal recessive
PTH/PTHrP	Blomstrand chondrodysplasia	Autosomal recessive

*With incomplete penetrance
ACTH = Adrenocorticotropic hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone–releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PTH = parathyroid hormone; PTHrP = parathyroid hormone–related protein; TSH = thyroid-stimulating hormone.

TABLE 222-2 DISEASES CAUSED BY G PROTEIN–COUPLED RECEPTOR GAIN-OF-FUNCTION MUTATIONS

RECEPTOR	DISEASE	INHERITANCE
LH	Familial male precocious puberty	Autosomal dominant
TSH	Sporadic hyperfunctional thyroid nodules	Noninherited (somatic)
TSH	Familial nonautoimmune hyperthyroidism	Autosomal dominant
Ca^{2+} sensing	Familial hypocalcemic hypercalciuria	Autosomal dominant
PTH/PTHrP	Jansen's metaphyseal chondrodysplasia	Autosomal dominant
V2 vasopressin	Nephrogenic inappropriate antidiuresis	Autosomal dominant

LH = Luteinizing hormone; PTH = parathyroid hormone; PTHrP = parathyroid hormone–related protein; TSH = thyroid-stimulating hormone.

REVIEW QUESTIONS

1. Hormones are synthesized and secreted by:

A. Specialized collections of cells that form endocrine glands
B. Cells dispersed throughout the lining of the small intestine and within the pancreas
C. Neurons that comprise the posterior pituitary
D. The kidney, adipose tissue, and some other organs
E. All of the above

Answer: E Research has shown that not only classical endocrine glands such as the thyroid and adrenal, but also dispersed enteroendocrine cells in the gut lining and islets in the pancreas, neuroendocrine cells in the posterior pituitary, and non-classical hormone-secreting sites such as kidney, heart, and adipose are all sources of hormone secretion.

2. A genetic hormone deficiency disorder may be caused by:

A. A mutation in the gene encoding the hormone's signal sequence
B. Exposure of the pregnant mother to an endocrine "disruptor"
C. A mutation in a gene encoding an enzyme in the TCA cycle
D. Paternal advanced age at time of conception
E. All of the above

Answer: A A mutation in the hormone gene altering the signal sequence of a peptide hormone and thereby impairing its ability to be secreted may cause genetic forms of hormone deficiency such as hypoparathyroidism.

3. Negative feedback suppression is:

A. The basis for the diurnal rhythm in serum cortisol
B. The mechanism whereby an "output" regulated by a hormone feeds back to regulate the secretion of that hormone
C. The basis for menopause in women and lower testosterone with age in men
D. Always involves one hormone regulating the secretion of another hormone
E. None of the above

Answer: B B is the correct definition of negative feedback suppression. The latter is not the primary cause of either A or C. D is incorrect because outputs other than hormones can exert negative feedback suppression (e.g., Ca^{++} suppressing PTH secretion).

4. Hormone receptors are:

A. Always located on the cell surface
B. When activated, may exert their effects via a second messenger cascade
C. When activated, may exert their effects by directly regulating gene transcription
D. Irrespective of starting location, always translocate to the nucleus to exert their actions
E. Both B and C

Answer: E Because there are cell surface receptors that do not translocate to exert their action, and nuclear receptors for steroid hormones, A and D are incorrect. Both B and C are true for cell surface and nuclear receptors, respectively.

5. Genetic hormone resistance disorders:

A. Are due to gain-of-function mutations in hormone receptors
B. Are always due to loss-of-function mutations in nuclear receptors
C. Are due to overactivity of enzymes that degrade hormones
D. May be caused by loss-of-function mutations in genes encoding cell surface or nuclear receptors or other components of the signal transduction pathway
E. Are generally associated with autoimmune disease

Answer: D All the cited examples may be causes of inherited hormone resistance diseases, not just B. A, C, and E do not apply.

NEUROENDOCRINOLOGY AND THE NEUROENDOCRINE SYSTEM

MARK E. MOLITCH

NEUROENDOCRINE REGULATION

Neuroendocrinology refers to the area of endocrinology in which the nervous system interacts with the endocrine system to link neural activity with metabolic and hormonal homeostatic activity. The neurohypophysial neurons originate from the paraventricular and supraoptic nuclei, traverse the hypothalamic-pituitary stalk, and release vasopressin and oxytocin from nerve endings in the posterior pituitary. The hypophysiotropic neurons localized in specific hypothalamic nuclei project their axons to the median eminence to secrete their peptide and bioamine releasing and inhibiting hormones into the proximal end of the hypothalamic-pituitary portal vessels (Fig. 223-1). The median eminence receives its blood supply from the superior hypophysial artery, which arborizes into a rich capillary bed. The capillary loops extend into the median eminence and coalesce to form the long portal veins that traverse the pituitary stalk and end in the pituitary. The neuroendocrine system operates through a series of feedback loops that regulate pituitary and target organ hormone levels. Target organ hormones can feed back at both the hypothalamic and the pituitary levels to complete the loop. The feedback loops can be perturbed, resulting in alterations of set points by such factors as length of day (circadian periodicity), stress, nutritional status, and systemic illness.

Hypophysiotropic Hormones

Regulation of pituitary hormones by the hypophysiotropic hormones is quite complex, in part because of the multiplicity of substances present in the hypothalamus that can affect pituitary hormone secretion and in part because of the redundancy and overlapping nature of the feedback loops alluded to earlier. In addition, some hypophysiotropic hormones exert effects on more than one pituitary hormone.

Thyrotropin-Releasing Hormone

The primary neuroendocrine functions of thyrotropin-releasing hormone (TRH) are to stimulate the synthesis and release of thyroid-stimulating hormone (TSH) and prolactin. In cases of hypothyroidism, the increased TRH synthesis and binding to the pituitary results in increased TSH and prolactin levels. Correction of the hypothyroidism with thyroid hormones decreases the elevated TSH and prolactin levels. Conversely, in cases of hyperthyroidism, TSH levels are markedly suppressed. Although TRH is the major regulator of TSH synthesis and secretion, the role of TRH as a physiologic prolactin-releasing factor (PRF) is unclear.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH) is a 10–amino acid peptide; its neurons originate in the epithelium of the medial part of the olfactory

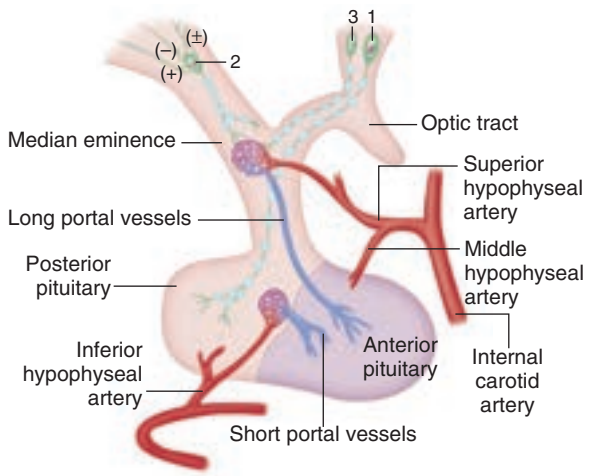

FIGURE 223-1. Neuroendocrine organization of the hypothalamus and pituitary gland. The posterior pituitary is fed by the inferior hypophyseal artery and the hypothalamus by the superior hypophyseal artery, both branches of the internal carotid artery. Most of the blood supply to the anterior pituitary is venous by way of the long portal vessels, which connect the portal capillary beds in the median eminence to the venous sinusoids in the anterior pituitary. Hypophysiotropic neuron 3 in the parvocellular division of the paraventricular nucleus and neuron 2 in the arcuate nucleus are shown to terminate in the median eminence on portal capillaries. These neurons of the tuberoinfundibular system secrete hypothalamic releasing and inhibiting hormones into the portal veins for conveyance to the anterior pituitary gland. Neuron 2 is innervated by monoaminergic neurons. Note that the multiple inputs to such neurons, using neuron 2 as an example, can be stimulatory, inhibitory, or neuromodulatory, in which another neuron may affect neurotransmitter release. Neuron 1 represents a peptidergic neuron originating in the magnocellular division of the paraventricular nucleus or supraoptic nucleus and projecting directly to the posterior pituitary by way of the hypothalamic-neurohypophyseal tract. (From Gay VL. The hypothalamus: physiology and clinical use of releasing factors. *Fertil Steril.* 1972;23:50-63, with permission of the American Society for Reproductive Medicine.)

placode. This origin of GnRH-producing neurons from olfactory epithelium is of clinical interest with respect to the entity of Kallmann's syndrome, in which GnRH deficiency is associated with agenesis of the olfactory bulbs. One form of Kallmann's syndrome is caused by loss of function of a protein (anosmin) that facilitates the embryologic migration of these GnRH-producing neurons. The primary function of GnRH is to stimulate the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Only one GnRH has been identified, and the differential secretion of LH and FSH is due to variations in sensitivity of the feedback effects of steroid and peptide hormones and variations in sensitivity to GnRH. GnRH pulsatile secretion directly increases its own receptor number, whereas continuous administration of GnRH is associated with a decrease. In women, positive and negative steroid hormone feedback regulation of the hypothalamic-pituitary-gonadal axis occurs at both the pituitary and hypothalamic levels, the hypothalamic effects being alteration of GnRH pulse amplitude and frequency, and the pituitary effects being modulation of the gonadotropin response to GnRH. In males, testosterone decreases GnRH pulsatile secretion, with a resultant decrease in gonadotropin pulse amplitude and frequency as well as a decreased gonadotropin response to exogenous GnRH.

The negative feedback effects of inhibin, a peptide produced by testicular Sertoli cells and ovarian granulosa cells, are predominantly on FSH at the pituitary, where inhibin causes a decrease in the sensitivity of gonadotrophs to GnRH. The related ovarian protein activin stimulates basal and GnRH-stimulated FSH synthesis and release from the pituitary, but its primary action is to facilitate the response of ovarian granulosa cells to FSH. Another gonadal peptide, follistatin, also inhibits the oophorectomy- and GnRH-induced rise in FSH selectively, primarily by binding to activin. These ovarian peptides are also found in the pituitary and may therefore have additional local effects on gonadotropin secretion.

GnRH has been administered with great success in pulsatile fashion to individuals with hypogonadotropic hypogonadism secondary to GnRH deficiency, leading to restoration of normal sexual function and fertility. Long-acting GnRH agonists have been used to downregulate GnRH receptors and gonadotropin secretion in a variety of conditions, including precocious puberty, prostate cancer, breast cancer, uterine fibroids, and endometriosis. Direct GnRH antagonists that compete for the GnRH receptor are used for similar conditions.

Somatostatin

Somatostatin (also known as somatotropin release inhibiting factor) inhibits GH secretion. The interaction of somatostatin and growth hormone–releasing hormone (GHRH) on GH secretion is complex. GH secretory episodes are associated with increased GHRH secretion, often accompanied by low somatostatin levels; the basal or trough GH levels are associated with low GHRH levels and more elevated somatostatin levels. Somatostatin also inhibits basal and stimulated TSH secretion. However, GH is about 10-fold more sensitive to inhibition by somatostatin than is TSH, suggesting that the physiologic role of somatostatin in inhibiting TSH secretion is limited. Somatostatin is also present in D cells of the pancreatic islets, the gut mucosa, and the myenteric neural plexus. Through paracrine and endocrine actions, it suppresses the secretion of insulin, glucagon, cholecystokinin, gastrin, secretin, vasoactive intestinal polypeptide (VIP), and other gastrointestinal hormones, as well as such functions as gastric acid secretion, gastric emptying, gallbladder contraction, and splanchnic blood flow. Analogues of somatostatin have been developed for the treatment of acromegaly, carcinoid tumors, VIP-secreting tumors, TSH-secreting pituitary tumors, and islet cell tumors.

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) releases adrenocorticotropic hormone (ACTH), β-endorphin, β-lipotropin, melanocyte-stimulating hormone (MSH), and other peptides generated from proopiomelanocortin (POMC) in equimolar amounts. CRH mediates 75% of the ACTH response to stress. The remaining 25% is due to vasopressin. CRH and vasopressin have synergistic effects on ACTH release. CRH and vasopressin are not always released coordinately, however, and stress selectively activates the vasopressin-containing subset of CRH neurons. Cortisol feeds back to decrease ACTH secretion at both the hypothalamic and the pituitary levels. ACTH and β-endorphin also feed back negatively to decrease CRH release by the hypothalamus. Central bioamines, opioids, and peptides influence CRH secretion. Monokines released by inflammatory tissue, such as interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α, stimulate the synthesis and release of CRH and vasopressin from the hypothalamus. The consequent increase in cortisol then reduces the intensity of the inflammatory response and release of these monokines, thus completing this inflammation-modulating feedback loop. CRH receptors are widely distributed in the brain, and increases in CRH are associated with activation of the sympathetic nervous system, suppression of the parasympathetic nervous system, stimulation of arousal, and increased learning performance. CRH may also be involved in the regulation of body weight; with overfeeding, increased leptin stimulates CRH, which causes decreased food intake and increased energy expenditure.

Biosynthetic human CRH has become available for clinical use. Its major utility is in the differential diagnosis of Cushing's disease versus ectopic ACTH syndrome, with the finding that patients with Cushing's disease respond with a greater than 35% increment, whereas those with ectopic ACTH secretion have a lesser response. If the results are equivocal, CRH testing during bilateral inferior petrosal sinus sampling for ACTH often provides additional discriminatory information.

Growth Hormone–Releasing Hormone

GHRH dose-dependently stimulates GH secretion. With repetitive administration, GHRH can cause the release of sufficient GH in children with GHRH deficiency to result in an increase in insulin-like growth factor (IGF)-I levels and an acceleration of growth. Both IGF-I and GH feed back negatively on GH secretion. This negative feedback results in both a decrease in GHRH and an increase in somatostatin. The feedback effect of IGF-I is clinically relevant, as documented by the high circulating GH levels that occur in IGF-I-deficient states such as renal insufficiency and cirrhosis. In children with mutations of the GH receptor resulting in their not being responsive to GH (GH insensitivity syndrome, also known as Laron-type dwarfism), IGF-I levels are very low and GH levels are correspondingly elevated.

Prolactin Inhibitory Factor

The inhibitory component of hypothalamic regulation of prolactin secretion predominates over the stimulatory component. Dopamine is the major physiologic prolactin inhibitory factor. It is likely that in most physiologic circumstances that cause a rise in prolactin (e.g., lactation), a simultaneous fall in dopamine occurs, along with a rise in a prolactin-releasing factor (PRF) such as VIP. Blockade of endogenous dopamine receptors by a variety of drugs, such as the antipsychotics, causes a rise in prolactin. Lesions that interrupt

A separate GH-stimulating system for GH secretion involves a distinct receptor, termed the *GH secretagogue* (GHS) receptor, that interacts with a 28–amino acid peptide called ghrelin that was initially isolated from the stomach. GHS receptor and ghrelin messenger RNA are both present in the pituitary and hypothalamus of humans. The interaction of ghrelin physiologically with GHRH and somatostatin is complex but appears to be of minor importance with regard to GH secretion. However, ghrelin may play a more important role in the regulation of appetite and food intake.

the basal hypothalamic neuronal pathways carrying dopamine to the median eminence or that interrupt portal blood flow, such as craniopharyngiomas or other large mass lesions, result in decreased dopamine reaching the pituitary and hyperprolactinemia.

Prolactin-Releasing Factor

A number of hypothalamic peptides other than TRH have also been shown to have PRF activity. VIP stimulates prolactin synthesis and release at concentrations found in hypothalamic-pituitary portal blood. Within the VIP precursor is another similarly sized peptide known as peptide histidine methionine, which also has PRF activity. The precise roles of VIP versus peptide histidine methionine are not clear. They appear to be of negligible physiologic importance in humans.

Endogenous Opioid Peptides

Most data now suggest a modest role for endogenous opioid peptides in neuroendocrine regulation. The endogenous opioid peptides have a common 5–amino acid sequence at their amino termini (Tyr-Gly-Gly-Phe-Met [or Leu]) that is important for their binding to endogenous opioid receptors and bioactivity. Three major opioid peptide receptors and three major groups of opioid peptides are recognized. The μ-receptor mediates most of the endocrine effects and analgesia. The primary peptide ligand for the μ-receptor is β-endorphin, which is derived from POMC. The δ-receptor mediates behavioral, analgesic, and some endocrine effects and has as its primary peptide ligands met- and leu-enkephalins, which are derived from proenkephalin A. It is much less well blocked by naloxone than is the μ-receptor. The κ-receptor mediates sedation and ataxia and binds primarily dynorphin and the neoendorphins. A fourth receptor has considerable sequence homology with the δ-receptor and binds to an endogenous 17–amino acid peptide called nociceptin (also known as orphanin FQ).

POMC is a 31-kD precursor peptide that harbors within it ACTH, β-lipotropin, and β-endorphin. POMC undergoes tissue-specific posttranslational processing. In the anterior pituitary, its major cleavage products are β-lipotropin and ACTH, with a significant proportion of β-lipotropin being further processed to β-endorphin. In the pituitary intermediate lobe, the major products are α-melanocyte stimulating hormone (α-MSH), corticotropin-like intermediate peptide, β-endorphin, and γ-lipotropin. Brain POMC, however, is processed primarily to β-endorphin, γ-lipotropin, and ACTH, with most of the ACTH being further processed to corticotropin-like intermediate peptide and α-MSH. The pentapeptide enkephalins are derived from the 28-kD precursor proenkephalin A. Neuronal perikarya containing the enkephalins are widely distributed throughout the brain. Dynorphin is a 17–amino acid peptide derived from a 28-kD precursor called proenkephalin B or prodynorphin. Shorter peptides called α- and β-neoendorphin, which have 10 and 9 amino acids, respectively, have also been isolated. These peptides react almost exclusively with the κ-receptor. Nociceptin is a 17–amino acid peptide derived from a κ precursor called pronociceptin. High concentrations of nociceptin and its receptor are present in the hypothalamus as well as in other areas of the brain that serve as the sources of monoamine neurotransmitters. In general, nociceptin appears to have an antiopioid or antinociceptive effect. The hypothalamus contains abundant opioid receptors. The effects of opioid peptides on anterior pituitary hormone secretion are produced through modulation of hypothalamic bioamines and hypophysiotropic factors.

The specific functions of the various opioid peptides and the opioid receptors are still not completely understood, although evidence links them to a number of body functions, including stress, mental illness, narcotic tolerance and dependence, eating, drinking, gastrointestinal function, learning, memory, reward, cardiovascular responses, respiration, thermoregulation, seizures, brain electrical activity, locomotor activity, pregnancy, and neuroimmune activity. Endogenous opioids have an inhibitory influence on gonadotropin secretion through action on GnRH secretion. Exogenous β-endorphin and enkephalin analogues increase serum GH and prolactin levels, but blockade of endogenous opioid pathways with naloxone does not alter basal or stimulated GH or prolactin levels. Opioids feed back negatively on ACTH and β-endorphin secretion, and naloxone can increase basal and stimulated ACTH levels. Overall, the effects of the endogenous opioids on normal physiologic regulation of the various pituitary hormones in humans is minimal. However, exogenous opioids in pharmacologic doses can impair GnRH and gonadotropin secretion, causing hypogonadism with reduced libido, sexual function, and fertility, and can also impair CRH and ACTH secretion, causing adrenal insufficiency.[1]

Central Nervous System Rhythms and Neuroendocrine Function

Pituitary hormones are secreted in a pulsatile fashion with a number of rhythms superimposed. The pulse amplitude of a pituitary hormone reflects the amount of releasing hormone and factors that alter sensitivity to that releasing hormone. Thus, the amplitude can be altered by the presence of inhibitory factors (e.g., GHRH versus somatostatin), nutritional factors, feedback effects of target organ hormones, and prior stimulation that depletes the releasable hormone pool. Pulse frequency is governed by the frequency of release of the hypophysiotropic factor, which is regulated by the hypothalamic pulse generator system.

The pituitary has an intrinsic rhythm of small amplitude with a frequency of every 2 to 10 minutes. Superimposed on this intrinsic rhythm is a rhythm caused by the pulsatile release of hypophysiotropic releasing factors, with or without the withdrawal of a corresponding inhibitory factor. Rhythms that are shorter than 1 day are referred to as ultradian rhythms. The next layer of rhythmicity is the circadian rhythm—that is, a rhythm with approximately 24-hour periodicity. These rhythms are usually synchronized with the 24-hour period by a periodic environmental cue such as the dark-light cycle. The suprachiasmatic nucleus functions as a circadian pacemaker and receives light-induced electrical impulses from the retina, transmitting those impulses to the pineal gland where they are converted to hormonal signals. Signals for a rhythm with a periodicity longer than 24 hours, an infradian rhythm, include the gravitational influence of the moon, which gives rise to the menstrual cycle.[2]

A number of factors may influence circadian and infradian rhythms. One of the most important is the sleep-wake cycle. GH, TSH, prolactin, ACTH, and pubertal LH secretion are all entrained more to the sleep-wake cycle than to the dark-light cycle (E-Fig. 223-1). Each has an increase and maximal level that occur following sleep onset. The profound diurnal variation in cortisol and ACTH is often used as an index of "normality" of the system. Loss of this diurnal rhythm occurs with disordered regulation by CRH, which may be due to endogenous depression or excessive alcohol intake, or autonomous secretion of ACTH in Cushing's disease (Chapter 224). Loss of the diurnal rhythm of cortisol has been used as a diagnostic test for Cushing's syndrome.

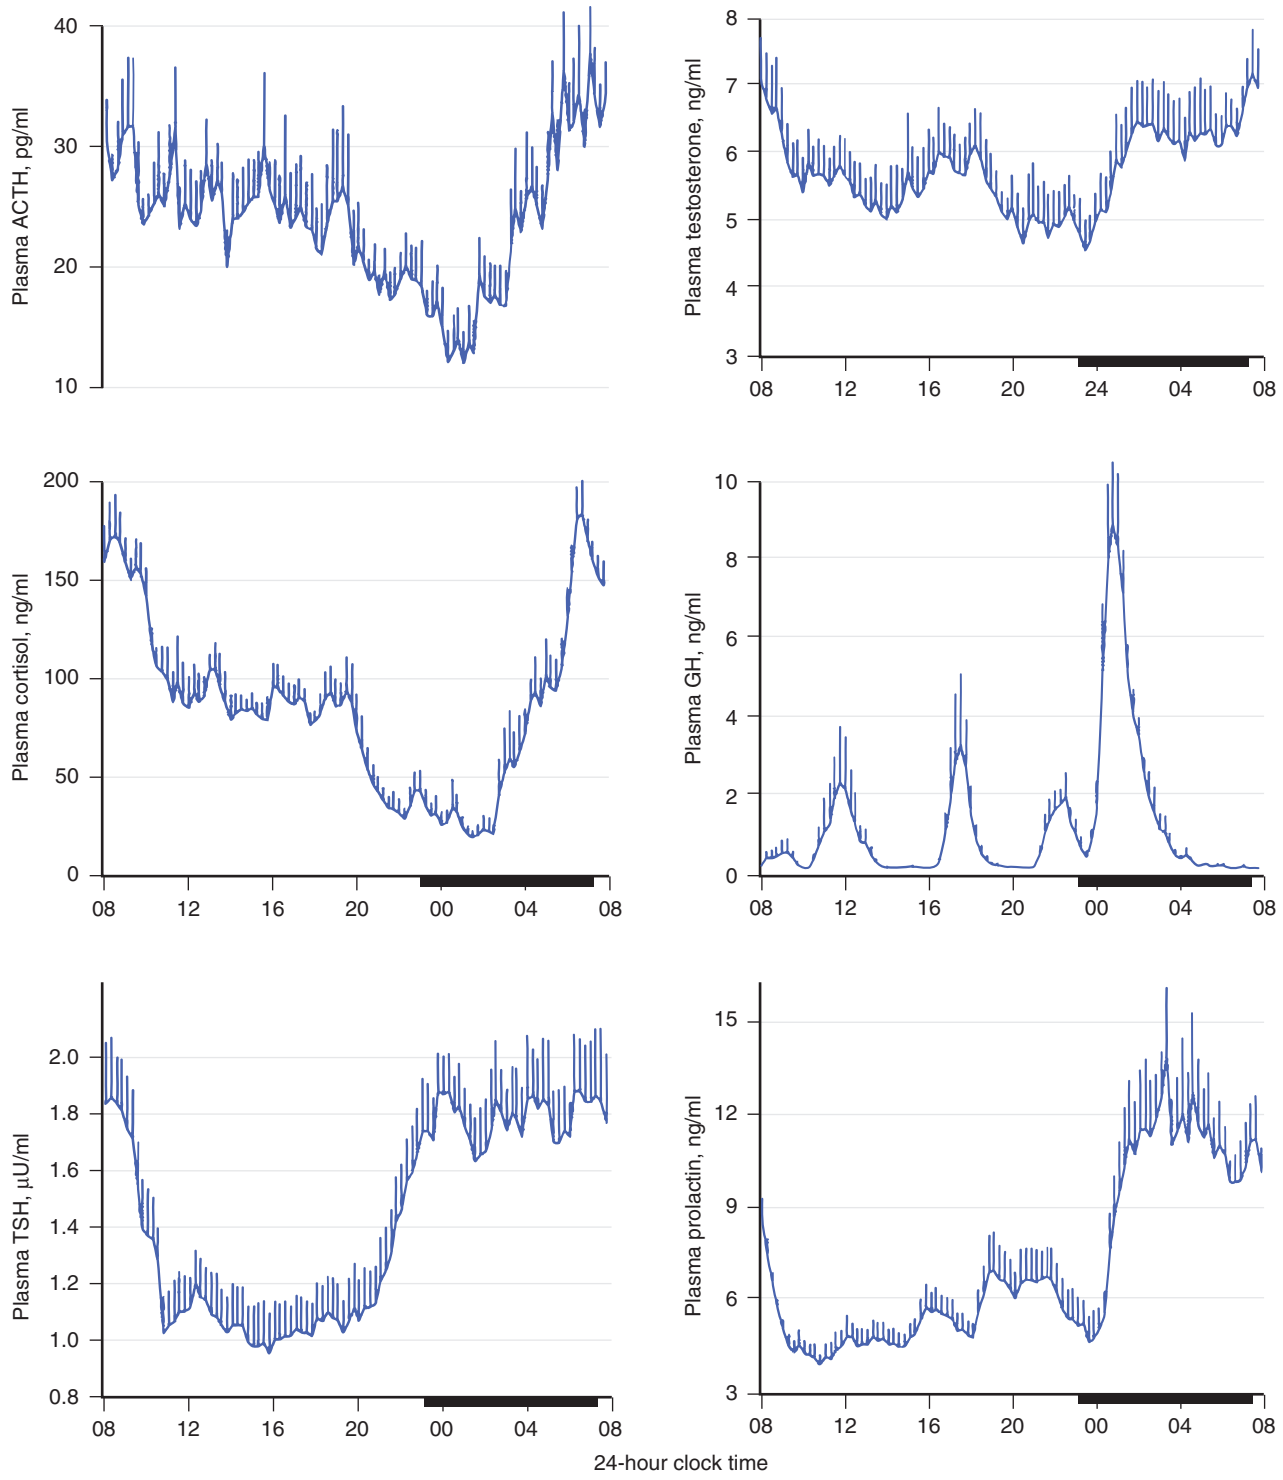
Interesting changes occur in gonadotropin secretion as a child passes through puberty into adulthood. Early in puberty, the amplitude of the pulses increases during sleep at night, especially for LH, but in adulthood, this nocturnal rise is lost. In patients with anorexia nervosa, the pattern of gonadotropin secretion often reverts to this pubertal pattern. This phenomenon suggests that body composition may in some way affect regulation of the pulsatile secretion of gonadotropins. The percentage of body fat has been proposed as being important in the timing of the onset of puberty. Recent studies implicate leptin as the signal indicating this change in body composition.

NEUROENDOCRINE DISEASE

Diseases of the Hypothalamus

Diseases may affect the hypothalamus by discrete localization in the hypothalamus, being part of a generalized central nervous system (CNS) disease such as neurosarcoidosis, or indirectly by a process such as hydrocephalus (Table 223-1). Furthermore, hormonal changes mediated by functional alterations in hypothalamic regulation may occur in systemic illnesses.

The axons projecting to the median eminence that contain the various hypophysiotropic factors are concentrated in the basal portion of the hypothalamus. Thus, lesions located within this final common pathway might be expected to cause significant decreases in secretion of some or all of the pituitary hormones except prolactin, which may increase because of the elimination of tonic inhibition by dopamine. Diabetes insipidus (Chapter 225) may also occur. Symptoms resulting from hypothalamic dysfunction are related to the size of the lesion and consequently to the area of the hypothalamus involved, as well as to the rapidity of the increase in lesion size. Slowly growing lesions tend to cause problems of hormone dysregulation rather than dramatic symptoms. Large, slowly growing lesions may cause more acute problems, such as when a slight increment in growth eliminates the remaining vestiges of vasopressin or ACTH secretion. The best way of discerning lesions affecting the hypothalamus is by magnetic resonance imaging (MRI) with gadolinium enhancement, although computed tomographic (CT) scanning with intravenous contrast is also effective. Formal visual field testing may discern impingement of the optic nerves and chiasm by hypothalamic lesions. Detailed testing of hypothalamic-pituitary function may reveal evidence of functional hypothalamic disruption with great sensitivity.



E-FIGURE 223-1. Hormonal circadian rhythms. Mean (+SEM) profiles of plasma levels of adrenocorticotropic hormone (ACTH), cortisol, thyroid-stimulating hormone (TSH), testosterone, growth hormone (GH), and prolactin from a group of 8 to 12 normal men studied at 15-minute intervals for 24 hours. The sleep times are indicated by black bars. (Redrawn with permission from Van Cauter E. Diurnal and ultradian rhythms in human endocrine function: a minireview. *Horm Res.* 1990;34:45-53.)

TABLE 223-1 ETIOLOGY OF HYPOTHALAMIC DISEASE

NEONATES
Congenital embryopathic disorders: agenesis of the corpus callosum, cleft palate *(HESX1)*
Congenital disorders: isolated hormone and receptor mutations, combined pituitary hormone deficiency *(PIT1, PROP1)*, Laurence-Moon-Bardet-Biedl syndrome, Prader-Labhart-Willi syndrome
Tumors: glioma, hemangioma
Trauma
Hydrocephalus, hydranencephaly, kernicterus
1 MONTH TO 2 YEARS
Tumors: glioma, especially optic glioma, hemangiomas
Infiltrative disease: Langerhans cell histiocytosis, meningitis
Hydrocephalus
2-10 YEARS
Tumors: craniopharyngioma, glioma, dysgerminoma, hamartoma, leukemia, ganglioneuroma, ependymoma, medulloblastoma
Infiltrative disease: Langerhans cell histiocytosis, meningitis, tuberculosis, encephalitis
Irradiation: for nasopharyngeal tumors, intracranial tumors, leukemia
Functional: psychosocial deprivation
10-25 YEARS
Congenital disorders: Kallmann's syndrome, gonadotropin-releasing hormone receptor defects
Tumors: craniopharyngioma, pituitary tumors, glioma, hamartoma, dysgerminoma, dermoid, lipoma, neuroblastoma
Trauma: subarachnoid hemorrhage, vascular aneurysm, arteriovenous malformation
Infiltrative diseases: Langerhans cell histiocytosis, sarcoidosis, tuberculosis, meningitis, encephalitis, leukemia
Chronic hydrocephalus or increased intracranial pressure
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
25-50 YEARS
Tumors: pituitary tumors, meningioma, craniopharyngioma, Rathke's cleft cyst, glioma, lymphoma, angioma, colloid cysts, ependymoma
Infiltrative diseases: sarcoidosis, Langerhans cell histiocytosis, tuberculosis, viral encephalitis
Subarachnoid hemorrhage, vascular aneurysms, arteriovenous malformation
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Nutritional: Wernicke's disease
Functional: hypogonadotropic hypogonadism associated with weight loss, exercise
50 YEARS AND OLDER
Tumors: pituitary tumors, meningioma, craniopharyngioma, sarcoma, glioblastoma, lymphoma, colloid cysts, ependymoma
Vascular: infarct, subarachnoid hemorrhage, pituitary apoplexy, aneurysm
Irradiation: for pituitary adenoma, nasopharyngeal tumors, intracranial tumors
Infiltrative diseases: encephalitis, sarcoidosis, meningitis
Nutritional: Wernicke's disease

CONGENITAL EMBRYOPATHIC DISORDERS

The most common embryopathic disorders to affect the hypothalamus are the midline cleft syndromes, which cause varying degrees of defects of midline structures, especially the optic and olfactory tracts, the septum pellucidum, the corpus callosum, the anterior commissure, the hypothalamus, and the pituitary. The clinical features of patients with midline cleft defects varies in severity from cyclopia to cleft lip and from isolated hypothalamic hormone defects to panhypopituitarism. The combination of absent septum pellucidum associated with optic nerve hypoplasia is referred to as septo-optic dysplasia and is associated with abnormalities of hypothalamic and other diencephalic structures. Some patients with septo-optic dysplasia and hypothalamic hypopituitarism have sexual precocity, presumably caused by a lack of inhibitory influences from other parts of the hypothalamus and intact GnRH-producing structures. Children with very mild midline cleft defects consisting of cleft lip, cleft palate, or both have an increased risk of GH and other pituitary hormone deficiencies. MRI studies of patients with "idiopathic" GH deficiency show absence of the infundibulum in nearly 50%.

Mutations responsible for these developmental defects are the subject of active investigation.[3] Mutations in the human *HESX1*, *SOX2*, *SOX3*, and *OTX2* transcription factor genes cause agenesis of the corpus callosum and panhypopituitarism. Case reports of mutations in other transcription factors, such as *Pitx2* (Rieger's syndrome) and *GLI2*, describe patients with varying brain and skull developmental abnormalities, along with varying degrees of hypopituitarism. Kallmann's syndrome is a condition characterized by anosmia or hyposmia and hypogonadotropic hypogonadism. The diagnosis is made by finding anosmia and low gonadotropin levels, and MRI will show absence or hypoplasia of the olfactory bulbs. The X-linked form of Kallmann's syndrome, representing about 85% of cases, is due to a gene defect *(KAL1)* resulting in loss of function of a protein called anosmin that facilitates the embryologic migration of GnRH-producing neurons from the olfactory placode to the hypothalamus and the olfactory nerves to the olfactory bulbs. Other genes implicated in Kallmann's syndrome include *PROK2*, *PROKR2*, *FGFR1*, and *FGF8*. The pituitary is usually intact in this condition, and treatment with pulsatile GnRH therapy or gonadotropins results in spermatogenesis and normal gonadal function. In some patients, other abnormalities may be present, including cerebellar ataxia, nerve deafness, color blindness, cleft lip and palate, mental retardation, disordered thirst, unilateral renal agenesis, synkinesia, dental agenesis, and skeletal anomalies such as syndactyly and polydactyly; these abnormalities tend to track with specific mutations of the genes outlined above.

TUMORS

The most common tumors affecting the hypothalamus are pituitary adenomas that have significant suprasellar extension. These tumors can cause varying degrees of hypopituitarism and hyperprolactinemia, either by compressing the normal pituitary or, more commonly, by affecting the pituitary stalk and mediobasal hypothalamus. Surprisingly, diabetes insipidus (Chapter 225) is a rare finding in patients with pituitary adenomas. In patients with normal or elevated prolactin levels, indicating a hypothalamic/stalk site of the lesion rather than pituitary destruction, pituitary function often returns following therapy.

Craniopharyngiomas are the next most common tumors affecting the hypothalamus.[4] Microscopically, craniopharyngiomas consist of cysts alternating with stratified squamous epithelium. The cyst fluid is usually thick and dark, and the material is often calcified. They arise from remnants of Rathke's pouch. A closely related lesion is Rathke's cleft cyst, which develops from the space between the anterior and rudimentary intermediate lobes. Rathke's cleft cysts are lined with cuboidal (as opposed to squamous) epithelium, and the cyst fluid is usually a white mucoid fluid. Craniopharyngiomas may be difficult to remove in their entirety, and postoperative radiation reduces recurrences. Rathke's cleft cysts less commonly recur. Craniopharyngiomas most commonly arise during childhood, but they may also occur in adults and even elderly people. These tumors come to attention because of mass effects, including headache, vomiting, visual disturbance, seizures, hypopituitarism, and polyuria. Some patients have galactorrhea, amenorrhea, and hyperprolactinemia, features suggestive of a prolactinoma. Careful endocrine testing reveals varying degrees of hypopituitarism in 50 to 75%, modest hyperprolactinemia in 25 to 50%, and often diabetes insipidus. Surgical extirpation of craniopharyngiomas commonly causes a worsening of pituitary function, often resulting in complete panhypopituitarism and diabetes insipidus because of stalk section, and may cause damage to the hypothalamic centers that regulate thirst, body temperature, and food intake, resulting in severe obesity. Recently, the technique of hypothalamic-sparing surgery for craniopharyngiomas has resulted in less obesity without increasing the recurrence rate.[5] Irradiation may also be helpful, especially in children.

Suprasellar dysgerminomas arise from primitive germ cells that have migrated to the CNS during fetal life and are structurally identical to germ cell tumors of the gonads. They most commonly occur in children, in whom they cause decreased growth because of hypopituitarism, as well as diabetes insipidus and visual problems. Hyperprolactinemia occurs in more than 50% of affected children, and 10% have precocious puberty from the production of human chorionic gonadotropin (HCG) by the tumor. The finding of an elevated HCG level in the spinal fluid may be diagnostic. As opposed to craniopharyngiomas, these tumors are very radiosensitive, and radiation therapy combined with chemotherapy is the preferred treatment.

A hypothalamic hamartoma is a nodule of growth of hypothalamic neurons, glia, and fiber bundles attached by a pedicle to the hypothalamus between the tuber cinereum and the mammillary bodies and extending into the basal cistern.[6] Asymptomatic hamartomas may be present in up to 20% of random autopsies; rarely, these lesions may enlarge and disrupt hypothalamic function because of compression of adjacent tissue. Less commonly, they may cause seizures, especially gelastic seizures. Some hamartomas can be associated with other congenital anomalies and mutations in the

transcription factor gene *GLI3*. A variant of hamartoma consisting of similar tissue present within the anterior pituitary but without a neural attachment to the hypothalamus is called a choristoma or gangliocytoma. These neuronal tumors are of particular endocrine interest because they can produce hypophysiotropic hormones. A number of cases associated with precocious puberty have been reported in which the hamartomas produced GnRH. Successful treatment has been reported with surgery and with the administration of a long-acting GnRH analogue that suppresses gonadotropin secretion but does not affect the tumor itself. If the hamartoma does not cause other problems from mass effects, medical therapy with the GnRH analogue may be the best choice because surgery can be noncurative or even fatal. Some gangliocytomas have been reported that produce GHRH and acromegaly or CRH and Cushing's syndrome.

Other tumors and space-occupying lesions occurring in the suprasellar area include arachnoid cysts, meningiomas, gliomas, astrocytomas, chordomas, infundibulomas, cholesteatomas, neurofibromas, lipomas, and metastatic cancer (particularly from the breast and lung). Any such lesion may manifest as varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia, and surgical therapy often worsens the hormonal deficit and may cause other hypothalamic damage.

INFLAMMATORY AND INFILTRATIVE DISORDERS

CNS involvement in cases of sarcoidosis (Chapter 95) occurs in 1 to 5% of patients as determined on clinical grounds, and in up to 16% of cases at autopsy. Isolated CNS sarcoidosis is uncommon. When sarcoidosis does involve the CNS, the hypothalamus is involved in 10 to 20% of cases. Sarcoid granulomas can involve the hypothalamus, stalk, or pituitary and may be infiltrative or occur as a mass lesion.[7] The most common endocrine findings are varying degrees of hypopituitarism, diabetes insipidus, and hyperprolactinemia. Obesity secondary to hypothalamic involvement by sarcoidosis has also been reported. In patients with isolated CNS sarcoidosis, the diagnosis may be extremely difficult. Examination of cerebrospinal fluid usually shows elevated protein levels, low glucose levels, pleocytosis, and variable elevations of angiotensin-converting enzyme. However, biopsy is often necessary. Although corticosteroid therapy has been reported to at least partially reverse the thirst disorders, anterior pituitary hormone deficits usually do not respond.

Langerhans cell histiocytosis infiltration of the hypothalamus may cause diabetes insipidus, varying degrees of hypopituitarism, and hyperprolactinemia.[8] It is the most common cause of diabetes insipidus in children. Usually, this infiltration appears as a thickening of the pituitary stalk, but it may also appear as a mass lesion of the hypothalamus or pituitary (Fig. 223-2). Osteolytic lesions may be present in the jaw or mastoid, so radiographs of the jaw are a worthwhile part of the diagnostic evaluation of an unknown suprasellar mass or diabetes insipidus. Therapy consists of local surgery, focal irradiation, or chemotherapy with alkylating agents and high-dose corticosteroids.

Other infiltrative diseases (e.g., tuberculosis, lymphomas, fungal diseases) can also cause a progressive alteration in hypothalamic regulation of pituitary hormone secretion (E-Fig. 223-2).

VASCULAR DISEASE

An enlarging aneurysm may manifest as a mass lesion of the hypothalamic-pituitary area and may cause hypopituitarism and visual field defects. Obviously, the distinction must be made before surgery. Tumors and aneurysms may also coexist, and careful radiologic evaluation with MRI is necessary to discern such association. Hypothalamic disease caused by vascular infarction is extremely rare. In the past several years, it has been found that subarachnoid hemorrhage may be associated with varying degrees of hypopituitarism in almost half of cases. On the other hand, diabetes insipidus is uncommon.

TRAUMA

Traumatic brain injury (TBI) (Chapter 399) can cause defects ranging from isolated ACTH deficiency to panhypopituitarism with diabetes insipidus. Within the first 72 hours of trauma, GH, LH, ACTH, TSH, and prolactin levels may actually be elevated in blood, perhaps because of acute release. These levels subsequently fall, and either pituitary function returns to normal or hypopituitarism develops. Overall, the frequency of hypopituitarism in TBI is less than in subarachnoid hemorrhage, occurring in about one fourth of surviving patients. In patients dying of head injury, damage to the hypothalamus, pituitary stalk, or anterior pituitary has been found in up to 86% of cases.[9] The paraventricular and supraoptic nuclei and median eminence are particularly involved with microhemorrhages, hence the high frequency of panhypopituitarism with diabetes insipidus. With frontal injuries, the brain travels backward, but the pituitary cannot move; consequently, the pituitary stalk becomes avulsed, with interruption of the portal vessels. Most patients with head injury are hyperprolactinemic, which clinically confirms that the hypothalamus or stalk is the primary site of injury. In the past, pituitary function in patients with TBI and subarachnoid hemorrhage has not been assessed, and the role of untreated hypopituitarism in the long-term disability of such patients is unknown. Acute deficiency of ACTH/cortisol may be life-threatening. Therefore, cortisol levels should be monitored carefully in the hours and days after such events, and hypocortisolism treated with stress doses of glucocorticoids when necessary.

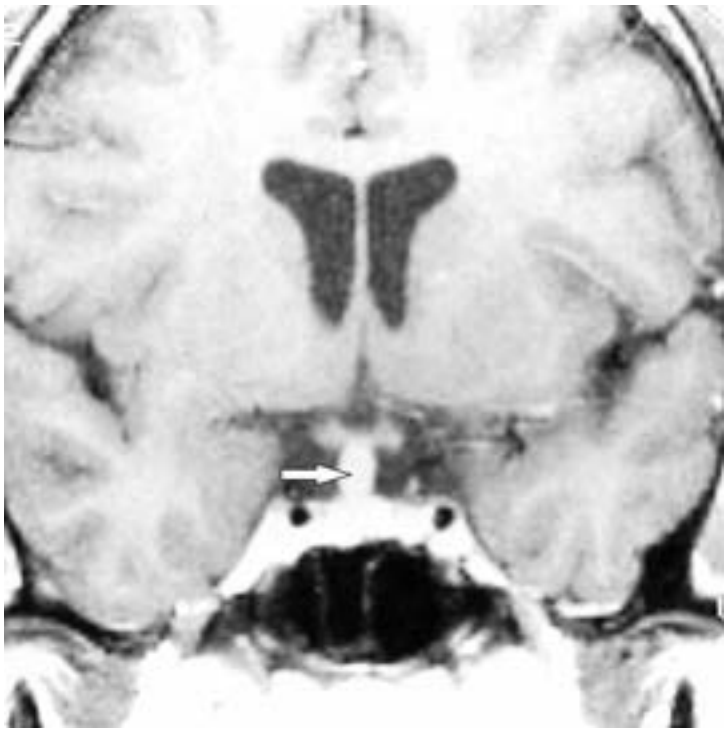

FIGURE 223-2. Thickened pituitary stalk in Langerhans cell histiocytosis. Magnetic resonance image of patient with Langerhans cell histiocytosis who manifested initially with amenorrhea, galactorrhea, and diabetes insipidus. Arrow points to the thickened pituitary stalk. (Reproduced with permission from Purdy LP, Molitch ME. Sudden onset of diabetes insipidus in an adolescent. *Endocr Trends.* 1998;5:1-7.)

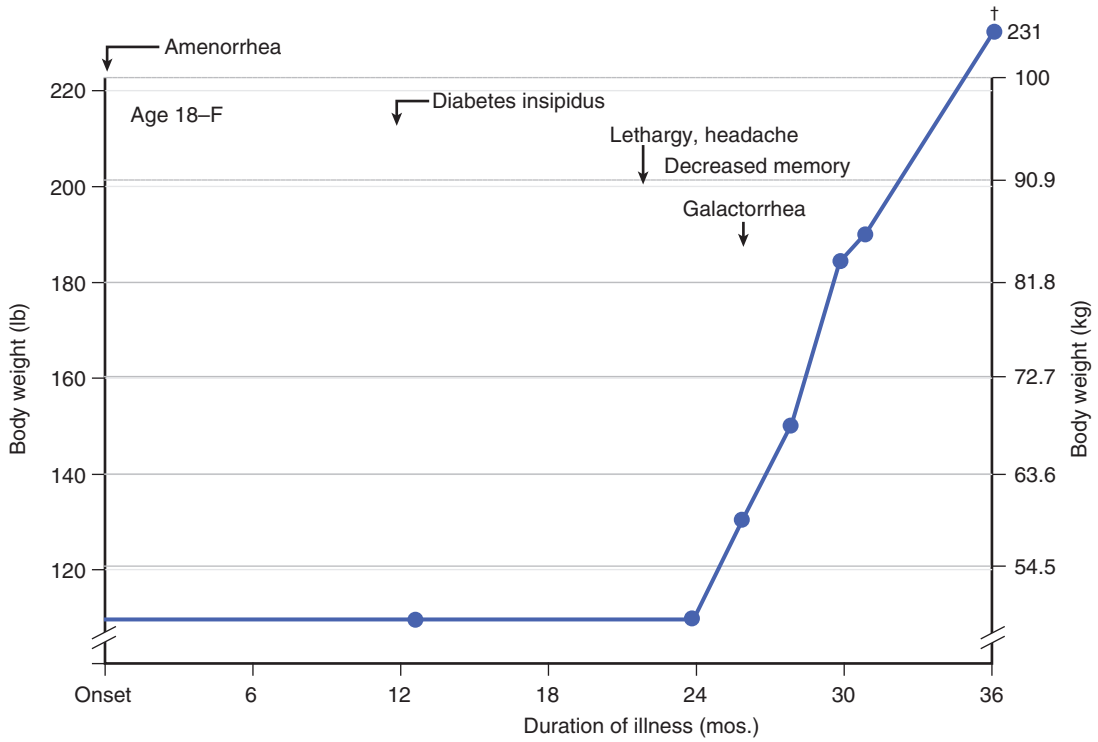
IRRADIATION

Whole-brain irradiation for intracranial neoplasms frequently results in hypothalamic dysfunction, as evidenced by endocrine abnormalities and behavioral changes. The most common endocrine abnormality is hyperprolactinemia, but hypopituitarism also occurs. When the radiotherapy is targeted to the hypothalamic area, hypopituitarism occurs even more frequently.[10] The frequency of loss of pituitary function is so high that all patients who have had their pituitary and hypothalamic areas irradiated must be monitored periodically for the purpose of detecting these deficits. However, the development of such deficiencies may take many years, so that yearly testing is warranted for up to 20 years. It appears that stereotactic irradiation using the gamma knife apparatus or a linear accelerator for pituitary and other parasellar tumors causes a risk of hypopituitarism similar to that of conventional irradiation.

Effects of Hypothalamic Disease on Pituitary Function

Hypothalamic disease can cause both pituitary hyperfunction and hypofunction in varying degrees of severity. Although severe disease can cause absolute deficiencies of the various hormones, milder disease may cause a subtle alteration in feedback loops and timing such that, for example, the integration of signals necessary for menstrual cycling is lost, with subsequent "hypothalamic" amenorrhea (Chapter 236). Furthermore, the hypothalamic defects may be interrelated. The rather common finding of hyperprolactinemia occurring with hypothalamic dysfunction causes a hypogonadotropic hypogonadism that is reversible when the elevated prolactin levels are brought down to normal. In many cases, no structural lesion can be found on MRI,



E-FIGURE 223-2. Progressive hypothalamic dysfunction from infiltrative disease of the hypothalamus. Clinical sequence in an 18-year-old woman with hypothalamic tuberculosis that progressed despite antituberculosis therapy. Her initial endocrine symptom was amenorrhea, which was followed over several months by the development of diabetes insipidus, lethargy, headache, decreased memory, galactorrhea, and culminating in a massive weight gain over the year prior to her demise. (Redrawn with permission from Bray GA, Gallagher TF Jr. Manifestations of hypothalamic obesity in man: a comprehensive investigation of eight patients and a review of the literature. *Medicine.* 1975;54:301-330.)

and a functional defect caused by altered neurotransmitter regulation is invoked.

GROWTH HORMONE

Loss of normal GH secretion is the most common hormonal defect occurring with structural hypothalamic disease. About three fourths of cases with congenital idiopathic GH deficiency have a normal GH response to exogenous GHRH, which implies that the defect is probably disordered hypothalamic regulation. Defects in the gene for GHRH have not been found, but a rare form of GH deficiency has been found to be caused by a mutation in the GHRH receptor. A reversible form of idiopathic GH deficiency caused by inadequate parental care and affection is referred to as the emotional deprivation syndrome or psychosocial dwarfism. Restoration of a proper social environment for such a child results in prompt normalization of GH secretion and growth. It has been hypothesized that the disordered GH regulation is due to psychogenic alteration of the neurotransmitter balance necessary for normal GHRH and somatostatin secretion. Other systemic illnesses such as inflammatory bowel disease may also cause decreased GH secretion and growth; treatment of the systemic illness will correct the growth abnormality. Treatment of children and adults with GH deficiency is discussed in Chapter 224.

GONADOTROPINS

Hypothalamic Hypogonadism

The primary defect in this group of disorders is thought to involve the secretion of GnRH, with resultant impairment in pituitary gonadotropin secretion and gonadal function. The disorders causing these conditions may be primary (i.e., congenital) defects or acquired. Depending on the time of onset, they are manifested as either delayed puberty, interruption of pubertal progression, or loss of adult gonadal function. The lesions causing these disorders may cause loss of other hormones or may be isolated to GnRH. Loss of gonadotropin secretion as the result of hypothalamic structural damage is the second most common defect after GH deficiency. However, a substantial portion of these defects are due to hyperprolactinemia and are reversible with correction of the hyperprolactinemia. In some cases, the defect is idiopathic. Defects in the gene for GnRH have not been found, but mutations in the GnRH receptor do occur.

In children, if the disorder is limited to GnRH and the gonadotropins, prior growth and development are normal, but the growth spurt occurring at puberty is lost. Undescended testes are present in 50% of patients with GnRH deficiency, probably secondary to the absence of gonadotropins during fetal development. The most common congenital lesion causing prepubertal GnRH deficiency is Kallmann's syndrome, which affects 50% of males and 37% of females seen with isolated gonadotropin deficiency (see earlier). In patients with GnRH deficiency, replacement of GnRH through subcutaneous administration every 2 hours with a portable pump causes a rapid rise in LH and FSH, a rise in testosterone to normal, and the development of normal spermatogenesis. Similar approaches in women result in ovulatory cycles in 80%. The success of such therapy confirms the original hypothesis of a primary defect of GnRH secretion. In men, comparable results can be obtained with exogenous gonadotropins given three times per week and is much more practical. GnRH therapy is not successful in those with GnRH receptor mutations. Replacement with testosterone alone causes adequate androgenization but does not result in an increase in testicular size or in spermatogenesis.

Loss of formerly normal GnRH secretion in adults may be due to structural hypothalamic damage such as a tumor, a functional change unassociated with a detectable lesion, or hyperprolactinemia.[11] Structural disease must be excluded in such patients by CT or MRI. Most cases of functional hypogonadotropic hypogonadism occur in women, the most common causes being weight loss, excessive exercise, psychogenic stress, or systemic illness, but idiopathic forms occur as well. In some patients, exercise results in a loss of body fat not detected with total body weight measures, and it is unclear whether the hypogonadism is directly due to the loss of body fat or to the exercise per se. Studies of pulsatile gonadotropin secretion in such patients reveal absent pulses. Usually, the gonadotropin response to injected GnRH is normal. Regain of weight and stopping of the exercise result in resumption of normal gonadal function. Furthermore, the administration of leptin to such women results in a resumption of normal gonadotropin pulsatile secretion and ovulation, confirming the key role leptin has in mediating the influence of body energy stores on reproductive function.[12] However, in the idiopathic form, spontaneous resolution does not occur. Hyperprolactinemia occurring postpubertally can also decrease GnRH and the pulsatile secretion of LH and FSH and thereby result in anovulation with oligomenorrhea and amenorrhea in women and impotence and infertility in men.

Two goals in the treatment of idiopathic functional hypogonadotropic amenorrhea are (1) restoration of a normal estrogen status to promote well-being and prevent osteoporosis and (2) facilitation of ovulation for fertility. The former can generally be achieved with cyclic estrogen and progesterone, whereas the latter may require clomiphene or GnRH or gonadotropin therapy. In men, similar goals may be achieved with testosterone or GnRH or gonadotropins.

Hypothalamic Hypergonadism (Precocious Puberty)

Precocious puberty is defined as the onset of puberty before the age of 8 years in girls or 9 years in boys. Pseudoprecocious puberty is that resulting from peripheral (gonadal or adrenal) causes. Central, "true," or GnRH-dependent precocious puberty is characterized by hormonal changes similar to those that occur at the time of normal puberty—that is, an increase in the pulsatile release of LH, an increase in the gonadotropin response to GnRH, and an increase in gonadal steroid secretion.[13] GnRH-dependent precocious puberty therefore represents premature activation of the GnRH pulse generator by a variety of lesions, or it may also be idiopathic. Only about 10% of cases of central precocious puberty occur in boys, but they tend to have more serious underlying disease. In boys with central GnRH-dependent precocious puberty, hypothalamic hamartomas account for 38% of cases, other CNS lesions represent 31%, familial disease accounts for 23%, and idiopathic disease accounts for only 8%. The picture is quite different in girls, however: hypothalamic hamartomas account for only 15% of cases, other CNS lesions represent 14%, the McCune-Albright syndrome (polyostotic fibrous dysplasia [Chapter 231]) accounts for 6%, and fully 65% are idiopathic. Dysgerminomas in the suprasellar or pineal region can produce HCG, which acts like LH in its stimulation of gonadal function. Usually, such tumors cause increased sex steroid formation but fail to cause ovulation.

Therapy for central GnRH-dependent precocious puberty consists of surgical removal of the tumor or medical therapy with a long-acting GnRH analogue, either in the form of monthly injections or yearly implants.[14] The latter can suppress gonadotropin and sex steroid hormone levels and cause a stabilization or even regression of secondary sex characteristics and a slowing of growth and bone maturation in most cases. When therapy is discontinued at the normal time of puberty, sex steroid levels increase, secondary sexual characteristics again develop, growth increases, and regular menses develop spontaneously.

PROLACTIN

Hypothalamic Hyperprolactinemia

Structural or infiltrative lesions of the hypothalamus, such as those discussed earlier, can decrease the amount of dopamine reaching the lactotrophs and thus cause modest hyperprolactinemia (usually < 100 ng/mL).[15] Because their therapy is quite different, it is very important to differentiate nonsecreting pituitary adenomas with extensive suprasellar extension causing prolactin elevations in this range from prolactin-secreting adenomas, which usually cause prolactin elevations 5 to 50 times higher. A peculiarity of some two-site immunoassays, referred to as the "hook effect," can sometimes cause a very high prolactin level to read falsely normal or just mildly elevated; a 1 : 100 dilution of the serum sample with saline will show the true level when the specimen is rerun. If there is any question about an assay being susceptible to the hook affect, in patients with very large tumors, prolactin should be measured undiluted and at 1 : 100 dilution to avoid this important spurious finding. A number of medications, antipsychotics in particular, can cause hyperprolactinemia, primarily by interfering with central catecholamines (Table 223-2).

Therapy is generally directed at the underlying cause. The hyperprolactinemia itself may impair gonadal function, so efforts may also be made to lower prolactin levels with dopamine agonists. Prolactin levels usually fall quite readily in such patients. Restoration of gonadal function is not automatic, however, because the primary hypothalamic lesion may also directly impair release of GnRH. In that circumstance, both dopamine agonists and sex steroid replacement may be necessary. When administration of psychotropic medications that cause the hyperprolactinemia cannot be stopped, dopamine agonists may be used but very rarely have been reported to exacerbate the psychosis. In such cases and in others in which fertility is not an issue, treatment with cyclic estrogen and progesterone replacement can be carried out safely.

Idiopathic Hyperprolactinemia

Idiopathic hyperprolactinemia is a diagnosis of exclusion. Prolactin levels in this condition are usually less than 100 ng/mL. In such cases, small pituitary or hypothalamic tumors could exist that are beyond the resolution of current imaging techniques, but when such patients are monitored for many years, it is very uncommon for tumors to later be visualized. Idiopathic hyperprolactinemia can cause amenorrhea, galactorrhea, impotence, infertility, and loss of libido, just as occurs with hyperprolactinemia of other causes, so the idiopathic hyperprolactinemia may need to be treated. Premature osteoporosis related to the estrogen deficiency may also occur. The only possible treatment is dopamine agonists, and these agents are successful in more than 90% of cases. Alternatively, cyclic estrogen and progesterone replacement may be given, but fertility will not be restored.

THYROID-STIMULATING HORMONE

Hypothalamic hypothyroidism is due to a central lesion that impairs the secretion of TRH, usually along with the loss of other hormones.[16] It occurs considerably less commonly than hypothalamic GH and gonadotropin deficiency. Defects in the gene for TRH have not been detected, but a case has been reported of a TRH receptor mutation causing hypothyroidism. TSH levels in this syndrome are generally normal or even slightly elevated. TSH in these patients is biologically less active than normal and binds to the TSH receptor less well because of altered glycosylation as a result of the TRH deficiency. Treatment is with L-thyroxine, and monitoring of therapy is done solely by measurement of free thyroxine (T_4) levels and not TSH levels.

ADRENOCORTICOTROPIC HORMONE

ACTH deficiency caused by hypothalamic lesions is uncommon.[17] It may occur with the loss of other hormones but may also appear as an isolated deficiency. The most common cause, of course, is prior suppression by exogenous or endogenous glucocorticoids. In the absence of CNS lesions or a history of trauma, many cases of isolated ACTH deficiency appear to be due to a pituitary autoimmune disorder. Treatment is with glucocorticoids; mineralocorticoids are not needed.

Effects of Hypothalamic Disease on Other Neurometabolic Functions

A number of functions that affect the internal milieu, in addition to anterior and posterior pituitary function, are regulated at least in part by the hypothalamus and include temperature control, behavior, consciousness, memory, sleep, food intake, and carbohydrate metabolism.

ALTERATIONS IN FOOD INTAKE

Hypothalamic Obesity

Destruction of the mediobasal hypothalamus will sometimes inhibit satiety and may result in hyperphagia and hypothalamic obesity.[18] The hyperphagia is due to destruction of noradrenergic fibers originating in the paraventricular nucleus and passing through the mediobasal hypothalamus. Because of their location, such lesions also usually produce hypopituitarism and diabetes insipidus. In a number of rare syndromes (Prader-Willi, Laurence-Moon-Biedl-Bardet) with obesity as a major characteristic, hypothalamic causes have been postulated but not proved.

Hypothalamic Anorexia

Lesions of the lateral hypothalamus, which destroy nigrostriatal dopaminergic fibers that pass through this area, produce hypophagia along with an increase in peripheral norepinephrine turnover and metabolic rate. This syndrome is very rare, probably owing to the requirement for bilateral lesions. The hormonal changes that occur in anorexia nervosa appear to all be secondary to the weight loss, and no evidence has been found for a primary hypothalamic disorder in this syndrome.

HYPERGLYCEMIA

Hypothalamic activation as part of the generalized response to stress can cause release of GH, prolactin, and ACTH, which serve as counter-regulatory hormones with respect to insulin. These hormones promote lipolysis, gluconeogenesis, and insulin resistance, resulting in glucose elevation. Of more importance in the acute response to stress, this hypothalamic response results in sympathetic activation with release of catecholamines that inhibit insulin secretion and stimulate glycogenolysis.

TEMPERATURE REGULATION

The anterior hypothalamus and preoptic area contain temperature-sensitive neurons that respond to internal temperature changes by initiating certain thermoregulatory responses necessary to restore a constant temperature. Measures that dissipate heat include cutaneous vasodilation, sweating, and panting, and measures that increase body heat include increasing metabolic heat production, shivering, and cutaneous vasoconstriction.

Rare patients have been reported with anterior hypothalamic lesions that cause paroxysmal or sustained hypothermia or hyperthermia from failure of these thermoregulatory activities. Some cases of paroxysmal hypothermia and hyperthermia respond to anticonvulsant medications, which suggests that the neuronal discharge effecting the temperature changes is seizure-like.

Poikilothermy results from an inability to dissipate or generate heat to keep the body temperature constant in the face of varying ambient temperatures. This condition results from bilateral lesions in the posterior hypothalamus and rostral mesencephalon, which are the areas responsible for the final integration of thermoregulatory neural efferents. Patients with this condition do not feel discomfort with temperature changes and are unaware of having a problem. Depending on the ambient temperature, they may experience life-threatening hypothermia or hyperthermia.

ANTERIOR PITUITARY

MARK E. MOLITCH

ANATOMY AND EMBRYOLOGY

The pituitary is divided into anterior (adenohypophysis) and posterior (neurohypophysis) lobes. The optic chiasm, formed by the decussation of the optic nerves, is positioned directly above the pituitary gland. Specialized vascular structures located in the median eminence of the hypothalamus drain into portal veins that course down the pituitary stalk to join the sinusoidal capillaries of the anterior lobe. Hypothalamic hormones enter these capillaries and flow to the anterior pituitary (Fig. 224-1). Venous drainage from the anterior lobe is into the cavernous sinuses, which drain into the petrosal sinuses. The six major pituitary cell types include somatotrophs (growth hormone [GH] producing), lactotrophs (prolactin [PRL] producing), corticotrophs (adrenocorticotropic hormone [ACTH] producing), thyrotrophs (thyroid-stimulating hormone [TSH] producing), and gonadotrophs (follicle-stimulating hormone [FSH] and luteinizing hormone [LH] producing). Somatotrophs constitute 40 to 50% of anterior pituitary cells; lactotrophs, 15 to 25%; corticotrophs, 10 to 20%; and gonadotrophs 10%. Only 5% of pituitary cells are thyrotrophs.

The pituitary is formed from the fusion of Rathke's pouch (which gives rise to the anterior pituitary) and a portion of the ventral diencephalon (which gives rise to the posterior pituitary). Several transcription factors are important in the development of the various types of pituitary cells. LHX3 and LHX4 are present in somatotrophs, lactotrophs, gonadotrophs and thyrotrophs, and mutations in these genes result in deficits of GH, PRL, TSH, and the gonadotropins, although the deficits with LHX4 mutations are more variable.[1] Mutations in *HESX1* usually are associated with dysplasia of the septum pellucidum and optic tracts, in addition to multiple pituitary hormone deficits. The transcription factor Pit-1 is produced in somatotrophs, lactotrophs, and thyrotrophs. Mutations in the *PIT1 (POU1F1)* gene prevent the development of these cells and cause deficiencies of GH, PRL, and TSH. This lineage relationship explains why some GH-producing tumors also secrete PRL, and some TSH-producing tumors co-secrete GH.[2] PROP-1, another transcription factor, is critical for the development of somatotrophs, lactotrophs, and thyrotrophs. Mutations in the *PROP1* gene result in deficiencies of GH, PRL, and TSH, and in some affected individuals there is delayed puberty. Combined pituitary hormone deficiency (GH, PRL, TSH) has an incidence of about 1 in 8000 births, and 10% have an affected relative. Between 25 and 50% of these cases are due to *PIT1* or *PROP1* mutations. Tpit is specific to corticotroph cells, and TPIT gene mutations cause isolated ACTH deficiency. Rare mutations in several other genes (*SOX 3*, *OTX2*, *FGF8*, and *GLI2*) have also been shown to cause hypopituitarism, and the list continues to grow.

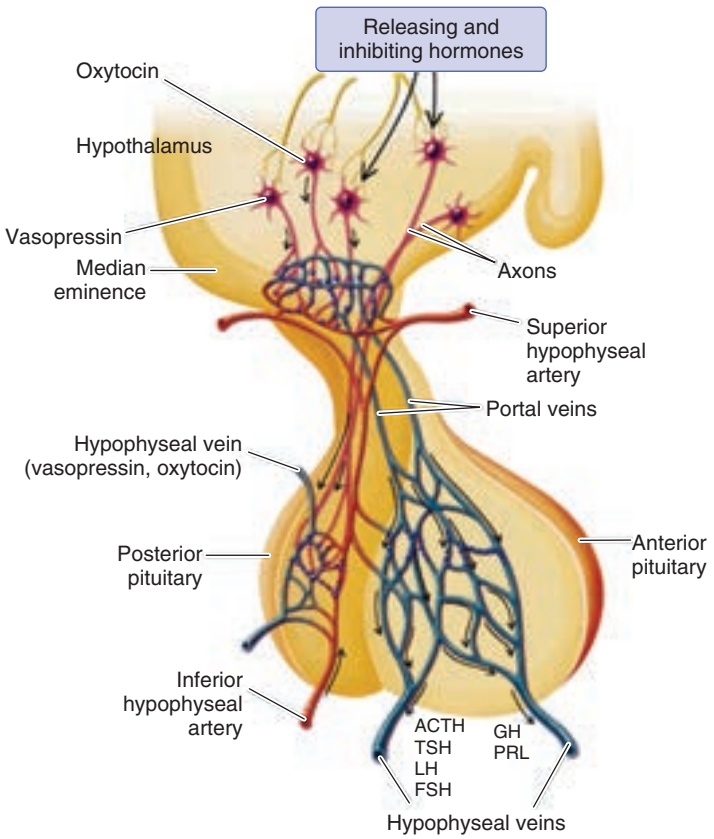

FIGURE 224-1. Structural-functional, humoral, endocrine, and neuroendocrine relationships within the hypothalamic-pituitary unit emphasize the unique and intimate interdependence of neural structures and hormone secretion with the circulation. Oxytocin and vasopressin neuron bodies located in the hypothalamus send axons through the pituitary stalk that terminate in the posterior pituitary, where they release oxytocin and vasopressin into blood vessels within the posterior pituitary. Hypothalamic neurons that produce growth hormone–releasing hormone, corticotropin-releasing hormone, thyrotropin-releasing hormone, and gonadotropin-releasing hormone send their axons through the median eminence to terminate and release their hormones into the hypophyseal-portal circulation. This network of blood vessels is located at the median eminence, which surrounds the pituitary stalk and penetrates into the anterior lobe of the pituitary. These hypothalamic neurohormones stimulate responsive anterior pituitary cells to secrete growth hormone (GH), adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH), respectively. Dopamine neurons reaching the median eminence are responsible for tonic inhibition of prolactin (PRL) secretion from the anterior pituitary, whereas somatostatin released from somatostatinergic neurons inhibit GH and TRH release. (From Melmed S. *The Pituitary.* 3rd ed. London: Elsevier; 2011.)

RADIOLOGY OF THE PITUITARY

Magnetic resonance imaging (MRI) provides excellent resolution of the pituitary and surrounding cerebrospinal fluid (CSF) and vascular and central nervous system structures (Fig. 224-2).[3] There is less radiation exposure with MRI than with computed tomography (CT), allowing repeated imaging. However, bone structures are not as well defined by MRI compared with CT. On MRI, the normal anterior pituitary appears isointense with brain white matter, whereas the posterior pituitary exhibits high signal intensity ("bright spot"). The optic chiasm is readily identified because it is surrounded by hypodense areas. Pituitary adenomas typically appear hypointense on T1-weighted images and show less enhancement with gadolinium than surrounding normal tissue (Figs. 224-3 and 224-4). Focal hypodense areas are also seen in about one fourth of normal individuals, which may correspond to cysts or nonfunctioning small adenomas, emphasizing the importance of endocrine evaluation.

REGULATION OF THE PITUITARY AXIS

The pituitary gland integrates the influences of an array of positive and negative signals to modulate hormone secretion. PRL is the only major pituitary

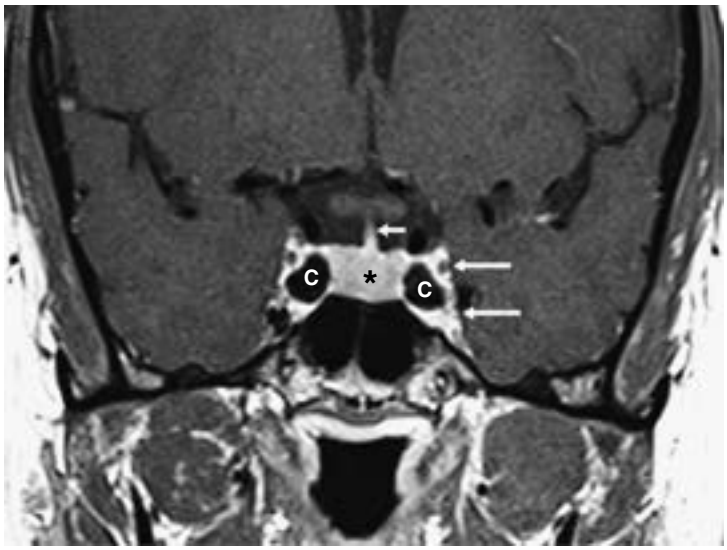

FIGURE 224-2. Magnetic resonance image of normal pituitary. Coronal postcontrast image shows homogeneously enhancing gland (*) and stalk (*short arrow*). Note the greater degree of contrast uptake in the cavernous sinuses, which contain the carotid arteries (C), easily depicted by their flow voids. Small hypointense dots (*long arrows*) are the cranial nerves within the cavernous sinuses. (From Melmed S. *The Pituitary.* 3rd ed. London: Elsevier; 2011.)

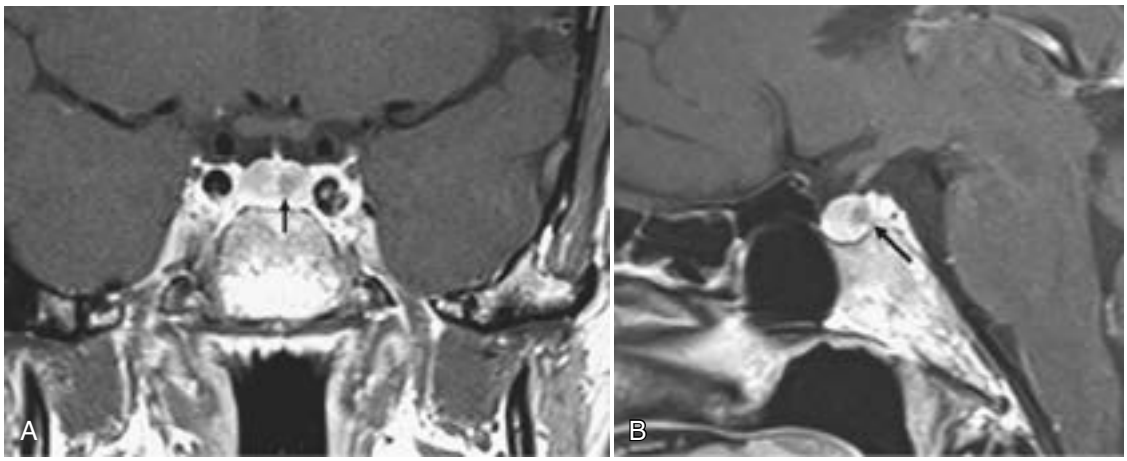

FIGURE 224-3. Magnetic resonance image showing a pituitary microadenoma. (**A**) Coronal and (**B**) sagittal T1-weighted images demonstrate a hypoenhancing lesion within the pituitary gland (*arrows*). (From Melmed S. *The Pituitary.* 3rd ed. London: Elsevier; 2011.)

hormone that is not subject to feedback inhibition by hormones produced in target tissues. It is controlled by positive and negative input from the hypothalamus, the latter being dominant.

The principles of feedback regulation are illustrated by the hypothalamic-pituitary-thyroid axis. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates TSH secretion from the pituitary. TSH increases thyroid hormone secretion, which in turn suppresses hypothalamic TRH as well as pituitary TSH. A typical regulatory loop therefore has both positive (TRH, TSH) and negative (thyroxine [T_4], triiodothyronine [T_3]) components, allowing a high degree of control of hormone levels. The pituitary gland integrates positive TRH signals and the negative effects of thyroid hormone. The concept of feedback regulation is important not only for understanding pituitary physiology but also because it provides the basis for analyzing pituitary gland function using stimulation and suppression tests.

The feedback regulatory systems just described are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycles, and stress have major impacts on the secretion of pituitary hormones (Chapter 2). Because many hormones are released in a pulsatile manner and in a rhythmic fashion, these characteristics of secretion should be considered when attempting to relate serum measurements to normal values. Although it is possible to characterize pulsatile patterns of hormone secretion using frequent blood sampling (every 10 minutes), this is not practical in a clinical setting. Alternative approaches include stimulation and suppression tests or the use of "integrated" measurements of hormone production, such as 24-hour urine free cortisol as an index of ACTH secretion, or insulin-like growth factor (IGF)-I as a biological marker of GH action.

HYPOPITUITARISM

Pituitary hormone deficiencies can be caused by loss of hypothalamic stimulation or by direct loss of pituitary function. When hypopituitarism is accompanied by diabetes insipidus or hyperprolactinemia, one should consider hypothalamic etiologies.

PATHOBIOLOGY

A variety of congenital and acquired causes of hypopituitarism have been described (Table 224-1). Congenital deficiencies of multiple pituitary hormones are often caused by mutations in the genes for the transcription factors mentioned previously *(HESX1, LHX3, PIT1, PROP1)*. Gene mutations have been found at several steps leading to pituitary hormone secretion, including those for the hypophysiotropic releasing factor receptors for gonadotropin-releasing hormone (GnRH), growth hormone–releasing hormone (GHRH), and TRH; those for the pituitary hormone structures for GH, ACTH, and the β-subunits of FSH, TSH, and LH; and those for the target organ receptors for GH, ACTH, TSH, and LH. Mutations of the GH gene have been shown to be heterogeneous. Some are large deletions that are inherited in an autosomal recessive manner and involve genetic recombination between related DNA sequences in the duplicated GH gene cluster. Point mutations have also been described, and some of these can be inherited in an autosomal dominant manner. Mutations of the other types described earlier generally cause autosomal recessive forms of selective hormone deficiencies.

Neoplastic lesions, particularly pituitary macroadenomas, are the most common cause of acquired hypopituitarism. Pituitary adenomas cause hypopituitarism in several different ways. In some cases, there is direct destruction

TABLE 224-1 CAUSES OF HYPOPITUITARISM

GENETIC DEFECTS
Hypophysiotropic hormone gene defects
Hypophysiotropic hormone receptor gene defects
GHRH receptor defect
GnRH receptor defect
TRH receptor defect
Pituitary hormone gene defects
Gonadotropins: LH β- and FSH β-subunit gene defects
GH: defects in GH gene
Thyrotropin: defects in TSH β-subunit gene
Multiple hormone (GH, PRL, TSH) defects due to mutation in *PIT1* and *PROP1* genes
Pituitary hormone receptor genetic defects
GH receptor defects: GH insensitivity syndrome (Laron-type dwarfism)
ACTH receptor defects: congenital insensitivity to ACTH
LH receptor defects
FSH receptor defects
TSH receptor defects
CONGENITAL EMBRYOPATHIC DEFECTS
Anencephaly
Midline cleft defects: septo-optic dysplasia, basal encephalocele, cleft lip and palate
Pituitary aplasia
Kallmann's syndrome (GnRH defect with anosmia)
ACQUIRED DEFECTS
Tumors: pituitary adenomas, craniopharyngiomas, dysgerminomas, meningiomas, gliomas, metastatic tumors, hamartomas, Rathke's cleft cysts
Irradiation
Trauma: surgery, external blunt trauma
Empty sella syndrome
Vascular
Pituitary apoplexy
Sheehan syndrome
Internal carotid aneurysm
Vasculitis
Subarachnoid hemorrhage
Inflammatory and infiltrative diseases
Sarcoidosis
Langerhans cell histiocytosis (histiocytosis X, eosinophilic granuloma)
Tuberculosis, syphilis
Meningitis
Lymphocytic hypophysitis, infundibulohypophysitis
Metabolic
Hemochromatosis
Amyloidosis
Critical illness
Malnutrition
Anorexia nervosa
Psychosocial deprivation
Idiopathic

ACTH = adrenocorticotropic hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

or compression of the normal pituitary. Compression of the pituitary stalk can impair blood supply to the pituitary as well as decrease input from hypothalamic hormones. Hemorrhage into tumors can lead to pituitary infarction. A mild degree of hyperprolactinemia (usually < 200 ng/mL) is characteristic of disorders that cause stalk compression, and hyperprolactinemia further impairs gonadotropin secretion. A variety of other neoplasms that occur near the sella, such as craniopharyngiomas, can also cause hypopituitarism (see Table 224-1).

Radiation causes hypopituitarism primarily because of its effects on hypothalamic function, although high-dose radiation (e.g., proton beam) can also cause direct pituitary damage. The sellar region is subjected to radiation in the treatment of pituitary adenomas, craniopharyngiomas, optic gliomas, meningiomas, dysgerminomas, and neoplasms of the oropharynx. The effects of radiation can be delayed several years, and patients at high risk should be evaluated yearly. Although GH and gonadotropin deficiencies develop first in most patients, ACTH or TSH deficiencies occasionally occur first, emphasizing the need to evaluate each of the major axes.

Empty sella syndrome can occur as a primary or as an acquired condition. It is caused by defects in the diaphragma sella that allow herniation of the arachnoid membrane into the hypophyseal fossa. In long-standing cases, sellar enlargement occurs, probably because of persistent transmission of intracranial pressure. Imaging studies reveal the pituitary gland as a flattened rim of tissue along the floor of the sella. Primary empty sella occurs most commonly in women and may be associated with features of benign intracranial hypertension. Pituitary function is usually normal, but 10% have mild hyperprolactinemia, probably because of stretching of the pituitary stalk. Acquired forms may occur as a result of surgery, radiation, or pituitary infarction (usually of an adenoma).

Pituitary apoplexy is a syndrome caused by hemorrhage into a tumor, with associated infarction and leakage of the blood into the arachnoid space and resultant fever and stiff neck. When the hemorrhage is large, there can be mass effects, with headache and cranial nerve compression within the cavernous sinus. Asymptomatic infarctions are found in about 10 to 15% of pituitary adenomas. In the absence of a tumor, predispositions to apoplexy include trauma, pregnancy, anticoagulation, sickle cell anemia, and diabetes mellitus. Pituitary infarction in the peripartum period (Sheehan syndrome) is usually associated with significant obstetric hemorrhage and hypovolemia. Although Sheehan syndrome can manifest acutely with vascular collapse, it more commonly has a subacute manifestation consisting of postpartum inability to lactate, amenorrhea, and symptoms of adrenal insufficiency.

In lymphocytic hypophysitis, there is infiltration of the pituitary by lymphocytes and plasma cells, with destruction of the parenchyma; it is believed to have an autoimmune basis. The lesion is usually large, and patients present with either symptoms or signs of hypopituitarism or those of a mass lesion (i.e., visual field defects and headaches). Some patients may have mild hyperprolactinemia and diabetes insipidus. Almost all cases have been reported in women, and most present during or after pregnancy. Because of the presentation as a mass lesion during pregnancy, such lesions may be confused with prolactinomas. Mild PRL elevation points to a nonsecretory lesion rather than a prolactinoma. MRI cannot reliably differentiate pituitary adenoma from hypophysitis, although hypophysitis usually manifests with a diffuse enlargement of the pituitary that enhances, rather than as a focal lesion. Diagnosis is usually made by biopsy, but the lesion may be suspected clinically if it manifests during or just after pregnancy. Careful pituitary function testing is mandatory because many patients have died of adrenocortical insufficiency. Although the prognosis is not clear, a number of cases have resolved spontaneously. An entity with similar histologic findings involving the stalk and posterior pituitary, referred to as infundibuloneurohypophysitis, can cause diabetes insipidus. A third variant, panhypophysitis, involves both lobes of the pituitary. These last two forms occur in both sexes and are generally not associated with pregnancy. The causes and interrelationships between these entities remain unknown. In the past several years, secondary hypophysitis has been described in association with ipilimumab, a CTLA-4 blocking antibody used as an immunostimulant in some cancer chemotherapy regimens, and a plasmacytic infiltrative form in which the plasma cells produce antibodies of the IgG4 subclass.[4]

The pituitary may undergo damage because of iron deposition in patients with hemochromatosis (Chapter 212) and amyloid fibrils in patients with systemic amyloidosis (Chapter 188). Functional reversible hypopituitarism of varying degrees occurs in patients with severe systemic illness, severe psychosocial and emotional deprivation, and severe weight loss—particularly in those with anorexia nervosa.

DIAGNOSIS AND TREATMENT

Rx

The diagnosis of hypopituitarism rests on the stimulation tests that are summarized in Table 224-2. Therapy depends on the nature and severity of the hormone deficiencies as well as on the desired clinical end points. The goals are to replace hormones in a physiologic manner and to avoid the consequences of over-replacement. Examples of hormonal replacement paradigms are provided in Table 224-3. Adjustment of hormone doses is done primarily based on clinical findings; TSH levels are not helpful for adjusting thyroxine doses in patients with central hypothyroidism. Even when conventional hormone replacement (adrenal, thyroid, gonadal) is carried out appropriately, there is an approximately two-fold excess risk for death. Although untreated GH deficiency has been hypothesized to be the cause of this excess risk, this has not been proved. Other causes of death in this population include infections with inappropriate increase in steroid dose, and brain tumors related to prior irradiation.[5] The benefits of GH therapy are less clear than those of the other pituitary hormones and include improvements in body composition, bone, lipids, and quality of life; although there are few adverse effects, treatment involves daily injections.[6]

TABLE 224-2 TESTS OF PITUITARY INSUFFICIENCY

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV, and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and GH.	If hypoglycemia occurs (glucose < 40 mg/dL), GH should increase to > 5 μg/L.*
	Arginine-GHRH test: GHRH 1 μg/kg IV bolus followed by 30-min infusion of L-arginine (30 g)	Normal response is GH > 4.1 μg/L.
	Glucagon test: 1 mg IM with GH measurements at 0, 60, 90,120, 150, and 180 min	Normal response is GH > 3 μg/L.
Adrenocorticotropic hormone (ACTH)	*Insulin tolerance test:* Regular insulin (0.05-0.15 U/kg) is given IV, and blood is drawn at −30, 0, 30, 45, 60, and 90 min for measurement of glucose and cortisol.	If hypoglycemia occurs (glucose < 40 mg/dL), cortisol should increase by > 7 μg/dL or to > 20 μg/dL.
	CRH test: 1 μg/kg ovine CRH IV at 8 AM, with blood samples drawn at 0, 15, 30, 60, 90, and 120 min for measurement of ACTH and cortisol	In most normal individuals, the basal ACTH increases two- to four-fold and reaches a peak (20-100 pg/mL). ACTH responses may be delayed in cases of hypothalamic dysfunction. Cortisol levels usually reach 20-25 μg/dL.
	ACTH stimulation test: $ACTH_{1-24}$ (cosyntropin), 0.25 mg IM or IV. Cortisol is measured at 0, 30, and 60 min.	A normal response is cortisol > 18 μg/dL. In suspected hypothalamic-pituitary deficiency, a low-dose (1-μg) test may be more sensitive.
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests:* free T_4, free T_3, TSH	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased
Luteinizing hormone (LH), follicle-stimulating hormone (FSH)	*Basal levels of LH, FSH, testosterone, estrogen*	Basal LH and FSH should be increased in postmenopausal women. Low testosterone levels in conjunction with low or low-normal LH and FSH are consistent with gonadotropin deficiency.

*Values are with polyclonal assays.
CRH = corticotropin-releasing hormone; GHRH = growth hormone–releasing hormone; IM = intramuscularly; IV = intravenously; T_3 = triiodothyronine; T_4 = thyroxine.

TABLE 224-3 HORMONAL REPLACEMENT THERAPY IN HYPOPITUITARISM*

PITUITARY AXIS	HORMONAL REPLACEMENTS
Growth hormone (GH)	In children, GH (0.25 mg/kg) SC daily. In adults, GH (0.3-1.2 mg) SC daily. Titrate dose to achieve IGF-I levels in middle to upper part of normal range. Women receiving oral estrogens require higher doses.
Prolactin	None
Adrenocorticotropic hormone–cortisol	Hydrocortisone (10-15 mg PO q AM; 5-10 mg PO q PM) or prednisone (2.5 mg PO q AM; 2.5 mg PO q PM). Dose adjusted on clinical basis. Stress dosing: 50-75 mg hydrocortisone IV q8h
Thyroid-stimulating hormone–thyroid	L-thyroxine (0.075-0.15 mg) PO daily
Gonadotropins–gonads	FSH and LH (or HCG) can be used to induce ovulation in women. HCG alone or with FSH can be used to induce spermatogenesis in men. In men, testosterone enanthate (100-300 mg) IM q1-3wk or testosterone cyclopentylpropionate (100-300 mg) IM q1-3wk. Testosterone transdermal patches can also be used (5 mg daily). Testosterone gel 5-10 g daily. In women, conjugated estrogens (0.625-1.25 mg) PO days 1-25 each month, cycled with medroxyprogesterone acetate (5-10 mg) PO days 15-25 each month. Low-dose contraceptive pills may also be used. Estrogen-containing transdermal patches are also available.
Posterior pituitary	Desmopressin, 0.05-0.2 mL (5-20 μg) intranasally once or twice daily, or tablets (0.1-0.4 mg q8-12h) or 0.5 mL (2 μg) SC

*Replacement therapy is dictated by the types of hormone deficiencies and by the clinical circumstances. In each case, the recommended preparations and doses are representative but need to be adjusted for individual patients. Other hormonal preparations are also available.
FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; HCG = human chorionic gonadotropin; IGF-I = insulin-like growth factor-I; IM = intramuscularly; LH = luteinizing hormone; PO, orally; SC = subcutaneously.

PITUITARY TUMORS

PATHOBIOLOGY

Pituitary tumors are classified according to the hormones they produce and their size: microadenomas, less than 10 mm in diameter; macroadenomas, more than 10 mm in diameter; and macroadenomas with extrasellar extension. In general, the levels of hormones produced by the tumors parallel the size of the tumors. The prevalence of the different types of pituitary adenomas, based on surgical data, is summarized in Table 224-4. Immunohistochemical studies using antibodies specific for each of the major pituitary hormones have been used to define tumor phenotype. Pituitary adenomas are rarely malignant but can be locally invasive.

Most pituitary tumors are monoclonal. This finding does not exclude a role for hormonal stimulation as a predisposing factor for somatic mutations, and the hormonal environment may also affect the rate of tumor growth (e.g., the growth of ACTH-secreting tumors following bilateral adrenalectomy). Supporting the concept that somatic mutations lead to pituitary tumorigenesis, a subset (35 to 40%) of somatotroph adenomas have activating mutations in the gene for the Gsα-subunit, resulting in two different amino acid (Arg201 and Glu227) substitutions.[7] Either mutation causes the Gsα-subunit to stimulate adenylyl cyclase in a constitutive manner. The elevated intracellular cyclic adenosine monophosphate levels lead to increased cell growth as well as GH production. Mutations in other oncogenes, such as *ras*, *Rb*, and *p53*, are uncommon in pituitary tumors. Thus, the nature of the somatic mutations causing most pituitary tumors remains unknown.

At least five types of inherited predispositions to pituitary tumors are recognized. Patients with McCune-Albright syndrome (Chapter 231) occasionally develop pituitary adenomas as well as characteristic abnormalities in other tissues, particularly the ovary, bone, and thyroid. Interestingly, the McCune-Albright syndrome is also caused by mutations in the gene for the Gsα-subunit. However, the somatic mutations in McCune-Albright occur early during development, so that multiple tissues are affected. In multiple endocrine neoplasia type 1 (MEN 1) (Chapter 231), the menin gene is mutated, so that the predisposition to pituitary tumors is inherited in an autosomal dominant manner and occurs in conjunction with tumors of the parathyroid and pancreas.[8] Familial isolated pituitary adenoma (FIPA) syndrome is autosomal dominant and has low or variable penetrance. Germline mutations have been found in the gene for the aryl hydrocarbon receptor–interacting protein *(AIP)*, which functions as a tumor suppressor. Such mutations have been found in about one third of FIPA families, most commonly

TABLE 224-4 PREVALENCE OF DIFFERENT TYPES OF PITUITARY ADENOMAS

TYPE OF PITUITARY ADENOMA	DISORDER	HORMONE PRODUCED	PREVALENCE (%)*
Somatotroph	Acromegaly and gigantism	Growth hormone	10-15
Lactotroph (prolactinoma)	Hypogonadism, galactorrhea	Prolactin	25-40
Corticotroph	Cushing's disease	Adrenocorticotropic hormone	10-15
Gonadotroph	Mass effects, hypopituitarism	Follicle-stimulating hormone and luteinizing hormone	15-20
Thyrotroph	Hyperthyroidism	Thyroid-stimulating hormone	<3
Nonfunctioning/ null cell	Mass effects, hypopituitarism	None	10-25

*The prevalence rates represent ranges described in several different large surgical series. Mixed tumors (e.g., growth hormone and prolactin) and plurihormonal adenomas are not shown. Rates vary depending on methods used to establish the diagnosis. Prolactinomas were underestimated in most recent pathologic series because they are largely managed medically. Most glycoprotein hormone–producing pituitary tumors were classified as nonfunctioning adenomas until the application of immunohistochemical studies.

in those with GH- and PRL-producing tumors. Carney's complex is an autosomal dominant condition consisting of pituitary adenomas, atrial myxomas, spotty skin pigmentation, and schwannomas. Primary pigmented nodular adrenocortical disease causing Cushing's syndrome occurs in about one third of patients with Carney's complex. The complex is caused by an inactivating mutation in the gene for the type 1A regulatory subunit of protein kinase A (PRKARIA).[7] The most recently discovered familial form involves mutations in the succinate dehydrogenase subunit genes, resulting in combinations of pituitary tumors and pheochromocytomas/paragangiomas.[9] In general, those tumors that arise as part of MEN 1 and FIPA tend to be more aggressive, occur at a younger age, and are less responsive to therapeutic interventions. It is now recommended that when a macroadenoma occurs in the context of a very young age or when there is a family history of pituitary or other endocrine tumors, that appropriate genetic screening be carried out.

CLINICAL MANIFESTATIONS

Many of the clinical manifestations of pituitary adenomas are related to the hypersecretion of hormones. However, the mass effects of the enlarging tumor can also lead to specific signs and symptoms (Chapter 189). Particularly in the case of nonfunctioning tumors or in those that produce gonadotropins, the primary clinical manifestations are related to effects of the tumor on surrounding structures.

Headaches are common in patients with macroadenomas and appear to be caused by expansion of the diaphragma sellae or by invasion of bone. The sudden onset of severe headache associated with nausea, vomiting, and altered consciousness can also be caused by hemorrhagic infarction with sudden enlargement of a pituitary adenoma. Severe cases require glucocorticoid treatment and possible surgical decompression.

Pituitary tumors that extend superiorly can affect visual fields. Expansion into the suprasellar region exerts pressure on the optic chiasm, usually in the central region where nerves emanating from the inferior and medial part of the retina (superior and temporal visual fields) cross, leading to bitemporal hemianopsia. Visual field loss is variable, however, and is affected by the location and flexibility of the chiasm as well as by the direction and extent of tumor growth.[10] Large tumors may invade the cavernous sinus or surround an optic nerve, leading to other patterns of visual field changes or loss of visual acuity. The tumor size and the direction and degree of extrasellar extension are best evaluated with MRI with gadolinium. If the tumor abuts the chiasm on MRI, formal visual field testing should be performed. Even long-standing visual loss may be reversible.

The normal pituitary is often compressed into a thin rim of tissue by large pituitary adenomas. Hypopituitarism probably results more from compression of the hypothalamic-pituitary stalk than from direct pressure on the normal pituitary. GH deficiency and hypogonadotropic hypogonadism are particularly common. Slightly elevated PRL levels (generally < 200 ng/mL) occur in cases of stalk compression because of diminished inhibition by dopamine. It is important not to mistake such tumors for prolactinomas, because they will only rarely decrease in size in response to medical therapy with dopamine agonists, unlike prolactinomas, which commonly do. A peculiarity of some two-site immunoassays, referred to as the "hook effect," can sometimes cause a very high PRL level to read falsely normal or just mildly elevated; a 1:100 dilution of the serum sample with saline will show the true PRL level.[11] Preoperative hypopituitarism caused by a large pituitary mass is reversible in up to half of patients after surgical decompression.[9] Diabetes insipidus (vasopressin deficiency) is rarely caused by pituitary tumors and should raise the suspicion of a craniopharyngioma or other hypothalamic disorders.[12]

TREATMENT Rx

Surgery

Except for prolactinomas, surgery is the primary mode of therapy for pituitary tumors that warrant intervention (Video 224-1). Indications for surgery include reduction in hormone levels and decompression to relieve mass effects or prevent further tumor expansion. Currently, the transsphenoidal route, usually with an endoscopic endonasal approach, is used almost exclusively for decompression or extirpation of pituitary tumors.[13] Because of substantially greater morbidity, subfrontal craniotomy is reserved for patients with tumors that require extensive exploration of the suprasellar region and surrounding structures. In experienced hands, transsphenoidal surgery is effective, and complications are uncommon (<5% complication rate) but include CSF leak, hemorrhage, optic nerve injury, hypopituitarism, and sinusitis. Transient diabetes insipidus occurs in about 5% of patients after surgery but rarely persists long term. Mortality rates are less than 1%. Complication rates increase with increasing size of the tumor and when a craniotomy is performed.

Surgical cure rates are largely a function of the size and location of the pituitary mass. When stringent hormonal criteria are used to assess surgical success rates, 30 to 60% of macroadenomas are cured by transsphenoidal surgery, although considerable improvements in hormone levels or mass effects can be achieved. On the other hand, hormone hypersecretion by microadenomas can be corrected completely in 80 to 90% of patients, although the cure rates vary considerably at different institutions. Even with apparent surgical cure, 10 to 20% of tumors may recur over several years, resulting in a redevelopment of the hormone oversecretion syndrome.

Radiation Therapy

Irradiation is usually used as adjunctive therapy after surgery or in combination with medical therapy. Radiation has typically been administered over 5 weeks at a dose of 45 Gy using cobalt-60 or a linear accelerator. Proton beam therapy delivers very high doses of radiation within a localized region, but it is limited to intrasellar lesions and is not widely available. More recently, a radiation therapy technique referred to as stereotactic radiotherapy has been employed for many patients with pituitary tumors. With this technique, approximately the same dosage of radiation is administered as a single dose through multiple ports, using a computerized matching of irradiation to tumor geometry.[14] Response rates are slow (several years, but somewhat more rapid with stereotactic therapy). Complete remission is rarely achieved with any of these types of irradiation. Because the time to recurrence for most nonfunctioning macroadenomas is 5 to 10 years, and not all tumors recur, it is often reasonable to follow patients with imaging techniques, reserving irradiation for those with evidence of residual tumor or recurrence if no tumor was visible postoperatively.

Complications of irradiation are dose related but can also be idiosyncratic. Partial or complete hypopituitarism occurs in 50 to 70% of patients and is primarily due to hypothalamic injury. Conventional irradiation is associated with an increased risk for stroke. Second tumors occur in the radiation field in about 2% of patients over a 20-year period. Less common complications include optic nerve damage, brain necrosis, and cognitive dysfunction. Whether stereotactic radiotherapy will have similar rates of complications is at present unknown. Early studies show that hypopituitarism is developing at a rate similar to that seen with conventional therapy.

Medical Therapy

The emergence of medical therapies for pituitary tumors has dramatically affected patient management. The dopamine agonists bromocriptine and cabergoline have a primary role in the management of prolactinomas. They induce a rapid fall in PRL levels and, importantly, decrease tumor size. Dopamine agonists are also used in the management of acromegaly, although the GH responses and effects on tumor size are much less pronounced than in prolactinomas. Somatostatin analogues such as octreotide, lanreotide, and pasireotide act to suppress the secretion of a number of hormones, including GH, TSH, and ACTH and have been used to treat acromegaly, TSH-producing tumors, and Cushing's disease. Other medical therapy for Cushing's disease has primarily been directed toward inhibition of steroid biosynthesis; these drugs include ketoconazole, metyrapone, etomidate, and mitotane. Because of

VIDEO 224-1. **Pituitary surgery.**

substantial side effects and because patients with Cushing's disease tend to escape from the cortisol-suppressing effects of these drugs, medical therapy is used primarily as an adjunctive treatment or to reduce cortisol levels preoperatively. Another new category of drugs to treat pituitary tumors includes the receptor blockers. Pegvisomant is a GH analogue with altered binding to the GH receptor that competitively inhibits GH binding to its receptor and is used in the treatment of acromegaly. Mifepristone can block the action of cortisol at its receptor and has been found to be effective for the treatment of Cushing's syndrome.

GROWTH HORMONE

The most important regulators of GH are the hypothalamic hormones: GHRH, which is stimulatory, and somatostatin, which is inhibitory. GH increases the production of IGF-I (formerly known as somatomedin C). The Gsα-subunit, which is coupled to the GHRH receptor, is one of the targets for activating mutations that lead to somatotroph adenomas.

IGF-I inhibits GH secretion, and it acts at both the pituitary and hypothalamic levels. In addition to reflecting GH action (primarily at the liver), serum IGF-I is also sensitive to nutritional and metabolic changes. In cases of starvation, anorexia nervosa, and poorly controlled diabetes, IGF-I levels are low, resulting in increased levels of GH. In cases of obesity, GH levels are low and GHRH responses are blunted, but IGF-I levels are generally normal and actually increase with increasing body mass index. Stress, exercise, and a variety of neurogenic stimuli also increase GH secretion. Estrogens stimulate GH secretion, but their effects are less pronounced than for PRL, and they inhibit the stimulatory effect of GH on IGF-I production.

Large bursts of GH secretion characteristically occur at night in association with slow-wave sleep. GH levels increase during puberty and decline gradually in adulthood. The amplitude of GH pulses is greater in women than in men, likely reflecting the effects of estrogens. Spontaneous GH pulses can reach 50 ng/mL; consequently, random GH levels can be quite variable. GH responses to GHRH are also variable even within an individual, owing to changes in endogenous somatostatin tone.

GH acts through a single transmembrane receptor that is structurally related to PRL and cytokine receptors. The GH molecule has two distinguishable receptor binding domains that allow it to contact two separate receptor molecules to induce receptor dimerization. Mutations in the gene for the GH receptor cause GH resistance and severe growth retardation, a condition referred to as the GH insensitivity syndrome (Laron-type dwarfism). In such patients, GH levels are elevated and IGF-I levels are low, reflecting the inability of the mutant receptor to transduce the GH signal. Mutations have also been found in signaling intermediates (e.g., the signal transducers of activators of transcription *STAT5b* gene) that mediate GH actions.

Many of the growth and metabolic effects of GH are transmitted indirectly through the actions of IGF-I. GH stimulates IGF-I production in most tissues, where it then exerts autocrine or paracrine effects. Circulating IGF-I is derived predominantly from the liver and is a useful marker of GH action because it has a longer half-life and integrates the effects of GH pulses. Although IGF-I levels are used in the diagnosis of acromegaly and to assess the integrity of the GH axis, factors other than GH (e.g., malnutrition) can alter IGF-I levels. IGF-I acts through widely distributed receptors that are structurally related to insulin receptors. In addition to its growth-promoting and anabolic effects, IGF-I also stimulates mitogenesis in many tissues. The bioactivity of IGF-I is itself modulated by six IGF-binding proteins (IGFBPs). These IGFBPs can inhibit or enhance IGF actions. IGFBP-3 is the major IGFBP in plasma; it is regulated by GH, and its levels generally parallel those of IGF-I.

GH has its major effects on linear growth but also influences a variety of metabolic pathways. Some of these effects are mediated by GH directly, whereas others are conferred by IGF-I. Although the relative roles of GH and IGF-I are debated, their actions are cooperative in many cases. The effects of GH on linear growth appear to be mediated largely by IGF-I, which has been used to stimulate growth in patients with the GH insensitivity syndrome. Linear growth in the fetus and neonate is not GH dependent, as illustrated by the fact that GH-deficient infants have normal birth lengths, although intrauterine IGF-I and IGF-II may be important for fetal growth independent of GH. In contrast, normal postnatal linear growth requires GH, as illustrated by the clinical manifestations of GH deficiency. GH and IGF-I act together to accelerate linear growth markedly, particularly at the time of puberty when sex steroids enhance GH and IGF-I levels.

GH also induces lipolysis and stimulates anabolic activity, including amino acid uptake and protein synthesis. As a result, it reduces body fat, increases lean body mass, and leads to positive nitrogen balance. These properties of GH are most strikingly seen in GH-deficient children who have undergone replacement. GH opposes many of the actions of insulin and can be considered diabetogenic. In diabetic individuals, nocturnal GH secretion accounts in large part for the so-called dawn phenomenon in which there is a decrease in glucose utilization, causing a tendency toward hyperglycemia.

Growth Hormone Deficiency

PATHOBIOLOGY

Causes of GH deficiency include hypothalamic-pituitary disorders, GHRH receptor mutations, GH gene mutations, combined pituitary hormone deficiencies, GH receptor mutations, IGF-I receptor mutations, radiation, and psychosocial deprivation (Chapter 223). Isolated idiopathic GH deficiency is the most common category, however, in children.

CLINICAL MANIFESTATIONS

The clinical manifestations of GH deficiency depend on the time of onset and the severity of hormone deficiency. Children with complete GH deficiency have slow linear growth rates (≈3 cm/year), and they rapidly fall below normal on standardized growth charts. GH-deficient children have normal skeletal proportions, and many have a pudgy, youthful appearance because of decreased lipolysis. Particularly in the setting of cortisol deficiency, there is a predisposition to hypoglycemia. Adults may acquire GH deficiency due to hypothalamic/pituitary disease such as tumors or infiltrative disease. Manifestations of adult GH deficiency include increased fat mass, decreased muscle mass, decreased bone mineral density, and decreased quality of life.

DIAGNOSIS

Basal GH does not provide a reliable measure of GH reserve, whereas low IGF-I is consistent with GH deficiency. However, not all patients documented to have GH deficiency by stimulation testing have IGF-I levels that are below the normal range. GH deficiency is assessed using insulin-induced hypoglycemia, which activates central nervous system pathways, leading to stimulation of both GH and ACTH secretion (see Table 224-2). The insulin tolerance test requires careful monitoring for symptoms of severe hypoglycemia, such as confusion or depressed consciousness. This test should be avoided in patients with seizure disorders or coronary artery disease. Insulin doses (0.1 to 0.15 U/kg) may need to be decreased if glucocorticoid deficiency is suspected or increased in conditions of insulin resistance (e.g., obesity). Alternatives to the insulin tolerance test for evaluation of GH are a combination of arginine and GHRH given intravenously or glucagon given intramuscularly.

TREATMENT

Rx

In children with well-documented GH deficiency, GH replacement is effective and is essential to increase final adult height. In a typical regimen, recombinant GH (0.025 mg/kg) is given daily as subcutaneous injections. The efficacy of GH treatment depends on when it is initiated as well as replacement of other hormone deficiencies, if they coexist. In the setting of multiple hormone deficiencies, replacement of thyroid hormone and cortisol is necessary for effective GH action. On the other hand, sex steroids lead to epiphyseal closure and limit linear growth. Consequently, GH is more effective before puberty; if exogenous sex steroids are given, low doses should be used. GH has also been shown to increase the final height of girls with Turner's syndrome (chromosomal XO state) (Chapter 236) and children with end-stage renal disease.

Only about one third of children with isolated idiopathic GH deficiency are found to be GH deficient when retested as adults. Thus, all such patients should be retested before GH therapy is continued or restarted unless they have proven molecular defects as the cause of their GH deficiency. Studies show that GH treatment can increase bone density and lean body mass, decrease fat mass, and improve the sense of well-being in adults with documented GH deficiency. In most studies, safety data for long-term GH administration show negligible adverse effects. Whether GH treatment in adults will affect the increased mortality rate associated with hypopituitarism remains to be seen. Adverse effects occur at lower doses in adults compared with children; a starting dose of 0.2 to 0.3 mg/day has been recommended, with gradual titration guided by clinical benefits, adverse effects, and IGF-I levels.

Growth Hormone Excess: Acromegaly and Gigantism

PATHOBIOLOGY

GH-producing pituitary tumors account for 10 to 15% of pituitary tumors (see Table 224-4). GH-producing tumors are frequently mixed tumors that secrete more than one hormone. PRL is produced in about 40% of somatotroph adenomas, and some patients may present because of symptoms due to the hyperprolactinemia (i.e., amenorrhea, galactorrhea, or both). Ectopic production of GHRH (usually carcinoid or pancreatic islets) is a well-documented but rare (<1%) cause of acromegaly that can result in somatotroph hyperplasia. Activating Gsα-subunit mutations occur in 35 to 40% of somatotroph adenomas. Molecular defects in the remaining 60 to 65% of somatotroph adenomas remain unidentified.

CLINICAL MANIFESTATIONS

Tumors that secrete GH cause acromegaly in adults and gigantism in children in whom GH excess occurs before epiphyseal closure. Acromegaly affects men and women with equal frequency and is most often recognized when patients are in their 30s or 40s, usually after a decade of GH excess. The most striking features of acromegaly usually involve the face, hands, and feet. The diagnosis is often suspected because of changes in facial appearance that include enlargement of the lower jaw (prognathism), the nose and lips, and the sinuses (causing frontal bossing) (Fig. 224-5). Oral cavity changes include malocclusion, increased spacing between the teeth, and enlargement of the tongue. A hollow, resonant voice is caused by changes in the vocal cords and the soft tissues of the hypopharynx. Sleep apnea may occur in patients with soft tissue obstruction of the pharynx but may also occur because of a central disorder. In addition to bony enlargement, there is a marked increase in the soft tissue of the hands and feet, leading to progressive increases in ring, glove, and shoe size. A moist, doughy, enveloping handshake is characteristic of acromegaly. Arthritis (hands, feet, hips, knees) is common (75%) and is caused by cartilage and synovial overgrowth. Some degree of carpal tunnel syndrome is seen in about half of patients. Skin changes include increased skinfolds, particularly over the brow and forehead. The skin is usually oily, owing to increased sebaceous activity and sweating. Skin tags are common, and their presence correlates with the presence of colonic polyps. Galactorrhea may be seen in women, and reproductive dysfunction occurs in both women and men when PRL levels are elevated. Headaches, visual field defects, and other neurologic symptoms depend on the location and extent of tumor growth.

Acromegaly causes a two- to three-fold increase in mortality rate.[15] Most of the increased mortality can be attributed to cardiovascular and cerebrovascular diseases and may be related to the increased prevalence of hypertension (25 to 35%) and diabetes mellitus (10 to 25%) in patients with acromegaly. There is evidence for cardiac hypertrophy in most patients, and symptomatic heart disease, consisting of coronary ischemia or congestive heart failure or both, occurs in 15 to 20% of patients. Sleep apnea may predispose patients to cardiac dysrhythmias. Some analyses have found an increased risk of premalignant polyps and colon cancer, and screening with colonoscopy is generally recommended. The disfigurement, metabolic complications, and increased mortality associated with acromegaly emphasize the importance of early diagnosis and implementation of appropriate therapy to lower the GH levels into the normal range.

DIAGNOSIS

Because GH is secreted in a pulsatile manner and because the amplitude of normal GH pulses can be large (>50 ng/mL), random GH level measurements are not very useful in making the diagnosis of acromegaly. IGF-I levels provide an integrated index of GH production and provide a better screening test for acromegaly. IGF-I levels decrease with age, so normal ranges must be age adjusted. IGF-I levels correlate well with 24-hour GH production rates and with disease activity. The most standardized test for acromegaly is the glucose tolerance test (Table 224-5). In acromegaly, increased glucose levels fail to suppress GH levels to below 1 ng/mL with polyclonal antibody immunoassays and to levels below 0.4 ng/mL using newer monoclonal antibody two-site assays. Co-secretion of PRL should be evaluated. After the diagnosis of acromegaly is made, radiologic studies, preferably using MRI, should be used to evaluate the extent of tumor growth. Unlike in Cushing's disease and prolactinomas, most patients with acromegaly have macroadenomas.

FIGURE 224-5. Clinical features of acromegaly. Serial photographs of a 64-year-old woman with acromegaly. Over an 11-year period, there is a progressive coarsening of facial features, including enlargement of the nose and lips and development of prognathism. She also experienced hypertension, arthropathy, and enlargement of the hands (not shown). (From Molitch ME. Clinical manifestations of acromegaly. *Endocrinol Metab Clin North Am.* 1992;21:597-614.)

TREATMENT

Rx

The goals of therapy are to reverse or prevent tumor mass effects and to reduce the long-term morbidity and mortality that result from excess GH production. Correction of the disorder prevents further physical disfigurement and can result in substantial resolution of soft tissue changes and improvements in metabolic derangements. Although reductions in GH levels are associated with improvements in symptoms, the ultimate goal is to achieve normal GH and IGF-I levels and to prevent tumor recurrence without incurring hypopituitarism.

Transsphenoidal surgery results in GH levels below 2.5 ng/mL in 80 to 90% of patients with microadenomas when performed by experienced neurosurgeons. This level, along with GH suppression below 1 ng/mL during an oral glucose tolerance test, and a normal IGF-I level have been associated with a normalization of the increased mortality of acromegaly. Patients with macroadenomas are less often cured by surgery (<30%) but usually have reductions in GH levels.

Medical therapies for acromegaly include: dopamine agonists such as cabergoline; somatostatin analogues such as octreotide, lanreotide, and pasireotide; and the GH receptor antagonist, pegvisomant. Although cabergoline can reduce GH and IGF-I levels in many patients, normal levels are achieved in only about one third. Long-acting preparations of octreotide, lanreotide, and especially pasireotide that can be given by intramuscular injection every 4 weeks reduce GH and IGF-I levels in almost all patients, with normal levels of IGF-I being achieved in about 50 to 60% of cases. A recent multicenter, randomized trial showed that the somatostatin analog pasireotide (long-acting release), at a dose of either 40 mg or 60 mg administered once every 28 days for 24 weeks, provides superior efficacy compared with continued treatment with octreotide or lanreotide, and could become the new standard pituitary-directed treatment in patients with acromegaly who are inadequately controlled with first-generation somatostatin analogs. Tumor size is reduced modestly in about one half of cases. Of those achieving normal levels of GH and IGF-I, about 10 to 20% can eventually be successfully withdrawn from treatment after several years. Somatostatin analogues are useful as adjunctive therapy in patients who are not cured by surgery or radiation and in some cases are used primarily when a surgical cure is not possible, such as in those with cavernous sinus invasion. Side effects of somatostatin analogues include diarrhea and increased risk of cholelithiasis, although cholecystitis and need for cholecystectomy are rare. Some patients experience additive beneficial effects from combining these two classes of medications while keeping the dose of each drug low enough to avoid adverse effects.

TABLE 224-5 SELECTED TESTS OF EXCESS PITUITARY FUNCTION

HORMONE	TEST	INTERPRETATION
Growth hormone (GH)	*Basal IGF-I*	Elevated IGF-I levels are consistent with acromegaly when interpreted in the context of age and nutritional status.
	Oral glucose suppression test: after 75-g glucose load, GH is measured at −30, 0, 30, 60, 90, 120 min	GH should be suppressed to < 1 μg/L in normal persons with polyclonal radioimmunoassays; < 0.4 μg/L with two-site monoclonal assays. GH may paradoxically increase in acromegaly.
Prolactin	*Basal prolactin levels*	Elevated prolactin (>200 μg/L) is consistent with a prolactinoma. When prolactin levels are between 20 and 200 μg/L, other causes of hyperprolactinemia should be considered.
Adrenocorticotropic hormone (ACTH)	*Measurement of 24-hr urine free cortisol*	Elevated level is suggestive of Cushing's syndrome, but it has several other causes as well.
	Midnight salivary cortisol: special tubes with cotton pledgets available to collect saliva at 11 PM to midnight	In normal persons, the midnight salivary cortisol is very low because of the normal diurnal variation. In patients with Cushing's syndrome, the salivary cortisol is elevated.
	Overnight dexamethasone suppression test: dexamethasone (1 mg) PO at midnight, followed by 8 AM plasma cortisol	In normal persons, AM cortisol should be suppressed to < 5 μg/dL. Normal test excludes Cushing's syndrome. Other disorders can cause failure to suppress normally.
	CRH test: ovine CRH (1 μg/kg) is administered IV, and ACTH and cortisol are drawn at −15, 0, 15, 30, 60, 90, and 120 min.	In Cushing's disease, there is usually a 50% increase in ACTH and a 20% increase in cortisol. Adrenal adenoma is associated with suppressed ACTH. Ectopic ACTH is associated with high basal ACTH and cortisol levels that are not affected by CRH.
	Petrosal sinus ACTH sampling: the inferior petrosal sinus is catheterized bilaterally, and plasma ACTH is compared with simultaneous peripheral samples. The sampling can be done in conjunction with CRH stimulation.	In Cushing's disease, the ratio of ACTH in the petrosal sinus to the periphery is at least 2 basally and at least 3 after CRH. In ectopic ACTH, the ratio of petrosal sinus to peripheral level is < 1.5.
Thyroid-stimulating hormone (TSH)	*Basal thyroid function tests*	An inappropriate normal or elevated TSH in the setting of increased free thyroid hormone levels is consistent with a TSH-producing tumor or other causes of inappropriate TSH secretion.
	Free α-subunit level	Elevated levels associated with inappropriately elevated TSH are suggestive of a TSH-producing tumor.
Follicle-stimulating hormone (FSH), luteinizing hormone (LH)	*Basal FSH, LH, testosterone*	Increased LH and testosterone levels in males are consistent with LH-secreting tumors. Elevated FSH and low-normal testosterone are suggestive of an FSH-producing tumor if primary gonadal failure is not present. In females, assessment of excess hormone secretion is difficult because of changes during the menstrual cycle and at menopause.

CRH = corticotropin-releasing hormone; IGF = insulin-like growth factor; TRH = thyrotropin-releasing hormone.

Pegvisomant is a biosynthetic GH analogue that prevents binding of GH to its receptor. It is capable of normalizing IGF-I levels in more than 90% of patients with corresponding clinical benefits, but it has no effects on the tumor itself. Pegvisomant is given by daily subcutaneous injection; although it generally has been held in reserve for patients not responding optimally to other treatment modalities, its high biochemical and clinical efficacy have led to increasing use now as initial medical therapy when tumors are not large. It has also been given in combination with somatostatin analogues. The most common adverse effect of pegvisomant is an increase in serum transaminase levels.

Radiation is not recommended as primary therapy for acromegaly because of the long time (5 to 10 years) required for reductions in GH levels and the high incidence of hypopituitarism and other complications. Adjunctive radiation therapy may be required for patients with macroadenomas when GH levels or mass effects persist after transsphenoidal surgery and medical therapy. Recent data suggest that stereotactic radiotherapy may be the most efficacious form of radiotherapy for acromegaly.

PROLACTIN

PRL and GH appear to be derived from a common ancestral gene, which accounts for the similarities in their structures and some overlap in their functional properties. Although large-molecular-weight forms of PRL (due to binding to immunoglobulin [Ig]G, termed *macroprolactin*) react in radioimmunoassays, they have diminished biologic potency. Estrogen stimulates lactotroph proliferation, and their number is consequently greater in females than in males and during pregnancy (≈70% of pituitary cells).

Secretion of PRL is controlled by tonic inhibition by dopamine, which acts through D_2-type receptors on lactotrophs. PRL biosynthesis and secretion are stimulated by the hypothalamic peptides TRH and vasoactive intestinal peptide (VIP). Hypothyroidism causes increased TRH output and increased sensitivity of the lactotrophs to TRH and can result in hyperprolactinemia. Dopamine inhibition is the dominant influence for PRL secretion; therefore, PRL is the one pituitary hormone that increases after pituitary stalk section. Secretion of PRL is pulsatile and increases with sleep, stress, chest wall stimulation, and pregnancy. PRL levels are usually less than 15 to 20 ng/mL in women and 10 to 15 ng/mL in men. The primary function of PRL is to induce and sustain lactation. During pregnancy, PRL levels increase, and in conjunction with other hormones (estrogens, progesterone, thyroid hormone, cortisol, and insulin), breast epithelium is stimulated to proliferate and milk synthesis is induced. High levels of estrogen and progesterone inhibit lactation during pregnancy, and their decline post partum permits lactation to occur. Neural pathways leading to the secretion of oxytocin provide the "let-down" reflex that induces lactation in response to suckling. Early in the postpartum period, PRL secretion is stimulated by suckling, but this response becomes damped with time as the frequency of suckling episodes decreases. PRL also suppresses gonadotropins. As a result, breast-feeding can suppress ovulation.

Prolactin Deficiency

PRL deficiency is rare and occurs primarily in the setting of combined hormone deficiencies. The only recognized consequence of PRL deficiency is the absence of postpartum lactation, and this scenario may be found with pituitary infarction occurring as a result of obstetric hemorrhage (Sheehan syndrome). No effects on breast development or other tissues have been described in PRL deficiency.

Hyperprolactinemia

PATHOBIOLOGY

Hyperprolactinemia can occur as a consequence of pharmacologic alterations in the pathways that control PRL secretion or of physiologic or metabolic effects on PRL production and clearance or as a neoplastic condition. Prolactinomas are neoplastic growths of lactotroph cells and are the most common type of pituitary adenoma (25 to 40%). Estrogen is a potent stimulus for lactotroph proliferation; however, there is no clear association between estrogens (e.g., oral contraceptive use) and the incidence of prolactinomas. However, the very high estrogen levels present during pregnancy may cause

about 30% of large prolactinomas to increase in size. Diminished dopamine tone, such as may occur with prolonged treatment with antipsychotic agents, results in increased PRL but has not been shown to cause prolactinomas.

Microprolactinomas constitute the great majority of tumors in premenopausal women. In contrast, macroadenomas are more commonly seen in men and postmenopausal women. The predominance of smaller tumors in premenopausal women may be accounted for by an ascertainment bias, because elevated PRL levels in this group lead to clinical manifestations (amenorrhea, galactorrhea, or infertility). Subclinical prolactinomas exist in men and many older women, and about 5% of apparently normal individuals have PRL-positive microadenomas in autopsy series. Prolactinomas in children tend to be macroadenomas, possibly owing to an increased prevalence of *AIP* mutations (see earlier).

CLINICAL MANIFESTATIONS

Hyperprolactinemia causes galactorrhea and oligomenorrhea or amenorrhea in premenopausal women. Estrogen facilitates PRL-induced galactorrhea, which explains why it is less common in postmenopausal women. Amenorrhea is primarily a consequence of PRL suppression of GnRH, although PRL may also have inhibitory effects at the level of the pituitary and the gonad. Amenorrhea is associated with infertility, and PRL levels should be a routine part of the hormonal evaluation of infertility. Estrogen deficiency can cause decreased libido, vaginal dryness, and dyspareunia. Long-standing estrogen deficiency also leads to osteopenia in many women. Oral contraceptives may mask PRL-induced oligomenorrhea or amenorrhea that becomes apparent on their discontinuation. In postmenopausal women, prolactinomas are often identified because of mass effects rather than because of their hormonal effects.

In men, hyperprolactinemia causes hypogonadism with suppressed LH and FSH levels and low testosterone levels. Hypogonadism causes diminished libido, impotence, infertility, and rarely, gynecomastia or galactorrhea. Diminished libido may also reflect suppression of GnRH, because testosterone replacement is not as effective as suppression of hyperprolactinemia. Hyperprolactinemia is found in 1 to 2% of men being evaluated for sexual dysfunction.

DIAGNOSIS

There are four primary categories of causes of hyperprolactinemia that must be distinguished if the correct therapy is to be instituted: (1) physiologic or metabolic hyperprolactinemia, (2) pharmacologic hyperprolactinemia, (3) hypothalamic or pituitary stalk compression, and (4) prolactinoma (see Table 224-4).[16] With the exception of pregnancy and renal failure, physiologic causes of increased PRL result in minor elevations in PRL, usually less than 50 ng/mL. Primary hypothyroidism should be excluded as a cause of mild hyperprolactinemia. A careful drug history should be obtained in all patients with hyperprolactinemia because of the large number of agents that can stimulate PRL secretion. Psychotropic medications in particular can increase PRL, either by reducing dopamine production or by blocking its action. In most cases, the degree of hyperprolactinemia caused by drugs is less than 150 ng/mL. A variety of suprasellar and parasellar mass lesions cause hyperprolactinemia (generally between 20 and 100 ng/mL) because of compression of the hypothalamus or pituitary stalk. Unless there is very good evidence for physiologic or drug-induced hyperprolactinemia, even patients with mild hyperprolactinemia should be evaluated with MRI to distinguish among idiopathic hyperprolactinemia, microprolactinomas, and other large mass lesions that cause stalk compression resulting in decreased dopamine reaching the lactotrophs. However, specific caution is needed when some two-site assays are used, because patients with very high PRL levels may appear to have PRL levels that are normal or only modestly elevated, owing to the hook effect, in which the very high PRL levels saturate the antibodies in the assay. To avoid this problem, PRL levels should be remeasured at 1 : 100 dilution in patients with large macroadenomas (>3 cm) and normal to modestly elevated PRL levels, because PRL levels in samples with the hook effect will then increase dramatically. When no pituitary lesions are seen by radiographic studies and physiologic and pharmacologic causes of hyperprolactinemia cannot be identified, the diagnosis of idiopathic hyperprolactinemia is made. Idiopathic hyperprolactinemia may represent microprolactinomas too small to be detected accurately by imaging or altered hypothalamic regulation of PRL secretion. Whether such patients should be treated depends on the clinical effects of hyperprolactinemia. When followed for several years, few of these patients develop large tumors, only 10 to 15% show MRI evidence of microadenomas, and in one third of cases, the hyperprolactinemia resolves.

TREATMENT Rx

The natural history of prolactinomas has been evaluated in several series. Although large prolactinomas evolve from smaller lesions, it is uncommon (≈7%) for microprolactinomas to progress to macroadenomas. Because of the slow rate of growth, it is reasonable to monitor patients with microprolactinomas without treatment by periodic measurement of PRL levels unless the hyperprolactinemia is causing symptoms that warrant therapy.

When hyperprolactinemia causes hypogonadism, osteopenia, or infertility, a dopamine agonist such as cabergoline or bromocriptine is the therapy of choice. Dopamine agonists normalize PRL levels and correct amenorrhea-galactorrhea in 80 to 90% of patients. Cabergoline is more effective, has fewer adverse effects than bromocriptine, and has the additional advantage in only having to be taken once or twice weekly. Bromocriptine must be started in low doses, with gradual increases to avoid side effects (nausea, dizziness, somnolence, and nasal stuffiness).

Cabergoline may cause a considerable reduction in tumor size in patients with macroprolactinomas (≈80 to 90% having > 50% reduction in tumor size), but such size reduction is seen in only about two thirds of patients treated with bromocriptine. Improvements in visual field defects can be seen in about 90% of patients with defects when treated with cabergoline. Thus, it is reasonable to use cabergoline as first-line therapy even in patients with visual field defects, so long as visual acuity is not threatened by rapid progression or recent tumor hemorrhage. Many patients treated with cabergoline whose tumors shrink to the point of nonvisualization on MRI and whose PRL levels are normal can maintain normal PRL levels and not experience tumor reexpansion after therapy has been tapered off. In some cases, prolactinomas appear to be resistant to a dopamine agonist. In these cases, switching from bromocriptine to cabergoline may be successful. Larger-than-standard doses (>2 mg/week) of cabergoline may be effective in normalizing PRL levels. The very high doses of cabergoline used in patients with Parkinson's disease have been associated with cardiac valvular abnormalities; such abnormalities have not been found with conventional doses of cabergoline used in patients with prolactinomas, but monitoring with echocardiography may be prudent in patients taking larger-than-standard doses. Alternatively, transsphenoidal surgery may be used. Although initial remission rates (80 to 90%) for transsphenoidal surgery of microprolactinomas are good, there is long-term recurrence in about 20% of patients. For macroprolactinomas, the initial remission rates with surgery are closer to 30%, with a similar recurrence rate. Radiation therapy, usually stereotactic, is reserved for patients with macroadenomas not responding to either medical or surgical treatment.

Dopamine agonist therapy for infertility, or when there is a possibility of pregnancy, deserves special consideration. These medications can induce ovulation in 80 to 90% of patients with hyperprolactinemia. Although neither bromocriptine nor cabergoline has been associated with congenital malformations, they should be stopped once pregnancy has been achieved. A form of barrier contraception is usually recommended until two to three regular menstrual cycles have occurred. Subsequently, pregnancy can be confirmed if a menstrual period is missed, allowing discontinuation of medication with exposure of the fetus to the drug for only 3 to 5 weeks. At present, the safety data for pregnancy outcome are more limited for cabergoline; therefore, some clinicians prefer bromocriptine when fertility is desired. Less than 3% of patients with microadenomas, but 23% of patients with macroadenomas, develop symptoms of tumor enlargement (headaches, visual field defects) during pregnancy (Fig. 224-6). If symptoms develop, MRI and formal visual field testing should be performed. If there is evidence of visual field compromise or tumor growth, dopamine agonist therapy should be restarted to shrink the tumor. PRL levels are not very useful because they are normally increased in pregnancy and an enlarging tumor may not cause PRL production to increase substantially. Because problems of tumor growth occur most often in patients with macroadenomas, consideration can also be given to the option of transsphenoidal decompression before pregnancy in women with large tumors, so long as fertility can be preserved. If the patient is far advanced in her gestation at the time tumor growth occurs, consideration could also be given to delivering the baby.

ADRENOCORTICOTROPIC HORMONE

ACTH is a 39–amino acid peptide that is derived from a precursor polypeptide, proopiomelanocortin (POMC; 241 amino acids), which encodes several peptides, including ACTH and β-lipotropin (Chapter 223). The biologically active portion of ACTH resides within the first 18 of its 39 amino acids. However, because a synthetic peptide (cosyntropin) that includes the first 24 amino acids has a longer half-life, it is used clinically to assess adrenocortical function. In cases with neoplastic ectopic production of ACTH, the levels of precursor peptides or their processed products may be elevated.

The primary effect of ACTH is to stimulate the adrenal gland to produce cortisol. It also stimulates secretion of adrenal androgens and mineralocorticoids, although production of mineralocorticoids is controlled primarily through non–ACTH-dependent mechanisms (i.e., the renin-angiotensin system) (Chapter 227). Consequently, mineralocorticoid function is preserved in ACTH deficiency, in contrast to primary adrenal insufficiency, which is characterized by loss of glucocorticoid and mineralocorticoid function. Long-term stimulation by ACTH causes adrenal hyperplasia and enlargement. On the other hand, ACTH deficiency leads to adrenal atrophy.

Hypothalamic corticotropin-releasing hormone (CRH) is the most important stimulator of ACTH secretion. Chronic stimulation by CRH causes corticotroph cell hyperplasia, which can be seen in cases of ectopic CRH production. Cortisol inhibits ACTH secretion, blunts the ACTH response to CRH, and inhibits CRH production. After prolonged glucocorticoid suppression of the hypothalamic-pituitary-adrenal axis, the amount of endogenous CRH secretion appears to be rate limiting and can require several months to recover.

Plasma ACTH is secreted in discrete pulses (10 to 80 pg/mL), so random measurements are of little value. Most clinical tests are therefore based on levels of cortisol or its metabolites, which tend to integrate the effects of ACTH. ACTH and cortisol secretion exhibit marked diurnal rhythms, being greatest at night several hours after the initiation of sleep. Cortisol levels are highest in the early morning and reach a nadir in the late afternoon and evening. Patients with Cushing's disease lose or exhibit a blunted diurnal rhythm of ACTH and cortisol secretion. ACTH secretion can be stimulated by a variety of different forms of stress, including psychological stimuli such as fright, anticipation of athletic competition, or surgery. Depression is associated with activation of the hypothalamic-pituitary-adrenal axis and impaired dexamethasone suppressibility. Hypoglycemia induces ACTH secretion through a central mechanism. The resulting increase in cortisol secretion represents one of several counter-regulatory mechanisms that increase glucose production. Insulin-induced hypoglycemia provides a mechanism for testing the integrity of the hypothalamic-pituitary-adrenal axis (see Table 224-2). Serious trauma and infection activate an array of cytokines that stimulate CRH and ACTH secretion. Because cortisol levels are often increased substantially in these circumstances, similar adjustments in cortisol replacement doses may be required in seriously ill patients with adrenal insufficiency.

Adrenocorticotropic Hormone Deficiency: Secondary Hypocortisolism

Secondary hypocortisolism causes symptoms of glucocorticoid deficiency, including nausea, vomiting, weakness, fatigue, fever, and hypotension. In addition to reduced levels of cortisol, abnormal laboratory test findings can include hyponatremia, hypoglycemia, and eosinophilia. Depending on its cause, the severity of cortisol deficiency in cases of secondary adrenal insufficiency is often not as marked as in primary adrenal insufficiency (Chapter 227). In addition, mineralocorticoid function is preserved in secondary adrenal deficiency. Consequently, the clinical manifestations of volume depletion are less pronounced, and hyperkalemia is not a feature of ACTH deficiency. Because ACTH levels are low, hyperpigmentation is not seen as in primary adrenal insufficiency. In women, reduced adrenal androgens can decrease libido and cause loss of axillary and pubic hair.

The most common cause of ACTH deficiency is treatment with exogenous glucocorticoids, which causes suppression of the hypothalamic-pituitary-adrenal axis. Sudden withdrawal of glucocorticoids or an increased requirement induced by the superimposition of severe illness can elicit symptoms of glucocorticoid deficiency. Congenital forms of ACTH deficiency are rare. When present, ACTH deficiency usually occurs in combination with the loss

of other pituitary hormones, although acquired, isolated ACTH deficiency does occur, particularly in women with lymphocytic hypophysitis.

ACTH reserve is most often evaluated using the insulin tolerance test. Caution should be exercised before inducing hypoglycemia in patients with suspected adrenal insufficiency. Insulin-induced hypoglycemia stimulates central responses to neuroglycopenia (Chapter 230) and mimics some stresses that activate ACTH secretion. ACTH stimulation tests using $ACTH_{1-24}$ (cosyntropin) can accurately evaluate primary adrenocortical insufficiency but may less accurately assess secondary adrenal insufficiency. A variation of the ACTH stimulation test using the low dose of 1 μg has been found to be useful for diagnosing secondary adrenal insufficiency in some studies.

Deficiency of ACTH is treated by replacement with glucocorticoids. Doses need to be individualized and are based largely on clinical criteria in which symptoms of glucocorticoid deficiency are balanced against features of glucocorticoid excess. Typical amounts of hydrocortisone are in the range of 15 to 20 mg/day in divided doses. Such doses are usually doubled in the event of mild to moderate illness. Patients should wear MedicAlert tags and be instructed in the warning signs of cortisol deficiency: nausea, vomiting, abdominal pain, low-grade fever, fatigue, and postural dizziness. Emergency injection kits of hydrocortisone are frequently provided for home use in the event that vomiting precludes taking oral steroids, or for severe sudden stress (e.g., a fracture). Stress doses of steroids should be used during times of illness. Current recommendations call for doses in the range of 50 to 75 mg every 8 hours for severe stress. Mineralocorticoid replacement is not required in patients with ACTH deficiency.

Cushing's Disease

PATHOBIOLOGY

Cushing's disease results from a pituitary adenoma that causes excess production of ACTH. It should be distinguished from a variety of other causes of Cushing's syndrome (glucocorticoid excess), which include adrenal causes (adenomas, carcinomas) of cortisol excess, ectopic production of ACTH and CRH, and physiologic states that result in overproduction of cortisol. Cushing's disease accounts for 60 to 70% of cases of Cushing's syndrome. Ten to 15% of pituitary tumors secrete ACTH. Cushing's disease occurs about eight times more often in women than in men.

Most ACTH-producing pituitary neoplasms, like other pituitary tumors, are monoclonal, implying a primary defect in corticotroph cells. In addition, there are rare cases of corticotroph hyperplasia causing Cushing's syndrome that are secondary to CRH production by either adjacent CRH-producing intrasellar gangliocytomas or ectopic CRH-producing cancers. Most (80 to 90%) of the ACTH-secreting tumors are microadenomas at the time of diagnosis. The clinical features of cortisol excess may allow detection of corticotroph adenomas before they have grown to a larger size. High levels of cortisol may also restrain tumor growth. ACTH-secreting macroadenomas may be locally invasive.

CLINICAL MANIFESTATIONS

The clinical features of Cushing's disease are caused by the effects of excess glucocorticoids and by the hypersecretion of ACTH and other POMC peptide products. The severity of the features of Cushing's disease varies greatly and appears to reflect not only the level of free cortisol but also the duration of the disease and perhaps the sensitivity to glucocorticoid action. In florid cases of Cushing's disease (Fig. 224-7), the constellation of symptoms and physical features is readily recognized. Early in the disease or in mild cases, it can be challenging to distinguish the clinical features of Cushing's disease from similar traits that are seen in the normal population. Clinical suspicion is of paramount importance. On the other hand, one must be discriminating and not formally evaluate everyone with obesity, hypertension, and glucose intolerance. Of the many features listed in Table 224-6, some are relatively specific for Cushing's disease. For example, the centripetal distribution of fat with the characteristic "buffalo hump," "moon facies," and deposition of fat in the supraclavicular area but not in the extremities is much more specific than generalized obesity. Striae that are wide (>1 cm) and purple reflect steroid-induced thinning of the dermis and can be distinguished from the more common "stretch marks." Numerous spontaneous ecchymoses also occur because of thinning of the skin and capillary fragility. Proximal muscle weakness represents another manifestation of glucocorticoid excess. Osteopenia and hypokalemia, when present, provide objective evidence consistent with ACTH excess. Hypokalemia results from the effects of ACTH on mineralocorticoid production but also from the ability of high levels of cortisol to saturate 11β-dehydrogenase, an enzyme in the kidney that inactivates cortisol. As a result, cortisol can "spill over" and act on mineralocorticoid receptors in the distal tubule. The hyperpigmentation associated with Cushing's disease is not as striking as that seen in Addison's disease or in ectopic ACTH syndrome, but in association with other findings, it should raise the suspicion of Cushing's disease and help distinguish it from adrenal causes of hypercortisolemia. Hirsutism and acne are caused by increased production of adrenal androgens and are more prominent in patients with Cushing's disease than in those with adrenal adenomas, in whom glucocorticoids tend to be the predominant product. Oligomenorrhea and amenorrhea probably have several causes, including androgen effects on the reproductive axis and glucocorticoid inhibition of GnRH, which may also account for diminished libido. Hypertension and glucose intolerance are caused by glucocorticoid excess. Immunosuppression, venous thrombo-

FIGURE 224-7. **(A) This 30 year old woman initially presented with a three year history of increasing facial hair, facial rounding, abdominal obesity, hypertension, diabetes, and oligomenorrhea. She had no muscle weakness or pigmented striae. (B) Following successful transsphenoidal resection of her ACTH-secreting microadenoma, she had a dramatic improvement in her clinical appearance with resolution of her diabetes and hypertension.**

TABLE 224-6 CLINICAL FEATURES OF CUSHING'S DISEASE

GENERAL
Obesity (centripetal distribution)
"Moon facies" and mild proptosis
Increased supraclavicular fat and "buffalo hump"
Hypertension
SKIN
Hyperpigmentation
Facial plethora
Hirsutism
Violaceous striae and thin skin
Capillary fragility and easy bruising
Acne
Edema
MUSCULOSKELETAL
Muscle weakness (proximal)
Osteoporosis and back pain
REPRODUCTIVE
Decreased libido
Oligomenorrhea and amenorrhea
NEUROPSYCHIATRIC
Depression
Irritability and emotional lability
Psychosis
METABOLIC
Hypokalemia and alkalosis
Hypercalciuria and renal stones
Glucose intolerance or diabetes mellitus
Impaired wound healing
Impaired resistance to infection
Granulocytosis and lymphopenia
TUMOR MASS EFFECTS
Headache
Visual field loss
Hypopituitarism

TABLE 224-7 TESTS USED IN THE DIFFERENTIAL DIAGNOSIS OF CUSHING'S SYNDROME*

ETIOLOGY	OVERNIGHT DEXAMETHASONE SUPPRESSION TEST	PLASMA ACTH	CORTICOTROPIN-RELEASING HORMONE STIMULATION OF ACTH	PETROSAL-TO-PERIPHERAL ACTH RATIO
Normal	Suppression	Normal	Normal	
Pituitary	No suppression	Normal or high	Normal or increased	>2
Ectopic	No suppression	High or normal	No response	<1.5
Adrenal	No suppression	Low	No response	

*Classic responses are indicated. Certain cases of ectopic adrenocorticotropic hormone (ACTH) production are suppressed by high-dose dexamethasone (not shown in this Table) or are stimulated by corticotropin-releasing hormone. In these cases, petrosal sinus sampling is the most reliable method for distinguishing pituitary and ectopic sources of ACTH.

embolism, opportunistic infections, and impaired wound healing can lead to considerable morbidity and mortality.[17] Neuropsychiatric symptoms, including depression, can be prominent effects of Cushing's disease. Suicide occurs with increased frequency in patients who receive no treatment for Cushing's disease.

DIAGNOSIS

The screening tests and differential diagnosis of Cushing's syndrome represent one of the greatest diagnostic challenges in endocrinology (Chapter 227). The first step is to determine whether a patient truly has cortisol excess. After confirmation of Cushing's syndrome, one must distinguish among (1) adrenal causes of cortisol excess, (2) pituitary causes of ACTH excess (Cushing's disease), (3) ectopic sources of ACTH, and (4) ectopic CRH (Table 224-7).

In screening for hypercortisolism, random cortisol levels are not useful because of diurnal variation of the hormone. The overnight dexamethasone test has been the most widely used screening test (see Table 224-5). A normal result of the dexamethasone test excludes Cushing's syndrome. It should be noted, however, that abnormal overnight dexamethasone suppression can be seen in up to 30% of hospitalized patients and in many patients with depression or during alcohol withdrawal. An elevated 24-hour urine free cortisol value provides an alternative or additional screening test for hypercortisolism. Often, two sequential specimens are collected because of day-to-day variations in hormone production. The sensitivity and specificity of urinary free cortisol measurements are greater than those of the overnight dexamethasone suppression test, particularly in hospitalized patients. A third test takes advantage of the observation that there is a loss of diurnal variation of cortisol levels in all forms of Cushing's syndrome. This test consists of finding elevation of a midnight cortisol level in the saliva. Kits are available for patients to obtain a late-night salivary cortisol sample. The sensitivity and specificity of late-night salivary cortisol measurements are very high, and this test now has become the one most commonly used by endocrinologists.

After demonstrating that cortisol excess is present, the next step is to determine the source of excess ACTH or cortisol. This is done by measuring an ACTH level along with a cortisol level, with primary adrenal disease causing suppressed ACTH levels. The classic approach of performing a low-dose, followed by a high-dose, dexamethasone suppression test has been largely abandoned (see Tables 224-5 and 224-7). The high-dose dexamethasone test is one of several means to to discriminate between pituitary and ectopic causes of ACTH-dependent Cushing's syndrome (see Table 224-7). Pituitary and ectopic causes of Cushing's disease are both ACTH dependent but respond differently to high-dose dexamethasone. Pituitary adenomas have an altered set point for glucocorticoid inhibition but retain a partial ability to respond to high-dose dexamethasone. The exact criteria for dexamethasone suppression in the high-dose test are debated. In most cases of ACTH-producing pituitary adenomas, urinary free cortisol is suppressed below 90% of baseline during the high-dose dexamethasone test.

The ectopic ACTH syndrome should be suspected in patients with known malignancies, particularly small-cell carcinoma of the lung; bronchial, thymic, or gastrointestinal carcinoids; islet cell tumors; and medullary carcinoma of the thyroid, among others. Plasma ACTH levels are often very high (>200 pg/mL) and can be associated with hyperpigmentation. Clinical features of Cushing's syndrome may be altered by the rapid onset of extreme hypercortisolemia coincident with elements of tumor cachexia. Pronounced weakness, fluid retention, glucose intolerance, hypokalemia, and poor skin integrity are often seen. Ectopic ACTH syndrome is readily recognized in its classic form. However, a subset of tumors, particularly carcinoids (Chapter 232), exhibit dexamethasone suppression that is similar to that seen with pituitary adenomas. When suspected, carcinoids can sometimes be detected by CT or MRI, but many are too small to be seen even with these techniques. Because of these exceptions to the high-dose dexamethasone test, a variety of procedures have been devised in an attempt to further distinguish ectopic and pituitary dependent sources of ACTH. CRH testing may also prove useful, with pituitary tumors exhibiting an increase in ACTH and tumors making ACTH ectopically having little or no response.

In recent years, inferior petrosal sinus sampling has been used to distinguish pituitary and ectopic sources of ACTH when the source of ACTH is not obvious based on the clinical circumstances, biochemical evaluation, and imaging studies. This test requires an experienced radiologist for safe and effective catheterization of the petrosal sinuses. Blood samples are taken simultaneously from the left and right petrosal sinuses and from the periphery before and after CRH stimulation. In the case of ACTH-producing pituitary adenomas, there is a gradient in ACTH levels between the central and peripheral blood specimens. When clinical and biochemical studies suggest the presence of a pituitary adenoma, pituitary imaging should be performed using CT or MRI. Most ACTH-secreting pituitary adenomas are small, and scans are normal in more than half of patients.

TREATMENT

Rx

The efficacy of transsphenoidal surgery for Cushing's disease is greatly aided by making the correct diagnosis preoperatively. In experienced hands, surgical cures of ACTH-producing microadenomas occur in 75 to 90% of patients undergoing a first operation. As in other pituitary tumors, complete remissions with macroadenomas are much less common. In the event of surgical remission or cure, postoperative hypocortisolism is to be expected because of suppression of the hypothalamic-pituitary axis. After coverage for steroid withdrawal in the postoperative period, cortisol replacement should gradually be decreased to allow recovery of the hypothalamic-pituitary-adrenal axis; recovery may take up to 1 year.

If transsphenoidal surgery is unsuccessful, reoperation may be indicated and can result in remission in up to 50% of patients[18]; in this circumstance, consideration should be given to performing a total hypophysectomy at reoperation. If transsphenoidal surgery cannot be performed or has failed, alternative forms of therapy should be used to prevent the long-term consequences of hypercortisolism.[19] Pituitary irradiation is often the second line of treatment for Cushing's disease. It is more efficacious in children and in younger patients, but even in older adults, remissions can be achieved in about 50% within 2 years. To prevent the continued ravages of hypercortisolism during this period, however, concomitant medical therapy (see later) is usually given. Bilateral adrenalectomy represents another alternative for patients with severe hypercortisolism after transsphenoidal surgery. It rapidly and effectively lowers cortisol levels but is associated with relatively high morbidity and mortality rates (as high as 5%) because of the associated metabolic and immune system alterations caused by hypercortisolism. The morbidity has been reduced in recent years by introduction of the laparoscopic approach. After adrenalectomy, patients must be maintained on glucocorticoids and mineralocorticoids and are at risk for the development of Nelson syndrome (see later).

Medical therapy for Cushing's disease has its primary role in preparation for surgery or control of hypercortisolism following unsuccessful surgery. It may also be used during the interval when radiation therapy is taking effect (Fig. 224-8). The antifungal agent ketoconazole is effective in decreasing glucocorticoid biosynthesis and also inhibits ACTH secretion, so it has been the most common medical therapy used; it has hepatotoxicity and is not actually approved for use for Cushing's syndrome. Other drugs that interfere with cortisol synthesis (e.g., mitotane, etomidate, metyrapone) have been used less commonly. In a few small studies, cabergoline has also been shown to cause a normalization of cortisol levels in about one third of patients with Cushing's disease, although it has not been approved for this indication. Recently, two new drugs have been approved for the treatment of Cushing's disease. Mifepristone is a progesterone receptor blocker that also is a glucocorticoid receptor blocker and is highly effective in improving clinical signs and symptoms of Cushing's syndrome; because of its mechanism of action, with

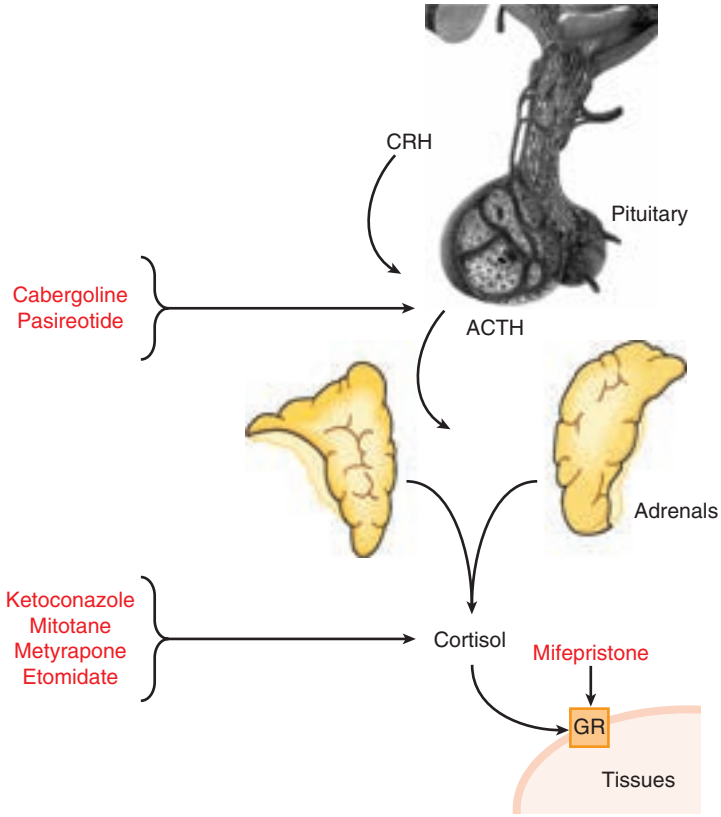

FIGURE 224-8. Medical therapies for Cushing's disease. Cabergoline and pasireotide act to decrease ACTH secretion from the corticotroph tumor. Several drugs (ketoconazole, metyrapone, mitotane, etomidate) work at the adrenal level to decrease cortisol synthesis. Mitotane works at the adrenal level by blocking cortisol action at the glucocorticoid receptor. ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; GR = glucocorticoid receptor. (Adapted from Petersenn S. Medical management of Cushing's disease. In: Swearingen B, Biller BMK (eds) Endocrine updates vol. 31: Cushing's disease. 2011, Springer, New York, pp 167–182, Figure 1. As adapted from Petersenn S, Endocrine Updates, 2011, Springer Science+Business Media B.V.)

treatment, cortisol and ACTH levels actually rise while the clinical signs improve. The higher levels of cortisol may "spill over" to the mineralocorticoid receptor, causing a blood pressure rise and hypokalemia. Symptoms of glucocorticoid withdrawal and even adrenal insufficiency may occur. Blockade of the progesterone receptor by mifepristone may cause menorrhagia. Pasireotide is a somatostatin receptor analog that has much greater activity on corticotroph adenomas than other somatostatin analogs because it has additional activity at the somatostatin-5 receptor. A large multicenter study has recently shown clinical and biochemical efficacy in patients with Cushing's disease[■]; the major adverse effect is hyperglycemia and a worsening of preexisting diabetes mellitus. This worsening of glucose levels is likely due to a reduction in insulin and glucagon-like peptide (GLP)-1 levels.

Nelson Syndrome

Nelson syndrome was initially described as the appearance of a pituitary adenoma after bilateral adrenalectomy. In addition to an enlarging pituitary mass, the syndrome is characterized by very high ACTH levels and hyperpigmentation. It is caused by a preexisting ACTH-producing tumor that grows in the absence of feedback inhibition by high levels of glucocorticoids. The incidence of clinically significant Nelson syndrome after adrenalectomy for Cushing's disease varies from 10 to 50% in different series.[20] Patients with Cushing's disease who have undergone adrenalectomy should be followed with imaging studies and plasma ACTH levels, because tumors that cause Nelson syndrome can be very aggressive. When there is evidence of mass effects or rapid growth, transsphenoidal surgery should be performed. Postoperative irradiation may provide additional benefit, although it appears to be less efficacious than in other ACTH-producing adenomas. In theory, Nelson syndrome could also occur in patients being treated with mifepristone, and such patients should also be monitored with periodic pituitary MRI scans, although short-term follow-up data are reassuring at this point.

GONADOTROPINS (FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE)

The pituitary glycoprotein hormones include FSH, LH, and TSH. Chorionic gonadotropin, which is structurally very similar to LH, is made in the placenta. Each of the glycoprotein hormones has a specific β-subunit that forms a noncovalently bound dimer with the common α-subunit. The α- and β-subunits each undergo glycosylation, which is important for correct hormone folding, intracellular transport, and secretion. Glycosylation is also required for biologic activity, presumably because of effects on the tertiary structure of the hormones. The gonadotropins are involved in sexual differentiation, sex steroid production, and gametogenesis. The regulation and physiologic roles of gonadotropins are quite different in males and females.

In males, receptors for FSH are located on Sertoli cells and seminiferous tubules, whereas LH receptors are located on Leydig cells in the testis. LH stimulates androgen production by the Leydig cells. FSH is involved primarily in sperm maturation in the seminiferous tubules. Thus, FSH and LH act together to induce spermatogenesis (Chapter 234).

In females, ovarian FSH receptors are located on granulosa cells, where they induce enzymes involved in estrogen biosynthesis. LH receptors are located predominantly on thecal cells in the ovary and stimulate the production of ovarian androgens and steroid precursors that are transported to granulosa cells for aromatization to estrogens. The pattern of FSH and LH secretion during the menstrual cycle results in follicular recruitment and maturation (largely FSH mediated), followed by ovulation (largely LH mediated) and steroid production by the corpus luteum (Chapter 235).

Gonadotropin secretion is regulated primarily by the hypothalamic decapeptide GnRH. The gonadotroph cell is exquisitely sensitive to the pattern of GnRH stimulation. Continuous, rather than pulsatile, exposure to GnRH causes gonadotroph desensitization and suppression of LH and FSH. Gonadotroph sensitivity to GnRH is modulated by sex steroids and probably other hypothalamic peptides such as neuropeptide Y. Increased GnRH secretion, in combination with a higher density of GnRH receptors and rising estradiol concentrations, accounts in part for the dramatic release of gonadotropins that induces ovulation.

Hypogonadotropic Hypogonadism

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical features of hypogonadotropic hypogonadism in women are primarily due to estrogen deficiency and include breast atrophy, vaginal dryness, and diminished libido. Hot flashes are uncommon, in contrast to postmenopausal estrogen deficiency. In premenopausal women, normal menstrual cycles provide evidence for an intact hypothalamic-pituitary-gonadal axis. LH and FSH levels should be increased in postmenopausal women, and normal levels may indicate deficiency. Hypogonadism in men causes decreased libido and sexual function. In men, low testosterone without elevation of LH and FSH is consistent with impaired hypothalamic-pituitary reserve. GnRH stimulation can distinguish hypothalamic and pituitary deficiency but may require multiple injections to prime the pituitary.

A congenital form of hypogonadotropic hypogonadism is caused by deficiency of GnRH, which in turn causes deficiencies of LH and FSH. When associated with anosmia (absent sense of smell), the condition is referred to as Kallmann's syndrome (Chapter 223).

Secondary hypogonadotropic hypogonadism is relatively common. In most cases, it is reversible and is caused by weight loss, anorexia nervosa, stress, heavy exercise, or severe illness. Reversible forms of secondary hypogonadotropic hypogonadism are caused by GnRH deficiency and are more common in women than men.

A variety of pathologic conditions can cause secondary hypogonadotropic hypogonadism, often in association with deficiencies of other pituitary hormones (see Table 224-1). These include hypothalamic lesions and central nervous system irradiation. Pituitary tumors can suppress gonadotropins because of stalk compression and disruption of pulsatile GnRH input, as well as by direct destruction of normal pituitary tissue. Hyperprolactinemia can suppress GnRH and lead to reduced gonadotropin levels.

In contrast to the aforementioned causes of hypogonadotropic hypogonadism that result from GnRH deficiency, primary deficiencies of LH and FSH are uncommon. An acquired form of isolated gonadotropin deficiency is rarely encountered and may have an autoimmune basis. Mutations in the *LHβ* or *FSHβ* genes have been described in case reports and cause selective loss of individual gonadotropins. Inactivating mutations in the GnRH

In women, the pattern of GnRH pulse frequency varies across the menstrual cycle (Chapter 235). The combination of GnRH stimulation in conjunction with ovarian feedback regulation results in a complex orchestration of positive and negative hormonal signals that converge at the gonadotroph to regulate LH and FSH secretion. The typical 28-day menstrual cycle is divided into follicular and luteal phases that are separated by ovulation on day 14. Unlike chronic exposure to low concentrations of estrogens, which exert negative feedback regulation and inhibit GnRH, the increasing concentration of estrogen before the LH surge exerts positive feedback regulation that results in increased GnRH pulse frequency. Increased GnRH in combination with increased gonadotroph sensitivity to GnRH results in the LH-FSH surge. During the luteal phase, the gonadotropin pulse frequency is reduced. In addition to feedback regulation by steroids, ovarian peptides such as inhibin also play a role in control of the reproductive axis. Inhibin causes selective suppression of FSH without affecting LH secretion. A homodimer of inhibin β-subunits, referred to as activin, has opposite actions and selectively stimulates FSH, but its predominant physiologic action is to increase ovarian granulosa cell responsivity to FSH. Circulating inhibin provides one of the negative feedback inputs that leads to FSH suppression as the follicle develops. The perimenopause is characterized by a gradual cessation of ovarian function. After several years of menstrual cycles that are sometimes anovulatory or irregular, menses cease, thereby defining the menopause (Chapter 240). At menopause, the decline in estrogen and progesterone causes loss of feedback inhibition and a marked increase in LH and FSH levels.

In males, the regulation of the hypothalamic-pituitary-gonadal axis is relatively constant. Testosterone inhibits the hypothalamic-pituitary axis, although its actions are mediated in part by aromatization to estrogens. Most of the inhibition by gonadal steroids occurs at the hypothalamic level. In contrast to menopause in women, there is no analogous abrupt change in hormone levels in men. There is, however, a gradual decline in testosterone levels associated with an increase in LH and FSH with aging.

receptor and the LH and FSH receptors causing hypogonadotropic hypogonadism have also been reported.

TREATMENT

In premenopausal women, preparations of estrogen and progestins should be used for hormonal replacement and to allow cyclical growth of the endometrium. Pulsatile GnRH (for GnRH-deficient patients) has been given to induce ovulation and fertility but is not commonly used at present. Gonadotropin injections are more commonly used when fertility is desired. Testosterone can be replaced in men, using intramuscular injections that are given at 2- to 4-week intervals. Doses and the intervals between injections should be adjusted on an individual basis using libido and testosterone levels before the next injection as a guide. Oral preparations of androgens should be avoided because of hepatotoxicity. Transdermal patch and gel preparations are also available and maintain more stable testosterone levels but are more expensive. With gels, care has to be used to prevent exposure of the partner or children. Although induction of spermatogenesis can be achieved using pulsatile GnRH (for GnRH-deficient patients), injections of gonadotropins are more commonly used.

Pulsatile GnRH has been used to induce puberty and fertility in both males and females with Kallmann's syndrome and other forms of GnRH deficiency, but more commonly, injections of gonadotropins are used.

Secondary hypogonadotropic hypogonadism is ideally treated by correcting the underlying cause.[21] Many women have a discrete threshold for weight or exercise level that will cause loss of menstrual periods. When it is not possible to correct the underlying abnormality, hormonal replacement can be used in women for protection against osteopenia and to cycle the endometrium. Permanent idiopathic hypogonadotropic hypogonadism can also occur in both sexes and will require hormone replacement.

Follicle-Stimulating Hormone– and Luteinizing Hormone–Producing Tumors

PATHOBIOLOGY

The majority (70 to 80%) of pituitary tumors classified previously as nonfunctioning adenomas can be shown to produce low levels of intact glycoprotein hormones or their uncombined α- or β-subunits. Biosynthetic defects in the tumor cells account for relatively inefficient hormone secretion as well as the propensity to produce uncombined subunits. FSH is produced more commonly than LH. Elevated levels of free α-subunits are noted more often than increased free β-subunits.

CLINICAL MANIFESTATIONS

Gonadotropin-producing tumors are somewhat more common in men than women and increase in prevalence with age. FSH- and LH-producing tumors do not usually cause a characteristic hormone excess syndrome. The tumors, typically large macroadenomas, present as clinically nonfunctioning tumors with symptoms and signs related to local mass effects. Visual field loss is found in more than 70% of patients. Many are detected incidentally by CT and MRI performed for unrelated indications. Symptoms of hypogonadism with loss of libido are also common. Men with predominantly FSH-secreting tumors may present with testicular enlargement from hypertrophy of the seminiferous tubules but may also be hypogonadal due to low levels of testosterone. These patients must be distinguished from those with primary hypogonadism due to testicular dysfunction. Tumors that primarily secrete LH are rare but can cause increased testosterone levels. Premenopausal women with gonadotropin-producing tumors may experience menstrual irregularity or secondary hypogonadism. Postmenopausal women often show reduced gonadotropin levels because the mass effects of the gonadotropin-producing tumors cause stalk compression, impairing GnRH stimulation of gonadotropins from normal pituitary cells.

DIAGNOSIS

Because of the absence of a clinical syndrome in most patients, almost all gonadotropin-producing pituitary tumors are diagnosed by postoperative immunohistochemistry, because they had presented with mass effects. There is no particular clinical benefit to distinguish whether a nonfunctioning adenoma is truly a gonadotroph adenoma. Some patients can have moderately elevated PRL levels that are caused by tumor mass effects. It is important to distinguish this group from patients with true prolactinomas. As noted earlier, many women, including those in the postmenopausal group, have paradoxically low gonadotropin levels. Thus, the absence of elevated gonadotropins does not exclude the diagnosis of a gonadotropin-producing tumor.

TREATMENT

Because the major symptoms of the gonadotropin-producing tumors are due to extrasellar extension and local mass effects, the main aim of treatment is reduction in tumor size. Complete or partial reversal of visual field defects and hypopituitarism can be accomplished by surgery unless these conditions have been of long standing. Transsphenoidal surgery is rarely curative, however, because of the large size of the tumors. Patients with significant residual tumor may benefit from radiation therapy. Because most tumors are slow growing, when no tumor is visible postoperatively by MRI, the patient may be followed with yearly monitoring for tumor recurrence, using visual fields and CT or MRI. If tumor markers such as free α- or β-subunit levels are available, they can also be used to monitor tumor function. When follow-up studies show tumor regrowth, repeat surgery, radiation therapy, or both are indicated. Medical therapy with dopamine agonists and somatostatin analogues has been successful in only a minority of patients.

THYROID-STIMULATING HORMONE

Like the other glycoprotein hormones, TSH is a heterodimer composed of the common α-subunit and the unique TSH β-subunit. Normal levels of TSH range from 0.4 to 4.0 μU/mL. The detection limit for current TSH assays is less than 0.01 μU/mL, allowing measurement of suppressed TSH levels in patients with hyperthyroidism. TSH controls thyroid hormone (T_4 and T_3) synthesis and secretion from the thyroid gland. Hypothalamic TRH stimulates TSH synthesis and secretion. Somatostatin and dopamine can inhibit TSH secretion, but their roles in normal physiology have not been clearly elucidated. Thyroid hormones have an inhibitory effect on the production of TRH and TSH and constitute a powerful negative feedback loop acting at both the hypothalamic and pituitary levels. Secretion of TSH is pulsatile, but the amplitude of the pulses is relatively small and does not create the difficulties in measurement of TSH that are encountered with measurements of other pituitary hormones. Because of the integrated nature of the hypothalamic-pituitary-thyroid axis, thyroid function tests are best interpreted when concentrations of TSH, free T_4, and free T_3 levels are known. Except in conditions of secondary hypothyroidism or TSH-secreting pituitary tumors (see later), TSH levels provide an excellent screening test for thyroid dysfunction.

Central Hypothyroidism

Central forms of hypothyroidism are due to loss of either TSH or TRH.[22] Three different types of congenital TSH deficiency are caused by genetic mutations. One type involves mutations in the *TSHβ* gene. A second involves mutations in *PIT1*, which causes combined deficiencies of GH, PRL, and TSH (see earlier). A third involves a mutation in the gene for TRH. Acquired central forms of hypothyroidism are usually associated with other pituitary hormone deficiencies, and usually there is no goiter because of low TSH levels.

Tests for TSH deficiency are best performed by analyzing free T_4 levels in combination with TSH. Low free T_4 without elevated TSH is consistent with central hypothyroidism. In some patients with hypothalamic disease, the TSH level is partially elevated in the presence of low levels of free T_4, but the bioactivity of the TSH is reduced. Central forms of hypothyroidism must be distinguished from the sick-euthyroid condition (Chapter 226). Laboratory tests in the sick-euthyroid syndrome progress through several phases but can include prolonged periods when both TSH and free thyroid hormone levels are low. It can be very difficult in these patients to exclude central hypothyroidism unequivocally. In addition to the clinical setting in which thyroid function tests are measured, the presence of normal thyroid function tests before the illness and the absence of known hypothalamic or pituitary disease make true central hypothyroidism unlikely. Increased levels of reverse T_3 are suggestive of sick-euthyroidism, and free T_4 and T_3 may be in the normal or low-normal range in sick-euthyroid patients. When TSH deficiency is documented, thyroid hormone is replaced using daily doses of L-thyroxine (0.05 to 0.15 mg/day). Because TSH cannot be used as an end point, one monitors the patient clinically and with serum levels of free T_4 and T_3.

Thyroid-Stimulating Hormone–Secreting Tumors

TSH-secreting tumors are rare and account for between 1 and 3% of pituitary tumors. A recent analysis from Sweden showed that the prevalence was only

2.8 per 1 million.[23] As many as 45% of TSH-producing tumors are plurihormonal. GH and PRL are co-secreted most often, perhaps reflecting the common cellular lineage for thyrotrophs, somatotrophs, and lactotrophs. Long-standing severe hypothyroidism can cause thyrotroph hyperplasia and pituitary enlargement. These hyperplastic masses regress with thyroid hormone replacement therapy, however. Most true TSH-producing tumors are relatively autonomous and respond weakly, if at all, to TRH stimulation or thyroid hormone suppression.

TSH-secreting tumors are usually macroadenomas by the time a diagnosis has been made. Consequently, many patients exhibit mass effects of the tumor, as well as hyperthyroidism. The clinical features of TSH-secreting tumors resemble those of Graves' disease, except that features of autoimmunity (e.g., ophthalmopathy) are absent. Circulating levels of T_4 and T_3 range widely but can be elevated as much as two- to three-fold. Diffuse goiter is present in most patients with TSH-producing tumors, and the 24-hour uptake of radioiodine is elevated.

Because feedback inhibition of TSH is impaired in TSH-producing tumors, TSH levels are inappropriately elevated in the presence of high levels of T_4 and T_3. TSH levels produced by tumors range from the low-normal range to as high as 500 μU/mL, but most levels are minimally elevated. Most TSH-producing tumors (>80%) secrete excess free α-subunit, and its assessment can be very useful in confirming the diagnosis. Thus, the diagnosis can usually be made by demonstrating that a hyperthyroid patient has a detectable serum TSH level associated with excess secretion of the free α-subunit. The finding of a mass lesion on CT or MRI confirms the diagnosis. Several other causes of inappropriate TSH secretion should be considered, including resistance to thyroid hormone and familial dysalbuminemic hyperthyroxinemia and other disorders that alter serum thyroid hormone binding proteins.

TREATMENT

Rx

The goals of therapy are to treat the underlying TSH-secreting tumor and to correct the hyperthyroidism. Transsphenoidal surgery alone is rarely curative because of the large size of most tumors, but it can alleviate mass effects and lower TSH levels. As in other large pituitary tumors, adjunctive irradiation may be required to control tumor growth. Somatostatin analogues have been used as adjunctive medical therapy, and they decrease TSH and α-subunit levels in about 80% of patients with TSH-secreting tumors, but consistent effects on tumor growth have not been demonstrated. Hyperthyroidism caused by TSH-secreting tumors can also be treated using antithyroid drugs or radioiodine.

CLINICALLY NONFUNCTIONING PITUITARY TUMORS

Most clinically nonfunctioning adenomas can be shown to produce low levels of the free α-subunit, free β-subunits of FSH and LH, and intact FSH and LH when analyzed by immunocytochemistry or messenger RNA expression. A smaller fraction can be shown to produce low levels of other pituitary hormones, particularly ACTH or GH, that escaped detection based on routine endocrine testing.[24] Even with detailed analyses of hormone production, a subset (10 to 20%) of nonfunctioning adenomas does not appear to produce any of the known pituitary hormones.

The clinical features and management of nonfunctioning tumors are similar to those for gonadotropin-producing tumors. The major signs and symptoms result from tumor mass effects that cause visual field defects, headache and other neurologic symptoms, and hypopituitarism. Transsphenoidal surgery is the primary mode of treatment, with a goal of debulking the tumor to relieve mass effects. Because there are no serum tumor markers, patients must be followed by CT or MRI in conjunction with visual field tests.

Some pituitary tumors are discovered as incidental findings on CT or MRI scans that were done for other reasons.[25] Such tumors should be screened for hormone oversecretion with measurement of PRL, IGF-I, and a midnight salivary cortisol or an overnight dexamethasone suppression test, but most will be found to be nonfunctioning. If the tumor abuts the optic chiasm, a formal visual field examination should be performed. Over several years, about 10% of incidental microadenomas and 20% of macroadenomas enlarge. Indications for surgery include compression of the optic chiasm, with or without visual field defects and significant tumor enlargement. Hypopituitarism is also a relative indication for surgery (Fig. e224-1). In the absence of these indications for surgery, it is reasonable to follow such patients with MRI scans to look for size change at yearly intervals initially and then at less frequent intervals.

REVIEW QUESTIONS

1. A 25-year-old woman has had amenorrhea and galactorrhea for 2 years and is found to have hyperprolactinemia. Her PRL level is 513 ng/mL (normal 2.5 to 23.6 ng/mL) and magnetic resonance imaging showed a 1.3-cm macroadenoma. The rest of her evaluation is normal, with the exception of a serum calcium of 11.4 mg/dL. She recalls that one of her cousins also has a pituitary tumor. Which of the following genes should be analyzed for a mutation?

A. *PROP1*
B. *Pit1*
C. *Menin*
D. *Ret* proto-oncogene
E. *Ras*

Answer: C Menin is encoded by the gene mutated in multiple endocrine neoplasia *(MEN1)*, characterized by multiple endocrine tumors of the parathyroid glands, pancreatic islets, and anterior pituitary, especially prolactinomas. For incorrect answers, see introductory section on "Anatomy and Embryology."

2. Which of the following medications used to treat pituitary tumor syndromes acts by blocking a hormone receptor?

A. Pasireotide
B. Cabergoline
C. Ketoconazole
D. Mifepristone
E. Bromocriptine

Answer: D See Figure 224-8 and its legend.

3. A 67-year-old man is found to have enlarging hands and feet and has been referred by his dentist because of prognathism. To determine whether he has acromegaly, which of the following tests should be carried out?

A. Pituitary magnetic resonance imaging
B. Overnight 1-mg dexamethasone suppression test
C. Insulin-induced hypoglycemia stimulation test
D. Measurement of insulin-like growth factor (IGF)-I
E. Inferior petrosal sinus sampling with GHRH stimulation

Answer: D See section on "Diagnosis" under "Growth Hormone Excess: Acromegaly and Gigantism."

4. Magnetic resonance imaging (MRI) on a 73-year-old woman experiencing dizziness reveals an incidental 3-mm lesion in her pituitary that is compatible with a pituitary adenoma. She has otherwise been well. Testing for hormone oversecretion is negative. What should be the next step in management?

A. Refer her to an experienced neurosurgeon.
B. Repeat the MRI in 1 year to look for size change.
C. Refer her to ophthalmology for a visual field examination.
D. Begin bromocriptine treatment.
E. Refer her for a preoperative cardiac stress test.

Answer: B See section on "Clinically Nonfunctioning Pituitary Tumors" at the end of the chapter and also e-Figure 224-1.

POSTERIOR PITUITARY

JOSEPH G. VERBALIS

ANATOMY AND HORMONE SYNTHESIS

The hormones of the posterior pituitary, vasopressin and oxytocin, are synthesized in specialized neurons in the hypothalamus, the neurohypophysial neurons. These neurons, notable for their large size, are termed *magnocellular neurons*. In the hypothalamus, the magnocellular neurons are clustered in the paired paraventricular and supraoptic nuclei (Fig. 225-1). Vasopressin and oxytocin are also synthesized in parvicellular (i.e., small cell) neurons of the paraventricular nuclei, and vasopressin (but not oxytocin) is also synthesized in the suprachiasmatic nucleus.

Transcription of vasopressin and oxytocin messenger RNA and translation of the vasopressin and oxytocin prohormones occur entirely in the cell bodies of the neurohypophysial neurons. The prohormones provasopressin and prooxytocin are packaged along with processing enzymes into neurosecretory granules that are transported out of the perikaryon of the neurohypophysial neurons via microtubules and down the long axons that form the supraopticohypophysial tract, which terminates in the posterior pituitary. During transport, the processing enzymes cleave provasopressin into vasopressin (9 amino acids), vasopressin-neurophysin (95 amino acids), and vasopressin glycopeptide, or copeptin (39 amino acids). Pro-oxytocin is similarly cleaved to oxytocin (which differs from vasopressin by only two of nine amino acids) and oxytocin-neurophysin. The neurophysins form neurophysin-hormone complexes that stabilize the hormones. Stimulatory (e.g., glutamatergic, cholinergic, and angiotensin) neurotransmitter terminals and inhibitory (e.g., γ-aminobutyric acid and noradrenergic) neurotransmitter terminals control the release of vasopressin through the activity of synaptic contacts on the neurohypophyseal cell bodies. Physiologic release of vasopressin or oxytocin into the general circulation occurs at the level of the posterior pituitary, where, in response to an action potential, intracellular calcium is increased and causes the neurosecretory granules to fuse with the axon membrane, thereby releasing each hormone into the general circulation. Although each of the other prohormone fragments are released into the circulation, vasopressin and oxytocin are the only biologically active components of the prohormones. Factors that stimulate the release of neurohypophysial hormones also stimulate their synthesis. Because synthesis is delayed, maintenance of a large store of hormone in the posterior pituitary is essential to enable the instantaneous release of each hormone that is necessary following acute hemorrhage (vasopressin) or during parturition (oxytocin). In most species, sufficient vasopressin is stored in the posterior pituitary to support maximal antidiuresis for several days and to maintain baseline levels of antidiuresis for weeks.

Vasopressin

Vasopressin and Regulation of Osmolality

The primary physiologic action of vasopressin is its function as a water-retaining hormone. The central sensing system (osmostat) for controlling the release of vasopressin is anatomically discrete, located in a small area of the hypothalamus just anterior to the third ventricle (see Fig. 225-1). The

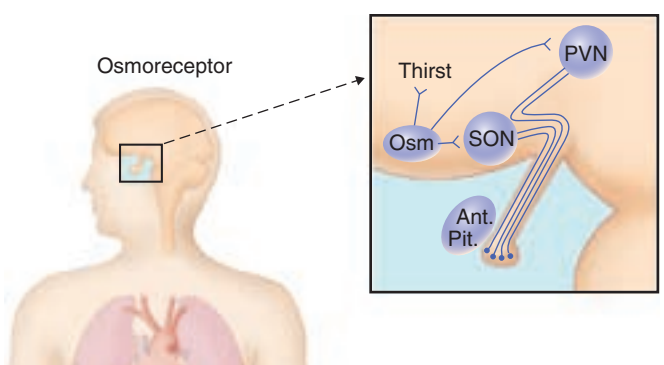

FIGURE 225-1. Sagittal view of the head, demonstrating the position of the neurohypophysis. The magnocellular neurons are clustered in two paraventricular nuclei (PVN) and two supraoptic nuclei (SON). Only one nucleus of each pair is illustrated. The supraoptic nuclei are lateral to the edge of the optic chiasm, whereas the paraventricular nuclei are central along the wall of the third ventricle. The axons of the four nuclei combine to form the supraopticohypophysial tract as they course through the pituitary stalk to their storage terminals in the posterior pituitary. The osmostat (Osm) is in the hypothalamus anterior to the third ventricle; the thirst center (Thirst) is distributed across different brain areas. Ant. Pit. = anterior pituitary. (From Buonocore CM, Robinson AG. Diagnosis and management of diabetes insipidus during medical emergencies. *Endocrinol Metab Clin North Am.* 1993;22:411-423.)

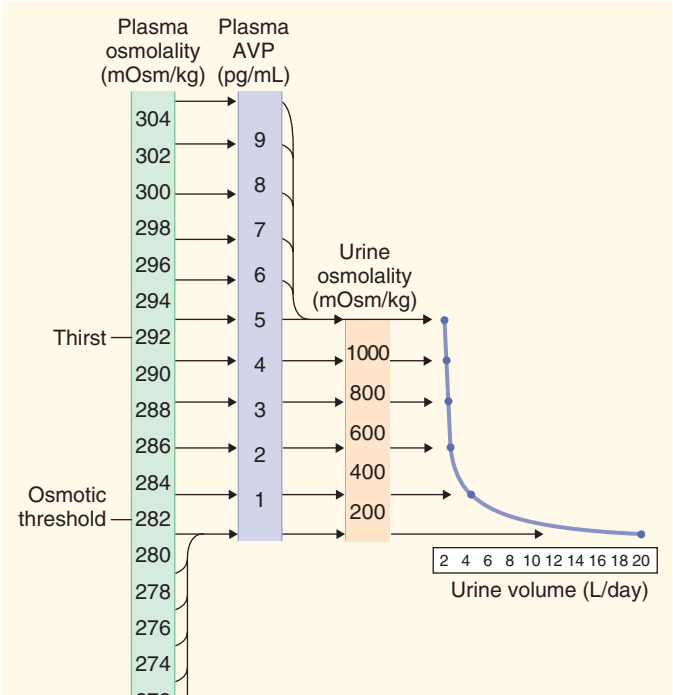

FIGURE 225-2. Idealized schematic of the normal physiologic relationships among plasma osmolality, plasma vasopressin (AVP), urine osmolality, and urine volume. The entire physiologic range of urine osmolality occurs with plasma vasopressin levels from 0 to 5 pg/mL. Increases in plasma osmolality above approximately 290 to 295 mOsm/kg H_2O result in increases in plasma vasopressin but no further concentration of the urine, which is limited by the maximal osmolality in the inner medulla. The relation of volume (calculated on the basis of a constant osmolar load) is inversely exponential to the other parameters. Because of this relationship, urine volume does not change substantially until there is nearly absent vasopressin secretion, after which urine volume increases dramatically. (Calculated from formulas presented in Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. *Kidney Int.* 1976;10:25-37. Figure drawn by J.G. Verbalis, Georgetown University, Washington, DC.)

osmostat controls the release of vasopressin to cause water retention and also stimulates thirst to cause water repletion.

Osmotic regulation of vasopressin release and osmotic regulation of thirst are usually tightly coupled, but they can be dissociated under pathologic conditions. The primary extracellular osmolyte to which the osmoreceptor responds is sodium. Under normal physiologic conditions, glucose and urea cross neuron cell membranes and do not stimulate the release of vasopressin. Although basal osmolality in normal subjects ranges between 280 and 295 mOsm/kg H_2O, extracellular fluid osmolality for each individual is maintained within narrow ranges. Increases in plasma osmolality as small as 1 to 2% are sufficient to stimulate vasopressin release. Basal plasma levels of vasopressin are generally 0.5 to 2 pg/mL, which maintains urine osmolality above plasma osmolality and urine volume in the range of 2 to 3 L/day. When vasopressin levels are suppressed below 0.5 pg/mL, maximal urine osmolality decreases to below 100 mOsm/kg H_2O, and a free water diuresis (or "aquaresis") ensues at levels that approach 800 to 1000 mL/hour (18 to 24 L/day). Increases in plasma osmolality cause a linear increase in plasma vasopressin and a corresponding linear increase in urine osmolality. At a plasma osmolality of approximately 295 mOsm/kg H_2O, urine osmolality is maximally concentrated to 1000 to 1200 mOsm/kg H_2O. Thus, the entire physiologic range of urine osmolality is accomplished by relatively small changes in plasma vasopressin levels of 0 to 5 pg/mL (Fig. 225-2).

To maintain fluid balance, water must be not only conserved but also consumed to replace insensible water losses and obligate urine output. Thirst is not stimulated until a somewhat higher plasma osmolality (5 to 10 mOsm/kg H_2O) than the threshold for release of vasopressin. Most humans derive sufficient water from habitual fluid intake and catabolism of food to maintain plasma osmolality below the threshold that activates thirst. Therefore, under normal physiologic conditions, water balance (and hence plasma osmolality) is regulated more by secretion of vasopressin than by thirst. However, with severe degrees of dehydration, thirst is essential to restore body water deficits.

Vasopressin acts on the V_2 subtype of vasopressin receptors in the collecting duct principal cells of the kidney to cause water retention, or antidiuresis. Vasopressin V_2 receptors are G protein–coupled receptors that activate adenylate cyclase, with subsequent increased intracellular cyclic adenosine monophosphate (cAMP) levels upon ligand activation of the receptor. The increased cAMP initiates the movement of aquaporin-2 (AQP2) water channels to the apical (luminal) membrane of the collecting duct cells. These channels allow facilitated rapid transport of water from the collecting duct lumen into the principal cell along osmotic gradients. The water then exits the cell through the basolateral membrane into the kidney medullary circulation through constitutively expressed aquaporin-3 and aquaporin-4 water channels.[1] This entire process is termed *antidiuresis*. In the absence of vasopressin, the AQP2 channels are reinternalized from the apical membrane into subapical vesicles. This prevents active reabsorption of water from the collecting duct lumen, resulting in diuresis. In addition to this rapid "shuttling" of the AQP2 channels to regulate water reabsorption on a minute-to-minute basis, vasopressin also acts through the V_2 receptors to regulate long-term stores of AQP2—that is, increased vasopressin stimulates AQP2 synthesis, and the absence of vasopressin results in decreased AQP2 synthesis. The hypertonic medullary interstitium is the determinant of the maximal concentration of the urine, which is in equilibrium with the osmolality of the inner medulla of the kidney under conditions of maximal antidiuresis (Chapter 115).

Vasopressin and Pressure and Volume Regulation

High-pressure baroreceptors are located in the aorta and carotid sinus, and low-pressure baroreceptors are located in the right and left atria. Decreases in blood pressure or intravascular volume stimulate vasopressin release, whereas situations that increase blood volume or left atrial pressure (e.g., negative-pressure breathing) decrease the secretion of vasopressin. The release of vasopressin in response to changes in volume or pressure is much less sensitive than the release in response to osmoreceptors; generally a 10 to 15% reduction in blood volume or pressure is needed to stimulate the release of vasopressin. However, once arterial pressure falls below this threshold, the stimulated response is exponential resulting in plasma levels of vasopressin that are markedly greater than those resulting from osmotic stimulation.

The pressor effects of vasopressin are mediated through a separate vasopressin receptor subtype, the V_{1a} receptors, located on vascular smooth muscle. The relatively insensitive regulation of vasopressin secretion by changes in volume and pressure and the modest role of vasopressin to regulate blood pressure are consistent with the notion that regulation of sodium homeostasis by the renin-angiotensin-aldosterone system (Chapter 227) is more important for controlling extracellular and blood volume than is the regulation of water homeostasis. However, the pressor effects of vasopressin to increase blood pressure can become prominent when other blood pressure

regulatory systems are deficient (e.g., autonomic neuropathy or renin-angiotensin-aldosterone system blockade) or in states of pathologic vasodilation (e.g., liver cirrhosis, septic shock).

Vasopressin and Adrenocorticotropic Hormone

Vasopressin stimulates adrenocorticotropic hormone (ACTH) secretion via stimulation of the vasopressin V_{1b} receptor subtypes that are located on anterior pituitary corticotroph cells. Although the major regulator of ACTH secretion is corticotropin-releasing hormone (Chapter 224), vasopressin activates a different signal transduction system in the corticotrophs, so these hormones have synergistic effects on ACTH secretion.

Interaction of Osmotic and Volume Regulation

The vasopressin system has evolved to optimize mammalian water homeostasis. Water is consumed as available in the absence of stimulated thirst, and vasopressin secretion then regulates water excretion to maintain plasma osmolality. Thirst serves as a backup mechanism if dehydration becomes excessive. Because pressure-volume regulation of vasopressin is less sensitive, modest changes in pressure or volume, which are exacerbated by upright posture, do not interfere with the regulation of osmolality. Yet the pressor effect of high vasopressin levels serves to maintain blood pressure if volume depletion or hypotension becomes excessive. Usually, the physiologic regulation of osmolality and pressure-volume are synergistic. Dehydration causes an increase in plasma osmolality and a decrease in blood volume, both of which stimulate the release of vasopressin. Conversely, excess fluid administration causes a decrease in plasma osmolality and an expansion of blood volume, both of which inhibit vasopressin secretion.

Other factors can also modulate osmotic release and action of vasopressin. With volume expansion, natriuretic factors such as atrial natriuretic peptide and brain natriuretic peptide are released from atrial myocytes and act at the kidney to induce a natriuresis. Brain natriuretic peptide is also synthesized in the hypothalamus, where it may act to decrease vasopressin secretion. During pregnancy, there is a decrease of plasma osmolality by approximately 10 mOsm/kg H_2O as a result of a resetting of the osmostat for vasopressin secretion, and the osmostat for thirst is reset downward in parallel. These effects appear to be mediated by the placental hormone relaxin.

Abnormalities in water and electrolyte balance are common in the elderly. This is due in part to age-related changes in body volume (as much as a 50% decrease in total body water occurs in those older than 75 years) and renal function. The elderly also have a decreased sense of thirst. Although there is a normal or even increased ability to secrete vasopressin with age, there is a decreased ability to achieve either maximal urine concentration to retain water or maximal dilution of urine to excrete water. Consequently, the elderly are particularly prone to both hypernatremia or hyponatremia with diseases that affect water balance or from the drugs used to treat various diseases.[2]

Oxytocin

Prolactin is the main hormone necessary for milk production, but oxytocin is essential for milk secretion. Suckling stimulates tactile receptors, producing an afferent signal to the hypothalamus that causes a synchronized release of oxytocin from the posterior pituitary. Oxytocin binds to oxytocin receptors in the breast and induces contraction of myoepithelial cells around the alveoli and ductules to eject milk. In addition, upregulation of uterine oxytocin receptors dramatically increases uterine smooth muscle contractions in response to oxytocin secretion at the end of pregnancy. The greatest release of oxytocin occurs with, not before, delivery of the infant, probably secondary to stretching of the vaginal wall. Because transgenic mice lacking either oxytocin or oxytocin receptors have normal parturition, oxytocin release may be more important to induce uterine contraction to inhibit blood loss after delivery than to initiate parturition. No pathologic syndromes of either increased or decreased secretion of oxytocin have yet been defined, but experimental studies have implicated oxytocin in maternal and affiliative behavior as well as bone formation.[3] However, because of the structural similarity between vasopressin and oxytocin, at high plasma levels oxytocin can activate vasopressin receptors, and vasopressin can activate oxytocin receptors, both of which can have pathologic consequences.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Excess secretion of vasopressin can be caused by abnormally regulated secretion from the posterior pituitary, or by ectopic synthesis and secretion of vasopressin by tumors. Osmotically inappropriate secretion of vasopressin causes renal water retention and volume expansion of body fluids, with consequent dilutional hyponatremia. This disorder is called the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and is discussed in Chapter 116.

DIABETES INSIPIDUS

DEFINITION

Diabetes insipidus is the excretion of a large volume of hypotonic insipid (tasteless) urine, usually manifested by polyuria (increased urination) and polydipsia (increased thirst).[4] The large urine volume, usually in excess of 50 to 60 mL/kg/day, must be distinguished from an increased frequency of small urine volumes and from large volumes of isotonic or hypertonic urine, both of which have different clinical significance.

PATHOBIOLOGY

Five pathophysiologic mechanisms must be considered in the differential diagnosis of diabetes insipidus.

1. Central diabetes insipidus is caused by the inability of the hypothalamus–posterior pituitary to secrete (and usually to synthesize) vasopressin in response to increased osmolality. No concentration of the dilute glomerular filtrate takes place in the renal collecting duct, and consequently, a large volume of hypotonic (i.e., dilute) urine is excreted. This produces a secondary increase in serum osmolality, with stimulation of thirst and secondary polydipsia. Levels of vasopressin in plasma are unmeasurable or inappropriately low for the plasma osmolality.
2. Nephrogenic diabetes insipidus is caused by the inability of an otherwise normal kidney to respond to vasopressin. As in hypothalamic (central) diabetes insipidus, the dilute glomerular filtrate entering the collecting duct is excreted as a large volume of hypotonic urine. The rise in plasma osmolality that occurs stimulates thirst and produces polydipsia. Unlike central diabetes insipidus, however, measured levels of vasopressin in plasma are high or appropriate for plasma osmolality.
3. Gestational diabetes insipidus is a rare condition produced by elevated levels or activity of placental cystine aminopeptidase (oxytocinase or vasopressinase) during pregnancy. The rapid destruction of vasopressin produces diabetes insipidus with polyuria and secondary stimulation of thirst with polydipsia. Because of the circulating vasopressinase, plasma vasopressin levels usually cannot be measured.
4. Primary polydipsia is a disorder of excess fluid ingestion rather than of vasopressin secretion or activity. Excessive ingested water produces a mild decrease in plasma osmolality that shuts off the secretion of vasopressin. In the absence of vasopressin action on the kidney, urine does not become concentrated, and a large volume of hypotonic urine is excreted. The amount of vasopressin in plasma is unmeasurable or low but is appropriate for the low plasma osmolality.
5. Osmoreceptor dysfunction is a variant of central diabetes insipidus in which the neurohypophysis is intact, but the osmoreceptive cells in the anterior hypothalamus have been damaged (see Fig. 225-1). Because the osmoreceptor cells are necessary for osmotically stimulated vasopressin secretion, the patient manifests polyuria. However, because the osmoreceptor cells also control thirst, these patients do not have polydipsia. As a result, they are characterized by elevated serum sodium levels and plasma osmolalities. For this reason, this disorder has also been called essential hypernatremia and adipsic hypernatremia, in recognition of the profound thirst deficits found in most of the affected patients.

Although the pathophysiologic mechanisms for each of these five disorders are distinct, patients in the first four categories usually manifest polyuria and polydipsia, and the serum sodium level is usually normal because an intact thirst mechanism is sufficiently sensitive to maintain water homeostasis in the first three disorders, and the normal kidney has sufficient capacity to excrete the excess water load in the fourth. The fifth category of osmoreceptor dysfunction is the exception, owing to a defective thirst mechanism leading to hypernatremia.

CLINICAL MANIFESTATIONS

Central Diabetes Insipidus

The sudden appearance of hypotonic polyuria[5] after transcranial surgery in the area of the hypothalamus or after head trauma with basal skull fracture and hypothalamic damage obviously suggests the diagnosis of central diabetes insipidus.[6] In these situations, if the patient is unconscious and unable to recognize thirst, hypernatremia is a common accompaniment. However, even in patients with more insidious progression of a specific disease or in patients

with idiopathic central diabetes insipidus, the onset of polyuria is often relatively abrupt and occurs over several days or weeks. Most patients do not notice polyuria until urine volume exceeds 4 L/day, and as illustrated in Figure 225-2, urine volume does not exceed 4 L/day until the ability to concentrate the urine is severely limited and plasma vasopressin is nearly absent. As few as 10 to 15% of the normal number of vasopressinergic neurons in the hypothalamus is sufficient to maintain an asymptomatic urine volume, but the further loss of just a small number of these neurons produces a rapid increase in urine volume and symptomatic polyuria. Urine volume seldom exceeds the amount of dilute fluid delivered to the collecting duct (≈18 to 24 L in humans); in many cases, urine volume is significantly less because patients voluntarily restrict fluid intake, which causes some mild volume contraction and increased proximal tubular reabsorption of fluid. Patients often express a preference for cold liquids, which are more effective in assuaging thirst. Both thirst and increased urine output persist through the night, impairing sleep. Patients with partial central diabetes insipidus have some ability to secrete vasopressin, but this secretion is markedly attenuated at normal levels of plasma osmolality. Therefore, these patients often have symptoms and urine volume similar to those of patients with complete central diabetes insipidus. Because most patients with central diabetes insipidus have sufficient thirst to drink fluid to match urine output, few laboratory abnormalities are present at the time of initial evaluation. The serum sodium level can be in the high-normal range, whereas the blood urea nitrogen level can be low secondary to the large urine volume. Uric acid is relatively high because of the modest volume contraction and lack of action of vasopressin on V_{1a} receptors in the kidney, which stimulate the clearance of uric acid. Uric acid levels greater than 5 mg/dL can distinguish diabetes insipidus from primary polydipsia.

Osmoreceptor Dysfunction

A variant of central diabetes insipidus is the syndrome of osmoreceptor dysfunction. Physiologic maneuvers demonstrate that when patients are euvolemic, an increase in plasma osmolality produces neither secretion of vasopressin nor a sensation of thirst. However, vasopressin is still synthesized by the hypothalamus and stored in the posterior pituitary, because stimulation of baroreceptors by hypovolemia or hypotension results in the prompt secretion of vasopressin; the kidney is responsive because vasopressin release by volume receptor stimulation causes urinary concentration. Because patients lack thirst, they are chronically dehydrated, often with markedly increased serum sodium levels. However, it is the dehydration-induced volume depletion, not the increased osmolality, that eventually stimulates the secretion of vasopressin. The volume of urine output depends on the degree of dehydration-induced secretion of vasopressin. If sufficient fluid replacement is given to return extracellular fluid volume to normal, these patients are unable to regulate vasopressin by osmolality and again become polyuric, thereby manifesting their underlying central diabetes insipidus. Lesions that cause osmoreceptor dysfunction are similar to lesions that can cause central diabetes insipidus, but in contrast to central diabetes insipidus these lesions usually occur more rostrally in the hypothalamus, consistent with the anterior hypothalamic location of the primary osmoreceptor cells (see Fig. 15-2). One lesion that is unique to this disorder is an anterior communicating cerebral artery aneurysm, particularly following resection of the aneurysm.

Central diabetes insipidus can be inherited as an autosomal dominant disease that is typically characterized by an asymptomatic infancy and an onset later in childhood. Most genetic defects are either in the signal peptide of the pre-prohormone or in the neurophysin portion of the prohormone.[7] Mutations involving the vasopressin sequence itself are few. Most cases are believed to result from disruption of cleavage from the signal peptide or abnormal folding of the neurophysin, which slows trafficking of the mutant prohormone through the endoplasmic reticulum, leading to neuronal cell dysfunction and/or death. Because this is a cumulative process, this explains the later onset of central diabetes insipidus with these types of mutations.

Myxedema and adrenal insufficiency both impair the ability to excrete free water by renal mechanisms. The simultaneous occurrence of either of these diseases with central diabetes insipidus (as can occur with a tumor of the hypothalamus or pituitary) can decrease an otherwise large urine output, thereby masking the symptoms of diabetes insipidus. Replacement treatment for the anterior pituitary deficiency, especially glucocorticoids, can then cause a sudden and massive excretion of dilute urine. Similarly, the onset of either hypothyroidism or adrenal insufficiency during the course of diabetes insipidus can decrease the need for vasopressin replacement and in some cases can even cause hyponatremia. Central diabetes insipidus occurs commonly in patients with severe brain ischemia, and is often indicative of brain death. Treatment of the diabetes insipidus along with any coexistent anterior pituitary hormone deficiencies can be used to preserve donor organs in such cases.

Nephrogenic Diabetes Insipidus

Nephrogenic diabetes insipidus is caused by mutations of the vasopressin V_2 receptor or the vasopressin-induced water channel AQP2, or by impairments in the signal transduction system linking V_2 receptor activation and AQP2 membrane insertion. Familial nephrogenic diabetes insipidus is a rare disease, most cases of which (>90%) are due to mutations of the V_2 receptor. More than 100 different V_2 receptor mutations have been described and can be classified into several different general categories based on differences in transport of the mutant receptor to the cell surface and vasopressin binding or stimulation of adenylate cyclase. Because the gene for the V_2 receptor is located on the X chromosome, this is an X-linked recessive disease. Symptoms are noted only in affected males, who often present with vomiting, constipation, failure to thrive, fever, and polyuria during the first week of life. Hypernatremia with a hypotonic urine is typically present. The phenotype is similar in the less than 10% of patients with mutations of the AQP2 water channel, but because the AQP2 gene is located on chromosome 12, mutations cause autosomal recessive disease; consequently, consanguinity and a family history of the disease in men and women is common, and this disorder should be suspected when the proband is female.[8]

Nephrogenic diabetes insipidus can also be acquired during treatment with certain drugs such as demeclocycline (which can be used to treat inappropriate secretion of vasopressin), lithium carbonate (used to treat bipolar disorders), and fluoride (previously used in fluorocarbon anesthetics), and from electrolyte abnormalities such as severe hypokalemia and hypercalcemia. All causes of acquired nephrogenic diabetes insipidus have in common the decreased synthesis and function of AQP2 due to impaired vasopressin signaling from V_2 receptor binding and activation. Other diseases of the kidney can produce polyuria and inability to concentrate the urine secondary to altered renal medullary blood flow or to other disorders that inhibit maintenance of the hyperosmolar concentrating gradient in the inner medulla. Renal manifestations of such disorders (e.g., sickle cell disease, sarcoidosis, pyelonephritis, multiple myeloma, analgesic nephropathy) are discussed in Chapter 121.

Gestational Diabetes Insipidus

In pregnancy, there is an increased metabolism of vasopressin due to cystine aminopeptidase (oxytocinase or vasopressinase), an enzyme that degrades oxytocin and prevents premature uterine contractions. Normally, this is compensated for by increased synthesis and secretion of vasopressin. Rarely, women with normal regulation of vasopressin develop diabetes insipidus because of markedly elevated levels of vasopressinase. Some of these patients have accompanying preeclampsia, acute fatty liver, and coagulopathies, but causal relations between diabetes insipidus and these abnormalities have not been identified. In general, diabetes insipidus does not persist after the pregnancy ends and does not recur in subsequent normal pregnancies.[9]

Polyuria can also manifest in patients who have limited vasopressin reserve (partial central diabetes insipidus) or who respond poorly to vasopressin action (compensated nephrogenic diabetes insipidus). Treatment may be required only during the pregnancy, and the patient often returns to her previous baseline function without the need for therapy when the pregnancy ends. Less commonly, central diabetes insipidus of another cause first becomes symptomatic during pregnancy and then persists afterward, following the usual course of diabetes insipidus.

Primary Polydipsia

Excessive fluid intake also causes hypotonic polyuria and, by definition, polydipsia. This disorder must be differentiated from the various causes of diabetes insipidus. Despite normal pituitary and kidney function, patients with this disorder share many characteristics of both central diabetes insipidus (vasopressin secretion is suppressed as a result of decreased plasma osmolality) and nephrogenic diabetes insipidus (kidney AQP2 expression is decreased as a result of suppressed plasma vasopressin levels). Many different names have been used for this excessive fluid intake, including dipsogenic diabetes insipidus, but primary polydipsia remains the best descriptor to avoid confusing this order with diabetes insipidus as classically defined.

Primary polydipsia is sometimes due to a severe mental illness such as schizophrenia, mania, or obsessive-compulsive disorder, in which case it is called psychogenic polydipsia. These patients usually deny true thirst and attribute their polydipsia to bizarre motives, such as a need to cleanse the

body of poisons. The incidence in psychiatric hospitals can be as high as 40%, and there is no obvious explanation for the polydipsia. Primary polydipsia can also be caused by an abnormality in the osmoregulatory control of thirst, in which case it is called dipsogenic diabetes insipidus. These patients have no overt psychiatric illness and invariably attribute their polydipsia to a nearly constant thirst. Dipsogenic diabetes insipidus is usually idiopathic, but it can also be secondary to organic structural lesions in the hypothalamus identical to those causing central diabetes insipidus, such as neurosarcoidosis of the hypothalamus, tuberculous meningitis, multiple sclerosis, or trauma. Consequently, all polydipsic patients should be evaluated with magnetic resonance imaging (MRI) of the brain before it is concluded that excessive water intake is due to an idiopathic or psychiatric cause. Primary polydipsia can also be produced by diseases or drugs that cause a dry mouth, or by any peripheral disorder causing marked elevations of renin or angiotensin.

Finally, primary polydipsia is sometimes caused by physicians, nurses, lay practitioners, or health writers who recommend a high fluid intake for valid (e.g., recurrent nephrolithiasis) or unsubstantiated health reasons. These patients lack overt signs of mental illness, but they also deny thirst and usually attribute their polydipsia to habits acquired from years of adherence to a drinking regimen. Laboratory studies in these patients are generally normal, although the serum sodium concentration is sometimes at the low end of the normal range, and the level of uric acid is lower than in patients with other forms of diabetes insipidus.

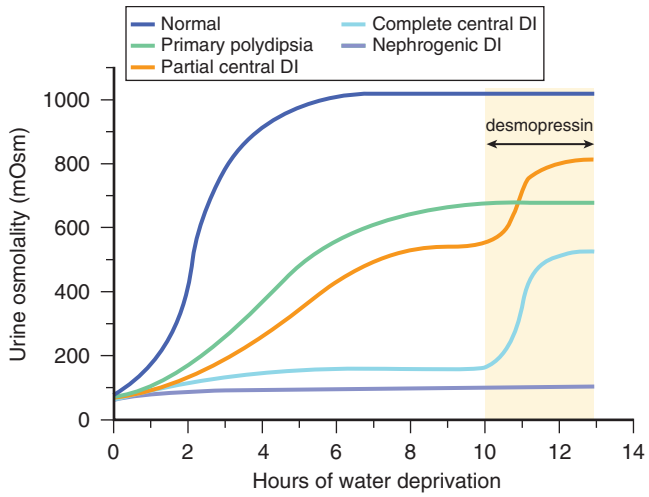

FIGURE 225-3. Responses to the water deprivation test to differentiate various types of diabetes insipidus (DI) and primary polydipsia (as described by Miller M, Dalakos T, Moses AM, et al. Recognition of partial defects in antidiuretic hormone secretion. *Ann Intern Med.* 1970;73:721-729). The response to dehydration reaches a plateau, and the subsequent change in urine osmolality in response to administered desmopressin is illustrated. See the discussion in the text.

DIAGNOSIS

Physiologic Diagnosis

Diabetes insipidus should be considered in all patients presenting with significant polyuria, defined as urine output greater than 50 mL/kg/day. Although osmotic diuresis secondary to hyperglycemia, intravenous contrast agents, or renal injury is a more common clinical cause of polyuria, the medical history, an isotonic urine osmolality, and routine clinical laboratory tests generally distinguish these disorders from diabetes insipidus. A diagnosis of diabetes insipidus can be made when urine osmolality is inappropriately low in the presence of an elevated plasma osmolality as a result of increased serum sodium concentration. These criteria are sometimes met at the initial examination, especially in cases of acute diabetes insipidus occurring after trauma or surgery with inadequate fluid replacement. In such patients with hypernatremia and hypotonic urine osmolality with normal renal function, one need only administer a vasopressin agonist to differentiate central diabetes insipidus, in which a renal response with decreased urine volume and increased urine osmolality occurs, from nephrogenic diabetes insipidus, in which a subnormal renal response is seen. Sometimes in the postoperative state, a water diuresis occurs as a result of water retention during the surgical procedure. Vasopressin is normally secreted in response to surgical stress, causing fluid administered intravenously during the procedure to be retained. During recovery, vasopressin levels fall, and a diuresis of the retained fluid occurs. In this case, the serum sodium level is almost always normal; however, if additional fluid is administered to match the urine output, persistent polyuria can be mistaken for diabetes insipidus. In this situation, the physician should decrease the rate of fluid administered and follow the urine output and serum sodium level. If the urine output decreases and the serum sodium level remains normal, no treatment is necessary; if serum sodium rises above the normal range and the urine remains hypotonic, diabetes insipidus is likely, and the response to a vasopressin agonist can ascertain the type (central versus nephrogenic).

Most outpatients with diabetes insipidus are not hypernatremic, because the polydipsia produced by a normal thirst response is generally sufficient to maintain water homeostasis. Instead, they present with polyuria, polydipsia, and a normal sodium level. In these patients, further testing is necessary to increase serum osmolality and then measure the plasma vasopressin level or the urinary response to an administered vasopressin agonist. The best described test is the water deprivation test (Fig. 225-3),[10] which should be carried out under controlled observation in the hospital or an appropriately equipped outpatient area. The exact timing of the test depends on the patient's symptoms. If the patient has marked polyuria during the night, it is best to begin the test during the day because the patient may become overly dehydrated overnight. However, if the patient has only two or three episodes of nocturia per night, it is best to begin the test in the evening so that the major part of the dehydration takes place when the patient is asleep. In either case, the patient is weighed at the beginning of the test, and all subsequent fluids are withheld. The volume and osmolality of all excreted urine are measured, and the patient is reweighed after each liter of urine output. When three consecutive urine samples have an osmolality differing by no more than 10% and the patient has lost at least 2% of body weight, a blood sample is obtained for the measurement of serum osmolality, sodium, and plasma vasopressin. The patient is then given 2 μg of desmopressin intravenously or intramuscularly and observed for an additional 2 hours.

Adults with normal vasopressin secretion concentrate their urine to greater than 800 mOsm/kg H_2O and have less than a 10% increase in urine osmolality in response to administered desmopressin. Patients with complete central diabetes insipidus have minimal concentration of the urine with dehydration, and a marked increase in urine osmolality (usually >50%) in response to administered desmopressin. Patients with nephrogenic diabetes insipidus usually have no increase in urine concentration in response to administered desmopressin, although in some cases of acquired nephrogenic diabetes insipidus, some increased urinary concentration (but generally < 10%) can occur. Nephrogenic diabetes insipidus is best distinguished from central diabetes insipidus by the measurement of vasopressin in plasma; plasma vasopressin levels are elevated in cases of nephrogenic diabetes insipidus, especially after dehydration.

In patients with partial central diabetes insipidus and patients with primary polydipsia, the urine is often somewhat concentrated in response to dehydration, but not to the maximum of a normal person. The chronically reduced level of vasopressin downregulates the synthesis of AQP2 water channels, and the large urine volume, regardless of cause, washes out the medullary osmotic gradient that is the determinant of maximal urine concentration. When desmopressin is administered, patients with partial central diabetes insipidus have a further increase (usually > 10% but < 50%) in urine osmolality, whereas most patients with primary polydipsia have no further increase (i.e., <10%). However, the reliability of distinguishing between these two disorders by the water deprivation test is suboptimal. Some patients with primary polydipsia may not become sufficiently dehydrated to secrete maximal vasopressin and hence have an increase in urine osmolality in response to administered desmopressin. Alternatively, some patients with partial central diabetes insipidus can become sufficiently dehydrated that their maximal concentration of urine is reached during the test, and no further concentration is seen with administered desmopressin. Plasma vasopressin levels at the end of dehydration are better at discriminating between these two disorders, but only at high serum sodium concentrations (i.e., >145 mmol/L). Consequently, some investigators recommend a limited infusion of hypertonic (3%) sodium chloride solution to achieve these elevated levels if they are not achieved by the water deprivation itself. Measurement of the C-terminal fragment of the vasopressin prohormone copeptin may be a better surrogate measure of vasopressin secretion.[11]

In some difficult cases, the response to treatment with a vasopressin agonist can be a useful aid to diagnosis. If a decrease in polyuria and thirst with maintenance of normal serum sodium concentration occurs, a diagnosis

of partial central diabetes insipidus is likely; however, if polydipsia persists and hyponatremia develops, a diagnosis of primary polydipsia is confirmed.

Etiologic Diagnosis

If the water deprivation test confirms that inadequate vasopressin secretion is responsible for the polyuria, the underlying cause must be determined. MRI of the hypothalamic-pituitary area is the most important diagnostic tool in these cases. The three areas of interest are the immediate suprasellar region of the hypothalamus, the pituitary stalk, and the posterior pituitary within the sella turcica (see the earlier discussion of anatomy). Most slow-growing tumors confined to the sella do not cause diabetes insipidus. To cause central diabetes insipidus, tumors in the hypothalamic area immediately above the sella must be either sufficiently large to destroy 80 to 90% of the vasopressin cells or located where the paths of the four nuclear groups converge at the origin of the pituitary stalk, just above the diaphragma sellae. Primary tumors, especially craniopharyngioma and suprasellar germinoma, metastatic tumors, and infiltrative diseases can also cause diabetes insipidus by infiltration of the pituitary stalk, which is then thickened (i.e., >2 mm) on MRI. On T1-weighted MRI, the vasopressin and oxytocin stored in neurosecretory granules in the posterior pituitary are visualized as a bright spot in the sella turcica. Most but not all normal subjects have this bright spot (it is absent more frequently in elderly and dehydrated patients); in most but not all patients with central diabetes insipidus, the bright spot is absent. Thickening of the stalk and absence of the bright spot are therefore especially suggestive of a hypothalamic disease process.[12]

Tumors that cause central diabetes insipidus are most often benign primary intracranial tumors such as craniopharyngioma, ependymoma (suprasellar germinoma), and pinealoma, which arise in the third ventricle. Primary tumors of the anterior pituitary (Chapter 224) cause diabetes insipidus only when substantial suprasellar extension is present. However, rapidly growing intrasellar lesions, such as metastases from carcinomas of the lung, breast, and melanoma or hemorrhage into pituitary adenomas, can cause diabetes insipidus because there is insufficient time for the vasopressin axons to adapt by releasing vasopressin from the hypothalamus. Metastases to the hypothalamus can also destroy the supraopticohypophysial tract and produce diabetes insipidus. Granulomatous diseases, such as Langerhans cell histiocytosis, sarcoidosis, tuberculosis, and leukemic infiltrates and lymphomas of the hypothalamus, can cause diabetes insipidus by destroying vasopressin cells. In such patients, the diagnosis is usually suspected on the basis of peripheral manifestations of the respective diseases. Lymphocytic infundibuloneurohypophysitis is an autoimmune disease similar to lymphocytic hypophysitis of the anterior pituitary (Chapter 224) in which lymphocytes infiltrate the neurohypophysis to produce diabetes insipidus. The hallmarks of this process are a thickened pituitary stalk and an absence of the pituitary bright spot in a patient with the abrupt onset of polyuria and polydipsia, particularly a postpartum female. The diagnosis was originally demonstrated by pituitary biopsy, but now is more commonly made by regression of the thickened stalk with continued MRI follow-up. When no specific cause is identified, the diagnosis of exclusion is idiopathic diabetes insipidus; but most such cases are probably caused by an autoimmune disease, and other autoimmune diseases, including anterior pituitary hypophysitis,[13] are often recognized in affected patients. When central nervous system disease is suspected but not diagnosed by MRI or general physical examination, cerebrospinal fluid obtained by lumbar puncture may be helpful in identifying tumor cells or markers of tumors or inflammatory processes (e.g., elevated angiotensin-converting enzyme levels with neurosarcoidosis, elevated β-HCG levels with germinomas). A family history suggestive of diabetes insipidus should be investigated with genetic testing for inherited mutations in the vasopressin or vasopressin receptor genes depending on the site of the defect.

TREATMENT

Rx

Because excess excretion of water is the primary manifestation of diabetes insipidus, water replacement in adequate quantities avoids the metabolic complications of all forms of this disease. However, oral or intravenous administration of the volume of fluid required to replace the often large urinary losses in diabetes insipidus is difficult and inconvenient. The goal of therapy is therefore to reduce the amount of polyuria and polydipsia to a tolerable level while avoiding overtreatment, which can produce water retention and hyponatremia.

Central Diabetes Insipidus

The best therapeutic agent for the treatment of central diabetes insipidus is the vasopressin agonist desmopressin.[14] Desmopressin is different from vasopressin in that the amino group of the N-terminal cystine residue has been removed to prolong the duration of action, and D-arginine has been substituted for L-arginine in position 8 to decrease the vasopressor effects. At therapeutic dosages, this agent acts primarily on V_2 or antidiuretic receptors, with minimal activity at V_{1a} or pressor receptors. Desmopressin is available as tablets of 0.1 or 0.2 mg for oral administration and in either a spray bottle that delivers a fixed dose of 10 µg in 100 µL or a bottle with a rhinal catheter that can deliver 50 to 200 µL (5 to 20 µg) for intranasal administration. When therapy is initiated, it is generally best to begin with a low dose (e.g., half of a 0.1-mg tablet, 5 µg by the rhinal tube, or a single 100 µL spray of 10 µg) at bedtime to allow the patient to sleep through the night, and then determine the duration of action by quantifying the polyuria the next day. The duration of action of a single dose varies from 6 to 24 hours, but in most patients, a good therapeutic response can be achieved on an every-12-hour schedule for the nasal spray or an 8- or 12-hour schedule for the tablets. Desmopressin is also available for parenteral use in 1-mL vials of 4 µg/mL. Parenteral administration is especially useful postoperatively or when a patient is unable to take the nasal preparation. In hospitalized patients, some physicians add vasopressin directly to a crystalloid solution to infuse doses in the range of 0.25 to 2.7 mIU/kg/hour to cause modest but persistent urinary concentration as a treatment of diabetes insipidus. With any form of desmopressin administration, serum sodium levels should be monitored regularly to prevent the development of hyponatremia.[15]

Osmoreceptor Dysfunction

Because the diabetes insipidus of patients with osmoreceptor dysfunction is central, they respond to desmopressin as do patients with central diabetes insipidus. However, because of their thirst defect, this is usually not sufficient to maintain normal plasma osmolality. Consequently, they must be given a "prescription" for amounts of fluids to be consumed each 24 hours in order to maintain normal serum sodium levels and plasma osmolalities. This must be individualized to each patient because overconsumption of fluid coupled with desmopressin administration can produce severe hyponatremia. Body weights using an accurate scale is useful as a guide to preventing under- or overhydration, but frequent monitoring of serum sodium levels is usually necessary as well.

Nephrogenic Diabetes Insipidus

Although most patients with nephrogenic diabetes insipidus do not respond to desmopressin, a small number have a partial response to higher doses (e.g., 10 to 20 µg subcutaneously or intranasally). For the majority of patients who have no response to desmopressin, some orally administered pharmacologic agents are also useful in treating nephrogenic diabetes insipidus. Thiazide diuretics cause sodium depletion and volume contraction and decrease urine volume by increasing proximal tubular reabsorption of glomerular filtrate. Prostaglandin synthase inhibitors (e.g., indomethacin) block the action of prostaglandin E to inhibit the action of vasopressin on the kidney. Chlorothiazide, amiloride, and prostaglandin synthase inhibitors are useful to reduce polyuria in nephrogenic diabetes insipidus. However, none of these agents has been approved by the U.S. Food and Drug Administration for the treatment of diabetes insipidus; therefore, the prescribing physician should be aware of potential toxicities and side effects. In cases of drug-induced nephrogenic diabetes insipidus, the most direct therapy is discontinuation of the offending agent, if possible. Symptomatic nephrogenic diabetes insipidus is usually treated with a thiazide diuretic, which is enhanced by coadministration of the potassium-sparing diuretic amiloride. Amiloride can be especially beneficial in cases of nephrogenic diabetes insipidus induced by lithium, because the drug decreases the entrance of lithium into cells in the distal tubule. When diuretics are used to treat nephrogenic diabetes insipidus, special attention should be paid to the possibility that the induced dehydration may increase the concentration of other drugs.

Gestational Diabetes Insipidus

During pregnancy, vasopressinase increases the metabolism of vasopressin but not of desmopressin, so desmopressin is the drug of choice for these patients. The vasopressinase activity subsides by a few weeks after delivery, and patients with the onset of partial diabetes insipidus during pregnancy may become asymptomatic after delivery. An additional advantage of desmopressin is that it has little action on the oxytocin receptors of the uterus. During pregnancy, normal plasma osmolality decreases by approximately 10 mOsm/kg H_2O because of changes in serum sodium, so pregnant patients with diabetes insipidus require only enough desmopressin to maintain the serum sodium at this lower level.

Correction of Hyperosmolality

Some situations require special attention during therapy. Rarely, if patients with diabetes insipidus are unable to drink or are given a hypertonic solution, severe hypernatremia can develop acutely. Osmotic equilibrium with the

intracellular water of neurons and glia produces shrinking of the brain. The brain is in a closed vault (i.e., the skull), and when the brain shrinks, traction on the vasculature of the central nervous system can cause the rupture of blood vessels and subarachnoid or intracerebral hemorrhage. If the hypernatremia persists for a longer time, the neurons accommodate by producing organic osmolytes (previously called idiogenic osmoles), which limit the amount of brain shrinkage. Once this adaptation has occurred, a too-rapid lowering of osmolality in the extracellular fluid will produce a shift of water into the brain and cause cerebral edema. In this situation, desmopressin can be administered to produce constant antidiuresis, and the amount of water given can be regulated to decrease osmolality by no more than approximately 12 mEq/L every 24 hours. Postoperatively or after head trauma, diabetes insipidus can be transient (see Prognosis), and the need for long-term maintenance therapy cannot be immediately established.

PROGNOSIS

The prognosis of properly treated diabetes insipidus is excellent. If nephrogenic diabetes insipidus is diagnosed and treated early, intracranial calcification and mental retardation do not occur. When the diabetes insipidus is secondary to a recognized disease process, that disease generally determines the ultimate prognosis. In some specific clinical situations, the course is different and characteristic. The development of diabetes insipidus after surgical or traumatic injury to the neurohypophysis can follow any of several well-defined patterns (Fig. 225-4). In some patients, polyuria develops 1 to 4 days after injury and resolves spontaneously. Less often, the diabetes insipidus is permanent and continues indefinitely. Most interestingly, one can see a "triphasic" response that has been well described after pituitary stalk transection. The first phase of diabetes insipidus is due to axon shock and lack of function of the damaged neurons. This phase lasts several hours to several days and is followed by a second, antidiuretic phase that is due to the uncontrolled release of vasopressin from the disconnected and degenerating posterior pituitary or from the remaining severed neurons. Overly aggressive administration of fluids during this second phase does not suppress the uncontrolled vasopressin release from the damaged neurohypophysis and can lead to hyponatremia. The antidiuresis can last 2 to 14 days, after which diabetes insipidus recurs after depletion of vasopressin from the degenerating posterior pituitary gland (third phase). Transient hyponatremia without preceding or subsequent diabetes insipidus has been reported after transsphenoidal surgery for pituitary microadenomas.

Once a deficiency of vasopressin secretion has been present for more than a few weeks, it rarely improves, even if the underlying cause of the neurohypophysial destruction is eliminated. The major exception to this is postoperative diabetes insipidus, in which spontaneous resolution is the rule. Although recovery from diabetes insipidus that persists more than several weeks postoperatively is less common, and is uncommon after 1 year of continued diabetes insipidus, well-documented cases of recovery as long as 10 years after the initiating event have been reported. Potential return of function is a reason to occasionally withhold therapy during long-term treatment. Diabetes insipidus should not be considered idiopathic until at least 4 years of follow-up. During this interval, annual computed tomography or MRI is indicated to search for a tumor or infiltrative process that may not have been detected at the initial examination.

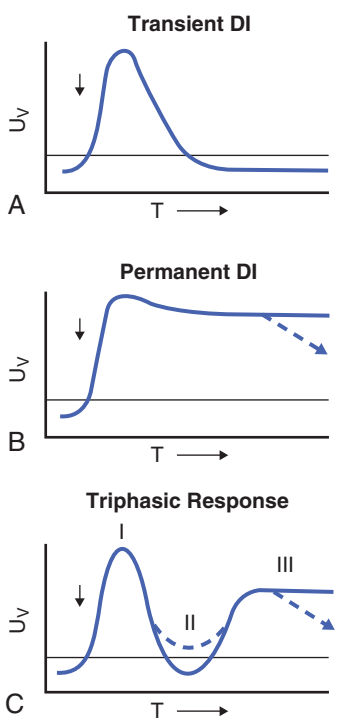

FIGURE 225-4. A to C, Diagrammatic summary of the major patterns of postoperative and post-traumatic diabetes insipidus (DI). The abscissa represents time (T) after the initial injury (*arrow*); the ordinate represents urinary volume (Uv) relative to a hypothetical "normal" urine output of 2 to 3 L/24 hours (*solid line*). See the discussion in the text. During the triphasic response (C), uncontrolled release of vasopressin from the disconnected or damaged posterior pituitary gland causes an antidiuresis that can lead to water retention and a dilutional hyponatremia. Diabetes insipidus returns as the third phase after the stored hormone in the posterior pituitary has been depleted. (From Verbalis JG, Robinson AG, Moses AM. Postoperative and post-traumatic diabetes insipidus. In: Czernichow AP, Robinson A, eds. *Diabetes Insipidus in Man: Frontiers of Hormone Research.* Basel: S Karger; 1985:247.)

REVIEW QUESTIONS

1. The hormone vasopressin (AVP) that regulates body water balance is synthesized where?

A. The anterior pituitary gland
B. The posterior pituitary gland
C. The supraoptic and paraventricular nuclei of the hypothalamus
D. The anterior hypothalamus near the osmoreceptor cells
E. The principal collecting duct cells of the kidney

Answer: C The supraoptic and paraventricular nuclei of the hypothalamus. The hormones of the posterior pituitary, vasopressin and oxytocin, are synthesized in specialized neurons in the hypothalamus, the neurohypophysial neurons. These neurons, notable for their large size, are termed *magnocellular neurons*. In the hypothalamus, magnocellular neurons are clustered in the paired paraventricular and supraoptic nuclei (see Fig. 232-1). The synthesized vasopressin prohormone is transported down the axons of the magnocellular neurons to the posterior pituitary gland, where vasopressin is released in response to specific stimuli.

2. Vasopressin secretion is stimulated at what levels of plasma osmolality?

A. Plasma osmolality above the thirst threshold of 295 mOsm/kg H_2O
B. Increases of plasma osmolality of 4 to 5%
C. Increases of plasma osmolality of 2 to 3%
D. Increases of plasma osmolality of 1 to 2%
E. Decreases in plasma osmolality of 1 to 2%

Answer: D Increases of plasma osmolality of 1 to 2%. Increases in plasma osmolality as small as 1 to 2% stimulate vasopressin release. Basal plasma levels of vasopressin are generally 0.5 to 2 pg/mL, which is sufficient to maintain urine osmolality above plasma osmolality and urine volume in the range of 2 to 3 L/day. When vasopressin levels are suppressed below 0.5 pg/mL, maximal urine osmolality decreases to less than 100 mOsm/kg H2O, and a free water diuresis (or "aquaresis") ensues at levels approaching 800 to 1000 mL/hour (18 to 24 L/day). Increases in plasma osmolality cause a linear increase in plasma vasopressin and a corresponding linear increase in urine osmolality. At a plasma osmolality of approximately 295 mOsm/kg H_2O, urine osmolality is maximally concentrated to 1000 to 1200 mOsm/kg H_2O. Thus, the entire physiologic range of urine osmolality is accomplished by relatively small changes in plasma vasopressin of 0 to 5 pg/mL (see Fig. 232-2).

3. Patients with diabetes insipidus and inability to concentrate their urine usually present with what manifestations?

A. Polyuria, polydipsia, and hyperosmolality
B. Polyuria, polydipsia, and dehydration
C. Polyuria, polydipsia, and hypernatremia
D. Polyuria, polydipsia, and elevated BUN and creatinine
E. Polyuria, polydipsia, and normal serum sodium, osmolality, BUN, and creatinine

Answer: E Polyuria, polydipsia, and normal serum sodium, osmolality, BUN, and creatinine. Most patients with diabetes insipidus are not hypernatremic, because the polydipsia produced by a normal thirst response is generally sufficient to maintain water homeostasis. Instead, they present with polyuria, polydipsia, and a normal sodium level and osmolality. Because their fluid intake is sufficient to maintain homeostasis, they are not dehydrated and do not have an elevated BUN or creatinine. In these patients, further testing is necessary to increase serum osmolality and then measure the plasma vasopressin level or the urinary response to an administered vasopressin agonist.

4. After a water deprivation test, a patient increases their urine osmolality from 350 to 375 mOsm/kg H_2O following administration of desmopressin (7% increase). What is the most likely diagnosis?

A. Primary polydipsia
B. Nephrogenic diabetes insipidus
C. Partial hypothalamic diabetes insipidus
D. Gestational diabetes insipidus
E. Osmoreceptor dysfunction

Answer: A Primary polydipsia. Adults with normal vasopressin secretion can concentrate their urine to greater than 800 mOsm/kg H_2O and have less than a 10% increase in urine osmolality in response to administered desmopressin. Patients with complete central diabetes insipidus have minimal concentration of the urine with dehydration, and a marked increase in urine osmolality (usually > 50%) in response to administered desmopressin. Patients with nephrogenic diabetes insipidus usually have no increase in urine concentration in response to administered desmopressin, although in some cases of acquired nephrogenic diabetes insipidus, some increased urinary concentration (generally < 10%) can occur. In patients with partial central diabetes insipidus and patients with primary polydipsia, the urine is often somewhat concentrated in response to dehydration, but not to the maximum of a normal person. The chronically reduced level of vasopressin downregulates the synthesis of aquaporin-2 water channels, and the large urine volume, regardless of cause, washes out the medullary osmotic gradient that determines the maximal urine concentration. When desmopressin is administered, patients with partial central diabetes insipidus have a further increase (usually > 10% but < 50%) in urine osmolality, whereas most patients with primary polydipsia have no further increase (i.e., <10%). Patients with gestational diabetes insipidus respond well to desmopressin because desmopressin is resistant to destruction by placental cystine aminopeptidase. Osmoreceptor dysfunction also responds well to desmopressin because it is a variant of central diabetes insipidus, with inadequate osmotic stimulation of vasopressin secretion.

5. What is the treatment of choice for patients with central diabetes insipidus?

A. Vasopressin
B. Desmopressin
C. Thiazide diuretics
D. Water
E. Insulin

Answer: B Desmopressin. The best therapeutic agent for the treatment of hypothalamic diabetes insipidus is the vasopressin agonist desmopressin. Desmopressin is different from vasopressin in that the amino group of the N-terminal cystine residue has been removed to prolong the duration of action, and D-arginine has been substituted for L-arginine in position 8 to decrease the vasopressor effects. At therapeutic dosages, this agent acts on V_2 or antidiuretic receptors, with minimal activity at V_{1a} or pressor receptors. Because excess diuresis of water is the primary manifestation of diabetes insipidus, water replacement in adequate quantities avoids the metabolic complications of this disease. However, oral or intravenous administration of the volume of fluid required to replace urinary losses in diabetes insipidus is difficult and inconvenient. Thiazide diuretics and amiloride are useful to reduce polyuria in nephrogenic diabetes insipidus by causing sodium depletion and volume contraction, thereby decreasing urine volume by increasing proximal tubular reabsorption of glomerular filtrate, but do not have as great an effect as desmopressin for hypothalamic diabetes insipidus. Insulin is used to treat diabetes mellitus, not diabetes insipidus.

226

THYROID

MATTHEW KIM AND PAUL W. LADENSON

The adult thyroid gland contains two lobes that wrap along the anterolateral aspects of the trachea, midway between the thyroid cartilage and the suprasternal notch. Each lobe is demarcated into upper, middle, and lower poles. The right and left lobes are connected by an isthmus on the anterior aspect of the trachea just below the cricoid cartilage. The normal terminus of the thyroglossal duct can persist as a pyramidal lobe, which is often palpably enlarged in diffuse thyroid disorders such as autoimmune thyroiditis and Graves disease.

With thyroid enlargement, the attachment of the sternothyroid muscle to the trachea limits upward expansion of the lobes, but further lateral, posterior, and downward growth may lead the gland to extend into the superior mediastinum, compressing the trachea and veins at the thoracic outlet. The parathyroid glands usually lie behind the superior and inferior poles of the thyroid lobes. The recurrent laryngeal nerves course upward along the tracheoesophageal groove, from which branches pass behind each thyroid lobe to innervate the larynx.

Thyroid tissue is composed of clustered spherical follicles, each containing a single layer of follicular epithelial cells known as thyrocytes that surround a lumen containing colloid. The principal component of colloid is thyroglobulin, a thyrocyte-specific protein. Parafollicular C cells, which are derived from neural crest tissue and produce calcitonin, are widely dispersed between follicles.

PHYSIOLOGY

Thyroid Hormone Synthesis and Secretion

Dietary iodine in the form of iodide (I^-) or iodate (IO_3^-) is absorbed by the gastrointestinal tract and distributed in the extracellular fluid. Daily iodine intake in the United States equals or exceeds the recommended daily intake of 150 μg because of the widespread use of iodized salt and iodate preservatives in baked goods. Circulating iodide is actively transported into the thyrocyte by the sodium-iodide symporter. Within the thyrocyte, iodide is rapidly oxidized by H_2O_2 in a reaction catalyzed by thyroid peroxidase. The reactive intermediate formed is covalently bound to tyrosyl residues present in thyroglobulin to generate monoiodotyrosine and diiodotyrosine residues through a process known as organification. Thyroid peroxidase also catalyzes the coupling of the monoiodotyrosine and diiodotyrosine residues to generate thyroxine (T_4) and triiodothyronine (T_3) residues in thyroglobulin,

which is secreted into the follicular lumen. Thyroglobulin is then pinocytosed at the apical membrane, and T_4 and T_3 are secreted after proteolysis of thyroglobulin. In the normal state, approximately 100 μg of T_4 and 5 μg of T_3 are directly released into the circulation each day. Pharmacologic amounts of iodine inhibit iodide trapping, organification, and release of the thyroid hormones. Lithium can also block thyroid hormone release.

Thyroid Hormone Transport and Metabolism

Circulating thyroid hormones are more than 99% bound to three classes of plasma proteins. Thyroxine-binding globulin (TBG) functions as the principal transport protein. Thyroxine-binding prealbumin (also known as transthyretin) and albumin make lesser contributions to T_4 and T_3 transport in blood. Pregnancy and exposure to pharmacologic doses of estrogens can increase the TBG level, as can hepatitis, familial TBG excess, and certain medications including 5-fluorouracil, tamoxifen, and methadone. Conversely, decreased TBG levels may occur with systemic illness, severe hepatic disease, nephrotic syndrome, and treatment with androgens, glucocorticoids, and slow-release nicotinic acid. Whereas total T_4 and T_3 levels rise and fall with changes in TBG, free T_4 and T_3 levels remain constant. Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder characterized by the production of an albumin fraction that binds T_4 with a higher-than-normal affinity. Affected individuals may present with high total T_4 levels with an inappropriately normal thyroid-stimulating hormone (TSH), and with normal free T_4 when this is measured by equilibrium dialysis.

The receptor binding and biologic activity of T_3 is eight-fold greater than that of T_4. More than 80% of the T_3 present in target tissues is derived from T_4 through the action of deiodinase enzymes that remove an outer-ring iodine, converting T_4 to T_3, generating the pool of T_3 in target tissues, and contributing to T_3 in the circulation. The type 2 deiodinase is present in the pituitary gland and brain, whereas type 1 deiodinase predominates in other peripheral tissues such as the liver and kidney. Activity of these deiodinases may be inhibited by systemic illness, iodide-containing compounds (e.g., amiodarone, radiocontrast agents), glucocorticoid therapy, and selenium deficiency. T_4 can also be converted by inner-ring deiodination to biologically inactive reverse T_3 (rT_3) by type 1 deiodinase and the type 3 deiodinase present in glial cells of the central nervous system. It deactivates thyroid hormone by inner-ring monodeiodination, a process that converts T_4 to inactive reverse T_3 (rT_3) and T_3 to inactive diiodothyronine (T_2). Type 3 deiodinase is also expressed in placenta, accounting for the increased thyroxine dose requirement in pregnant women.

Control of Thyroid Function

The growth of thyroid tissue and the production of thyroid hormones are controlled by the hypothalamus and the pituitary gland. Thyrotropin-releasing hormone (TRH) is a tripeptide synthesized by the hypothalamus and transported to the pituitary gland by the hypothalamic-pituitary portal system, where it binds to receptors on thyrotrophic cells, stimulating the synthesis and secretion of TSH (thyrotropin). TSH is a heterodimeric glycoprotein composed of a unique β-subunit coupled to an α-subunit identical to that present in follicle-stimulating hormone, luteinizing hormone, and chorionic gonadotropin (CG). It is transported in the circulation to the thyroid gland, where it binds to the TSH receptor on thyrocytes. The binding of TSH to the TSH receptor stimulates thyrocyte growth and all of the steps in synthesis and secretion of thyroid hormone. Circulating T_4 and T_3 exert negative feedback at the levels of both the hypothalamus and the pituitary gland, inhibiting the synthesis and secretion of TRH and TSH, respectively.

Thyroid Hormone Action

Thyroid hormone binds receptors that are members of the nuclear receptor superfamily, regulating expression of thyroid hormone–responsive genes. Isoforms of the thyroid hormone receptors (α_1, β_1, and β_2) bind to a specific hexameric oligonucleotide sequence in the transcriptional regulatory region of thyroid hormone–responsive genes. For example, in liver, T_3 increases expression of the low-density lipoprotein (LDL) receptor, resulting in accelerated LDL cholesterol clearance. In myocardium, T_3 increases myocyte contractility and relaxation by promoting expression of alpha myosin heavy chain and sarcoplasmic reticulum adenosine triphosphatase (ATPase), respectively. In the cardiac conducting system, T_3 increases the heart rate by accelerating sinoatrial node depolarization and repolarization. Other physiologic effects of thyroid hormone include increases in basal metabolic rate, mental alertness, ventilatory drive, gastrointestinal motility, and bone turnover. During fetal development, thyroid hormone plays critical roles in brain development and skeletal maturation.

DIAGNOSIS

Physical Examination

Examination of the thyroid begins with inspection of the lower anterior portion of the neck to check for diffuse or asymmetrical gland enlargement, tracheal deviation, lymphadenopathy, and jugular venous distention. Palpation can be performed by an anterior or posterior approach. Anterior palpation can be performed by using the thumb of one hand to locate the isthmus of the gland beneath the cricoid cartilage. The right lobe of the thyroid gland can be palpated by placing the left thumb along the left side of the trachea to displace the contralateral lobe, using the tips of the fingers of the right hand medial to the right sternocleidomastoid muscle at the level of the isthmus, and using the pads of the fingers of the right hand to define, while the patient swallows, the characteristics of that thyroid lobe (i.e., its size, firmness, contour, mobility, and potential tenderness). The maneuver is reversed to examine the left lobe.

Laboratory Findings

TSH and Thyroid Hormone Levels

The serum TSH level is a sensitive indicator of primary thyroid gland dysfunction. Contemporary TSH immunoassays permit accurate detection of all common causes of thyroid hormone deficiency and excess. Indeed, TSH levels even become abnormal when patients' thyroid hormone levels remain within broad reference ranges, conditions termed *subclinical hypothyroidism* and *subclinical thyrotoxicosis*. In most patients with primary thyroid gland dysfunction, measurement of a single TSH level permits an accurate classification of the thyroid status. Limitations of TSH testing occur when there is TSH-mediated secondary thyroid dysfunction, reduced biologic activity of T_3 or TSH itself, temporary disequilibrium of the hypothalamic-pituitary-thyroid axis, or analytic problems affecting the TSH immunoassay. A longitudinal community-based cohort study has documented that aging is associated with increased serum TSH concentrations with no change in free T_4 levels.[1] These findings suggest that the TSH increase in many elderly individuals arises from age-related alteration in the TSH set point or reduced TSH bioactivity, rather than occult thyroid disease.

Measurements of serum T_4 and T_3 levels confirm the significance of an abnormal TSH level, define the severity of thyroid dysfunction, and provide a clue to the underlying cause. Whereas assays that measure total T_4 and T_3 levels are accurate, their results do not distinguish between large plasma protein–bound and free fractions of each hormone. Consequently, congenital and acquired derangements of TBG (and, less commonly, transthyretin and albumin) can alter the total, but not the free T_4 and T_3 levels. These conditions can be misdiagnosed as abnormal thyroid function unless a discordance in TSH is noted or one of these underlying conditions is suspected (Tables 226-1 and 226-2). There are several methods of estimating unbound T_4 and T_3 levels. Free T_4 and free T_3 immunoassays are now widely employed for this purpose and yield reliable results in common conditions that alter plasma protein levels, such as estrogen-induced TBG excess. Free T_4 measurement after equilibrium dialysis of serum is the most accurate approach, but it is technically demanding and less readily available.

Other Laboratory Tests

Measurement of thyroid autoantibody titers can be useful in the evaluation of thyroid dysfunction. Antithyroid peroxidase and antithyroglobulin antibody titers can confirm the diagnosis of autoimmune thyroiditis. TSH receptor binding and stimulating immunoglobulin levels can be used to confirm the diagnosis of Graves disease. The erythrocyte sedimentation rate (ESR) can be helpful in the diagnosis of subacute thyroiditis. Serum thyroglobulin and calcitonin levels are used as tumor markers when observing patients treated for differentiated and medullary thyroid cancers, respectively.

Imaging

Anatomic Imaging

Ultrasonography provides images that characterize the thyroid gland's size, symmetry, texture, vascularity, and structural abnormalities including solid nodules, simple cysts, and partially cystic nodules. Diffuse heterogeneity suggests autoimmune thyroiditis. Certain characteristics of nodules—including their number, echogenicity, capsular regularity, vascularity, and patterns of calcification—alter the probability of malignancy but rarely confirm or

    - Phenytoin (high dose)
    - Furosemide (intravenous)

T_4 = thyroxine; TSH = thyroid-stimulating hormone.

exclude thyroid cancer with certainty. Imaging of surrounding structures may identify cervical lymphadenopathy not detectable on physical examination.

The value of computed tomography (CT) and magnetic resonance imaging (MRI) lies in their ability to delineate tracheal deviation, narrowing, and substernal extension of the thyroid into the mediastinum. Cervical CT scanning can also help define and localize regional lymphadenopathy. Positron emission tomography (PET) plays a role in the localization of metastatic thyroid cancer.

Functional Imaging

Radionuclide scanning takes advantage of the fact that gamma ray–emitting tracers transported into thyrocytes by the sodium-iodide symporter can generate images that reflect the regional activity of thyroid tissue. Technetium-99m (^{99m}Tc) and iodine-123 (^{123}I) are commonly used for this purpose. ^{99m}Tc-pertechnetate is rapidly trapped by thyrocytes, and scans obtained using this tracer can be acquired 20 to 30 minutes after injection. ^{123}I and ^{131}I thyroid scans generate images that more precisely reflect thyroid tissue function—for example, indicating whether a nodule is hypofunctioning (cold), hyperfunctioning (hot), or equivalent in function to extranodular tissue (warm). However, radionuclide imaging no longer plays a central role in the differential diagnosis of most thyroid nodules. When needed, ^{123}I is the preferred tracer because of its lower thyroidal and whole body radiation dose.

Thyroid Uptake

The fraction of an administered radioactive iodine or technetium dose taken up and retained by the thyroid gland during a defined period represents an index of the gland's activity. Typically, technetium pertechnetate uptake at 20 minutes ranges from 0.5 to 3%, whereas radioiodine uptake at 24 hours ranges from 8 to 28%. These fractional thyroid uptakes can be useful in the differential diagnosis of thyrotoxicosis. Radioiodine uptake values are also used to calculate effective ^{131}I doses to be administered for the treatment of hyperthyroidism and thyroid cancer.

TABLE 226-3 ETIOLOGIES OF HYPOTHYROIDISM

PRIMARY HYPOTHYROIDISM

- Insufficient functioning thyroid tissue
  - Congenital absence of thyroid tissue
  - Autoimmune destruction of thyroid tissue
    - Autoimmune thyroiditis (Hashimoto's thyroiditis)
  - Surgical removal of thyroid tissue
  - Radioablation of thyroid tissue by radioactive iodine or external beam radiation
  - Infiltrative destruction of thyroid tissue
    - Hemochromatosis
    - Scleroderma
    - Amyloidosis
- Impaired thyroid hormone synthesis
  - Iodine deficiency
  - Congenital enzymatic defects that disrupt thyroid hormone synthesis
  - Drug-mediated inhibition of thyroid hormone production and release
    - Thionamides
    - Amiodarone
    - Lithium
    - Aminoglutethimide
    - Certain tyrosine kinase inhibitors (e.g., sunitinib)

SECONDARY HYPOTHYROIDISM

- Insufficient secretion of TRH or TSH
  - Hypothalamic disorders
    - Tumor (lymphoma, germinoma, glioma)
    - Irradiation
    - Inflammation (sarcoidosis, vasculitis)
  - Hypopituitarism
    - Mass lesions
    - Pituitary surgery
    - Pituitary radiation
    - Hemorrhagic apoplexy (Sheehan syndrome)
    - Infiltration (hemochromatosis, tuberculosis, fungal infection)
    - Lymphocytic hypophysitis
- Thyroid hormone resistance syndrome

HYPOTHYROIDISM

DEFINITION

Primary hypothyroidism (termed *myxedema* when it is severe) refers to hormone deficiency caused by intrinsic thyroid gland dysfunction that disrupts the synthesis and secretion of T_4 and T_3 (Table 226-3). Overt primary hypothyroidism is characterized by an elevated TSH level (usually > 10 mIU/L) in conjunction with a free T_4 level below the lower limit of the reference range. In subclinical hypothyroidism, the TSH level is only modestly elevated; the free T_4 level remains in the low-normal to normal range.

Secondary or central hypothyroidism refers to deficient thyroid gland function that is the result of inadequate stimulation by TSH. This is due in turn to production of either insufficient or inactive TSH from a number of congenital or acquired pituitary and hypothalamic disorders (Chapter 224).

EPIDEMIOLOGY

Primary hypothyroidism is common, occurring in 5% of individuals. Mild hypothyroidism is present in as many as 15% of older adults. Hypothyroidism is more common in women. It is more prevalent among whites and Latin Americans. Secondary hypothyroidism is rare, representing less than 1% of cases.

PATHOBIOLOGY

Dietary iodine deficiency is a cause of primary hypothyroidism in regions where this micronutrient deficiency exists and is uncorrected by iodine supplementation. The most common cause of primary hypothyroidism in developed countries is autoimmune (or Hashimoto's) thyroiditis, a condition in which defective immune tolerance leads to inflammatory destruction of thyroid tissue and impaired gland function.[2] The condition is characterized by a lymphocytic infiltrate and fibrosis. Circulating antithyroid

antibodies directed against thyroid peroxidase and thyroglobulin are markers of the disease, but glandular inflammation is principally the result of altered T-cell-mediated immunity. There is a genetic predisposition to the condition, with linkage studies suggesting a polygenic basis. Patients with autoimmune thyroiditis may have other endocrine and nonendocrine autoimmune disorders. It may be a component of the type 2 polyglandular autoimmune syndrome associated with autoimmune adrenal insufficiency and type 1 diabetes mellitus. It is less commonly a component of the type 1 syndrome, which includes adrenal insufficiency, hypoparathyroidism, and chronic mucocutaneous candidiasis (Chapter 231). Other nonendocrine autoimmune conditions associated with autoimmune thyroiditis include atrophic gastritis, pernicious anemia, systemic sclerosis, Sjögren's syndrome, celiac disease, and vitiligo. Individuals treated with the immunomodulatory agent interferon-α may develop autoimmune thyroiditis with transient or permanent hypothyroidism.

Surgical resection of the thyroid gland predictably leads to hypothyroidism. Radioactive iodine therapy for treatment of hyperthyroidism commonly destroys sufficient thyroid tissue to cause postablative hypothyroidism. External beam radiation therapy for head and neck cancer can also cause thyroid gland failure. Exposure to pharmacologic and radiocontrast agents that contain large amounts of iodine (e.g., amiodarone, radiocontrast dyes, some expectorants, topical disinfectants) can disrupt thyroid hormone production. Lithium inhibits secretion of T_4 and T_3, leading to hypothyroidism in 10% of treated patients. Other pharmacologic agents reported to cause hypothyroidism include stavudine, thalidomide, lenalidomide, imatinib, sunitinib, sorafenib, motesanib, bexarotene, ipilimumab, and aminoglutethimide.

There are a number of other rare causes of primary hypothyroidism (see Table 226-3). Congenital hypothyroidism can be due to agenesis or dysgenesis of the thyroid gland or to mutations in genes encoding the enzymes catalyzing thyroid hormone synthesis. Infiltrative disorders that can disrupt thyroid function include hemochromatosis, amyloidosis, systemic sclerosis, and invasive fibrous thyroiditis (also known as Riedel's thyroiditis). The thyroid gland inflammation that occurs with subacute thyroiditis and painless (postpartum) thyroiditis causes transient hypothyroidism from which most patients recover. Consumptive hypothyroidism can occur in individuals with hemangiomas expressing the type 3 deiodinase, which converts T_4 to biologically inactive reverse T_3.

Secondary or central hypothyroidism may be caused by a number of disorders that impair normal hypothalamic or pituitary control of the thyroid gland (Chapter 224). Infiltrative disorders affecting the hypothalamus that can interfere with TRH secretion include sarcoidosis, hemochromatosis, and histiocytosis. Masses that impinge on the pituitary stalk can impede TRH delivery through the hypophyseal portal system. Compression of thyrotrophic cells by pituitary adenomas and other masses in the sella turcica can inhibit synthesis and secretion of TSH. Surgery and radiation therapy to treat pituitary adenomas can destroy thyrotrophic cells, leading to secondary hypothyroidism that develops as a component of panhypopituitarism. Other disorders associated with secondary hypothyroidism include lymphocytic hypophysitis, pituitary metastases from primary malignant neoplasms, apoplexy, infarction caused by hemorrhage at the time of delivery in women (also known as Sheehan syndrome [Chapter 224]), and head trauma.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Symptoms of hypothyroidism include fatigue, lethargy, weight gain despite poor appetite, cold intolerance, hoarseness, constipation, weakness, myalgias, arthralgias, paresthesias, dry skin, and hair loss. Females may develop precocious puberty, menorrhagia, amenorrhea, and galactorrhea. Affected individuals may experience depressed mood with limited initiative and sociability. Cognitive deficits can range from mild lapses in memory to delirium, dementia, seizures, and coma. The nonspecific nature of most of these symptoms makes it difficult to determine which patients presenting with them have hypothyroidism rather than other causes. Furthermore, in most cases, hypothyroidism is insidious in onset, making its recognition difficult. Symptoms that are new, progressive, or present in combination are more likely to be due to hypothyroidism.

The physical findings associated with hypothyroidism vary according to the age at onset and disease severity. Children may present with delayed linear growth despite weight gain, precocious or delayed puberty, and pseudohypertrophy of muscle. Adults can present with bradycardia, diastolic hypertension, and mild hypothermia. The skin may be coarse, dry, yellow, and cool to the touch as a result of peripheral vasoconstriction. Diffuse thinning of scalp hair accompanied by thinning of the lateral eyebrows may occur. The nails may become brittle. Examination of the chest may reveal distant heart sounds. The extremities may reveal diffuse nonpitting edema caused by the deposition of glycosaminoglycans. Neurologic examination may reveal slow, dysarthric speech and diffuse slowing of deep tendon reflexes with a marked delay in the terminal relaxation phase.

Examination of the neck may reveal a range of findings. Healed cervical incisional scars in this region may indicate a history of surgical resection of thyroid tissue. In autoimmune thyroiditis, the thyroid gland may be normal in size, diffusely enlarged, or atrophic to the degree it may be difficult to palpate at all. It may be soft and smooth with a lobular texture, or firm and irregular with a variegated nodular texture.

Other Routine Test Abnormalities

Routine blood tests may reveal anemia (which is typically macrocytic), hyponatremia, hypoglycemia, and elevated creatine phosphokinase, prolactin, homocysteine, triglyceride, and total and LDL cholesterol levels. Electrocardiography may show sinus bradycardia with low voltage in the limb leads. Chest radiography may show a widened cardiac silhouette, and echocardiography may confirm a pericardial effusion.

DIAGNOSIS

Suspected primary hypothyroidism is confirmed by an elevated TSH level (Fig. 226-1). Established reference ranges for TSH levels typically extend from 0.5 to 4.5 mIU/L. However, the distribution of values within this range is skewed toward the lower half, such that the mean TSH level in adults is

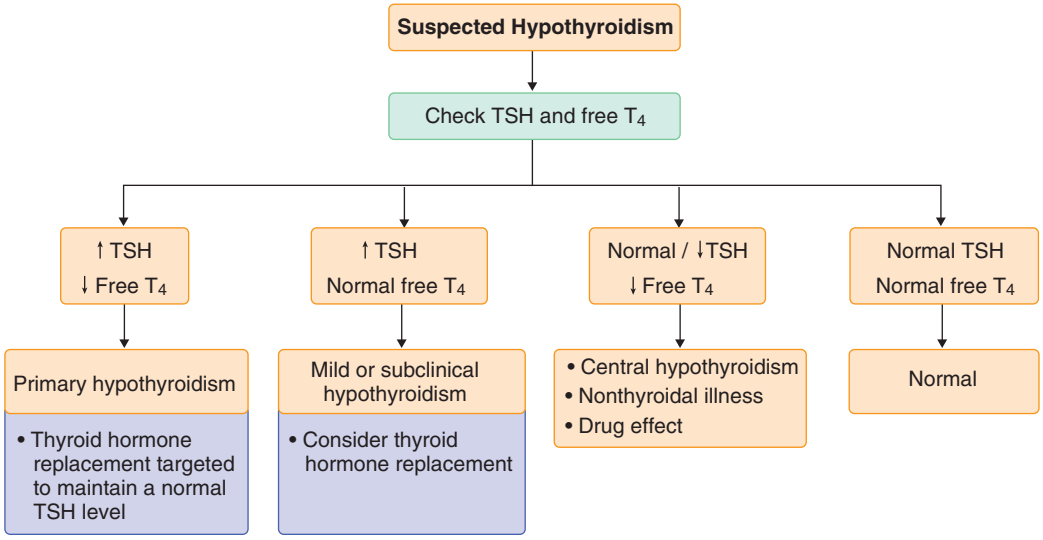

FIGURE 226-1. Laboratory assessment of suspected hypothyroidism. TSH = thyroid-stimulating hormone.

1.5 mIU/L. Measurement of the free T_4 level confirms the diagnosis of primary hypothyroidism and characterizes its severity. A low free T_4 level in conjunction with a persistently elevated TSH level represents overt primary hypothyroidism, whereas a low-normal free T_4 level with an elevated TSH level is termed *mild* or *subclinical primary hypothyroidism*. Other uncommon causes of isolated TSH elevation should be considered in appropriate settings, including recovery from severe systemic illness, renal failure, and adrenal insufficiency.

The underlying cause of primary hypothyroidism is usually clinically obvious, and laboratory testing is unnecessary in most cases. When confirmation is required (e.g., to convince a patient the condition is permanent), serum antithyroid antibodies may be assessed. Measurement of thyroid peroxidase antibody is a more sensitive test than thyroglobulin antibody for this purpose. However, 10% of patients with histologically documented autoimmune thyroiditis have no circulating antithyroid antibodies.

When clinical findings such as the presence of a sellar mass, previous pituitary surgery or irradiation, or other pituitary axis hormone deficiencies suggest the possibility of secondary hypothyroidism, the TSH level cannot be relied on to provide an accurate index of thyroid function. In these settings, the serum free T_4 level must be assessed, and a low or even low-normal free T_4 level can confirm the diagnosis. The TSH level in patients with secondary hypothyroidism can be low, normal, or even modestly elevated.

TREATMENT

Rx

The goals of thyroid hormone replacement therapy are straightforward: to replace endogenous thyroid hormone production, to avoid iatrogenic thyrotoxicosis, and (rarely) to treat systemic complications of severe hypothyroidism. Levothyroxine sodium (hereafter thyroxine) is the hormonal preparation of choice.[3] Thyroxine has a number of favorable pharmacokinetic characteristics. It is well absorbed, and its plasma protein binding gives it a 7-day half-life, permitting daily dosing. Thyroxine is physiologically deiodinated to the more biologically active T_3 in peripheral tissues. However, thyroxine has a narrow therapeutic index, and doses differing by as little as 12% can have clinical consequences. Tablets of multiple dose strengths ranging from 25 to 300 µg are available. Regulatory standards ensure pharmaceutical equivalence in terms of mass of thyroxine, but bioavailability may differ by as much as 12% among different preparations. Consequently, adherence to a single thyroxine formulation is advisable.

The optimal dose of thyroxine for replacement therapy is related to lean body weight, with most adults requiring a daily dose of approximately 1.8 µg/kg. The dose requirement for elderly adults is typically lower (e.g., 1 µg/kg/day) because of slower metabolic clearance. Patients with postsurgical or postablative hypothyroidism usually require a higher daily dose than patients with autoimmune thyroiditis, who may have some residual gland function. Patients with coexisting malabsorptive disorders may require higher and variable doses. Certain medications, mineral supplements, and foods can interfere with thyroxine absorption, including ferrous sulfate, calcium carbonate, aluminum hydroxide, sucralfate, cholestyramine, and soy-containing foods (Table 226-4). Thyroxine doses should be separated from these substances by 8 hours or longer.

Thyroxine dose requirements may increase as a result of accelerated metabolic clearance in several circumstances. Patients with nephrotic syndrome and other systemic illnesses that lead to rapid clearance of thyroid hormone require higher daily doses. Dose requirements increase by an average of 75% in most pregnant women as a result of placental deiodinative metabolism of thyroxine.[4] Simultaneous treatment with phenytoin, phenobarbital, carbamazepine, or rifampin also typically accelerates thyroxine metabolism.

Most adults without known or suspected coronary artery disease can be started on a full replacement dose of thyroxine. The initial dose can be calculated on the basis of the patient's weight and age, rounding down to the nearest available dose strength. For patients with primary hypothyroidism, adequacy of thyroxine therapy can be assessed by TSH measurement 4 to 6 weeks after therapy is started. The target TSH level for most treated individuals should be the lower half of the reference range (i.e., 0.5 to 2.0 mIU/L). Once an adequate dose has been established, the TSH level should be checked annually. In patients with secondary hypothyroidism, the serum free T_4 level should be monitored 2 to 4 weeks after the thyroxine dose is started or adjusted, with a target free T_4 level in the upper half of the reference range.

Management of Complications

Complications of thyroxine therapy are limited to iatrogenic thyrotoxicosis and, rarely, adverse effects of restoring euthyroidism. Typical symptoms and signs of thyrotoxicosis usually accompany significant degrees of overtreatment. However, even a modestly excessive thyroxine dose can induce bone mineral loss, especially in postmenopausal women, and it can increase the risk of atrial fibrillation in older individuals. In patients with underlying coronary artery disease, the positive chronotropic and inotropic effects of thyroxine may exacerbate myocardial ischemia.[5] Consequently, adults with known or suspected ischemic heart disease should be started on a low dose that is titrated upward in small increments once tolerance is ensured (e.g., starting with 25 µg daily, then increasing the dose by 12.5 to 25 µg every 4 to 6 weeks). In some cases, β-blocker therapy may need to be intensified to counter the induction of myocardial ischemia. However, deliberate suboptimal dosing of thyroxine should be avoided. If necessary, coronary revascularization may be required before euthyroidism can be fully restored. Coexisting adrenal insufficiency associated with hypopituitarism or the type 2 polyglandular autoimmune syndrome may be unmasked when cortisol clearance is accelerated by a return to the euthyroid state. Other adverse effects that infrequently occur with thyroxine therapy include transient hair loss, acute sympathomimetic symptoms that resolve with dose reduction and slow advancement, and pseudotumor cerebri in children.

A minority of patients with thyroxine-treated hypothyroidism continue to report bothersome symptoms despite biochemical evidence of adequate thyroid hormone replacement. Several randomized clinical trials have shown that combinations of T_3 and T_4—in the form of desiccated thyroid or synthetic thyroid hormone preparations—are not superior to T_4 alone.

Subclinical and Mild Hypothyroidism

Whether individuals diagnosed with subclinical hypothyroidism (i.e., an elevated or high-normal TSH level with a free T_4 level within the reference range) benefit from thyroxine therapy remains controversial.[6] In practice, many providers opt for a trial of therapy in mildly hypothyroid patients who are symptomatic, have underlying hypercholesterolemia, or have a high likelihood of progressing to overt hypothyroidism. Predictors of progressive thyroid failure include age older than 65 years, TSH level higher than 10 mIU/L, and the presence of circulating thyroid autoantibodies, indicating underlying autoimmune thyroiditis.

Myxedema Coma

Severe hypothyroidism can culminate in myxedema coma, a life-threatening condition characterized by hypothermia, bradycardia, hypotension, altered mental status, and multisystem organ failure. Risk factors include advanced age, poor access to health care, and other underlying major organ system diseases. Most patients have severe and long-standing thyroid hormone deficiency. Treatment should include thyroxine (1.8 µg/kg/day, with or without a 500-µg loading dose). Some experts advocate coadministration of triiodothyronine in divided doses to compensate for impaired conversion of T_4 to T_3. No controlled trials have been performed to evaluate the relative benefits and risks of these different approaches. Glucocorticoids should be administered in stress doses after a cosyntropin stimulation test has been performed to check for evidence of concomitant adrenal insufficiency (Chapter 227). Care should be taken to avoid exposure to potent sedative or analgesic agents that may exacerbate altered mental status. Hypothermia should be treated with external warming to reduce the risk of circulatory collapse.

TABLE 226-4 INTERFERENCE WITH THYROXINE REPLACEMENT THERAPY

FACTORS CONTRIBUTING TO UNDERREPLACEMENT
Inadequate prescribed dose
Limited compliance
Decreased absorption due to ingestion of agents that bind thyroxine
Ferrous sulfate
Calcium carbonate
Aluminum hydroxide
Sucralfate
Cholestyramine
Soy protein
Increased metabolism of thyroxine
Pregnancy
Drugs
Phenytoin
Phenobarbital
Carbamazepine
Rifampin
Diminishing residual thyroid function
Changing formulations
FACTORS CONTRIBUTING TO OVERREPLACEMENT
Excessive prescribed dose
Factitious ingestion of additional doses
Decreased metabolism of thyroxine due to aging
Increasing residual thyroid function
Changing formulations

Nonthyroidal Illness

In patients with severe nonthyroidal illness, a characteristic constellation of thyroid function test changes occurs that often appears to be consistent with hypothyroidism (see Fig. 226-1).[7] The T_3 level usually declines as a result of decreased extrathyroidal T_4-to-T_3 conversion. With increasingly severe disease, total T_4 and free T_4 levels also decline. TSH levels are usually low to low-normal. During the course of recovery, the TSH level can rise above the upper limit of the normal range, producing a profile that can be mistaken for primary hypothyroidism. Clinical correlation is essential to assess thyroid function in severely ill patients (e.g., a history of preexisting thyroid or pituitary disease, the presence of a goiter, or features suggesting other elements of hypopituitarism). Because no benefit of thyroid hormone treatment has been shown for these patients, observation with retesting 6 to 8 weeks after recovery is the preferred approach.

THYROTOXICOSIS

DEFINITION AND EPIDEMIOLOGY

Thyrotoxicosis is a systemic syndrome caused by exposure to excessive thyroid hormone (Table 226-5). Its prevalence is 1 in 2000 adults, affecting 1% of all individuals during the course of their lifetime.

PATHOBIOLOGY

Thyrotoxicosis is the result of excessive circulating and tissue effects of thyroid hormone. Strictly speaking, hyperthyroidism refers to those forms of thyrotoxicosis that are caused by excessive production of thyroid hormone by the thyroid gland due to a thyrotropic stimulus or autonomous thyroid tissue function (see Table 226-5). In Graves disease, the most common cause of hyperthyroidism, the thyroid gland is stimulated by autoantibodies that bind to and activate the TSH receptor. Excessive secretion of TSH causes hyperthyroidism in patients with rare TSH-secreting pituitary adenomas (Chapter 224). CG, a glycoprotein with high TSH homology, can cause transient gestational hyperthyroidism during pregnancy, when a choriocarcinoma or a germ cell tumor produces variant forms of HCG that are more active or when mutant TSH receptors bind HCG more avidly, as occurs in familial gestational thyrotoxicosis.

Autonomous production of thyroid hormone occurs when thyrocytes function independently of TSH receptor activation. This can occur as a result of growth of a benign functioning thyroid adenoma or growth of multiple autonomously functioning nodules forming a toxic multinodular goiter. In rare cases, it can occur when patients with well-differentiated thyroid cancer present with functioning metastases. In some toxic adenomas, somatic mutations in the TSH receptor gene lead to constitutive activation. In patients whose thyroid glands have the potential for autonomous function, exposure to excessive amounts of iodine in the form of amiodarone or iodinated contrast agents can provoke hyperthyroidism.

Transient thyrotoxicosis can also be caused by inflammatory conditions that release an excessive amount of thyroid hormone stored in the gland (see the section on thyroiditis). These include subacute thyroiditis, which is believed to be caused by a viral infection; acute or suppurative thyroiditis, caused by bacterial infection; radiation-induced thyroiditis; and pharmacologic thyroiditis (e.g., due to amiodarone). Autoimmunity can also provoke an inflammatory thyroiditis that causes transient thyrotoxicosis. This commonly occurs in the setting of lymphocytic thyroiditis (also known as silent, painless, or postpartum thyroiditis). It rarely occurs in the setting of autoimmune thyroiditis (also known as Hashimoto's thyroiditis).

In rare cases, excess thyroid hormone can be secreted by ectopic thyroid tissue located anywhere from the base of the tongue to the mediastinum, or by heterotopic thyroid tissue that develops as part of an ovarian teratoma (a condition known as struma ovarii).

Thyrotoxicosis can also be caused by ingestion of excessive amounts of thyroid hormone. This is most often the result of the prescription of excessive doses of pharmacologic preparations of thyroid hormone, but it can rarely be due to surreptitious or accidental ingestion.

TABLE 226-5 ETIOLOGIES OF THYROTOXICOSIS

HYPERTHYROIDISM
Antibody-mediated stimulation of thyroid tissue
Graves disease
Autonomously functioning thyroid tissue
Toxic multinodular goiter
Toxic adenoma

CLINICAL MANIFESTATIONS

Symptoms and Signs

The classic symptoms of thyrotoxicosis include weight loss despite a hearty appetite, heat intolerance, palpitations, tremor, and hyperdefecation (increased frequency of formed bowel movements). Thyrotoxicosis can escape early detection because of its presentation with common nonspecific symptoms such as fatigue, insomnia, anxiety, irritability, weakness, atypical chest pain, or dyspnea on exertion. Delayed recognition may also occur when atypical symptoms such as headache, weight loss, periodic paralysis, or nausea and vomiting dominate the clinical picture. Elderly patients may present with apathetic thyrotoxicosis typified by weight loss and the absence of sympathomimetic symptoms and signs.

Signs of thyrotoxicosis include resting tachycardia, systolic hypertension with a widened pulse pressure, warm moist skin with a velvety texture, onycholysis, and a staring gaze with lid lag (noted to be present when a rim of sclera is visible between the upper eyelid and the superior margin of the iris on downward gaze). Cardiac examination may reveal a prominent apical impulse and a systolic flow murmur. Neurologic findings may include a restless, impatient demeanor, pressured speech, proximal muscle weakness, distal hand tremor, and brisk deep-tendon reflexes.

Clinical findings often provide clues to the underlying cause.[8] In Graves disease, the gland is diffusely enlarged with a smooth or slightly lobulated contour, and may manifest an audible bruit or palpable thrill. Thyroid ophthalmopathy and dermopathy are also unique to Graves disease. In patients with toxic nodular goiter, one or more discrete nodules may be appreciated. In subacute thyroiditis, the gland is modestly enlarged, extremely tender, and firm. A history of recent pregnancy suggests possible painless thyroiditis. Recent exposure to amiodarone, other iodine-containing compounds, interferon-α, or pharmacologic preparations of thyroid hormone may suggest the characteristic forms of thyrotoxicosis associated with these agents.

Graves Disease

DEFINITION

Graves disease is an autoimmune disorder characterized by a variable combination of hyperthyroidism, ophthalmopathy (also known as thyroid eye disease), and dermopathy.

EPIDEMIOLOGY

Graves disease is more common among women, but it also affects men. It can develop at any time during life, but the onset most often occurs between 30 and 60 years of age.

PATHOBIOLOGY

The proximate cause of hyperthyroidism in Graves disease is the production of thyroid-stimulating immunoglobulins that bind to and activate the TSH receptor, promoting thyroid hormone secretion and gland growth. Thyrotropin (TSH) receptor antibodies of the stimulating variety are the hallmark of hyperthyroidism in Graves disease. Other thyroid autoantibodies commonly identified in the setting of Graves disease include thyroid peroxidase

antibodies, thyroglobulin antibodies, and TSH receptor antibodies. Although the fundamental cause of Graves disease remains unknown, a genetic predisposition is implicated by a higher incidence in monozygotic twins and first-degree relatives of affected individuals. Environmental factors implicated in triggering the onset of Graves disease include exposure to cigarette smoke, high dietary iodine intake, and perhaps stressful life events and certain antecedent infections.

CLINICAL MANIFESTATIONS

Affected individuals usually present with thyrotoxicosis and a thyroid gland that is diffusely enlarged with a rubbery consistency, smooth contour, definable pyramidal lobe, and audible bruit or palpable thrill due to increased blood flow. When it is clinically evident, thyroid eye disease usually presents within a few months of onset. In rare cases, it may develop long before, long after, or without any biochemical confirmation of hyperthyroidism.

PROGNOSIS

The hyperthyroidism associated with this condition often follows a persistent and progressive course, but one fourth of patients with Graves disease demonstrate spontaneous disease remission.

OPHTHALMOPATHY

DEFINITION

Thyroid eye disease is a distinctive disorder characterized by inflammation and swelling of the extraocular muscles and orbital fat, eyelid retraction, periorbital edema, episcleral vascular injection, conjunctival swelling (chemosis), and proptosis (also called exophthalmos).[9] Swelling of soft tissues within the confines of the orbits precipitated by fibroblast growth and inflammatory cell infiltrate can cause proptosis, entrapment of extraocular muscles, and compression of the optic nerve.

CLINICAL MANIFESTATIONS

Affected individuals typically complain of a change in eye appearance, ocular irritation, foreign body sensation, dryness, and ironically, excessive tearing. More severe involvement may cause exposure keratitis with corneal ulceration, diplopia, and blurred vision. On examination, patients may have a staring gaze, a rim of sclera visible between the upper eyelid and the superior margin of the iris during downward gaze (lid lag), signs of conjunctival inflammation, periorbital edema, and abnormalities of conjugate gaze, color vision, and visual acuity (Fig. 226-2). The precise degree of proptosis can be measured with an exophthalmometer. Orbital imaging with CT scanning or ultrasonography can confirm the diagnosis, which must sometimes be distinguished from other causes of bilateral and unilateral proptosis.

FIGURE 226-2, Graves ophthalmopathy. A, A 59-year-old woman with excess proptosis, moderate eyelid edema, and erythema with moderate eyelid retraction affecting all four eyelids. Conjunctival chemosis (edema) and erythema with bilateral edema of the caruncles, with prolapse of the right caruncle, are evident. **B,** A 40-year-old woman with excess proptosis, minimal bilateral injection, and chemosis with slight erythema of the eyelids. On slit lamp examination, she also had evidence of moderate superior limbic keratoconjunctivitis. (From Bahn RS. Graves' ophthalmopathy. *N Engl J Med.* 2010;362:726-738. TREATMENT

Rx

Treatment of mild thyroid eye disease focuses on protecting the cornea from exposure and desiccation with moisturizing drops and ointment, glasses, and sometimes taping the eyelids closed at bedtime. Selenium supplementation may help to relieve some of the symptoms associated with active inflammation in mild to moderate cases. High-dose systemic glucocorticoid therapy can attenuate orbital inflammation in more severe cases. Orbital irradiation may be helpful in controlling inflammatory symptoms in some patients. Persistent corneal exposure, diplopia, altered vision due to optic nerve compression, and cosmetic issues may require surgery to decompress the orbits and readjust the extraocular muscles. Immunosuppressive agents and plasmapheresis have been used in severely affected patients, with anecdotal success.

DERMOPATHY

Infiltrative dermopathy, the least common aspect of Graves disease, is precipitated by the deposition of glycosaminoglycans in the dermis of the skin. Affected individuals usually present with mildly pruritic, orange peel–like thickening of the skin along the anterior aspects of the shins, known as pretibial myxedema. The dorsal aspects of the feet and fingers, the extensor surface of the elbows, and the face are more rarely affected.

The diagnosis can be confirmed by skin biopsy. Treatment of early infiltrative dermopathy with topical glucocorticoids under an occlusive wrap may limit its progression. Treatments involving the use of intradermal or systemic glucocorticoids, long-acting somatostatin analogues, and even surgical resection of soft tissue have demonstrated limited success.

Toxic Adenoma

A toxic adenoma is a solitary, autonomously functioning thyroid neoplasm that synthesizes and secretes excessive amounts of thyroid hormone independent of TSH stimulation. These neoplasms are almost always benign. Most grow large enough to be palpated by the time they present with thyrotoxicosis. Somatic gene mutations causing constitutive activation of the TSH receptor and the α-subunit of the stimulatory guanine nucleotide binding protein ($G_s\alpha$) have been identified in a subset of toxic adenomas. Hyperthyroidism caused by a toxic adenoma does not remit spontaneously, except in unusual cases complicated by hemorrhagic infarction of the neoplasm.

Toxic Multinodular Goiter

A toxic multinodular goiter is composed of multiple autonomously functioning thyroid nodules that synthesize and secrete excessive amounts of thyroid hormone. In some patients with nontoxic multinodular goiters, hyperthyroidism can be precipitated by exposure to excessive amounts of iodine. Most affected individuals have a goiter with multiple palpable thyroid nodules. Progressive enlargement may go undetected when there is substernal extension of nodular tissue. Toxic multinodular goiters are more common among older individuals.

TSH-Secreting Pituitary Adenoma

TSH-secreting pituitary adenomas represent less than 1% of all functioning pituitary tumors (Chapter 224). Patients may present with typical clinical manifestations of thyrotoxicosis, a diffuse goiter, symptoms and signs precipitated by an expanding sellar mass, syndromes associated with co-secretion of other anterior pituitary hormones (growth hormone, prolactin, or adrenocorticotropic hormone), or symptoms and signs of hypopituitarism. The key to suspecting the condition is usually recognition of an inappropriately nonsuppressed TSH level in a patient with thyrotoxicosis. The diagnosis is confirmed in most cases when laboratory testing reveals an elevated circulating level of the pituitary glycoprotein α-subunit in conjunction with a radiographically definable sellar mass.

DIAGNOSIS

Laboratory Findings

Abnormalities detected in routinely ordered laboratory tests are often the first clues to the presence of thyrotoxicosis. Thyrotoxic patients may have hypercalcemia or hypercalciuria, increased alkaline phosphatase levels, modestly elevated transaminase levels, and low or declining total and LDL

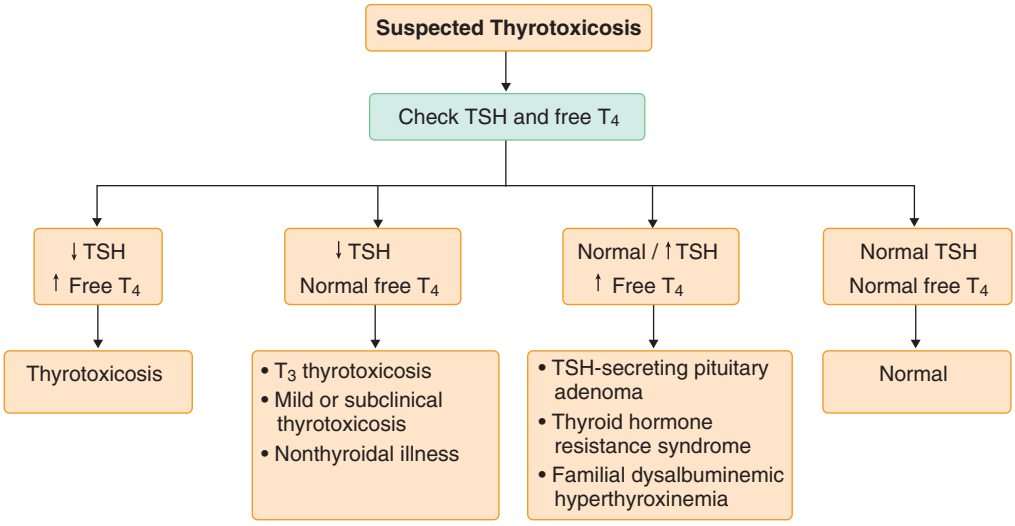

FIGURE 226-3. **Laboratory assessment of suspected thyrotoxicosis.** TSH = thyroid-stimulating hormone.

cholesterol levels. When they are measured, ferritin and angiotensin-converting enzyme levels are often increased. Electrocardiography typically reveals resting sinus tachycardia or atrial tachyarrhythmias, particularly atrial fibrillation with a rapid ventricular response. In severe cases, chest radiography may reveal cardiomegaly.

In most patients with suspected thyrotoxicosis, the diagnosis can be confirmed by measurement of a TSH level (Fig. 226-3). Sensitive TSH immunoassays with a detection limit of less than 0.02 mIU/L can accurately discriminate between clearly suppressed TSH levels, characteristic of all common forms of thyrotoxicosis, and mildly suppressed levels that fall just beneath the reference range, as may occur in otherwise sick individuals. Only the rare conditions associated with TSH-mediated hyperthyroidism (TSH-secreting pituitary tumors and isolated pituitary resistance to thyroid hormone) lack TSH suppression when testing for thyrotoxicosis. Measurement of serum free T_4 and T_3 levels confirms the diagnosis of thyrotoxicosis, defines its severity, and occasionally provides a clue to its underlying cause. Overt thyrotoxicosis is characterized by free T_4 or T_3 levels above the upper limit of the reference range, whereas mild or subclinical thyrotoxicosis is characterized by a suppressed TSH level with free T_4 and T_3 levels within the normal reference range. When only the free T_4 or T_3 concentrations are elevated, the terms *T_4 toxicosis* and *T_3 toxicosis* are applied, respectively.

Differential Diagnosis

Once thyrotoxicosis is confirmed, it is important to define its underlying cause to determine the most appropriate course of treatment. The relative degrees of T_4 and T_3 elevation sometimes can be helpful. Predominantly T_3 toxicosis is typical of Graves disease and can also occur with toxic nodular goiter. In contrast, predominantly T_4 toxicosis is more typical of subacute or painless thyroiditis. T_4 toxicosis is also more common in patients with iodine-induced hyperthyroidism.

Other laboratory tests are sometimes helpful in differential diagnosis. Antithyrotropin-receptor antibodies are pathognomonic of Graves disease. Levels of antithyrotropin-receptor antibodies are especially high in thyroid dermopathy and correlate positively with the clinical features and prognosis of Graves ophthalmopathy. An elevated ESR is typically seen in subacute thyroiditis.

Imaging studies can be helpful for the differential diagnosis. The fractional thyroidal uptake of radiotracer by the thyroid and its distribution in the gland on scintigraphic scanning often helps establish a definitive diagnosis (Table 226-6). Thyroid ultrasonography can confirm the presence of solitary or multiple thyroid nodules. Chest radiography and CT scanning may help delineate a substernal goiter.

TABLE 226-6 RADIOGRAPHIC EVALUATION OF SUSPECTED THYROTOXICOSIS

ETIOLOGY	FRACTIONAL 24-HOUR RADIOIODINE UPTAKE (%)	THYROID SCAN APPEARANCE
Graves disease	35-95	Diffuse increased homogeneous uptake; visible pyramidal lobe extending from isthmus
Toxic adenoma	20-60	Solitary focus of intense uptake; suppression of uptake in remainder of thyroid
Toxic multinodular goiter	20-60	Patchy heterogeneous foci of increased uptake interspersed with regions of diminished uptake
Subacute thyroiditis	0-2	Minimal to absent uptake
Autoimmune thyroiditis	0-2	Minimal to absent uptake; patchy heterogeneous uptake during recovery
Iodine-induced hyperthyroidism	0-2	Minimal to absent uptake
Exogenous thyroid hormone intoxication	0-2	Minimal to absent uptake
Metastatic differentiated thyroid cancer	0-5	Focal uptake in metastases
TSH-secreting pituitary adenoma	30-80	Diffuse increased homogeneous uptake

TSH = thyroid-stimulating hormone.

TREATMENT

Rx

Selection of the most effective treatment for a specific condition causing thyrotoxicosis requires an understanding of the underlying pathophysiologic process and natural history. For example, toxic multinodular goiter does not remit and requires definitive radioiodine treatment or surgery; subacute thyroiditis subsides spontaneously and requires only temporizing symptomatic therapy.

β-Blockers

β-Blockers help alleviate the sympathomimetic manifestations of thyrotoxicosis, regardless of the underlying cause. Palpitations, tremor, and anxiety can often be promptly controlled. However, other clinical features of thyrotoxicosis, including weight loss, heat intolerance, and fatigue, are not ameliorated by these agents. In thyrotoxic patients with marked sinus tachycardia or atrial fibrillation with a rapid ventricular response rate, β-blockers can be used as rate-controlling agents. Propranolol also partially inhibits extrathyroidal conversion of T_4 to T_3, which may be of added benefit in patients with severe thyrotoxicosis.

Propranolol can be started at a dose of 20 to 40 mg every 8 hours and titrated upward to a maximal daily dose of 240 mg on the basis of symptom control. Sustained-release propranolol or longer-acting β-blockers, such as

metoprolol and atenolol, can also be used. β-Blockers should be used with caution in thyrotoxic patients with a history of obstructive pulmonary disease, Raynaud's phenomenon, or heart failure. Esmolol can be used when a short-acting parenteral agent is required for heart rate control in patients with thyrotoxic heart failure.

For patients with transient forms of thyrotoxicosis (subacute thyroiditis, autoimmune thyroiditis, or exogenous thyroid hormone intoxication), a β-blocker may be the only treatment required. In patients with more sustained conditions, such as Graves disease or toxic nodular goiter, β-blockers provide prompt initial relief of symptoms while definitive treatment with antithyroid drugs, radioiodine, or surgery is implemented.

Antithyroid Drugs

The thionamides inhibit thyroid hormone biosynthesis by competitively inhibiting iodine organification and iodotyrosine coupling. These agents are used for the treatment of thyrotoxicosis caused by overproduction of thyroid hormones. Because the thionamides block only new thyroid hormone synthesis, glandular stores of preexisting thyroid hormone must be exhausted before they are fully effective. This may require 3 to 8 weeks in patients with Graves disease or toxic multinodular goiter. Although antithyroid drugs can provide long-term control of hyperthyroidism, they are most appropriately used when there is a possibility that the underlying condition will remit, as in Graves disease, or when thyrotoxicosis must be attenuated before radioiodine treatment or surgery.

Two thionamide agents are currently available: methimazole and propylthiouracil. Methimazole can be taken as a single daily dose because of its longer half-life and higher effective intrathyroidal concentration. This can bolster patients' adherence and drug effectiveness. Propylthiouracil also inhibits extrathyroidal conversion of T_4 to T_3, an effect that may be beneficial in patients with severe complicated thyrotoxicosis. Propylthiouracil is preferred for pregnant hyperthyroid women in the first trimester because methimazole has been rarely associated with the congenital anomalies of choanal atresia and cutis aplasia.[10] However, the shorter half-life of propylthiouracil necessitates its administration three or four times daily. Furthermore, risk of severe hepatotoxicity associated with the use of propylthiouracil has prompted the recommendation that methimazole be the first-line antithyroid drug to treat hyperthyroidism in children and adults, including women after the first trimester of pregnancy.

For patients with mild to moderate hyperthyroidism, methimazole is usually started at a dose of 10 to 30 mg once daily and increased to as much as 90 mg daily. For patients with more severe hyperthyroidism, thyrotoxicosis complicated by cardiac disease, or concomitant pregnancy, propylthiouracil can be started at a dose of 50 to 200 mg every 6 to 8 hours. Methimazole can be given rectally if necessary. The anticipated duration of treatment depends on the underlying cause. In patients with toxic multinodular goiter, antithyroid drugs are generally used only to restore euthyroidism in anticipation of definitive therapy. An effective dose can be continued for 6 to 24 months in a patient with Graves disease, before it is tapered off to determine whether there has been a remission of the patient's autoimmune thyroid disease. Patients most likely to respond are those who present with mild clinical and biochemical hyperthyroidism, a small thyroid gland, and no active ophthalmopathy.

Patients treated with antithyroid drugs should have thyroid function tests checked every 3 to 12 weeks during dose titration to monitor for iatrogenic hypothyroidism. Common side effects include rash, pruritus, fever, and arthralgias, which affect 5% of thionamide-treated patients. Agranulocytosis and hepatitis are rare but potentially fatal adverse reactions to thionamide medications. Their presentations are relatively sudden in onset and unpredictable. Monitoring of leukocyte counts and liver function test results is not useful as a preventive measure. Patients who are prescribed antithyroid drugs should be cautioned about manifestations of these adverse reactions and should be instructed to discontinue treatment and seek medical attention if they develop a high fever, pharyngitis, jaundice, or abdominal pain.

Radioactive Iodine

The selective uptake and concentration of iodide in thyrocytes permits the use of radioactive iodine to treat hyperthyroidism.[11] Once it is concentrated in the gland after oral administration, ^{131}I destroys thyroid tissue and controls hyperthyroidism, usually within 1 to 2 months. The dose of ^{131}I can be calculated on the basis of the fractional uptake of radioiodine, but the outcome of dosimetry is not superior to that achieved with the administration of empirical doses. Patients can be treated on an outpatient basis, with precautions taken to prevent exposure of others. Approximately three quarters of patients are cured with a single dose of radioiodine.

The principal side effect of radioactive iodine therapy is postablative hypothyroidism, which develops in most individuals receiving treatment for Graves disease and in a lesser proportion of patients treated for toxic nodular goiter. Lifelong monitoring of thyroid function is required because patients develop postablative hypothyroidism at a rate of 3% per year. Another less common complication is a transient exacerbation of thyrotoxicosis, which occurs in one quarter of patients during the first month after treatment as a result of radiation thyroiditis. Long-term follow-up studies have shown that radioiodine-treated patients with Graves disease do not have any greater risk of thyroid cancer or other malignant neoplasms. However, hyperthyroid children and adolescents treated with radioactive iodine are more likely to develop benign nodules. Among hyperthyroid women treated with radioiodine, the incidences of infertility, spontaneous abortion, and children with birth defects are not increased. Diagnostic or therapeutic radioactive iodine is contraindicated in women during pregnancy, and treated women should avoid pregnancy until euthyroidism has been confirmed 3 to 6 months after administration of a dose.

Other Drugs

Saturated solution of potassium iodide (SSKI) or Lugol's solution transiently inhibit the synthesis and release of thyroid hormone from the gland. They may be used to accelerate recovery after radioactive iodine treatment, to prepare patients for thyroidectomy, and to augment other treatments used to control severe thyrotoxicosis (see later). Iodinated radiocontrast agents inhibit the release of thyroid hormone while blocking peripheral conversion of T_4 to T_3. Lithium carbonate also inhibits the release of thyroid hormone. Rarely, these agents are used in combination with thionamides to treat patients with severe thyrotoxicosis. They may also help provide temporary control of hyperthyroidism when severe allergies preclude the continued use of thionamides. Cholestyramine can be used to bind thyroid hormone in the gut to interrupt enterohepatic circulation in cases of suspected exogenous thyroid hormone intoxication.

Surgery

Surgery has a limited role because of its potential to injure the adjacent recurrent laryngeal nerves and parathyroid glands. Resection of a toxic adenoma by lobectomy is curative and often preserves sufficient normal thyroid tissue for euthyroidism to be maintained. Consequently, it is often recommended in younger individuals. Toxic multinodular goiters causing compressive symptoms or cosmetic disfigurement may be appropriately managed with surgical resection. Although surgery is seldom recommended in the United States for the treatment of hyperthyroid Graves disease, it may be appropriate when other modalities are contraindicated, such as when there has been an adverse reaction to an antithyroid drug in pregnancy, when a thyroid nodule is thought to be malignant, or when hyperparathyroidism also requires surgical intervention.

Specific Treatment Scenarios

Pregnancy

Pregnant patients with hyperthyroidism present special challenges. Diagnosis requires a careful assessment of symptoms, especially heat intolerance, palpitations, and vomiting, which also occur during normal pregnancy. The serum total T_4 level is elevated because of increased TBG, and the TSH level can be suppressed in the first trimester as a result of HCG-mediated thyroid stimulation. Diagnostic radionuclide imaging studies are contraindicated. After diagnostic confirmation, hyperthyroidism must be treated because it is associated with an increased risk of spontaneous abortion, premature labor, low birth weight, and toxemia. β-Blockers should be used only transiently to control severe symptoms. Propylthiouracil is the preferred thionamide for treatment of Graves disease during the first trimester of pregnancy, because it crosses the placenta less readily than methimazole and because methimazole has been rarely linked to congenital malformations (i.e., choanal atresia and cutis aplasia). However, owing to the risk of very rare but potentially fatal propylthiouracil-related hepatitis, methimazole is preferred after the first trimester. Because Graves disease often remits later in pregnancy, antithyroid drug dose requirements often decline as gestation progresses. Measurement of maternal thyroid-stimulating immunoglobulin levels can help predict the risk of an infant developing neonatal Graves disease.

Subclinical and Mild Hyperthyroidism

Patients with subclinical or mild hyperthyroidism (i.e., a suppressed serum TSH with normal free T_4 and T_3 levels) may have symptoms that justify treatment. In patients with a serum TSH level suppressed to less than 0.1 mIU/L, bone mineral loss can lead to osteoporosis, particularly in postmenopausal women. Atrial fibrillation occurs more commonly in mildly hyperthyroid patients aged 60 years and older with TSH suppression below normal. It is less clear, however, whether younger asymptomatic patients with modestly suppressed TSH levels (e.g., 0.1 to 0.5 mIU/L) require anything more than periodic monitoring.

Thyrotoxic Crisis

Thyrotoxic crisis, also known as thyroid storm, is a potentially life-threatening syndrome that is usually the end result of severe and sustained thyrotoxicosis. It can affect patients with other medical conditions that render them vulnerable to the cardiovascular, neuropsychiatric, and gastrointestinal effects of exposure to excessive amounts of thyroid hormone. Thyrotoxic crisis typically develops in the setting of inadequately treated Graves disease and may be precipitated by intercurrent illness, surgery, or treatment with radioactive iodine. Affected individuals present with fever, atrial tachyarrhythmias,

congestive heart failure, nausea and vomiting, diarrhea, and seizures. Mental status changes can include agitation, delirium, psychosis, and coma. Prompt recognition and treatment in a monitored setting are crucial. A multifaceted treatment regimen should incorporate antipyretics, β-blockers, thionamides, iodinated contrast agents, and glucocorticoids, as well as aggressive evaluation and management of underlying medical problems.

THYROIDITIS

Subacute (de Quervain's) Thyroiditis

PATHOBIOLOGY

Transient thyrotoxicosis results from the uncontrolled release of thyroid hormone from the inflamed gland. After 2 to 8 weeks, when the supply of stored hormone is exhausted, thyrotoxicosis resolves spontaneously. Hypothyroidism ensues because the gland's biosynthetic capabilities remain impaired. This is also transient (lasting ≈ 1 month), with subsequent restoration of normal thyroid function in most patients.

CLINICAL MANIFESTATIONS

Subacute thyroiditis is characterized by painful enlargement of the thyroid, systemic inflammatory symptoms, and transient thyrotoxicosis that is often followed by transient hypothyroidism. The histologic pattern shows inflammatory cell infiltrates that are believed to be the result of a viral infection. Many patients with subacute thyroiditis report antecedent upper respiratory infections.

Patients usually present with pain localized to the thyroid or radiating to the throat, ears, or jaw. Constitutional symptoms, including fever, chills, sweats, and malaise, are often present. On occasion, these inflammatory features may dominate the presentation. Examination of the thyroid typically reveals an exquisitely tender, modestly enlarged, and woody, hard gland.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of thyroid pain must be considered in the evaluation of patients presenting with pain and tenderness localized to the lower anterior neck. In addition to subacute thyroiditis, potential causes of thyroid pain include acute (suppurative) thyroiditis, hemorrhage into an existing thyroid nodule, and rapid growth of anaplastic thyroid cancer, diffusely infiltrating thyroid cancer, or thyroid lymphoma.

Laboratory Findings

Laboratory testing in patients with subacute thyroiditis reveals a profile of overt thyrotoxicosis. Elevated T_4 levels are usually proportionately higher than T_3 levels. Patients typically have an elevated ESR during the acute phase. The fractional uptake of radioiodine is typically less than 2% at 24 hours (see Table 226-6).

TREATMENT

Rx

High-dose aspirin or naproxen sodium can be used to treat thyroid pain and systemic inflammatory symptoms. Patients who fail to respond may require glucocorticoid therapy, but it must be tapered over several weeks to prevent a relapse, prolonging the overall course of the illness. Symptoms ascribed to transient thyrotoxicosis may respond to treatment with a β-blocker continued for a limited course of 1 to 3 weeks. Patients who progress to symptomatic hypothyroidism may need short-term thyroxine replacement therapy, but most do not require long-term thyroid hormone replacement.

Lymphocytic (Postpartum, Painless, Silent) Thyroiditis

EPIDEMIOLOGY

Lymphocytic thyroiditis occurs most commonly in postpartum women, affecting as many as 6% of women 2 to 12 months after delivery or termination. Rarely, this condition occurs in non-postpartum women or in men. Predisposing factors include a history of previous episodes of postpartum thyroiditis, type 1 diabetes mellitus, and circulating antithyroid autoantibodies.

PATHOBIOLOGY

This painless inflammation of the thyroid gland can cause transient thyrotoxicosis followed by transient or persistent hypothyroidism. Each of these phases of thyroid dysfunction typically lasts 2 to 8 weeks. This condition is believed to reflect transient autoimmunity.

DIAGNOSIS

The diagnosis of lymphocytic thyroiditis is often overlooked when nonspecific symptoms of thyrotoxicosis (e.g., weight loss, insomnia, anxiety) or hypothyroidism (e.g., fatigue, depression) are misinterpreted as common postpartum complaints. The thyroid gland is nontender and either normal in size or modestly enlarged. Once it is considered, a diagnosis of lymphocytic thyroiditis can be readily confirmed or excluded by laboratory testing, which reveals a suppressed TSH level during phases of thyrotoxicosis and an elevated TSH level during phases of hypothyroidism. This condition must be distinguished from Graves disease, which can also present in the same time frame after delivery. Relative degrees of T_4 and T_3 elevation can sometimes provide a clue to which condition is present; lymphocytic thyroiditis is typically characterized by predominant increases in T_4 levels. Fractional uptake of radioiodine is either absent or very low in the setting of lymphocytic thyroiditis, whereas it is increased in active Graves disease (see Table 226-6).

TREATMENT

Rx

Lymphocytic thyroiditis can often be managed with reassurance and observation alone. Symptomatic thyrotoxicosis can be treated with a course of β-blocker therapy. Overt hypothyroidism may require short-term thyroxine replacement.

PROGNOSIS

Most patients with lymphocytic thyroiditis eventually return to a euthyroid state, but 25% develop persistent hypothyroidism due to classic autoimmune thyroiditis.

Acute (Suppurative) Thyroiditis

Infection of the thyroid gland is a rare condition that typically presents with severe thyroid pain, fever, and other systemic manifestations of infection. Bacterial infection of thyroid tissue can be the result of direct spread of gram-positive or gram-negative pathogens through fistulas communicating with the piriform sinus or the skin. Hematogenous spread of bacterial, mycobacterial, fungal, or parasitic organisms, especially *Pneumocystis carinii*, can occur in immunocompromised individuals. On examination, affected patients are typically febrile, with asymmetrical swelling of a thyroid that is tender, warm, and fluctuant to firm in consistency beneath erythematous skin. Ultrasonography may reveal an abscess that can be aspirated to identify a pathogen. Patients with suppurative thyroiditis require prompt treatment with appropriate antibiotics. Surgical drainage of abscesses may be required.

Other Forms of Thyroiditis

Certain drugs can cause thyroid gland inflammation. Amiodarone can produce a painless thyroiditis associated with thyrotoxicosis. Whenever possible, this should be distinguished from the iodine-induced form of thyrotoxicosis that can also be associated with amiodarone therapy. The former is optimally treated with glucocorticoid therapy, whereas the latter is managed with antithyroid drugs.[12] Interferon-α can provoke a painless thyroiditis associated with transient thyrotoxicosis. This must be differentiated from interferon-α–induced Graves disease; the former is managed with β-blockers and the latter with antithyroid drugs.

Riedel's thyroiditis or struma is characterized by fibrotic replacement of the thyroid, with adherence and infiltration of adjacent structures that causes local compressive symptoms. In this idiopathic condition, the thyroid is substantially enlarged, hardened, and fixed. Affected patients may also develop mediastinal and retroperitoneal fibrosis, sclerosing cholangitis, or orbital pseudotumor. Diagnosis requires open biopsy. Surgical excision is difficult or impossible. Glucocorticoid therapy and tamoxifen therapy have been anecdotally reported to be effective.

GOITER

DEFINITION

Goiters can be classified as diffuse or nodular, nontoxic or toxic (i.e., associated with thyroid hormone overproduction), and benign or malignant. Thyroid enlargement can be the result of thyrocyte proliferation stimulated by circulating factors (e.g., TSH and thyroid-stimulating autoantibodies), infiltration of the gland by inflammatory or malignant cells, or benign or malignant neoplastic changes within the gland itself. In a patient with a goiter, three clinical issues must be considered: enlargement causing local compressive or cosmetic concern, gland hyperfunction or hypofunction, and potential malignancy.

EPIDEMIOLOGY

Dietary iodine deficiency represents the most common cause of goiter worldwide. It is encountered in the United States only among immigrants from iodine-deficient regions. Younger patients present with diffuse or simple goiters that shrink in response to adequate iodine supplementation. In older individuals, iodine-deficient goiters become multinodular and do not decrease in size with iodine repletion. Excessive iodine exposure can provoke thyrotoxicosis in these patients.

PATHOBIOLOGY

Benign multinodular goiter or adenoma can be the result of genetic defects that lead to dyshormonogenesis, including mutations in the thyroglobulin, thyroid peroxidase, dual oxidase, and pendrin genes. Similarly, exposure to goitrogenic substances in foodstuffs, water, or drugs (e.g., lithium carbonate) that inhibit the normal steps in thyroid hormone synthesis can lead to goiter. In most patients, the underlying cause is unknown.

Autoimmune thyroiditis typically produces a modest goiter as a result of glandular infiltration with lymphocytes, inflammatory changes in thyrocytes, and fibrosis. The hypothyroid state caused by autoimmune thyroiditis results in increased TSH, which further stimulates thyroid enlargement. Graves disease is also characterized by diffuse thyroid enlargement due to the action of thyroid-stimulating immunoglobulins. Other forms of thyroiditis can present with goitrous enlargement of the thyroid gland, including subacute, lymphocytic, and acute (suppurative) thyroiditis (see earlier sections).

Malignant neoplasms that involve the gland diffusely, including thyroid lymphoma and infiltrative papillary, medullary, and anaplastic thyroid cancers, may present as rapidly enlarging goiters (see later sections). Affected patients often experience local pain and symptoms related to tumor expansion.

DIAGNOSIS

Clinical Examination

The first step in evaluating a suspected goiter is to confirm whether neck swelling represents enlargement of the thyroid. Redundant skin and subcutaneous fat in the lower anterior neck can be mistaken for an enlarged thyroid. These findings can usually be distinguished from true thyroid enlargement by palpating a normal thyroid beneath the misleading soft tissue and by observing that the fullness does not rise and fall with deglutition. Ultrasonography may help resolve uncertainty.

A patient's history can provide important clues to the underlying cause. A childhood social history may confirm previous iodine deficiency. Symptoms of hypothyroidism may suggest autoimmune thyroiditis, whereas clinical evidence of thyrotoxicosis may suggest Graves disease or toxic multinodular goiter. Clinical findings may lead to recognition of one of the various forms of thyroiditis (e.g., pain in subacute thyroiditis or postpartum status in lymphocytic thyroiditis). Symptoms suggesting the invasion of adjacent structures may raise concerns about malignant disease or Riedel's thyroiditis.

On examination, diffuse enlargement favors one of the forms of thyroiditis, Graves disease, or a diffusely infiltrating malignant neoplasm. Nodular enlargement is more likely to reflect a benign multinodular goiter or malignant neoplasm. The precise size of the gland should be documented. Dysphonia, tracheal deviation, cervical lymphadenopathy, and venous engorgement in the neck should be noted. Subtotal obstruction of the thoracic outlet may be revealed by having the patient touch his or her hands together above the head (Pemberton's maneuver) while checking for signs of facial plethora and cervical venous distention.

Laboratory Findings

A TSH level determines whether there is primary hypothyroidism or thyrotoxicosis. Elevated antithyroid peroxidase antibody titers can confirm suspected autoimmune thyroiditis. In asymptomatic patients with a modest diffuse goiter, no further evaluation may be indicated. Other blood tests (e.g., ESR for subacute thyroiditis or calcitonin for medullary thyroid cancer) can be useful when clinical clues suggest specific diagnoses.

Imaging

Cervical ultrasonography is the best imaging technique to define the character and extent of a goiter limited to the neck. It can help determine whether a goiter is diffuse or nodular, whether the thyroid is impinging on other cervical structures, and whether lymphadenopathy is present. Ultrasonography is also essential for guidance of fine-needle aspiration for cytologic differential diagnosis (see later). When a goiter extends posteriorly or beneath the sternal notch into the thorax, CT or MRI may be required. The administration of iodine-containing radiocontrast dye should generally be avoided in the evaluation of patients with goiters, because the stable iodide load may interfere with subsequent radioiodine imaging or therapy. Thyroid radionuclide uptake studies with ^{99m}Tc pertechnetate or ^{123}I can help characterize the functional status of the gland. Radionuclide scanning can help determine the cause of a goiter and whether a superior mediastinal mass is thyroid tissue. Barium swallow radiographs with fixed-diameter markers and pulmonary function testing with flow-volume loops can help determine whether symptoms are directly related to compression of the esophagus or trachea, respectively. Laryngoscopy is useful to evaluate vocal cord function in patients with potential recurrent laryngeal nerve involvement.

TREATMENT

Rx

Once thyroid dysfunction and malignant disease have been excluded, asymptomatic patients with goiters can be observed with periodic clinical assessment. Ultrasonography can be relied on as a reproducible technique for monitoring the size of an enlarged thyroid gland. Thyroxine therapy to suppress TSH levels is effective in shrinking goiters in only a minority of patients. Furthermore, chronic thyroid hormone treatment carries the risks of symptomatic thyrotoxicosis, atrial fibrillation, and bone mineral loss.

Patients with benign multinodular goiters causing local compressive symptoms or cosmetic concerns can be treated with surgery or radioactive iodine therapy. Surgery is often preferred when a patient has substantial gland enlargement causing compressive complications, especially when there is substernal extension of the goiter or acute obstructive symptoms. When surgery is contraindicated by the patient's health status, radioactive iodine therapy has been shown to reduce goiter size by an average of 50% over 12 to 24 months.

THYROID NODULES

EPIDEMIOLOGY

Thyroid nodules are common, being detected by palpation in 6% of women and 2% of men. Contemporary high-resolution ultrasonography identifies thyroid nodules in as many as 50% of all adults. Although the majority of these represent small, benign adenomatoid nodules or cysts, 5 to 10% of thyroid nodules are malignant. Less commonly, thyroid nodules are clinical problems by virtue of being hyperfunctioning or causing local compressive symptoms or cosmetic dissatisfaction.

DIAGNOSIS

Thyroid nodules can be noted by the patient or their physician in the absence of any other complaints.[13] It is also common for thyroid nodules to be detected incidentally on imaging procedures, such as carotid ultrasonography and cervical spine CT or MRI. Symptoms of compression or invasion of adjacent tissues suggest that a nodule may be malignant. These include pain in the lower anterior neck, cough or dyspnea due to tracheal compression, hemoptysis due to tracheal invasion, dysphonia due to recurrent laryngeal nerve encasement, and dysphagia or odynophagia due to esophageal compression. Certain other symptoms and signs lead to the consideration of specific underlying conditions. A toxic adenoma should be suspected in a patient with a thyroid nodule and the classic clinical manifestations of thyrotoxicosis. Hypothyroid symptoms and signs suggest autoimmune thyroiditis

with asymmetrical thyroid enlargement. Hypercalcitoninemia associated with the metastatic spread of medullary thyroid cancer can cause pruritus, flushing, and diarrhea. The clinical assessment should also include symptoms and signs related to common sites of thyroid cancer metastasis, such as chest pain, dyspnea, bone pain, and neurologic findings. Thyroid nodules rarely can be due to metastasis from other primary malignant neoplasms including kidney, colon, and breast cancers.

History

A special predisposition to thyroid cancer is suggested by a personal history of therapeutic neck irradiation in childhood. Family history can be informative if relatives have had medullary or papillary thyroid cancers, which are familial in 50% and 10% of cases, respectively. The possibility of medullary thyroid cancer should also be considered when there is a personal or family history of clinical problems associated with multiple endocrine neoplasia type 2 (MEN 2) syndromes, including hyperparathyroidism and pheochromocytoma (Chapter 231).

Physical Examination

Physical examination of a thyroid nodule should seek to define its size, consistency, surface texture, mobility, and tenderness. The presence of malignant disease is suggested by fixation and ipsilateral regional adenopathy or vocal cord paresis. Multinodularity of the gland may reflect benign nodular goiter, but it is not sufficiently reassuring to dispense with further diagnostic testing.[14] This is particularly true for a so-called dominant nodule that is larger, enlarging faster, or more symptomatic than others present in the thyroid.

Laboratory Findings

Routine laboratory testing includes measurement of TSH levels to identify patients with hyperthyroidism or hypothyroidism. When the TSH level is low or undetectable, the possibility of a benign autonomously functioning toxic adenoma can be pursued with radionuclide thyroid scanning (see Table 226-6). If an elevated TSH level indicates primary hypothyroidism, antithyroid peroxidase antibody titers can confirm whether the patient has autoimmune thyroiditis. Ultrasonography can distinguish asymmetrical enlargement caused by autoimmune thyroiditis from a discrete nodule. Calcitonin levels should be measured in patients with a known or suspected family history of MEN 2 or familial medullary thyroid cancer. Serum thyroglobulin measurement is not helpful in distinguishing benign from malignant thyroid abnormalities.

Imaging

Cervical ultrasonography helps confirm that a mass is within the thyroid, accurately defines its size, classifies it as cystic or solid, and determines whether additional nodules are present. Ultrasonography occasionally reveals other suspicious findings in nodules, such as fine calcifications, irregular nodule borders, and cervical adenopathy.

Radionuclide scanning with radioiodine or technetium pertechnetate is helpful only in selected cases. In patients with a thyroid nodule and a suppressed TSH level, scanning can confirm that the nodule is hyperfunctioning or "hot," in which case biopsy is usually not required.

Invasive Evaluation

Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy is the most accurate test to exclude or confirm malignant disease in patients with a nodule and a normal TSH level (Fig. 226-4). Most solid nodules and complex cysts larger than 1.0 to 1.5 cm in diameter should be sampled. Although aspiration can be directed by palpation alone when a nodule is readily definable, ultrasonography provides more certain guidance for the sampling of poorly localized lesions, often revealing additional nodules that should be assessed.

The cytologic assessment of aspirated material must first confirm that there is adequate material for assessment (e.g., 6 clumps of 10 cells on 2 slides). Biopsies with inadequate specimens, which are more common in cystic lesions, must be repeated. Ultrasonographic guidance and on-site preliminary cytologic assessment can improve the yield of biopsy. In accordance with the Bethesda System for Reporting Thyroid Cytopathology, a sampled nodule can be categorized as benign, atypical, suspicious for a follicular neoplasm, suspicious for malignancy, or malignant (Table 226-7).[15]

Benign nodules typically yield samples containing clusters of normal-appearing follicular epithelial cells with colloid. Pure colloid cysts may have scant epithelium. This classification is highly accurate, with a false-negative rate of less than 3% in sonographically directed biopsy specimens, and surgical resection is not required. In most cases, conservative observation based on yearly clinical or sonographic reassessment can be recommended. Further enlargement during observation (i.e., >20% increase in two of three dimensions) should prompt a repeat biopsy. Surgical resection should be considered if a cytologically benign nodule continues to grow, causing compressive symptoms or cosmetic disfigurement.

Cytologic material classified as malignant typically contains abundant epithelial cells with atypical nuclear features, overlapping, and scant or absent colloid. This is also a highly reliable finding, with 98% of such lesions found to be thyroid cancers on subsequent resection. Consequently, bilateral thyroidectomy is indicated in patients without contraindications to operation. Samples that contain sparser quantities of epithelial cells with similar atypical nuclear features may be classified as suspicious for malignancy. Approximately 75% of nodules in this category represent thyroid cancers.

One in five biopsies yields adequate but diagnostically indeterminate cytologic material.[16] Specific findings that classify an indeterminate nodule as suspicious for a follicular neoplasm include abundant follicular or Hürthle cells in microfollicles with little or no colloid and minor degrees of nuclear atypia, potentially indicative of papillary cancer. Although the majority of such indeterminate nodules are benign follicular adenomas, 15 to 30% are thyroid carcinomas. Biopsy samples that reveal nuclear or architectural features considered to be abnormal but not clearly suspicious for malignancy or a follicular neoplasm are classified as demonstrating atypia of undetermined significance. Nodules that initially fall into this category have been estimated to harbor malignancy at rates ranging from 5 to 25%. Repeat sampling may provide a more specific diagnosis to guide further management in 75% of cases.

Definitive determination of whether a suspicious or atypical nodule represents a focus of malignancy requires surgery targeted to remove either the lobe of the thyroid containing the nodule or the entire gland for surgical pathologic examination. Unilateral thyroid lobectomy has the advantage of a lower incidence of surgical complications and postoperative hypothyroidism when the lesion is benign, but it necessitates a subsequent completion thyroidectomy for most patients who prove to have cancer.

Molecular diagnostic testing is available to reduce the number of surgeries performed in patients with cytologically indeterminate nodules, approximately 75% of which prove to be histopathologically benign. There are two general strategies: (1) testing aspirated material for oncogenic mutations associated with thyroid malignancies and (2) gene expression classifier microarrays designed to identify benign nodules. For a typical population of cytologically indeterminate nodule patients with a prevalence of thyroid cancer of 20 to 35%, the negative predictive value of oncogenic testing and gene expression classification have been shown to be approximately 85% and 95%, respectively. For patients with no clinical features of malignancy, particularly middle-aged or older women with multinodular glands in whom the prevalence of malignancy is 5% or less, vigilant observation with serial sonography is an alternative.

THYROID CANCER

Cancers of the thyroid gland have a spectrum of behavior that ranges from incidentally detected and clinically inconsequential microcarcinomas to aggressive and virtually untreatable anaplastic malignant neoplasms. When thyroid cancer is diagnosed early, treatment is effective for most types. Most thyroid cancers present as thyroid nodules that are either asymptomatic or associated with local cervical symptoms or adenopathy. Less often, thyroid cancers first present with manifestations of metastatic disease, such as a pulmonary mass or bone pain.

Papillary and Follicular (Epithelial) Thyroid Carcinomas

Papillary and follicular thyroid cancers arise from follicular epithelium and often retain responsiveness to TSH, produce thyroglobulin, and concentrate iodide. They are distinguished by their histopathologic appearances and characteristic patterns of progression. Hürthle cell carcinoma of the thyroid is composed of thyrocytes with abundant mitochondria-laden cytoplasm, and behaves like a follicular thyroid cancer, although it typically does not have iodine-concentrating ability.

EPIDEMIOLOGY

Approximately 60,000 new cases of thyroid cancer are diagnosed annually in the United States. Thyroid cancer is three times more common in women, in

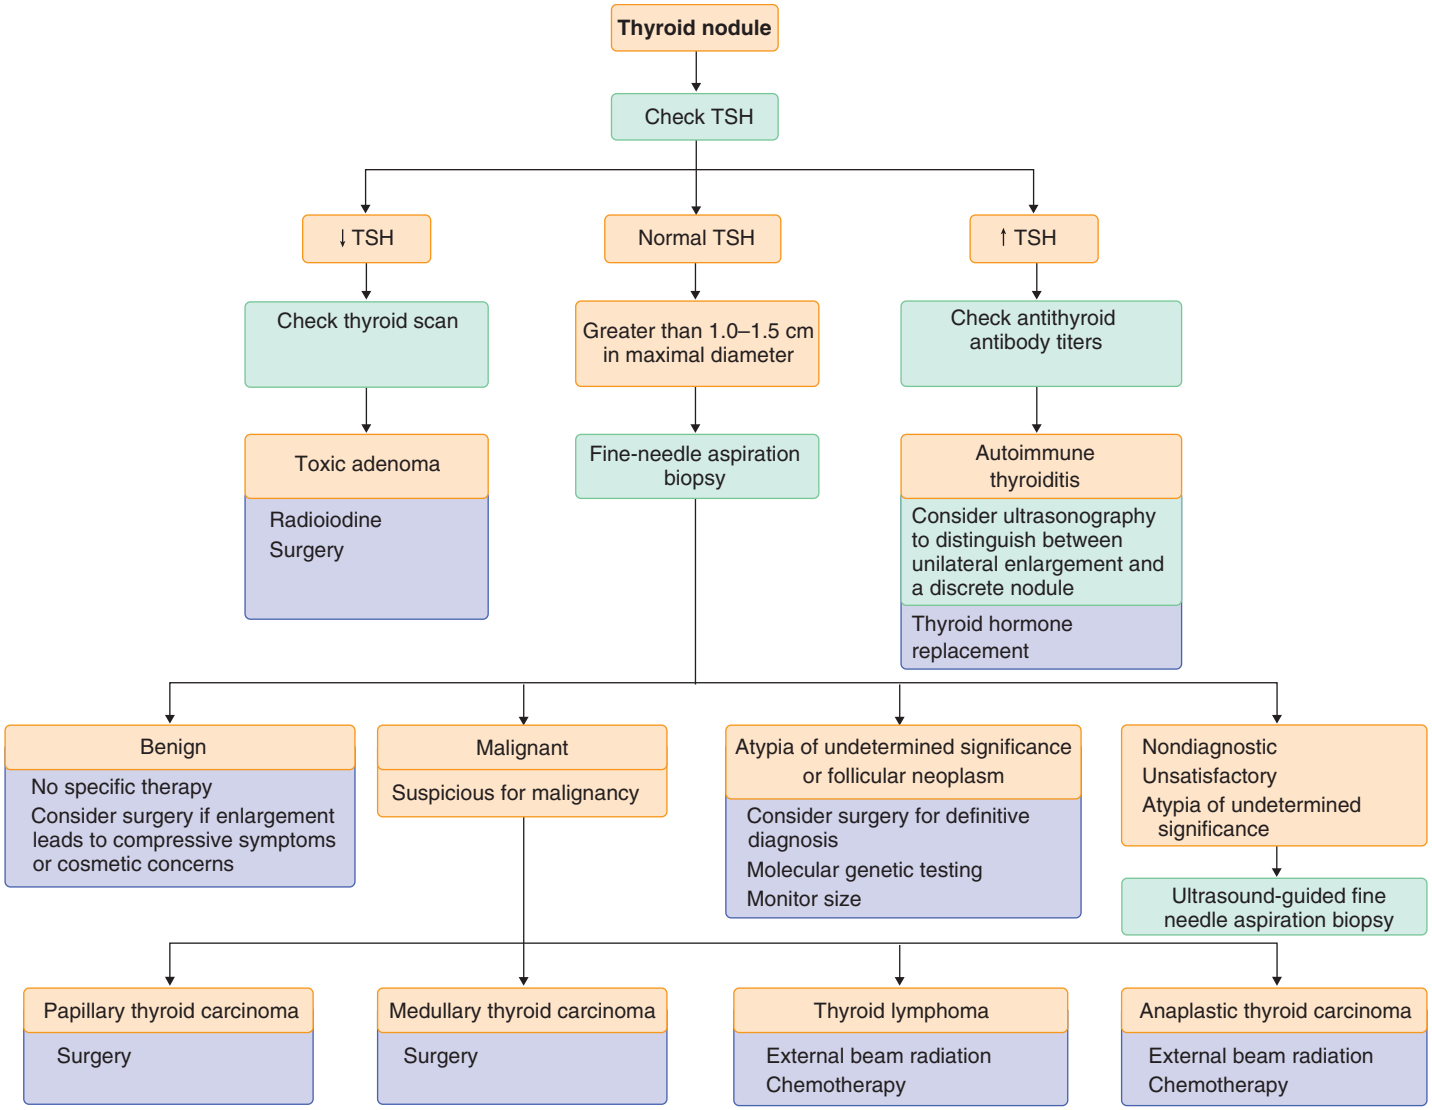

FIGURE 226-4. Evaluation of a thyroid nodule. TSH = thyroid-stimulating hormone.

TABLE 226-7 BETHESDA SYSTEM FOR REPORTING CYTOPATHOLOGY

CYTOLOGIC DIAGNOSIS	RISK OF MALIGNANCY
Benign	0-3%
Atypia of undetermined significance	20-25%
Suspicious for a follicular neoplasm	15-30%
Suspicious for malignancy	60-77%
Malignant	97-99%

Diagnostic categories associated with risk of malignancy.
Adapted from Bongiovanny M, Spitale A, Faquin WC, et al. The Bethesda System for Reporting Thyroid Cytopathology: a meta-analysis. *Acta Cytol.* 2012;56:333-339.

whom its incidence is currently rising faster than that of any other malignancy. There are estimated to be 450,000 U.S. thyroid cancer survivors who require lifelong follow-up for recurrence. Papillary thyroid carcinoma is the most common form of thyroid cancer, representing 90% of cases. The mean age at diagnosis is 45 years, but papillary thyroid carcinoma does occur in children and increases in incidence with age.

PATHOBIOLOGY

Irradiation of the thyroid gland in childhood is a risk factor, as evidenced by the epidemics of thyroid cancer that have followed both external beam radiation therapy for benign childhood conditions (e.g., tonsillitis and acne) and radioiodine exposure after nuclear incidents. A substantial body of evidence now implicates *RET/PTC* and *BRAF* gene mutations that activate the MAP kinase signaling pathway in the pathogenesis and progression of papillary thyroid cancer. Most papillary thyroid carcinomas are slow growing and either remain confined to the gland or metastasize to cervical lymph nodes. Papillary microcarcinomas are a common incidental pathologic finding in 5% of thyroid glands excised for other reasons. However, papillary thyroid carcinomas can be more aggressive, with extension into adjacent tissues, extensive nodal involvement, and distant metastatic spread, most commonly to the lungs. Such aggressive behavior is, in general, more common in older patients.

Follicular and Hürthle cell thyroid carcinomas account for 9% of all thyroid cancers. When these tumors show histologic evidence of invading only the tumor capsule, they are termed *minimally invasive* and generally behave like papillary thyroid carcinomas. However, follicular and Hürthle cell carcinomas with vascular invasion are more likely to be associated with distant metastatic disease, which most commonly involves the lungs and skeleton.

TREATMENT

Rx

Treatment of epithelial thyroid cancer entails surgery, often followed by radioiodine ablation of remnant thyroid tissue. Total or near-total thyroidectomy with selective central compartment lymph node resection is usually the appropriate initial surgical procedure. Thyroid surgery can be complicated by hypoparathyroidism or recurrent laryngeal nerve injury, which causes hoarseness if it is unilateral and airway obstruction if it is bilateral. The rationale for bilateral surgery is the frequent presence of bilateral disease in papillary

thyroid cancer and the lower risk of recurrence after bilateral gland removal. In addition, there is greater accuracy in detecting residual disease after the eradication of all remaining normal thyroid tissue.

A prospective cohort study of a national database of 30-day follow-up of patients undergoing thyroidectomy (for cancer or other indications) documented the increased risk of major pulmonary, cardiac, and infectious complications in the elderly. Elderly patients (65 to 79 years old) are twice as likely, and the most elderly (80 years or older) are 5 times as likely as young patients (16 to 64 years old) to have major systematic complications.[17]

Follow-up

Postoperatively, ^{131}I administration after TSH stimulation can be employed to ablate the small amount of normal thyroid tissue that usually remains after surgery. This tissue, if it is not destroyed, leaves patients with circulating thyroglobulin and iodine-concentrating tissue on whole body scanning, decreasing the accuracy of these tests to identify residual disease. In controlled but nonrandomized trials, radioiodine has been associated with a lower rate of tumor recurrence in patients with advanced disease (stages 3 and 4) at presentation (see later), but there is no demonstrated clinical benefit of adjunctive radioiodine therapy for patients with lower stages of disease. TSH stimulation of residual thyroid tissue, which is essential for effective radioiodine therapy, can be accomplished either by the temporary withdrawal of thyroid hormone therapy to promote endogenous TSH production or by the administration of recombinant thyrotropin, which avoids the morbidity of hypothyroidism.

Thyroxine therapy is appropriate for all patients with treated thyroid cancer, regardless of the extent of surgery and whether they received radioiodine ablative therapy. In addition to providing thyroid hormone replacement, thyroxine can be adjusted to suppress the patient's circulating TSH level to the low or low-normal range to reduce the likelihood of tumor recurrence. In determining the extent to which the TSH level should be suppressed, the patient's risk of cancer recurrence must be balanced against potential thyrotoxic complications such as bone mineral loss in postmenopausal women and atrial fibrillation in older patients.

Long-term monitoring of patients entails periodic clinical assessment, measurement of serum thyroglobulin levels, radioiodine imaging in the early postoperative phase, and occasional use of ultrasonography. Clinically, patients should be assessed for local neck symptoms or recurrent cervical masses, as well as for optimization of thyroid hormone therapy. For patients with treated epithelial thyroid cancers, thyroglobulin is a more specific tumor marker if all remaining normal thyroid tissue has been ablated. For patients with undetectable thyroglobulin levels on TSH-suppressive thyroid hormone therapy, thyroglobulin measurement after recombinant TSH stimulation can sometimes reveal residual disease. Radioiodine scanning after TSH stimulation can be helpful in patients who have previously undergone radioiodine ablation, but once radioiodine imaging is negative, it offers little or no advantage over measurement of stimulated thyroglobulin levels. This is particularly true in recurrent papillary thyroid cancers, which often lose the ability to concentrate iodine. Unfortunately, thyroglobulin testing is impossible in the 20% of patients who have circulating thyroglobulin autoantibodies that interfere with thyroglobulin immunoassays. Because most epithelial thyroid cancer recurrences are in cervical nodes or soft tissues, ultrasonography is useful for postoperative monitoring, particularly in patients who presented with extensive cervical disease or who have persistently detectable serum thyroglobulin. CT scanning of the chest should be employed to detect intrathoracic disease in patients whose findings suggest recurrence outside the neck. In patients with substantial detectable thyroglobulin levels (>10 ng/mL) and negative findings on standard imaging studies, PET scanning can identify sites of residual disease in more than 50% of patients.

Localization of recurrent cervical disease is usually an indication for comprehensive compartmental neck dissection. Distant and nonresectable metastases that are iodine avid, which occur more commonly in patients with invasive follicular thyroid cancer, can be treated with repeated doses of ^{131}I. Symptomatic hilar node and bone metastases can be treated palliatively with external beam radiation therapy. Surgery can be employed for isolated metastatic disease sites. Conventional chemotherapy has limited efficacy in the treatment of differentiated thyroid cancer, but newer biologic agents targeting the molecular pathways involved in the pathogenesis of thyroid cancer hold promise.[18] For example, the multikinase inhibitor sorafenib was shown in a phase 3 trial to double progression free survival to almost 11 months in patients with metastatic non–iodine avid epithelial thyroid cancers and shrink disease sites in 12% of patients.[A6] Another multikinase inhibitor, vandetanib, is also effective against locally advanced or metastatic differentiated thyroid cancer.[A6] However, multikinase inhibitors commonly have adverse effects, and because they are only tumoristatic must be used continuously.

PROGNOSIS

The TNM (tumor, node, metastasis) staging system is commonly used to stage epithelial thyroid cancers. In addition to tumor size, extent of node involvement, and presence of distant metastatic disease, the age of the patient at presentation is an important predictor of outcome. Patients younger than 45 years have a better prognosis than older individuals. The overall age-adjusted 10-year survival rates for patients with papillary and follicular thyroid cancer are 98% and 92%, respectively. However, disease recurrence is relatively common, occurring in approximately one third of patients with papillary thyroid cancer. Consequently, patients with treated thyroid cancer must be monitored for recurrent disease.

Medullary Thyroid Carcinoma

Patients with medullary thyroid cancer (Chapter 246) typically present with a thyroid nodule, cervical adenopathy, distant disease, or symptoms of flushing, diarrhea, and pruritus when the circulating calcitonin level is markedly elevated. Features of the other elements of MEN 2a (e.g., hypertension) or MEN 2b (e.g., marfanoid habitus, submucosal neuromas) should be sought.

Anaplastic Thyroid Carcinoma

Anaplastic thyroid carcinoma is a rare, histologically undifferentiated, clinically aggressive malignant neoplasm that typically arises in older patients, one fourth of whom present with evidence of a preceding differentiated thyroid cancer. Affected patients present with a rapidly enlarging mass in the anterior or lateral neck associated with pain, tenderness, and compressive symptoms including dysphagia, dysphonia, and stridorous dyspnea. Fine-needle aspiration biopsy of the mass usually yields large, pleomorphic, undifferentiated cells, but open surgical biopsy is sometimes required to confirm the diagnosis.

Most cases are unresectable at presentation because of invasion of cervical structures. Surgery is not curative and should aim to secure the patient's airway. A percutaneous gastrostomy tube is often placed to ensure adequate nutrition in the face of esophageal impingement. Conventional therapy consisting of combined external beam radiation therapy and chemotherapy with doxorubicin with or without cisplatin produces an initial response in 25% of patients. Rare patients with disease limited to the neck may have extended survival, but almost all patients relapse within a few months and succumb to their disease, with median survival ranging from 3 to 7 months. Current research is focused on the use of targeted antiangiogenic agents to treat unresponsive disease.

Thyroid Lymphoma

Lymphoma rarely arises in the thyroid gland, typically presenting in older persons as a rapidly enlarging and painful diffuse goiter. Patients often have a preceding history of autoimmune thyroiditis. The diagnosis is further suspected when fine-needle aspiration biopsy yields abundant lymphocytes without other cellular features of autoimmune thyroiditis. Immunohistochemical staining and flow cytometry of sampled material can characterize a monoclonal lymphocyte population. Surgical biopsy is sometimes required to establish the diagnosis. In 50% of cases, lymphoma is primary to the thyroid gland, and it is usually an intermediate-grade non-Hodgkin's–type lymphoma (Chapter 185).

Surgical resection of the thyroid is usually not indicated, but elective tracheostomy may be required if tracheal compression is imminent. Most patients respond to treatment with combined external beam radiation therapy and chemotherapy. Disease-free survival rates vary with the disease stage at diagnosis and the initial response to combination therapy.

REVIEW QUESTIONS

1. A 74-year-old man with a history of hypertension and hypercholesterolemia is hospitalized after presenting with a 3-month history of progressive fatigue and dyspnea on exertion. His weight on admission is 164 lbs, his pulse is 44 bpm, and lab tests show CPK 528 U/L, TSH 65 mU/L, free T_4 0.2 ng/dL, and T_4 2.3 µg/dL. A pharmacologic nuclear stress test reveals findings consistent with diffuse myocardial ischemia. Subsequent coronary angiography reveals diffuse three-vessel disease that is not amenable to percutaneous stenting. A consulting cardiologist has recommended that he undergo coronary artery bypass surgery. What would you recommend?

A. Start levothyroxine at a dose of 125 µg daily.
B. Administer a 60-µg intravenous dose of levothyroxine daily.
C. Check antithyroid peroxidase and antithyroglobulin antibodies.
D. Start levothyroxine at a dose of 12.5 µg daily.

Answer: D Start levothyroxine at a dose of 12.5 µg daily. This patient requires treatment with levothyroxine, but it should be started at the lowest possible dose, with provisions to gradually increase it as tolerated in light of his coronary artery disease. A full replacement dose given orally or an adjusted dose given intravenously could exacerbate cardiac ischemia to the point of causing an infarction. Checking antithyroid peroxidase and antithyroglobulin antibodies would not provide any additional information. In the absence of any known history of thyroid surgery or external radiation treatment to the head and neck, it can be presumed that his severe hypothyroidism is due to autoimmune thyroiditis.

2. A 28-year-old woman with a 6-year history of hypothyroidism has been treated with levothyroxine at a dose of 125 µg daily. Lab tests checked 5 months ago right before she stopped taking cyclic oral contraceptives showed TSH 1.3 mU/L. Three weeks ago she checked a home pregnancy test that was positive. She had lab tests checked by her obstetrician that showed hemoglobin 10.2 g/dL, T_4 12.5 µg/dL, and T_3 185 ng/dL. She is estimated to be at 8 weeks' gestation and has started taking prenatal vitamins and iron sulfate at a dose of 325 mg twice daily. What should you do?

A. Have her continue levothyroxine at a dose of 125 µg daily, with instructions to take it regularly with other medications.
B. Increase her dose of levothyroxine to 150 µg daily.
C. Decrease her dose of levothyroxine to 112 µg daily.
D. Check a thyroid uptake and scan.
E. Check a TSH level.

Answer: E Check a TSH level. The only way to determine whether her current dose of levothyroxine is providing an adequate level of replacement is to check a TSH level. Total T_4 and T_3 levels measured while taking oral contraceptives or during pregnancy may be elevated or high-normal owing to increased production of thyroxine-binding globulin stimulated by increased estrogen levels. As such, they may not correlate with free thyroid hormone levels. Decreasing her dose of levothyroxine would be inappropriate because she may require a moderate to substantial increase in her dose during the course of a pregnancy. Empirically increasing a dose of levothyroxine may cause iatrogenic thyrotoxicosis characterized by symptoms that may be difficult to distinguish from normal physiologic changes of pregnancy. Exposure to radionuclide tracer is contraindicated during pregnancy, and in any event a thyroid uptake and scan would be unnecessary in a patient with known hypothyroidism. Doses of levothyroxine should always be separated from doses of iron sulfate by at least 4 hours to avoid interactions that can block absorption of both agents.

3. A 76-year-old woman presenting with a 1-week history of a cough, fever, and audible stridor is diagnosed with community-acquired pneumonia. A chest x-ray does not show evidence of an infiltrate but does reveal marked rightward tracheal deviation with a visible mediastinal soft tissue mass. A non-contrast chest computed tomography scan reveals multiple bilateral thyroid nodules, with an 8.5-cm left lower-pole nodule extending below the clavicle and sternum, with compression and narrowing of the trachea. Lab tests show TSH less than 0.001 mU/L, free T_4 2.8 ng/dL, and T_3 245 ng/dL. A thyroid uptake and scan reveals 24-hour uptake of 37%, with tracer accumulation localized to two right-sided thyroid nodules and the substernal left-sided thyroid nodule. What should you do next?

A. Check pulmonary function tests with flow-volume loops.
B. Prescribe a 12-month course of methimazole 10 mg daily.
C. Refer the patient to a thyroid surgeon.
D. Administer a 30-mCi dose of I-131.
E. Start levothyroxine at a dose of 137 µg daily.

Answer: C Refer the patient to a thyroid surgeon. A multinodular goiter that has extended substernally to the point of causing tracheal compression should be resected by an experienced thyroid surgeon, irrespective of its functional status. The presence of audible stridor and evidence of tracheal narrowing on radiographic images obviates the need for pulmonary function testing with flow-volume loops. Treatment with methimazole might help control hyperthyroidism caused by autonomously functioning thyroid nodules but will not be a permanent solution and would not shrink the dominant nodule to any extent. Treatment with I-131 might help shrink the dominant nodule over time but will require 12 to 24 months to be effective. Treatment with levothyroxine to try to suppress further enlargement of thyroid tissue may be marginally effective at best in euthyroid patients and would be completely ineffective—and potentially dangerous—in an elderly woman presenting with hyperthyroidism.

4. A 33-year-old man is noted to have palpable enlargement of the right side of his thyroid on a routine physical exam. A thyroid ultrasound reveals a solitary 3.1-cm right-sided nodule with smooth borders. Lab tests show TSH 0.1 mU/L and T_4 11.5 µg/dL. He reports a history of occasional symptomatic palpitations and weight loss of 5 lbs over the course of 3 months despite an increase in his appetite. He is not taking any medications and has not noted any problems with dysphagia or dysphonia. What should you do next?

A. Perform a fine-needle aspiration biopsy of the right-sided nodule.
B. Administer a 15-mCi dose of I-131.
C. Refer the patient to a thyroid surgeon.
D. Start methimazole at a dose of 5 mg daily.
E. Perform a 123-I thyroid scan.

Answer: E Perform a 123-I thyroid scan. When a patient presenting with a thyroid nodule who is not taking levothyroxine is noted to have a suppressed TSH level, a radionuclide thyroid scan should be checked to determine if the nodule is an autonomously functioning toxic adenoma. If a nodule is "hot" on the scan, it does not need to be biopsied. If it is "cold" on the scan, with evidence of increased tracer uptake in surrounding tissue consistent with Graves disease, fine-needle aspiration biopsy should be performed to confirm it is benign. Treatment of a toxic adenoma or Graves disease with methimazole or radioactive iodine may be indicated but should only be considered after it has been determined whether a biopsy is necessary. Referral for thyroid surgery would only be indicated if a biopsy of a cold nodule revealed suspicious or malignant cytopathology, or if there were contraindications to treatment of a toxic adenoma with radioactive iodine or methimazole.

5. A 55-year-old woman is noted to be tachycardic with a resting pulse of 104 during a routine physical exam. Lab tests checked to evaluate this show TSH 0.002 mU/L, with follow-up lab tests showing free T_4 2.3 ng/dL and T_3 289 ng/dL. She denies any history of anterior neck discomfort, weight loss, palpitations, anxiety, tremor, heat intolerance, or insomnia. Physical examination reveals tachycardia with a regular rhythm, a slightly enlarged thyroid without any discrete nodularity, and no evidence of proptosis or ocular irritation. She does have a history of osteopenia, with a lumbar spine T-score of −2.3 identified on a DEXA scan checked soon after the onset of menopause. What should you do next?

A. Check antithyroid peroxidase and antithyroglobulin antibodies.
B. Check a radionuclide thyroid uptake and scan.
C. Start methimazole at a dose of 10 mg daily.
D. Refer the patient to a thyroid surgeon.
E. Check an ESR.

Answer: B Check a radionuclide thyroid uptake and scan. This patient is presenting with thyrotoxicosis without any referable symptoms or clinical findings suggestive of a specific cause. Checking a thyroid uptake would help distinguish between a high-uptake state caused by hyperthyroidism driven by increased production of thyroid hormone, and a low-uptake state caused by inflammation with leakage of stored thyroid hormone. If a high-uptake state is identified, a scan will help distinguish whether hyperthyroidism is caused by Graves disease, a toxic adenoma, or a toxic multinodular goiter. Elevated antithyroid peroxidase and antithyroglobulin antibodies may identify underlying autoimmune thyroiditis but will not definitively determine the proximate cause of thyrotoxicosis. Treatment with methimazole or referral for thyroid surgery would only be considered after confirmation of a diagnosis. Checking an erythrocyte sedimentation rate (ESR) would not be informative, because subacute thyroiditis would be unlikely in the absence of localized discomfort.

227

ADRENAL CORTEX

LYNNETTE K. NIEMAN

The adrenal glands weigh 6 to 8 g in adults (Fig. 227-1). Each contains a cortex, which makes steroid hormones, and a medulla, which produces catecholamines. Diseases of the adrenal medulla are discussed in Chapter 228. In the adrenal cortex, production of the three major classes of steroids occurs in specific zones: the outermost layer, the glomerulosa, produces mineralocorticoids, primarily aldosterone; the middle layer, the fasciculata, produces glucocorticoids, primarily cortisol; the innermost layer, the reticularis, produces adrenal "androgens," primarily dehydroepiandrosterone (DHEA) and its sulfated conjugate (DHEA-S) (Fig. 227-2). This division reflects the fact that certain critical enzymes are restricted to specific zones, resulting in the ability or inability to synthesize specific end products.

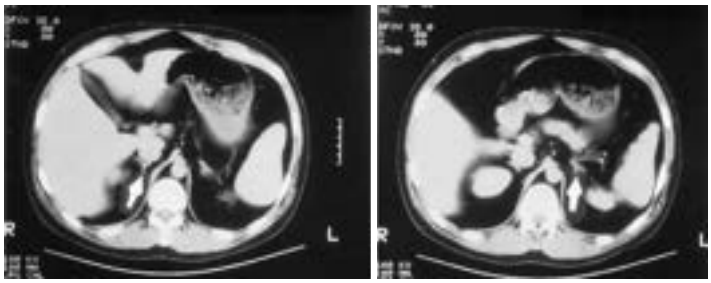

FIGURE 227-1. Magnetic resonance images of the abdomen showing the position and relative size of the normal adrenal glands.

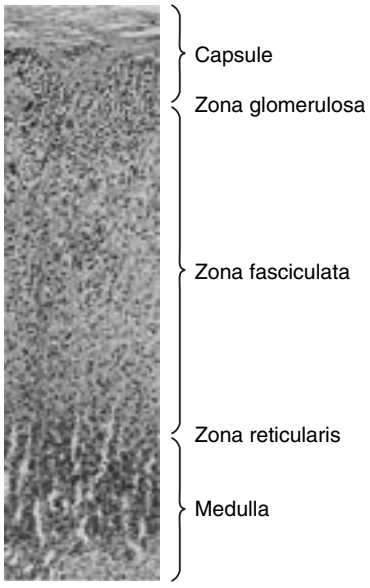

FIGURE 227-2. Histologic section through a normal adult adrenal gland showing the progression (from outside to inside) of the zona glomerulosa, zona fasciculata, zona reticularis, and medulla.

FUNCTION

The actions and regulation of these steroid classes differ. Mineralocorticoids act through the renal mineralocorticoid receptor to promote the reabsorption of sodium and the secretion of potassium. In addition to this classic action, mineralocorticoids have important action on the vasculature and may exacerbate the metabolic syndrome.[1] Aldosterone secretion is stimulated primarily by hyperkalemia and angiotensin II (which itself is stimulated by hypovolemia and excess renin). These agents increase the production of aldosterone synthase to restore homeostasis through this feedback loop. Aldosterone production is stimulated to a much smaller degree by adrenocorticotropic hormone (ACTH).

Cortisol and other glucocorticoids act through the glucocorticoid receptor type 2 and its isoforms. The actions of this class of steroids are much broader, including effects on carbohydrate handling, lipid and calcium metabolism, and the immune and nervous systems. Cortisol production is regulated primarily by ACTH, which is secreted in a circadian rhythm in response to corticotropin-releasing hormone (CRH) so that cortisol levels are highest in the morning and fall to a nadir around midnight. Cortisol coordinates ACTH production through negative feedback at the pituitary (ACTH) and hypothalamus (CRH). Vasopressin secretion also plays a role in stimulating ACTH release.

DHEA and DHEA-S are the most abundant products of the adrenal gland. They exert their estrogenic and androgenic effects as prohormones, being converted to estrogens and testosterone in the peripheral tissues and activating the androgen and estrogen receptors. There is no known regulator of DHEA synthesis, but its production declines with age.

DISORDERS OF ADRENAL FUNCTION

Most disorders of the adrenal cortex reflect overproduction or underproduction of the products of a single synthetic zone—cortisol, aldosterone, or testosterone or estrogen (Fig. 227-3). The congenital adrenal hyperplasias are an exception and are manifested with both overproduction and underproduction. Abnormal secretion is suggested by clinical features of each disorder and is reflected in plasma or urine levels of the relevant hormones or by the consequent increases or decreases in feedback systems, which form the basis of the biochemical diagnostic tests.

Glucocorticoid Excess: Cushing Syndrome

CLINICAL MANIFESTATIONS

Cushing syndrome is a symptom complex that reflects excessive tissue exposure to cortisol. Classic features of Cushing syndrome include weight gain, plethora, hypertension, and striae (Table 227-1). Not all patients have all features; the number and severity of features correlate roughly with the duration and severity of hypercortisolism. Because many of the signs and symptoms are nonspecific, the diagnosis may be confused with psychiatric disorders, polycystic ovary syndrome, the metabolic syndrome, simple obesity, fibromyalgia, or acute illness. However, because worsening hypercortisolism may precipitate hypertension, glucose intolerance, infections, psychiatric disturbances, impaired cognition, and hypercoagulability, it is important to identify this treatable disorder to prevent its associated morbidity and mortality.[2]

Changes in mood and cognition are useful markers of hypercortisolism. These include irritability, crying, and restlessness; depressed mood; decreased libido; insomnia; anxiety; and decreased concentration and impaired memory.

DIAGNOSIS

Clinical Examination

Cushing syndrome screening is most likely to be positive in the presence of signs that are typical of glucocorticoid excess, such as abnormal fat distribution in the supraclavicular and temporal fossae, proximal muscle weakness, wide (>1 cm) purple striae, and new irritability, decreased cognition, and decreased short-term memory. Testing is indicated when clinical features have progressed over time. For example, oligomenorrhea is more suggestive of Cushing syndrome if a woman previously had regular menses. Serial seven subtractions and recall of three cities (or objects) are useful bedside strategies to identify deficits in cognition and memory.

Laboratory Findings

Exogenous administration of glucocorticoid should be excluded before screening for endogenous Cushing syndrome. In the absence of pseudo-Cushing states (see later), at least two different screening test results should

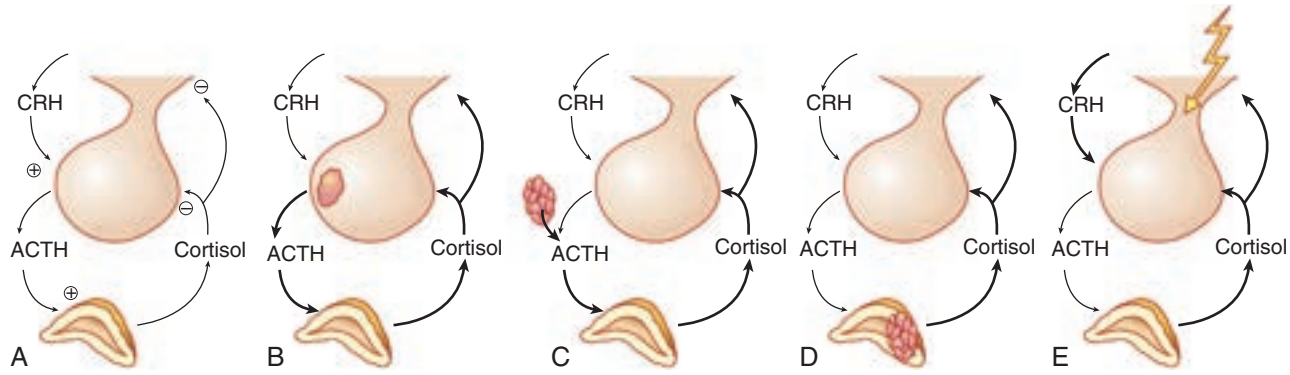

FIGURE 227-3. Physiology of the adrenal axis in health, Cushing syndrome, and pseudo-Cushing states. A, In healthy individuals, cortisol production is stimulated by the increased hypothalamic release of corticotropin-releasing hormone (CRH), which then travels down the pituitary stalk to stimulate adrenocorticotropic hormone (ACTH) secretion and release by corticotropes. Circulating ACTH stimulates adrenal gland production and secretion of cortisol. Cortisol then functions in a negative feedback mechanism to inhibit both CRH and ACTH. **B,** In Cushing disease, a pituitary tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **C,** In ectopic ACTH secretion, a nonpituitary ACTH-secreting tumor releases excessive amounts of ACTH, which results in increased cortisol secretion by the adrenal glands. **D,** In ACTH-independent adrenal forms of Cushing syndrome, the adrenal tumor autonomously releases excess amounts of cortisol. In all forms of Cushing syndrome, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that circulating ACTH levels reflect the underlying tumor (levels are normal or increased) or independent cortisol production (levels are suppressed). **E,** In pseudo-Cushing states, central stimulation increases CRH secretion, which in turn increases ACTH and hence cortisol production. In this setting, the negative feedback effects of excessive cortisol inhibit endogenous CRH and ACTH secretion, so that cortisol levels are ultimately constrained, albeit at an increased level.

TABLE 227-1 THE FREQUENCY OF CLINICAL SIGNS AND SYMPTOMS OF CUSHING SYNDROME

SIGN OR SYMPTOM	PERCENTAGE
Decreased libido in men and women	100
Obesity or weight gain	97
Plethora	94
Round face	88
Menstrual changes	84
Hirsutism	81
Hypertension	74
Ecchymoses	62
Lethargy, depression	62
Striae	56
Weakness	56
Electrocardiographic changes or atherosclerosis	55
Dorsal fat pad	54

Abnormal glucose tolerance	50
Osteopenia or fracture	50
Headache	47
Backache	43
Recurrent infections	25
Abdominal pain	21
Acne	21
Female balding	13

be abnormal to establish the diagnosis. Tests for the differential diagnosis of Cushing syndrome should not be used to make the diagnosis. Figure 227-4 is the Endocrine Society's recommended algorithm for testing of patients suspected of having Cushing syndrome.[3]

Urine, Saliva, and Serum Cortisol Measurements

Urine free cortisol (UFC) excretion during 24 hours is a good screening test. Specific, structurally based assay techniques, such as high-performance liquid chromatography and tandem mass spectrometry, are the "gold standard." The upper-normal limit of these tests is much lower and more specific than that of antibody-based assays, in which other steroids may cross-react. This cross-reactivity may be an advantage in screening for hypercortisolism.

UFC excretion also may be increased in the so-called *pseudo-Cushing states*, including psychiatric disorders (depression, anxiety disorder, obsessive-compulsive disorder), chronic pain, severe exercise, alcoholism, uncontrolled diabetes, and morbid obesity. Here, it is hypothesized that higher brain pathways stimulate CRH release and activation of the entire hypothalamic-pituitary-adrenal axis (see Fig. 227-3E). Cortisol negative feedback inhibition on CRH and pituitary ACTH release restrains the resulting hypercortisoluria to less than four-fold greater than normal. Thus, Cushing syndrome cannot be diagnosed with certainty unless values reach this threshold. Conversely, patients with Cushing syndrome may have normal UFC excretion because of mild or intermittent hypercortisolism or altered renal metabolism of cortisol. If UFC is only mildly elevated and clinical features are minimal, it is best to treat any pseudo-Cushing state and to remeasure UFC excretion with the expectation that it will normalize. Alternatively, if UFC values are normal but clinical suspicion is high, repeated measurement might disclose intermittent hypercortisolism.

Measurement of plasma cortisol at midnight distinguishes pseudo-Cushing states from Cushing syndrome with 95% diagnostic accuracy; a level greater than 7.5 μg/dL is required for the diagnosis of Cushing syndrome. Measurement of salivary cortisol at bedtime or at midnight works as well, is more convenient, and may be the best screening test in patients with mild or intermittent hypercortisolism.[4,5] However, the criteria for its interpretation differ, so each assay must be validated before it is used for this purpose.

Dexamethasone Suppression Tests

The dexamethasone suppression test is a simple screening test that takes advantage of the negative feedback effect of glucocorticoids to reduce ACTH (and hence serum cortisol). Dexamethasone 1 mg is given orally between 11:00 PM and midnight, and plasma cortisol is measured between 8:00 and 9:00 the next morning. The test has an 8% false-negative rate in patients with Cushing disease and a 30% false-positive rate in chronic illness, obesity, psychiatric disorders, and normal individuals. As a result, Cushing syndrome cannot be diagnosed by this test alone unless the result is extremely abnormal.

The 2-day, 2-mg dexamethasone suppression test discriminates patients with a pseudo-Cushing state if plasma cortisol end points of less than 1.4 or 2.2 μg/dL are used. Dexamethasone 500 μg is given orally every 6 hours for eight doses, and plasma cortisol is measured 2 hours after the last dose. The test has excellent sensitivity (90 to 100%) and specificity (97 to 100%) for discriminating Cushing syndrome, but it is costly and requires excellent compliance of the patient. The immediate subsequent administration of CRH (1 μg per kilogram of body weight intravenously) and the measurement of cortisol 15 minutes later increased the sensitivity and specificity to 100% in a small study of patients, with values above 1.4 μg/dL indicating Cushing syndrome. Although this combined dexamethasone-CRH test has high diagnostic accuracy, it has the same disadvantages as the 2-day dexamethasone suppression test and the added cost of CRH testing. Because of these drawbacks, these tests are usually reserved for patients with ambiguous or confusing results on other screening tests. CRH is available commercially (Acthrel), with Food and Drug Administration–approved labeling for the differential diagnosis of Cushing syndrome. Its use in the dexamethasone-CRH test is an off-label use.

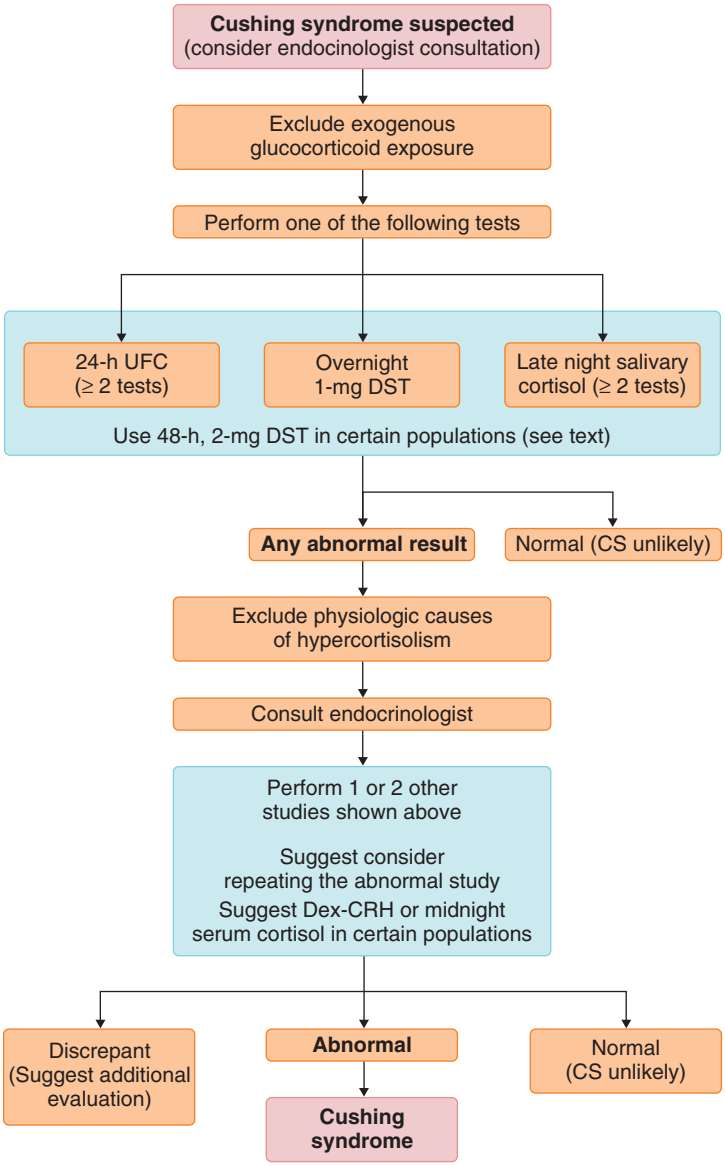

FIGURE 227-4. Algorithm for testing of patients suspected of having Cushing syndrome (CS). All statements are recommendations except for those prefaced by "suggest". Diagnostic criteria that suggest Cushing syndrome are urine free cortisol (UFC) greater than the normal range for the assay, serum cortisol greater than 1.8 µg/dL (50 nmol/liter) after 1 mg dexamethasone (1-mg DST), and late-night salivary cortisol greater than 145 ng/dL (4 nmol/liter). Dex-CRH = dexamethasone–corticotropin-releasing hormone test; DST = dexamethasone suppression test. (Reprinted with permission from Nieman LK, Biller BM, Findling JW, et al. The diagnosis of Cushing syndrome: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2008;93:1526-1540.)

Any dexamethasone test may give false results in patients with abnormal metabolic clearance of the drug. Agents that induce the cytochrome P-450 CYP3A4 enzymes (alcohol, rifampin, phenytoin, phenobarbital) increase dexamethasone clearance, whereas renal or hepatic failure decreases it. Measurement of a dexamethasone level can determine whether its clearance has been altered.

Differential Diagnosis

The causes of endogenous Cushing syndrome can be divided broadly into ACTH-dependent (80%) and ACTH-independent (20%) forms (Table 227-2). Hypercortisolism from autonomously functioning adrenal tumors suppresses ACTH, whereas in primary disorders of ACTH excess, the adrenal glands respond to tumor-derived ACTH. Plasma ACTH concentration distinguishes between these causes. ACTH is usually less than 10 pg/mL in primary adrenal disorders but is also suppressed by exogenous steroids, whether they are prescribed intentionally (iatrogenic Cushing syndrome) or taken factitiously. Patients in the latter group often have had multiple surgical procedures and do not reveal that they are self-administering steroids. As a result, patients must be queried closely about exogenous steroid administration, recognizing that parenteral, inhaled, and topical steroids can all cause glucocorticoid excess. Patients with endogenous Cushing syndrome and low ACTH concentrations should undergo adrenal imaging to identify the site of adrenal abnormality. Nonautonomous adrenal tissue atrophies when ACTH support is subnormal. Because of this, the common ACTH-independent forms of Cushing syndrome—adrenal adenoma and carcinoma—are manifested as a unilateral adrenal mass, with atrophy of the adjacent and contralateral tissue on magnetic resonance imaging or computed tomography.

TABLE 227-2 ETIOLOGY OF CUSHING SYNDROME

EXOGENOUS	ENDOGENOUS
Most common cause of Cushing syndrome: Glucocorticoid or ACTH driven May be factitious or iatrogenic	ACTH independent—autonomous adrenal activation (20% of all cases) Adrenal adenoma (40-50%) Adrenal carcinoma (40-50%) Primary pigmented nodular adrenal disease McCune-Albright syndrome Massive macronodular adrenal disease Gastric inhibitory polypeptide or food induced ACTH dependent—adrenal activation by excessive ACTH (80% of all cases) Corticotrope adenoma (80%) Ectopic ACTH secretion (20%) Ectopic CRH secretion (rare)

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

Bilateral forms of primary adrenal disease are rare and may be manifested with small or large adrenal nodules.[6] Primary pigmented nodular adrenal disease occurs primarily in children and young adults and is characterized by small to normal-sized adrenal glands containing small (<5 mm) black-brown cortical nodules. About half of these patients have additional features, termed *Carney complex*, which are often inherited in an autosomal dominant fashion. The clinical features of Carney complex include myxomas of the skin, breast, and heart; spotty pigmentation, such as lentigines and blue nevi; and other endocrine overactivity, such as acromegaly and testicular tumors. Some of these patients have mutations leading to a truncated form of protein kinase A regulatory 1α subunit. The resultant increase in protein kinase A activation by cyclic adenosine monophosphate presumably allows tumor formation. Bilateral nodular hyperplasia with Cushing syndrome can occur in the setting of *McCune-Albright syndrome*, mostly in infants or children. Massive macronodular adrenal disease generally is manifested after the age of 40 years with huge adrenal glands and aberrant expression of "illicit" receptors for various ligands (gastric inhibitory polypeptide, β-adrenergic, vasopressin), which presumably mediates autonomous cortisol production.

A normal or elevated plasma ACTH level (>15 pg/mL; 3.3 pmol/L) is consistent with an ACTH-producing tumor.[7] Intermediate ACTH concentrations between 5 and 15 pg/mL (1.1 to 3.3 pmol/L) in a two-site sandwich assay are not diagnostic. In these patients, suboptimal cortisol responses to CRH stimulation may identify the minority of cases of ACTH-independent Cushing syndrome with borderline basal ACTH values. In addition, a suppressed plasma DHEA-S value supports the diagnosis of an ACTH-independent disorder.

Cushing disease,[8] an ACTH-secreting pituitary adenoma, is the most common cause of Cushing syndrome. It is more common in women than in men (6 : 1 ratio), with a mean age at onset in the fourth decade. ACTH also may be secreted ectopically by a variety of neuroendocrine tumors, as shown in Table 227-3.

Pituitary magnetic resonance imaging shows a tumor in only about 40 to 50% of patients with Cushing disease, but it is obtained routinely in patients with ACTH-dependent disease to exclude a macroadenoma or abnormal anatomy before petrosal sinus sampling or surgery. A pituitary lesion less than 6 mm is seen in up to 10% of healthy individuals and so does not always indicate Cushing disease. Biochemical tests must be used to distinguish among the ACTH-dependent causes of Cushing syndrome, and they must be performed after a 6- to 8-week period of sustained hypercortisolism sufficient to suppress normal corticotrope function.

Inferior petrosal sinus sampling is the best test to distinguish between a pituitary and an ectopic source of excess ACTH; worldwide, the overall

TABLE 227-3 THE INCIDENCE AND TYPES OF TUMORS CAUSING THE SYNDROME OF ECTOPIC ACTH SECRETION

TUMOR TYPE	PERCENTAGE
Carcinoma of lung (small cell or oat cell)	19-50
Carcinoid of bronchus	2-37
Carcinoid of thymus	8-12
Pancreatic tumors, carcinoid and islet cell	4-12
Pheochromocytoma, neuroblastoma, ganglioma, paraganglioma	5-12
Medullary carcinoma of the thyroid	0-5
Miscellaneous*	<1

*Miscellaneous tumors reported to secrete ACTH in 1 to 10 cases include carcinoma of the ovary, prostate, breast, thyroid, kidney, salivary glands, testes, gallbladder, esophagus, and appendix; gastric carcinoid and renal carcinoid; acute myeloblastic leukemia; melanoma; and cloacogenic carcinoma of the anal canal.
ACTH = adrenocorticotropic hormone.

sensitivity and specificity are about 94%. The test involves catheterization of a peripheral vein and also the petrosal sinuses draining the pituitary gland; simultaneous measurement of ACTH levels at each site before and 3, 5, and 10 minutes after administration of CRH; and calculation of the central-to-peripheral ACTH ratio at each time point. Ratios of more than 2 before CRH administration or more than 3 after CRH administration are consistent with Cushing disease.

Although it is accurate in experienced hands, inferior petrosal sinus sampling carries a small risk of stroke, is expensive, and is not widely available. Other tests, such as the CRH test and the 8-mg dexamethasone suppression test, may be useful if both responses indicate Cushing disease. In this setting, the likelihood of ectopic ACTH secretion is low. However, the diagnosis is not clear if both responses are negative or if they are mixed.

If endocrine tests suggest ectopic ACTH secretion, imaging is obtained to localize the tumor. Computed tomography and magnetic resonance imaging of the chest are the best initial screens because these tumors are most often in the thoracic cavity. Octreotide scintigraphy is a useful adjunctive test. Measurement of serum calcitonin and gastrin and measurement of plasma or urine catecholamines may identify medullary carcinoma of the thyroid, gastrinoma, and pheochromocytoma. The process can be repeated every 6 to 12 months; tumors that make ACTH ectopically have a spectrum of malignant potential, and annual screening should continue, regardless of treatment for hypercortisolism.

TREATMENT

Rx

Surgical Therapy

The optimal treatment of Cushing syndrome is surgical resection of the lesion that is producing excessive ACTH or cortisol. In ACTH-dependent Cushing syndrome, if this is unsuccessful or cannot be done, bilateral adrenalectomy is an option.

Transsphenoidal resection of a microadenoma is the optimal therapy for a patient with Cushing disease, with up to a 90% chance of cure in the hands of an experienced neurosurgeon. A successful outcome is less likely if the initial surgery is not curative, in cases of recurrence, and for macroadenomas. Controversy exists about the criteria for remission; although a low postoperative cortisol level is encouraging, it does not preclude later recurrence. If recurrence develops, additional resection or alternative therapy should be considered.

Patients with ectopic ACTH secretion can be cured if the tumor can be removed and is not metastatic. Otherwise, adrenalectomy or medical therapy is chosen (see later). Adrenalectomy is appropriate when the patient cannot tolerate the medical toxicity, cost, or adverse psychological effects of long-term medical therapy and monitoring; when rapid correction of hypercortisolism is needed; or if maximal daily doses of ketoconazole (1600 mg) and metyrapone (2 g) given in combination do not render the patient eucortisolemic.

Nonmalignant primary adrenal causes of Cushing syndrome are cured by resection of the abnormal tissue. Laparoscopy is the preferred approach. Surgery is the mainstay in the treatment of adrenal cancer; multiple operations may be needed to resect primary lesions, local recurrences, and hepatic, thoracic, and intracranial metastases. Adjuvant adrenolytic therapy with mitotane may provide a chemotherapeutic benefit.

Radiation Therapy

Radiation therapy to the pituitary gland, with adjunctive therapy with steroidogenesis inhibitors to normalize cortisol levels, is a good option for patients with Cushing disease who cannot undergo surgery, for those in whom the risk of Nelson syndrome (Chapter 224) is deemed great, and for those with recurrent disease. This is usually delivered in 200-rad daily increments to a total dose of 4500 cGy. The disadvantage of radiation therapy is the length of time needed for a full response—up to 10 years—and the possibility of hypopituitarism. There is less experience with high-energy radiosurgery, such as the gamma knife, which has the advantage of requiring only one or two treatments. Adrenalectomy is preferable if rapid normalization of hypercortisolism is needed, and this option may be chosen by patients who have concerns about radiation-induced hypopituitarism and loss of reproductive function.

Medical Therapy

Medical therapy can also be used for patients with occult ectopic ACTH-secreting tumors or in combination with pituitary irradiation to treat Cushing disease.

Medical therapy with steroidogenesis inhibitors alone is rarely appropriate for Cushing disease because it requires close monitoring and adjustment of dose. Cabergoline or pasireotide may normalize UFC in 40% and 20% of patients, respectively.[8] There are limited data on the long-term efficacy of any medical therapy in Cushing disease.

For advanced adrenocortical carcinoma, rates of response and progression-free survival but not overall survival are significantly better with first-line therapy using a combination of etoposide (100 mg/m^2 on days 2 to 4), doxorubicin (40 mg/m^2 on day 1), and cisplatin (40 mg/m^2 on days 3 and 4) plus oral mitotane (to achieve a blood level of 14 to 20 mg/L) than with streptozocin plus mitotane as first-line therapy, with similar rates of toxic events.[8]

Mineralocorticoid Excess

DIAGNOSIS

Patients with mineralocorticoid excess often have few clinical symptoms apart from fatigue and muscle weakness or cramps related to hypokalemia. Most often the condition is suspected because of hypertension, especially if it occurs at an early age in association with spontaneous hypokalemia or is difficult to control.[9] Mineralocorticoid excess can result from primary adrenal disease, in which aldosterone (or another mineralocorticoid) is produced autonomously (and renin levels are low), or it may be due to nonadrenal causes as a result of elevated renin values, which stimulate aldosterone secretion. The latter situations include states of contracted arterial intravascular volume, such as congestive heart failure or cirrhosis with ascites, decreased renal arterial blood flow, and tumor production of renin (Table 227-4).

RENIN-INDEPENDENT MINERALOCORTICOID EXCESS

DIAGNOSIS

Although most of these conditions result from excessive aldosterone production by one or both adrenal glands, excessive production of other mineralocorticoids or constitutive activation of the renal sodium channel must be excluded. In these latter conditions, both aldosterone and renin values are low, resulting in the so-called syndrome of apparent mineralocorticoid excess. In this setting, diagnostic information is obtained by history (licorice ingestion) or measurement of other mineralocorticoids (see Table 227-4).

Primary hyperaldosteronism is diagnosed when there is an increased ratio (>20) of morning aldosterone to plasma renin activity (Fig. 227-5). One of four tests (usually salt loading) is used to confirm primary hyperaldosteronism by demonstrating a lack of aldosterone suppression.[10]

Differential Diagnosis

Having made the diagnosis of aldosterone-dependent mineralocorticoid excess, one must differentiate between the two most common adrenal causes—hyperplasia and adenoma—after excluding potential rare causes of hyperaldosteronism. Two rare autosomal dominant forms of familial hyperaldosteronism are type 1, a glucocorticoid-suppressible hyperaldosteronism, and type 2. Familial hyperaldosteronism type 1 is caused by a genetic swap of the promoter for *CYP11B1* (11β-hydroxylase) with that of *CYP11B2* (aldosterone synthase), forming a chimeric gene in which ACTH stimulates aldosterone synthase. It should be suspected in the setting of familial disease, particularly if there is a history of early-onset cardiovascular events, and is confirmed by gene testing (see http://www.brighamandwomens.org/Departments_and_Services/medicine/services/endocrine/Services/gra/default.aspx). The genetic abnormality in familial hyperaldosteronism

TABLE 227-4 CAUSES OF MINERALOCORTICOID EXCESS

PRIMARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, LOW RENIN
Aldosterone-producing adenomas (30-50%)
Bilateral zona glomerulosa hyperplasia
Familial hyperaldosteronism
Type 1: glucocorticoid-remediable hyperaldosteronism—this results from formation of a chimeric gene containing the regulator portion of 11β-hydroxylase (normally regulated by ACTH) and the synthetic region of aldosterone synthase; as a result, ACTH stimulates aldosterone synthase and hence aldosterone production
Type 2: adrenal adenomas or hyperplasia expressed in a familial pattern
Type 3: caused by mutant KCNJ5, often younger and more severe than Type 2
Aldosterone-producing adrenal carcinoma
Ectopic aldosterone secretion (rare): kidney, ovary
SECONDARY HYPERALDOSTERONISM: HIGH ALDOSTERONE, HIGH RENIN
Renovascular hypertension and aortic stenosis
Diuretic use
Renin-secreting tumors
Severe cardiac failure
APPARENT MINERALOCORTICOID EXCESS: LOW ALDOSTERONE, LOW RENIN
Licorice ingestion: licorice (candy or flavored tobacco) containing glycyrrhetinic acid (or similar compounds such as carbenoxolone) inhibits renal 11β-hydroxysteroid dehydrogenase type 2, reducing cortisol conversion to cortisone and enabling cortisol to act as an endogenous mineralocorticoid
Severe hypercortisolism: similar in mechanism to licorice ingestion; very high cortisol levels are thought to overwhelm the ability of 11β-hydroxysteroid dehydrogenase type 2 to convert cortisol to cortisone in the kidney; cortisol itself then acts as a potent mineralocorticoid
Liddle's syndrome: mutation of the β or γ subunit of the collecting tubule sodium channel leads to a constitutive increase in sodium reabsorption and potassium excretion
11β-Hydroxylase deficiency form of congenital adrenal hyperplasia: 11-deoxycortisol accumulates because of an inability to convert it to cortisol
17-Hydroxylase deficiency form of congenital adrenal hyperplasia: deoxycorticosterone and corticosterone are increased

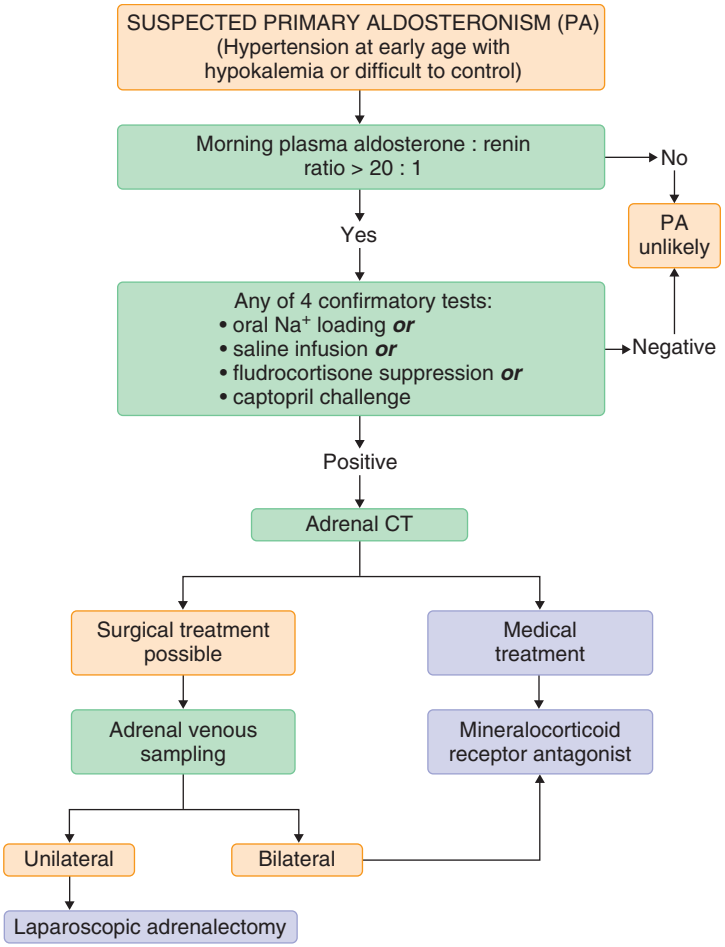

FIGURE 227-5. Algorithm for the detection, confirmation, subtype testing, and treatment of primary aldosteronism (PA). We recommend the case detection of PA in patient groups with relatively high prevalence of PA. These include patients with moderate, severe, or resistant hypertension; spontaneous or diuretic-induced hypokalemia; hypertension with adrenal incidentaloma; or a family history of early-onset hypertension or cerebrovascular accident at a young age (<40 years). We recommend use of the plasma aldosterone-to-renin ratio (ARR) to detect cases of PA in these patient groups. We recommend that patients with a positive ARR undergo testing, using any of four confirmatory tests, to definitively confirm or exclude the diagnosis. We recommend that all patients with PA undergo an adrenal computed tomography (CT) scan as the initial study in subtype testing and to exclude adrenocortical carcinoma. When surgical treatment is practicable and desired by the patient, the distinction between unilateral and bilateral adrenal disease should be made by adrenal venous sampling (AVS). We recommend that treatment by unilateral laparoscopic adrenalectomy be offered to patients with AVS-documented unilateral aldosterone-producing adenoma. If a patient is unable or unwilling to undergo surgery, we recommend medical treatment with a mineralocorticoid receptor (MR) antagonist. In patients with PA due to bilateral adrenal disease, we recommend medical treatment with an MR antagonist. *In patients with confirmed PA who have a family history of PA or of strokes at young age (<40 years), or with onset of hypertension earlier than at 20 years of age, we suggest genetic testing for glucocorticoid-remediable aldosteronism. In patients with glucocorticoid-remediable aldosteronism, we recommend the use of the lowest dose of glucocorticoid receptor agonist that can normalize blood pressure and serum potassium levels. (Reprinted, with slight modification of text, from Funder JW, Carey RM, Fardella C, et al. Case detection, diagnosis, and treatment of patients with primary aldosteronism: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2008;93:3266-3281.)

type 2 is not known; its clinical presentation is similar to sporadic hyperaldosteronism. Recent studies demonstrate rare germline mutations of a potassium channel in familial hyperalsosteronism, and somatic adrenal mutations in about 40% of patients.

For the more common conditions, adrenal computed tomography scans may show nonfunctioning nodules and falsely suggest an adenoma.[11] The responses to physiologic maneuvers, such as upright posture, and salt loading with oral or intravenous sodium tend to be preserved in patients with hyperplasia, but there is significant overlap among groups of patients. The best diagnostic test involves the measurement of cortisol and aldosterone in bilateral adrenal venous effluent and a peripheral vein before and during an ACTH infusion. Cortisol is used to evaluate catheter placement in the adrenal veins, as levels from the two sides should be similar. When an adenoma is present, the aldosterone-to-cortisol ratio on one side is usually at least five-fold greater than the other, which may be similar to the periphery, indicating suppression. Bilateral hyperplasia tends to produce similar values on each side.

TREATMENT

Rx

Treatment of primary hyperaldosteronism includes laparoscopic resection for adenomas.[12] Afterward, hypokalemia generally resolves, but hypertension persists in up to 65% of patients. A mineralocorticoid antagonist, spironolactone or eplerenone, is used to treat patients unable to undergo surgery or those with hyperplasia. Eplerenone is a more selective mineralocorticoid antagonist (with fewer side effects of sexual dysfunction and gynecomastia compared with spironolactone). A sodium channel blocker (e.g., amiloride) may be helpful, and antihypertensive agents are continued as needed.

Androgen Excess

DEFINITION

Women with excess circulating androgens or increased sensitivity to androgens present with complaints of hirsutism, acne, and anovulation or infertility. When testosterone is secreted in great excess, women may virilize and exhibit a deepened voice, clitorimegaly, masculinized body habitus, and alopecia.

DIAGNOSIS

The adrenal causes of hyperandrogenism—congenital adrenal hyperplasia, Cushing disease, adrenal cancer, and androgen-producing adrenal adenoma—are uncommon. Most women have no clear-cut cause (idiopathic hirsutism) or polycystic ovary syndrome. Rarely, androgen-secreting ovarian tumors, hyperprolactinemia, glucocorticoid resistance, or exogenous drugs cause hyperandrogenism. Patients with an adrenal source of hyperandrogenism usually have increased serum levels of DHEA, DHEA-S, or androstenedione, in contrast to the testosterone excess that is more typical of an ovarian source. DHEA and DHEA-S are weak androgens that can be converted locally to

testosterone in the hair follicles. Because DHEA and DHEA-S levels decline throughout adult life, these values must be interpreted within age-specific normal ranges. Although a tumor is more likely if DHEA-S is greater than 500 μg/dL or testosterone is greater than 200 ng/mL, it is not excluded at lower levels.

Imaging identifies nearly all adrenal tumors but may miss a small intraovarian one. UFC may be elevated in patients with virilizing adrenal carcinoma or Cushing disease (see earlier) and in those with glucocorticoid resistance. By contrast, androgen-secreting adrenal adenomas do not have glucocorticoid excess. In women suspected of having nonclassic forms of congenital adrenal hyperplasia, precursor and product hormones should be measured before and after ACTH to confirm the diagnosis.

TREATMENT Rx

Treatment of adrenal causes of hyperandrogenism varies according to the disorder. Classic congenital adrenal hyperplasia is treated by glucocorticoids to normalize ACTH and hence androgen levels (typically, dexamethasone 0.125 to 0.375 mg at bedtime). The nonclassic forms respond well to oral contraceptive or antiandrogen treatment, with dexamethasone reserved for ovulation induction. Surgery with adjunctive medical treatment may be used in adrenal carcinoma (see earlier).

Mixed Mineralocorticoid and Glucocorticoid Deficiency: Adrenal Insufficiency

PATHOBIOLOGY

Primary Adrenal Insufficiency

Autoimmune Destruction

Autoimmune destruction is the most common cause of primary adrenal insufficiency in industrialized countries and may occur alone or, rarely, in association with autoimmune polyglandular syndromes. These syndromes tend to be manifested either in childhood (type 1), in association with hypoparathyroidism and mucocutaneous candidiasis, or in adulthood (type 2), in association with insulin-dependent diabetes mellitus, autoimmune thyroid disease, alopecia areata, or vitiligo. The glands are small on imaging.

Adrenoleukodystrophy

Adrenoleukodystrophy, a rare (1 in 25,000) X-linked condition, is characterized by a deficiency of peroxisomal membrane adrenoleukodystrophy protein, which transports activated acyl-coenzyme A derivates into the peroxisomes, where they are shortened by β-oxidation. This deficiency results in the accumulation of very long chain fatty acids in the central nervous system and other tissues and increased plasma $C_{26:0}$ fatty acids. Incomplete penetrance of the genetic defect and variable accumulation of very long chain fatty acids in the adrenal gland, brain, testis, and liver account for the clinical phenotypes, which differ by age and presentation.[13]

Replacement of Adrenal Tissue

Infections cause about 15% of primary adrenal insufficiency. Typical infections include tuberculosis and systemic fungal diseases (histoplasmosis, coccidioidomycosis, blastomycosis), in which the adrenal tissue is replaced by caseating granulomas. End-stage AIDS-associated opportunistic infections, such as cytomegalovirus or *Mycobacterium avium-intracellulare*, may reduce adrenal function. Adrenal tissue may be replaced by bilateral metastases (most commonly primary carcinoma of the lung, breast, kidney, or gut) or primary lymphoma, although adrenal insufficiency is uncommon. Intraadrenal hemorrhage may also lead to insufficient steroidogenesis. Hemorrhage typically occurs in a stressed, hospitalized patient receiving long-term prophylactic anticoagulation and is often accompanied by back pain. The adrenal glands tend to be large on imaging.

Congenital Adrenal Hyperplasias

The congenital adrenal hyperplasias[14] are a disparate group of diseases caused by a genetic deficiency of one of the enzymes needed for adrenal steroidogenesis. Patients with nearly complete deficiency of an enzyme required for cortisol synthesis present in infancy with adrenal insufficiency and salt-wasting crisis. This is most problematic in patients with mutation of the 21-hydroxylase (*CYP21A2*) or 11β-hydroxylase (*CYP11B1*) gene. The increase in ACTH levels caused by cortisol deficiency drives the intact steroidogenic pathways so that there is excessive production of the steroids just proximal to the enzymatic block—17-hydroxyprogesterone and 11-deoxycortisol, respectively, in 21-hydroxylase and 11β-hydroxylase deficiency. The increased levels of precursor steroids enable increased adrenal androgen synthesis, so that severely affected girls may be virilized in utero. Girls and women with nonclassic congenital adrenal hyperplasia present later. They have greater enzyme activity, so that cortisol production is adequate, but increased ACTH levels cause hyperandrogenism.

Rare Causes

Other rare causes of primary adrenal insufficiency include ACTH resistance, congenital adrenal hypoplasia, Smith-Lemli-Opitz syndrome, and amyloidosis. Patients with primary adrenal insufficiency should undergo further evaluation to determine its cause (Table 227-5). Detection of antibodies to 21-hydroxylase identifies nearly all patients with idiopathic disease. In a male with negative results, measurement of plasma $C_{26:0}$ fatty acids will detect adrenoleukodystrophy. Taken together, this strategy identifies the cause in

TABLE 227-5 CAUSES OF ADRENAL INSUFFICIENCY AND ANCILLARY TESTS

SPECIFIC CAUSES	SUGGESTIVE CLINICAL FEATURES	USEFUL ANCILLARY TESTS
Primary adrenal insufficiency	Hyperpigmentation, orthostatic hypotension	Hyperkalemia, elevated ACTH
Idiopathic autoimmune destruction	Most common cause (80%) in developed countries; with or without other endocrinopathies, as below	Antibodies to 21-hydroxylase are present; on imaging, adrenal glands are small
Polyglandular failure type 1	Hypoparathyroidism, mucocutaneous candidiasis, vitiligo; age <20 years	
Polyglandular failure type 2	Insulin-dependent diabetes, autoimmune thyroid disease, alopecia areata, vitiligo; age >40 years	On imaging, adrenal glands are small
Infections: tuberculosis, systemic fungal diseases, AIDS-associated opportunistic infections (e.g., cytomegalovirus)	15% of patients in U.S. series	Adrenal glands tend to be large on CT and may be calcified
Space-occupying adrenal lesions	Metastases from carcinoma of lung, breast, kidney, gut; lymphoma or hemorrhage (heparin use)	Abnormal shape of adrenal glands on CT; evidence of hemorrhage
Bilateral adrenalectomy or treatment with steroidogenesis inhibitors		Ketoconazole, mitotane, aminoglutethimide, trilostane, and metyrapone reduce cortisol levels
Adrenoleukodystrophy	X-linked—screen males; in childhood, cognitive and gait disturbances; in adults, spastic paraparesis	Deficiency of peroxisomal very long chain acyl-coenzyme A synthetase leads to elevated plasma $C_{26:0}$ fatty acid levels
Secondary adrenal insufficiency		
Suppression of the adrenal axis by exogenous or endogenous glucocorticoids	Medication history; history of Cushing syndrome	Adrenal glands are small on imaging
Structural lesions of the hypothalamus or pituitary gland (tumors, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis)	Other pituitary deficiencies	Adrenal glands are normal or small on imaging; MRI or CT may show pituitary or hypothalamic lesion
Isolated ACTH deficiency		
Head trauma		

ACTH = adrenocorticotropic hormone; AIDS = acquired immunodeficiency syndrome; CT = computed tomography; MRI = magnetic resonance imaging.

nearly all adult patients with idiopathic adrenal insufficiency. Patients with autoimmune disease should be tested for other endocrine deficiencies, and those with adrenoleukodystrophy require neurologic evaluation.

Secondary Adrenal Insufficiency

Suppression of the Pituitary Axis

Suppression of the hypothalamic-pituitary-adrenal axis by exogenous or endogenous glucocorticoids is the most common cause of secondary adrenal insufficiency. This phenomenon depends on the dose, duration, and schedule of glucocorticoid administration. Thus, adrenal suppression is unusual with "replacement" doses of glucocorticoid that are roughly equivalent to daily production (e.g., total daily doses of 20 mg hydrocortisone, 5 mg prednisone, or 0.3 to 0.5 mg dexamethasone). At higher doses, adrenal suppression is usually not seen until after 3 weeks of administration, and a single morning administration is less suppressive than are divided doses given during the day. When potentially suppressive doses of glucocorticoids are stopped, symptoms of adrenal insufficiency may occur within 48 hours, and the entire axis may not recover for up to 18 months. During this time, the patient should receive replacement glucocorticoid treatment or supplemental steroids at times of physiologic stress, depending on the degree of impairment (see later).

Lesions of the Hypothalamus or Pituitary

Secondary adrenal insufficiency also may result from structural lesions of the hypothalamus or pituitary gland that interfere with CRH production or transport or with corticotrope function. These causes include tumors, trauma, destruction by infiltrating disorders, x-irradiation, and lymphocytic hypophysitis. In general, these are not reversible conditions. Patients with secondary adrenal insufficiency not ascribed to glucocorticoid use should undergo imaging of the pituitary and hypothalamus to exclude a structural or infiltrating lesion as well as tests of other pituitary function to exclude additional deficiencies.

CLINICAL MANIFESTATIONS

The clinical presentation of adrenal insufficiency reflects the cause and duration of this uncommon condition. Primary adrenal insufficiency eventually destroys the entire adrenal cortex, with loss of both glucocorticoid and mineralocorticoid activity. By contrast, secondary adrenal insufficiency reflects an inability of the hypothalamic-pituitary unit to deliver CRH or ACTH, thus reducing trophic support to otherwise normal glands. As a result, only cortisol production decreases because mineralocorticoid production is not very ACTH dependent (Fig. 227-6).

The characteristic clinical presentation of acute primary adrenal insufficiency includes orthostatic hypotension, agitation, confusion, circulatory collapse, abdominal pain, and fever.[15] These features are most likely to be caused by hemorrhage, metastasis, or acute infection and can lead to death if not treated. In contrast, the typical history and clinical findings of chronic primary adrenal insufficiency include a longer history of malaise, fatigue, anorexia, weight loss, joint and back pain, and darkening of the skin (especially in the creases of the hands, extensor surfaces, recent scars, buccal and vaginal mucosa, and nipples). Patients may crave salt and may develop unusual food preferences, such as drinking the brine from pickles. Associated biochemical features for both acute and chronic presentations include hyponatremia, hypoglycemia, hyperkalemia, unexplained eosinophilia, and mild prerenal azotemia.

Chronic secondary adrenal insufficiency is manifested in a similar way, but without hyperpigmentation or mineralocorticoid abnormalities.

DIAGNOSIS

Biochemical testing confirms the diagnosis of adrenal insufficiency. A morning serum cortisol measurement is an inexpensive but relatively insensitive screening test for adrenal insufficiency in patients who are not acutely ill. The diagnosis is virtually excluded by values greater than 19 μg/dL (524 nmol/L) and is likely if the value is less than 3 μg/dL (83 nmol/L). However, both healthy individuals and patients with adrenal insufficiency may have indeterminate results (3 to 19 μg/dL) that require additional evaluation.

Patients with acute adrenal insufficiency should be evaluated for sepsis, adrenal metastases, and hemorrhage. Imaging of the glands and other testing may reveal an infectious cause. In acute adrenal insufficiency, a serum cortisol value is generally inappropriately normal or subnormal in the setting of hypotension, in which cortisol values are usually well above 18 μg/dL.

There is controversy about the best test to diagnose chronic adrenal insufficiency. Many use the cortisol response to exogenous ACTH as a gold standard test of adrenal steroidogenic ability. In the classic test, 250 μg of ACTH (1-24, cosyntropin) is given intravenously at any time of day. This dose of ACTH is a maximal stimulus to the adrenal gland, so that the serum cortisol level measured 30 to 60 minutes later is greater than 18 μg/dL. Lower values indicate adrenal insufficiency. Insulin-induced hypoglycemia, metyrapone stimulation, and lower doses of ACTH stimulation have been proposed as better tests for patients with mild or recent secondary adrenal insufficiency, who may respond to pharmacologic doses of ACTH. None of these is ideal. Also, because there is no commercial formulation of ACTH for lower-dose tests, the product must be diluted on site, leading to concerns about the accuracy of the administered dose and the validity of results. Metyrapone has limited availability in the United States.

Cerebral adrenoleukodystrophy, presenting in childhood, is characterized by cognitive and gait disturbances; the adult form, adrenomyeloneuropathy, is characterized by spinal cord and peripheral nerve demyelination. In both forms, the accumulation of very long chain fatty acids in the adrenal cortex alters membrane function and inhibits signal transduction by ACTH. Because a substantial minority of patients in both groups present first with adrenal insufficiency, boys and young men with adrenal insufficiency should be screened for adrenoleukodystrophy.

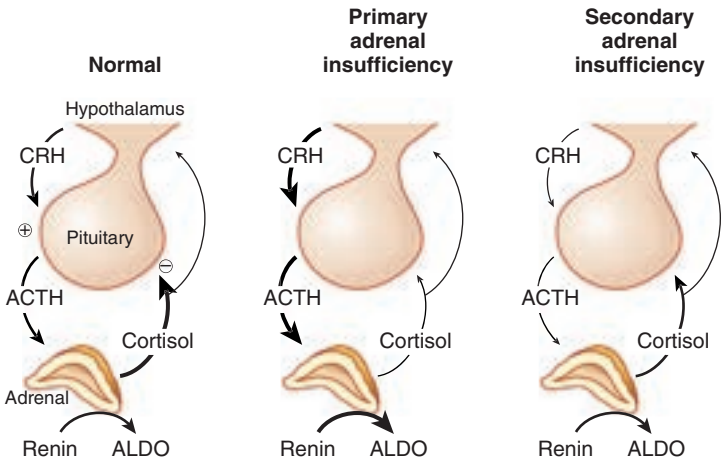

FIGURE 227-6. Physiology of the adrenal axis in health, primary adrenal insufficiency, and secondary adrenal insufficiency. ***In healthy individuals*** **(Normal), cortisol production is stimulated by the increased hypothalamic release of corticotropin-releasing hormone (CRH), which then travels down the pituitary stalk to stimulate adrenocorticotropic hormone (ACTH) secretion and release by corticotropes. Circulating ACTH stimulates adrenal gland production and secretion of cortisol. Cortisol then functions in a negative feedback mechanism to inhibit both CRH and ACTH.** ***In patients with primary adrenal insufficiency,*** **destruction or replacement of the entire adrenal cortex results in decreased cortisol, aldosterone, and dehydroepiandrosterone (DHEA, not shown) secretion by the adrenal glands. As a result of decreased cortisol negative feedback, the normal hypothalamus and pituitary gland increase CRH and ACTH secretion. The decreased aldosterone levels lead to an increase in renin levels.** ***In patients with secondary adrenal insufficiency,*** **ACTH or CRH secretion is reduced because of destruction or replacement of the hypothalamus or pituitary gland or because of disruption of the pituitary stalk. The decreased ACTH stimulation results in decreased cortisol (and, not shown, DHEA) secretion by the adrenal glands. Aldosterone production is only slightly affected by ACTH stimulation, and levels remain normal. The abnormal hypothalamus and pituitary gland do not increase CRH and ACTH secretion in response to the decreased cortisol negative feedback.**

Differential Diagnosis

Primary and secondary adrenal insufficiency can be distinguished by measurement of plasma ACTH. In primary adrenal insufficiency, ACTH levels are generally above the normal range and may exceed the normal range before the cortisol response to exogenous ACTH stimulation is subnormal. In addition, hyperkalemia and elevated renin values are characteristic of primary but not of secondary adrenal insufficiency, which is identified by a suppressed or inappropriately normal ACTH level.

TREATMENT Rx

Acute Adrenal Insufficiency

In suspected acute adrenal insufficiency, hydrocortisone is the treatment of choice because it has both glucocorticoid and mineralocorticoid activity.

Treatment with intravenous saline for volume expansion, glucose for hypoglycemia, and intravenous hydrocortisone (100 mg) is started immediately after placement of an intravenous line and withdrawal of blood for documentation of the cortisol value.

Chronic Adrenal Insufficiency

Therapy for chronic adrenal insufficiency[16] aims to provide the physiologic replacement of steroids. Glucocorticoid replacement is achieved by administration of 10 to 12 mg/m^2 of hydrocortisone daily in one to three oral doses, attempting to mimic the physiologic diurnal variation of cortisol concentrations. Hydrocortisone offers the advantage of multiple-dose tablets, which allows fine adjustment and splitting of the daily dose. Ideally, the morning dose is given as soon after waking as possible; for individuals who feel extremely fatigued in the morning before the agent is absorbed, a strategy of taking the medication 30 minutes before arising may be helpful. Although many patients do well with a single dose, others complain of pronounced fatigue in the afternoon and evening. For them, a split-dose regimen, in which about one third of the daily dose is given around 4:00 PM or two afternoon doses are given, may be useful.

Other glucocorticoids may be used for daily replacement therapy. Prednisone, 5 to 7.5 mg daily, has the advantage of a long half-life and may be particularly helpful in patients with afternoon or evening fatigue. Dexamethasone may be used, but because of variable interindividual metabolism, it is difficult to recommend a specific replacement dose; in addition, few options for fixed doses are available, so it is difficult to adjust the dose.

Patients with primary adrenal insufficiency should be encouraged to salt their food and not to limit salt intake. Nearly all patients also require a mineralocorticoid, such as fludrocortisone 50 to 300 µg/day. The dose is adjusted until plasma renin activity is normal. If a mineralocorticoid is not given, the dose of hydrocortisone or other steroid with mineralocorticoid activity is often mistakenly increased to reduce an "unwell" feeling or hyperkalemia or salt craving. However, if a supraphysiologic dose is given, the patient becomes cushingoid.

Patients with primary adrenal insufficiency also have decreased serum DHEA levels. Controversy exists about its replacement. A meta-analysis concluded that there is insufficient evidence to support its routine use in these patients.

Ensuring Proper Dosing

Education of the Patient

All patients receiving chronic glucocorticoid replacement therapy should be instructed that they must take the glucocorticoids as prescribed and that failure to take or to absorb the medication will lead to adrenal crisis and possibly death. They should wear medical information bracelets or necklaces that identify this requirement. It is important to educate patients and their families about glucocorticoid adjustment during physiologic stress conditions, including the emergency administration of intramuscular glucocorticoid by means of a kit containing prefilled syringes with injectable steroid.

Dosing for Stress

The daily oral glucocorticoid dose is usually doubled for "stressful" physiologic conditions, such as fever, nausea, and diarrhea, although there are few data to support this strategy. In addition, this practice may lead to chronic overmedication by the patient because of a liberal interpretation of what constitutes physical stress. Thus, education about when and how to change the dose of steroid should be reinforced periodically, preferably with written material, and the dangers of excessive steroid use should be emphasized. If the patient is vomiting, has severe diarrhea, or has collapsed, intramuscular glucocorticoids should be given before transport to a medical facility.

The glucocorticoid dose is increased in proportion to the amount of stress. Thus, during maximally stressful situations (e.g., adrenal crisis, major surgery, trauma, labor and delivery), the daily hydrocortisone dose is 100 to 300 mg. Few data support the need for this supraphysiologic dose, but the safety of not following this practice has not been established. The dose may be tapered by 50% per day if the patient is clinically stable. For more moderate stress, such as that of cholecystectomy, 75 to 100 mg of hydrocortisone is given on the day of surgery, and the dose is tapered more rapidly. Patients undergoing minimal stress, such as tooth extraction or short operative orthopedic procedures, may not require any additional supplementation.

Assessment to Ensure Proper Dosing

Clinical assessment is the best way to judge whether the glucocorticoid dose is correct. Symptoms of adrenal insufficiency improve with adequate therapy. The development of cushingoid features or osteopenia suggests frank or subtle overreplacement, respectively, and the presence of adrenal insufficiency symptoms (fatigue, anorexia, weight loss) suggests underreplacement. In women, DHEA replacement increases testosterone levels, so that hirsutism, acne, or other signs of androgen excess may suggest overreplacement. In primary adrenal insufficiency, adequate hormone replacement results in plasma ACTH levels that decrease but remain elevated, in the range of 100 to 200 pg/mL. Renin values, however, normalize completely and may be used to judge the adequacy of mineralocorticoid replacement. Although hydrocortisone is metabolized to cortisol, plasma cortisol values should not be used to monitor therapy because clearance from the blood stream is rapid, and circulating values are low for most of the day. UFC does not reflect adequate replacement; the increase in plasma cortisol levels after a single daily dose may exceed corticosteroid-binding globulin capacity, resulting in excessive urine levels and overestimation of integrated cortisol levels.

Mineralocorticoid Deficiency

Hypoaldosteronism may be classified as a low-normal or a high renin state on the basis of plasma renin activity after 4 hours of upright posture. Renin deficiency is the most common cause of hypoaldosteronism, occurring most often in older patients with mild, nonoliguric renal disease who often have insulin-dependent diabetes and potentially diabetic nephropathy. Indomethacin and other prostaglandin synthesis inhibitors as well as autonomic dysfunction associated with prolonged bedrest can also result in hyporeninemic hypoaldosteronism.

CLINICAL MANIFESTATIONS

There are few clinical features associated with mineralocorticoid deficiency; as a result, it is usually suspected when laboratory results reveal hyperkalemia, hyponatremia, and a mild metabolic alkalosis. If glucocorticoid deficiency is excluded, isolated hypoaldosteronism is established if the circulating level of aldosterone is inappropriately low.

High renin states of hypoaldosteronism include congenital adrenal hyperplasias with mineralocorticoid deficiency and primary adrenal insufficiency when it is treated with pure glucocorticoid replacement.

Treatment of these conditions involves sodium replacement with at least 10 mEq/kg/day, roughly equivalent to the 4 g of sodium chloride found in a typical diet in the United States. For individuals who do not maintain such a diet (often the elderly or the young), fludrocortisone can be given at the same doses used in primary adrenal insufficiency.

REVIEW QUESTIONS

1. A 35-year-old woman has had weight gain, insomnia, decreased short-term memory, and depression for the last year. She states that her symptoms are worsening. Two recent urine free cortisol (UFC) test results are three-fold increased. She takes lisinopril for recent-onset hypertension. What is the next best diagnostic test?

A. A 1-mg dexamethasone suppression test
B. A pituitary magnetic resonance imaging study
C. An adrenocorticotropic hormone (ACTH) measurement
D. Another UFC determination
E. A dexamethasone–corticotropin-releasing hormone test

Answer: A Recent guidelines and expert opinion suggest that at least two different screening test results should be abnormal to confirm the clinical suspicion of Cushing syndrome (see Fig. 227-4). This patient has had two abnormal UFC results and should undergo another screening test, either measurement of late-night salivary cortisol or a 1-mg or 2-day 2-mg dexamethasone suppression test. Another UFC determination will not obviate the need for a different screening test. The dexamethasone–corticotropin-releasing hormone stimulation test is more cumbersome and expensive than the dexamethasone suppression test and would not be a better choice. Tests that are used for the differential diagnosis, such as ACTH level or magnetic resonance imaging, should not be used to establish the diagnosis of Cushing syndrome.

2. A 32-year-old white woman with known idiopathic primary adrenal insufficiency complains of recent fatigue and a feeling of being unwell. This has been worse lately when she has been more active with gardening and is worse in the afternoon and evening. She denies dizziness, anorexia, increase in pigmentation, or change in weight. On physical examination, she weighs 125 pounds, with a height of 63 inches. Blood pressure is 110/75, and pulse is 86 without orthostasis. She has pigmented palmar creases and some buccal pigmentation, unchanged from the last visit. There are no other skin lesions. She does not appear cushingoid, there is no abdominal tenderness, and the joint examination findings are normal. Her only medications are hydrocortisone, 15 mg in the morning and 5 mg in the afternoon, and fludrocortisone, 50 mg every other day. What is the next best step?

A. Measure a plasma renin level
B. Increase the afternoon hydrocortisone dose to 10 mg
C. Measure the urine free cortisol excretion
D. Add a late afternoon hydrocortisone dose of 5 mg
E. Measure plasma ACTH before the morning hydrocortisone dose

Answer: A This woman has somewhat nonspecific symptoms that are exacerbated by gardening (perhaps by heat). She is receiving adequate hydrocortisone replacement but taking a low fludrocortisone dose. Such nonspecific symptoms may occur in the setting of relative mineralocorticoid deficiency, which can be evaluated through renin measurement. If the renin were elevated, an increased fludrocortisone dose might eliminate her vague symptoms of being unwell. The history and the amount of prescribed hydrocortisone do not suggest that she needs additional glucocorticoid. If she is mineralocorticoid deficient, she might feel better with a higher hydrocortisone dose because of its mineralocorticoid activity; however, a slightly supraphysiologic dose would put her at risk for osteopenia and other features of glucocorticoid excess. (See the section on adrenal insufficiency, assessment to ensure proper dosing.) Measurement of ACTH and urine free cortisol usually is not helpful in assessing adequacy of dosage.

3. A 30-year-old woman presents to the emergency department with the acute onset of nausea, vomiting, diarrhea, and dizziness. Her only medication is levothyroxine, 88 mcg daily. On examination, she is hypotensive, tachycardic, and orthostatic. She has dark skin, and no hyperpigmentation is seen on cursory examination. She has abdominal pain and increased bowel sounds. She is extremely weak but able to move all extremities and to respond to questions. The sodium concentration is 129 mEq/L, potassium concentration is 5.3 mEq/L, and blood urea nitrogen level is 40 mg/dL. Apart from initiating fluid resuscitation and evaluation for sepsis, what treatment and testing should be ordered immediately?

A. Draw blood for cortisol measurement before giving hydrocortisone 100 mg IV.
B. Give dexamethasone 8 mg and perform an ACTH stimulation test.
C. Measure an ACTH level and give hydrocortisone 100 mg IV.
D. Give dexamethasone 8 mg and defer further testing.
E. Give hydrocortisone 100 mg IV and obtain an adrenal computed tomography scan to evaluate for hemorrhage.

Answer: A This woman presents with the signs and symptoms of acute primary adrenal insufficiency. The knowledge that she takes thyroid hormone suggests polyglandular failure. However, it is possible that this constellation of features is caused by sepsis, renal failure, or hypothyroidism. Thus, it is prudent to measure cortisol in blood obtained during intravenous line insertion to confirm the diagnosis of adrenal insufficiency. Other biochemical and stimulation testing can be deferred. She has no apparent reason to have adrenal hemorrhage. Dexamethasone 8 mg is more than what is needed for treatment of adrenal insufficiency; hydrocortisone 100 mg is the recommended initial dose. (See the section on adrenal insufficiency, replacement of adrenal tissue, and treatment.)

4. A 50-year-old man is evaluated for hyperaldosteronism because of difficult-to-control hypertension. He is otherwise healthy. Evaluation was done during treatment with agents that do not affect aldosterone or renin levels and include an aldosterone-to-renin ratio of more than 40 and lack of aldosterone suppression to oral salt loading. A computed tomography (CT) scan of the adrenal glands shows a 1-cm mass on the right with a density of 10 HU. What is the next best step?

A. Adrenal venous sampling
B. Right laparoscopic adrenalectomy
C. Treatment with eplerenone
D. Review of CT scan to exclude hyperplasia of the left adrenal gland
E. Ultrasound ablation of the adrenal gland

Answer: A Adrenal venous sampling should be performed to identify the source of excess aldosterone. It is possible that the visualized mass is a nonfunctioning tumor. This man is a good surgical candidate, and laparoscopic adrenalectomy would be recommended if venous sampling is consistent with unilateral disease. The CT scan is not helpful in identifying bilateral disease. Treatment with eplerenone and ultrasound ablation would be possibilities if he were not a surgical candidate; eplerenone would be an appropriate treatment for bilateral disease. (See section on mineralocorticoid excess, diagnosis and treatment.)

5. A 35-year-old woman presents with a 6-month history of increasing body hair growth. Before that time, she states that she was mildly "hairy" but now needs to shave her face daily. (She has stopped shaving for 3 days so that her hair growth would be visible.) She has had only two episodes of vaginal spotting during this time. Her menses started at the age of 13 years and are usually irregular, occurring every 30 to 45 days. The extra hair growth started in her teens and until 6 months ago was similar to the hair pattern of her mother and sister. She admits to some recent irritability and perhaps has gained 5 pounds. She has always had a low voice and does not notice any recent change. She has a 3-year-old daughter. She has been able to continue her 35 minutes of daily cardiovascular exercise. On physical examination, body mass index is 30, blood pressure 125/85 mm Hg, pulse 82. The Ferriman-Galway score is 17. Fat distribution is normal with some increased abdominal fat, and she appears "well developed" but not especially muscular. There is no temporal hair recession, but her scalp hair appears thin. Acne is present on the chest and back. The clitoral index is 100 mm. Laboratory results include low luteinizing hormone and follicle-stimulating hormone, estradiol 50 pg/mL, dehydroepiandrosterone sulfate (DHEA-S) 653 ng/dL (reference range, 4 to 332), and testosterone 235 ng/dL. These abnormalities are confirmed on a second set of tests. What is the next best diagnostic step?

A. Obtain a CT scan of the adrenal glands
B. Obtain an ovarian ultrasound
C. Perform a 1-mg overnight dexamethasone suppression test
D. Measure a morning17-hydroxyprogesterone level
E. Measure an androstenedione level.

Answer: A This woman has recent-onset hirsutism and virilization. Whereas worsening polycystic ovary syndrome is a possibility, the degree of DHEA-S and testosterone elevation suggests the possibility of an adrenal tumor. The slight weight gain and irritability might also point to possible cortisol excess. Although androstenedione would confirm an adrenal source, it is unlikely to point to another cause, and so proceeding to adrenal CT scan is reasonable, particularly because adrenal cancer is part of this differential diagnosis. An ovarian ultrasound is less likely to be abnormal (i.e., an ovarian tumor is less likely). Congenital adrenal hyperplasia is consistent with these signs and symptoms but not with the time course of rapid worsening. Cushing syndrome is a possibility, but it is less likely to be Cushing disease with these levels of hormones; adrenal cancer is a possibility that would be identified by the CT scan, making a 1-mg dexamethasone suppression test less urgent. (See the section on androgen excess.)

ADRENAL MEDULLA, CATECHOLAMINES, AND PHEOCHROMOCYTOMA

WILLIAM F. YOUNG, JR.

ADRENAL MEDULLA AND CATECHOLAMINES

The adrenal medulla occupies the central portion of the adrenal gland. Adrenomedullary cells are called chromaffin cells (they stain brown with chromium salts). Chromaffin cells differentiate in the center of the adrenal gland in response to cortisol; some chromaffin cells also migrate to form paraganglia. The largest cluster of chromaffin cells outside the adrenal medulla is near the level of the inferior mesenteric artery and is referred to as the organ of Zuckerkandl.

The term *catecholamine* refers to substances that contain catechol (*o*-dihydroxybenzene) and a side chain with an amino group—the catechol

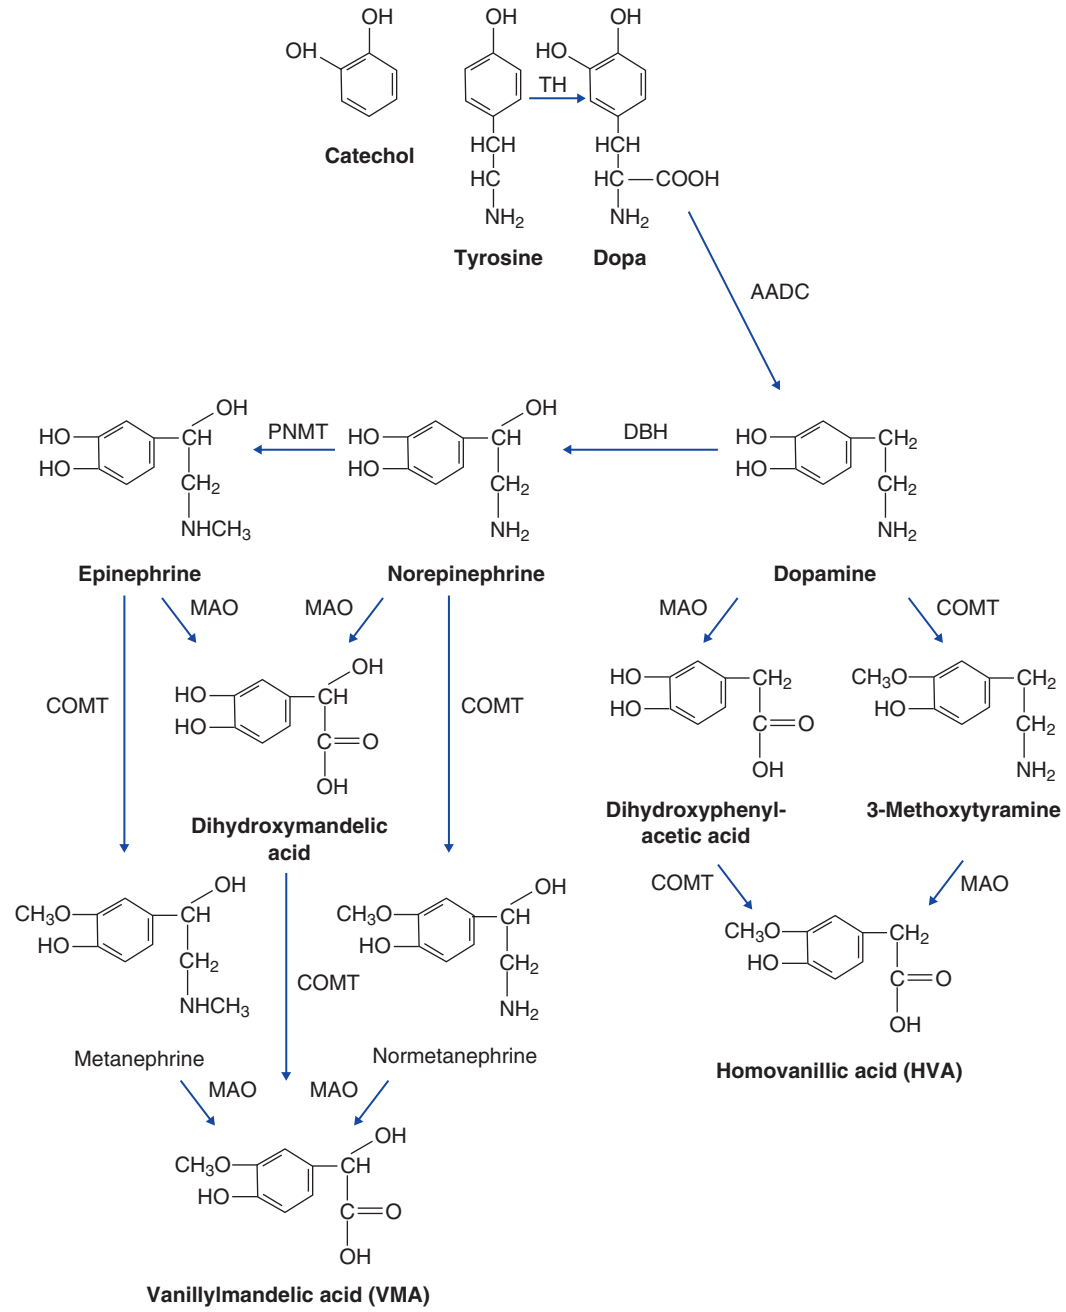

FIGURE 228-1. Biosynthetic and metabolic pathways for catecholamines. The term *catecholamine* comes from the catechol (*o*-dihydroxybenzene) structure and a side chain with an amino group—the catechol nucleus (*top left*). Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) in the rate-limiting step by tyrosine hydroxylase (TH). Aromatic L-amino acid decarboxylase (AADC) converts dopa to dopamine. Dopamine is hydroxylated to norepinephrine by dopamine β-hydroxylase (DBH). Norepinephrine is converted to epinephrine by phenylethanolamine *N*-methyltransferase (PNMT); cortisol serves as a cofactor for PNMT, and this is why epinephrine-secreting pheochromocytomas are almost exclusively localized to the adrenal medulla. Metabolism of catecholamines occurs through two enzymatic pathways. Catechol-*O*-methyltransferase (COMT) converts epinephrine to metanephrine and norepinephrine to normetanephrine by meta-*O*-methylation. Metanephrine and normetanephrine are oxidized by monoamine oxidase (MAO) to vanillylmandelic acid by oxidative deamination. Monoamine oxidase also may oxidize epinephrine and norepinephrine to dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. Dopamine is also metabolized by monoamine oxidase and catechol-*O*-methyltransferase, with the final metabolite homovanillic acid.

nucleus (Fig. 228-1). Epinephrine is synthesized and stored in the adrenal medulla and released into the systemic circulation. Norepinephrine is synthesized and stored not only in the adrenal medulla but also in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and peripheral sympathetic nerves.

Catecholamines affect many cardiovascular and metabolic processes, including increasing the heart rate, blood pressure, myocardial contractility, and cardiac conduction velocity. Specific receptors mediate the biologic actions. The three types of adrenergic receptors are α, β, and DA; their receptor subtypes are α_1, α_2, β_1, β_2, β_3, DA_1, and DA_2. The α_1 subtype is a postsynaptic receptor that mediates vascular and smooth muscle contraction; stimulation causes vasoconstriction and increased blood pressure. The α_2-receptors are located on presynaptic sympathetic nerve endings and, when activated, inhibit the release of norepinephrine; stimulation causes suppression in central sympathetic outflow and decreased blood pressure. Stimulation of the β_1-receptor causes positive inotropic and chronotropic effects on the heart, increased renin secretion in the kidney, and lipolysis in adipocytes as well as bronchodilation, vasodilation in skeletal muscle, glycogenolysis, and increased release of norepinephrine from sympathetic nerve terminals. The β_3-receptor regulates energy expenditure and lipolysis. DA_1 receptors are localized to the cerebral, renal, mesenteric, and coronary vasculature; stimulation causes vasodilation in these vascular beds. DA_2 receptors are presynaptic and localized to sympathetic nerve endings, sympathetic ganglia, and brain; stimulation inhibits the release of norepinephrine, inhibits ganglionic transmission, and inhibits prolactin release.

Catecholamines are synthesized from tyrosine by a process of hydroxylation and decarboxylation (see Fig. 228-1). Tyrosine is derived from ingested food or synthesized from phenylalanine in the liver, and it enters

neurons and chromaffin cells by active transport. Tyrosine is converted to 3,4-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase, the rate-limiting step in catecholamine synthesis. α-Methyl-*p*-tyrosine (metyrosine) is a tyrosine hydroxylase inhibitor that may be used therapeutically in patients with catecholamine-secreting tumors. Aromatic L-amino acid decarboxylase catalyzes the decarboxylation of dopa to dopamine. Dopamine is actively transported into granulated vesicles to be hydroxylated to norepinephrine by the dopamine β-hydroxylase. These reactions occur in the synaptic vesicle of adrenergic neurons and the chromaffin cells of the adrenal medulla. In the adrenal medulla, norepinephrine is released from the granule into the cytoplasm, where phenylethanolamine *N*-methyltransferase converts it to epinephrine. Expression of phenylethanolamine *N*-methyltransferase is positively regulated by glucocorticoids. Thus, catecholamine-secreting tumors that secrete primarily epinephrine are localized to the adrenal medulla. In normal adrenal medullary tissue, approximately 80% of the catecholamine released is epinephrine.

The biologic half-life of circulating catecholamines is between 10 and 100 seconds. Thus, plasma concentrations of catecholamines fluctuate widely. Catecholamines are removed from the circulation by either reuptake by sympathetic nerve terminals or metabolism through two enzyme pathways (see Fig. 228-1), followed by sulfate conjugation and renal excretion. Almost 90% of catecholamines released at sympathetic synapses are taken up locally by the nerve endings (uptake 1). Uptake 1 can be blocked by cocaine, tricyclic antidepressants, and phenothiazine. Extraneuronal tissues also take up catecholamines (uptake 2). Most of these catecholamines are metabolized by catechol-*O*-methyltransferase. Metanephrine and normetanephrine are oxidized by monoamine oxidase to vanillylmandelic acid by oxidative deamination. Monoamine oxidase may also oxidize epinephrine and norepinephrine to 3,4-dihydroxymandelic acid, which is then converted by catechol-*O*-methyltransferase to vanillylmandelic acid. In the storage vesicle, norepinephrine is protected from metabolism by monoamine oxidase. Monoamine oxidase and catechol-*O*-methyltransferase metabolize dopamine to homovanillic acid (see Fig. 228-1).

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

DEFINITION

Catecholamine-secreting tumors that arise from chromaffin cells of the adrenal medulla and the sympathetic ganglia are referred to as pheochromocytomas and extra-adrenal catecholamine-secreting paragangliomas, respectively. Because the tumors have similar clinical presentations and are treated with similar approaches, many clinicians use the term *pheochromocytoma* to refer to both entities. However, the distinction between pheochromocytoma and paraganglioma is an important one because there are differences in the risk for associated neoplasms, risk for malignant transformation, and type of genetic testing that should be considered.

EPIDEMIOLOGY

Catecholamine-secreting tumors are rare; the annual incidence is 2 to 8 cases per million people. Nevertheless, it is important to suspect, confirm, localize, and resect these tumors. The associated hypertension is curable with surgical removal of the tumor, a risk of lethal paroxysm exists, and at least 10% of the tumors are malignant. Approximately 30% of cases are familial, so detection of this tumor in the proband may result in early diagnosis in other family members.

PATHOBIOLOGY

Genetics

Approximately 30% of patients with catecholamine-secreting tumors have germline mutations (inherited mutations present in all cells of the body) in genes associated with the genetic disease.[1] Hereditary catecholamine-secreting tumors typically are manifested at a younger age than sporadic neoplasms are. Sporadic pheochromocytoma is typically diagnosed on the basis of symptoms or incidental discovery on computed imaging, whereas syndromic pheochromocytoma and paraganglioma are frequently diagnosed earlier in the course of disease because of biochemical surveillance or genetic testing.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN) type 2A is an autosomal dominant disorder (Chapters 231 and 246). The phenotype includes adrenal pheochromocytoma in 50% (usually bilateral and may be asynchronous), medullary carcinoma of the thyroid in 100%, hyperparathyroidism in 20 to 30%, and cutaneous lichen amyloidosis in 5%.[2] Medullary carcinoma of the thyroid is usually detected before pheochromocytoma. Numerous activating mutations in the *RET* proto-oncogene have been documented in persons with MEN type 2A (these are described in detail in Chapter 246).

MEN type 2B is also an autosomal dominant disorder, and it represents approximately 5% of all MEN type 2 cases. The phenotype includes pheochromocytoma in 50% (usually bilateral), aggressive medullary carcinoma of the thyroid in 100%, mucosal neuromas (typically involving the tongue, lips, and eyelids) in most patients, thickened corneal nerves, intestinal ganglioneuromatosis, and marfanoid body habitus. MEN 2B–associated tumors are caused by mutations in the RET protein's intracellular domain, as described in detail in Chapter 246.

Von Hippel–Lindau Disease

Von Hippel–Lindau (VHL) disease is an autosomal dominant disorder characterized by pheochromocytoma (frequently bilateral), paraganglioma (mediastinal, abdominal, pelvic), hemangioblastoma (involving the cerebellum, spinal cord, or brain stem), retinal angioma, clear cell renal cell carcinoma, pancreatic neuroendocrine tumor, endolymphatic sac tumor of the middle ear, serous cystadenoma of the pancreas, and papillary cystadenoma of the epididymis and broad ligament.[3] Pheochromocytoma occurs in about 10 to 20% of patients with VHL disease. Nearly 100% of patients have an identifiable gene mutation (VHL tumor suppressor gene). Certain missense mutations appear to be associated with a "pheochromocytoma only" presentation of VHL disease.

Neurofibromatosis

Neurofibromatosis type 1 (NF1) is an autosomal dominant disorder characterized by neurofibromas, multiple café au lait spots, axillary and inguinal freckling, iris hamartomas (Lisch nodules), bone abnormalities, central nervous system gliomas, pheochromocytoma and paraganglioma, macrocephaly, and cognitive deficits. The expression of these features is variable. Approximately 2% of patients with NF1 develop catecholamine-secreting tumors; in these patients, the tumor is usually a solitary benign adrenal pheochromocytoma, occasionally bilateral adrenal pheochromocytomas, and rarely an abdominal paraganglioma. Inactivating *NF1* mutations cause the disorder (NF1 tumor suppressor gene).

Familial Paraganglioma

Familial paraganglioma is an autosomal dominant disorder characterized by paragangliomas that are located in the skull base and neck, thorax, abdomen, and pelvis. Most cases of familial paraganglioma are caused by mutations in the succinate dehydrogenase (SDH; succinate:ubiquinone oxidoreductase) subunit genes (*SDHB*, *SDHC*, *SDHD*, *SDHAF2*, *SDHA*), which compose portions of mitochondrial complex II. Inactivating germline mutations in *SDHD* have been identified in multigenerational families with head and neck parasympathetic paragangliomas that are usually nonfunctional and occasionally in those with adrenal pheochromocytoma. In patients with *SDHD* mutations, penetrance depends on the mutation's parent of origin. Hence, the disease does not manifest when the mutation is inherited from the mother but is highly penetrant when it is inherited from the father. This phenomenon is known as maternal imprinting. Multiple cofactors are required for normal activity of the SDH complex, including flavin adenine dinucleotide (FAD) in the SDH1subunit. FAD is covalently attached to Sdh1, and deletion of *SDHAF2* causes a complete loss of FAD cofactor attachment (flavination) of Sdh1. Germline loss-of-function mutations in the *SDHAF2* gene, located on chromosome 11q13.1, have been associated with disease in a family with hereditary paraganglioma. Like families with mutations in *SDHD*, those with mutations in *SDHAF2* also exhibit maternal imprinting and parasympathetic paragangliomas that typically occur in the skull base and neck. Inactivating mutations in the tumor suppressor gene *SDHB*, located on chromosome 1p35-36, are associated with paragangliomas in the abdomen, pelvis, and mediastinum. Adrenal pheochromocytomas may also be found in patients with *SDHB* mutations. Patients with *SDHB* mutations have an increased risk for malignant paraganglioma.

Genetic Testing

Since 1990, 15 different pheochromocytoma and paraganglioma susceptibility genes have been reported: *NF1*, *RET*, *VHL*, *SDHD*, *SDHC*, *SDHB*, *EGLN1/PHD2*, *KIF1B*, *SDHAF2*, *IDH1*, *TMEM127*, *SDHA*, *MAX*, *HIF2A*, and *FH* gene encoding fumarate hydratase.[4,5]

Genetic testing should be considered if a patient has one or more of the following: paraganglioma, bilateral adrenal pheochromocytomas, unilateral adrenal pheochromocytoma and a family history of pheochromocytoma or paraganglioma, onset of unilateral adrenal pheochromocytoma at a young age (before 45 years), or other clinical findings suggestive of one of the previously discussed syndromic disorders.[6] Genetic testing can be complex; testing of one family member has implications for related individuals.[7] Genetic counseling is recommended to help families understand the implications of genetic test results; to coordinate the testing of at-risk individuals; and to help families work through the psychosocial issues that may arise before, during, or after the testing process. A list of clinically approved molecular genetic diagnostic laboratories is available at www.genetests.org.

CLINICAL MANIFESTATIONS

Catecholamine-secreting tumors occur with equal frequency in men and women, primarily in the third, fourth, and fifth decades of life. These tumors are rare in children; when discovered, they may be multifocal and associated with a hereditary syndrome. When symptoms are present, they are due to the pharmacologic effects of excess concentrations of circulating catecholamines (Table 228-1). The resulting hypertension may be sustained (in approximately half of patients) or paroxysmal (in approximately a third of patients). The remaining patients have normal blood pressure. Episodic symptoms may occur in spells, or paroxysms, that can be extremely variable in presentation but typically include forceful heartbeat, pallor, tremor, headache, and diaphoresis.[8] The spell may start with the sensation of a "rush" in the chest and a sense of shortness of breath, followed by a "pounding" heartbeat in the chest that typically progresses to a throbbing headache. Peripheral vasoconstriction with a spell results in cool or cold hands and feet and facial pallor. Increased sense of body heat and sweating are common symptoms that occur toward the end of the spell. Spells may be spontaneous or precipitated by postural change, anxiety, medications (e.g., metoclopramide, β-adrenergic inhibitors, anesthetic agents), exercise, or maneuvers that increase intra-abdominal pressure (e.g., change in position, lifting, defecation, exercise, colonoscopy, pregnancy, trauma). Although the types of spells experienced by patients are highly variable, spells tend to be stereotypical for each patient. Spells may occur multiple times a day or as infrequently as once a month. The typical duration of a pheochromocytoma spell is 15 to 20 minutes, but it may be much shorter or last several hours. The clinician must recognize that most patients with spells do not have a pheochromocytoma.

Additional clinical signs of catecholamine-secreting tumors include hypertensive retinopathy, orthostatic hypotension, angina, nausea, constipation (megacolon may be the presenting symptom), hyperglycemia, diabetes mellitus, hypercalcemia, Raynaud's phenomenon, livedo reticularis, erythrocytosis, and mass effects from the tumor. Fasting hyperglycemia and diabetes mellitus are caused in part by the α-adrenergic inhibition of insulin release. Painless hematuria and paroxysmal attacks induced by micturition and defecation are associated with urinary bladder paragangliomas. Some of the co-secreted hormones that may dominate the clinical presentation include corticotropin (Cushing's syndrome), parathyroid hormone–related peptide (hypercalcemia), vasopressin (syndrome of inappropriate antidiuretic hormone secretion), vasoactive intestinal peptide (watery diarrhea), and growth hormone–releasing hormone (acromegaly) (see Table 228-1). Cardiomyopathy and congestive heart failure are the symptomatic presentations of pheochromocytoma that are most frequently unrecognized by clinicians. Cardiomyopathy, whether dilated or hypertrophic, may be totally reversible with tumor resection. Some patients with pheochromocytoma may be asymptomatic despite high circulating levels of catecholamines, probably reflecting adrenergic receptor desensitization related to chronic stimulation.

Symptomatic pheochromocytomas are localized to the adrenal glands, with an average diameter of 4.5 cm (Fig. 228-2). Paragangliomas are found where there is chromaffin tissue: along the para-aortic sympathetic chain, within the organs of Zuckerkandl (at the origin of the inferior mesenteric artery), in the wall of the urinary bladder, and along the sympathetic chain in the neck or mediastinum. Paragangliomas in the head and neck region (e.g., carotid body tumors, glomus tumors, chemodectomas) usually arise from parasympathetic tissue and typically do not hypersecrete catecholamines and metanephrines, whereas paragangliomas in the mediastinum, abdomen, and pelvis usually arise from sympathetic chromaffin tissue and usually do hypersecrete catecholamines and metanephrines.

TABLE 228-1 SIGNS AND SYMPTOMS ASSOCIATED WITH CATECHOLAMINE-SECRETING TUMORS

SPELL RELATED
Anxiety and fear of impending death
Diaphoresis
Dyspnea
Epigastric and chest pain
Headache
Hypertension
Nausea and vomiting
Pallor
Palpitation (forceful heartbeat)
Tremor
CHRONIC
Anxiety and fear of impending death
Cold hands and feet
Congestive heart failure—dilated or hypertrophic cardiomyopathy
Constipation
Diaphoresis
Dyspnea
Ectopic hormone secretion–dependent symptoms (e.g., CRH/ACTH, GHRH, PTH-RP, VIP)
Epigastric and chest pain
Fatigue
Fever
General increase in sweating
Grade II to IV retinopathy
Headache
Hyperglycemia
Hypertension
Nausea and vomiting
Orthostatic hypotension
Painless hematuria (associated with urinary bladder paraganglioma)
Pallor
Palpitation (forceful heartbeat)
Tremor
Weight loss
NOT TYPICAL OF PHEOCHROMOCYTOMA
Flushing

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; GHRH = growth hormone–releasing hormone; PTH-RP = parathyroid hormone–related peptide; VIP = vasoactive intestinal polypeptide.
Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab.* 1993;4:122-127.

DIAGNOSIS

Differential Diagnosis

Numerous disorders can cause signs and symptoms that may lead the clinician to test for pheochromocytoma. These disorders span much of medicine and include endocrine disorders (e.g., primary hypogonadism), cardiovascular disorders (e.g., idiopathic orthostatic hypotension), psychological

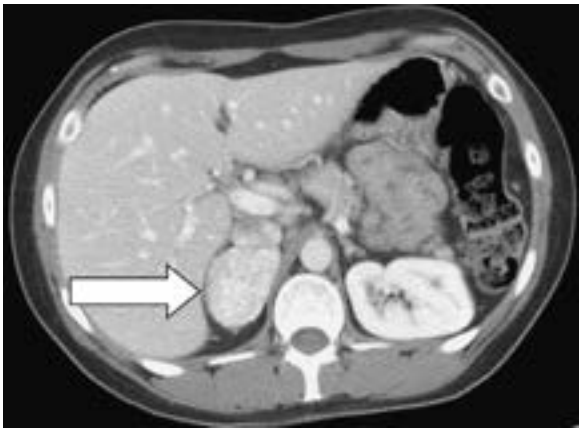

FIGURE 228-2. Contrast-enhanced computed tomography of the abdomen in a 32-year-old second-year medical student with the peripartum discovery of a pheochromocytoma. The plasma fractionated metanephrines were abnormal: metanephrine, 0.19 nmol/L (normal, <0.5 nmol/L); normetanephrine, 28.6 nmol/L (normal, <0.9 nmol/L). The 24-hour urine values were abnormal: norepinephrine, 781 µg (normal, <170 µg); epinephrine, 2.4 µg (normal, <35 µg); dopamine, 197 µg (normal, <700 µg); metanephrine, 117 µg (normal, <400 µg); normetanephrine, 8760 µg (normal, <900 µg). The axial image shows a typical 5-cm heterogeneously enhancing right adrenal mass, consistent with pheochromocytoma (*arrow*). After α- and β-adrenergic blockade, a 5.3 × 5.0 × 2.0-cm, 40-g pheochromocytoma was removed laparoscopically.

disorders (e.g., panic disorder), pharmacologic causes (e.g., withdrawal from an adrenergic inhibitor), neurologic disorders (e.g., postural orthostatic tachycardia syndrome), and miscellaneous disorders (e.g., mast cell disease). Indeed, most patients tested for pheochromocytoma do not have it. In addition, fractionated catecholamines and metanephrines may be elevated in several clinical scenarios: withdrawal from medications or drugs (e.g., clonidine, alcohol), any acute illness (e.g., subarachnoid hemorrhage, migraine headache, preeclampsia), and administration of many drugs and medications (e.g., tricyclic antidepressants, levodopa, cocaine, phencyclidine, lysergic acid diethylamide, amphetamines, ephedrine, pseudoephedrine, phenylpropanolamine, isoproterenol) (Table 228-2).

Pheochromocytoma should be suspected in patients who have one or more of the following: hyperadrenergic spells (e.g., self-limited episodes of nonexertional palpitations, diaphoresis, headache, tremor, or pallor); resistant hypertension; a familial syndrome that predisposes to catecholamine-secreting tumors (e.g., MEN type 2, NF1, VHL disease); a family history of pheochromocytoma or a history of a resected pheochromocytoma and a present history of recurrent hypertension or spells; an incidentally discovered adrenal mass; hypertension and diabetes; pressor response during anesthesia, surgery, or angiography; onset of hypertension at a young age (before 20 years); and idiopathic dilated cardiomyopathy.

Laboratory Findings

The diagnosis must be confirmed biochemically by increased concentrations of fractionated metanephrines in the plasma or fractionated catecholamines and metanephrines in a 24-hour urine collection (Fig. 228-3).[9] Most laboratories now measure fractionated catecholamines (dopamine, norepinephrine, and epinephrine) and metanephrines (metanephrine and normetanephrine) by high-performance liquid chromatography with electrochemical detection or tandem mass spectroscopy.[10] These techniques have overcome the problems with fluorometric analysis (e.g., false-positive results caused by α-methyldopa, labetalol, sotalol, and imaging contrast agents). One of the most reliable methods of identifying catecholamine-secreting tumors is measurement of fractionated metanephrines and catecholamines in a 24-hour urine collection (sensitivity, 98%; specificity, 98%).[11] If clinical suspicion is high, plasma fractionated metanephrines should also be measured. Some groups have advocated the measurement of plasma fractionated metanephrines as a first-line test for pheochromocytoma; the predictive value of a

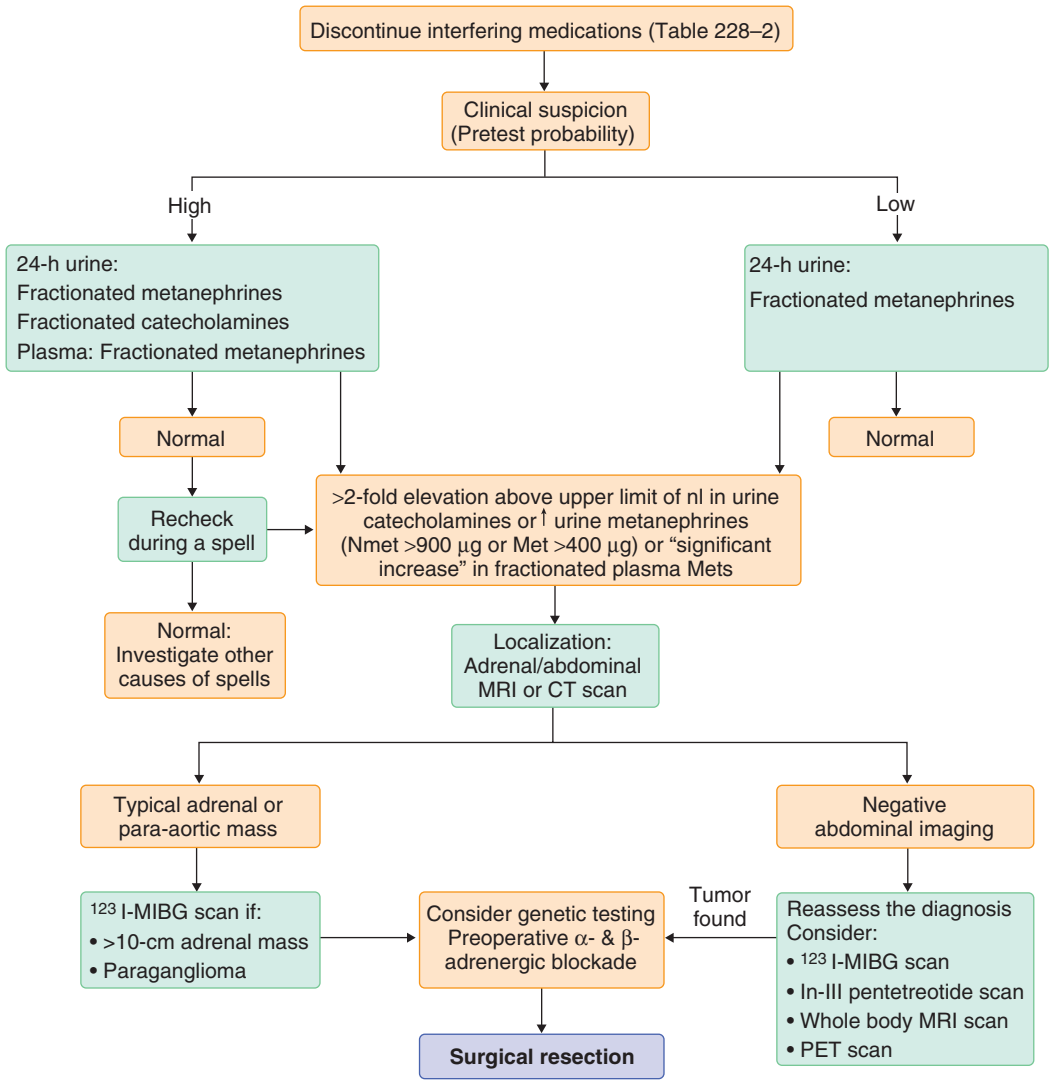

FIGURE 228-3. Evaluation and treatment of catecholamine-secreting tumors. Clinical suspicion is triggered by the following: paroxysmal symptoms (especially hypertension); hypertension that is intermittent, unusually labile, or resistant to treatment; family history of pheochromocytoma or associated conditions; or incidentally discovered adrenal mass. The details are discussed in the text. CT = computed tomography; ^{123}I-MIBG = ^{123}I-metaiodobenzylguanidine; Met = metanephrine; MRI = magnetic resonance imaging; nl = normal; Nmet = normetanephrine; PET = positron emission tomography. (Modified from Young WF Jr. Pheochromocytoma: 1926-1993. *Trends Endocrinol Metab.* 1993;4:122.)

negative test result is extremely high, and the finding of normal plasma fractionated metanephrines excludes pheochromocytoma, except in patients with early preclinical disease and those with strictly dopamine-secreting neoplasms.[12] A plasma test is also attractive because of its simplicity. Although measurement of plasma fractionated metanephrines has a sensitivity of 96 to 100%, the specificity is poor at only 85 to 89%; the specificity falls to 77% in patients older than 60 years. It has been estimated that 97% of patients with hypertension seen in a tertiary care clinic who have abnormal plasma fractionated metanephrine measurements do not have pheochromocytoma. This high false-positive rate results in excessive health care expenditures because of subsequent imaging as well as potentially inappropriate surgery. Thus, plasma fractionated metanephrines lack the necessary specificity to be recommended as a first-line test; this measurement is reserved for cases in which the index of suspicion is high. However, measurement of plasma fractionated metanephrines is a good first-line test for children, in whom it is difficult to obtain a complete 24-hour urine collection.

The index of suspicion for pheochromocytoma should be high (see Fig. 228-3) in patients with the clinical scenarios described earlier and in those with an incidentally discovered adrenal mass that has imaging characteristics consistent with pheochromocytoma. These include increased baseline computed tomography (CT) Hounsfield unit density (e.g., >20 HU), marked enhancement with intravenous contrast medium on CT, high signal intensity on T2-weighted magnetic resonance imaging (MRI), cystic and hemorrhagic changes, bilaterality, and large size (>4 cm) (see later).

Although it is preferable for patients not to receive any medications during the diagnostic evaluation, treatment with most medications can be continued. Tricyclic antidepressants interfere most frequently with the interpretation of fractionated catecholamines and metanephrines. For the effective detection of catecholamine-secreting tumors, treatment with tricyclic antidepressants and other psychoactive agents listed in Table 228-2 should be tapered and discontinued at least 2 weeks before any hormonal assessments. Furthermore, catecholamine secretion may be appropriately increased in situations of physical stress or illness (e.g., stroke, myocardial infarction, congestive heart failure, obstructive sleep apnea). Therefore, the clinical circumstances under which catecholamines and metanephrines are measured must be assessed in each case.

Imaging

Localization studies should not be initiated until biochemical studies have confirmed the diagnosis of a catecholamine-secreting tumor (see Fig. 228-3). Computer-assisted imaging of the adrenal glands and abdomen with CT or MRI should be the first localization test (sensitivity, >95%; specificity, >65%). Approximately 85% of these tumors are found in the adrenal glands, and 95% are found in the abdomen. If the results of abdominal imaging are normal, scintigraphic localization with ^{123}I-labeled metaiodobenzylguanidine (^{123}I-MIBG) is indicated (see Fig. 228-3). This radiopharmaceutical agent accumulates preferentially in catecholamine-producing tumors (sensitivity, 88%; specificity, 94%). If a typical (<10 cm) unilateral adrenal pheochromocytoma is found on CT or MRI, ^{123}I-MIBG scintigraphy is superfluous, and the results may even cause confusion. If the adrenal pheochromocytoma is larger than 10 cm in diameter or if a paraganglioma is identified on CT or MRI, ^{123}I-MIBG scintigraphy is indicated because the patient has an increased risk of malignant disease and additional paragangliomas.^{18}F-Fluorodeoxyglucose positron emission tomography is an excellent imaging modality to detect metastatic disease.[13,14]

Other localizing procedures that can be used but are rarely required include computer-assisted imaging of the chest and neck as well as somatostatin receptor imaging with [^{111}In]pentetreotide (see Fig. 228-3). Because of marked gradients between the adrenal glands in non-pheochromocytoma patients, adrenal venous sampling for catecholamines is not helpful in the investigation of adrenal pheochromocytoma.

TREATMENT

Medical Therapy

Some form of preoperative pharmacologic preparation is indicated for all patients with catecholamine-secreting neoplasms. However, no randomized controlled trials have compared the different approaches. Combined α- and β-adrenergic blockade is one approach to control blood pressure and to prevent intraoperative hypertensive crises. α-Adrenergic blockade should be started 7 to 10 days preoperatively to normalize blood pressure and to expand the contracted blood volume. A longer duration of preoperative α-adrenergic blockade is indicated in patients with recent myocardial infarction, catecholamine cardiomyopathy, and catecholamine-induced vasculitis. Blood pressure should be monitored with the patient in the seated and standing positions twice daily. Target blood pressure is less than 120/80 mm Hg (seated), with systolic blood pressure greater than 90 mm Hg (standing); both targets should be modified on the basis of the patient's age and comorbid disease. On the second or third day of α-adrenergic blockade, patients are encouraged to start a diet high in sodium content (≥5000 mg daily) because of the catecholamine-induced volume contraction and the orthostasis associated with α-adrenergic blockade. This degree of volume expansion may be contraindicated in patients with congestive heart failure or renal insufficiency. After adequate α-adrenergic blockade has been achieved, β-adrenergic blockade is initiated, which typically occurs 2 or 3 days preoperatively.

Phenoxybenzamine is the preferred drug to control blood pressure and arrhythmia preoperatively.[15] It is an irreversible, long-acting, nonspecific α-adrenergic blocking agent. The initial dosage is 10 mg once or twice daily, and the dose is increased by 10 to 20 mg in divided doses every 2 or 3 days as needed to control blood pressure and spells. The final dosage of phenoxybenzamine is typically between 20 and 100 mg daily.

The β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective; with β-adrenergic blockade alone, hypertension may be more severe from the unopposed α-adrenergic stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. The clinician should exercise caution if the patient is asthmatic or has congestive heart failure. Chronic catecholamine excess can produce a cardiomyopathy that may become evident with the initiation of β-adrenergic blockade, resulting in acute pulmonary edema. Therefore, the β-adrenergic blocker should be administered cautiously and at a low dose. Other agents that may be used to prepare the patient with pheochromocytoma for surgery include α-methyl-*p*-tyrosine (metyrosine) and calcium-channel blockers. Acute hypertensive crises may occur before or during an operation, and they should be treated with intravenous sodium nitroprusside, phentolamine, or nicardipine.

Surgical Therapy

The treatment of choice for pheochromocytoma is complete surgical resection. Surgical survival rates are 98 to 100% and are highly dependent on the skill of the endocrinologist–endocrine surgeon–anesthesiologist team. Careful preoperative pharmacologic preparation is crucial for successful treatment. Most catecholamine-secreting tumors are benign and can be totally excised. Tumor excision usually cures hypertension.

In the past, an anterior midline abdominal surgical approach was generally used to resect adrenal pheochromocytoma. However, the laparoscopic approach to the adrenal gland is currently the procedure of choice for a solitary intra-adrenal pheochromocytoma smaller than 8 cm in diameter.[16] Laparoscopic adrenalectomy for pheochromocytoma should be converted to open adrenalectomy in cases of difficult dissection, invasion, adhesions, or an inexperienced surgeon. An anterior midline abdominal surgical approach is indicated for abdominal paragangliomas. The midline abdomen should be inspected carefully. Paragangliomas of the neck, chest, and urinary bladder require specialized approaches.

Management of Complications

Hypotension may occur during and after surgical resection of the pheochromocytoma, and it should be treated with fluids and colloids and then intravenous pressor agents if necessary. Postoperative hypotension is less frequent in patients who have had adequate preoperative α-adrenergic blockade and volume expansion. If both adrenal glands were manipulated during surgery, adrenocortical insufficiency should be considered a potential cause of postoperative hypotension. Because hypoglycemia can occur in the immediate postoperative period, blood glucose levels should be monitored, and intravenous fluids should contain 5% dextrose.

Approximately 1 to 2 weeks after surgery, fractionated catecholamines and metanephrines should be measured by collection of a 24-hour urine specimen. If the levels are normal, resection of the pheochromocytoma should be considered complete. Increased levels of fractionated catecholamines and metanephrines detected postoperatively are consistent with residual tumor due to either a second primary lesion or occult metastases. Common sites of metastasis include lymph nodes, liver, lung, and bone.

Follow-up

The 24-hour urinary excretion of fractionated catecholamines and metanephrines or plasma fractionated metanephrines should be checked annually for life. Annual biochemical testing assesses for metastatic disease, tumor recurrence in the adrenal bed, or delayed appearance of multiple primary tumors. Follow-up CT or MRI is not needed unless the metanephrine or catecholamine levels become elevated or the original tumor was associated with minimal or no catecholamine or metanephrine excess.

MALIGNANT PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Distinguishing between benign and malignant catecholamine-secreting tumors is difficult on the basis of clinical, biochemical, or histopathologic characteristics. Malignant disease is rare in patients with an adrenal familial syndrome but common in those with familial paraganglioma caused by mutations in *SDHB*. Although the 5-year survival rate for patients with malignant pheochromocytoma is less than 50%, the prognosis is variable[17]; approximately 50% of patients have an indolent form of the disease, with a life expectancy of more than 20 years, and the other 50% have rapidly progressive disease, with death occurring 1 to 5 years after diagnosis. The clinician should assess the pace of the malignant disease and base the level of therapy on the aggressiveness of the tumor's behavior. A multimodality, multidisciplinary, individualized approach is indicated to control catecholamine-dependent symptoms, local mass effects, and overall tumor burden.

PHEOCHROMOCYTOMA IN PREGNANCY

Pheochromocytoma in pregnancy can cause the death of both the fetus and the mother. The approach to the biochemical diagnosis is the same as for nonpregnant patients. MRI without gadolinium enhancement is the preferred imaging modality.[123]I-MIBG scintigraphy is contraindicated. The treatment of hypertensive crises is the same as for nonpregnant patients, except that nitroprusside should be avoided. Although the most appropriate management is debated, adrenal pheochromocytomas should be removed promptly after α- and β-adrenergic blockade if the diagnosis is made during the first two trimesters of pregnancy.[18] The preoperative preparation is the same as for nonpregnant patients. If the pregnancy is in the third trimester, one operation is recommended for cesarean delivery and removal of the adrenal pheochromocytoma at the same time. Spontaneous labor and delivery should be avoided. The management of catecholamine-secreting paragangliomas in pregnancy may require modification of these guidelines, depending on tumor location.

REVIEW QUESTIONS

1. An effective class of antihypertensive drugs could be based on which of the following?

A. Postsynaptic α_1-receptor agonists
B. Presynaptic α_2-receptor agonists
C. Tyrosine hydroxylase activators
D. β_1-Receptor agonists
E. β_2-Receptor agonists

Answer: B See introduction section of the chapter on catecholamines and adrenergic receptors. Agonism at the presynaptic α_2-receptor is the only option listed that would decrease catecholamine synthesis or release. Central α_2-receptor agonists are Food and Drug Administration–approved antihypertensive drugs (e.g., clonidine, guanfacine).

2. Your patient has a disease-causing mutation in succinate dehydrogenase subunit D (*SDHD*) and is currently pregnant. She asks you if her child inherits the *SDHD* mutation from her, what is the chance that her child will develop a paraganglioma in his or her lifetime? You advise her that if her child inherits the *SDHD* mutation, the risk for development of a paraganglioma is closest to

A. 0%
B. 25%
C. 50%
D. 75%
E. 100%

Answer: A See section on familial paraganglioma under Pathobiology and Genetics. In patients with *SDHD* mutations, penetrance depends on the mutation's parent of origin. Hence, the disease does not manifest when the mutation is inherited from the mother but is highly penetrant when it is inherited from the father. This phenomenon is known as maternal imprinting.

3. In a patient with an incidentally discovered adrenal mass, which of the following imaging characteristics is consistent with pheochromocytoma?

A. Lack of enhancement with intravenous contrast medium on computed tomography (CT)
B. Low signal intensity on T2-weighted magnetic resonance imaging (MRI)
C. Homogeneous mass with absent cystic and hemorrhagic changes
D. Precontrast CT Hounsfield unit density (e.g., >20 HU)
E. Rapid contrast washout with more than 50% washout at 10 minutes

Answer: D See section on diagnosis. Imaging characteristics of an incidentally discovered adrenal mass consistent with pheochromocytoma include increased baseline CT Hounsfield unit density (e.g., >20 HU); marked enhancement with intravenous contrast medium on CT; high signal intensity on T2-weighted MRI; cystic and hemorrhagic changes; bilaterality; and large size (>4 cm). In addition, pheochromocytomas are characterized by slow contrast washout (e.g., <50% at 10 minutes after administration of contrast material).

4. Medications and agents that frequently increase measured levels of catecholamines and metanephrines include

A. β-Adrenergic inhibitors
B. Presynaptic α_2-receptor agonists
C. Tyrosine hydroxylase inhibitors
D. Tricyclic antidepressants
E. Calcium-channel blockers

Answer: D See Table 228-2. In addition, β-adrenergic inhibitors do not affect circulating levels of catecholamines or metanephrines in a clinically important way. Central α-receptor agonists (e.g., clonidine) decrease the release of catecholamines. Tyrosine hydroxylase is the rate-limiting step in catecholamine synthesis, and inhibition of this step decreases total body catecholamine production. Use of tricyclic antidepressants is the most common cause of false-positive results of biochemical testing for pheochromocytoma.

5. In preparing the patient with pheochromocytoma for surgery, which of the following statements is correct with regard to β-adrenergic blockade?

A. The β-adrenergic antagonist should be administered before the α-adrenergic blocker is started.
B. It is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade.
C. The dosing of the β-adrenergic antagonist is not affected by asthma or congestive heart failure in this unique setting of catecholamine excess.
D. The dose of the β-adrenergic antagonist should be titrated for a heart rate of 50 beats per minute.
E. The dose of the β-adrenergic antagonist should be titrated for a systolic blood pressure of 100 mm Hg.

Answer: B See medical therapy section on treatment. The β-adrenergic antagonist should be administered only after α-adrenergic blockade is effective; with β-adrenergic blockade alone, hypertension may be more severe from the unopposed α-adrenergic stimulation. Preoperative β-adrenergic blockade is indicated to control the tachycardia associated with both the high concentrations of circulating catecholamines and the α-adrenergic blockade. The clinician should exercise caution if the patient is asthmatic or has congestive heart failure. Chronic catecholamine excess can produce a cardiomyopathy that may become evident with the initiation of β-adrenergic blockade, resulting in acute pulmonary edema. Therefore, the β-adrenergic blocker should be administered cautiously and at a low dose.

DIABETES MELLITUS

JILL CRANDALL AND HARRY SHAMOON

Diabetes mellitus is a chronic disorder characterized by abnormal metabolic regulation as well as by the potential for vascular and neuropathic complications. Diabetes comprises a cluster of heterogeneous disorders with elevated blood glucose levels as a common diagnostic feature; however, as genetic and molecular studies have suggested, it is likely that the cluster includes many subcategories, each of which requires tailored prevention, diagnosis, and treatment approaches. Depending on the context in which the patient presents, diabetes can be an acute life-threatening condition, a pregnancy-associated disorder, or a gradually evolving chronic disorder that carries with it secondary complications that may be ultimately more debilitating than hyperglycemia. Other factors make diabetes an unusual clinical challenge, including the need for active participation by patients in their treatment, the varying presentations across the age spectrum, and the unstable and evolving clinical presentation. Because the severity of the underlying metabolic defects does not remain static, diabetes management always requires changes in treatment according to the stage of the disease. These patterns of evolution are superimposed on the phenotypes at presentation and depend on a host of factors including age, sex, race, societal setting, and others.

It is now established that diabetes-related vascular and neuropathic complications stem from imperfect treatment of the metabolic disturbances, defined principally by hyperglycemia. There is also evidence that genetic factors may predispose or protect individual patients from the deleterious effects of hyperglycemia. Regardless of the specific subtype of diabetes, all have in common some degree of insulin deficiency; insulin deficiency may be absolute, as in type 1 diabetes, or a relative deficit with coexisting insulin resistance, as in type 2 diabetes. Deficient insulin is the primary driver of impaired fuel homeostasis, whereas hyperglycemia plays the dominant role in disease-related complications. Major strides in our understanding of diabetes have been made during the last 40 years, with accompanying additions to the diagnostic and treatment armamentarium.

TABLE 229-1 CLASSIFICATION OF DIABETES

	TYPE 1	TYPE 2
Age at onset	Childhood or early adulthood, but can be manifested at any age	Middle age or older, but can be manifested in obese children and adolescents
Family history/genetic factors	Genetic risk defined, but most cases are sporadic	Strong genetic component, polygenic in most cases
Environmental triggers	Largely unknown	Obesity, sedentary lifestyle
Requirement for insulin therapy	Universal	Variable
Frequency among people with diabetes	5-10%	~90%
Associated disorders	Autoimmunity, especially thyroid, other endocrine disorders	Hypertension, dyslipidemia, metabolic syndrome, polycystic ovary syndrome

DEFINITIONS

Despite the heterogeneity of phenotypes, it is possible to generally classify diabetes into two major subgroups, type 1 (previously referred to as juvenile-onset or insulin-dependent diabetes) and type 2 (previously referred to as adult-onset or non–insulin-dependent diabetes). The major clinical features of type 1 and type 2 are shown in Table 229-1 and are described in detail in the corresponding sections later.

In addition to these two large categories, diabetes may occur in association with other disorders, with use of certain medications, or, rarely, as a result of a specific genetic mutation, such as maturity-onset diabetes of youth (MODY).

Diabetes Associated with Other Disorders or Syndromes

Diabetes may occur as part of several inherited syndromes, including the Turner, Klinefelter, Prader-Willi, Down, and Wolfram syndromes, among others. The genetic and metabolic defects involved are heterogeneous but usually result in impaired β-cell function. The obesity (and resulting insulin resistance) associated with many of these syndromes also contributes. Diseases of the exocrine pancreas, such as pancreatitis, pancreatic cancer, hemochromatosis, and cystic fibrosis, can be accompanied by impaired pancreatic endocrine function, leading to insulin-deficient diabetes. Several endocrinopathies that are associated with insulin resistance, including acromegaly, Cushing syndrome, and pheochromocytoma, may result in impaired glucose tolerance or frank diabetes in predisposed individuals. Viral infections, such as congenital rubella and cytomegalovirus, may cause diabetes by β-cell destruction. Finally, hyperglycemia may be associated with the use of certain drugs, including those that worsen insulin resistance (e.g., glucocorticoids, nicotinic acid, thiazide diuretics) and those that impair β-cell function (e.g., pentamidine, diazoxide, interferon gamma).

Diagnostic Criteria for Diabetes

Diabetes is diagnosed on the basis of one of several criteria, including fasting plasma glucose concentration, plasma glucose concentration after a standard 75-g oral glucose challenge (oral glucose tolerance test), and percentage of glycosylated hemoglobin (HbA_{1c}) (Table 229-2). In most cases, abnormal results require a confirmatory test, but diabetes can be diagnosed in the presence of unequivocal hyperglycemia (casual plasma glucose concentration > 200 mg/dL) and typical symptoms of polyuria, polydipsia, and weight loss.

Because plasma glucose levels exist on a continuum, the selection of a specific diagnostic threshold is in some respects arbitrary. Current criteria are based on the plasma glucose or HbA_{1c} level above which the risk of diabetes-specific microvascular complications (e.g., retinopathy) is perceptibly

TABLE 229-2 DIAGNOSTIC CRITERIA FOR DIABETES

	NORMAL	IMPAIRED (PRE-DIABETES)	DIABETES
Fasting glucose concentration (mg/dL)	<100	100-125	≥126
OGTT 2-hour glucose concentration (mg/dL)	<140	140-199	≥200
HbA_{1c} (%)	<5.7	5.7-6.4	≥6.5

OGTT = oral glucose tolerance test.
Modified from American Diabetes Association. Standards of medical care in diabetes—2014. *Diabetes Care.* 2015;38(Suppl 1):S8-S16.

increased. In situations of altered red blood cell turnover or certain hemoglobinopathies, HbA_{1c} may not accurately reflect mean plasma glucose levels (see later section on glycosylated hemoglobin), and direct glucose measurement should be used. Separate glucose criteria exist for the diagnosis of gestational diabetes (see section on gestational diabetes under clinical manifestations of type 2 diabetes).

States of impaired glucose regulation, not meeting the criteria for diabetes, have also been defined (fasting glucose concentration of 100 to 125 mg/dL, 2-hour glucose concentration of 140 to 199 mg/dL, or HbA_{1c} level of 5.7 to 6.4%). Individuals in these categories are at increased risk for diabetes, although not all will progress and some may revert to normal glucose regulation. Impaired glucose tolerance (oral glucose tolerance test 2-hour glucose concentration of 140 to 199 mg/dL) has also been associated with increased risk of atherosclerotic cardiovascular disease (CVD), which may be independent of future development of diabetes.

Glycosylated Hemoglobin

Measurements of glycosylated hemoglobin have been in clinical use since the 1980s as a means of assessing glucose control in patients with diabetes and more recently for the diagnosis of diabetes and pre-diabetic states. Hemoglobin A_{1c} (HbA_{1c}) is formed by the nonenzymatic glycosylation of hemoglobin, and its percentage reflects the exposure of the hemoglobin A molecule to glucose during the lifespan of red blood cells (~120 days). Thus, HbA_{1c} has a predictable (but nonlinear) relationship with mean plasma glucose levels during the preceding 3 to 4 months, although more recent exposure (preceding 4 weeks) contributes relatively more to the percentage of glycosylation. The relationship between HbA_{1c} and mean glucose levels was initially based on data obtained from the Diabetes Control and Complications Trial (DCCT) and recently updated on the basis of data obtained from studies using continuous glucose monitoring in ambulatory individuals, including those with and without diabetes (Table 229-3).

Although several different types of assays (e.g., affinity chromatography, immunoassay) are used to measure HbA_{1c}, most methods have been harmonized to a common standard and generally allow results from different laboratories to be used interchangeably. HbA_{1c} results may be influenced by a number of factors, including conditions that alter red cell survival (e.g., hemolytic anemia) or cause interference with a specific assay. In these situations, measurement of fructosamine (glycosylated serum proteins) or glycated albumin, both of which reflect mean glucose levels during the preceding 2 to 3 weeks, may provide more accurate assessment of recent glucose levels. However, these assays have not been as well standardized, and the relationship with mean plasma glucose levels is less well established (Table 229-4).

PATHOBIOLOGY OF DIABETES

Figure 229-1 summarizes the effects of insulin deficiency on body fuel metabolism.

Given the dominant role of insulin in carbohydrate metabolism, it is not surprising that its availability and effectiveness play a role in every form of diabetes. However, because many other diabetogenic factors can be invoked and there is interdependence of many of these homeostatic mechanisms, teasing out their individual contributions is virtually impossible in any given patient.

Normal insulin physiology is orchestrated in a complex dynamic involving metabolic fuels, neurotransmitters, and other hormones. Insulin is synthesized as preproinsulin in the ribosomes of the rough endoplasmic reticulum of pancreatic islet β cells and is then converted to proinsulin, which in turn

TABLE 229-3 THE RELATIONSHIP BETWEEN HbA_{1c} AND ESTIMATED AVERAGE GLUCOSE LEVELS DURING THE PRECEDING 3 MONTHS

	ESTIMATED AVERAGE GLUCOSE LEVEL	
HbA_{1c} (%)	*mg/dL*	*mmol/L*
5	97	5.4
6	126	7.0
7	154	8.6

TABLE 229-4 CONDITIONS THAT MAY AFFECT MEASUREMENT OR INTERPRETATION OF HbA_{1c}

MECHANISM OF HbA_{1c} INTERFERENCE	CONDITION OR DISEASE	EFFECT ON HbA_{1c}
Reduced red cell lifespan	Hemolytic anemia Acute blood loss Hypersplenism	Falsely low
Increased red cell lifespan	Iron deficiency anemia	Falsely high
Altered glycation	High-dose vitamin supplementation (vitamins A and C)	Falsely low
Assay interference	Hemoglobins S, G, D, C, E Hemoglobin F	Falsely high Falsely low
Miscellaneous	Chronic renal disease Chronic liver disease Red cell transfusion African ancestry	Falsely high Falsely low Falsely low or high Falsely high

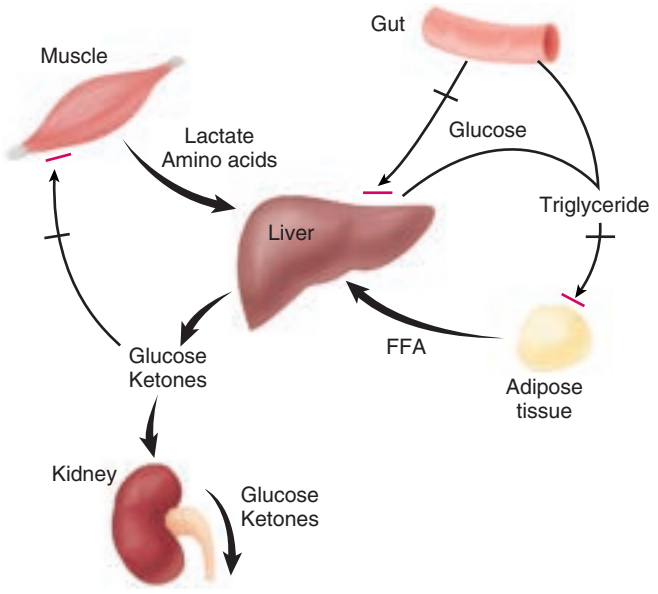

FIGURE 229-1. Effects of insulin deficiency on body fuel metabolism. Lack of insulin leads to mobilization of substrates for gluconeogenesis and ketogenesis from muscle and adipose tissue, accelerated production of glucose and ketones by the liver, and impaired removal of endogenous and exogenous fuels by insulin-responsive tissues. The net results are severe hyperglycemia and hyperketonemia that overwhelm renal removal mechanisms. FFA = free fatty acids.

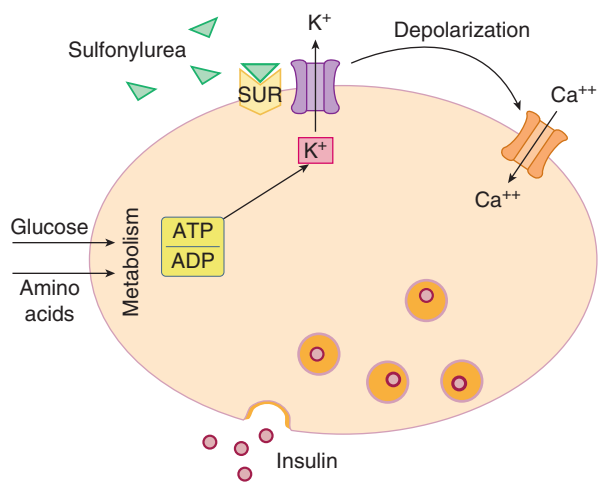

FIGURE 229-2. Nutrient regulation of insulin secretion. Glucose is taken up by the β cell through the GLUT2 glucose transporter and is metabolized (initially through phosphorylation by the glucokinase to glucose 6-phosphate). This leads to an increase in intracellular ATP (and an increase in the cytoplasmic ATP/ADP ratio), which causes closure of the ATP-dependent potassium channel, followed by membrane depolarization and the subsequent opening of voltage-gated calcium channels. The influx of calcium mobilizes the insulin secretory granules to fuse with the cell membrane and to release insulin into the extracellular fluid. The sulfonylurea 1 receptor (SUR1) is a component of the ATP-dependent potassium channel. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

is transported to the Golgi apparatus, where it is packaged into secretory granules. Proinsulin is cleaved into equimolar amounts of insulin and a connecting segment (C-peptide) in the secretory granules. The stimulation of insulin secretion results in release of equimolar quantities of insulin and C-peptide (as well as a small amount of proinsulin) into the hepatic portal vein. Whereas a large proportion of insulin is bound to its hepatic receptor and metabolized in its "first pass" through the liver, C-peptide is much less prone to hepatic metabolism and is a better reflection of insulin secretion, although it is quantitatively of limited usefulness in the clinical diagnosis or treatment of diabetes.

The principal regulator of insulin secretion is glucose. The process of β-cell insulin secretion is shown schematically in Figure 229-2. Glucose is taken up by the β cells through the GLUT2 glucose transporter system and then phosphorylated to glucose 6-phosphate by an islet-specific glucokinase. Thus, glucokinase can be considered the "glucose sensor" of the β cell; mutations in this enzyme can lead to a specific diabetes syndrome (MODY2), and there is evidence of its role in common forms of type 2 diabetes. The conversion of glucose to glucose 6-phosphate results in a sequential increase in intracellular adenosine triphosphate (ATP), closing of the ATP-dependent potassium (K_{ATP}) channels in the β-cell membrane, membrane depolarization and influx of calcium, migration of the insulin secretory granules to the cell membrane and their fusion with the membrane, and finally release of insulin into the extracellular fluid. The K_{ATP} channel is made up of the sulfonylurea 1 receptor (SUR1) and an inward potassium channel subunit, Kir6.2. Mutations in either the SUR1 gene or the Kir6.2 gene lead to loss of K_{ATP} activity; as a result, the cell is depolarized, resulting in chronic release of insulin and a syndrome termed *persistent hyperinsulinemic hypoglycemia of infancy*. Mutations in Kir6.2 and SUR1 have also been identified in patients with permanent neonatal diabetes mellitus; treatment with sulfonylurea can normalize insulin secretion in these patients.

The magnitude of the insulin secretory response is determined by the level of blood glucose as well as by the mode of glucose entry. Compared with intravenous administration of glucose, higher insulin levels are produced when glucose is taken orally because of the simultaneous release of gut-derived incretins that include glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), both of which augment insulin secretion. In fact, drugs that mimic or enhance this incretin effect are useful in the treatment of type 2 diabetes.

Rapid increases in blood glucose concentration (e.g., after intravenous administration of glucose) cause a spike of insulin secretion that peaks within a few minutes and declines quickly (so-called first-phase insulin secretion). With more persistent elevations of plasma glucose concentration, insulin secretion is sustained (so-called second-phase insulin secretion). The earliest pathophysiologic indicator of defective β-cell function may be the loss of first-phase secretion of insulin, which precedes by years the decline in insulin secretory reserve sufficient to lead to overt glucose intolerance or diabetes.

TABLE 229-5 THE METABOLIC EFFECTS OF INSULIN

METABOLIC EFFECT	STIMULATED BY INSULIN	INHIBITED BY INSULIN
Carbohydrate metabolism	Glucose transport Glycolysis Glycogen synthesis	Glycogen breakdown Gluconeogenesis
Protein metabolism	Amino acid transport Protein synthesis	Protein breakdown
Lipid metabolism	Triglyceride uptake Lipogenesis	Lipolysis Fatty acid oxidation

Insulin Action

The actions of insulin on its principal target organs (i.e., muscle, fat, liver) have complex and coordinated effects on the metabolism of carbohydrates, proteins, and lipids and are mediated by its interaction with the insulin receptor. Insulin receptor signaling through insulin receptor substrate 1 and phosphatidylinositol 3-kinase is a major pathway in the mediation of insulin-stimulated glucose transport, notably by stimulating the translocation of the glucose transporter GLUT4 to the cell membrane. This pathway is also responsible for the vasodilator effects of insulin (through increased expression of endothelial nitric oxide synthase), which may contribute to glucose utilization by increasing nutrient delivery to tissues. Defects in these intracellular signaling pathways are an important cause of impaired insulin action, or "insulin resistance" (see section on impaired insulin action [insulin resistance] under pathobiology of type 2 diabetes).

The overall actions of insulin tend to promote uptake and storage of nutrients in the fed state and release of nutrients from body stores in the fasting state, as summarized in Table 229-5.

In the *postprandial period*, rising glucose levels simultaneously trigger insulin secretion and suppress glucagon release. The resulting rise in the insulin-to-glucagon ratio increases hepatic glycogen synthesis and inhibits release of glucose from the liver. Insulin stimulates glucose uptake into skeletal muscle and adipose tissue, promoting the synthesis of protein and triglycerides. In the *fasting state*, declining glucose levels inhibit insulin release, thereby increasing glycogenolysis and gluconeogenesis and the resulting delivery of glucose into the circulation. In states of absolute or relative insulin deficiency, inadequate basal insulin levels allow unrestrained hepatic glucose production, which results in fasting hyperglycemia. Inadequate insulin in the fed state impedes peripheral (predominantly skeletal muscle) glucose uptake, thereby contributing to postprandial hyperglycemia. Impaired suppression of hepatic glucose production also contributes to postprandial hyperglycemia in patients with diabetes (see also the section on type 2 diabetes).

TYPE 1 DIABETES

EPIDEMIOLOGY

Type 1 diabetes may be manifested at any age but most typically appears in childhood, especially around puberty. However, new cases of type 1 diabetes can appear at any time in life, and in the United States, approximately 30% of patients are diagnosed after young adulthood.[1]

Worldwide, the incidence of type 1 diabetes varies 50- to 100-fold, with the highest rates occurring in individuals of northern European descent. Both sexes are equally affected in childhood, but men are affected more commonly in early adult life. The incidence of childhood type 1 diabetes is rising rapidly in all populations, especially in the age group younger than 5 years, with a doubling time of less than 20 years in Europe. The increasing incidence of type 1 diabetes suggests a major environmental contribution, but the role of specific pathogenic factors remains largely unsettled. The distinction between type 1 and type 2 diabetes can become blurred in later life, and the true lifetime incidence of the condition is therefore unknown.

In Europe, the highest rates of childhood diabetes are found in Scandinavia, with an incidence for children from birth to 14 years of age ranging from 57/100,000 per year in Finland to 4/100,000 in Macedonia. In the United States, the overall annual incidence in youths is about 19/100,000. Prevalence rates are strikingly different among ethnic groups living in the same

geographic region, probably because of genetic differences in susceptibility to the disease. Early-onset diabetes carries a higher familial risk, and affected fathers are more likely to transmit type 1 diabetes to their offspring than affected mothers are, with risks being 6 to 9% and 1 to 3%, respectively.

Given that the United States does not have a systematic health registry and that its population is multiethnic, previous estimates of the prevalence and incidence of type 1 diabetes have been based on extrapolations from limited cohorts. The SEARCH for Diabetes in Youth multicenter study (funded by the Centers for Disease Control and Prevention and the National Institutes of Health) examined diabetes among children and adolescents in the United States. During 2008-2009, an estimated 18,436 people younger than 20 years in the United States were newly diagnosed with type 1 diabetes annually, and 5089 people younger than 20 years were newly diagnosed with type 2 diabetes annually. For those younger than 10 years, new cases of type 1 far outweighed type 2 (22.2/100,000 per year for type 1 diabetes vs. 0.8/100,000 for type 2 diabetes). Among youth aged 10 years or older, the rate of new cases of type 1 was about double that of type 2 (21.9/100,000 per year for type 1 diabetes vs. 11.0/100,000 for type 2 diabetes). Non-Hispanic white youth had the highest rate of new cases of type 1 diabetes in all age groups. Diabetes incidence rates by age and race/ethnicity are summarized in Figure 229-3.

Higher body mass index (BMI) is associated with younger age at diagnosis of type 1 diabetes, but this appears to be the case only in children with already compromised β-cell function. In addition, low birth weight may be a factor in accelerating the onset of type 1 diabetes, suggesting that the intrauterine environment may be an important determinant of age at onset for type 1 diabetes.

PATHOBIOLOGY

In type 1 diabetes, a complex interplay of genetic, environmental, and autoimmune factors selectively targets insulin-producing β cells and ultimately produces complete β-cell destruction. The role of genetic factors in type 1 diabetes has long been appreciated, emphasized by familial clustering with other autoimmune endocrine disorders and by concordance rates in identical twins of 30 to 40%. Because these concordance rates are not as high as in type 2 diabetes (i.e., >80%), environmental factors must clearly play a major role. Although the presence of an environmental trigger for type 1 diabetes is highly likely, even identical twins do not express identical T-cell receptor and immunoglobulin genes; as a result, total concordance might not be expected. Siblings who are HLA identical to the proband have a 12 to 15% risk for development of diabetes by the age of 20 years.

Although many of the genes linked to type 1 diabetes have yet to be identified, some are known. HLA genes, located on the short arm of chromosome 6, contribute about 50% of genetic susceptibility to type 1 diabetes. Two HLA class II haplotypes, DR4-DQ8 and DR3-DQ2, are present in about 90% of children with type 1 diabetes. The genotype containing both haplotypes carries the highest risk of diabetes (about 5%) and is most commonly seen in early-onset disease. In contrast, the DR15-DQ6 haplotype is highly protective, being found in only 1% of children with type 1 diabetes in contrast to 20% in the general population. HLA susceptibility haplotypes are overrepresented in adult-onset type 1, but at lower frequency than in classic type 1 diabetes in youth. Other genes likely contribute to the genetic susceptibility to type 1 diabetes. These include the insulin gene (on chromosome 11) and a number of other loci that are associated with other autoimmune conditions, suggesting the existence of common pathways predisposing to loss of self-tolerance. Another gene, *IFIH1*, located on chromosome 2, encodes a protein involved in innate immunity and plays a role in recognition of the RNA genomes of certain viruses. It is suggested that high IFIH1 levels might provoke exaggerated antiviral immune responses that predispose to autoimmunity. Many other genes have also been implicated, underscoring the polygenic nature of this disease.

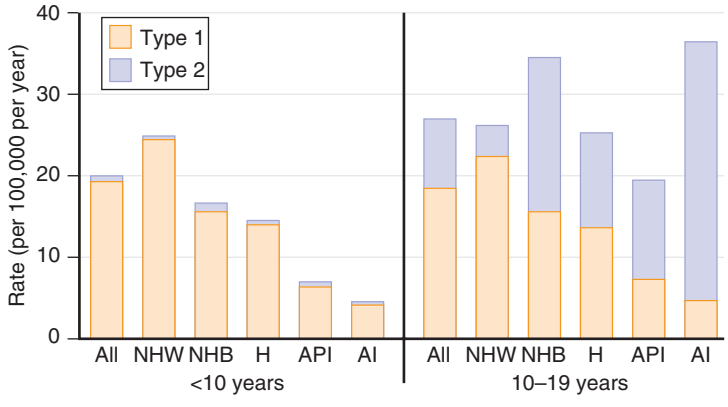

FIGURE 229-3. Rate of new cases of type 1 and type 2 diabetes among people younger than 20 years in the United States, by age and race/ethnicity, 2008-2009. AI = American Indians; API = Asian/Pacific Islander Americans; H = Hispanics/Latinos; NHB = non-Hispanic blacks; NHW = non-Hispanic whites. (From Centers for Disease Control and Prevention. *National Diabetes Statistics Report: Estimates of Diabetes and Its Burden in the United States, 2014.* Atlanta, GA: US Department of Health and Human Services; 2014. Source: SEARCH for Diabetes in Youth Study).

Historically, environmental causes of type 1 diabetes focused on viruses because of associations with seasonal pandemics of infections and rarely because of the isolation of a specific pathogen. Epidemics of mumps, rubella, and coxsackievirus infection have been associated with an increased frequency of type 1 diabetes. Moreover, specific and convincing rare examples of virus-induced diabetes have been reported. However, it is believed that virus-mediated β-cell damage is not responsible for the massive destruction of β cells but that it triggers an autoimmune response in genetically predisposed individuals. Thus, viruses may contain molecules that resemble a β-cell protein, and viral infection could thus nullify self-tolerance and trigger autoimmune responses.

It has long been recognized that about 80% of patients with new-onset type 1 diabetes have antibodies directed against various islet cell proteins, including insulin, glutamic acid decarboxylase (GAD65 and GAD67), and the secretory granule protein islet cell antigen 512 (IA-2). These antibody biomarkers have been important tools for studying the potential for early identification and prevention of total β-cell destruction in individuals susceptible to type 1 diabetes. Until the mid-1980s, it was mistakenly surmised that the autoimmune destruction of β-cells was mediated by these antibodies rather than their being epiphenomena, as is now understood. Rather, β-cell destruction is mediated by a variety of cytokines or by direct T-lymphocyte activity that causes apoptosis or cellular destruction. Both animal models and human pathologic studies have established that islet-targeted inflammatory cell infiltrates (termed insulitis) that are composed of $CD8^+$ and $CD4^+$ T cells, macrophages, and B cells are linked to the onset of diabetes. Over time, the islets become completely devoid of β cells and inflammatory infiltrates; α, δ, and pancreatic polypeptide cells are left intact, thus illustrating the specificity of the autoimmune attack on β cells.

A critical role for T cells is suggested by studies involving pancreatic transplantation in identical twins. Monozygotic twins with diabetes who received kidney and pancreas grafts from their nondiabetic, genetically identical siblings required little or no therapeutic immunosuppression. However, these patients eventually experienced a resumption of insulitis, with the subsequent recurrence of diabetes. Evidence implicating T cells in diabetes autoimmunity also derives from clinical trials using immunosuppressive drugs. Drugs such as cyclosporine or antibodies directed against a component of the T-cell receptor (anti-CD3) or that alter antigen presentation by B cells (anti-CD20) slow the progression of recent-onset diabetes, but this effect is not sustained if immunosuppression is withdrawn.

CLINICAL MANIFESTATIONS

It has been clearly established that type 1 diabetes has a long preclinical phase, best described in Figure 229-4. At the time of clinical diagnosis, about 10 to 20% of the original β-cell mass may still be functional. In most cases, overt hyperglycemia (and ketosis if it is present) may be precipitated by an unrelated medical illness or stress placed on an already-limited islet reserve, thus triggering the diagnosis. Typically, symptomatic hyperglycemia, manifested by polyuria, polydipsia, weight loss, and fatigue, occurs abruptly in an otherwise healthy child or young adult. For a minority of patients, the initial presentation may be diabetic ketoacidosis (DKA), which can occur if there is a delay in recognizing the symptoms of diabetes. Whereas the disease has an increased incidence in the winter months, classically attributed to respiratory viral infections, this seasonal pattern may be the result of illness-associated counter-regulatory hormones that drive hyperglycemia in individuals with already compromised β-cell function. Similarly, the coincidence of type 1diabetes with puberty has been attributed to insulin resistance associated with increases in sex and growth hormone secretion.

The diagnosis of diabetes is made according to glucose criteria (see Table 229-2). Measurement of anti–glutamic acid decarboxylase antibodies is sometimes performed, but the determination of type 1 etiology is generally

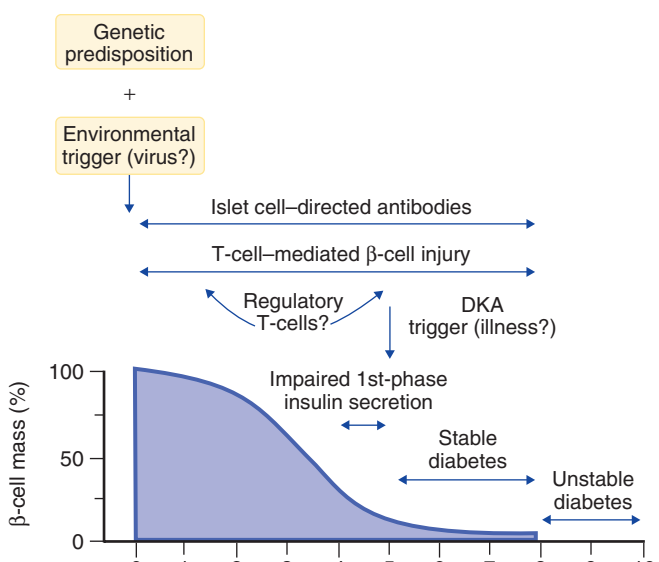

FIGURE 229-4 **Summary of the sequence of events that lead to pancreatic β-cell loss and ultimately to the clinical evolution of type 1 diabetes.** DKA = diabetic ketoacidosis.

made on clinical grounds. After initiation of insulin therapy and stabilization of plasma glucose levels, the patient may experience a period of weeks to months of relatively mild and easily controlled hyperglycemia. This so-called honeymoon phase of type 1 diabetes results from transient improvement in β-cell function and reflects the phenomenon of severe but not total β-cell destruction with ongoing (albeit reduced) insulin secretion. Ultimately, patients with type 1 diabetes experience progressive decline in insulin production, generally to undetectable levels after a few years. However, with highly sensitive C-peptide assays, low levels of insulin production have been detected in some patients with long-standing type 1 diabetes and are associated with more stable glycemic control and reduced risk of vascular complications.[2] In patients with onset of type 1 diabetes in adulthood, the clinical presentation may follow a more indolent course (termed latent autoimmune diabetes in adults), perhaps because β-cell mass declines at a slower pace. In fact, type 1 diabetes may be misdiagnosed as type 2 in many of these patients until the progression of insulin deficiency reveals the phenotype of permanent and complete insulin dependence.

TREATMENT

Rx

The key to successful treatment of type 1 diabetes is to achieve physiologic insulin replacement, that is, to replicate the normal and tightly regulated relationship between plasma glucose and insulin secretion. Although current technology can only mimic this normal physiology, substantial progress has been made to permit maintenance of relative euglycemia by many patients. Successful glucose management requires substantial commitment by the patient and health care practitioner.

Insulin Therapy

All patients with type 1 diabetes require insulin treatment to maintain life. The approach to insulin replacement in type 1 diabetes requires consideration of both basal insulin requirements (insulin required to maintain homeostasis in the fasting state) and insulin required for the influx of nutrients that occurs with meals. A variety of insulin preparations are available, which differ by their pattern of absorption after subcutaneous injection. Most currently used insulin preparations are analogues of human insulin that have been modified (usually by changing one or more amino acids) to alter pharmacokinetics to speed or to delay absorption (Table 229-6).

Patients with type 1 diabetes are treated with both a long-acting "basal" insulin and a shorter-acting "prandial" insulin at mealtime, by a multiple daily insulin injection regimen or a continuous subcutaneous insulin infusion pump. Typically, the daily insulin requirement for patients with type 1 diabetes is between 0.3 and 1.0 unit/kg/day, with half given as basal insulin and the remainder divided into pre-meal boluses. Prandial insulin doses are determined by meal carbohydrate content plus a "correction factor" if glucose is elevated before the meal. For example, a common approach is to use 1 unit for every 10 to 15 g of meal carbohydrate plus a correction factor of 1 unit to lower plasma glucose concentration by 20 to 50 mg/dL. However, insulin requirements are influenced by a number of factors (e.g., age, body size, insulin sensitivity) and vary substantially among patients; therefore, these algorithms need to be individualized. A number of mobile phone applications and computer programs are available to assist patients with dose calculation. Critical to the success of physiologic insulin replacement is the need for the patient to monitor blood glucose concentration, generally several times a day (see later).

A continuous subcutaneous insulin infusion pump using a short-acting insulin analogue can be programmed to deliver both a basal infusion and a preprandial bolus. Most insulin pumps contain an insulin reservoir attached by thin flexible tubing to a very small catheter that is inserted subcutaneously by the patient and changed every 2 or 3 days to avoid local inflammation and fibrosis, which can interfere with insulin absorption. The basal insulin delivery rate can be programmed to vary throughout the day and may be especially useful to prevent hyperglycemia associated with the "dawn phenomenon" (rising blood glucose levels in the early morning hours, thought largely to be due to increased growth hormone secretion). Most insulin pumps can be programmed to calculate prandial insulin doses, based on pre-meal glucose level and meal carbohydrate content, which is entered by the patient. However, in the event of pump malfunction, metabolic decompensation, including DKA, can develop within several hours because there is no subcutaneous reservoir of long-acting insulin. Successful use of an insulin pump requires a motivated and educated patient plus the support of a specialized diabetes team, including a certified diabetes educator. When it is used appropriately, continuous subcutaneous insulin infusion provides patients with maximal lifestyle flexibility and the best chance to achieve near-normal blood glucose levels.

Some patients who find adherence to a multiple injection or insulin pump regimen difficult can be treated with premixed "biphasic" insulin combinations, for example, a mixture of NPH and regular insulin given twice daily. This approach may be appropriate for patients with recent onset of type 1 diabetes who still maintain some endogenous insulin production. However, for most patients, this regimen is rarely optimal because it lacks flexibility and often increases the risk of hypoglycemia.

TABLE 229-6 INSULIN PREPARATIONS

TYPE OF INSULIN	ONSET OF ACTION	PEAK EFFECT	DURATION OF ACTION
BASAL INSULIN			
Glargine	~ 2 hours	None	~ 24 hours
Detemir	~ 2 hours	3-9 hours	6-24 hours
Degludec	~ 2 hours	None	~ 40 hours
NPH/NPL	~ 2 hours	6-12 hours	14-24 hours
PRANDIAL INSULIN			
Lispro, aspart, glulisine	5 to 15 minutes	45-75 minutes	2-4 hours
Regular	~ 30 minutes	2-4 hours	5-8 hours

NPH = neutral protamine Hagedorn; NPL = neutral protamine lispro.

Diet and Lifestyle Treatment

In type 1 diabetes, the focus of dietary planning is on accurate estimation of meal carbohydrate content to allow appropriate prandial insulin dosing. This can be approached by promotion of "carbohydrate consistency" from meal to meal and the use of relatively fixed pre-meal insulin dosing. A more flexible approach is for the patient to learn "carbohydrate counting," which specifies an insulin dose per amount of carbohydrate in the meal. With either approach, patients need to monitor the nutrient content of their meals. Avoidance of concentrated sweets and other high-carbohydrate meals, including those with a high "glycemic index," tends to facilitate accurate insulin dosing and to minimize postprandial glycemic excursions. In contrast to type 2 diabetes, most patients with type 1 diabetes are not overweight or obese, and calorie restriction is neither required nor helpful. A variety of eating patterns are considered acceptable, and recommendations for a "heart healthy" diet (low in saturated fat and cholesterol) are the same as for the general population.[3]

Glucose Self-monitoring

Successful management of type 1 diabetes requires consistent self-monitoring of blood glucose concentration by the patient or caregiver several times a day. Small portable meters with disposable strips are easy to use and reasonably accurate in most ambulatory care settings. Frequent testing (i.e., before meals and at bedtime) allows appropriate prandial insulin dosing and correction of unexpected hyperglycemia as well as detection or confirmation of hypoglycemia. Most current meters store a large number of readings, which

can be downloaded to a computer for analysis by the patient and health care team. Subcutaneous glucose monitors that provide continuous reading of interstitial glucose levels are available and are most commonly used in conjunction with an insulin pump. These monitors are most useful to determine glucose patterns and can be programmed to sound an alarm when the glucose level exceeds a preset range or rate of change. However, the accuracy of current monitors is such that they cannot replace conventional blood glucose monitoring for immediate treatment decisions. Research is progressing in the development of a "closed loop" system combining an insulin pump with a highly accurate continuous glucose monitor, allowing adjustments of insulin dosing without direct input of the patient. The first such device has received Food and Drug Administration approval for patients older than 16 years, but experience with this approach remains limited.

Patients with type 1 diabetes should be instructed to test urine ketones (with a reagent strip) in situations in which blood glucose concentration is unexpectedly and persistently elevated, especially if it is accompanied by symptoms suggestive of DKA (see section on diabetic ketoacidosis under hyperglycemic states in acute metabolic complications of diabetes). Small or trace amounts of urinary ketones are not cause for concern, but moderate or large amounts may indicate the onset of DKA and should prompt the patient to seek urgent medical attention.

Whole Pancreas and Islet Cell Transplantation

The ultimate goal of a "cure" of type 1 diabetes could most likely be achieved by successful transplantation of insulin-producing β cells. Whole pancreas transplantation has been performed for more than two decades and has a reasonable success rate, with 5-year graft survival rates of about 70%. However, the surgical procedure is complicated, and lifelong immunosuppression is required, as with any organ transplant. For these reasons, pancreas transplantation is generally reserved for patients who already have or are concurrently receiving a kidney transplant. In the absence of indications for kidney transplantation, pancreas-alone transplantation may be considered for patients who have a history of frequent, acute and severe metabolic complications (especially severe hypoglycemia) or severe and incapacitating psychosocial problems related to insulin therapy. Pancreatic islet cell transplants hold significant potential advantages over whole-gland transplants. However, at this time, islet cell transplantation is an experimental procedure, also requiring systemic immunosuppression, and is performed only within the setting of controlled research studies.

PREVENTION OF TYPE 1 DIABETES

Given that type 1 diabetes is an immunologically mediated disease, it has long been supposed that immune intervention should alter its natural history and perhaps even prevent it altogether. Furthermore, the significant heritability of type 1 diabetes suggests that treatment could target only susceptible individuals, and the existence of known biomarkers (antibodies that reflect disease activity as well as levels of insulin or C-peptide that reflect islet function) also lends credence to experimental immunologic treatments. Unfortunately, however, the major challenge for most immunologic interventions has been their lack of specificity for immune-mediated insulitis or the risks of spillover immune suppression in otherwise healthy persons. Given the experimental nature of all the tested therapies, we provide only a brief overview here.[4]

Prevention of type 1 diabetes can theoretically be undertaken at three stages: (1) in susceptible individuals before there is evidence of immune attack against islet cells (primary prevention); (2) in nondiabetic people who already have evidence of immune activation (antibodies, insulin defects) to prevent progression to actual diabetes (secondary prevention); and (3) in newly diagnosed patients in whom the goal is to slow the β-cell destructive process (tertiary prevention).

Avoidance of putative environmental triggers of islet autoimmunity (e.g., cow's milk) is one approach, and dietary supplementation with nutrients that may diminish islet autoimmunity (e.g., omega-3 fatty acids or vitamin D) has been attempted. On the basis of positive results of an earlier small cohort study, the first large trial of primary prevention by removal of cow's milk from the infant diet was initiated in 2002 and is expected to be completed in 2017. Secondary prevention trials have also been undertaken with oral, inhaled, or injected insulin and with nicotinamide, but the results have been equivocal. There are secondary prevention studies with teplizumab (an FcR-nonbinding anti-CD32 monoclonal antibody) and with abatacept (a costimulation modulator) under way. Several tertiary prevention studies (i.e., after the diagnosis of diabetes) have been published. Nonspecific immune interventions, such as cyclosporine, demonstrate that immunotherapy can indeed rescue β cells from ongoing destruction, but it is not an acceptable therapeutic alternative given that it preserves β-cell function only transiently and carries heightened risks of adverse effects, such as nephropathy. Anti-CD3 antibodies currently appear more promising and are being evaluated in clinical trials.

PROGNOSIS

Substantial progress has been made in recent decades in improving the prognosis for patients affected by type 1 diabetes. This is largely due to adoption of more intensive glucose control and more effective nonglycemic treatment of early stages of renal disease and retinopathy. Data from long-term follow-up of the intensively treated DCCT cohort showed that after 30 years' duration of diabetes, rates of serious diabetes complications were substantially lower than in historical controls, and less than 1% became blind, required renal replacement, or had an amputation due to diabetes. In the absence of renal disease, life expectancy for type 1 patients in the United States is comparable to that of the general population.[5] However, the mortality rate of all type 1 diabetic patients from age 35 onward is about twice as high as in nondiabetics even if the $HgbA_{1c}$ level is 6.9% or lower and becomes progressively higher for $HgbA_{1c}$ levels above 7.9%.[6] Analysis of nationally representative hospitalization and registry data has shown large reductions in the incidence of a broad spectrum of diabetes-related complications between 1990 and 2010 in the U.S. population of adults with diabetes; however, despite the substantial decline in the rates of diabetes-related complications in the past two decades, a large burden of disease persists because of the continued increase in the prevalence of diabetes.[7]

TYPE 2 DIABETES

EPIDEMIOLOGY

Type 2 diabetes is one of the most common chronic diseases, affecting more than 25 million people in the United States and an estimated 366 million worldwide. The prevalence of type 2 diabetes has been increasing in the United States, from approximately 3% of the population in 1995 to more than 9% in 2012. This increase is in part due to demographic shifts (i.e., the aging of the population), but incidence rates are also increasing and parallel the rise of overweight and obesity as well as increasingly sedentary lifestyles. A similar pattern is observed globally, with projections of 550 million (approximately half undiagnosed) to be affected by 2030. Although type 2 diabetes is being increasingly recognized in obese adolescents and young adults, older age remains a major risk factor for type 2 diabetes. More than one quarter of adults aged 65 years and older have diabetes, and another 50% have glucose or HbA_{1c} levels in the impaired or pre-diabetic range. Type 2 diabetes in the United States is more common among some racial and ethnic groups, with prevalence rates highest among non-Hispanic blacks (13%), Hispanics (12%), and American Indians (16%) and lowest among non-Hispanic whites (7%). Individuals from the Indian subcontinent (i.e., India, Pakistan, Bangladesh) and the Pacific Islands (e.g., Hawaii, Nauru, Samoa) also have high rates of type 2 diabetes. In general, men and women have about equal prevalence of type 2 diabetes.

PATHOBIOLOGY

Type 2 diabetes is characterized by variable defects in both insulin secretion and insulin action.[8] The underlying metabolic phenotype of type 2 diabetes is distinctly heterogeneous among individuals with the disease; some have a more pronounced defect in insulin secretion, and others have greater resistance to insulin action. The metabolic profile also varies within a given patient over time, as insulin secretion progressively declines with longer duration of disease. Although heterogeneous, type 2 diabetes is characterized in all cases by inadequate insulin secretion for the prevailing glucose level and degree of insulin sensitivity.

Impaired Insulin Secretion

The relative insulin deficiency characteristic of type 2 diabetes appears to be a consequence of both functional (i.e., reduced responsiveness to secretagogues) and quantitative (i.e., reduction in β-cell mass) factors. Insulin secretory capacity is difficult to directly measure in humans, but reductions of β-cell mass up to 60% are estimated to occur in type 2 diabetes. However, this alone is insufficient to explain insulin deficiency in type 2 diabetes, as evidenced by the observation that 50% surgical pancreatectomy does not lead to hyperglycemia in otherwise healthy individuals. Classic studies in diabetic patients have demonstrated failure of insulin secretion in response to glucose but a normal response to the amino acid arginine, providing further evidence

for the presence of a functional defect specific to glucose sensing. Abnormalities in the usual pulsatile and oscillatory patterns of insulin secretion and inefficient insulin biosynthesis have also been demonstrated in type 2 diabetes. For example, abnormal peptide processing results in increased secretion of intact proinsulin, which serves as a useful biomarker of future diabetes risk. Increased accumulation of amyloid also occurs within diabetic islets and may contribute to impaired secretory function. Ultimately, the β-cell defects in type 2 diabetes appear to be multifactorial, in part genetically determined (see later) but also influenced by environmental exposure, for example, to high levels of circulating glucose (glucotoxicity) and lipids (lipotoxicity). In addition, the β-cell defects are not static but worsen with increasing duration of diabetes.

Impaired Insulin Action (Insulin Resistance)

Resistance to the metabolic effects of insulin is also a characteristic although variable feature of type 2 diabetes. Hyperinsulinemia, thought to be a compensatory response to impaired insulin action, can be demonstrated in patients with pre-diabetes and in many patients with established type 2 diabetes, particularly early in its course. More precise techniques to measure insulin action (e.g., the euglycemic hyperinsulinemic clamp) have demonstrated resistance to insulin action primarily in peripheral tissues (reduced capacity to stimulate glucose uptake in muscle and fat) but also in the liver (reduced capacity of insulin to suppress hepatic glucose production). Insulin resistance is closely associated with obesity (see later) but also has genetic determinants, reflected by the observation that some obese patients do not have severe insulin resistance. Insulin resistance frequently occurs as part of a constellation of features, termed the metabolic syndrome, which include hypertension, abdominal obesity, dyslipidemia, glucose intolerance, and increased cardiovascular risk. Insulin resistance is also a common feature of the polycystic ovary syndrome.

There are multiple molecular mechanisms that can lead to resistance to physiologic insulin action, including pre-receptor defects (e.g., an abnormal insulin molecule) and abnormal insulin receptors (e.g., due to gene mutations). However, common forms of insulin resistance that occur in association with type 2 diabetes are generally due to post-receptor defects, that is, abnormalities in intracellular signaling. In insulin target tissues, signaling through the phosphatidylinositol 3-kinase pathway is responsible for translocation of the glucose transporter GLUT4, which is necessary for uptake of glucose into the cell. Several defects in this pathway have been described in humans with insulin resistance, including abnormalities in insulin receptor substrate 1 and protein kinase B/Akt2. Some specific gene mutations associated with insulin resistance have been identified, but insulin resistance may also be acquired as a consequence of obesity (see later), increases in circulating free fatty acids, certain medications (e.g., glucocorticoids, niacin), and inflammatory states.

Evidence from natural history and genetic association studies (see later) indicates that defects in either insulin action or insulin secretion can remain clinically silent. For example, insulin resistance can induce compensatory hyperinsulinemia, which early in the course of the disease is sufficient to maintain euglycemia. However, in individuals with inherited or acquired defects in β-cell function, this compensation ultimately fails and hyperglycemia ensues. Viewed another way, a subclinical β-cell defect may remain silent in the setting of normal insulin sensitivity but be manifested as hyperglycemia when acquired insulin resistance develops because of weight gain, aging, or some other factor. A unifying theory that explains the coexistence of defects in both insulin action and insulin secretion is appealing but so far elusive.

Genetics

The evidence for familial aggregation of type 2 diabetes is substantial and supports the presence of an important genetic influence. An individual with one parent with type 2 diabetes has a lifetime risk for development of type 2 diabetes of approximately 40%, with risk increasing to approximately 70% if both parents are affected. Further, the concordance rate among monozygotic twins is as high as 70%. The greater risk of type 2 diabetes among certain racial and ethnic groups also supports an important genetic component. The overall heritability of type 2 diabetes is estimated to be between 25 and 50%, although the specific gene or genes ultimately responsible for common forms of type 2 diabetes have not been established.[9]

Single-Gene Mutations Linked to Type 2 Diabetes Phenotype

A number of syndromes, termed maturity-onset diabetes of youth (MODY), characterized by impaired β-cell function have been recognized and linked to specific single-gene mutations. The phenotypes vary with the mutation but generally include early onset of relatively mild hyperglycemia in nonobese children or young adults and an autosomal dominant pattern of inheritance. Although not common (representing 1 to 3% of diabetes cases worldwide), their discovery has provided insight into the role of β-cell function in the more common forms of type 2 diabetes. MODY 2 is associated with a mutation of glucokinase, which acts as a glucose sensor within the β cell. In this case, higher levels of glucose are required to stimulate release of insulin from the β cell. MODY 3 is due to a mutation of the gene for hepatic nuclear factor 1α, which is involved in early pancreatic development and in the regulation of insulin gene expression. Other MODY forms (1, 4, 5, 6) are much less common, having been described in only a few families (Table 229-7).

TABLE 229-7 SINGLE-GENE MUTATIONS RESPONSIBLE FOR THE MORE COMMON FORMS OF MATURITY-ONSET DIABETES OF YOUTH (MODY)

	MUTATION	METABOLIC DEFECT	CLINICAL PHENOTYPE
MODY 2	Glucokinase	Decreased β-cell sensitivity to glucose	Mild nonprogressive hyperglycemia, may not require pharmacologic treatment; diabetes complications rare
MODY 3	Hepatic nuclear factor 1α	Abnormal regulation of β-cell gene transcription	Mild hyperglycemia, may be progressive; renal glycosuria; increased sensitivity to sulfonylurea drugs; susceptibility to microvascular complications

Other examples of single-gene mutations associated with specific diabetes syndromes include activating mutations of *KCNJ11* (encoding a portion of the β-cell sulfonylurea receptor), which causes severe neonatal diabetes, and *WFS1*, which encodes a protein that is defective in Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness).

Polygenic, Common Type 2 Diabetes

Common forms of type 2 diabetes are likely polygenic and multifactorial and represent a complex interaction between genes and environment. In the past several years, more than 50 genetic risk loci for common forms of type 2 diabetes have been identified by genome-wide association studies, but collectively these explain only about 15% of the heritability of the disorder. The gene with the strongest effect size to date (odds ratio for diabetes, 1.4), *TCF7L2*, is associated with reduced insulin secretion, as are the majority of other recognized gene variants. Others include a β-cell zinc transporter (ZnT-8; odds ratio, 1.15), the sulfonylurea receptor (*KCNJ11*; odds ratio, 1.1), and melatonin receptor 1B (*MTNR1B*; odds ratio, 1.10). A smaller number of gene variants associated with insulin resistance have been identified and include genes encoding peroxisome proliferator-activated receptor γ (odds ratio, 1.20) and insulin receptor substrate 1 (odds ratio, 1.10). Sequence variants in *SLC16A11*, a gene involved in intracellular lipid metabolism, were discovered to be a relatively common risk allele (odds ratio, 1.29) in Mexican populations. Current knowledge about genetic variants associated with type 2 diabetes risk is not useful for clinical disease prediction, offering no advantage to simple clinical tools based on traditional risk factors.

There is emerging evidence that epigenetic changes may play an important role in development of type 2 diabetes. Epidemiologic studies suggest that "metabolic programming" may occur in utero, with both fetal starvation and fetal overnutrition predisposing to diabetes in adult life. One example comes from experience with the Pima Indians, who have an extremely high prevalence of type 2 diabetes. Children born to mothers who were diabetic during their pregnancy had higher rates of adult diabetes than did children born to the same mothers before they became diabetic, suggesting that intrauterine exposure can have long-lasting metabolic effects. Studies of DNA methylation in animal models support this hypothesis, although human epigenome-wide studies are just now being conducted. Conversely, maternal undernutrition is associated with diabetes in offspring. Low birth weight has been linked to predisposition to CVD and diabetes in adulthood. According to the widely cited Barker hypothesis, nutrient deficiency in utero (e.g., due

to maternal starvation or placental insufficiency) impairs development of the endocrine pancreas, leading to inadequate insulin production later in life.[10] The available data suggest that maternal nutrition may play an important role in metabolic programming, resulting in increased diabetes susceptibility in adulthood.

Obesity

The presence of overweight or obesity (Chapter 220) substantially increases the risk for type 2 diabetes and likely accounts for the dramatic increase in diabetes prevalence during the past several decades. In fact, the presence of overweight or obesity is the single most important clinical predictor of type 2 diabetes, particularly for young or middle-aged individuals. The relationship between BMI and type 2 diabetes is linear, and increased risk can be observed even within the BMI range defined as normal (<25 kg/m^2). Related factors, such as sedentary lifestyle and diet (increased consumption of foods with high glycemic load, increased *trans* and saturated fat), may also contribute to diabetes risk, independent of BMI. Distribution of body fat also plays an important role, with visceral adiposity (as assessed by waist circumference or waist-to-hip ratio) being a particularly strong diabetes risk factor in Asian populations, who tend to develop type 2 diabetes at a lower BMI than some other racial or ethnic groups do. Ectopic accumulation of adipose tissue in the liver, often manifested as nonalcoholic fatty liver disease, is also strongly associated with increased diabetes risk.

The increase in adipose tissue mass impairs insulin action by a number of proposed mechanisms, including alterations in fatty acid metabolism, accumulation of triglycerides in the liver, and low-grade systemic inflammation. Adipose tissue macrophages produce proinflammatory cytokines, including tumor necrosis factor-α and interleukin-6, which can interfere with insulin signaling. Obesity is also associated with reduced levels of the fat-derived peptide adiponectin, which exhibits both anti-inflammatory and insulin-sensitizing properties. The increase of circulating free fatty acids that is characteristic of obese states can interfere with insulin action in skeletal muscle and liver, and increased intramyocellular lipid is also associated with insulin resistance. Further, increased lipid accumulation in pancreatic islets may lead to impaired insulin secretion. Interestingly, some obese individuals have apparently normal insulin sensitivity and glucose metabolism, sometimes referred to as the obesity paradox. The mechanisms that may protect someone from the diabetogenic effects of excess adiposity are not known, but intact cardiorespiratory fitness may play a role.

CLINICAL MANIFESTATIONS

Typical Type 2 Diabetes

The classic hyperglycemic symptoms of polyuria, polydipsia, and weight loss occur when the renal threshold for glucose reabsorption (~180 mg/dL) is exceeded and glycosuria with osmotic diuresis occurs. Therefore, patients may have plasma glucose concentration that is elevated but below this threshold, for years if not for decades, before specific symptoms appear. In the current era, many patients are found to have diabetes during routine screening or in the course of investigation for another disorder (typically, CVD). The initial presentation for some patients may be severe decompensated hyperglycemia, with profound dehydration, electrolyte imbalance, and plasma glucose levels of 400 mg/dL or higher, with the most striking examples being hyperosmolar hyperglycemic state (HHS) and DKA (see corresponding sections later).

A key feature of type 2 diabetes is that the metabolic defects are not static but tend to worsen over time. A patient early in the course of type 2 diabetes may maintain acceptable glucose control with simple dietary modification and modest weight loss. For many patients, these measures alone fail over time, and combinations of oral medications and often insulin therapy become necessary to control blood glucose levels.

Although the defining clinical feature of type 2 diabetes is hyperglycemia, it is actually the vascular complications of the disorder that cause the greatest morbidity and mortality. For a minority of patients, the initial clinical presentation of diabetes may be the presence of diabetic microvascular complications (retinopathy, neuropathy, nephropathy), which usually indicates many years of unrecognized hyperglycemia. More typical is the insidious onset of symptomatic microvascular complications after many years of diabetes, especially if it is poorly controlled.

Atypical Diabetes

DKA may be the initial clinical presentation for a minority of patients with type 2 diabetes, who subsequently recover β-cell function and do not require insulin treatment. This entity, referred to as ketosis-prone type 2 or Flatbush diabetes (named for the New York City neighborhood where it was first described), appears to be more common among African Americans and some other ethnic minorities. These patients typically lack markers of β-cell autoimmunity and have a strong family history of type 2 diabetes. Once the initial episode of DKA is treated and glucose levels stabilize, patients may have near-normoglycemic remissions lasting many years. The pathogenesis of this form of diabetes is not clear, but a unique β-cell predisposition to glucose desensitization ("glucose toxicity") has been proposed.

Gestational Diabetes

Diabetes that appears for the first time during pregnancy and typically regresses after delivery is termed gestational diabetes (Chapter 239). Women who develop gestational diabetes usually have risk factors including overweight or obesity, older age (>30 years), and a family history of type 2 diabetes. The majority will develop permanent type 2 diabetes during their lifetime. Hormonal changes (increases in placental lactogen, estrogen, progesterone) induce insulin resistance during pregnancy and may uncover latent β-cell defects in predisposed women. Babies born to mothers with diabetes mellitus are at risk for a number of adverse outcomes, especially macrosomia but also preterm birth, neonatal hypoglycemia, and hyperbilirubinemia. Routine screening, with an oral glucose tolerance test, of all pregnant women at 24 to 28 weeks of gestation is currently recommended. Because glucose levels tend to be lower than in the nonpregnant state, separate criteria have been developed for the diagnosis of diabetes in pregnancy. These include the presence of any of the following: fasting glucose concentration of 92 mg/dL or higher; glucose concentration of 180 mg/dL or higher at 1 hour or 153 mg/dL or higher at 2 hours after a 75-g oral glucose load. Aggressive glycemic control has been shown to reduce adverse pregnancy outcomes, including macrosomia and traumatic delivery, although its effects on long-term outcomes in offspring have not been established. Medical nutrition therapy is recommended for all women with gestational diabetes, with emphasis on moderate carbohydrate intake and avoidance of excessive weight gain. If diet modification is inadequate to maintain euglycemia, insulin has historically been considered first-line pharmacologic treatment for gestational diabetes. Oral diabetic medications, including glyburide and metformin, are increasingly being used to treat gestational diabetes, although they are not approved for this indication by the U.S. Food and Drug Administration. After delivery, women with gestational diabetes should continue to be observed for the development of type 2 diabetes.

TREATMENT

Effective treatment of type 2 diabetes is uniquely challenging because it encompasses management of lifestyle factors (including diet, exercise, and weight control), use of multiple oral or injectable medications, self-monitoring of blood glucose concentration, and surveillance and treatment for acute and chronic diabetic complications. The active participation of the patient in this complex program is critical for successful diabetes management, and many patients benefit from participation in a program of diabetes self-management education.

Goals of Therapy Including Glucose Targets

The primary goals of diabetes management are to prevent symptomatic hyperglycemia and hypoglycemia and to prevent the vascular complications associated with diabetes (see later section on chronic vascular complications). Intensive glycemic control (near-normoglycemia) has been shown to reduce microvascular and neuropathic complications of diabetes but not CVD or mortality.■ The current consensus view is that lowering of the HbA_{1c} level to 7% or below is an appropriate goal for most patients with diabetes. More stringent glycemic control (HbA_{1c} level close to the normal range) may be appropriate for some individuals (e.g., young patients with short duration of disease) if it can be achieved without excessive hypoglycemia. Conversely, less stringent goals may be suitable for patients with established vasculopathy, significant comorbidities, or reduced life expectancy. Generally accepted targets for fasting and postprandial glucose levels are 70 to 130 mg/dL and less than 180 mg/dL, respectively. Glycemic targets during pregnancy are different, in part because plasma glucose levels normally are lower during pregnancy and because of the risk of adverse fetal outcomes with even modest hyperglycemia (Table 229-8).

Diet and Lifestyle Management

Dietary recommendations for patients with type 2 diabetes have varied over the years and in the past included strict avoidance of sugars and the use

TABLE 229-8 RECOMMENDED GLYCEMIC TARGETS FOR ADULTS WITH DIABETES

	FASTING GLUCOSE LEVEL	POSTPRANDIAL GLUCOSE LEVEL	HbA_{1c}
Nonpregnant adults	70-130 mg/dL	<180 mg/dL	<7%
Gestational diabetes	≤95 mg/dL	<140 mg/dL (1 hour after meal) or <120 mg/dL (2 hours after meal)	—
Pre–gestational diabetes	60-99 mg/dL	100-129 mg/dL	<6%

Modified from American Diabetes Association. Standards of medical care in diabetes—2014. *Diabetes Care.* 2015;38(Suppl 1):S33-S40.

of specific diet plans (e.g., "exchange systems") that provided prescribed amounts of carbohydrate, fat, and protein. Current approaches for most patients focus on calorie restriction to achieve and to maintain modest (approximately 5 to 10% of body weight) weight loss, moderate carbohydrate intake, and avoidance of concentrated sweets and foods high in saturated fats and cholesterol. An optimal macronutrient distribution for patients with type 2 diabetes has not been established, and individualization of nutrition plans, depending on such factors as renal function, weight status, and the patient's preference, is recommended. Evidence suggests that a low-fat, low-carbohydrate (Atkins-type) diet and a Mediterranean-type diet can each be effective in promoting weight loss and improving glucose control in patients with diabetes. Moderate alcohol consumption is not prohibited, with the proper consideration of calorie intake (7 kcal/g) and hypoglycemia risk if alcohol is consumed without food, particularly in insulin-treated patients. Referral to a registered dietitian for medical nutrition therapy should be considered for patients newly diagnosed with type 2 diabetes and those who are not achieving glycemic or weight targets.

Regular exercise is an important but often overlooked component of diabetes management. Both aerobic exercise and resistance training can improve blood glucose control, even in the absence of significant weight change. Current recommendations are for a minimum of 150 minutes per week of moderate-intensity physical activity, such as brisk walking, biking, or swimming, and muscle-strengthening exercises two or three times per week. Assessment of cardiovascular status before beginning of an exercise program should be considered for selected patients, but routine screening (e.g., with an exercise stress test) of asymptomatic patients is not recommended. The presence of some diabetic complications may require restriction of certain activities. For example, in patients with proliferative retinopathy, vigorous aerobic or resistance exercise could precipitate retinal hemorrhage or detachment. The presence of significant sensory loss due to peripheral neuropathy can increase the risk of foot injury, including skin ulceration and Charcot joint destruction. Use of proper footwear and careful foot inspection are recommended, and avoidance of weight-bearing exercise may be required for high-risk patients. Finally, exercise-induced hypoglycemia can occur in patients treated with insulin or some secretagogues (i.e., sulfonylureas) and may require adjustment of the medication regimen or added carbohydrate before exercise.

Bariatric Surgery

Weight loss is considered the cornerstone for treatment of patients with type 2 diabetes, the majority of whom are overweight or obese. It has been clearly shown to improve glucose control. As expected, diabetic patients who undergo bariatric (weight reduction) surgery (Chapter 220) also show improvement in glucose control, which in some cases is dramatic. Improvements in glycemia often occur almost immediately after surgery, before significant weight loss has occurred, and appear to be related to changes in gut hormones (including GLP-1 and GIP) or bile acid metabolism. Many patients are able to discontinue diabetes medications, and diabetes remission rates above 50% have been reported. Among obese patients with uncontrolled type 2 diabetes, 3 years of intensive medical therapy plus bariatric surgery was reported to result in glycemic control in significantly more patients than did medical therapy alone; bodyweight, use of glucose-lowering medications, and quality of life also showed more favorable results at 3 years in the surgical groups.

Pharmacologic Therapy

Although weight control and nutrition form the foundation of effective management, most patients with type 2 diabetes will require use of pharmacologic agents, often multiple, to maintain recommended levels of glycemic control. During the last two decades, several new classes of drugs, targeting different metabolic pathways, have become available for treatment of type 2 diabetes. However, some of the most effective drugs are the oldest, and the long-term safety profile of newer agents remains to be established. Medications can be broadly categorized as those that enhance insulin availability (insulin and insulin secretagogues), those that enhance insulin action, or a miscellaneous group with other targets. Insulin therapy is also covered later and in the section on type 1 diabetes.

Insulin Sensitizers

Metformin

The biguanide drug metformin is the most widely used antidiabetic medication and is considered preferred initial therapy for patients with type 2 diabetes. The pleiotropic effects of metformin are thought to be mediated primarily through inhibition of mitochondrial complex 1 (i.e., effects on mitochondrial oxidative phosphorylation and cellular energy charge) and, in part, through regulation of the activity of 5′-adenosine monophosphate–activated protein kinase and the mammalian target of rapamycin. Metformin lowers glucose levels primarily through suppression of hepatic glucose production, but it also may enhance insulin sensitivity (improved insulin-mediated glucose uptake) and limit intestinal glucose absorption. Modest and sustained weight loss (~2 to 4 kg) is common with metformin.[11] Metformin is used orally twice a day, and extended-release forms are available for once-daily dosing. Hypoglycemia occurs rarely if at all with metformin monotherapy. The most common adverse effect is gastrointestinal intolerance (dyspepsia, diarrhea), which can be minimized by slow upward dose titration. Vitamin B_{12} malabsorption, leading to clinical B_{12} deficiency, has also been reported. The occurrence of lactic acidosis is the most serious although rare adverse effect, which occurs almost exclusively in patients with renal insufficiency and another precipitating factor, such as sepsis or shock. Renal function should be monitored periodically; metformin must be used with caution in those with an estimated glomerular filtration rate (GFR) of 45 mL/minute or lower and should be discontinued for an estimated GFR of 30 mL/minute or lower. Unique among available antidiabetic therapies, metformin was shown to reduce cardiovascular and all-cause mortality in the U.K. Prospective Diabetes Study (UKPDS), which adds to its appeal as a first-line agent. Metformin has also been used for diabetes prevention and for treatment of polycystic ovary syndrome.

Thiazolidinediones

The thiazolidinediones, which include rosiglitazone and pioglitazone, improve insulin-mediated glucose uptake and reduce hepatic glucose production. They bind to a nuclear receptor, peroxisome proliferator-activated receptor γ, and thus regulate the transcription of a variety of genes involved in carbohydrate and lipid metabolism. Thiazolidinedione therapy has pronounced effects on adipose tissue, reducing lipolysis, increasing fat mass, and causing redistribution of fat away from visceral to subcutaneous depots. Increases in circulating adiponectin, an adipokine with insulin-sensitizing and anti-inflammatory properties, may also play a role in the glucose-lowering effect of these drugs. Thiazolidinediones are given orally in once-a-day dosing. Common adverse effects include weight gain and fluid retention, including precipitation or worsening of congestive heart failure. Also reported have been an increase in fractures in postmenopausal women and increased risk of bladder cancer. The potential cardiovascular toxicity of rosiglitazone remains controversial, and its use has been restricted in many countries; these effects have not been observed for pioglitazone.

Insulin Secretagogues

Sulfonylureas

The sulfonylurea class of insulin secretagogues is among the oldest available oral antidiabetes drugs. Sulfonylureas currently in common use include glipizide, glyburide, and glimepiride; older sulfonylureas (chlorpropamide, tolbutamide) are still sometimes used outside of the United States. Their mechanism of action is to bind to the ATP-sensitive potassium channel in the β-cell membrane (at a site termed the sulfonylurea receptor), resulting in membrane depolarization and, ultimately, release of insulin from preformed secretory granules. Therefore, the presence of a sufficient mass of intact β cells is required for efficacy of these drugs. They can be used as monotherapy or in combination with other drugs. The major adverse effect of sulfonylureas is their potential to cause hypoglycemia because insulin secretion occurs regardless of ambient plasma glucose. Modest weight gain is also common. Results of a study conducted in the 1970s (University Group Diabetes Program) suggested that sulfonylurea drugs may increase the risk of cardiovascular events and mortality. These findings were not confirmed in other trials, but the issue remains controversial. Despite this, sulfonylureas are among the most widely used antidiabetic medications.

Glinides

Repaglinide and nateglinide are chemically distinct non-sulfonylurea insulin secretagogues that also bind to the ATP-sensitive potassium channel in the β-cell membrane. Their onset and duration of action are much shorter than those of sulfonylureas, and the frequency of fasting hypoglycemia may be less. They are administered orally before each meal, making them

somewhat less convenient than medications with a single daily dose but potentially providing an advantage for patients with inconsistent meal timing or content.

Incretin-Based Therapies/GLP-1 Agonists

Exenatide and liraglutide are analogues of the endogenous incretin hormone GLP-1 and stimulate insulin secretion by binding to GLP-1 receptors on β cells. These drugs augment glucose-stimulated insulin secretion and thus have less potential to cause hypoglycemia than sulfonylureas and glinides do. They also suppress hepatic glucose production (by reduction of glucagon secretion), delay gastric emptying, and suppress appetite, resulting in modest weight loss for many patients. GLP-1 agonists are given by injection once or twice a day, and a weekly long-acting formulation is also available. Major adverse effects include gastrointestinal intolerance (nausea and vomiting), which can be minimized by initiation with a low dose and gradual titration. An increased risk of acute pancreatitis has been reported with GLP-1 agonists (and DPP-4 inhibitors; see later), but the magnitude of the risk is uncertain and requires additional research. An increase in C-cell hyperplasia and medullary thyroid cancer was found in laboratory animals, although the relevance of this to humans is unclear.

Incretin-Based Therapies/DPP-4 Inhibitors

Inhibitors of dipeptidyl peptidase 4 (DPP-4), a ubiquitous serine protease, work by preventing the breakdown of endogenous GLP-1, thus prolonging its effects. DPP-4 inhibitors, including sitagliptin, saxagliptin, and linagliptin, are given orally in a single daily dose. Similar to GLP-1 agonists, they rarely cause hypoglycemia, but they are generally weight neutral and cause fewer gastrointestinal side effects. Concern about potential risk of pancreatitis and medullary thyroid cancer has also been raised but unconfirmed.

Other Pharmacologic Agents

SGLT2 Inhibitors

Canagliflozin and dapagliflozin are inhibitors of the sodium glucose cotransporter 2 (SGLT2) in the proximal renal tubule. This inhibition prevents the reabsorption of filtered glucose and results in glycosuria, which is accompanied by mild osmotic diuresis and modest weight loss. Experience to date with SGLT2 inhibitors is limited, and little is known about long-term efficacy and toxicity. The most common adverse effect is an increase in mycotic genital infections; hyperkalemia, urinary tract infections, and reductions in blood pressure have also been reported.

α-Glucosidase Inhibitors

Acarbose and miglitol are inhibitors of α-glucosidase enzymes in the intestinal lumen that are required for the breakdown and absorption of complex carbohydrates. Use of α-glucosidase inhibitors slows carbohydrate absorption in the small intestine, thus delaying the systemic delivery of glucose in the postprandial period and allowing better coordination with sluggish endogenous insulin secretion. α-Glucosidase inhibitors are given with meals, are weight neutral, and do not cause hypoglycemia when used as monotherapy. The major limiting factor for α-glucosidase inhibitor use is gastrointestinal side effects, predominantly flatulence and bloating due to the action of colonic bacteria on intestinal contents. Extremely slow dose titration may overcome this effect, but many patients cannot or will not tolerate these symptoms.

Pramlintide

Pramlintide is an analogue of the peptide amylin, which is co-secreted from the β cell along with insulin. The primary effects of pramlintide are to suppress hepatic glucose production in the postprandial period and to delay gastric emptying. Pramlintide is given by injection at mealtime and is approved for use in insulin-treated patients. Mild nausea and anorexia are common, which results in modest weight loss in some patients.

Bromocriptine

The dopamine agonist bromocriptine has been in use for many years as a therapy for Parkinson's disease and hyperprolactinemia. It was observed to have a glucose-lowering effect and has been approved as an antidiabetic drug. Its mechanism of action is thought to be through reduction in sympathetic nervous system activation, resulting in lower rates of hepatic glucose production and lipolysis. Its glucose-lowering effect is modest, and adverse effects (nausea, dizziness, weakness) are common.

Colesevelam

The bile acid–binding resin colesevelam was originally approved as a cholesterol-lowering drug and was also discovered to have a glucose-lowering effect. The mechanism of its antidiabetic action is not well understood but may involve enhanced availability of incretin hormones, including GLP-1. Colesevelam treatment requires two- or three-times-daily dosing and is accompanied by gastrointestinal side effects, notably constipation. The drug has a modest low-density lipoprotein (LDL)–lowering effect, but increases in triglycerides are common and may be limiting for some patients.

Insulin Therapy

Insulin treatment can be considered for patients with type 2 diabetes at any point in the course of the disorder, although typically it is used after "failure" of oral or other noninsulin therapies. Insulin may also be preferred therapy in specific situations, such as during hospitalizations (especially in the perioperative period) or in pregnancy. In contrast to patients with type 1 diabetes, patients with type 2 diabetes may be adequately controlled with basal insulin alone or in combination with other antidiabetic medications. Basal insulin is frequently used in combination with oral medications (e.g., metformin, DPP-4 inhibitors) or GLP-1 agonists (exenatide, liraglutide). However, reflecting the heterogeneity of type 2 diabetes, some patients may require physiologic insulin replacement similar to that used in type 1 diabetes, and insulin pump therapy is a safe and valuable option in patients who otherwise require multiple daily injections. Daily insulin requirements tend to be higher for patients with type 2 compared with type 1 diabetes, reflecting the existence of insulin resistance. Information about available insulin preparations and insulin regimens is provided in the section on insulin therapy under type 1 diabetes earlier and in Table 229-6.

Treatment Algorithms

Use of multidrug regimens is common in type 2 diabetes, and algorithms have been developed to guide therapy; however, the current evidence base to support these recommendations is limited. There is general agreement that metformin should be initial therapy for most patients and that subsequent drugs (when needed) are added to but do not replace metformin. The choice of a specific drug combination is driven by a number of factors, including efficacy, cost, side effect profile (e.g., hypoglycemia, weight gain), and preference of the patient (Fig. 229-5).

Metabolic Monitoring

Ongoing assessment of glycemic control is necessary to ensure optimal outcomes in patients with diabetes. Measurement of HbA_{1c}, which reflects mean glucose levels during the preceding 2- to 3-month period, should be performed routinely in all patients with diabetes, beginning at diagnosis and periodically thereafter. Quarterly tests should be done for patients whose therapy has been recently changed or who are not meeting glycemic goals. More stable patients can be tested twice a year. Self-monitoring of blood glucose levels is recommended for all patients using insulin and may be useful for any patient trying to achieve target glucose control. Monitoring for the development of vascular complications is addressed in the later section on chronic vascular complications.

Inpatient Management

Management of blood glucose levels during hospitalization is increasingly recognized as an important clinical issue, especially because 40 to 70% of hospitalized patients carry a concomitant diagnosis of diabetes. Frequently, diabetes is not the reason for admission, and attention to glucose management is secondary to other more critical medical problems. However, both hyperglycemia and hypoglycemia are associated with adverse outcomes in hospitalized patients, which has stimulated the development of algorithms and guidelines for inpatient glucose management, although the evidence base to support them is limited. Obviously, all patients with type 1 diabetes require continued insulin use during hospitalization.

Critically Ill Patients

After initial enthusiasm for intensive glucose control (maintenance of near-normoglycemia) for critically ill patients, more recent evidence suggests that it may be harmful, particularly when it is accompanied by hypoglycemia. Current guidelines recommend intravenous administration of insulin for critically ill patients in intensive care settings, with a goal of maintaining plasma glucose concentration between 140 and 180 mg/dL.[12] Application of standardized infusion protocols, which include frequent glucose monitoring, is recommended.

Non–Critically Ill Patients

The evidence base to support specific treatment guidelines for non–critically ill hospitalized patients is weak because this has not been systematically studied in randomized trials. However, there is agreement that subcutaneous administration of insulin is the preferred therapy to control glucose for most hospitalized (non–critically ill) patients with diabetes. Generally accepted targets are below 140 mg/dL for fasting glucose concentration and below 180 mg/dL for random or postprandial glucose concentration, if this can be achieved with minimal hypoglycemia risk. The patient's status needs to be reassessed frequently and insulin doses adjusted as needed to maintain target glucose levels. Use of basal insulin (see Table 229-6) is sufficient for many type 2 patients, but some may require the addition of prandial or corrective doses of short-acting insulin. However, prolonged dependence on insulin "sliding scales" to manage hyperglycemia should be avoided as this is rarely successful and carries increased risk of hypoglycemia. For stable patients who are eating consistent meals and those nearing hospital

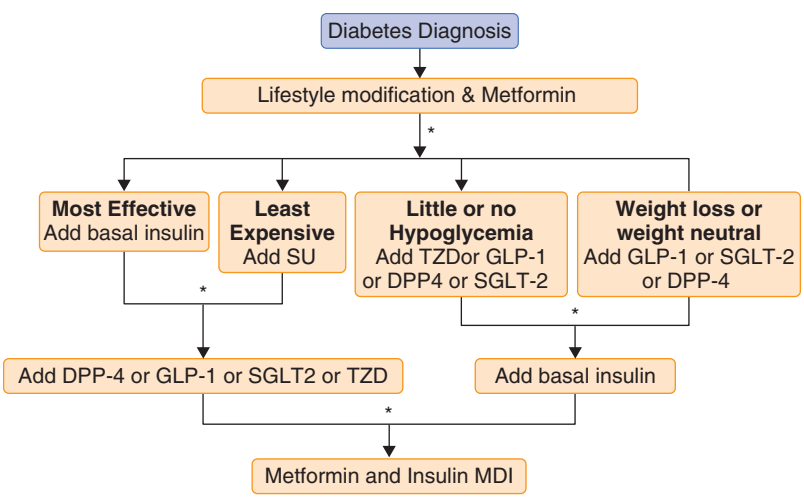

FIGURE 229-5. Algorithm for pharmacologic treatment of type 2 diabetes. DPP-4 = dipeptidyl peptidase 4; DPP-4-i = DPP-4 inhibitor; GLP-1 = glucagon-like peptide 1; GLP-1-RA = GLP-1 receptor agonist; HbA_{1c} = glycosylated hemoglobin; TZD = thiazolidinedione.

discharge, resumption of their usual oral or noninsulin injectable medications can be considered. Most patients with type 1 diabetes can be managed with their usual insulin injection regimen during hospitalization, but extra attention should be paid to hypoglycemia risk due to missed or delayed meals. Insulin pump therapy can be continued during hospitalization if the patient is able to direct its use and hospital personnel are sufficiently familiar with this form of treatment.

PREVENTION OF TYPE 2 DIABETES

The substantial burden, both human and societal, that accompanies type 2 diabetes and the difficulty in treating it effectively once it has developed make it an appropriate target for prevention. Further, the existence of a defined state of increased risk, pre-diabetes (i.e., impaired glucose tolerance and impaired fasting glucose), allows identification of patients who are most likely to benefit. Interventions that have been studied to date include lifestyle change (i.e., weight loss and exercise) and several antidiabetic medications.

Lifestyle Change

The largest and longest diabetes prevention study to date was the Diabetes Prevention Program, conducted in the United States beginning in the 1990s. Individuals at high risk for type 2 diabetes on the basis of the presence of overweight or obesity and pre-diabetic hyperglycemia (fasting glucose concentration of 95 to 125 mg/dL and 2-hour glucose concentration of 140 to 199 mg/dL) were randomly assigned to an intensive lifestyle program or a medication arm (metformin vs. placebo) and observed for a mean of 3 years. The lifestyle intervention stressed modest weight reduction (minimum 7% of body weight) with a reduced fat, hypocalorie diet and moderate-intensity physical activity for 150 minutes/week. Incident diabetes (determined by oral glucose tolerance test) was reduced by 58% compared with placebo, although the risk reduction was somewhat diminished (34%) with longer-term follow-up of the cohort. Successful weight loss was the major predictor of diabetes prevention, with every kilogram of weight loss reducing diabetes risk by 16%. Similar findings were reported from other studies, including the Finnish Diabetes Prevention Study. Even among individuals who did not lose weight, achieving the physical activity goal was associated with lower diabetes risk.

Medication

Several classes of antidiabetic drugs have been studied for diabetes prevention, including metformin, which reduced the risk of diabetes by 31% in the Diabetes Prevention Program. In smaller studies, the α-glucosidase inhibitor acarbose showed modest reduction in diabetes risk (~25%). The thiazolidinediones (e.g., troglitazone and rosiglitazone) have also shown diabetes prevention effects but are not widely used for this purpose because of concerns about their long-term safety. None of these drugs is approved by the Food and Drug Administration for diabetes prevention.

Recommendations

Lifestyle modification and metformin can both be recommended for individuals at high risk of diabetes. Candidates for prevention include those with defined glucose abnormalities (impaired glucose tolerance, impaired fasting glucose) and those with overweight or obesity plus an additional risk factor, such as family history of diabetes. The curriculum for the lifestyle intervention used in the Diabetes Prevention Program is available online (http://www.bsc.gwu.edu/dpp/lifestyle/dpp_part.html) and has been widely implemented in community settings, including the YMCA. Both lifestyle modification and metformin have shown positive effects on cardiovascular risk factors, but whether interventions to prevent diabetes will result in lower rates of microvascular or macrovascular complications remains to be determined.

Screening for Type 2 Diabetes

Individuals with risk factors for type 2 diabetes should be considered for screening for diabetes and impaired glucose regulation. This is especially important given that hyperglycemia can be present for years without specific symptoms and up to 30% of people with diabetes in the United States are undiagnosed. Screening will also allow identification of people with pre-diabetes, who may benefit from prevention interventions (Table 229-9).

Diabetes screening may be conducted with HbA_{1c} level, fasting glucose concentration, or oral glucose tolerance test, with the choice of test depending on the clinical setting and the preference of the patient. Screening should also be considered for asymptomatic children with BMI above the 85th percentile for age and sex plus any two of the following risk factors: family history of type 2 diabetes, high-risk race/ethnicity, or evidence of insulin resistance or features associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small-for-gestational-age birth weight). Pregnant women with risk factors for diabetes should be screened for undiagnosed diabetes at the first prenatal visit. Otherwise, a 75-g oral glucose tolerance test should be performed at 24 to 28 weeks of gestation to detect gestational diabetes.

PROGNOSIS

Type 2 diabetes is a chronic and, in most cases, progressive condition with potentially serious health consequences. However, it is also uniquely sensitive to modification of nutritional and lifestyle factors, which has been shown to be effective for both prevention and treatment of diabetes. Further, several classes of effective antihyperglycemic medications are available. There is substantial evidence that early intervention with a multifactorial approach to achieve and to maintain metabolic control, plus aggressive control of CVD

TABLE 229-9 CRITERIA FOR DIABETES SCREENING IN ASYMPTOMATIC ADULTS

Testing should be considered for any adult who is overweight (BMI >25 kg/m^2) and has at least one additional risk factor:
- Physical inactivity
- First-degree relative with type 2 diabetes
- High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
- Women with history of gestational diabetes or who delivered a baby weighing > 9 lb
- Hypertension
- HDL cholesterol < 35 mg/dL or triglyceride level > 250 mg/dL
- Women with polycystic ovary syndrome
- Clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)

In the absence of the above risk factors, testing should begin at the age of 45 years. If results are normal, screening should be repeated at least at 3-year intervals.

BMI = body mass index; HDL = high-density lipoprotein.

TABLE 229-10 CLASSIFICATION OF IATROGENIC HYPOGLYCEMIA IN TREATED DIABETIC PATIENTS

	CLINICAL FEATURES
Severe hypoglycemia	Episode with neurocognitive impairment that requires another person to administer treatment
Documented symptomatic hypoglycemia	Measured glucose concentration ≤70 mg/dL that coincides with sympathoadrenal or neurologic symptoms. Episode is self-managed.
Asymptomatic hypoglycemia	Measured glucose concentration ≤70 mg/dL, but without concomitant symptoms. Absence of symptoms may be due to hypoglycemia unawareness or hypoglycemia-associated autonomic failure.
Pseudo-hypoglycemia	Typical hypoglycemia symptoms, but with measured glucose concentration >70 mg/dL. Symptoms may be caused by resetting of counter-regulatory system in the setting of chronic poor glucose control.

risk factors, will substantially reduce the burden of diabetes complications and improve quality of life.

ACUTE METABOLIC COMPLICATIONS OF DIABETES

Hypoglycemia

Iatrogenic hypoglycemia in people with diabetes is the most frequent cause of low blood glucose concentration. Hypoglycemia (Chapter 230) affects the daily lives of persons with diabetes and can have a dramatic effect on quality of life. It can induce great fear, preclude comfortable engagement in routine activities (e.g., driving, uninterrupted sleep), and lead both patient and clinician to set higher glycemic targets and hence worse metabolic control. Thus, hypoglycemia continues to be a major limiting factor in the treatment of diabetes with most medications, particularly the use of insulin.[13]

Whereas insulin-stimulatory drugs (e.g., sulfonylureas) and parenteral insulin are the primary causes of drug-induced iatrogenic hypoglycemia, underlying defects in some parts of the counter-regulatory cascade contribute to the greater frequency and potential morbidity and mortality of hypoglycemia among patients with diabetes. The normal counter-regulatory response to hypoglycemia and the typical adrenergic and neuroglycopenic hypoglycemia symptoms are described in Chapter 230.

The threshold plasma glucose value that results in hypoglycemic symptoms is not constant; it is lower after recent antecedent hypoglycemia and higher in patients with poor glycemic control. However, there is general consensus that a self-monitored glucose level of 70 mg/dL or lower is a value that should alert the patient or caregiver, regardless of the presence of symptoms. A more detailed classification system to describe hypoglycemia has been established and widely adopted in research settings (Table 229-10).

However, these distinctions are not commonly used in clinical practice, and the severity of symptoms is often confused with severity of the actual prevailing physiologic state. Thus, a patient may feel intense symptoms at a glucose level of 50 to 60 mg/dL, for which there is no evidence of cognitive impairment or imminent danger, whereas potentially dangerous plasma glucose levels in the range of 20 to 40 mg/dL might go unappreciated owing to lack of classical symptoms. This also has implications for the epidemiology of hypoglycemia; most studies have reliably ascertained only the rates of severe hypoglycemia because other episodes are less likely to be documented. In type 1 diabetes, the DCCT reported 62 severe hypoglycemic episodes per 100 patient-years, although the actual risk may be higher in clinical settings. An episode of severe hypoglycemia can be the immediate cause of death in patients with type 1 diabetes, with recently reported mortality rates ranging from 4 to 10%. There remains uncertainty about the temporal relationship between hypoglycemia and death, and although prolonged episodes of very low circulating glucose (<15 mg/dL) can cause brain death, episodes of fatal hypoglycemia may be due to other mechanisms, such as ventricular arrhythmias. Episodes of severe hypoglycemia are much less common in patients with type 2 diabetes (see later).

In patients with treated diabetes, the initiation of the hypoglycemic event is due to mismatching of prevailing insulin levels to the underlying physiologic state of the individual. Thus, even absent overt insulin overdosage, factors such as missed meals, exercise, recent weight loss, alcohol, or insulin-sensitizing drugs create this mismatch and may set the plasma glucose concentration on a downward trajectory. In addition, the counter-regulatory systems that normally would counteract the decline of glucose to dangerous levels may be impaired. In patients with type 1 diabetes, glucagon release during hypoglycemia may become impaired shortly after the onset of diabetes, although glucagon is still secreted in response to other secretagogues, suggesting the presence of a functional defect. Epinephrine release during hypoglycemia also becomes progressively defective in type 1 diabetes; it is not triggered until the plasma glucose level is lower, and the maximal concentration of epinephrine released is significantly reduced. This decrease in epinephrine response during hypoglycemia is accompanied by an attenuated autonomic neural response, which results in the clinical syndrome of *impaired awareness of hypoglycemia*. Without autonomic symptoms, mild hypoglycemia may proceed unnoticed to more advanced and dangerous phases. Patients who have both impaired awareness of hypoglycemia and defective counter-regulation are at the greatest risk for development of severe hypoglycemia.

Hypoglycemia-associated autonomic failure in type 1 diabetes apparently results from antecedent episodes of mild hypoglycemia that further degrade the counter-regulatory response. In experiments in people without diabetes, recurrent or recent episodes of hypoglycemia are associated with reduced autonomic (epinephrine and norepinephrine), symptomatic, and cognitive functional responses to subsequent episodes of hypoglycemia, impairing the endogenous defense mechanisms and the clinical signs required for hypoglycemia detection. Because patients with type 1 diabetes already have a reduced counter-regulatory response, hypoglycemia-associated autonomic failure may play a role in the vicious circle of hypoglycemia begetting hypoglycemia. Meticulous avoidance of hypoglycemia is the only current approach proven to improve the epinephrine response and to reverse impaired awareness of hypoglycemia.

Compared with type 1 diabetes, type 2 diabetes is associated with a much lower risk of hypoglycemia. However, hypoglycemia remains a major clinical problem in this population. Episodes of severe hypoglycemia become progressively more common in patients with longer duration of type 2 diabetes, due in part to progressive β-cell failure and increased dependence on pharmacologic treatments. Use of sulfonylureas accounts for a substantial proportion of cases of drug-induced hypoglycemia, and severe episodes characterized by coma have been reported with all the agents in common use. The hypoglycemic potential of an agent is related to its potency, its plasma and biologic half-lives, its metabolism, and the concomitant use of other drugs. For example, liver disease prolongs the hypoglycemic actions of glyburide and glipizide because these drugs are partially metabolized in the liver. Similarly, renal disease may prolong the action of insulin (due to impaired insulin clearance) or potentiate the effects of hypoglycemic drugs by other mechanisms. Other antidiabetic agents, such as metformin, thiazolidinediones, and incretin-based drugs, have been associated with measureable albeit lower risks of hypoglycemia; however, symptomatic hypoglycemia is rare unless these drugs are used in combination with insulin. The elderly are at

particularly high risk for iatrogenic hypoglycemia because the intensity of adrenergic symptoms may be reduced and hypoglycemia-induced cognitive impairment greater.

CLINICAL APPROACH TO HYPOGLYCEMIA PREVENTION AND TREATMENT

Rx

Patients with diabetes need to be well informed about the symptoms of hypoglycemia and the factors that predispose to its occurrence: meal timing and content, exercise, and the expected time course of the drugs in use (especially insulin). Patients should also be made aware that the accuracy of some home glucose meters may be reduced in the hypoglycemia range and that the typical sympathoadrenal symptoms may wane during years of diabetes. A history of recurrent hypoglycemia should be carefully evaluated and attempts made to determine whether the patient had experienced events that went unrecognized. For example, reports of unexplained night sweats or a clouded mental state on arising in the morning may be due to nocturnal hypoglycemia and should be investigated. Patients should be encouraged to document episodes of hypoglycemia and to contact the care team if they have unexpected or more frequent episodes.

Table 229-11 lists several risk factors for severe hypoglycemia. Patients with these characteristics require greater vigilance, both in selection of treatment regimen and in the recognition and treatment of acute episodes.

Most mild or moderate episodes of hypoglycemia can be self-treated by ingestion of fast-acting carbohydrates such as glucose tablets, glucose gels, or food (juices, soft drinks, or a meal). The suggested amount of carbohydrate to be ingested is about 15 g, which will increase the plasma glucose concentration by about 15 mg/dL. Importantly, foods that are rich in fat delay glucose absorption and are thus less effective. If plasma glucose levels are still below 70 mg/dL and if symptoms have not abated after 15 minutes, the patient should take an additional 15 g of carbohydrate. Because the glycemic response to oral glucose is relatively transient, ingestion of a snack or a meal shortly after correction of hypoglycemia is recommended.

Parenteral treatment of hypoglycemia is recommended if the patient is unwilling or unable to ingest carbohydrates (e.g., due to impaired mental status) or if a patient has sulfonylurea- induced hypoglycemia (which may be prolonged). Intravenous administration of glucose (25 g) is the preferred treatment of hypoglycemia. Parenteral glucagon (1 mg subcutaneously) is an alternative, especially in patients with type 1 diabetes who may have to be treated by family members for severe hypoglycemia. Because glucagon stimulates secretion of insulin in addition to promoting glucose production, it is less effective in patients with type 2 diabetes.

Nocturnal hypoglycemia may be a particular problem for patients with type 1 diabetes. It may be asymptomatic and unsuspected because plasma glucose concentration is rarely measured during the night. Risk factors for nocturnal hypoglycemia include increased physical activity in the last 24 hours, certain insulin regimens (e.g., use of NPH or regular insulin), meal content (e.g., the amount of fat), and alcohol consumption. In addition, sleep is associated with a decrease in the autonomic response to hypoglycemia. Currently, the only practical approaches to detection of nocturnal hypoglycemia are regular nocturnal (3 AM) self-monitoring or the use of continuous glucose monitors with alarm features. Some patients with nocturnal hypoglycemia present with sleep disturbances, morning headache, chronic fatigue, or depression. Children in particular may present with seizures or enuresis. Strategies to prevent nocturnal hypoglycemia include eating "long-acting" bedtime snacks (slowly absorbed carbohydrate, such as uncooked cornstarch) and regular monitoring of blood glucose concentration at bedtime. The bedtime glucose level has been reported to be highly predictive of subsequent development of hypoglycemia during sleep.

TABLE 229-11 RISK FACTORS FOR SEVERE HYPOGLYCEMIA IN PATIENTS WITH DIABETES

Youth (children)
Elderly taking sulfonylurea drugs or insulin
Altered consciousness
Ethanol use
Strenuous exercise in the previous 24 hours
Recent antecedent hypoglycemia
Use of pentamidine, quinine, or nonselective β-blocker drugs
Concomitant illnesses, such as sepsis, or hepatic, renal, or cardiac failure
Type 1 diabetes with history of recurrent severe hypoglycemia
Recent rapid improvement in HbA_{1c} into the normal range

Hyperglycemic States

DKA and HHS are the most serious acute hyperglycemic complications of diabetes. DKA is typically associated with severe insulin-deficient states (i.e., type 1 diabetes). It may also occur rarely in type 2 diabetes under conditions of extreme stress, such as major infection or trauma or as a presentation of a variant of type 2 diabetes (ketosis-prone or Flatbush diabetes). On the other hand, HHS typically occurs in patients with type 2 diabetes. However, the distinction between the two clinical scenarios is sometimes blurred (e.g., patients with HHS may present with ketosis and acidosis), and these states may be considered as parts of the spectrum of severe metabolic decompensation. Despite aggressive treatment, mortality rates remain high for both conditions, approaching 5% for DKA and 15% for HHS. Mortality is associated with the extremes of age (i.e., the very young and the elderly) and comorbidities but, importantly, with the severity of the precipitating illness or event. Thus, in addition to correction of fluid and electrolyte imbalance and administration of insulin, treatment also includes prompt recognition of and therapy for any precipitating illness or event. A list of precipitating conditions commonly associated with DKA and HHS is shown in Table 229-12.

PATHOBIOLOGY

The pathogenesis of DKA and HHS mirrors the underlying respective forms of diabetes. The three fundamental biochemical features of DKA—hyperglycemia, ketosis, and acidosis—result from the combined effects of deficient circulating insulin and counter-regulatory hormone excess. This hormonal milieu promotes the delivery of substrates from muscle (amino acids, lactate, pyruvate) and adipose tissue (free fatty acids, glycerol) to the liver, where they are converted to glucose or to ketone bodies (β-hydroxybutyrate, acetoacetate, acetone). Glucose and ketones are thus released into the circulation at greater rates than their utilization, resulting in severe hyperglycemia (>250 mg/dL), ketoacidosis (arterial pH <7.30), and an osmotic diuresis that promotes dehydration and electrolyte loss. In HHS, despite comparable elevations of glucagon, the presence of some endogenous insulin modulates the ketosis even though the plasma glucose concentration in HHS typically exceeds 600 mg/dL, whereas in DKA it is usually more than 250 mg/dL.

In both states, fluid depletion plays a major role in causing dramatic elevations in circulating glucose. Indeed, the hyperosmolality accompanying DKA and HHS is best linked to the patient's level of neural and cognitive function, and treatment of both conditions depends on restoration of fluid balance. Finally, other factors have been invoked, including other hormones (such as epinephrine, growth hormone, and cortisol), proinflammatory cytokines (such as tumor necrosis factor-α, interleukin-1β, interleukin-6, and interleukin-8), and lipid peroxidation markers as well as plasminogen activator inhibitor 1 and C-reactive protein. Whether all these factors are simply "stress markers" reflecting the disordered metabolic state or true pathogenetic factors remains uncertain.

TABLE 229-12 PRECIPITANTS OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC STATE

MOST COMMON
Inadequate insulin treatment or noncompliance
New-onset diabetes
Infections
Myocardial infarction
OTHER PRECIPITATING FACTORS
Cerebrovascular accident
Acute pulmonary embolism
Acute pancreatitis
Intestinal or mesenteric thrombosis
Alcohol intoxication
Endocrinopathies: Cushing syndrome, thyrotoxicosis, acromegaly
Severe burns, hyperthermia, hypothermia
Drugs: clozapine, olanzapine, cocaine, lithium, sympathomimetics, corticosteroids, thiazide diuretics

DIABETIC KETOACIDOSIS

CLINICAL MANIFESTATIONS

DKA (Chapter 118) may signal the onset of type 1 diabetes, but changes in medical practice in the developed world during the past several decades have enhanced earlier diagnosis of type 1 diabetes, and now the majority of childhood cases are detected and treated before ketoacidosis occurs. Thus, DKA is more frequently seen in those with established diabetes, usually in the setting of coexisting illness or poor adherence. For example, a patient may be unable to maintain adequate hydration during an illness, such as a viral gastroenteritis, and may mistakenly omit insulin because of inability to eat. A key component of a diabetes treatment program is education in "sick-day" rules focused on home-based prevention of DKA (e.g., frequent blood glucose monitoring, serum or urine ketone testing, fluid intake, determination of insulin dosing or delivery problems). Behavioral factors may also be involved; some younger patients may omit insulin deliberately to promote weight loss or to call attention to a dysfunctional home situation. This should be suspected in cases of recurrent episodes of DKA.

The clinical history of DKA typically involves deterioration during several hours to days, with progressive polyuria, polydipsia, and other symptoms of hyperglycemia. Other common clinical features are weakness, lethargy, nausea, and anorexia. Nonlocalizing upper abdominal pain in the setting of DKA can mimic an acute abdomen. Reduced motility of the gastrointestinal tract or, in severe cases, paralytic ileus may further contribute to diagnostic confusion. Nausea and vomiting are symptoms that indicate the need for in-hospital treatment because they preclude oral fluid intake. Physical findings in DKA are mainly secondary to dehydration, hyperosmolality, and acidosis; these include dry skin and mucous membranes, reduced jugular venous pressure, tachycardia, orthostatic hypotension, depressed mental function, and deep, rapid respirations (Kussmaul breathing).

DIAGNOSIS

In DKA, glucose levels may vary from modestly elevated to more than 1000 mg/dL, serum bicarbonate concentration drops below 18 mEq/L, and there is an excess anion gap that is generally proportional to the decrease in serum bicarbonate (Table 229-13). Hyperchloremia may be superimposed if the patient maintains an adequate GFR and is able to exchange keto acids for chloride in the kidney. The degree of depression of arterial pH depends largely on respiratory compensation. In mild cases, the pH may range from 7.20 to 7.30; in severe cases, it can fall below 7.00. On occasion, a degree of superimposed metabolic alkalosis (e.g., caused by vomiting or diuretic use) may obscure the true severity of the ketoacidosis. An anion gap out of proportion to the fall of bicarbonate should suggest this possibility. Other laboratory abnormalities commonly seen in DKA include a reduced measured serum sodium concentration (due to hyperosmolarity and the resulting osmotic shift of intracellular water into the intravascular space), prerenal azotemia, and elevated serum amylase. The last is usually of nonpancreatic origin and can lead to an erroneous diagnosis of pancreatitis. Normal, elevated, or reduced concentrations of potassium, phosphate, and magnesium may exist when DKA is diagnosed; however, large deficits of these electrolytes invariably accompany the osmotic diuresis and become readily apparent during the course of treatment. The serum triglyceride concentration is frequently elevated, a reflection of deranged lipid metabolism in the setting of insulin deficiency. The white blood cell count is typically elevated; the hemoglobin and hematocrit may be elevated, reflecting volume contraction.

Special care should be taken in interpreting serum or urine ketone results. Because quantitative measurements of β-hydroxybutyrate and acetoacetate are not readily available, rapid diagnosis usually requires qualitative assessment of serum ketones by the use of serum dilutions and reagent strips (e.g., Ketostix) or tablets (e.g., Acetest), which depend on a nitroprusside reaction with acetoacetate. However, acetone reacts weakly with nitroprusside, and β-hydroxybutyrate does not react at all; thus, the results of qualitative testing for ketones can be misleadingly low. Furthermore, because of the presence of intracellular acidosis, β-hydroxybutyrate levels are often much higher than acetoacetate levels, which may further conceal the true degree of ketoacidosis. Conversely, after insulin therapy is begun, the nitroprusside reaction may give the "false" impression of sustained ketoacidosis for hours or even days. This results because nonacidic acetone is slowly cleared from the circulation and also because, as acidosis improves, β-hydroxybutyrate is converted to acetoacetate, giving the false impression that ketosis is worsening.

TREATMENT

Rx

An overview of the treatment of DKA and HHS is shown in Figure 229-6.

In the early hours of treatment, the primary considerations are to restore intravascular volume, to correct tissue hypoperfusion, and to restore insulin sensitivity. With DKA, large total body deficits of water (5 to 10 L), sodium (5 to 10 mEq/kg), and other electrolytes may exist (Chapter 118). These losses are even more profound in HHS, which typically develops during a longer time. Although water loss usually exceeds the loss of sodium, it is almost always preferable to begin fluid replacement with isotonic normal saline (0.9% NaCl solution) for efficient intravascular volume restoration. Fluid replacement regimens vary, but it is common to administer 1 L of normal saline within the first hour, followed by a continuous infusion with either 0.45% NaCl or 0.9% NaCl, depending on the corrected serum sodium concentration, the patient's hemodynamic status, and the clinical assessment of tissue perfusion. Likewise, the rate of infusion (commonly 250 to 500 mL/hour) should be adjusted according to both biochemical responses and the age and clinical status of the patient (e.g., oliguria or underlying CVD). In children, isotonic solutions are generally preferred because they are less likely than hypotonic solutions to accelerate water shifts into the intracellular space and contribute to cerebral edema. As the blood glucose concentration falls below 250 mg/dL, dextrose should be added to intravenous fluids to avoid later insulin-induced hypoglycemia because continued insulin delivery may be required to correct the persistent acidemia.

Although insulin resistance is present in both DKA and HHS, supraphysiologic doses of insulin are unnecessary and are more likely to provoke hypokalemia, hypophosphatemia, and delayed hypoglycemia. A typical insulin replacement regimen uses an intravenous bolus of 0.15 U/kg of rapid-acting (e.g., regular) insulin, followed by 0.1 U/kg/hour thereafter. Intravenous administration is the most predictable way to deliver insulin to target tissues, particularly in severely hypovolemic patients with reduced peripheral blood flow. If intravenous administration is not possible, intramuscular or subcutaneous routes of administration can be used. It is ideal if blood glucose levels fall at a steady and predictable rate (50 to 75 mg/dL/hour), so it is important to monitor blood glucose levels hourly during insulin therapy to ensure an appropriate rate of decline. Blood glucose levels should not fall too rapidly, especially in young children, in whom accelerated correction of plasma glucose concentrations has been associated with cerebral edema.

After a stable blood glucose level of 150 to 250 mg/dL is achieved, with resolution of the anion gap acidosis, subcutaneous administration of insulin can be started and the intravenous insulin infusion discontinued. With DKA, it is important to overlap the intravenous and subcutaneous routes by at least 1 to 2 hours to avoid the rebound ketoacidosis if insulin levels drop precipitously. After stabilization, and with resumption of oral food intake, long-term

TABLE 229-13 DIAGNOSTIC CRITERIA FOR DIABETIC KETOACIDOSIS (DKA) AND HYPEROSMOLAR HYPERGLYCEMIC STATE (HHS)

CRITERION	MILD DKA	MODERATE DKA	SEVERE DKA	HHS
Plasma glucose concentration (mg/dL)	≥250	≥250	≥250	≥600
Effective serum osmolality (mOsm/kg)	Variable	Variable	Variable	≥320
Urine or serum ketones (nitroprusside reaction)	Positive	Positive	Positive	Negative to small
Arterial pH	7.25-7.30	7.00-7.24	<7.00	>7.30
Serum bicarbonate (mEq/L)	15-18	10-15	<10	>15
Anion gap (mEq/L)	>10	>12	>12	Variable, usually <12
Typical mental status	Alert	Drowsy	Stupor or coma	Stupor or coma

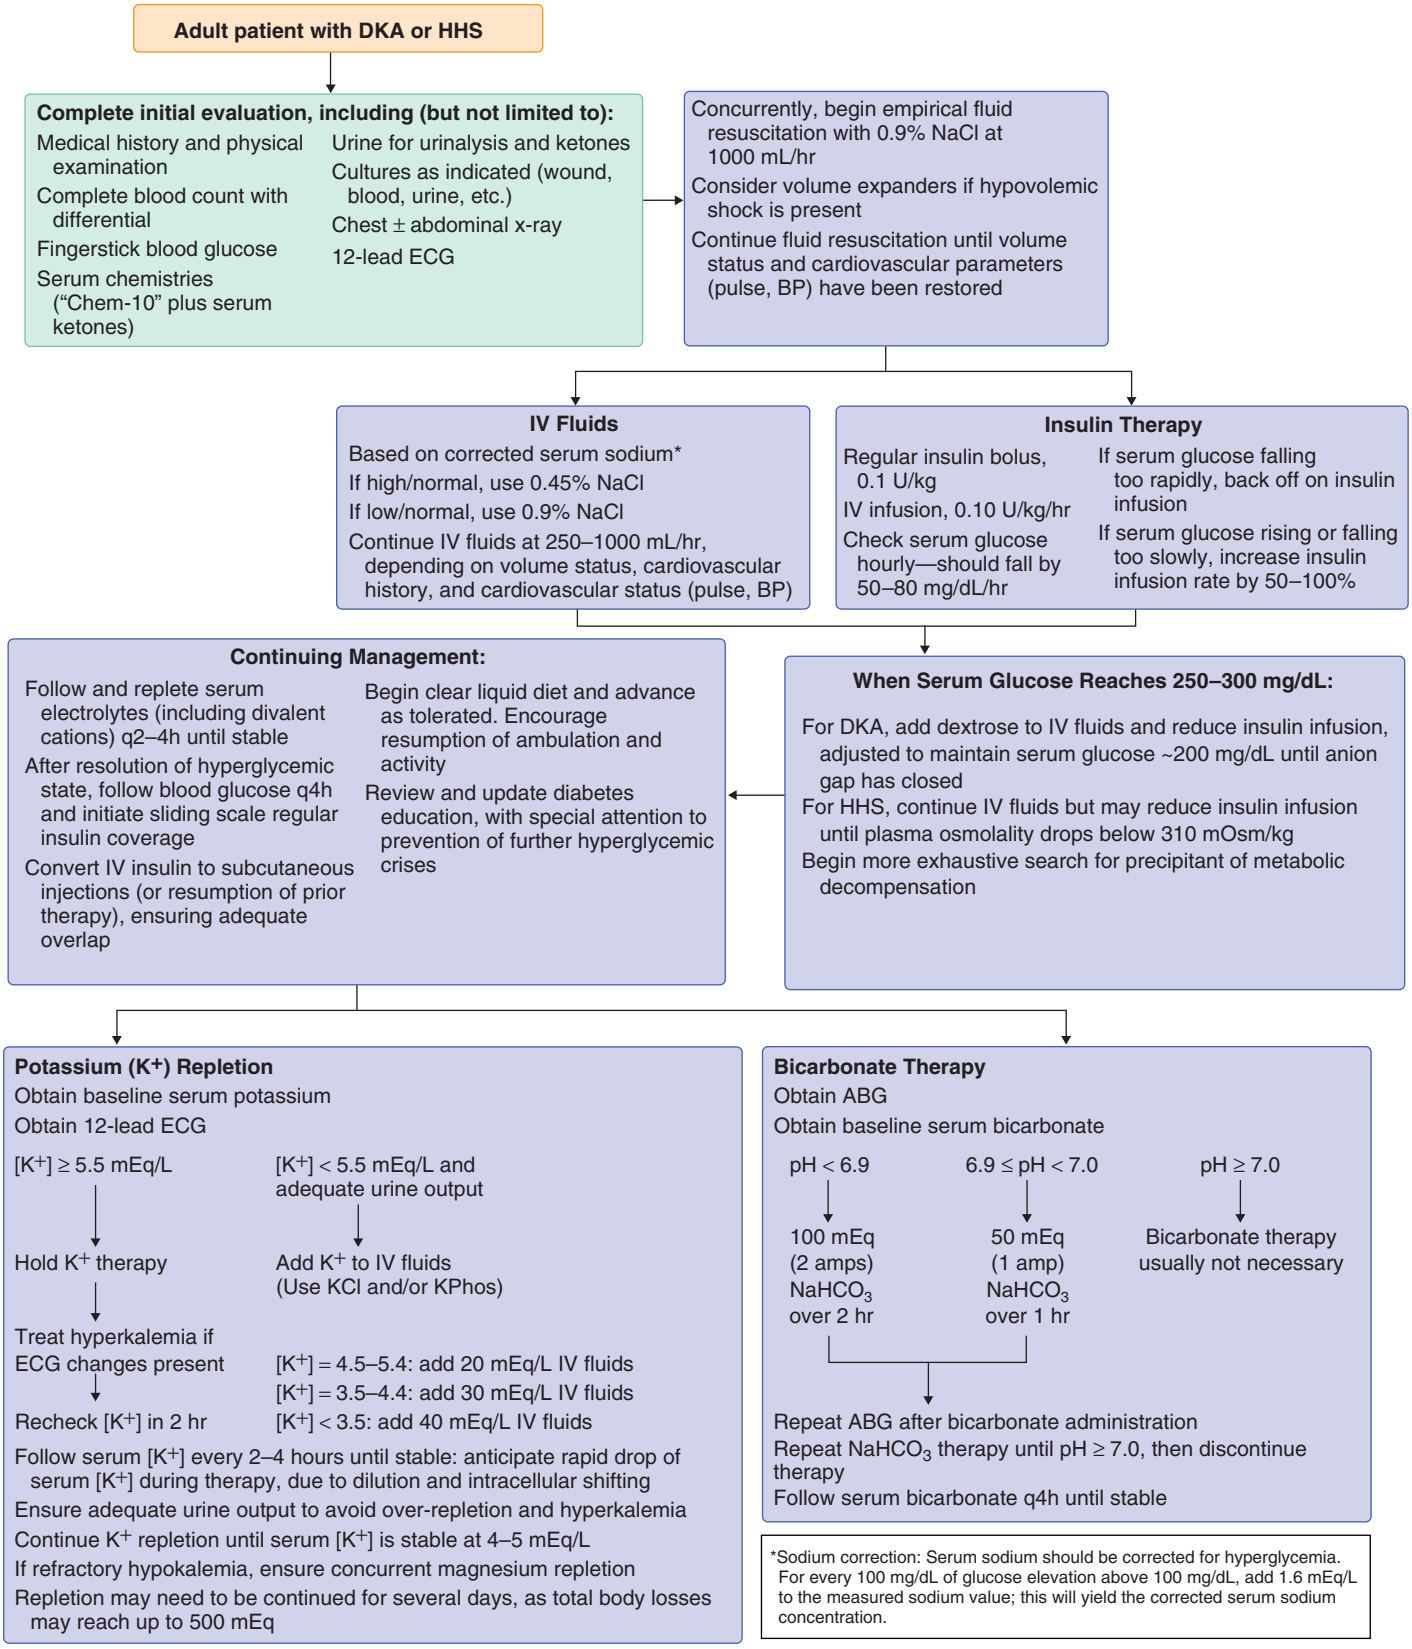

FIGURE 229-6. Management of diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic syndrome (HHS). ABG = arterial blood gas; BP = blood pressure; ECG = electrocardiogram; IV = intravenous.

medical management should be initiated (or resumed), with both long-acting and short-acting insulins, to approximate the desired outpatient regimen. A temporary "regular insulin sliding scale" should be avoided because such therapy is reactive to hyperglycemia and the swings in glycemia will not allow safe discharge of the patient. The eventual dosage and frequency of insulin depend on multiple factors, including body weight, comorbidity, insulin sensitivity, and effectiveness of prior therapeutic regimens.

Potassium replacement is usually required in DKA. Overt hypokalemia can result in muscle weakness, cramps, and nausea; both hyperkalemia and hypokalemia are associated with cardiac arrhythmias. Even absent severe hypokalemia, patients have a significant total body potassium deficit (about 3 to 7 mEq/kg), and measured serum potassium levels may be normal or high as acidosis and renal failure can mask the potassium deficiency. As insulin is infused, potassium will move into the intracellular space, further lowering

serum potassium to levels that may trigger life-threatening arrhythmias. In addition, fluid replacement causes extracellular dilution of potassium, leading to improved renal perfusion and increased urinary potassium excretion. Thus, potassium replacement should be initiated as soon as it is established that the patient is not in renal failure. A low potassium level (<3.5 mEq/L) requires prompt treatment with up to 40 mEq/hour, whereas "normal" serum levels (3.5 to 5.0 mEq/L) call for less aggressive repletion of potassium (10 to 30 mEq/hour), assuming adequate urine output. In patients who may have lost potassium for additional reasons, such as diuretic use or gastrointestinal loss, there will be need for greater potassium supplementation.

In the majority of patients with mild to moderate DKA, keto acids clear spontaneously with standard therapeutic measures, and correction of the pH with alkali (as bicarbonate) is unnecessary. Suppression of lipolysis by insulin reduces free fatty acid flux to the liver and blocks ketogenesis, and circulating keto acids are then cleared or oxidized, with subsequent regeneration of bicarbonate and restoration of arterial pH. However, in cases of severe acidosis (pH <6.9 to 7.0), bicarbonate administration may be indicated if the clinical picture dictates (e.g., hypotension that is unresponsive to fluids, cardiac dysfunction, respiratory exhaustion). Bicarbonate therapy should be used with caution and only at the minimal doses required to stabilize the patient because it can further provoke hypokalemia. In addition, by causing a sudden left shift of the dissociation curve for oxyhemoglobin, bicarbonate may impair oxygen delivery to the tissues. Therefore, if alkali therapy is given, small amounts should be administered slowly: 50 mEq of $NaHCO_3$ during 1 hour for arterial pH 6.9 to 7.0, and 100 mEq during 2 hours for pH below 6.9. After bicarbonate administration, arterial pH (and serum potassium levels) should be rechecked every 2 hours, and alkaline therapy should be discontinued when the pH rises above 7.0.

In the setting of DKA, phosphate losses average 3 to 7 mmol/kg; magnesium losses reach 1 to 2 mEq/kg. Phosphate is shifted extracellularly during hyperosmolar states, so initial serum levels may be falsely elevated and may drop rapidly during therapy. Complications of hypophosphatemia generally occur at serum levels below 1.0 mg/dL and include respiratory and skeletal muscle weakness, impaired cardiac systolic performance, and hemolytic anemia. Phosphate repletion should be used in patients with serum phosphate levels below 1.0 mg/dL and in patients with evidence of cardiac or respiratory compromise, hypoxia, or hemolytic anemia. An effective means of replacing phosphate is to replace one third to one half of the potassium losses (discussed previously) as potassium phosphate. In severe hypophosphatemia, cautious intravenous administration of additional small amounts of potassium phosphate may be necessary. Because of calcium binding, hypocalcemic tetany may complicate phosphate therapy unless magnesium supplements are also provided; for this reason, serum calcium, phosphate, and magnesium levels should be monitored during any phosphate infusion.

HYPEROSMOLAR HYPERGLYCEMIC SYNDROME

CLINICAL MANIFESTATIONS

The metabolic state formerly known as the hyperglycemic hyperosmolar nonketotic state or coma has been renamed the *hyperosmolar hyperglycemic syndrome* (HHS) to highlight two important points: (1) ketosis (and acidosis) may in fact be present to varying degrees in HHS, and (2) alterations in sensorium most commonly occur in the absence of coma. In fact, only 10% of HHS patients present with frank coma, and an equal percentage show no signs whatsoever of mental status change. Major risk factors for HHS include older age (most cases occur in patients aged 65 years and older) and impaired cognition (i.e., impaired ability to recognize thirst or to obtain access to water).

As shown in Table 229-13, the hallmarks of the HHS are severe hyperosmolarity (>320 mOsm/L) and hyperglycemia (>600 mg/ dL). Severe hyperglycemia occurs because patients cannot consume enough liquid to keep pace with a vigorous osmotic diuresis. The resulting impairment in renal function eventually further reduces glucose excretion through the kidney, leading to remarkable blood glucose elevations, sometimes exceeding 1000 mg/dL. In contrast to DKA, even though glucose concentrations are generally higher, severe acidosis and ketosis are usually absent in the HHS. This is probably explained by the presence of some residual insulin secretory capacity that is sufficient to suppress lipolysis and to avoid significant keto acid production. However, some type 2 patients with depressed endogenous insulin secretion may be unable to suppress ketone production fully in the face of elevated counter-regulatory hormones produced by physical illness. However, because HHS patients have higher portal vein insulin concentrations than do patients with DKA, keto acid production by the liver is quantitatively less, yielding only mild acidosis. In the HHS, in the absence of concurrent acid-base disturbances, arterial pH rarely drops below 7.30, and serum bicarbonate levels typically do not fall below 18 mEq/L.

In the HHS, clinical severity and levels of consciousness generally correlate with the severity and duration of hyperosmolarity. Clinical signs indicate profound dehydration; gastrointestinal symptoms are seen less frequently than in DKA. A variety of often reversible neurologic abnormalities may exist, including grand mal or focal seizures, extensor plantar reflexes, aphasia, hemisensory or motor deficits, and worsening of a preexisting organic mental syndrome. The laboratory picture is dominated by the effects of uncontrolled diabetes and dehydration; renal function is impaired, hemoglobin and hematocrit are elevated, and liver function test results may be abnormal because of baseline hepatic steatosis. Although severe hyperglycemia would be expected to lower measured serum sodium concentration, it is not uncommon to see normal or even elevated sodium levels because of the severity of dehydration. The serum osmolarity can be measured directly or estimated.

TREATMENT

Rx

The approach to treatment of HHS is similar to that of DKA and requires aggressive management of fluids and electrolytes (see Fig. 229-6). Importantly, patients with HHS tend to have more dramatic volume contraction, and by definition, acidosis is not present or is minimal in degree. It is important to volume resuscitate the patient adequately before insulin is administered because intracellular fluid shifts that occur as glucose levels are reduced may worsen systemic tissue perfusion. In fact, glucose levels usually drop substantially with hydration alone, in part because of improved renal perfusion, thus promoting glycosuria. Coadministration of dextrose along with insulin, as is recommended in patients with DKA to allow ketones to clear and the acidosis to resolve, is rarely required. Further, because recurrent acidosis is less of a concern, patients may be transitioned directly from insulin infusion to subcutaneous injections. Because altered mental status (and, in some cases, coma) is a frequent feature of HHS, attention should be paid to respiratory status and appropriate airway protection. A diligent search for underlying precipitating illness should be made, keeping in mind that the typical HHS patient is elderly and may well have overt or subclinical CVD. The presence of impaired cardiac function, also more common among the elderly, needs to be considered in the management of intravenous fluid resuscitation.

After resolution of the HHS episode, some patients may ultimately be able to be managed with oral agents alone. However, the development of HHS signifies a significant degree of insulin deficiency. As a consequence, it is always best to prescribe insulin injections before the patient is discharged and to reserve judgment about the appropriateness of using oral agents until the patient's progress can be monitored and reassessed in the outpatient setting.

CHRONIC VASCULAR COMPLICATIONS

EPIDEMIOLOGY

The major clinical burden associated with long-standing diabetes is the development of vascular disease, which includes characteristic microvascular complications (retinopathy, nephropathy, neuropathy) and accelerated medium- and large-vessel atherosclerosis. Diabetes is the leading cause of kidney failure, nontraumatic lower limb amputations, and new cases of blindness among adults in the United States. Diabetes is also a major cause of coronary heart disease, heart failure, and stroke and is the seventh leading cause of death in the United States. The microvascular complications are directly linked to hyperglycemia, with both the duration of diabetes and the degree of glucose elevation constituting the major risk factors. Other factors, including genetic susceptibility, smoking, and concomitant conditions like hypertension, also contribute to the risk of complications (Fig. 229-7). Diabetic microvascular complications occur in both type 1 and type 2 diabetes; given that most patients with type 1 diabetes develop it when younger, they may face greater lifetime risk of complications.

The central role for hyperglycemia in the development of diabetic complications was long suspected and ultimately confirmed by the landmark DCCT, which was reported in 1993.[14] In this study, 1441 adolescents and younger adults with type 1 diabetes were randomly assigned to conventional treatment designed to avoid symptomatic hypoglycemia or hyperglycemia (standard therapy at the time) or to an experimental treatment group designed to achieve near-normoglycemia. The experimental group received intensive management with multiple daily insulin injections or use of a continuous subcutaneous insulin pump; frequent self-monitored blood glucose determinations; and adoption of detailed algorithms to guide the patient in

determining insulin dosing in response to meals, glucose, and exercise. During the course of the study, mean HbA_{1c} levels were 7.2% in the intensive group compared with 9% for the conventional treatment group. The unequivocal DCCT results showed substantially lower rates of retinopathy, nephropathy, and neuropathy in the intensively treated group and led to major changes in the approach to diabetes treatment in the United States and worldwide. Results of the UKPDS, conducted in a cohort of recently diagnosed patients with type 2 diabetes, later confirmed the benefits of more intensive glucose control in the prevention of microvascular complications. These and other studies have provided convincing evidence that hyperglycemia is the driving force behind diabetic microvascular disease. Indeed, the long-term follow-up studies of the DCCT cohort showed that the benefits seen in the intensively treated group persisted for at least a decade after the study ended, even after HbA_{1c} levels between the two treatment groups converged, suggesting that the mechanisms underlying microvascular complications are conditioned by the prevailing metabolic milieu.

PATHOBIOLOGY

The cellular and molecular mechanisms that mediate hyperglycemic tissue damage are complex and still being elucidated. We now know that multiple interrelated pathways are involved, including four that have received the most attention as key mediators of vasculopathy (Fig. 229-8).

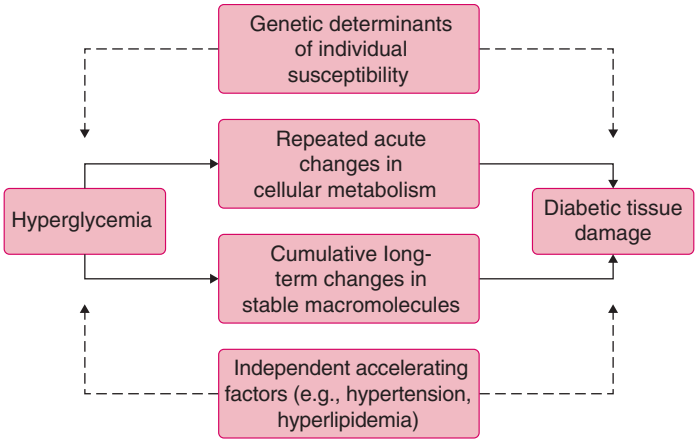

FIGURE 229-7. Factors related to the pathogenesis of diabetes complications. (From Brownlee M. The pathobiology of diabetic complications: a unifying mechanism. *Diabetes*. 2005;54:1615-1625.)

Advanced Glycation End Products

Advanced glycation end products (AGEs) are a heterogeneous group of compounds that form by the nonenzymatic interaction of glucose with amino groups on proteins. This process occurs continuously in vivo but is markedly accelerated in the presence of hyperglycemia. Indeed, the HbA_{1c} test to monitor the chronic level of glycemia was the result of observations of the glycosylation of subfractions of adult hemoglobin. Levels of AGEs in serum and tissues (e.g., skin collagen) correlate with diabetic vascular complications and mean glucose levels over time. AGEs can alter the properties and function of long-lived proteins, such as collagen and elastin, leading to vascular stiffness and increases in basement membrane thickness. AGE binding to specific cell surface receptors (e.g., receptors for AGE, RAGE), particularly on macrophages and endothelial cells, stimulates activation of signaling cascades that promote inflammation and oxidative stress. For example, AGE-RAGE interaction activates the transcription factor NF-κB, leading to multiple pathologic changes in gene expression. Further, AGEs formed intracellularly alter the function of many important cellular proteins. Studies in animal models provide strong evidence that AGE formation is a key process mediating hyperglycemic damage. However, to date, studies of anti-AGE compounds (e.g., aminoguanidine) have failed to demonstrate efficacy in preventing or ameliorating diabetic complications in humans.

Increased Polyol Pathway Flux

Metabolism of glucose through the aldose reductase pathway is generally minor because this enzyme has a low affinity for glucose. However, in the setting of intracellular hyperglycemia (most likely to occur in tissues that cannot downregulate glucose uptake, such as neurons and endothelial cells), there is increased flux through this pathway, leading to an accumulation of osmotically active sorbitol within the cell. Increased cellular osmolarity occurs, along with an increase in redox stress due to depletion of the reduced form of nicotinamide adenine dinucleotide phosphate and reduced glutathione. Inhibitors of aldose reductase have been proposed as a therapeutic strategy to reduce diabetic complications. Current evidence from clinical trials does not support their use, but this remains an active area of research.

Activation of Protein Kinase C

Intracellular hyperglycemia leads to increased de novo synthesis of diacylglycerol, which is a major activator of the protein kinase C family of enzymes. Activation of protein kinase C initiates a complex network of intracellular signaling that alters gene expression and results in enhanced angiogenesis, vasoconstriction, vascular permeability (by increases in vascular endothelial growth factor), cytokine activation, and extracellular matrix expansion. These alterations in cellular function have been linked to the development of

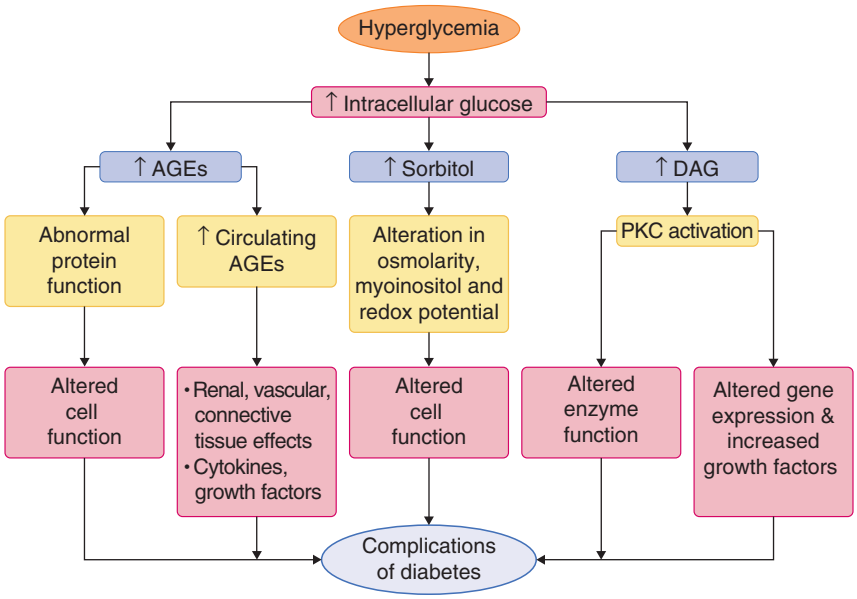

FIGURE 229-8. Proposed mechanisms of hyperglycemia-induced vascular complications. See text for discussion. AGEs = advanced glycation end products; DAG = diacylglycerol; PKC = protein kinase C.

microvascular complications (especially retinopathy) and atherosclerosis. Inhibitors of specific protein kinase C isoforms are being studied in clinical trials as agents specific for diabetic retinopathy and macular edema.

Increased Hexosamine Pathway Flux

In the setting of hyperglycemia and excess fatty acid oxidation, there is also increased flux of glucose through the hexosamine pathway, leading to increases in glucosamine 6-phosphate and ultimately post-translational modification of certain cytoplasmic and nuclear proteins. Associated with this are increases in expression of key genes, including those for transforming growth factor (α and β_1) and plasminogen activator inhibitor 1, and inhibition of endothelial nitric oxide synthase activity. Whereas the pathway has been linked to defective insulin action, its role in specific complications remains unclear.

These multiple and complex pathways are not mutually exclusive but are interconnected and may have a common antecedent process, which is overproduction of superoxide by the mitochondrial electron transport chain. Superoxide generates the production of other reactive oxygen species that can lead to cellular damage in a variety of ways. Data from animal models support the possibility that correction of diabetes-induced superoxide overproduction will have positive downstream effects on the various pathways leading to hyperglycemic tissue damage, but this remains to be confirmed in human studies.

Microvascular Complications

DIABETIC RETINOPATHY

Diabetic retinopathy (Chapter 423) is a highly prevalent, pathognomonic, microvascular complication, eventually affecting more than 50% of patients with long-term diabetes, although it causes vision impairment less frequently. The occurrence of vision loss due to diabetic retinopathy has declined during the past few decades as glucose and blood pressure control have improved in the population with diabetes. Nonetheless, it remains an important cause of preventable blindness, especially among patients with poor metabolic control. Both vascular and neural tissues in the retina are affected by chronic hyperglycemia. Early changes include the loss of retinal supporting cells (pericytes), basement membrane thickening, and retinal blood flow changes. Damaged retinal capillaries leak protein, red blood cells, and lipids, leading to retinal edema. Chronic retinal hypoxia (due to capillary occlusion) promotes neovascularization; these new vessels are abnormal and prone to rupture. Retinal hemorrhage, inflammation, and scarring can ultimately lead to traction retinal detachment and permanent vision loss (Table 229-14).

Diabetic retinopathy can be detected by dilated funduscopy, with early signs being the presence of microaneurysms, exudates, and intraretinal hemorrhages. Additional tests, including fluorescein angiography and ocular coherence tomography, are helpful to detect abnormal vessel permeability and macular edema, which can threaten vision. Regular screening by an eye care specialist (an ophthalmologist or optometrist) is recommended for all patients with diabetes because significant and potentially vision-threatening retinopathy can be present in the absence of any symptoms. Screening should begin at diabetes diagnosis for patients with type 2 diabetes because hyperglycemia has typically been present for years before it is recognized clinically. For patients with type 1 diabetes, screening can begin at 5 years after diagnosis or after puberty for childhood onset. Because retinopathy can progress rapidly during pregnancy, screening and follow-up should be more aggressive during this time (Table 229-15).

As with other diabetic complications, intensive glycemic control can prevent diabetic retinopathy and delay its progression but has limited effects on advanced retinal disease. Blood pressure control is also important to prevent worsening of retinopathy; there is some evidence that renin-angiotensin system (RAS) blockers may be especially beneficial.

Treatment of diabetic retinopathy (Chapter 423) includes laser photocoagulation, which can ablate abnormal vessels (thus reducing the risk of hemorrhage) and treat macular edema. Laser photocoagulation can be focal (to treat clinically significant macular edema or nonproliferative diabetic retinopathy) or panretinal (to treat severe nonproliferative diabetic retinopathy or proliferative diabetic retinopathy). Vitrectomy is a surgical procedure to remove hemorrhage and scar tissue that is obscuring vision. Nonsurgical therapies include intravitreal injection of glucocorticoids or anti–vascular endothelial growth factor monoclonal antibodies (e.g., ranibizumab) to treat macular edema. The established efficacy of retinopathy treatment, particularly photocoagulation, in preventing vision loss provides strong justification for routine retinopathy screening. There is evidence that treatment with fenofibrate reduces the progression of retinopathy, although the medication has not been approved for this indication in the United States. In addition to its well-known effects on lipid metabolism, fenofibrate appears to have significant anti-inflammatory, antiangiogenic, and antioxidant properties that are relevant to retinal disease. The presence of retinopathy is not considered a contraindication to the use of aspirin for CVD prevention.

Other eye conditions also affect patients with diabetes. Transient osmotically induced refractive error is common, especially at the time of diabetes diagnosis, but resolves with glucose control. Age-related eye conditions, such as cataracts and glaucoma, tend to occur at younger ages among diabetic patients. Diplopia and other gaze disorders due to acute mononeuropathy involving the cranial nerves (typically III or VI) are also more common in diabetes.

DIABETIC NEPHROPATHY

Diabetic nephropathy (Chapter 125) remains the most common single cause of end-stage renal failure, accounting for up to 50% of the cases in Western societies. Further, despite advances in the management of glucose and hypertension, the prevalence of chronic kidney disease among patients with diabetes has not declined in the past several decades. Overall, 20 to 30% of type 1 and type 2 diabetic patients develop evidence of nephropathy, although fewer type 2 patients progress to end-stage renal disease (ESRD). This may be because of competing mortality from CVD, with fewer surviving to ESRD. However, because of their much greater frequency in the population, the majority of diabetic patients presenting for treatment of ESRD (dialysis or transplantation) have type 2 diabetes. The major risk factor for the development of diabetic neuropathy is the duration and severity of hyperglycemia, but there is evidence for variation in genetic susceptibility. For example, African Americans and individuals with a family history of diabetic or nondiabetic renal disease are at higher risk for diabetic nephropathy. An insertion/deletion polymorphism in the gene encoding angiotensin-converting enzyme (ACE) has been widely reported to be associated with increased risk of diabetic nephropathy, but variants in genes involved in the polyol pathway, lipid metabolism, inflammatory cytokines, angiogenesis, and oxidative stress have also been identified.

Diabetic nephropathy develops during many years to decades, with a prolonged "silent" period before clinical detection, followed by more rapid progression to overt renal disease (Chapter 125). In the classic view, the hallmark of diabetic nephropathy is the development of proteinuria, which is due to alteration in glomerular basement membrane permeability and increases in intraglomerular pressure. The first clinical evidence of incipient nephropathy is the development of albuminuria, which is quantitatively minor at first

TABLE 229-14 CLASSIFICATION OF DIABETIC RETINOPATHY

	CLINICAL FEATURES
Mild NPDR	At least one microaneurysm
Moderate NPDR	Microaneurysms, intraretinal (blot) hemorrhage, soft exudates, venous beading, intraretinal microvascular abnormalities
Severe NPDR	More extensive intraretinal hemorrhages (>20 in each of four quadrants) *or* venous beading in at least two quadrants *or* prominent intraretinal microvascular abnormalities
PDR	Neovascularization and/or vitreous or pre-retinal hemorrhage; traction retinal detachment
Clinically significant macular edema	Retinal thickening or hard exudates approaching or involving the center of the macula

NPDR = nonproliferative diabetic retinopathy; PDR = proliferative diabetic retinopathy.

TABLE 229-15 RECOMMENDED INTERVALS FOR DIABETIC RETINOPATHY SCREENING

DIABETES TYPE	FIRST EXAMINATION	FOLLOW-UP
Type 1	5 years after diagnosis	Annual
Type 2	At time of diagnosis	Annual
Established diabetes during pregnancy	Before or soon after conception	At least every 3 months

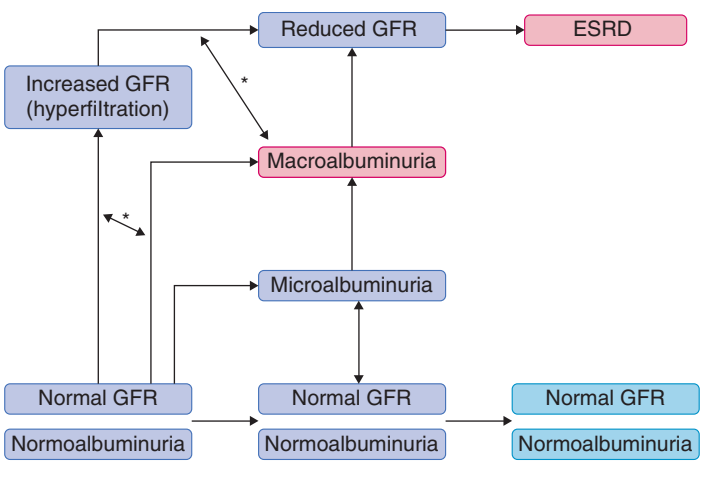

FIGURE 229-9. Development of diabetic nephropathy. See text for discussion. GFR = glomerular filtration rate; ESRD = end-stage renal disease. *GFR and albuminuria may progress independently of each other, i.e., patients may have micro- or macroalbuminuria even though their GFR is normal or even slightly elevated. However, macroalbuminuria is usually associated with reduced GFR, and is a strong risk for progressive ESRD. (From Boger CA, Sedor JR. GWAS of diabetic nephropathy: is the GENIE out of the bottle? *PLoS Genet*. 2012;8:e1002.)

(microalbuminuria, urine albumin-to-creatinine ratio of 30 to 300 mg/g) and then progresses to overt proteinuria, sometimes in the nephrotic range (>2 g/day). During the microalbuminuria phase, GFR is preserved but begins to decline in parallel with increasing proteinuria, leading to ESRD 5 to 15 years after the first detection of abnormal albumin excretion. However, recent evidence suggests that chronic kidney disease in diabetes is more heterogeneous than previously thought, with some patients progressing to advanced stages of chronic kidney disease in the absence of albuminuria (Fig. 229-9). Nonalbuminuric diabetic kidney disease appears more likely to occur in older patients with type 2 diabetes and may reflect, in part, the concurrence of multiple renal risk factors, including hypertension, obesity, and dyslipidemia. Further, microalbuminuria does not inevitably progress, with some patients regressing to normal or maintaining small but stable amounts of albuminuria. However, persistent and increasing albuminuria is a marker of high risk for progression to clinical nephropathy. Pathologic changes that are typical of diabetic nephropathy include an increase in glomerular basement membrane thickness and increased accumulation of extracellular matrix leading to mesangial expansion and the classic Kimmelstiel-Wilson nodular lesion.

Patients with diabetes should be screened annually for renal involvement (Chapter 125) by measurement of albumin on a spot urine sample with a sensitive immunoassay to detect microalbuminuria and by measurement of serum creatinine for calculation of estimated GFR. The finding of moderately increased urine albumin-to-creatinine ratio (30 to 300 mg albumin per gram of creatinine) should be confirmed on two of three repeated tests because transient increases are not uncommon but may not be clinically important. Data from the DCCT and other studies provide strong evidence that aggressive glycemic control can prevent the development of diabetic nephropathy and can retard the progression of microalbuminuria. However, there is little evidence that glycemic control can modulate the course once clinical albuminuria (>300 mg/day) and declining GFR occur. Central to the treatment of patients with albuminuria (micro or clinical) is intensive blood pressure control, preferentially by blockade of the RAS. Both ACE inhibitors and angiotensin receptor blockers have been shown to delay the progression of diabetic nephropathy and are recommended for patients with albuminuria even in the absence of hypertension. Despite initial enthusiasm, combined ACE inhibitor and angiotensin receptor blocker therapy is not recommended because of high rates of hyperkalemia and acute renal injury. In hypertensive patients, other drugs, such as calcium-channel blockers, diuretics, and β-blockers, can be used as additional therapy if needed to achieve adequate blood pressure control. There is little evidence to support use of RAS blockade in diabetic patients who are normotensive and normoalbuminuric, although there may be a therapeutic rationale for use of these agents in patients who cannot achieve adequate glycemic control. Dietary protein restriction has been recommended in the past for patients with nephropathy, but recent trials have been unable to demonstrate an effect of a low-protein diet on the rate of deterioration of GFR.[15]

DIABETIC NEUROPATHY

Diabetic neuropathy (Chapter 420) is a common complication of diabetes, with an estimated lifetime prevalence of about 50%. Diabetic neuropathy can be manifested in a variety of syndromes, including radiculoplexopathy and autonomic neuropathy, but the most common form is a characteristic distal symmetrical polyneuropathy (DSP), resulting from large-fiber nerve damage. Despite its high prevalence, there is no distinct neuropathic symptom or lesion that is specific to diabetes, and separation of diabetic neuropathy from other causes of nerve damage can be problematic. As for other microvascular complications, the etiology of DSP is attributed to hyperglycemic damage, as demonstrated by the dramatic 60% reduction in neuropathy in the intensive treatment group in the DCCT study. However, the possibility that the pathogenesis of DSP may differ in type 2 diabetes, with dyslipidemia and insulin resistance also contributing, has recently emerged. Support for this view comes from largely negative neuropathy results of clinical trials of intensive glucose control in type 2 diabetes (e.g., Action to Control Cardiovascular Risk in Diabetes [ACCORD] trial, VA Cooperative study) and the observation that the prevalence of DSP is already increased in the setting of prediabetes and the metabolic syndrome.

The clinical manifestations of DSP include symptoms of pain, paresthesias, and numbness that typically begin in the feet and progress more proximally in a "stocking and glove" distribution (Chapter 420). For some patients, neuropathic pain can be severe and disabling, resulting in a major reduction in quality of life. Loss of sensation, which may not be noticed by the patient, constitutes an important risk factor for falls due to gait instability. Ulceration, uncontrolled infection, and amputation can also occur from altered foot mechanics and inability to perceive repetitive trauma or other foot injury. DSP can be diagnosed by the presence of classic symptoms and by loss of ability to perceive pressure from a nylon (Semmes-Weinstein) monofilament. Additional tests, such as nerve conduction studies or electromyography, are occasionally indicated to distinguish DSP from radiculopathy. Current treatment options are mostly limited to control of metabolic risk factors (i.e., glucose, lipids) and symptoms, although some agents in clinical trials (e.g., aldose reductase inhibitors) show some promise. The chronic pain of DSP can be difficult to manage. Available therapies include tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, anticonvulsants (such as gabapentin and pregabalin), and opioids.

Other forms of diabetic nerve damage (Chapter 420)[16] include small-fiber predominant neuropathy, radiculoplexopathy (diabetic amyotrophy), noncompressive radiculopathy, and mononeuritis multiplex. Autonomic neuropathy can be manifested as gastroparesis, urinary retention, erectile dysfunction, sudomotor dysfunction (typically anhidrosis of the extremities with or without hyperhidrosis of the trunk), cardiac arrhythmias, and disturbance of gut motility (diabetic diarrhea or constipation). Cardiac autonomic neuropathy is an especially ominous form of diabetic autonomic neuropathy. Typical clinical manifestations of cardiac autonomic neuropathy include resting tachycardia, diminished heart rate variability, and orthostatic blood pressure changes. Patients with cardiac autonomic neuropathy are at high risk for myocardial infarction, congestive heart failure, and sudden cardiac death.

DIABETIC FOOT

The combination of sensory impairment due to peripheral neuropathy and reduced tissue perfusion due to large-vessel atherosclerosis (peripheral arterial disease) or microvascular dysfunction can result in ulceration, infection, and ultimately lower extremity amputation. A typical case involves development of an ulceration (often surrounded by callus formation) on the plantar surface of the foot, often underneath the metatarsal heads. Ulceration can be slow to heal because of repetitive trauma from walking and impaired blood flow; hyperglycemia may also impair wound healing by effects on white blood cell migration and function. In the absence of protective sensation, an infection may fester for weeks and eventually invade the bone, leading to osteomyelitis. Altered foot mechanics can also lead to repeated (and usually undetected) fractures that destroy normal foot architecture and result in the classic Charcot foot deformity.

For many patients, foot amputation is the most feared diabetic complication; fortunately, it can be prevented in most cases but requires vigilance on the part of the patient and health care team. Routine foot examination,

especially for patients who have evidence of sensory loss, should be performed at every medical visit, and patients should be instructed to inspect their feet daily for cracks, fissures, ulcers, or inflammation. Patients should avoid walking barefoot (even at home) and should wear protective covering (avoid sandals) outside. Thermal injuries can be prevented by avoiding use of heating pads or hot-water bottles on the feet. Referral to a foot care specialist should be considered for patients with sensory loss, foot deformity, extensive callus formation, and nonhealing ulcers. Ulcers are treated with aggressive débridement of necrotic tissue and systemic antibiotics (guided by culture of infected tissue) if infection is present. Pressure "off-loading" by use of special shoes, orthotics, or application of total contact casts may be necessary to allow healing. Additional treatments include use of topical platelet-derived growth factor, bioengineered skin substitutes, hyperbaric oxygen, and negative-pressure wound therapy, although none of these has shown conclusive evidence of effectiveness in promoting wound healing.

OTHER ASSOCIATED CONDITIONS

Although not traditionally recognized as diabetic complications, there are a number of disorders that are increased in frequency or severity in patients with diabetes and that have a plausible or established relationship with hyperglycemia. These include periodontal disease, Alzheimer dementia, and musculoskeletal disorders, such as limited joint mobility, adhesive capsulitis, Dupuytren contracture, and trigger finger (flexor tenosynovitis). Patients with poorly controlled diabetes are widely thought to have increased susceptibility to infection, particularly with fungal pathogens. Defects in immune function (impaired neutrophil chemotaxis) have been described in diabetes, but whether this occurs in reasonably controlled diabetes or contributes to clinical infection is unclear. The incidence of osteoporotic fractures appears to be increased in women with diabetes, despite the presence of normal or even increased bone density. There is also emerging evidence that the frequency of some cancers (e.g., pancreatic, endometrial, colorectal, breast) is increased among people with diabetes.

Cardiovascular Disease in Diabetes

Atherosclerotic CVD is the major cause of morbidity and mortality for patients with diabetes and contributes substantially to its economic costs. The clinical and pathologic features of CVD in diabetes are generally not distinguishable from those occurring in nondiabetic individuals, but they are manifested at an earlier age, are more aggressive, and are associated with mortality rates that are two to four times higher in patients with diabetes (Chapter 52). This increased CVD risk is true for both type 1 and type 2 diabetes, with CVD in type 1 diabetes being strongly associated with concurrent presence of renal disease. Diabetes is also an important risk factor for peripheral vascular disease and stroke, which carries greater mortality risk than in nondiabetic patients.

PATHOBIOLOGY OF CARDIOVASCULAR DISEASE IN DIABETES

The pathogenesis of atherosclerotic CVD in diabetes is complex and multifactorial, with several mechanisms playing key roles. *Metabolic factors*, including hyperglycemia, insulin resistance, dyslipidemia, and increases in circulating free fatty acids, contribute to atherosclerotic plaque formation. Increases in *oxidation and glycoxidation* of lipoproteins increase their atherogenicity and enhance foam cell formation. *Endothelial dysfunction*, an early event in the development of atherosclerosis, has been described in association with several metabolic syndrome components, including hyperglycemia, insulin resistance, hypertension, and dyslipidemia. Systemic *inflammation*, which contributes to accelerated plaque formation, is increased in diabetes and obesity as a consequence of increased cytokine production by adipose tissue. Finally, diabetes is characterized by a *prothrombotic* state due to enhanced platelet reactivity and alterations in coagulation factors, including increased circulating levels of fibrinogen and plasminogen activator inhibitor 1.

DIABETIC CARDIOMYOPATHY AND HEART FAILURE

Diabetic cardiomyopathy is defined as alterations in cardiac structure and function that are not directly attributable to coronary artery disease or hypertension (Chapters 58 and 59). Characteristic features include cardiac hypertrophy, left ventricular dysfunction (diastolic may precede systolic), and altered myocardial metabolism. Diabetes is a recognized risk factor for the development of heart failure, even in the absence of atherosclerotic heart disease. For example, in the Framingham Heart Study, the frequency of heart failure was twice in diabetic men and five times in diabetic women compared with age-matched controls and persisted despite correction for hypertension, obesity, dyslipidemia, and coronary artery disease. Increased activation of the renin-angiotensin-aldosterone system and formation of AGEs are thought to contribute to myocardial fibrosis and stiffness, and altered substrate utilization (preferential use of free fatty acids) can promote myocyte dysfunction by enhanced production of reactive oxygen species and other mechanisms. Characteristic changes in myocardial function and structure were reported in type 1 diabetes in the DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) study and were related to long-term glycemic control.

PREVENTION OF CARDIOVASCULAR DISEASE IN DIABETES

Aggressive control of CVD risk factors is recommended for most patients with diabetes, keeping in mind that the presence of diabetes is considered the risk equivalent of a prior myocardial infarction by most risk assessment algorithms (e.g., Framingham risk score, Adult Treatment Panel III Report of the National Cholesterol Education Program). Assessment of blood pressure, lipid profile, and smoking status should be included as part of routine diabetes care. Determination of the optimal targets for risk factor control has been the subject of several large randomized trials, which have informed consensus guidelines.

GLUCOSE CONTROL

Hyperglycemia is a major risk for atherosclerotic CVD. In population-based studies including diabetic and nondiabetic cohorts, HbA_{1c} has been reported as an independent predictor of all-cause and CVD mortality, and among individuals with diabetes, every 1% rise in HbA_{1c} is associated with a 30% increase in all-cause mortality and a 40% increase in CVD mortality. Compelling evidence for the benefit of intensive glucose control in patients with type 1 diabetes was shown in the DCCT/EDIC study, in which CVD events were reduced by 58%. However, in type 2 diabetes, hyperglycemia occurs in the setting of multiple other CVD risk factors, including hypertension, dyslipidemia, and obesity, which also contribute to risk, so the contribution of glucose control is unclear. Several large clinical trials in patients with type 2 diabetes have failed to show that control of hyperglycemia has important effects on CVD outcomes (see later), highlighting the complex pathogenesis of vascular disease in diabetes. Similarly, an intensive lifestyle program designed to achieve weight loss and exercise goals also failed to demonstrate significant effects on CVD outcomes in type 2 diabetes patients.

The strongest evidence in favor of intensive glucose control comes from the long-term follow-up of the UKPDS, which demonstrated 15% reduction in myocardial infarction and 13% reduction in all-cause mortality in the intensive versus conventional treatment group. More recently, in the ACCORD trial, an intensive treatment arm, designed to maintain HbA_{1c} below 6%, was compared with conventional treatment with HbA_{1c} goal of 7.5% in a cohort of type 2 diabetes patients at high risk for CVD. This trial was stopped early because of unexpected increased mortality, largely CVD related, in the intensive treatment group. The reasons for increased mortality with intensive treatment are not known for certain, but increased frequency and severity of hypoglycemia or the toxicity of specific drugs or combinations has been proposed. Secondary analysis of ACCORD data showed a reduction in nonfatal myocardial infarction in the intensive treatment group, leading to speculation that some patients might still benefit. Other studies designed to address this, including the VA Cooperative Study and ADVANCE, also failed to show CVD benefit for intensive glucose control. These trials differed somewhat in patient characteristics, HbA_{1c} goal, and specific treatment regimens, and the largely negative results stimulated controversy. However, some consensus views have emerged[17]: (1) in the current era of effective treatment of other CVD risk factors (i.e., with statins, RAS blockers, antiplatelet therapy), the additional benefits of intensive glycemic control are modest at best; (2) patients with long-standing diabetes or established CVD are least likely to benefit from intensive glucose lowering; (3) the benefits of glucose lowering in the prevention of microvascular complications provide an independent rationale for strict glucose control for many patients; and (4) specific glycemic targets should be individualized according to the patient's characteristics (e.g., comorbidities, life expectancy, hypoglycemia risk) and preferences.

HYPERTENSION

Hypertension (Chapter 67) is a common comorbidity in diabetes, affecting the majority of patients with type 2 diabetes, and constitutes an important modifiable CVD risk factor. Further, in even the earliest stages of diabetic nephropathy (i.e., microalbuminuria), hypertension is further accelerated. In

type 1 diabetes, hypertension is generally the result of concurrent renal disease, with both contributing to CVD risk. The importance of blood pressure control in reducing CVD events as well as microvascular outcomes in patients with diabetes was established by several major trials, including the UKPDS, Systolic Hypertension in the Elderly Program (SHEP), Hypertension Optimal Treatment (HOT) study, and others. However, analysis of these and other trials failed to show evidence of improved outcomes (i.e., in myocardial infarction or mortality) with systolic blood pressure targets of 130 mm Hg or lower. An even more aggressive target systolic blood pressure of less than 120 mm Hg was shown to be of no additional benefit in reducing CVD events in the ACCORD trial. The current consensus is that blood pressure goals should be less stringent than previously recommended. The Eighth Joint National Committee (JNC8) guidelines recommend a blood pressure goal of less than 140/90 mm Hg for all patients younger than 60 years, regardless of diabetes or renal status, and less than 150/90 mm Hg for patients 60 years and older.[18] Other guidelines, including those from the American Diabetes Association (ADA), suggest a blood pressure target of less than 140/80 mm Hg for patients with diabetes but with the further recommendation that a lower target may be considered for younger patients if it can be achieved without excessive treatment burden. However, many of these recommendations are based on expert opinion rather than on evidence from randomized trials, and some uncertainty remains.

The choice of antihypertensive agent has also received considerable study, which is complicated by the fact that many patients will require treatment with two or more drugs to achieve target blood pressure. ACE inhibitors and angiotensin receptor blockers are generally considered first-line therapy for patients with diabetes, in part on the basis of their demonstrated renoprotective benefits. In addition, results from several randomized trials, including the Heart Outcomes Protection Study (HOPE), Fosinopril versus Amlodipine Cardiovascular Events Trial (FACET), and Appropriate Blood Pressure Control in Diabetes (ABCD), indicated improved cardiovascular outcomes with ACE inhibitors compared with other antihypertensive drugs, although this was not the case for the UKPDS, in which β-blockers were equally effective. Calcium-channel blockers and low-dose diuretics are also recommended as add-on therapy if needed to achieve blood pressure targets. Use of β-blockers should be considered in the setting of established CVD because of their proven benefits in patients with prior myocardial infarction and congestive heart failure. However, β-blockers should be used with caution in patients at high risk for hypoglycemia because they may blunt the autonomic warning symptoms associated with low glucose concentration. Both β-blockers and thiazide diuretics have been reported to increase the risk for development of diabetes, although there is little evidence for significant deterioration of glycemic control in patients with diabetes.

DYSLIPIDEMIA

The characteristic dyslipidemia of type 2 diabetes and insulin-resistant states, which includes low levels of high-density lipoprotein (HDL) cholesterol, elevated triglycerides, and small dense LDL particles, is highly atherogenic (Chapter 206). LDLs also are prone to oxidative modification in the setting of hyperglycemia, which enhances their atherogenicity. There is substantial clinical trial evidence to support lowering of LDL cholesterol levels with statin drugs in the majority of patients with diabetes older than 40 years. These findings come from trials limited to diabetes (Collaborative Atorvastatin Diabetes Study [CARDS]) and to diabetes subset analysis of larger trials (Heart Protection Study), all of which report similar CVD benefits of statin therapy among diabetics and nondiabetics. ADA recommendations are for target LDL levels of less than 100 mg/dL for most adult patients with diabetes and less than 70 mg/dL for diabetic patients with established CVD or multiple risk factors. Recent guidelines from the American Heart Association (AHA) and American College of Cardiology (ACC) have focused on CVD risk stratification to determine the need for and intensity of statin therapy.[19] With this approach, virtually all patients with diabetes (aged 40 to 75 years) would be candidates for statin therapy, regardless of baseline level of LDL cholesterol. Diabetic patients with established atherosclerotic CVD or estimated 10-year CVD risk of more than 7.5% would receive high-intensity statin treatment (regimens sufficient to lower LDL cholesterol >50% from untreated baseline); all others would be considered for moderate-intensity treatment (lowering of LDL cholesterol 30 to <50%). The evidence base to support these new recommendations is considered relatively strong. Although the ADA and the AHA/ACC guidelines differ in structure, ultimately the recommendations for most patients with diabetes will be similar with either approach.

Recent observations from several trials (e.g., JUPITER) and observational cohort studies of an increase in incident diabetes with statin therapy have generated concern, although the risk appears to be small in magnitude (hazard ratio, ~1.2) and is outweighed by the substantial benefits of CVD protection.[20] Clinically relevant effects of statins on glucose control among established diabetics have not been reported. In patients intolerant of statins, nicotinic acid (niacin) can be used, although CVD outcome trials have been disappointing despite substantial improvement in lipid parameters, including lowering of LDL cholesterol and increasing of HDL cholesterol levels. Further, nicotinic acid may worsen insulin resistance and glycemic control in some patients. Bile acid sequestrants, such as colesevelam or cholestyramine, can also be used but may exacerbate the hypertriglyceridemia characteristic of diabetic dyslipidemia.

In contrast to the definitive benefits of LDL lowering, there is less evidence that pharmacologic treatment of hypertriglyceridemia or of low HDL cholesterol levels reduces CVD risk. This may be in part due to the lesser efficacy of available drugs to alter these lipid subfractions. Trials with fibrate derivatives (gemfibrozil and fenofibrate) have yielded mixed results, and the addition of fenofibrate to a statin did not reduce the rate of major CVD events compared with statin alone in the ACCORD trial. Because most statins have some triglyceride-lowering effect, maximizing statin dose should be considered for patients with high triglyceride levels. Lifestyle factors are also effective, including weight loss and dietary modification (reduced fat diet, avoidance of alcohol). Omega-3 fatty acid supplementation is another option to lower triglyceride levels, although CVD outcome data are lacking. Pharmacologic treatment (i.e., with fibrates or fish oil supplements) of severe hypertriglyceridemia (triglyceride level >1000 mg/dL) is indicated to prevent acute pancreatitis.

ANTIPLATELET THERAPY

Prophylactic aspirin therapy is widely used for prevention of cardiovascular events in high-risk patients (i.e., those with prior myocardial infarction or stroke), with reported risk reductions of about 12% (Chapter 38). Results from clinical trials in patients with diabetes suggest that aspirin may be somewhat less effective for CVD prevention than in patients without diabetes, although this has not been a consistent finding. Current guidelines recommend aspirin therapy for diabetic patients with a prior CVD event (secondary prevention) or with increased CVD risk (10-year risk of >10%). This includes most men older than 50 years or women older than 60 years who also have one or more additional CVD risk factors: smoking, hypertension, albuminuria, dyslipidemia, or family history of CVD. For patients at lower CVD risk, the potential adverse effects from bleeding may outweigh the potential benefits, and routine use is not recommended. The optimal dose (balancing thrombosis prevention with the risk of bleeding) of aspirin has not been established and may differ according to patient characteristics, but 75 to 162 mg/day is commonly recommended. For high-risk patients who are unable to tolerate aspirin, clopidogrel is an effective alternative.

TREATMENT OF ESTABLISHED CARDIOVASCULAR DISEASE IN DIABETES

Rx

In general, treatment of clinically established CVD, including acute coronary syndromes and stable angina, is similar in diabetic and nondiabetic patients. There is some evidence that ischemic symptoms may be less intense, atypical, or absent in diabetic patients, leading to higher rates of "silent" myocardial infarction. However, a strategy of screening for ischemic heart disease, by exercise stress testing, in asymptomatic patients did not result in lower event rates or improved outcomes. Therefore, current recommendations are for coronary artery disease screening in patients with symptoms suggestive of ischemia.

The role of intravenous insulin (with or without potassium and glucose infusion) in the setting of acute myocardial infarction has been considered in a few studies. In the Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) study, acute myocardial infarction patients with diabetes were treated with standard therapy or with insulin infusion during the first 48 hours, followed by continued insulin use after hospital discharge. Mortality after 1 year was reduced by 30% in the insulin-treated group. However, the implications of these results have been debated because factors other than insulin treatment differed between the two groups (i.e., sulfonylureas were routinely used in the standard therapy group but withdrawn from the insulin group). These findings subsequently were not confirmed in a follow-up study, and this approach has largely been abandoned.

Several studies have addressed the roles of medical therapy and revascularization in diabetic patients with coronary artery disease. Among them, the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) study demonstrated that a policy of medical management (including aggressive risk factor modification) was as effective as early revascularization in diabetic patients with stable angina. In the Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) trial, diabetic patients with multivessel coronary disease had better outcome (reduced rates of death from any cause or nonfatal myocardial infarction) with coronary bypass surgery compared with percutaneous intervention with drug-eluting stents, although strokes were more frequent in the surgical group.

REVIEW QUESTIONS

1. A 51-year-old man has a history of type 2 diabetes mellitus for 6 years. Past medical history is significant for chronic hepatitis C infection, chronic kidney disease stage 3, and a recent hospitalization for an upper gastrointestinal bleed. He takes a sulfonylurea for blood glucose control and rarely checks his blood glucose level. Fasting plasma glucose concentration in the office is 195 mg/dL, and his HbA_{1c} is 6.8%. What do you conclude about his glucose control?

A. His average blood glucose concentration during the past 3 months is approximately 140 mg/dL.
B. HbA_{1c} may be falsely high because of chronic kidney disease.
C. HbA_{1c} may be falsely low because of liver disease.
D. HbA_{1c} levels are increased after acute blood loss.
E. HbA_{1c} levels are more reflective of postprandial than of fasting glucose concentration.

Answer: C This patient has several reasons that his HbA_{1c} may not accurately reflect his mean plasma glucose concentration. HbA_{1c} results may be influenced by a number of factors, including conditions that alter red cell survival or cause interference with a specific assay. The HbA_{1c} may be falsely low in this patient because of cirrhosis (increased red cell turnover), recovery from recent acute blood loss (greater percentage of younger erythrocytes with shorter exposure to glucose), or transfusion (dilution of patient's blood with nondiabetic donor blood). In these instances, measurement of glycated serum proteins (fructosamine) or direct measurement of plasma glucose concentration will more accurately reflect glycemic control.

Additional information about HbA_{1c} assay methodology and interpretation of results can be obtained from the National Glycohemoglobin Standardization Program: http://www.ngsp.org.

2. A 38-year-old woman has had type 1 diabetes mellitus since the age of 12 years. She has maintained excellent control (HbA_{1c} 6.0%) with a basal/bolus injection regimen. She tests her glucose level four or five times a day, and review of her meter download shows many glucose levels in the 30s and 40s. However, the patient is unconcerned because she has no symptoms at these times. On questioning, she admits to recently "spacing out" while driving, which led to a minor traffic accident. Regarding the etiology and treatment of hypoglycemia in this patient:

A. She has adapted to low blood glucose concentration and no change in treatment is required.
B. She has developed hypoglycemia unawareness and her target HbA_{1c} should be increased.
C. Strict avoidance of hypoglycemia is of little benefit in reversing hypoglycemia-associated autonomic failure.
D. An excessive counter-regulatory hormone response to hypoglycemia may contribute to her lack of symptoms.
E. Treatment with β-blocker should be considered.

Answer: B In patients with long-standing diabetes, the counter-regulatory systems that normally would counteract the decline of glucose to dangerous levels may be impaired. This is especially true for patients with type 1 diabetes, who often have defects in glucagon and epinephrine response during hypoglycemia. This decrease in epinephrine response during hypoglycemia is accompanied by an attenuated autonomic neural response, which results in the clinical syndrome of *impaired awareness of hypoglycemia*. Without autonomic symptoms, mild hypoglycemia may proceed unnoticed to more advanced and dangerous phases. There is, however, evidence that hypoglycemia-associated autonomic failure can be reversed by strict avoidance of hypoglycemia, which can be facilitated by increasing target glucose levels.

Reno CM, Litvin M, Clark AL, Fisher SJ. Defective counterregulation and hypoglycemia unawareness in diabetes: mechanisms and emerging treatments. *Endocrinol Metab Clin North Am*. 2013;42:15-38.

3. A mother brings her 19-year-old son, who has type 1 diabetes and uses an insulin pump, to see you and to ask for referral to a dietitian. She complains that her son refuses to follow his "diabetic diet" and frequently eats junk food, including fast food (burgers, fries, pizza) and ice cream. She also worries that he sometimes skips meals, saying he is not hungry. His body mass index is 22, and his recent laboratory results show an HbA_{1c} of 7.8%, low-density lipoprotein cholesterol of 95, and normal triglycerides. Which of the following dietary recommendations is most appropriate for this patient?

A. An 1800-calorie/day American Diabetes Association diet
B. A low-carbohydrate diet
C. A low-protein diet
D. A low-fat, high-fiber diet
E. A flexible "heart healthy" meal plan that limits concentrated sweets and emphasizes fruits and vegetables

Answer: E Dietary recommendations for patients with diabetes have changed substantially over time, from the extremely low-carbohydrate, high-fat diets used before the discovery of insulin as a therapy, to "exchange diets," to more flexible meal plans. For patients with type 1 diabetes, the key element is for the patient to learn to match mealtime insulin doses to the carbohydrate content of the meal. Severely restricted diets (very low carbohydrate or low calorie) are neither required nor advisable, although avoidance of large carbohydrate loads will help minimize post-meal glycemic excursions. For most patients with type 2 diabetes who are typically overweight or obese, moderate carbohydrate intake and reduction in total calories are advised. Current recommendations allow a variety of eating styles and ethnic food preferences, with emphasis on fruits and vegetables, low-fat protein sources, and use of monounsaturated or polyunsaturated fats.

Lasa A, Miranda J, Bullo M, et al. Comparative effect of two Mediterranean diets versus a low-fat diet on glycaemic control in individuals with type 2 diabetes. *Eur J Clin Nutr*. 2014;68:767-772.

4. A 54-year-old woman presents to her physician for treatment of hypertension. She had gestational diabetes during her last pregnancy 15 years ago, and there is a family history of type 2 diabetes (mother and older brother). Her body mass index is 36. Fasting glucose concentration is 110 mg/dL, and HbA_{1c} is 6.2%. Which of the following have been shown to reduce the progression to diabetes in high-risk patients?

A. Weight loss by reduced calorie diet
B. Treatment with metformin
C. Treatment with acarbose
D. Bariatric surgery
E. All of the above

Answer: E This patient has multiple risk factors for the development of type 2 diabetes, including family history, prior history of gestational diabetes, obesity, and hypertension. In addition, her glucose and HbA_{1c} levels are already elevated above normal, in the defined "pre-diabetes" range. All of the treatments listed have been shown to prevent or to delay the onset of diabetes in randomized clinical trials. The most consistent evidence comes from weight loss trials. Both the Finnish Diabetes Prevention Study and the U.S. Diabetes Prevention Program reported 58% reduction in diabetes with a hypocalorie, reduced fat diet combined with moderate-intensity physical activity. Weight loss achieved with bariatric surgery is also highly effective in preventing (or even reversing) diabetes. Medications, including metformin, the α-glucosidase inhibitor acarbose, and troglitazone (a thiazolidinedione), have also been shown to reduce diabetes in high-risk patients, although somewhat less effectively than by lifestyle modification. Lifestyle changes and metformin are reported to be cost-effective interventions, but whether delay or prevention of type 2 diabetes will result in lower rates of cardiovascular disease and diabetes microvascular complications will require longer-term follow-up studies.

Schwarz PE, Greaves CJ, Lindstrom J, et al. Nonpharmacologic interventions for the prevention of type 2 diabetes mellitus. *Nat Rev Endocrinol*. 2012;8:363-373.

5. A 28-year-old woman with type 1 diabetes since the age of 12 years is considering having a child. Currently, her blood glucose is reasonably well controlled, although she admits this was not the case during her teens and early 20s, when her HbA_{1c} was in the 9 to 11% range. She has mild background diabetic retinopathy, normal blood pressure, urine albumin-to-creatinine ratio of 25 mg/g, and normal findings on foot examination. Which of the following is true?

A. She should delay pregnancy until she has achieved optimal glucose control (HbA_{1c} ~6.5%).
B. She should be treated with an angiotensin-converting enzyme inhibitor to prevent progression of renal disease during pregnancy.
C. Progression of her retinopathy during pregnancy is likely to result in vision loss.
D. The risk of her child's developing type 1 diabetes is 25 to 50%.
E. She should be advised to avoid pregnancy because of the risk of both maternal and fetal complications.

Answer: A Although pregnancies in women with type 1 diabetes are generally considered "high risk," the outlook for patients with minimal complications and good metabolic control is good. Women with advanced renal disease (proteinuria, reduced glomerular filtration rate) or proliferative retinopathy may experience rapid progression during pregnancy because of the influence of hormonal and hemodynamic changes and should be monitored closely by specialists. Use of angiotensin-converting enzyme inhibitors is contraindicated during pregnancy because of the risk of fetal renal damage. The key to successful pregnancy outcomes is achieving optimal glucose control before conception because the developing fetus is most susceptible to the teratogenic effects of hyperglycemia in the first 6 to 8 weeks of pregnancy, before the time that most women are aware of being pregnant. Maintaining strict glucose control during the pregnancy will reduce the risk of fetal complications, such as macrosomia and hyperbilirubinemia. Many patients benefit from use of an insulin pump and continuous glucose monitoring during this time. Although a child of a mother with type 1 diabetes is at increased risk of diabetes compared with the general population, the risk is less than 10%.

HYPOGLYCEMIA AND PANCREATIC ISLET CELL DISORDERS

KHALID HUSSAIN

DEFINITIONS

Hypoglycemia is one of the most common biochemical abnormalities observed in clinical practice. It is a biochemical finding and not a diagnosis. Hypoglycemic disorders are more common in neonates, infants and children as compared to adults. Inappropriately treated hypoglycemia can have severe consequences, including seizures, permanent brain injury, or death. This is especially the case in neonates with persistent forms of hypoglycemia, who are at high risk of brain injury from delays in diagnosis and effective therapy.

Hypoglycemic disorders in neonates, infants, and children differ from adults in important aspects. First, they are most often due to congenital or genetic disorders, such as disorders of insulin secretion, as well as a range of metabolic and endocrine diseases. Second, during a transitional period of 1 to 3 days after birth, low plasma glucose concentrations are common in normal neonates, which makes it difficult to identify the minority who have a persistent hypoglycemia disorder or a genetic hypoglycemia disorder. Third, the importance of early recognition and treatment of such persistent hypoglycemia disorders in neonates is emphasized by reports that developmental handicap, which might have been avoidable by early recognition and treatment, occurs in 25 to 50% of cases with congenital hyperinsulinism.[1]

There is no absolute number that defines hypoglycemia in adults and in children. The current adult recommendations define clinical hypoglycemia as a plasma (or serum) glucose concentration low enough to cause symptoms and/or signs, including impairment of brain function. Because the clinical manifestations and symptoms of hypoglycemia are nonspecific, it is therefore not possible to state a single plasma glucose concentration that categorically defines hypoglycemia. The measured plasma or serum glucose concentration may be low owing to an artifact (e.g., when the blood sample is collected in a tube that does not contain an inhibitor of glycolysis and when separation of the plasma or serum from the formed elements is delayed).

For these reasons, guidelines in adults emphasize the value of Whipple triad for confirming hypoglycemia: (1) symptoms and/or signs compatible with hypoglycemia, (2) a low measured plasma glucose concentration, and (3) resolution of symptoms and signs when glucose concentrations are raised. Because circulating fuels such as ketone bodies can be used by the brain, lower plasma glucose concentrations can occur in healthy individuals, particularly in women and children, without symptoms or signs during extended fasting. Therefore, for all of these reasons, it is not possible to state a single plasma glucose concentration that categorically defines hypoglycemia.

The aim of this chapter is to outline the physiologic and biochemical changes associated with maintenance of a normal blood glucose level, describe the role of the counter-regulatory hormones, review the different hypoglycemia disorders observed in adults and children, and then finally discuss the various management strategies.

PATHOBIOLOGY

Physiologic and Biochemical Changes During Fasting and Feeding

Overview

Plasma glucose concentration is tightly controlled by a balance between glucose production and utilization. Glucose is derived from three sources: (1) intestinal absorption that follows digestion of dietary carbohydrates; (2) glycogenolysis, the breakdown of glycogen, which is the polymerized storage form of glucose; and (3) gluconeogenesis, the formation of glucose from precursors including lactate (and pyruvate), amino acids (especially alanine and glutamine), and to a lesser extent, glycerol. Normally, there is tight coordination between rates of endogenous glucose influx into the circulation and glucose efflux out of the circulation into insulin-dependent tissues (skeletal muscle, adipose tissue, and liver). This coordination, despite periods of feeding and fasting, maintains the plasma glucose concentration in a relatively narrow range between 70 and 110 mg/dL (3.8 to 6 mmol/L). Figure 230-1 shows an outline of glucose physiology.

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. Unlike other body tissues, the brain cannot oxidize fatty acids, and neither can it synthesize/store glucose for later use. It is dependent on a continuous supply of glucose from the circulation. Given the vital importance of brain function and the above circumstances, it is not surprising that physiologic mechanisms have evolved for the maintenance of plasma glucose concentrations.

Changes During Fasting

During fasting, the basal rate of glucose output by the liver is precisely matched to glucose uptake by various body tissues. They average 2.2 mg/kg/minute in healthy adults after an overnight fast. In infants, these rates are much higher (≈6 mg/kg/minute) because of their greater brain mass relative to their body weight. The brain is responsible for nearly two thirds of basal glucose utilization. The remaining one third is used by red blood cells, renal medulla, and to some extent muscle and fat.

Hepatic glucose production results from a combination of glycogenolysis and gluconeogenesis. Endogenous glucose production is also contributed by gluconeogenesis in the kidneys. Breakdown of stored hepatic glycogen is a readily available source of free glucose. However, in an average adult, this process can only provide less than an 8-hour supply of free glucose. (In infants, this may provide only 4 hours of free glucose.) Considering this

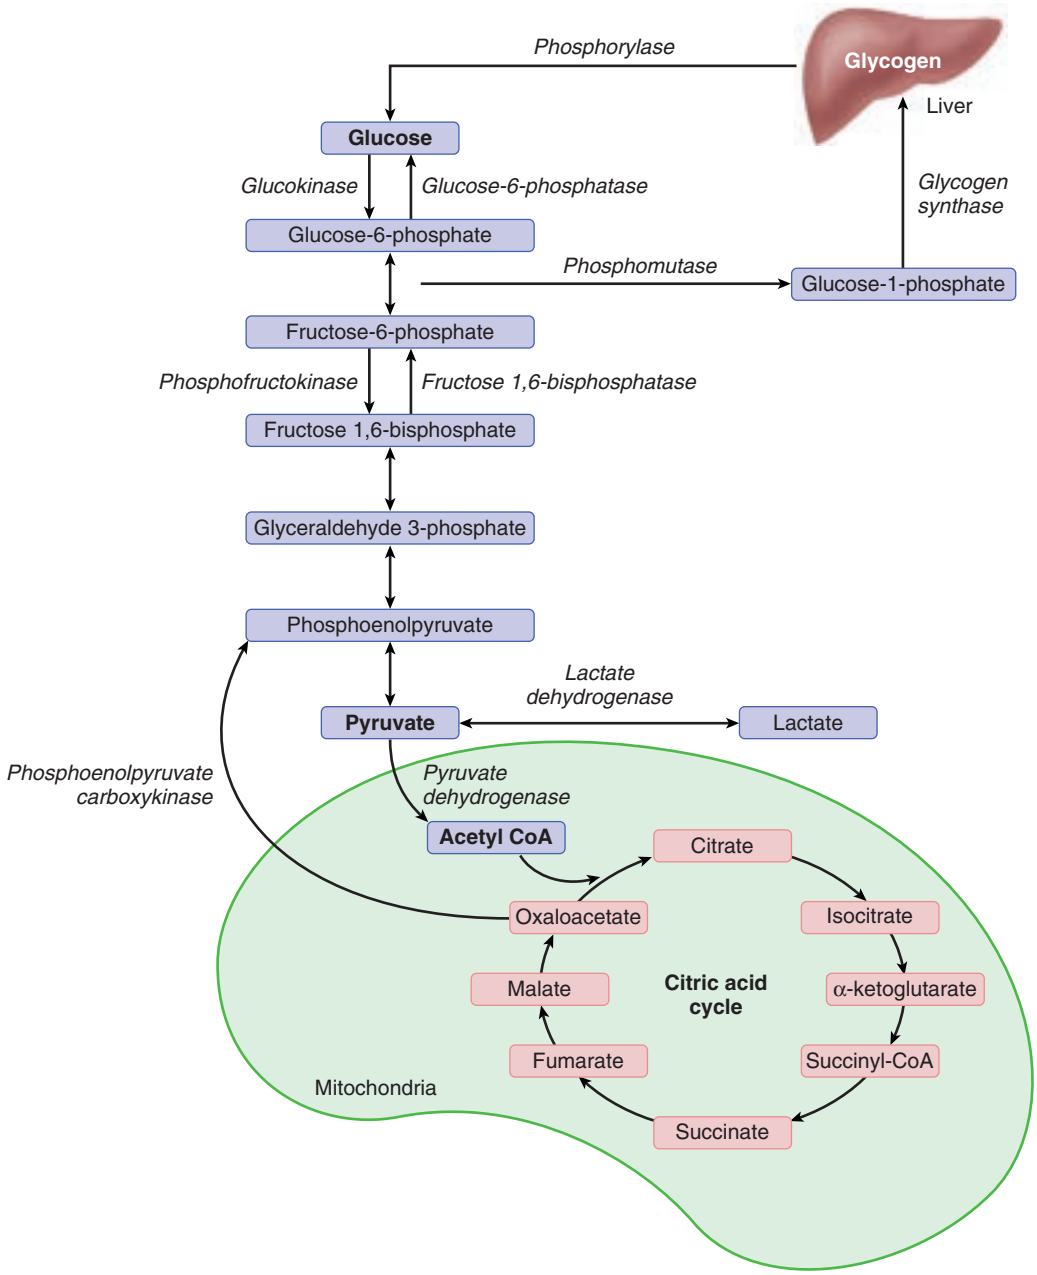

FIGURE 230-1. Outline of the biochemical pathways involved in glucose physiology.

limited capacity of glycogenolysis, gluconeogenesis is very important in supporting hepatic glycogen stores during an overnight fast.

Gluconeogenesis uses a number of key enzymes: pyruvate carboxylase, phosphoenolpyruvate carboxykinase (PEPCK), and fructose-1,6-bisphosphatase and its precursors, including lactate, alanine, glutamine, glycerol, and pyruvate. Muscle and adipose tissue, which utilize glucose in the fed state, respond to prolonged fasting by reducing their glucose uptake virtually to zero and satisfying their energy requirements by the β-oxidation of fatty acids. Additionally, through the process of proteolysis, muscle tissue provides amino acids to the liver to serve as gluconeogenic precursors for net glucose formation. Changes in the hormonal milieu during fasting (suppressed insulin and elevated counter-regulatory hormones) stimulate ketogenesis. Ketones become a major source of fuel for the brain when glucose utilization by the brain declines. This results in a decrease in the rate of gluconeogenesis required to maintain the plasma glucose concentration and hence in diminished protein wasting.

Changes During Feeding

After a meal, glucose absorption into the circulation increases glucose concentrations, which stimulates secretion of insulin from the pancreatic β-cells and suppresses secretion of glucagon from the pancreatic α-cells. This change in the hormonal milieu switches off endogenous hepatic glucose production and accelerates glucose utilization by liver, muscle, and adipose tissue. Glucose concentration then returns gradually to the postabsorptive level, at which endogenous glucose production is equal to the glucose uptake by peripheral tissues.

Counter-Regulatory Hormonal Responses to Hypoglycemia

The counter-regulatory hormones play a key role in the maintenance of normal blood glucose concentration.[2] If counter-regulation is intact, hypoglycemia (irrespective of the cause) will result in a decrease in insulin secretion and an increase in glucagon, epinephrine, norepinephrine, cortisol, and growth hormone (GH) secretion. Glucagon secretion increases rapidly in response to hypoglycemia, and studies have shown that the glucagon response is the primary essential defense mechanism against acute hypoglycemia. GH and cortisol have numerous effects on glucose metabolism, including increasing the rate of gluconeogenesis and antagonizing the effects of insulin. In adults, the glycemic thresholds for the activation of glucose counter-regulatory hormones such as GH and cortisol lie within or just below the physiologic blood glucose concentration and slightly higher than the threshold for symptoms. This suggests that GH and cortisol secretion increase in response to blood glucose concentrations within the normoglycemic range,

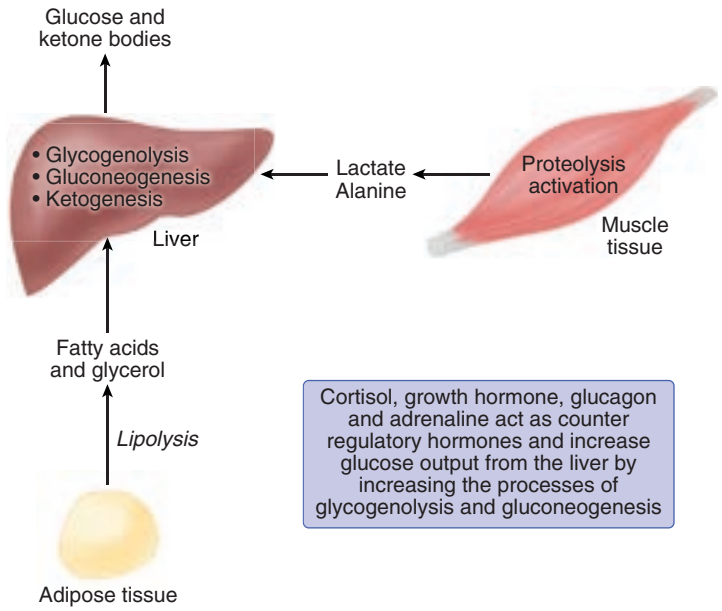

FIGURE 230-2. **The role of the counter-regulatory hormones, glycogenolysis, gluconeogenesis, and lipolysis in glucose physiology.**

and these increases are inversely proportional to the nadir in blood glucose. Figure 230-2 outlines the role of the counter-regulatory hormones.

Insulin secretion from β-cells of the pancreas in healthy individuals is inhibited as blood glucose concentration falls below 72 mg/dL (4.0 mmol/L). As insulin secretion is reduced, the repressive effect of insulin on pancreatic α-cell function is removed, thereby rapidly increasing glucagon secretion. Glucagon acts on the liver to increase hepatic glycogenolysis and gluconeogenesis. When the blood glucose concentration falls further (≈68 mg/dL [3.8 mmol/L]), epinephrine and norepinephrine are released both from the adrenals and directly into interstitial fluid from nerve terminals, further suppressing insulin secretion, increasing glucagon secretion, and decreasing peripheral glucose utilization in the muscle and increasing lipolysis in the adipose tissues.

Additional responses include GH and cortisol secretion, which occur below a blood glucose concentration of around 66 mg/dL (≈3.7 mmol/L) and are initiators of the adaptive response to hypoglycemia (e.g., during prolonged starvation); glucose-raising actions are much slower in onset (several hours). These hormone responses stimulate lipolysis, ketogenesis, and gluconeogenesis. Permissive amounts of cortisol and GH are required for a normal hepatic response to glucagon and epinephrine. In healthy individuals, this system ensures that hypoglycemia is rarely experienced and would only occur during starvation or ultra-endurance sports. Drugs or diseases that inhibit counter-regulatory secretion or action predispose patients to hypoglycemia.

Activation of counter-regulation depends on effective detection of falling blood glucose levels. This is achieved by the complex integration of various glucose-sensing systems in both the periphery and central nervous system.[3] Fluctuations in peripheral glucose levels are detected by glucose-sensing neurons in the oral cavity, gut, portal/mesenteric vein (PMV), and carotid body. PMV neurons detect changes in blood glucose prior to entry into the liver from the gut. This information is then relayed through the vagus nerve and spinal cord to the hindbrain and then to the hypothalamus. In addition, the hypothalamus, because of its location adjacent to the third ventricle and median eminence, may sample factors from peripheral circulation, including glucose, as well as hormones such as insulin and leptin. Although a complex network of glucose sensors has been described in the central nervous system and peripherally, the brain appears to have the dominant role during hypoglycemia and, specifically, the ventromedial region of the hypothalamus (VMH). VMH neurons contain the same glucose-sensing mechanisms (e.g., glucokinase, ATP-sensitive K^+ channels) as found in pancreatic β-cells.

CLINICAL MANIFESTATIONS

Symptoms of Hypoglycemia

The symptoms of hypoglycemia reflect the responses of the brain to a decrease in the blood glucose level; such symptoms may be nonspecific and vague, especially in the childhood period. Children may not be able to communicate their hypoglycemic symptoms. The symptoms of hypoglycemia may be categorized into two main groups: (1) those that arise as a result of the central nervous system being deprived of glucose (neuroglycopenic) and (2) symptoms arising from the perception of physiologic changes caused by the central nervous system–mediated sympatho-adrenal discharge triggered by hypoglycemia (neurogenic or autonomic).[4] The neurogenic symptoms of hypoglycemia are largely the result of sympathetic neural, rather than adrenomedullary, activation.

Neuroglycopenic symptoms (e.g., dizziness, confusion, tiredness, difficulty with speaking, headache, inability to concentrate, coma, and seizures) arise from the failure of brain function itself and are caused by deficient supply of glucose to the brain.[5] Neurogenic symptoms include both adrenergic responses (catecholamine-mediated symptoms such as palpitations, tremor, and anxiety) and cholinergic responses (acetylcholine-mediated symptoms such as sweating, hunger, paresthesias). Awareness of hypoglycemia chiefly depends on perception of the central and peripheral effects of neurogenic (as opposed to neuroglycopenic) responses to hypoglycemia.

In nondiabetic adults during acute insulin-induced hypoglycemia, autonomic symptoms become apparent at a threshold of approximately 60 mg/dL (3.3 mmol/L), and impairment of brain function manifested by neuroglycopenic symptoms occurs at a threshold of approximately 50 mg/dL (2.8 mmol/L) in arterialized venous blood (venous levels would be ≈ 3 mg/dL [0.16 mmol/L] less). However, in patients with recurrent hypoglycemia, the glycemic thresholds for responses to hypoglycemia are reset at a lower plasma glucose concentration. The glucose thresholds for the activation of neuroglycopenic and autonomic symptoms in children are not as clearly defined as in adults. The symptoms and signs of hypoglycemia are not influenced by the rate of blood glucose decline in nondiabetic individuals.

Clinical Approach to the Patient with Hypoglycemia

A careful clinical history, description of symptoms, physical examination, and a systematic step-by-step approach are the cornerstones of establishing a diagnosis. The symptoms of hypoglycemia may be very nonspecific, hence any symptomatic child or adult must have the blood glucose level measured and documented.

The relationship of a hypoglycemic episode to the most recent meal can be important diagnostically. Hypoglycemia occurring after a short fast (2 to 3 hours) may be suggestive of hyperinsulinism or glycogen storage disease. Hypoglycemia occurring after a long fast (12 to 14 hours) may suggest a disorder of gluconeogenesis. Postprandial hypoglycemia may indicate galactosemia, hereditary fructose intolerance, dumping syndrome, insulinoma, insulin autoimmune syndrome, and noninsulinoma pancreatogenous hypoglycemia syndrome. In both children and adults, a clear documentation of the medication history is important.

DIAGNOSIS

After the clinical history has been taken and the examination completed, a diagnostic cascade of appropriate tests is necessary. These may be guided in the context of the most common causes of hypoglycemia as listed in Table 230-1.

The current adult recommendations[6] state that evaluation and management of hypoglycemia should only be undertaken in patients in whom Whipple's triad—symptoms, signs, or both consistent with hypoglycemia, a low plasma glucose concentration, and resolution of those symptoms or signs after the plasma glucose concentration is raised—is documented. However, this does not apply to children for the reasons discussed earlier.

Causes of Hypoglycemia

Hypoglycemia is more common in the childhood period than in adults and can be due to a large number of causes. Table 230-1 summarizes the differential diagnosis of hypoglycemia.

Hypoglycemia Due to Excess Production of Hormones

Inappropriate and excess production of certain hormones can lead to hypoglycemia. The two most common conditions associated with excess production of a hormone are hyperinsulinemic hypoglycemia (HH) and non–islet cell tumor hypoglycemia (NICTH) or IGF-2-oma (insulin-like growth factor–secreting tumor). Inappropriate production of insulin can either lead to fasting hypoglycemia or postprandial hypoglycemia.

TABLE 230-1 DIFFERENTIAL DIAGNOSIS OF HYPOGLYCEMIA*

HYPERINSULINEMIC HYPOGLYCEMIA (INCLUDING POSTPRANDIAL)
Transient: infant of diabetic mother, perinatal asphyxia, Rhesus disease, intrauterine growth retardation, Beckwith-Wiedemann syndrome
Congenital: *ABCC8*, *KCNJ11*, ***GCK***, *GDH*, *HADH*, *HNF4A*, ***SLC16A1***
Dumping syndrome
Insulin receptor mutations and antibodies
Insulinoma
Noninsulinoma pancreatogenous hypoglycemia (adults)
Gastric bypass surgery for morbid obesity
Non–islet cell tumor hypoglycemia (NICTH) or IGF-2-oma
Insulin autoimmune syndrome
Insulin factitious hypoglycemia
HORMONAL DEFICIENCY/RESISTANCE
Adrenocorticotropic hormone
Cortisol
Growth hormone
Glucagon†
Adrenaline†
DEFECTS IN HEPATIC GLYCOGEN RELEASE/STORAGE
Glycogen storage diseases: **glucose-6-phosphatase**, **amylo-1,6-glucosidase deficiency**, liver phosphorylase deficiency, glycogen storage disease type 0
DEFECTS IN GLUCONEOGENESIS
Fructose-1,6-bisphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency, pyruvate carboxylase deficiency
CARNITINE METABOLISM
Carnitine deficiency (primary and secondary)
Carnitine palmitoyltransferase deficiency (CPT 1 and 2)
Carnitine transporter defects
FATTY ACID OXIDATION
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency
Very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency
Short-chain acyl-CoA dehydrogenase (SCAD) deficiency
Long/short-chain L-3-hydroxyacyl-CoA (L/SCHAD) deficiency
DEFECTS IN KETONE BODY SYNTHESIS/UTILIZATION
HMG-CoA synthase deficiency, HMG-CoA lyase deficiency
Succinyl-CoA: 3-oxoacid-CoA transferase (SCOT) deficiency
METABOLIC CONDITIONS (COMMON ONES)
Organic acidemias (propionic, methylmalonic)
Maple syrup urine disease, galactosemia, fructosemia, tyrosinemia
Hereditary fructose intolerance
Mitochondrial respiratory chain complex deficiencies
Congenital disorders of glycosylation (CGD)
DRUG INDUCED
Sulfonylureas
Insulin
β-Blockers
Salicylates
Alcohol
Quinine
Haloperidol
Pentamidine
Levofloxacin
Methadone
Disopyramide
Indomethacin
Cibenzoline
Gatifloxacin
MISCELLANEOUS CAUSES (MECHANISM[S] NOT CLEAR)
Idiopathic ketotic hypoglycemia (diagnosis of exclusion)
Infections (sepsis, malaria), congenital heart disease

*Boldface indicates more common in adults.
†No human case yet reported with glucagon or adrenaline deficiency.
HMG = 3-hydroxy-3-methylglutaryl; IGF = insulin-like growth factor.

Hyperinsulinemic Hypoglycemia

HH is a heterogeneous group of disorders characterized by unregulated insulin secretion from pancreatic β-cells. In the face of hypoglycemia, patients have inappropriately detectable serum insulin levels, low ketone bodies, and low fatty acids and show a glycemic response to glucagon.[7]

Congenital Forms of Hyperinsulinemic Hypoglycemia

In patients with congenital forms of HH, mutations in the key genes (*ABCC8*, *KCNJ11*, *GLUD1*, *GCK*, *HADH*, *SLC16A1*, *HNF4A*, *HNF1A*, and *UCP2*) regulating insulin secretion have been identified.[8] Children with inactivating mutations in the genes *ABCC8* and *KCNJ11* present with the most severe forms of congenital HH, typically in the newborn period. Hyperinsulinism-hyperammonemia syndrome due to activating mutations in the *GLUD1* gene and activating mutations in the *GCK* gene, leading to HH, have both been described in adults as well as children. Exercise-induced HH due to activating mutations in the *SLC16A1* gene has also been recognized in adults.

Insulinoma

An insulinoma is the commonest cause of endogenous HH in adults. Insulinomas have the highest incidence in the fifth and sixth decades.[9] Insulinomas are insulin-secreting tumors of pancreatic origin, with an incidence of 1 to 4 per million. The majority (90%) of them are benign, solitary, intrapancreatic and less than 2 cm in diameter. Classically, symptoms become evident in the fasting state or following exercise. However, it is now known that insulinoma can also present with postprandial symptoms. Diagnosis is based on findings of abnormal serum levels of insulin and C-peptide (also proinsulin) at the time of fasting hypoglycemia. An insulinoma can occur either in isolation or in association with multiple endocrine neoplasia type 1 (MEN 1), with a lifetime prevalence of 10% among adults carrying mutations in *MEN1* (Chapter 231). Around 6% of insulinomas occur in patients with MEN 1, and most insulinomas are benign, but 5 to 10% are malignant.

Postprandial Hyperinsulinemic Hypoglycemia

Postprandial hyperinsulinemic hypoglycemia (PPHH) refers to hypoglycemia within a few hours of meal ingestion, secondary to inappropriate insulin secretion in response to a meal. If PPHH is clinically suspected, then an oral glucose tolerance test (OGTT) or a mixed-meal provocation test is performed. (See later in section "Investigations for Hypoglycemia.") A physiologic dip in the blood glucose level seen in OGTT might lead to misdiagnosis. However, corresponding biochemical evidence of endogenous HH and symptoms of neuroglycopenia during a hypoglycemic episode would help distinguish between pathologic PPHH and reactive hypoglycemia. A decrease of more than 108 mg/dL (6 mmol/L) between peak and nadir blood glucose during OGTT has been used as a diagnostic criterion for dumping syndrome in adults.

DUMPING SYNDROME. Dumping syndrome seen in infants after Nissen fundoplication is a classic example of PPHH. Precipitous emptying of hyperosmolar carbohydrate-containing solutions into the small bowel results in rapid glucose absorption, hyperglycemia, and reactive hypoglycemia. These children also tend to have abnormally exaggerated secretion of glucagon-like peptide-1 (GLP-1), which may contribute to the exaggerated insulin surge and resultant hypoglycemia.[10]

INSULIN AUTOIMMUNE SYNDROME. Insulin autoimmune syndrome, or Hirata's disease, is a rare condition characterized by HH associated with high titers of antibodies to endogenous insulin in the absence of pathologic abnormalities of pancreatic islets and prior exposure to exogenous insulin. The disease is extremely uncommon in Western countries. Insulin autoimmune syndrome affects men and women equally and is seen more frequently in patients older than 40 years. The binding kinetics of endogenous insulin by the antibodies are thought to lead to physiologically inappropriate levels of bioavailable insulin, causing either hyper- or hypoglycemia.

In this syndrome, the insulin levels are markedly elevated, usually above 100 mU/L. After a meal or glucose load, these patients often demonstrate initial hyperglycemia, followed by hypoglycemia a few hours later. The hyperglycemia is caused by the anti-insulin antibodies that bind the insulin secreted in response to rising blood glucose levels after a meal. This binding reduces the bioavailability of the secreted insulin to the receptors in the liver and peripheral tissues, resulting in hyperglycemia and further insulin secretion. As blood glucose concentrations begin to decrease and insulin secretion declines, the insulin bound to the antibodies is released, resulting in inappropriately high free insulin concentrations for the blood glucose, causing hypoglycemia.

PPHH IN PATIENTS WITH INSULIN-RECEPTOR MUTATIONS. PPHH has been described in patients who carried a heterozygote mutation (Arg-1174Gln) in the insulin-receptor gene. Hyperinsulinism seems to be associated with decreased degradation rather than increased secretion of insulin, as evidenced by increased fasting levels of serum insulin despite normal levels of serum C-peptide and reduced clearance of exogenous insulin during clamp studies.

PPHH AFTER GASTRIC BYPASS SURGERY. A consequence of the obesity epidemic is the increasing use of gastric bypass surgery for patients with severe, medically complicated obesity (Chapter 220), which has led to a number of reports of postprandial HH.[11] In a review of the Swedish Bariatric Surgery registry, the incidence of hospitalization for hypoglycemia in post–gastric bypass patients was reported as less than 1%.

A number of different explanations have been suggested to explain hypoglycemia post gastric bypass surgery. This can either be a manifestation of dumping syndrome or improved insulin sensitivity following weight loss unmasking an underlying hyperinsulinemia syndrome. The hypoglycemia could also be due to an effect on the enteroinsular axis induced by the diversion of nutrients into the small intestine.

The principal reason seems to be enhanced postprandial insulin secretion, thought to be due primarily to increased secretion of glucose-dependent insulinotropic polypeptide (GIP) and especially GLP-1. GLP-1 levels are now well documented to be increased two- to five-fold after gastric bypass. The elevations of incretins tend to be seen early, even as early as 2 days after gastric bypass, and levels may decline as substantial weight loss and normalization of insulin sensitivity occurs. In patients with PPHH, elevated levels of GIP and GLP-1 persist for years after surgery.

Increased postprandial insulin secretion by incretins is mediated by islet cell hypertrophy and hyperplasia. Both GIP and GLP-1 have been implicated in increasing pancreatic β-cell mass in rodent models. GLP-1 regulates islet growth by inducing the expression of the transcription factor pancreatic-duodenum homeobox-1 (PDX-1).

Overexpression of IGF-2 and IGF-1 receptor alpha (IGF1Rα) have been found in pancreatic tissue removed from patients with persistent PPHH after gastric bypass surgery as compared to controls. These findings are suggestive of the role of growth factors in islet hyperfunction seen in post–gastric bypass patients.

NONINSULINOMA PANCREATOGENOUS HYPOGLYCEMIA SYNDROME. Noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) is characterized by postprandial neuroglycopenia in the presence of negative prolonged fasting tests and negative perioperative localization studies for insulinoma.[12] However, in some patients the selective arterial calcium stimulation test is positive, with the histology of the resected pancreas showing nesidioblastosis. The underlying genetic basis of NIPHS is not known.

These patients are negative for *ABCC8/KCNJ11* mutations and show islet hypertrophy histologically (as observed in diffuse congenital HH).

Immunohistologic studies of the resected pancreatic tissue have failed to show an increased rate of proliferation of β-cells or abnormal synthesis and/or processing of either proinsulin or amylin. Neither has there been any evidence of overexpression of pancreatic differentiation factors, PDX-1, and Nkx-6.1, nor the calcium-sensing receptor (CaSR).

Insulin Factitious Hypoglycemia

Hypoglycemia can also be induced pharmacologically, either intentionally as a diagnostic tool, accidentally as a complication of the treatment of diabetes mellitus, or as a consequence of poisoning either with insulin itself or with drugs (e.g., sulfonylureas) that stimulate insulin release. Whenever severe hypoglycemia occurs with documented hyperinsulinism, the possibility of Munchausen's syndrome by proxy should be considered in children. The possibility of malicious administration of insulin or an oral sulfonylurea should always be suspected in cases of sudden onset of hypoglycemia in a previously healthy individual. In the case of insulin administration, the clue in the biochemistry will be a raised insulin level accompanied by normal C-peptide.

Non–Islet Cell Tumor Hypoglycemia, or IGF-2-oma

NICTH, or IGF-2-oma, denotes the syndrome of hypoglycemia produced by or associated with any neoplasm other than an insulinoma. These are usually tumors of mesenchymal and epithelial origin (including hepatomas, fibromas, and fibrosarcomas). The underlying mechanism of hypoglycemia in nearly all patients with this syndrome is overproduction of IGF-2 by the tumor, which includes mature IGF-2 and incompletely processed forms of IGF-2, referred to collectively as "big" IGF-2.[13] The elevated IGF-2–related peptides mimic the fasting hypoglycemia characteristic of patients with insulin-producing islet cell tumors. Rarely, markedly elevated IGF-2 levels produce somatic changes suggestive of acromegaly. Typically, the elevated IGF-2 levels are associated with suppressed plasma levels of insulin, IGF-1, and GH.

Hypoglycemia Due to Hormone Deficiency

Deficiency of glucagon, adrenaline, GH, and cortisol can cause hypoglycemia. Glucagon and adrenaline deficiency is extremely rare, and so far no true human, genetically proven defects in glucagon and adrenaline deficiency have been described. Children and adults can present with hypoglycemia due to deficiency of various hormones. This might be either in isolation (e.g., isolated GH, adrenocorticotropic hormone [ACTH], or cortisol deficiency) or in combination with other hormones, such as in patients with hypopituitarism. The etiology of the hypoglycemia resulting from cortisol and GH deficiency is due to a combination of factors, including reduced gluconeogenic substrate availability (decreased mobilization of fats and proteins) and increased glucose utilization due to increased insulin sensitivity of tissues in the absence of these two hormones.

Acquired hypopituitarism may result from tumors (most commonly craniopharyngioma), radiation, infection, hydrocephalus, vascular anomalies, and trauma. Addison disease (AD) results from adrenal cortex hypofunction/dysfunction, with deficient production of glucocorticoids, mineralocorticoids, and androgens, and with high levels of both ACTH and plasma renin activity (Chapter 227). Autoimmune AD is the most frequent etiologic form in adult patients, accounting for about 80% of cases, followed by post-tuberculosis AD in 10 to 15%; the remaining 5% of cases are due to vascular, neoplastic, or rare genetic forms.

The markers of autoimmune AD are adrenal cortex (ACA) or 21-hydroxylase autoantibodies (21-OHAbs), and they are present at diagnosis in more than 90% of cases. In autoimmune AD, the adrenal cortex is infiltrated by lymphocytes and plasma cells, and the glands are sclerotic and reduced in volume. Autoimmune AD occurs mainly in middle-aged women, alone or associated with other (clinical, subclinical, or potential) autoimmune diseases, giving rise to various forms of autoimmune polyglandular syndrome. Replacement therapy with gluco- and mineralocorticoids is life-saving for patients with chronic adrenal insufficiency.

Hypoglycemia Due to Defects in Hepatic Glycogen Release/Storage

Glucose-6-phosphatase deficiency (glycogen storage disease [GSD] type I, Von Gierke disease) is the commonest of the glycogen storage diseases causing hypoglycemia (Chapter 207). Deficiency of this enzyme results in the inability to release free glucose from glucose-6-phosphate, with resultant hepatomegaly due to stored glycogen. These children and adults present with recurrent hypoglycemia associated with lactic acidosis, hyperuricemia, and hyperlipidemia.[14] The two other glycogen storage diseases causing hypoglycemia are due to deficiencies of the enzymes amylo-1,6-glucosidase (GSD type III) and liver phosphorylase (GSD type VI). The clinical and biochemical features of GSD-III subjects are quite heterogeneous.

Hypoglycemia Due to Defects in Gluconeogenesis

Gluconeogenesis, or the formation of glucose from mainly lactate/pyruvate, glycerol, glutamine, and alanine, plays an essential role in the maintenance of normoglycemia during fasting. Inborn deficiencies are known in each of the four enzymes of the glycolytic-gluconeogenic pathway that ensure a unidirectional flux from pyruvate to glucose: pyruvate carboxylase, phosphoenolpyruvate carboxykinase (PEPCK), fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Gluconeogenesis can essentially be viewed as a reversal of glycolysis but with a few important differences. Patients with defects in gluconeogenesis present with fasting hypoglycemia and lactic acidosis. Pyruvate carboxylase deficiency may lead to a more widespread clinical presentation, with lactic acidosis, severe mental and developmental retardation, and proximal renal tubular acidosis.

Hypoglycemia Due to Disorders of Carnitine Metabolism and Defects of Fatty Acid Oxidation

Serious clinical consequences may occur if fatty acid oxidation (FAO) is impaired, including hypoglycemic seizures, muscle damage, cardiomyopathy, metabolic acidosis, and liver dysfunction. Fatty acids are taken up by

hepatocytes and muscle, where they are subsequently activated to their coenzyme A (CoA) esters. FAO disorders are individually rare, but they are collectively common because of the number of different enzymes affected. When defects occur in fatty acid degradation, excess acylcarnitine intermediates accumulate in the tissues, including heart, liver, and skeletal muscle, which can lead to organ dysfunction. The diversion of acyl-CoA intermediates into β-oxidation results in accumulation of toxic dicarboxylic acids. Acylcarnitines that spill into the blood provide a marker for diagnosis.

Primary carnitine deficiency is an autosomal recessive disorder of fatty acid oxidation that can present at different ages with hypoketotic hypoglycemia and cardiomyopathy and/or skeletal myopathy (Chapter 205). This disease is suspected based on reduced levels of carnitine in plasma and confirmed by measurement of carnitine transport in the patient's fibroblasts. Carnitine transport is markedly reduced (usually < 5% of normal) in fibroblasts from patients with primary carnitine deficiency. Patients with the hepatic isoform of carnitine palmityltransferase (CPT)-1 deficiency present with hypoketotic hypoglycemia in the neonatal period.

The commonest disorder of fatty acid β-oxidation is medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, an autosomal recessive disease presenting in children who are typically asymptomatic except during times of fasting and metabolic stress, usually associated with a viral illness, when they present with fasting nonketotic hypoglycemia; if undiagnosed, 20 to 25% of affected patients will die during the first episode.

Metabolic Diseases

Hypoglycemia can also be due to a number of metabolic conditions (Chapter 205), including galactosemia, fructosemia, tyrosinemia, organic acidemias, maple syrup urine disease, glutaric aciduria type II, and in mitochondrial respiratory chain defects. Hereditary fructose intolerance, caused by catalytic deficiency of aldolase B (fructose-1,6-phosphate aldolase), is a recessively inherited condition in which affected homozygotes develop hypoglycemia and severe abdominal symptoms after taking foods containing fructose and cognate sugars. Continued ingestion of noxious sugars leads to hepatic and renal injury and growth retardation.

Noninsulinoma Islet Cell Tumors

Islet cell tumors present an important challenge to the clinician because of their protean manifestations and potential lethality. These tumors can be clinically silent or active (functioning). Early diagnosis is essential and depends on recognition of the classic and variant clinical syndromes followed by confirmation of elevated peptide levels by radioimmunoassay.[15] Glucagonoma, gastrinoma, VIPoma (VIP = vasoactive intestinal peptide), somatostatinoma, and ACTHoma are functioning tumors that may occur in isolation but can also be part of MEN 1 syndrome (Chapter 231) and von Hippel-Lindau disease (Chapter 417).

Tumor marker measurement gives useful information for the follow-up and management of patients with noninsulinoma islet cell tumors (neuroendocrine tumors). The currently used tumor markers are neuron-specific enolase (NSE) and chromogranin A (CgA). The clinical accuracy of these biomarkers depends on histotype and disease extent. CgA is thought to be the optimal marker for most neuroendocrine tumors, because it is independent of the biological characteristics of the tumor.

Glucagonoma

Glucagonomas are α-cell tumors that, when they are active, produce a syndrome characterized by necrolytic migratory erythema, diabetes mellitus, weight loss, anemia, glossitis, thromboembolism, neuropsychiatric disturbances, and hyperglucagonemia. Tumor characterization is made by computed tomography (CT) and/or pancreatic endoscopic ultrasonic and indium-labeled octreoscan. The diagnosis is established by documenting the presence of hyperglucagonemia, with diagnostic levels being generally above 500 pg/mL (normal, <120). It is important to remember that other diseases can also cause hyperglucagonemia, including cirrhosis, pancreatitis, diabetes mellitus, prolonged fasting, sepsis, burns, renal failure, acromegaly, and familial hyperglucagonemia. Surgery is the main component of treatment, in some cases in association with chemotherapy.

Gastrinoma

Gastrinomas are uncommon tumors of the endocrine system, occurring within the pancreas and duodenum. Overproduction of the hormone gastrin by these tumors produces a sustained increase in gastric acid secretion, leading to complications of peptic ulceration known as the Zollinger-Ellison syndrome (ZES). Gastrinomas can occur sporadically or in a familial pattern as a component of the MEN 1 syndrome. Gastrinomas have the potential to metastasize to regional lymph nodes, the liver, and other distant sites.

VIPoma

VIPoma is very rare, with 80% of these tumors originating from the pancreas, mostly in the tail. The majority of cases are sporadic. About 50 to 60% of cases have metastasized by the time the diagnosis is made. Most patients have secretory watery diarrhea, resulting in electrolyte disturbances, such as hypokalemia, hypophosphatemia, hypomagnesemia, and metabolic acidosis (Verner-Morrison syndrome, pancreatic cholera, WDHA syndrome). Hypochlorhydria or achlorhydria occurs in 75% of cases, owing to the inhibition of gastric acid production by VIP. Hyperchloremic acidosis can also occur as a result of low bicarbonate levels from severe intestinal loss. Occasionally, hypercalcemia, glucose intolerance, and hypotension may be present. The VIP level is elevated in almost all cases, but it can also be normal between episodes of diarrhea.

Somatostatinoma

Somatostatinomas are rare neuroendocrine tumors with an incidence of 1 in 40 million. These unusual tumors arise predominantly in the pancreas and peripancreatic duodenum, and patients often present with nonspecific symptoms. Rarely, patients present with somatostatinoma syndrome (diabetes, gallstones, and steatorrhea) when the tumor is secretory.

Investigations for Hypoglycemia

From the clinical history, description of symptoms, and physical examination, there might be important clues to the underlying cause of hypoglycemia, and the investigations can then be tailored to the particular cause. However, in some cases the clinical history and physical examination may not provide any clues, and in these cases the patient will need to be investigated more extensively.

Reagent strips in combination with a reflectance meter are the most common method of measuring bedside blood glucose levels. However, it is important to remember that these should be used only as a guide (they can be inaccurate), and the blood glucose concentration should always be checked in the laboratory. Whole-blood glucose is approximately 15% lower than serum glucose levels because of the lower glucose content and intracellular water content of the red cells. Glucose concentrations in venous blood are 10% lower than arterial blood. The blood sample for glucose measurement should be collected in a fluoride container to inhibit glycolysis. It should also be analyzed immediately because, even in the presence of fluoride, the blood glucose concentration will decrease over time.

In an ideal situation, the blood glucose level should be measured at the time of a spontaneous episode of hypoglycemia, and samples for plasma glucose, insulin, C-peptide, proinsulin, and β-hydroxybutyrate concentrations and toxicology screen for oral hypoglycemic agents taken. The blood glucose must be considered in the context of the whole fuel economy and in the light of concurrent hormone concentrations. However, this is not always possible, and patients may require further tests (e.g., fasting, mixed-meal, or provocation testing) to unravel the cause of the hypoglycemia. The various tests used for eliciting hypoglycemia in adults and children are described next. Table 230-2 shows the routine baseline investigations that should be performed in children and adults presenting with hypoglycemia.

TABLE 230-2 ROUTINE BASELINE INVESTIGATIONS IN PATIENTS WITH SUSPECTED HYPOGLYCEMIA

BLOOD	URINE
Glucose	Ketones
Insulin	Reducing substances
Cortisol	Organic acids
Lactate	
Growth hormone	
Nonesterified fatty acids	
3β-Hydroxybutyrate	
Carnitine (free and total)	
Blood spot acylcarnitine	
Ammonia	

TABLE 230-3 PROTOCOL FOR 72-HOUR FAST IN ADULTS

1. Start the fast from the last ingestion of a meal. Stop all medications that might interfere with test.
2. The patient can drink water during the test.
3. The patient must be active during waking hours.
4. Measure plasma glucose, insulin, C-peptide, and β-hydroxybutyrate (on the same venipuncture specimen) every 6 hours until plasma glucose reaches 60 mg/dL (3.3 mM). Then measure every 1 to 2 hours.
5. End the fast when the plasma glucose is 45 mg/dL (2.5 mM) and the patient has symptoms or signs of hypoglycemia, or plasma glucose is 55 mg/dL if Whipple triad had been demonstrated previously.
6. At the end of the fast, measure plasma glucose, insulin, C-peptide, β-hydroxybutyrate, and sulfonylurea (on the same venipuncture specimen). Then inject glucagon, 1 mg intravenously, and measure plasma glucose every 10 minutes three times. Once the fast is completed, allow the patient to eat normally.

Adapted from Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:709-728.

TABLE 230-4 SUGGESTED PROTOCOL FOR A MIXED-MEAL DIAGNOSTIC TEST IN ADULTS

1. Fast patient overnight. Stop all medications that might interfere with test.
2. Use a mixed meal similar to one that causes patient to experience symptoms.
3. Collect samples for plasma glucose, insulin, C-peptide, and proinsulin before ingestion and every 30 minutes through 300 minutes after meal ingestion.
4. Observe the patient for symptoms and/or signs of hypoglycemia, and ask the patient to keep a written log of all symptoms, timed from the start of meal ingestion.
5. The mixed-meal test should be interpreted on the basis of laboratory measured plasma glucose concentrations, not those estimated with a point-of-care glucose monitor. If it is judged necessary to treat before 300 minutes because of severe symptoms, obtain samples for all the following *before* administering carbohydrates: plasma insulin, C-peptide, and proinsulin (sent for analysis only in those samples in which plasma glucose is < 60 mg/dL [3.3 mmol/L]), and a measurement of oral hypoglycemic agents. If Whipple triad is demonstrated, antibodies to insulin should also be measured.

Adapted from Cryer PE, Axelrod L, Grossman AB, et al. Evaluation and management of adult hypoglycemic disorders: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab.* 2009;94:709-728.

Fasting Tests

Controlled fasting tests are important procedures for eliciting the cause of hypoglycemia in both children and adults. In adults it is recommended that a prolonged supervised (72-hour) fast be conducted in a standardized fashion (Table 230-3). During the fast, if patients have any signs or symptoms of hypoglycemia, with a documented low blood glucose level, the fast should be terminated. It is currently recommended that the fast not be prolonged beyond 72 hours if patients do not have any symptoms or signs of hypoglycemia and no documentation of low blood glucose. Monitoring for symptoms or signs of hypoglycemia during the fast is essential because patients may experience some symptoms but have serum glucose levels higher than the hypoglycemic range. In some healthy women (thin and lean) and men, blood glucose levels may drop to 40 mg/dL (2.2 mmol/L) during prolonged fasting. Some patients have lower glycemic thresholds without symptoms or signs of hypoglycemia.

In an adult patient where Whipple triad has been demonstrated, the 72-hour fast may be terminated if the plasma glucose concentration is 55 mg/dL (3 mmol/L) or less. The interpretation of serum insulin, C-peptide, and proinsulin during the 72-hour fast will depend on the concurrent plasma glucose concentration. Pancreatic β-cell insulin secretion becomes undetectable in healthy persons when the plasma glucose concentration is down to 55 mg/dL (3 mmol/L). Most patients with an insulinoma become hypoglycemic before 72 hours. However, continuation of the fast to 72 hours is necessary to rule out the likelihood of organic hypoglycemia.

HH in adults is characterized by plasma insulin concentrations of 3 μU/mL or greater (C-peptide of 200 pmol/L or more and proinsulin 5 pmol/L or more). Insulinoma patients have plasma insulin concentrations that rarely exceed 100 μU/mL, and plasma insulin levels greater than 1000 μU/mL suggest exogenous insulin administration or the presence of insulin antibodies. In the childhood period, any detectable plasma insulin in the presence of hypoglycemia is inappropriate and is highly suggestive of HH.

Measurement of the plasma β-hydroxybutyrate concentration is used as a surrogate marker of insulin action at the end of the 72-hour fast in healthy adult individuals and when Whipple triad is fulfilled in patients during a diagnostic fast. In patients with HH, because of the suppressive action of insulin on ketogenesis, plasma concentrations of β-hydroxybutyrate are typically less than 2.7 mmol/L. This is in contrast to healthy individuals, who will show a progressive rise in the concentration of β-hydroxybutyrate during the 72-hour test. If a value above 2.7 mmol/L is documented at any time point in the fast, the test can be terminated. In the childhood period, there is no clear-cut plasma level of β-hydroxybutyrate that can be used to confirm HH.

Another useful marker of insulin action in both adults and children is the glycemic increment in response to an intravenous/intramuscular injection of glucagon (1-mg dose in adults). Patients with HH will have increased glycogen stores, and giving glucagon will result in glycogenolysis. A positive response is defined as a maximal increment at least 25 mg/dL (1.3 mmol/L) greater than the terminal fasting serum glucose.

During the 72-hour prolonged fast, blood should also be collected for measurement of plasma sulfonylureas and meglitinides if the patient develops hypoglycemia. Sulfonylureas stimulate pancreatic β-cell insulin and C-peptide secretion, and the biochemical pattern is similar to that of an insulinoma.

Mixed-Meal Test

A mixed-meal test is performed in patients in whom there is a history suggestive of neuroglycopenic symptoms for up to 5 hours after food ingestion (Table 230-4). A positive test is defined as the onset of neuroglycopenic symptoms in association a documented low blood glucose level (e.g., ≤50 mg/dL). In postprandial HH, plasma insulin and C-peptide levels might be inappropriately elevated. Neuroglycopenic symptoms after a meal are reported in patients with insulinoma, patients with NIPHS, and patients who have undergone surgery for obesity.

The combination of a positive mixed-meal test and a negative 72-hour fast may occur in a patient with insulinoma or with NIPHS. The 5-hour oral glucose tolerance test should not be used as a diagnostic test for hypoglycemia, because a substantial percentage of healthy persons may have a serum glucose concentration of 50 mg/dL (2.7 mmol/L) or less.

Insulin Antibodies

Insulin autoimmune syndrome (IAS) is an uncommon cause of HH characterized by autoantibodies to endogenous insulin in individuals without previous exposure to exogenous insulin. IAS is the third leading cause of spontaneous hypoglycemia in Japan, and is increasingly being recognized worldwide in non-Asian populations. In patients with insulin autoimmune hypoglycemia from the spontaneous generation of insulin antibodies, such antibodies may be monoclonal or polyclonal and are present in very high titers, in contrast to the much lower titers in insulin-treated diabetes. It is important to test for the presence of insulin antibodies, because even low titers—which may have no diagnostic significance—may cause spurious results of the assay for insulin. Hypoglycemia due to IAS typically occurs in the fasting period but can occur postprandially as well.

Radiologic Investigations

Noninvasive imaging procedures such as CT and magnetic resonance imaging (MRI) are used when a diagnosis of insulinoma has been made to localize the source of pathologic insulin secretion. Invasive modalities, such as endoscopic ultrasonography (EUS) and arterial stimulation venous sampling (ASVS), are highly accurate in the preoperative localization of insulinomas and have frequently been shown to be superior to noninvasive localization techniques.[16] Intraoperative manual palpation of the pancreas by an experienced surgeon and intraoperative ultrasonography are both sensitive methods with which to finalize the location of insulinomas.

The sensitivity of transabdominal ultrasonography in the localization of insulinomas is poor (ranging from 9% to 64%). However, insulinomas demonstrate characteristic features when imaged with both CT and MRI, and the sensitivity of these techniques is 33 to 64% and 40 to 90%, respectively. The sensitivity and specificity of MRI is generally superior to that of CT, as is the detection of extrapancreatic extensions. Insulinomas generally demonstrate low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

Invasive modalities such as EUS and ASVS have been shown to be highly accurate in the preoperative localization of insulinomas and have frequently been shown to be superior to noninvasive localization techniques. EUS is

currently the test of choice in most Western centers, with reported detection rates of 86.6 to 92.3%.

ASVS has greatly facilitated the precise regionalization of insulinomas smaller than 2 cm, which noninvasive techniques like ultrasonography, CT, and MRI often fail to localize. This test requires access to intra-abdominal vessels, including the right hepatic vein, splenic artery, gastroduodenal artery, and superior mesenteric artery. A two- to three-fold increase in insulin concentration in the right hepatic vein in response to calcium injection into one or more of the arteries supplying the pancreas suggests that the region served by that artery may harbor abnormally functioning β-cells, whether from insulinoma or islet hypertrophy or nesidioblastosis. Calcium injection will stimulate a brisk response of insulin, C-peptide, and proinsulin simultaneously, and the magnitude of increase of both insulin and C-peptide appears to be correlated well with the degree of differentiation of the tumor cells.

Insulinomas have been shown to express GLP-1R in high density, and GLP-1R imaging has been used in a few patients for insulinoma localization. Fluorine-18-L-dihydroxyphenylalanine (18F-DOPA) positron emission tomography (PET) has also been used in localizing neuroendocrine tumors. In children with congenital HH, 18F-DOPA PET/CT is the gold standard for localizing focal lesions prior to surgery. 18F-DOPA PET has been found to be useful in some patients with insulinoma who had negative CT, MRI, and ultrasound results.

The positive responses to selective arterial calcium stimulation in some patients with NIPHS, despite negative radiologic localizing studies, establish that this technique should be performed in all adults with HH of unknown etiology.

Protein/Leucine Sensitivity Testing

Protein sensitivity is observed in some patients with congenital HH. Typically, mutations in the genes *ABCC8/KCNJ11*, *GDH*, and *HADH* lead to protein-induced hypoglycemia. These patients will demonstrate severe hypoglycemia in response to a protein or leucine load.

Exercise Test

In some patients, exercise can trigger unregulated insulin secretion. This is referred to as exercise-induced hyperinsulinism. Promoter-activating mutations induce expression of the *SLC16A1* gene in β-cells, where this gene is not usually transcribed, permitting pyruvate uptake and pyruvate-stimulated insulin release despite ensuing hypoglycemia. A physical exercise test will identify this group of patients.

Genetic Studies

Genetic testing should be undertaken in children who have been diagnosed with congenital HH and other causes of hypoglycemia that might have a genetic basis. Mutation in the genes *ABCC8/KCNJ11* is the commonest cause of medically unresponsive congenital HH. All patients with insulinoma and noninsulinoma islet cell tumors should be tested for mutations in the *MEN1* gene.

TREATMENT

The correct management of hypoglycemia will depend on the underlying cause. Therefore, establishing the correct diagnosis is fundamentally important in both children and adults.

Emergency Management

Acute management of hypoglycemia involves giving a bolus of intravenous glucose (in adults a bolus of 50% dextrose) to correct the blood glucose level. This will then need to be followed by an infusion of 10% dextrose to maintain normoglycemia. Glucagon can be used in the emergency management of hypoglycemia (in emergency, give 1 mg stat intramuscularly). Glucagon can cause rebound hypoglycemia, so the patient will need blood glucose monitoring after the administration of glucagon.

Management of Specific Causes of Hypoglycemia

The long-term management of hypoglycemia depends on the underlying cause. Below is a summary of the management of the different types of hypoglycemia.

Hyperinsulinemic Hypoglycemia

Diazoxide (5 to 20 mg/kg/day given orally three times daily) is the first-line medical therapy in children and adults with HH. Fluid retention is a major side effect. Diazoxide may be combined with a diuretic to reduce the side effect of fluid retention. Second-line therapies include the use of octreotide (5 to 35 μg/kg/day as an infusion or injection 3 or 4 times daily) and glucagon (1 to 10 μg/kg/hour given as a subcutaneous or intravenous infusion).

For adult patients with insulinoma, pancreatectomy is the treatment of choice.[17] However, there are reports of insulinoma in adults responding to therapy with diazoxide and octreotide (including long-acting octreotide). The mTOR inhibitor everolimus has been reported to be effective in controlling hypoglycemia in patients with malignant insulinomas or those who cannot undergo surgical resection. Adult patients with PPHH after gastric bypass surgery can be treated with diazoxide and octreotide, but some will require pancreatectomy.[18] The insulin autoimmune syndrome will respond to therapy with glucocorticoids, but some patients have responded to diazoxide and octreotide. NICTH or IGF-2-oma patients will require resection of the primary tumor.

Hypoglycemia Due to Hormonal Deficiencies

Adult patients and children with GH and cortisol deficiency will require replacement therapy with recombinant GH and hydrocortisone (prednisolone), respectively. Replacement therapy with gluco- and mineralocorticoids can be life-saving in patients with adrenal insufficiency.

Hypoglycemia Due to Glycogen Storage Diseases

Patients with hypoglycemia due to disorders of hepatic glycogen storage and release need to avoid prolonged periods of fasting. Children will require overnight continuous feeding. Raw, uncooked cornstarch is commonly used as a slow-release source of glucose and helps with prolonging the period of fasting.

Hypoglycemia Due to Defects in Fatty Acid Oxidation, Disorders of Gluconeogenesis, and Disorders of Ketone Body Metabolism

Principles similar to those already discussed also apply to these patients. However, patients with fatty acid oxidation disorders should have carnitine supplementation.

REVIEW QUESTIONS

1. Which of the following is true in relation to glucose physiology?

A. Insulin stimulates gluconeogenesis.
B. Glycogenolysis predominantly takes place in the kidney.
C. Lipolysis is dependent on ketogenesis.
D. Glucagon stimulates glycogenolysis.
E. Pancreatic beta cells stop producing insulin when the blood glucose level reaches 2.4 mmol/L.

Answer: D Glucagon stimulates glycogenolysis and releases stored glucose.

2. In the counter-regulatory hormonal response to hypoglycemia:

A. Growth hormone is the first hormone to increase in response to a falling blood glucose level.
B. Serum cortisol levels increase in parallel to glucagon.
C. Adrenaline and noradrenaline are the first line of defense against a falling blood glucose level.
D. Pancreatic delta cells produce glucagon in response to hypoglycemia.
E. The main glucosensors for hypoglycemia are located in the carotid body.

Answer: C Adrenaline and noradrenaline are the first line of defense against a falling blood glucose level. Adrenaline and noradrenaline with glucagon are the key counter-regulatory hormones produced in response to a falling blood glucose level.

3. Which of the following does *not* constitute Whipple triad?

A. A low measured plasma glucose concentration
B. Symptoms and/or signs compatible with hypoglycemia
C. Occurrence of any symptoms and/or signs during hypoglycemia
D. Resolution of symptoms and signs when glucose concentrations are corrected

Answer: C Whipple triad includes a low measured plasma glucose concentration, symptoms and/or signs compatible with hypoglycemia, and resolution of symptoms and signs when glucose concentrations are corrected.

POLYGLANDULAR DISORDERS

LYNNETTE K. NIEMAN AND ALLEN M. SPIEGEL

DEFINITION AND CLINICAL SIGNIFICANCE

Polyglandular syndromes are disorders in which there is dysfunction and pathology of more than one endocrine gland. These disorders can be classified into (a) neoplastic syndromes in which there is abnormal endocrine cell proliferation, and often, but not invariably, hormone hypersecretion, and (b) into autoimmune syndromes in which there is evidence of immune destruction of endocrine cells, often resulting in hypofunction and reduced hormone secretion. Both the neoplastic and autoimmune polyglandular syndromes often have nonendocrine manifestations that are relatively syndrome specific.

With few exceptions, the polyglandular syndromes are due to germline mutations of key growth regulatory genes (neoplastic syndromes) or immune regulatory genes (autoimmune syndromes).[1] It is important to recognize these disorders and differentiate them from sporadic single–endocrine gland diseases for several reasons. First, recognition of a specific polyglandular syndrome should alert the clinician to look for other endocrine and extra-endocrine manifestations of the syndrome. Although some patients will present with multiple endocrine gland manifestations, some will initially present with only a single endocrine gland affected. Careful family history and screening for other endocrine and characteristic extra-endocrine manifestations is needed in such cases. Second, treatment of polyglandular disease may differ from treatment of individual gland disease. Third, because of the

*With the exception of McCune-Albright, all syndromes are caused by heterozygous germline mutations of the gene listed and show autosomal dominant inheritance.
CA = cancer; CNS = central nervous system.

genetic basis of most of these syndromes, taking a careful family history and, in some cases, screening other family members to allow disease prevention in affected individuals is indicated.

This chapter discusses the best-characterized polyglandular disorders. Other chapters on the anterior pituitary (Chapter 224), thyroid (Chapter 226), adrenal cortex (Chapter 227), adrenal medulla (Chapter 228), pancreatic islets (Chapters 195 and 230), and parathyroids (Chapter 245) should be consulted for more detailed discussion of the diseases of individual glands.

NEOPLASTIC SYNDROMES

Six distinct neoplastic syndromes involve more than one endocrine gland. These include multiple endocrine neoplasia type 1 (MEN 1), multiple endocrine neoplasia types 2A (MEN 2) and 2B (sometimes referred to as MEN 3), multiple endocrine neoplasia type 4 (MEN 4), Carney complex,[2] von Hippel-Lindau disease (VHL), and McCune-Albright syndrome (MAS) (Table 231-1).[3] All but the latter are caused by heterozygous germline mutations and are inherited in autosomal dominant fashion. The genes responsible for MEN 1 and 4, Carney complex, and von Hippel-Lindau disease act as tumor suppressor genes. Germline loss-of-function mutations in one allele are followed by somatic mutations inactivating the second normal allele, leading to tumorigenesis. The basis for the tissue-specific expression of both the endocrine and extra-endocrine manifestations of these syndromes is not well understood, but the germline nature of the mutation and the expression of the affected gene in more than one endocrine gland explains the polyglandular aspect of the disorder. MEN 2A and B, in contrast, are caused by germline activating mutations of an oncogene, *RET*. The pattern of expression of this gene, involving chromaffin cells, helps explain the specific clinical manifestations. McCune-Albright syndrome is caused by a somatic rather than germline mutation that constitutively activates the ubiquitously expressed *GNAS* gene. This mutation, which may occur early in embryogenesis, leads to unregulated cyclic adenosine monophosphate (cAMP) formation in affected cells. The resultant mosaic distribution of the mutant gene helps explain the pleiotropic manifestations of the disease.

Patients with polyglandular neoplastic syndromes typically present with their respective endocrine tumors at a younger age than patients with single-gland sporadic endocrine tumors. Treatment of the polyglandular neoplastic syndromes, both in terms of the neoplastic component and the hormone hypersecretion, poses greater challenges than treatment of individual endocrine tumors.[4] For disorders with high risk of fatal cancer, such as medullary thyroid cancer in MEN 2, early genetic diagnosis and prophylactic surgical removal of the thyroid is indicated.[5] In other disorders such as MEN 1 and Carney complex, less aggressive approaches such as selective tumor resection and pharmacologic treatment to reduce hormone hypersecretion may be more appropriate. More detailed discussion of the clinical features, diagnosis, and treatment of these neoplastic syndromes may be found in other chapters (MEN 1 in Chapter 245; MEN 2 and 3 in Chapter 246; McCune-Albright syndrome in Chapters 233 and 235).

TABLE 231-2 CLINICAL FEATURES OF AUTOIMMUNE POLYGLANDULAR SYNDROMES

FEATURE	TYPE 1	TYPE 2
Mucocutaneous candidiasis	Very common	Not seen
Hypoparathyroidism	Common	Rare
Addison's disease	Common	Common
Primary hypogonadism	Common	Occurs
Autoimmune thyroid disease	Rare	Common
Autoimmune diabetes	Occurs	Common
Hypophysitis	Occurs	Occurs
Autoimmune hepatitis	Occurs	Not seen
Pernicious anemia	Occurs	Occurs
Vitiligo	Occurs	Occurs
Malabsorption syndrome	Occurs	Occurs as celiac disease
Alopecia	Common	Occurs
Myasthenia gravis	Not seen	Occurs
Keratopathy	Common	Not seen
Tympanic membrane calcification	Common	Not seen
Inheritance	Autosomal recessive	HLA association
Age at onset	Usually childhood	Usually adulthood

HLA = human leukocyte antigen.

AUTOIMMUNE SYNDROMES

Organ-specific autoimmune disease, characterized by lymphocytic infiltration and organ-specific autoantibodies, commonly results in endocrine hypofunction. Not uncommonly, however, disorders of more than one endocrine gland appear in families or individual patients. Characteristic patterns of disease presentation and genetic inheritance allow the definition of two syndromes with overlapping manifestations (Table 231-2).[6]

Autoimmune Polyglandular Syndrome Type 1

DEFINITION

Autoimmune polyglandular syndrome (APS) type 1 is a rare disease that is also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy syndrome. It typically manifests in early childhood.

PATHOGENESIS

APS type 1 is an autosomal recessive disorder caused by a variety of inactivating mutations in the gene encoding autoimmune regulator-1 (AIRE-1),[7] which controls the expression of autoantigens by medullary epithelial cells of the thymus. These antigens are also expressed in peripheral tissues. Their expression in the thymus is important for negative selection (elimination) of autoreactive T cells, which underlies the development of (self-) tolerance. These autoreactive T cells escape to the periphery in the absence of AIRE, and if activated, induce autoimmune destruction of the specific tissue. The appearance of organ-specific autoantibodies precedes disease presentation and predicts the development of specific end-organ damage. The role of these antibodies is unknown, however.

CLINICAL MANIFESTATIONS

Mucocutaneous candidiasis (Chapter 338) occurs in virtually all patients and is usually the first manifestation of disease. Hypoparathyroidism and Addison's disease are the most common endocrine manifestations; each of these diseases occurs in 70 to 80% of patients. Hypoparathyroidism usually precedes Addison's disease; both diseases typically manifest before age 15 years. Premature ovarian failure (in 60% of affected women) usually presents as secondary amenorrhea; testicular failure occurs less frequently. Insulin-dependent diabetes mellitus occurs in 12% of patients, usually in adulthood; hypothyroidism is uncommon.

Nonendocrine components of this syndrome, in addition to the mucocutaneous candidiasis, include alopecia, vitiligo, corneal opacities, autoimmune hepatitis, enamel hypoplasia of teeth, tympanic membrane calcification, nail dystrophy that correlates only loosely with obvious candidiasis, parietal cell atrophy and vitamin B_{12} malabsorption, and more general intestinal malabsorption with steatorrhea. Asplenism, with Howell-Jolly bodies on peripheral blood smears (Chapter 157), has been noted in several patients. Each of the disease components should be sought when any patient presents with hypoparathyroidism, primary adrenal insufficiency, or mucocutaneous candidiasis.[8]

TREATMENT

Rx

The hypoparathyroidism is treated, like the sporadic disease, with oral calcium and 1,25-dihydroxyvitamin D, although variable intestinal malabsorption can present a particular therapeutic challenge. The candidiasis can be satisfactorily controlled with ketoconazole. Primary adrenal insufficiency is treated with glucocorticoid and mineralocorticoid replacement.

PROGNOSIS

The prognosis of the variably expressed hormonal disorders is similar to that of their sporadic counterparts. When the diagnosis of APS type 1 is made, surveys for other components of the syndrome can allow earlier treatment than would otherwise occur.

Autoimmune Polyglandular Syndrome Type 2

PATHOGENESIS

APS type 2 is usually inherited in families with characteristic (normal) variants of genes that regulate the presentation of antigens to T cells and subsequent T-cell function. The most common genetic locus associated with this syndrome is the human leukocyte antigen (HLA) locus, particularly the B8, DR3, and D4 alleles.[9] The HLA associations do not predict disease absolutely, even in identical twins, so environmental factors must contribute to disease presentation. Abnormal expression of the gene encoding cytotoxic T-lymphocyte antigen-4 (CTLA-4) can also predispose to APS type 2. The protein tyrosine phosphatase nonreceptor type 22 gene that encodes the lymphoid tyrosine phosphatase opposes signaling from the activated T-cell receptor. A variant of this gene is enriched in families with both type 1 diabetes mellitus and autoimmune thyroid disease. Genome-wide association studies have identified a large number of genes associated with type 1 diabetes. Although this approach has not yet been used for APS type 2, it seems likely that many of the genes identified in these studies will prove relevant because a large fraction of them appear to influence immune responsiveness.

CLINICAL MANIFESTATIONS

APS type 2 is considerably more common than type 1 and typically manifests in the fourth decade of life. Insulin-dependent diabetes mellitus and thyroid dysfunction, either autoimmune hypothyroidism or Graves disease, are the most frequent manifestations. Addison's disease (Chapter 227) is the third major endocrine component of this disorder. Although most patients who present with autoimmune diabetes or thyroid disease have clinical involvement of only one gland, many patients with autoimmune Addison's disease develop clinically evident disease in other endocrine glands. Less common components of the type 2 APS include primary hypogonadism and hypophysitis. Pernicious anemia, vitiligo, celiac disease, alopecia, and myasthenia gravis are also associated with this syndrome.

Organ-specific antibodies appear before clinical disease and predict subsequent disease. The role of these antibodies in organ hypofunction has not been established, however.

TREATMENT

Rx

The treatment of each component of this syndrome is identical to the treatment of each disorder in isolation, although possible clustering of diseases must be kept in mind during the evaluation and follow-up of all patients with each individual component disorder. Thyroid hormone therapy can precipitate symptoms of adrenal insufficiency in patients with both disorders. Consequently, a careful history (including family history), physical examination, and a low threshold for specific laboratory testing for adrenal insufficiency should be part of the evaluation of every patient with autoimmune hypothyroidism. Further, combinations of hypothyroidism, adrenal insufficiency, and hypogonadism can mimic hypopituitarism, although specific hormonal testing (Chapter 224) can easily distinguish these disorders. Because multiple components of the syndrome can appear asynchronously, periodic evaluation for the early appearance of additional disease components is indicated.

PROGNOSIS

The prognosis of the individual components of APS type 2 is the same as for the sporadic versions of each component.

REVIEW QUESTIONS

1. Which of the following polyglandular neoplastic syndromes is ***not*** caused by a germline mutation?

A. McCune-Albright syndrome
B. MEN 1
C. Carney complex
D. von Hippel-Lindau disease
E. MEN 2

Answer: A The polyglandular neoplastic syndromes are all due to germline mutations in either tumor suppressor genes (*MEN1*, *MEN4*, Carney complex, *VHL*) or in an oncogene (*MEN2*). Only McCune-Albright syndrome is due to a somatic mutation, but because the mutation may occur early in embryogenesis, multiple endocrine and nonendocrine organs may be affected.

2. A 25-year-old man presents with kidney stones and is found to be hypercalcemic with an elevated PTH. All the following steps are indicated ***except:***

A. Ultrasound localization of parathyroids and immediate parathyroidectomy
B. Take a careful family history and consider screening first-degree relatives for hypercalcemia.
C. Consider testing the patient for anterior pituitary and pancreatic islet lesions.
D. Test the patient's germline DNA for *MEN1* gene mutations.

Answer: A Age 25 is quite young to present with primary hyperparathyroidism on a sporadic basis and raises suspicion of familial disease, particularly MEN 1. Steps in B through D are indicated because a positive family history for parathyroid, anterior pituitary, and/or pancreatic islet tumors would bolster the likelihood of MEN 1, as would positive results of screening for pituitary and pancreatic islet disease, and of course if *MEN1* gene mutation is identified.

3. A 35-year-old woman with type 1 diabetes and Hashimoto's thyroiditis presents for routine follow-up. She has no specific complaints, and her physical examination is normal except for a small thyroid gland. Which additional screening test should be done to evaluate adrenal function?

A. Measurement of antiadrenal antibodies
B. Measurement of morning serum cortisol
C. No screening test is necessary; adrenal insufficiency is unlikely
D. A Cortrosyn stimulation test

Answer: A Antiadrenal antibodies predict the development of adrenal insufficiency, and in the absence of clinical features are a reasonable screening test in this woman with a high probability of having autoimmune polyglandular syndrome 2. One might argue that no test is needed in the absence of clinical symptoms; however, many would advocate measurement of the antibodies, which if positive, might increase the frequency of clinical surveillance.

4. A patient with autoimmune adrenal insufficiency and type 1 diabetes presents with complaints of abdominal discomfort and occasional diarrhea. This is not precipitated by food. She does not have orthostasis, nausea, vomiting, or joint aches and otherwise feels well, although she recently lost 5 pounds. What is the next best step?

A. Consider increasing her hydrocortisone dose to test whether this represents subtle glucocorticoid deficiency.
B. Measure tissue transglutaminase (TTG) antibody to exclude celiac disease.
C. Assess gastric motility to evaluate for gastroparesis.
D. Measure liver function tests to exclude hepatitis.

Answer: B This patient may have celiac disease, which is associated with autoimmune adrenal insufficiency. These symptoms do not suggest that the other conditions are more likely.

5. A 22-year-old woman with autoimmune polyglandular syndrome (APS) 1 mentions during a routine visit that she is thinking of becoming pregnant. She wants to know whether she will pass on the disorder to her child and what genetic testing should be done. She is not related to her partner. You reassure her that it is extremely unlikely that her child will have APS 1 because of its recessive genetic transmission. What else should you tell her regarding testing for the *AIRE* gene.

A. She could get the *AIRE* gene tested to see if her child will carry a mutation.
B. Her partner could get the *AIRE* gene tested to see if her child will carry a mutation.
C. The child should be tested for *AIRE* mutations at birth.
D. No gene testing is necessary.

Answer: D Her child will be an obligate carrier of an *AIRE* haplotype mutation; this is not sufficient to cause the disease and does not need to be documented by analysis of her mutations. Given that she is not related to her partner, it is unlikely that he will carry a mutation, thus testing of the partner is not indicated. There is no reason to test the child at birth.

232

NEUROENDOCRINE TUMORS AND THE CARCINOID SYNDROME

KENNETH R. HANDE

NEUROENDOCRINE TUMORS: DESCRIPTION, INCIDENCE, AND PRESENTATION

Neuroendocrine tumors are cancers that arise from enterochromaffin cells found throughout the body. A "carcinoid tumor" implies a well-differentiated neuroendocrine tumor and excludes high-grade or poorly differentiated neuroendocrine tumors. Although several classification systems for neuroendocrine tumors currently exist, there has been a shift away from the term *carcinoid tumor* in favor of the term *well-differentiated neuroendocrine tumor*.[1]

Well-differentiated neuroendocrine tumors, or carcinoids, occur most often in the lung (30% of all carcinoid tumors), small intestine (25%), rectum (15%), appendix (10%), and stomach (5%) but may be seen in many other organs. Typical well-differentiated neuroendocrine tumors demonstrate a histologic pattern of dense nests of cells of uniform size and nuclear appearance that contain secretory granules. The neurosecretory granules contain various amines such as 5-hydroxytryptamine (serotonin), peptides, tachykinins, and prostaglandins. Low-grade neuroendocrine

tumors have a low mutation rate compared to most neoplasms. Mutations in key oncogenic pathways, such as the PI3K/AKT/mTOR pathway, have been identified.[2] The incidence of carcinoid tumors (2 to 5 per 100,000 population) has been increasing over the past 20 years.[3] Because carcinoid tumors are relatively slow growing, their prevalence is actually greater than that of esophageal, gastric, or pancreatic cancers. Carcinoid tumors may be associated with multiple endocrine neoplasia type 1 (MEN 1) syndrome (Chapter 231). Thymic carcinoid tumors present in patients with MEN 1 portend a worse prognosis.[4]

Patients with neuroendocrine tumors present either with symptoms related to tumor mass or symptoms resulting from the release of biologically active peptides into blood. Abdominal pain from a tumor mass or bowel obstruction related to the desmoplastic reaction in the surrounding mesentery is a common presenting symptom. The desmoplastic reaction is believed to develop in response to the secretion of growth factors such as platelet-derived growth factor, insulin-like growth factor, epidermal growth factor, and transforming growth factor-β. Infrequently, primary tumors cause hemoptysis or gastrointestinal bleeding. Hepatomegaly may be noted at diagnosis. Other patients may present with symptoms related to the systemic release of peptides from tumor cells, referred to as the carcinoid syndrome.

THE CARCINOID SYNDROME

The term *carcinoid syndrome* refers to the systemic signs and symptoms resulting from the release of neuroendocrine mediators by some carcinoid tumors. Cutaneous flushing, diarrhea, and cardiac valvular lesions are the most common manifestations of the carcinoid syndrome. Only 8 to 10% of all neuroendocrine tumors are associated with the carcinoid syndrome, usually ileal carcinoids with hepatic metastases. Carcinoids from different primary sites possess unique clinical characteristics. Carcinoid tumors arising from organs of the embryonic foregut (e.g., bronchus, stomach, pancreas, and thyroid) are infrequently associated with the carcinoid syndrome; carcinoids from the distal large intestine may metastasize but do not exhibit endocrine effects.

PATHOPHYSIOLOGY OF THE CARCINOID SYNDROME

The carcinoid syndrome results from the production of a variety of biologically active substances by the neuroendocrine tumor cells, including serotonin, tachykinins, histamine, and prostaglandins. Most low-grade neuroendocrine tumors contain the enzyme tryptophan hydroxylase, which catalyzes the formation of 5-hydroxytryptophan (5-HTP) from tryptophan (Fig. 232-1). The typical ileal carcinoid tumor also contains aromatic L-amino-acid decarboxylase, which catalyzes the conversion of 5-HTP to 5-hydroxytryptamine (5-HT or serotonin). Following its release, serotonin is oxidized to 5-hydroxyindoleacetaldehyde and rapidly converted to 5-hydroxyindoleacetic acid (5-HIAA) by aldehyde dehydrogenase. This acid is excreted into the urine, and almost all circulating serotonin can be accounted for as urinary 5-HIAA. Tachykinins are also stored in neuroendocrine tumors. Of these, neuropeptide K, neurokinins A and B, and substance P have been identified in tumors and blood from patients with the carcinoid syndrome. Some carcinoid tumors, particularly those of gastric origin, release excessive amounts of histamine. Secretion of a variety of prostaglandins by carcinoids has also been demonstrated. Neuroendocrine tumors, particularly of the thymus and lung, have been associated with ectopic production of adrenocorticotropic hormone and growth hormone–releasing hormone.

Serotonin contributes to the intestinal hypermotility and diarrhea associated with the carcinoid syndrome. A secondary effect of serotonin overproduction occurs when a large fraction of dietary tryptophan is shunted into the hydroxylation pathway, leaving less tryptophan available for the formation of nicotinic acid and protein. When urinary excretion of 5-HIAA exceeds 100 mg/day, low levels of plasma tryptophan and evidence of nicotinic acid deficiency (pellagra) can be seen. The interaction of serotonin with platelets and the cardiac endothelium is considered the cause of carcinoid heart disease. This hypothesis is supported by the finding of valvular heart disease in patients who took appetite suppressants, such as fenfluramine, that release serotonin. The risk of valvular heart disease in patients with the carcinoid syndrome is correlated with the amount of 5-HIAA excreted in the urine.

Most evidence points to the tachykinins as mediators of the carcinoid flush. Tachykinins are known vasodilators. Tachykinin levels are increased during pentagastrin-induced flushing; when pentagastrin-induced flushing is inhibited by somatostatin, the rise in tachykinin levels is also blocked. Serotonin does not appear to be the mediator of flushing. Flushing attacks can be attributed to histamine in certain gastric carcinoids. Flushing can be triggered by catecholamines, and this probably accounts for the association of flushing with exercise and emotional stimuli. Injection of isoproterenol or pentagastrin can also trigger flushing, an action that may explain the provocation of flushes by eating in some patients. The carcinoid syndrome occurs when mediators produced by the tumor and normally metabolized by the liver escape into the systemic circulation. Thus, most patients with the carcinoid syndrome have hepatic metastasis.

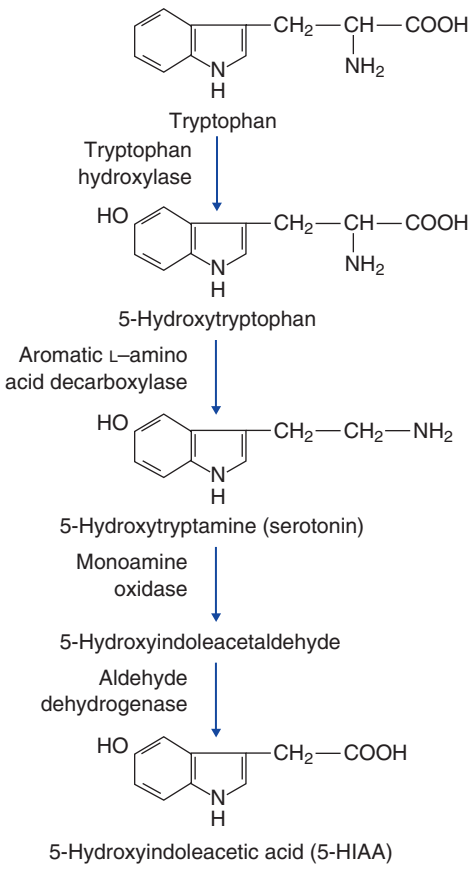

FIGURE 232-1. Synthesis and degradation of serotonin.

CLINICAL MANIFESTATIONS OF THE CARCINOID SYNDROME

VASODILATOR PAROXYSMS. Cutaneous flushing, which occurs in 80% of patients with the carcinoid syndrome, is the most common clinical feature. The typical flush is dark red to violaceous and involves the head, neck, and upper trunk (blush area). The flush usually lasts for 30 seconds to 3 minutes. Neuroendocrine tumors of the foregut produce a slightly different flush, characteristically bright salmon pink to red. Prolonged flushing attacks may be associated with lacrimation and periorbital edema. The flush may be accompanied by tachycardia. The blood pressure usually falls or does not change. A rise in blood pressure during flushing is rare, and the carcinoid syndrome is not a cause of sustained hypertension. Flushing may be provoked by excitement, exertion, eating, and ethanol ingestion. In patients with the bronchial carcinoid variant, flushing may last for hours. In addition to paroxysms of cutaneous vasodilatation, some patients develop telangiectasias, which are most marked in the malar area. These patients may have the characteristic features of rosacea.

GASTROINTESTINAL SYMPTOMS. Intestinal hypermotility with borborygmi and cramping occurs in 50 to 70% of patients with the carcinoid syndrome. Explosive secretory diarrhea may occur, although chronic diarrhea with a secretory component is more common. When diarrhea is severe, malabsorption may occur. Gastrointestinal transit times through the small and large bowel are two- to six-fold faster than in physiologically normal patients.

PELLAGRA. Tryptophan is normally used to form nicotinic acid. In patients with the carcinoid syndrome, up to 60% of dietary tryptophan may be used to form 5-HTP and 5-HT. Nicotinic acid levels are occasionally depleted, resulting in symptoms of pellagra (dermatitis, diarrhea, and dementia) (Chapter 218).

CARDIAC MANIFESTATIONS. Symptomatic valvular heart disease is present in 15 to 20% of patients with the carcinoid syndrome (Chapter 60). Up to 50% of patients have echocardiographic evidence of heart disease.[5] Plaque-like thickening of the endocardium of the valvular cusps and cardiac chambers occurs primarily on the right side of the heart but may rarely involve the left side (<10%). Lesions of the tricuspid valve (usually regurgitation) are present in 65% of patients with carcinoid heart disease, and pulmonic valvular disease (again, usually regurgitation) is seen in 20%.

OTHER SYMPTOMS. Generalized fatigue and debilitation are underappreciated features of the carcinoid syndrome. Bronchoconstriction, usually most pronounced during flushing attacks, is a less common feature of the syndrome, but when it occurs it may be severe. Attacks of severe and sustained flushing with life-threatening hemodynamic compromise and bronchoconstriction are referred to as carcinoid crisis. Precipitating factors include anesthesia, surgery, tumor necrosis, and catecholamine infusion. Cognitive impairment has also been associated with the carcinoid syndrome.[6]

DIAGNOSIS

When all its clinical features are present, the carcinoid syndrome is easily recognized. The diagnosis also must be considered when any one of its clinical manifestations is present. The diagnostic hallmark consists of overproduction of 5-hydroxyindoles accompanied by increased excretion of urinary 5-HIAA in a patient with a biopsy-proven carcinoid tumor. Normally, excretion of 5-HIAA does not exceed 10 mg/day. Ingestion of foods containing serotonin may complicate the biochemical diagnosis of the carcinoid syndrome; bananas, walnuts, and certain other foods contain enough serotonin to produce abnormally elevated urinary excretion of 5-HIAA after their ingestion. Selected drugs (e.g., guaifenesin, acetaminophen) may also falsely elevate urinary 5-HIAA measurements. When dietary 5-hydroxyindoles are excluded, urinary excretion of 25 mg/day of 5-HIAA is diagnostic of the carcinoid syndrome. Elevation in the range of 9 to 25 mg/day may be seen with the carcinoid syndrome, nontropical sprue, vomiting, or acute intestinal obstruction. Measurement of serotonin in blood or platelets is of interest but has less diagnostic value than assay of the major metabolite of serotonin in the urine. Plasma chromogranin A concentrations are often elevated in carcinoid patients, including those who do not have the carcinoid syndrome, and may serve as a marker of tumor mass. The diagnostic value of plasma chromogranin A is relatively low, however, because this substance is increased in patients with renal failure, atrophic gastritis, and patients taking proton pump inhibitors. Assessment of the extent and localization of both primary and metastatic tumor is aided by computed tomography of the abdomen and chest and by imaging with radionuclide-labeled somatostatin receptor ligands.

The typical carcinoid syndrome usually results from tumors of midgut origin, which almost invariably secrete serotonin. In contrast, tumors arising from the embryonic foregut have a lower serotonin content and may secrete 5-HTP. Patients with gastric carcinoids may exhibit unique flushing, beginning as bright, patchy erythema with sharply delineated serpentine borders that coalesce as the blush heightens. Food ingestion is especially likely to produce flushes. With carcinoid tumors arising from the bronchus, attacks of flushing tend to be prolonged and severe and may be associated with periorbital edema, excessive lacrimation and salivation, hypotension, tachycardia, anxiety, and tremulousness. This group is therapeutically unique in that severe flushes can sometimes be prevented by corticosteroids.

Differential Diagnosis of the Carcinoid Syndrome

Attacks of flushing in a patient with normal urinary excretion of 5-HIAA raise other diagnostic possibilities. Systemic mastocyte activation disorders, including systemic mastocytosis (Chapter 255) and idiopathic anaphylaxis (Chapter 253), produce flushing and diarrhea and should be considered when 5-HIAA excretion is not elevated. Flushing also occurs in genetically predisposed individuals following ethanol ingestion, in the postmenopausal state (Chapter 240), and in conjunction with other neuroendocrine tumors such as VIPomas and medullary carcinomas of the thyroid.

TREATMENT

Rx

Treatment of the carcinoid syndrome is directed toward pharmacologic therapy for humorally mediated symptoms and at measures designed to reduce the tumor mass.

Somatostatin Analogues

More than 80% of neuroendocrine tumors have somatostatin receptors on the cell surface. Somatostatin can bind to these receptors and prevent flushing and other endocrine symptoms. The development of analogues of somatostatin with longer biologic half-lives than the native hormone has made subcutaneous and intramuscular administration feasible and has been a major advance in the treatment of these patients.

Roughly 70% of patients with carcinoid syndrome have a 50% or greater reduction in the frequency of diarrhea and/or flushing with the use of octreotide, one of the somatostatin analogs. Therapy is usually associated with a decrease in urinary 5-HIAA excretion and in plasma tachykinin levels. With the improvement of endocrine symptoms and fatigue, a considerable improvement in quality of life may be achieved. Symptom control with octreotide can be durable, with 50 to 60% of patients continuing to have improvement in symptoms of diarrhea and flushing following 12 months of therapy.[7] Long-acting somatostatin analogues (octreotide LAR and lanreotide) have been developed, permitting once-monthly dosing. Two to 4 weeks may be required to achieve steady-state levels of octreotide following administration of octreotide LAR, during which time supplementation with subcutaneous octreotide may be needed. Octreotide is generally well tolerated. However, it may suppress pancreatic exocrine function, causing steatorrhea, abnormal glucose control, and inhibition of the release of cholecystokinin. Hyperglycemia, symptomatic cholelithiasis, steatorrhea, and hypoglycemia are seen in 9, 15, 3, and 2% of patients, respectively. Octreotide should be used to prevent carcinoid crises that accompany the massive release of mediators that may occur during operative procedures. In patients with histamine-secreting gastric neuroendocrine tumors, blockade of both histamine $(H)_1$ and H_2 receptors ameliorates flushing. In patients receiving octreotide, regression in tumor mass is uncommon. However, octreotide slows the growth rate of low-grade neuroendocrine tumors. With octreotide therapy, disease stability is seen in 65% of patients at 6-month follow-up, compared to only 35% of patients not receiving octreotide.

Surgery

Early diagnosis of the carcinoid syndrome leads to complete surgical cure in the few neuroendocrine tumors that release their humoral mediators directly into the systemic circulation (e.g., bronchial carcinoids). In contrast, tumors that release humoral substances into the portal circulation usually produce the syndrome only after hepatic metastases occur. Given the slow growth rate of low-grade neuroendocrine tumors, effective reduction in tumor mass can ameliorate morbidity and improve quality of life even after metastases have occurred. In selected patients, this goal can be achieved by surgical debulking of tumor, including partial hepatectomy for unilobar metastases, excision of large superficial hepatic metastases, and removal of the primary tumor and regional lymph nodes. In selected series,[8] over 90% of patients report symptom relief from pain and/or carcinoid syndrome following cytoreductive surgery (50 to 70%, complete relief). Median time to recurrence of symptoms is 3 years, and overall survival is greater than 5 years. Elective cholecystectomy during the surgical intervention prevents cholelithiasis that may result from octreotide treatment. Because the blood supply of hepatic metastases is largely arterial, percutaneous embolization of the hepatic arterial supply to the most involved hepatic lobe can shrink inoperable hepatic metastases; however, the procedure carries a risk of serious complications, with mortality of up to 6%.[9] In selected series, 90% of patients report improvement in symptoms for an average of 2 years' duration. Median survival in embolized patients has been 24 to 30 months. Valve replacement surgery is indicated in severe disease, in which it can usually improve life expectancy (Chapter 60).[10]

Chemotherapy

In contrast to high-grade, poorly differentiated neuroendocrine cancers, chemotherapy with single or combination cytotoxic agents rarely produces tumor regression in low-grade neuroendocrine tumors. However, recent studies suggest that several drugs, including the antiangiogenic agents bevacizumab and sunitinib and the mTOR inhibitor everolimus, may slow the growth rate of low-grade neuroendocrine tumors. In a randomized double-blind placebo-controlled study, 10 mg/day of everolimus increased progression-free survival from 11 months in control patients to 16 months (hazard ratio, 0.77). No overall survival advantage was noted, however, and stomatitis, rash, fatigue, and diarrhea are noted treatment side effects. For patients who exhibit tumor progression or whose clinical syndrome has failed to improve following cytoreduction and octreotide, everolimus may be considered for palliative therapy.

PROGNOSIS

The metastatic potential of localized carcinoid tumors correlates with tumor size, location, and histologic grade. Even when metastatic, typical neuroendocrine tumors generally have a slow rate of growth, and many patients survive for years after metastatic disease is recognized. Prior to development

of therapies for the carcinoid syndrome, morbidity resulted from the endocrine manifestations of the tumor. However, with current therapy, symptoms of the carcinoid syndrome can usually be controlled. Death from typical neuroendocrine tumors is usually caused by complications associated with tumor growth, such as bowel obstruction or hepatic failure. A concerted strategy consisting of removal of the primary tumor, reduction in tumor bulk, and administration of octreotide can lead to considerable amelioration of symptoms, improvement in the quality of life, reduction in the release of the humoral substances that engender cardiac lesions, and prolongation of survival.[11] The median survival of patients with metastatic neuroendocrine tumors and the carcinoid syndrome now exceeds 5 years in carefully managed patients, with patients having small bowel primaries living longer than those with lung or colon primaries.

REVIEW QUESTIONS

1. A 56-year-old woman presents with diarrhea, episodes of facial flushing, and fatigue. An enlarged liver is noted on exam, and a computed tomography scan shows metastatic nodules within the liver. A biopsy of one of these nodules shows a well-differentiated neuroendocrine tumor. The most likely primary site for this cancer is:

A. Thymus
B. Lung
C. Stomach
D. Small intestine
E. Rectum

Answer: D Small bowel carcinoid with hepatic metastases is the neuroendocrine tumor most commonly associated with carcinoid syndrome (General Reference 5).

2. Evaluation to identify a primary tumor site and corroborate the diagnosis in the patient in question 1 should include:

A. FDG-PET scan
B. Echocardiogram
C. Upper endoscopy
D. Bone scan
E. Radionucleotide-labeled somatostatin receptor ligand imaging

Answer: E Most (80%) low-grade neuroendocrine tumors will have somatostatin receptors (Grade A Reference A2).

3. Initial therapy for the patient in question 1 should be:

A. Octreotide
B. Chemoembolization of hepatic metastasis
C. Everolimus
D. Surgical tumor debulking
E. Benadryl

Answer: A Octreotide reduces symptoms of flushing and diarrhea in the majority of patients and should be used before any surgical intervention to prevent carcinoid crisis (General Reference 6).

4. A 24-hour urine for 5-HIAA is collected from the patient in question 1 and found to be elevated at 180 mg excretion per 24 hours (normal, <10 mg/day). The increased secretion of serotonin is associated with all of the following ***except***:

A. Flushing episodes
B. Diarrhea
C. Hepatic metastasis
D. Risk of carcinoid heart disease
E. Development of pellagra

Answer: A Histamine and catecholamines (the latter as the trigger) but not serotonin are the mediators of carcinoid flushing in many cases. Serotonin is most likely responsible for diarrhea, valvular heart disease, and niacin deficiency. In patients with carcinoid syndrome, up to 60% of dietary tryptophan may be used to form 5-HTP and 5-HT. Because tryptophan is used to form nicotinic acid, depletion of the latter in such patients can result in symptomatic pellagra.

5. The prognosis for the patient listed above is most likely:

A. Cure following surgical resection
B. 4- to 6-month survival
C. 1- to 2-year survival
D. 4- to 6-year survival
E. >10-year survival

Answer: D Metastatic neuroendocrine tumors are rarely curable, but because of their slow rate of growth, appropriately managed patients may live many years with good quality of life (General References 1 and 10).

DISORDERS OF SEXUAL DEVELOPMENT

PERRIN C. WHITE

DEFINITION

This chapter reviews the concepts underlying the initial evaluation and management of patients with disorders of sexual development (DSD). By definition, such an individual has lack of concordance of various aspects of gender. These include chromosomal sex (46,XX, 46,XY, or other), gonadal or reproductive sex (ovaries, fallopian tubes, and uterus vs. testes, seminal vesicles, prostate gland, and ejaculatory ducts), genital sex (vagina and clitoris vs. scrotum and penis), and gender-specific behavior. Depending on chromosomal sex, most patients can be classified as incompletely masculinized 46,XY males, virilized 46,XX females, and patients with abnormalities of sex chromosomes, such as those with mixed gonadal dysgenesis. (In the past, 46,XY and 46,XX DSD patients were referred to as male and female pseudohermaphrodites, respectively, but these terms are no longer preferred.) Many conditions can cause DSD (Table 233-1).

TABLE 233-1 DISORDERS OF SEXUAL DEVELOPMENT*

VIRILIZATION OR SEX REVERSAL IN XX FEMALES
Virilizing forms of congenital adrenal hyperplasia
21-Hydroxylase deficiency (1 : 16,000 births) [*CYP21*]: salt-wasting or simple virilizing forms
11β-Hydroxylase deficiency [*CYP11B1*]
3β-Hydroxysteroid dehydrogenase deficiency [*HSD3B2*]
Cytochrome P-450 oxidoreductase deficiency (also has a maternal effect) [*POR*]
Maternal or exogenous androgens
Drugs (danazol, progestins)
Luteoma
Aromatase deficiency [*CYP19*]
Transcription factor mutations
Mutations in genes affecting gonadal differentiation
SRY (translocation to X)
SOX9 (duplication)
WT1 (Denys-Drash syndrome)
Structural/idiopathic
UNDERVIRILIZATION OR SEX REVERSAL IN XY MALES
Biosynthetic defects
Lipoid adrenal hyperplasia [*STAR*]
17α-Hydroxylase/17,20 lyase [*CYP17*]
3β-Hydroxysteroid dehydrogenase [*HSD3B2*]
17-Ketosteroid reductase [*HSD17B3*]
5α-Reductase [*SRD5A2*]
Cytochrome P-450 oxidoreductase deficiency [*POR*]
Smith-Lemli-Opitz syndrome (1 : 20,000) [*DHCR7*]
Androgen insensitivity (1 : 20,000) [*AR*]: complete or partial
Luteinizing hormone insensitivity [*LHR*]
Mutations in genes affecting gonadal differentiation
SRY
SOX9 (campomelic dysplasia)
SF1 (sometimes associated with adrenal hypoplasia)
WT1 (WAGR and Denys-Drash syndromes)
DAX1 or WNT4 duplications
DHH (associated with peripheral neuropathy)
ATRX (X-linked α-thalassemia and mental retardation)
Exposure to 5α-reductase inhibitors, other endocrine disruptors
MICROPENIS
Panhypopituitarism [including *PROP1* mutations]
Septo-optic dysplasia [including *HESX* mutations]
Hypogonadotropic hypogonadism
Kallmann syndrome [*KAL1*]
Prader-Willi syndrome [paternal chromosome 15q11 deletion]
Adrenal hypoplasia congenita [*DAX1*]
Vanishing testes (may also cause ambiguous genitalia)
OTHER SYNDROMES AFFECTING REPRODUCTIVE SYSTEMS
Chromosomal aneuploidy
Turner syndrome (1 : 2500): 45,X; 45,X/46,XX mosaics; 46,XXr; 46,XXq−
Klinefelter's syndrome (1 : 1000): 47,XXY
Mixed gonadal dysgenesis (1 : 20,000): 45,X/46,XY; 45,X/47,XXY
Other: Trisomy 13, trisomy 18, triploidy, 4p−, 13q−
Persistent müllerian duct syndrome in XY males
Type 1 [*AMH*]
Type 2 [*AMHR2*]
Mayer-Rokitansky-Küster-Hauser syndrome (vaginal atresia) (1 : 6000)

*Frequencies of relatively common (at least 1:20,000) diseases are noted in parentheses. When causative genetic mutations have been identified, the affected locus is noted in square brackets. WAGR = Wilms' tumor, aniridia, genitourinary abnormalities or gonadoblastoma, and mental retardation.

Normal Sexual Differentiation

Gonadal Differentiation

At 5 to 6 weeks' gestation, the gonadal primordia (gonadal ridges) develop from the coelomic epithelium overlying the medial surface of the mesonephros (primitive kidneys; Fig. 233-1). These primitive gonads are identical in both sexes. Germ cells form at 3 to 4 weeks' gestation and migrate through the gut mesentery into the gonads at this early bipotential stage. Whether germ cells are directed toward male or female gametogenesis depends largely on the environment generated by surrounding somatic cells rather than on factors intrinsic to the germ cells.

During the seventh week, XY male gonads begin to differentiate under the influence of testis-determining genes.[1,2] The first to be expressed is *SRY*, the key gene on the Y chromosome controlling male differentiation, which initiates the development of Sertoli cells. Sertoli cells surround germ cells to form testis cords, which nourish primordial germ cells and direct them into the pathway for male gametogenesis. Recruitment of endothelial cells leads to development of a testis-specific vasculature that is required for normal organization of the testis.

Steroidogenic cells develop from the mesonephros and migrate into the developing adrenal cortex and testis at 8 weeks. In the testis, they become Leydig cells, which secrete the testosterone required for subsequent male reproductive development. In the first trimester, testosterone secretion is mainly under the control of human chorionic gonadotropin (HCG); it subsequently requires luteinizing hormone (LH) secreted by the fetal anterior pituitary.

Ovaries are recognizable at approximately 10 weeks. The signaling molecule WNT4 plays an active role in ovarian development, repressing expression of testis-specific genes and vascular development.[3] Germ cells in the ovary continue into the first meiotic prophase beginning at 12 weeks' gestation and continuing until 7 months' gestation.

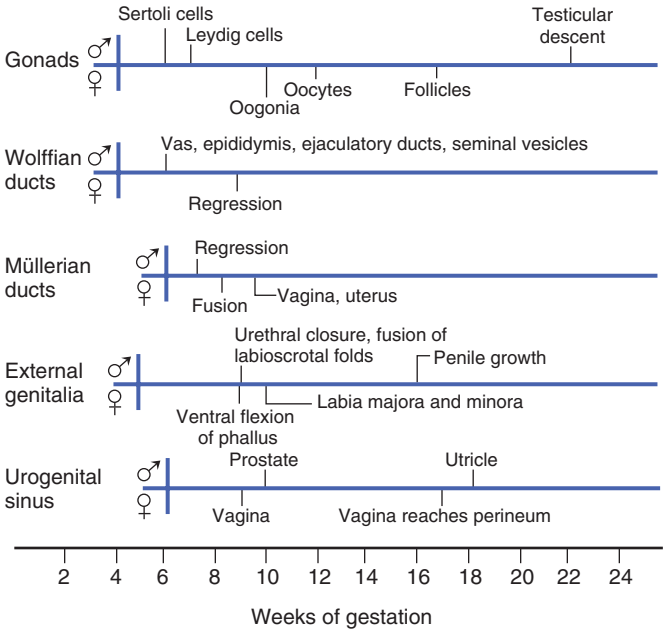

FIGURE 233-1. Time course of prenatal sexual differentiation in male and female fetuses. (Modified from Barthold JS, Gonzalez R. Intersex states. In: Gonzales ET, Bauer SB, eds. *Pediatric Urology Practice*. Philadelphia: Lippincott Williams & Wilkins; 1999.)

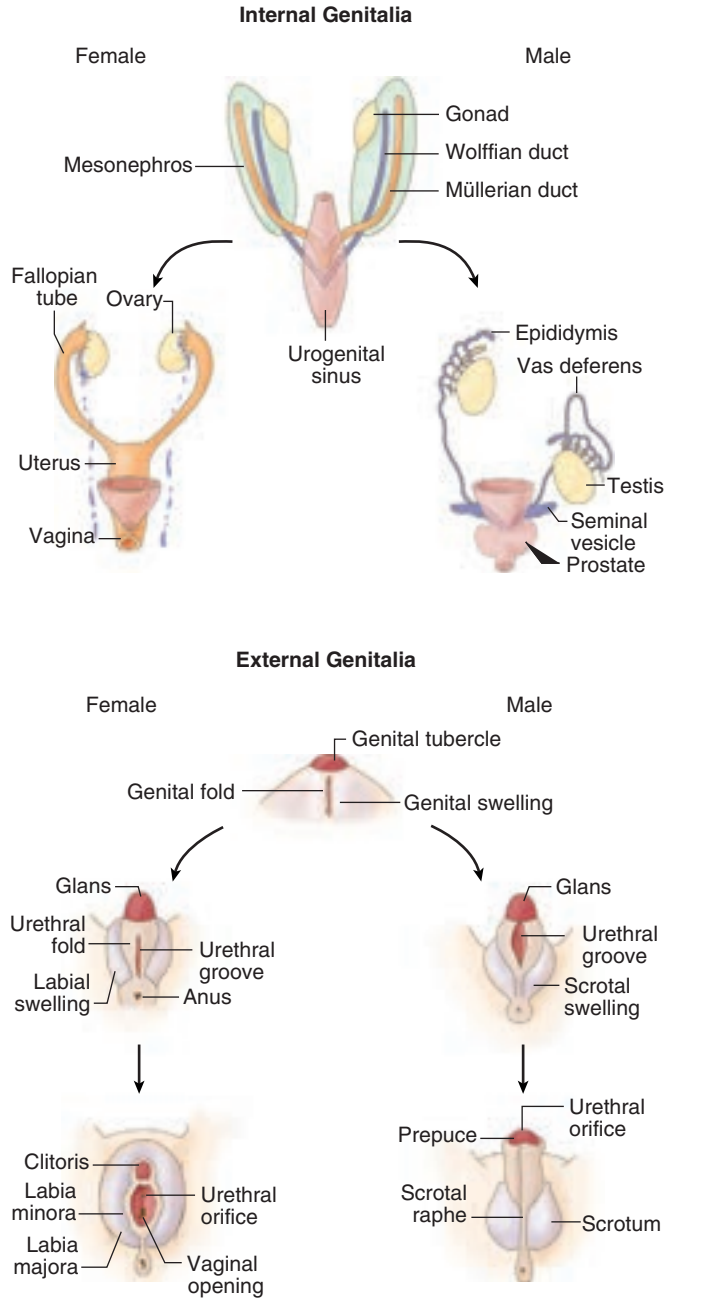

FIGURE 233-2. Differentiation of the internal and external genitalia of the human fetus. (Modified from Griffen JE, Ojeda SR, eds. *Textbook of Endocrine Physiology*. New York: Oxford University Press; 1996.)

Development of Male and Female Internal Reproductive Tracts

The reproductive tracts are derived from intermediate mesoderm. The male reproductive tract develops from the mesonephric (wolffian) ducts, and the female reproductive tract develops from the paramesonephric (müllerian) ducts (Fig. 233-2). Both sets of ducts are present in normal embryos.

Development of wolffian or müllerian structures depends on the presence or absence of normally functioning testes. The Sertoli cells secrete antimüllerian hormone (AMH, also termed müllerian inhibiting substance) starting when the testes differentiate.[4] Expression of AMH is controlled by several transcription factors: SF1 and WT1 (Wilms' tumor locus) synergize to promote transcription, whereas DAX1 antagonizes it. The overall effect of AMH is to induce regression of müllerian structures between 8 and 12 weeks' gestation. In its absence, development of the müllerian ducts proceeds, and the female internal structures (fallopian tubes, uterus, cervix, and upper vagina) are formed.

Development of the structures derived from the wolffian ducts, including the epididymis, ductus deferens, ejaculatory ducts, and seminiferous tubules, requires high local concentrations of testosterone secreted from Leydig cells of the testis beginning at approximately 7 weeks' gestation. In the absence of testosterone, wolffian ducts regress. Levels of testosterone in the circulation are insufficient to develop wolffian structures. Thus, in conditions in which the gonads develop asymmetrically (e.g., true hermaphroditism or mixed gonadal dysgenesis; see later), wolffian structures develop asymmetrically as well. Development of wolffian structures requires an intact androgen receptor.

Development of the External Genitalia

External genital structures are also bipotential in early gestation and consist of the genital tubercle, genital folds (later, urethral-labial folds), and genital swelling (later, labioscrotal folds) (see Fig. 233-2). Differentiation to male genitalia occurs from approximately 8 to 14 weeks' gestation under the influence of dihydrotestosterone, which must interact with an intact androgen receptor. The genital tubercle becomes the glans penis; the genital folds fuse to become the shaft of the penis and penile urethra, and the labioscrotal folds (derived from the genital swelling) fuse to become the scrotum. Without androgens, these structures become the clitoris, labia minora, and labia majora, respectively.

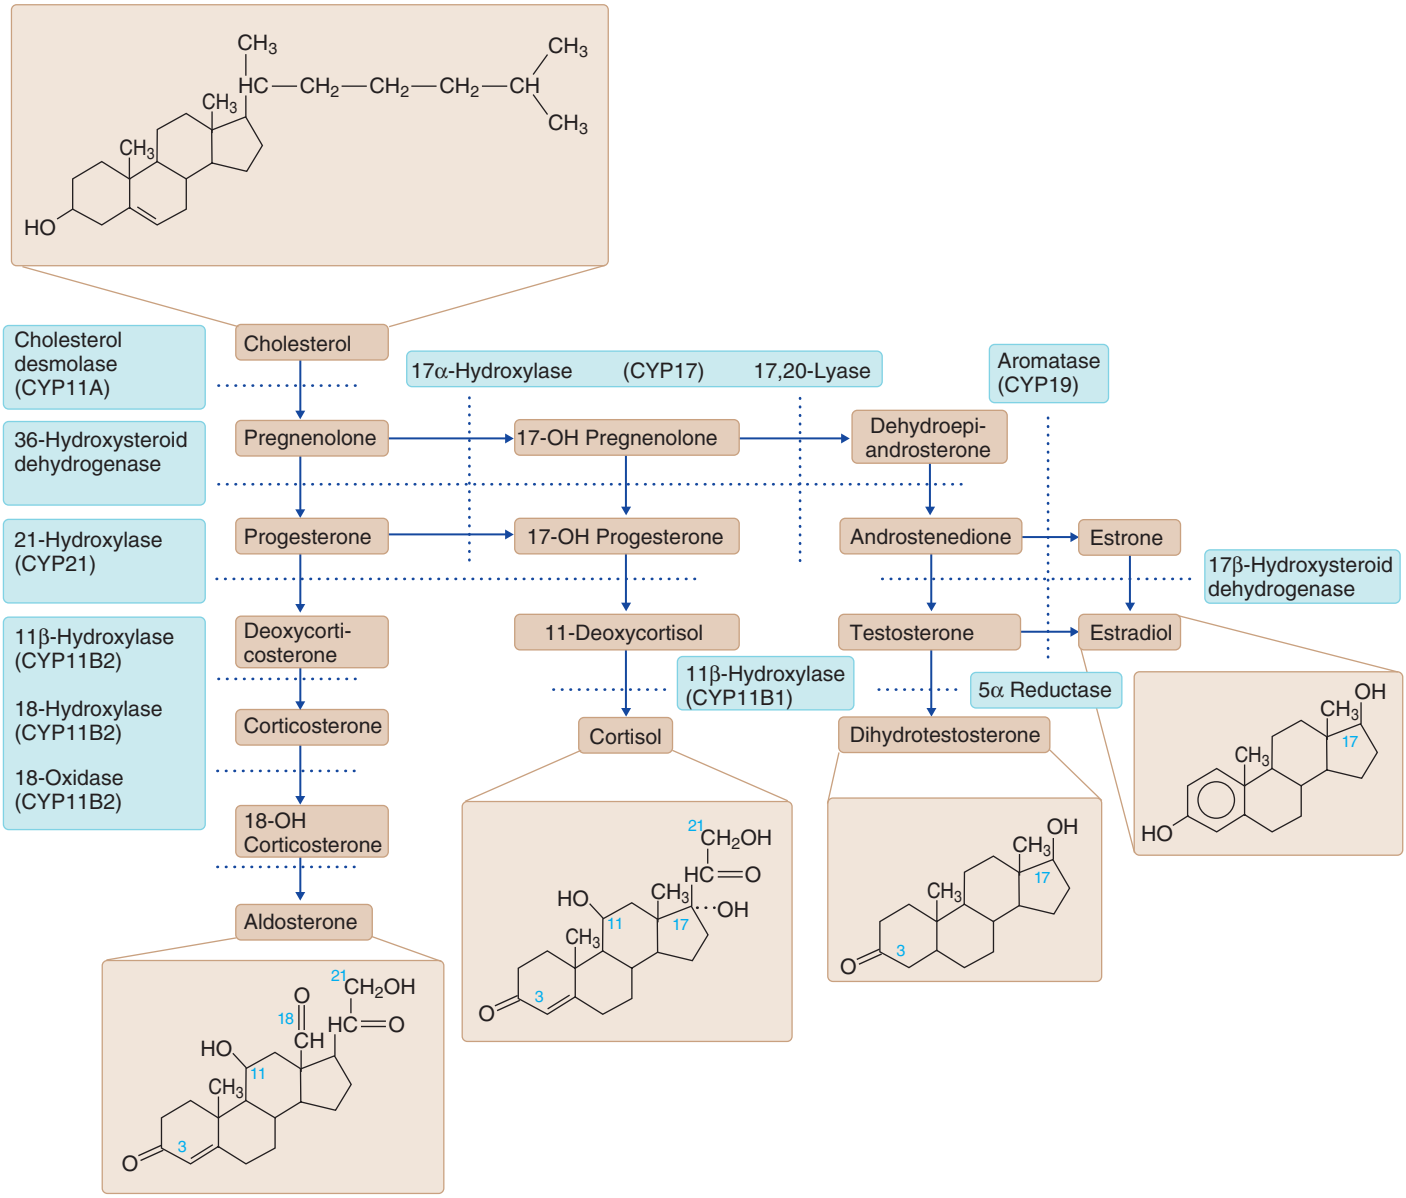
Normal Gonadal and Adrenal Steroidogenesis

Many forms of genital ambiguity result from defects in steroid biosynthesis in the testes or adrenal cortex or from defective steroid metabolism in the placenta or in target tissues[5] (Fig. 233-3 and E-Fig. 233-1).

Steroid biosynthesis in the testes and adrenals begins with the importation of cholesterol into mitochondria, a highly regulated process controlled largely by the steroidogenic acute regulatory (StAR) protein; levels of StAR are controlled within the adrenals by adrenocorticotropic hormone (ACTH) and within the testis by HCG during the first trimester and by LH later in pregnancy.

Within mitochondria, the side chain of cholesterol is cleaved between carbons 20 and 22 by the cholesterol side-chain cleavage enzyme (cholesterol desmolase, CYP11A), a cytochrome P-450 enzyme. The product is pregnenolone, which is transported to the endoplasmic reticulum. Some pregnenolone is converted by 17α-hydroxylase (CYP17) to 17-hydroxypregnenolone. Both 17-hydroxypregnenolone and the remaining pregnenolone are converted by 3β-hydroxysteroid dehydrogenase (HSD3B2) to 17-hydroxyprogesterone and progesterone, respectively. The side chain of 17-hydroxypregnenolone is cleaved by the 17,20-lyase activity of CYP17 to dehydroepiandrosterone (DHEA). DHEA may also be converted to androstenedione by HSD3B2.

All the preceding steps can occur in the adrenal cortex, in Leydig cells of the testis, and (after puberty) in theca cells of ovarian follicles. Subsequent



E-FIGURE 233-1. Steroidogenesis. The pathways for synthesis of progesterone and mineralocorticoids (aldosterone), glucocorticoids (cortisol), androgens (testosterone and dihydrotestosterone), and estrogens (estradiol) are arranged from left to right. Planar structures are shown for cholesterol and the end products of each pathway. The enzymatic activities catalyzing each bioconversion are written in boxes. For those activities mediated by specific cytochrome P-450 subsets, the systematic name of the enzyme (CYP followed by a number) is listed in parentheses. CYP11B2 and CYP17 have multiple activities.

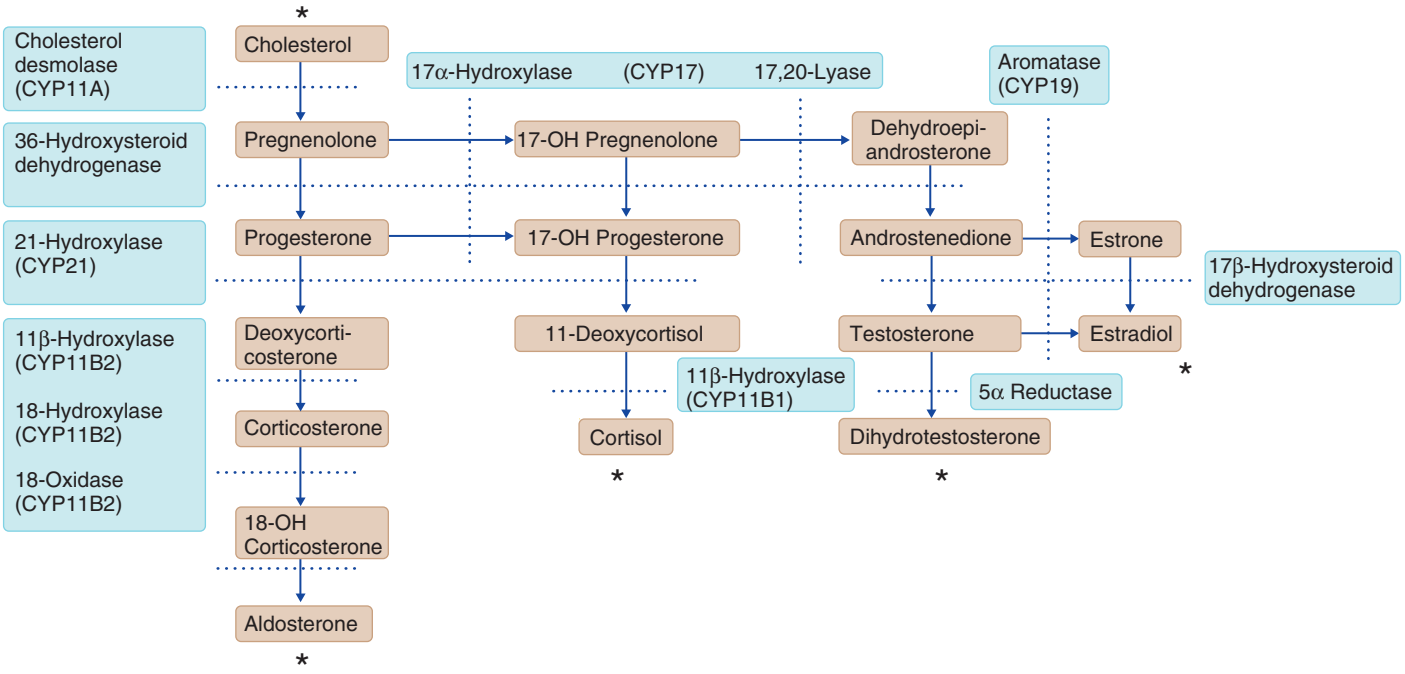


FIGURE 233-3. Steroidogenesis. Pathways for the synthesis of progesterone and mineralocorticoids (aldosterone), glucocorticoids (cortisol), androgens (testosterone and dihydrotestosterone), and estrogens (estradiol) are arranged from left to right. The enzymatic activities catalyzing each bioconversion are written in boxes. For those activities mediated by specific cytochrome P-450 subsets, the systematic name of the enzyme (CYP followed by a number) is listed in parentheses. CYP11B2 and CYP17 have multiple activities. *For an expanded version of this image, including planar structures for cholesterol and the end products of each pathway, see E-Figure 233-1.

biosynthetic steps are specific to different glands. In the adrenal cortex, 17-hydroxyprogesterone is converted by 21-hydroxylase (CYP21, a microsomal P-450) to 11-deoxycortisol, which is then converted in mitochondria to cortisol by 11β-hydroxylase (CYP11B1). Additionally, progesterone is converted to deoxycorticosterone by CYP21, which is then converted to aldosterone by aldosterone synthase (CYP11B2).

In Leydig cells of the testis, androstenedione is converted to testosterone by 17-ketosteroid reductase (17β-hydroxysteroid dehydrogenase type 3 [HSD17B3]); the same reaction occurs in theca cells of the ovary, catalyzed by 17β-hydroxysteroid dehydrogenase type 1 (HSD17B1). In granulosa cells of the ovary (after puberty), androstenedione and testosterone are converted by aromatase (CYP19) to estrone and estradiol, respectively. In skin of the developing male external genitalia, steroid 5α-reductase (SRD5A2) converts testosterone to a more potent androgen, dihydrotestosterone.

The placenta is a steroid-synthesizing and steroid-metabolizing tissue as well; it has high steroid sulfatase activity that converts DHEA sulfate from the fetal adrenal gland back to DHEA. This is then successively converted by 3β-hydroxysteroid dehydrogenase type 1 (HSD3B1) and aromatase (CYP19) to androstenedione and estrone, respectively, which are then converted to estradiol by HSD17B1.

DEFECTS OF SEX DIFFERENTIATION

Defects of Steroidogenesis

PATHOBIOLOGY

Genital ambiguity in genetic females is usually the result of exposure to excessive levels of androgens. Virilizing congenital adrenal hyperplasia (CAH), the most common cause of genital ambiguity in female infants, occurs in 1 in 16,000 births.[6]

Conversely, severe deficiencies of androgens, if present early in gestation, cause ambiguous or female-appearing external genitalia in male infants. Usually, müllerian structures such as the uterus, cervix, and upper vagina are not present because the testes are able to secrete müllerian inhibitory substance. Thus, individuals with these conditions have a short vagina ending in a blind pouch.

CONGENITAL ADRENAL HYPERPLASIA

The fundamental defect among patients with any form of CAH is inadequate synthesis of cortisol (see Fig. 233-3 and E-Fig. 233-1). Inefficient cortisol synthesis signals the hypothalamus and pituitary to increase corticotropin-releasing hormone and ACTH, respectively (Chapter 223). Consequently, the adrenal glands become hyperplastic, and steroid precursors accumulate proximal to the block in biosynthesis. In some conditions, these precursors can be converted to androgens.

Lipoid Hyperplasia

Lipoid hyperplasia results from mutations in the *STAR* gene. Cholesterol is not imported efficiently into mitochondria and thus accumulates in cells. Steroid biosynthesis is drastically reduced because of the lack of substrate, and the lipid accumulation quickly kills steroid-synthesizing cells in both the adrenals and the testes. Thus, affected male patients are born as phenotypically female because they cannot synthesize testosterone. Affected female patients may undergo transient spontaneous puberty because human ovarian granulosa cells do not synthesize steroid hormones (and thus do not accumulate cholesterol) until puberty. Both sexes have adrenal insufficiency and are unable to synthesize either cortisol or aldosterone.

17α-Hydroxylase/17,20 Lyase Deficiency

Severe mutations in the *CYP17* gene prevent the synthesis of any sex hormones. Affected male patients have female-appearing external genitalia but have no müllerian structures because the testes synthesize AMH. Affected female patients remain sexually infantile without hormone replacement. Milder mutations result in ambiguous genitalia in male patients. Although cortisol synthesis is also abolished, even severely affected individuals are able to synthesize corticosterone, an active glucocorticoid, as well as aldosterone. Thus, they do not develop adrenal insufficiency. On the contrary, they secrete excessive amounts of deoxycorticosterone, which has mineralocorticoid activity, and are therefore prone to develop hypertension.

Whereas most *CYP17* mutations affect both the hydroxylase and lyase activities, rare mutations can affect the lyase activity alone. Additionally, mutations in genes other than *CYP17* can have the same phenotype as 17,20, lyase deficiency (i.e., deficient androgen synthesis with normal cortisol synthesis). These include an accessory electron transfer protein, cytochrome b_5, and mutations in the genes for two aldo-keto reductases, AKR1C2 and AKR1C4. These AKR1C isozymes normally catalyze 3α-hydroxysteroid dehydrogenase activity, which allows synthesis of the potent androgen, dihydrotestosterone, through an alternative "backdoor" biosynthetic pathway that does not include testosterone as an intermediate.

3β-Hydroxysteroid Dehydrogenase Deficiency

Severe mutations in the *HSD3B2* gene prevent the synthesis of aldosterone, cortisol, testosterone, and estrogens. Because DHEA, a weak androgen, is synthesized and secreted at high levels, some degree of phallic growth is present. Thus, affected male patients have severely ambiguous genitalia, but affected female patients may have clitorimegaly. Both sexes develop adrenal insufficiency if they are untreated.

Because many children with premature adrenarche (early development of axillary and pubic hair), as well as many women with polycystic ovary syndrome, have elevated levels of DHEA, it was once thought that such individuals could have a mild form of HSD3B2 deficiency. However, mutations in *HSD3B2* are rarely if ever found in such individuals, who instead have an imbalance in the relative levels of HSD3B2 and CYP17 activity within the adrenal cortex.

21-Hydroxylase Deficiency

More than 90% of cases of CAH are caused by 21-hydroxylase deficiency resulting from mutations in the *CYP21* (or *CYP21A2)* gene. *CYP21* and a highly homologous pseudogene, *CYP21P (or CYP21A1P),* are located within the major histocompatibility complex on chromosome 6p21.3, a genomic region noteworthy for a high rate of recombination. More than 90% of all mutations are the result of intergenic recombination between *CYP21* and *CYP21P*. Most are transfers of deleterious mutations from *CYP21P* to *CYP21,* whereas 20% are net deletions of *CYP21* resulting from unequal meiotic crossover.

In patients with 21-hydroxylase deficiency, the adrenals produce excess 17-hydroxyprogesterone, 17-hydroxypregnenolone, and progesterone, which are further metabolized to DHEA and androstenedione. Once secreted, these substances are further metabolized to active androgens (testosterone and dihydrotestosterone) and, to a lesser extent, to estrogens (estrone and estradiol).

Adrenal secretion of excess androgen precursors does not significantly affect male sexual differentiation. In affected female patients, the urogenital sinus is in the process of septation when the fetal adrenal begins to produce excess androgens, which function to prevent the formation of separate vaginal and urethral canals. Further adrenal-derived androgens interact with androgen receptors in genital skin and induce clitoral enlargement, promote fusion of the labial folds, and cause rostral migration of the urethral/vaginal perineal orifice. However, internal wolffian structures such as the prostate gland and spermatic ducts are usually not virilized, presumably because development of the wolffian ducts requires markedly higher local concentrations of testosterone than the external genitalia. Nevertheless, severely affected female patients occasionally have some development of typically male internal genital structures.

Thus, the typical result in severely affected girls is ambiguous or male-appearing external genitalia with perineal hypospadias and chordee, but without palpable testes (Fig. 233-4). The severity of virilization is often quantitated using a five-point scale developed by Prader (Fig. 233-5). Not all female patients with classic CAH develop the same degree of genital ambiguity. One could speculate that the physical signs of androgen excess depend not only on direct adrenal secretion of androgen precursors but also on the efficiency with which such hormones are converted to more potent products, such as dihydrotestosterone, by peripheral enzymes such as 5α-reductase. Additionally, the concentration and transcriptional activity of androgen receptors may play a role in determining genital phenotype.

Most patients (75%) cannot synthesize sufficient aldosterone to maintain sodium balance and are termed *salt wasters.* These patients are predisposed to episodic and potentially life-threatening hyponatremic dehydration. Patients with sufficient aldosterone production to prevent salt wasting and who have signs of prenatal virilization and/or markedly increased production of hormonal substrates of 21-hydroxylase (e.g., 17-hydroxyprogesterone) are termed *simple virilizers.*

11β-Hydroxylase Deficiency

Patients with 11β-hydroxylase deficiency have mutations in the *CYP11B1* gene. They have elevated levels of deoxycorticosterone and 11-deoxycortisol, as well as earlier cortisol precursors such as 17-hydroxyprogesterone. These patients secrete excess adrenal androgens, with consequences similar to those

FIGURE 233-4. Virilized external genitalia in a female infant with congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. No gonads are present in the scrotum.

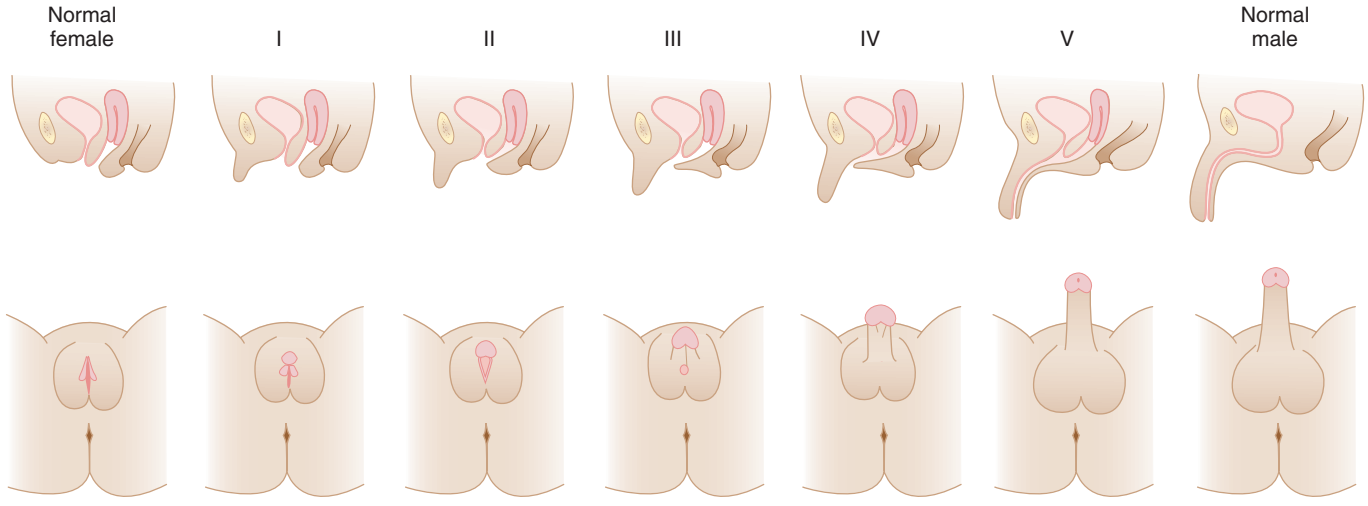

FIGURE 233-5. Abnormal differentiation of the urogenital sinus and external genitalia. Schematic representations of normal female and male anatomy flank a series of schematics illustrating different degrees of virilization of females, graded using the scale developed by Prader. The uterus (*shaded*) persists in virilized females even when the external genitalia have a completely masculine appearance (Prader grade V). (Modified from Prader A. Der Genitalbefund beim Pseudohermaphroditismus femininus der kengenitalen adrenogenitalen Syndroms. *Helv Paediatr Acta*. 1954;9:231-248.)

seen in 21-hydroxylase deficiency. However, patients with 11β-hydroxylase deficiency synthesize aldosterone normally and do not have problems with salt wasting. Instead, they are likely to become hypertensive as a result of elevated levels of deoxycorticosterone and its metabolites.

DEFECTS OF ANDROGEN BIOSYNTHESIS

Lipoid hyperplasia, 17-hydroxylase/17,20 lyase deficiency, and HSD3B2 deficiency affect the biosynthesis of both corticosteroids and sex hormones. In contrast, two enzymatic defects affect only androgen biosynthesis. They have similar phenotypes. Affected male patients are born with ambiguous genitalia, but they virilize at puberty and often reassign themselves to a male gender if they were raised as females. They have absent müllerian structures as a result of the secretion of AMH by the testes.

17-Ketosteroid Reductase (17-Hydroxysteroid Dehydrogenase 3) Deficiency

This disorder is caused by mutations in the *HSD17B3* gene. Although testosterone is not synthesized well, androstenedione, an active androgen, is synthesized. Because several other isozymes have 17-ketosteroid reductase activity in other tissues, some testosterone is invariably synthesized, especially at puberty, when circulating levels of androstenedione increase.

5α-Reductase Deficiency

Patients with 5α-reductase deficiency resulting from mutations in the *SRD5A2* gene synthesize entirely normal amounts of testosterone, but they cannot synthesize adequate amounts of dihydrotestosterone, the most potent naturally occurring androgen. This enzyme is not expressed at high levels in the testes (circulating levels of dihydrotestosterone are relatively low); instead, it is expressed in genital skin. Internal wolffian structures do not require this enzyme and are intact; high testosterone levels at puberty induce significant phallic growth without 5α-reductase activity.

OTHER DEFECTS OF STEROIDOGENESIS

Aromatase Deficiency

Mutations in *CYP19* cause aromatase deficiency in both the fetus and the placenta. The placenta can convert DHEA sulfate to androstenedione and testosterone normally, but it cannot convert these androgens to estrone and estradiol. These androgens accumulate in both the fetal and maternal circulations and virilize both the mother and the affected fetus if it is female. Affected male infants are phenotypically normal. Affected female patients virilize further at puberty if they are untreated. The lack of aromatase activity within bone leads to tall stature in both sexes (because estrogens are required to close the growth plates) and later to osteoporosis.

Cytochrome P-450 Oxidoreductase Deficiency

This deficiency is one form of Antley-Bixler syndrome, which is characterized by skeletal anomalies and craniosynostosis; most patients also have ambiguous genitalia associated with mutations in the *POR* gene. Antley-Bixler syndrome without genital abnormalities is caused by mutations in the FGF receptor (*FGFR2*) gene.

Because this disorder affects the activity of all microsomal cytochrome P-450 subsets, complete deficiency of cytochrome P-450 oxidoreductase (POR) is lethal, and identified mutations in humans yield POR with partial activity. *POR* mutations may cause skeletal anomalies by interfering with cholesterol synthesis. Genital ambiguity is caused by several mechanisms. Decreased activity of 17α-hydroxylase/17,20 lyase (CYP17) affects androgen synthesis and leads to undervirilization in males. Conversely, decreased activity of 21-hydroxylase (CYP21) can virilize affected females. These two deficiencies also can cause adrenal insufficiency. Finally, decreased activity of placental aromatase (CYP19) virilizes both the mother and the affected fetus (if female).

Smith-Lemli-Opitz Syndrome

This relatively frequent (1 in 20,000 northern Europeans) disorder of the final step of cholesterol biosynthesis (conversion from 7-dehydrocholesterol) is caused by mutations in the *DHCR7* gene encoding 7-dehydrocholesterol reductase. The syndrome is characterized by multiple congenital anomalies, including being small for gestational age, short stature, microcephaly, mental retardation, aggressive behavior, seizures, hypotonia, polydactyly, cleft palate, cardiac defects, lung hypoplasia, and renal anomalies. Male patients have ambiguous genitalia. The range of clinical severity is wide and depends on the nature of the mutations. Pathogenetic mechanisms for the ambiguous genitalia may include insufficient provision of cholesterol for steroid hormone biosynthesis or toxic effects of the precursor, 7-dehydrocholesterol, on steroidogenic cells.

MATERNAL CONDITIONS AFFECTING THE FETUS

LUTEOMA OF PREGNANCY

Luteomas are the most common causes of maternal virilization during pregnancy. They often occur bilaterally. Although many luteomas are discovered incidentally during cesarean sections or postpartum tubal ligations, one fourth of mothers virilize during the latter half of pregnancy, and half of female infants born to these mothers also exhibit signs of virilization, most typically clitorimegaly and labial fusion. Spontaneous regression of the luteoma generally begins within days after delivery.

DRUG EXPOSURE

Depending on the agent, maternal drug exposure may affect either male or female fetuses. Females may be virilized by androgens such as 19-nor-testosterone or progestins administered to prevent spontaneous abortion. Undervirilized males can be born to women exposed to 5α-reductase inhibitors such as finasteride. The antifungal agent fluconazole can inhibit many cytochrome P-450 enzymes and can lead to a condition closely resembling Antley-Bixler syndrome.

The synthetic estrogen diethylstilbestrol was used several decades ago to prevent spontaneous abortion (it was actually ineffective for this purpose). Males exposed to this agent in utero were born with testicular hypoplasia, cryptorchidism, hypospadias, and/or microphallus. Females had uterine, cervical, and vaginal abnormalities and an increased risk for clear cell adenocarcinoma of the vagina. Considering that many cases of genital ambiguity are idiopathic, it is likely that additional endocrine disruptors in the environment have not yet been identified.[7]

HORMONE INSENSITIVITY SYNDROMES AND OTHER HORMONE DEFICIENCIES

ANDROGEN INSENSITIVITY

Males normally carry a single copy of the X-linked androgen receptor (AR) gene.[8] Thus, a single mutation can completely inactivate the receptor in males and lead to complete androgen insensitivity (formerly termed *testicular feminization syndrome*). This is one of the most frequent forms of 46,XY DSD, occurring in approximately 1 in 20,000 male births.[9]

Patients with the complete form of androgen insensitivity have normal female external genitalia. Unless suspicion is raised by prior knowledge of the infant's karyotype, the condition is rarely discovered before puberty unless the testes are palpated in the groin or labia on routine examination. Because the testes secrete AMH, müllerian structures are absent, including the uterus, fallopian tubes, and cervix. Thus, the vagina is usually shallow and ends blindly. Wolffian structures are also absent. The testes may be located in the abdomen or in the labia majora and do not undergo spermatogenesis. AMH levels are elevated during the first year and (if the testes have not been removed) after puberty. Testosterone and LH levels in infancy and at puberty are elevated as a result of defective feedback regulation caused by androgen resistance at the level of the hypothalamus.

At puberty, pubic and axillary hair is scant or absent. Testosterone can be aromatized to estradiol by CYP19 in breast fat, and estrogen receptors are unaffected in this condition. Thus, breast development is that of a normal female.

Partial androgen insensitivity (Reifenstein's syndrome) is characterized by a variable degree of genital ambiguity, and both virilization and breast development occur at puberty. Mild androgen insensitivity also can occur with a male phenotype, with gynecomastia and infertility as the sole manifestations. Mutations in the androgen receptor are not detected in many mild cases, which may result from defects in other transcription factors affecting actions of the receptor.

LEYDIG CELL AGENESIS

Leydig cell agenesis or hypoplasia is a rare autosomal recessive syndrome caused by mutations in the *LHGCR* gene encoding the LH receptor. Without stimulation by LH (or by HCG early in gestation), Leydig cells do not differentiate normally and do not secrete testosterone. Thus, affected male infants are born with female-appearing or ambiguous external genitalia. Müllerian structures are absent because of unaffected secretion of AMH by Sertoli cells. LH levels are high in infancy and at puberty, and they respond normally to gonadotropin-releasing hormone, whereas testosterone levels are low and do not respond to stimulation by HCG. Affected females are

phenotypically normal but may have oligomenorrhea resulting from primary ovarian dysfunction.

PERSISTENT MÜLLERIAN DUCT SYNDROME

Persistent müllerian duct syndrome (PMDS) is a rare autosomal recessive condition that results from mutations in the genes for either AMH (PMDS type I) or the AMH receptor (*AMHR2* gene, PMDS type II). The two are distinguished clinically by low or absent AMH levels in patients with AMH mutations and by AMH levels in the high-normal range in those with AMH receptor mutations.

Affected male patients have unimpaired testosterone secretion and thus have normal external genitalia and wolffian structures. However, the lack of AMH action prevents regression of müllerian structures, so these patients also retain a uterus and fallopian tubes. These structures are often closely approximated to the vas deferens. The müllerian structures are usually dragged into the inguinal canal by the descending testes. However, these structures typically prevent the testes from descending into the scrotum and thus cause bilateral inguinal hernias (with the uterus on one side) and bilateral or occasionally unilateral cryptorchidism. The condition is usually discovered only at surgery. Fertility in affected patients may be normal or impaired, with an increased risk for malignant disease in undescended testes left in the abdomen.

HYPOGONADOTROPIC HYPOGONADISM

Milder or later appearing deficiencies of androgen biosynthesis (after 13 to 14 weeks) may allow complete fusion of the labioscrotal folds and normal positioning of the urethral meatus, but subsequent growth of the phallus is suboptimal. Such individuals have a micropenis. The most common cause is lack of gonadotropin (specifically, LH) secretion; even when LH is lacking, early male development is normal because testosterone secretion is controlled mostly by HCG during the first trimester.

Defective LH and follicle-stimulating hormone secretion can result when the neurons that normally secrete gonadotropin-releasing hormone fail to migrate into the hypothalamus.[10] This condition, *Kallmann syndrome,* is most often X-linked, resulting from mutations in the *KAL1* gene. It is often associated with anosmia. Other conditions that affect hypothalamic development and cause hypogonadotropic hypogonadism include *Prader-Willi syndrome,* which is a result of paternal deletions, methylation defects, and maternal uniparental disomy of imprinted loci on chromosome 15q12. Children with this syndrome have a characteristic appearance consisting of a narrow bitemporal diameter, almond-shaped eyes with an antimongoloid slant, and small hands and feet. They typically have marked hypotonia as infants, with subsequent moderate developmental delay and slow somatic growth. Hypothalamic obesity develops during childhood. Patients with adrenal hypoplasia congenita resulting from mutations in the DAX1 transcription factor have defective development of the ventromedial hypothalamus and consequent hypogonadotropic hypogonadism, associated with adrenal insufficiency that typically manifests with aldosterone deficiency and salt wasting. Steroidogenic factor-1 (SF-1), encoded by the *NR5A1* gene, is an orphan nuclear receptor that is critical for the development and function of the adrenal glands, gonads, pituitary gonadotropes, ventromedial nucleus of the hypothalamus, and male sexual differentiation. Heterozygous null mutations or homozygous milder mutations have been identified mainly among undervirilized 46,XY individuals and 46,XX women with premature ovarian failure. Only a minority have adrenal insufficiency.

Hypogonadotropic hypogonadism often results from failure of the entire anterior pituitary gland, or particular cellular populations therein, to develop.[11] Pituitary gland abnormalities can be associated with other midline defects, including hypoplasia of the optic nerves and the septum pellucidum, a condition termed *septo-optic dysplasia.* Associated pituitary hormone deficiencies may include growth hormone, ACTH, and thyroid-stimulating hormone. These deficiencies may manifest in the neonatal period as hypoglycemia or hypothyroidism (detected by newborn screening programs). Optic nerve dysfunction is difficult to detect by routine examination in the neonatal period, but it causes a characteristic wandering nystagmus after a few months of age.

Although panhypopituitarism is most often sporadic, mutations in transcription factors controlling pituitary development have been documented (Chapter 224), particularly PROP1, and septo-optic dysplasia has been associated with mutations in the *HESX* gene. Rarely, mutations in the gene encoding the β-subunit of LH may yield a phenotype similar to hypogonadotropic hypogonadism.

OTHER GENETIC CONDITIONS

ANEUPLOIDY OF SEX CHROMOSOMES

Turner Syndrome

Patients with Turner syndrome have normal female external genitalia and a normal uterus and fallopian tubes, but they have dysgenetic streak ovaries.[12] Most fetuses with Turner syndrome spontaneously abort, but the incidence in live births is approximately 1 in 2500. Classically, the karyotype is 45,X, but many patients retain an abnormal second X chromosome or even a fragment of a Y chromosome lacking *SRY*. Other patients are mosaic for 46,XX and 45,X cells and may have relatively mild phenotypes.

Untreated patients are short. Many have typical dysmorphic features, including lymphedema of the neck at birth, webbed neck, low posterior hairline, increased carrying angle of the arms, shield chest with widely spaced nipples, low-set ears, and micrognathia. Patients typically have primary amenorrhea and are infertile, but they occasionally have menarche followed by premature ovarian failure.

Klinefelter's Syndrome

In this condition, male patients have normal development of the penis and scrotum, but the testes are small and firm. Patients tend to be tall. At adolescence, gynecomastia is frequent. Signs of testosterone deficiency occur in most affected adults, and most have azoospermia. The usual karyotype is 47,XXY. Hormonal findings include elevated gonadotropin levels and a decreased serum testosterone concentration. Klinefelter's syndrome is a common disorder that occurs in 1 in 500 to 1000 men.

Mixed Gonadal Dysgenesis

Mixed gonadal dysgenesis, a frequent cause of sexual ambiguity, occurs in approximately 1 in 20,000 births.[13] The karyotype is usually mosaic 45,X/46,XY. Gonadal pathologic features can vary from fibrous streaks indistinguishable from those in Turner syndrome to normally developed testes and a normal male phenotype. Typically, patients have a testis on one side and a fibrous streak on the other. Some patients may have a Turner-like phenotype. A fallopian tube is usually present on the side of the streak gonad. Leydig cell function, evaluated by testosterone response to HCG, and Sertoli cell function, evaluated by serum AMH levels, vary from poor to normal.

XX MALE SYNDROME

Males with a 46,XX karyotype have normal external and internal male genitalia; however, they resemble patients with Klinefelter's syndrome in that they have small testes, azoospermia, and infertility. Translocation of the *SRY* gene to the X chromosome is detected in 75 to 90% of sporadic cases; this can occur because the gene is located very near the pseudoautosomal region, where the short arms of the X and Y chromosomes are homologous and meiotic recombination is possible. Duplication of the SOX9 transcription factor may be responsible for some familial cases of XX sex reversal.

XY FEMALE SYNDROMES

Patients with pure XY gonadal dysgenesis (Swyer syndrome) have a normal female phenotype, including a uterus and fallopian tubes, but they have streak gonads. These patients are free of Turner-like malformations and attain normal height. Mutations of the *SRY* gene have been identified in 15% of cases. Unlike 45,X patients with Turner syndrome, these patients have an increased risk for gonadoblastoma.

Similar phenotypes result from duplication of the region of the X chromosome containing the *DAX1* gene, from duplication of the *WNT4* gene, or from haploinsufficiency of the SF1 transcription factor (see earlier). XY sex reversal also can result from mutations in the SOX9 transcription factor associated with campomelic dysplasia, a form of dwarfism. Mutations of *DHH* cause XY gonadal dysgenesis, associated with peripheral neuropathy.

Some 46,XY patients with absent gonads have various degrees of sexual ambiguity and no müllerian derivatives. The implication that some testicular tissue was functional at least up to 10 weeks' gestation and subsequently regressed led to the name *fetal testicular regression syndrome.* Testicular regression may occur in late pregnancy or even postnatally; these fully virilized male patients have isolated anorchia.

VAGINAL ATRESIA

Mayer-Rokitansky-Küster-Hauser syndrome refers to aplasia of the uterus and upper vagina, occurring in approximately 1 in 5000 women. In approximately

one third of cases, it occurs along with other abnormalities including unilateral renal aplasia, and cervicothoracic somite dysplasia (MURCS association). The genetic basis is unknown in most cases. Rare affected individuals have heterozygous mutations of *WNT4;* such patients usually have clinical and biochemical signs of androgen excess.

TRUE HERMAPHRODITISM (OVOTESTICULAR DISORDER OF SEXUAL DEVELOPMENT)

True hermaphroditism (ovotesticular DSD), a rare and usually sporadic disorder, is defined as the coexistence of seminiferous tubules and ovarian follicles. Most patients have an ovotestis with either an ovary or a testis on the opposite side; a gonad in the scrotum is usually a testis but may be an ovotestis.

The genitalia are usually ambiguous, but they may appear completely masculine or feminine. The anatomy of the internal reproductive tract depends on the nature of the gonads, particularly whether they secrete AMH. A uterus or uterine horn is present in 90% of cases. Testosterone response to HCG is variable, and AMH levels are usually low. Most patients experience breast development, ovulation, and even menstruation at puberty; pregnancy and successful childbirth are possible if selective removal of testicular tissue is feasible. Unless sex of rearing has already been chosen, male gender assignment should be restricted to patients with no uterus and descended testicular tissue because the latter is usually dysgenetic and prone to malignant degeneration. Most patients with ovotesticular DSD have a 46,XX karyotype. Despite the presence of testicular tissue, they usually lack *SRY;* this suggests that the condition is the result of constitutive activation of a gene normally triggered by *SRY*.

MANAGEMENT OF INDIVIDUALS WITH DISORDERS OF SEXUAL DEVELOPMENT: GENDER ROLE AND IDENTITY

The influence of prenatal sex steroid exposure or epigenetic changes in the estrogen receptor[14] on personality is controversial.[15] In considering this question, it is important to distinguish among gender role, sexual orientation, and gender identity.

Gender Role

Gender role refers to gender-stereotyped behaviors, such as the choice of toys by young children. For example, parents of young girls with CAH often report that their daughters prefer to play with trucks rather than dolls and tend to be tomboyish later in childhood. Decreased interest in maternal behavior, beginning with infrequent doll play in early childhood and extending to lack of interest in child rearing in older girls and women, occurs frequently.

Sexual Orientation

Sexual orientation refers to homosexual versus heterosexual preferences. In many studies, a significant minority of women with CAH have been actively homosexual or bisexual or have had an increased tendency toward homoerotic fantasies. These characteristics occur more frequently in women with the salt-wasting form of 21-hydroxylase deficiency, suggesting that they are a consequence of prenatal exposure of the brain to androgens. However, the vast majority of both male and female homosexuals have no identifiable endocrinologic abnormality.

Gender Identity

Gender identity refers to self-identification as male or female. Gender self-reassignment back to male has been reported in cases of male patients with penile trauma or exstrophy of the bladder who were raised as girls. This may also occur in 46,XY patients with disorders of sexual development (DSD) raised as girls, especially in cases of 5α-reductase or 17-ketosteroid reductase deficiencies, in which the brain may be exposed to high circulating levels of androgens. Self-reassignment to the male gender is unusual in women with CAH. When it occurs, it may be related to delays in gender assignment or genital surgery or to inadequate suppression of adrenal androgens with glucocorticoid therapy.

Transgendered individuals rarely have identifiable hormonal abnormalities; nonhormonal mechanisms governing gender identity are poorly understood. Gender identity disorders are much more likely to occur in both identical twins than in fraternal twins, suggesting a high degree of heritability. Neuroanatomic studies suggest that the bed nucleus of the stria terminalis is larger in males and female-to-male transsexuals and smaller in females and male-to-female transsexuals. Similar findings involving other sexually dimorphic brain regions have been identified by MRI. Thus, gender identity disorder may be considered a brain-limited form of DSD.

DIAGNOSIS

Management of a child born with ambiguous genitalia presents a difficult challenge to medical personnel.[16] It is important to refrain from assigning sex until diagnostic information can be gathered. Usually, test results can be obtained within 24 to 48 hours and parents can be advised about the child's chromosomal and gonadal sex and the anatomy of internal sexual structures.

In addition, the physician must keep in mind that DSD may be associated with life-threatening biochemical or anatomic abnormalities. In particular, the most common cause of severely masculinized external genitalia in females, the salt-wasting form of CAH resulting from steroid 21-hydroxylase deficiency, may cause hyponatremia, hyperkalemia, hypovolemia, and shock. In contrast, male patients with ambiguous genitalia may have lipoid adrenal hyperplasia or a salt-wasting form of 3/3-hydroxysteroid dehydrogenase (HSD3B2) deficiency. Males with micropenis may have panhypopituitarism; in this case they are at risk for significant hypoglycemia and hyponatremia resulting from low cortisol (because of low ACTH) and low growth hormone levels, or they may have adrenal hypoplasia congenita, in which case they could have adrenal insufficiency. Finally, patients with ambiguous genitalia are at increased risk for renal anomalies, or they may have chromosomal syndromes with other associated anomalies.

History

The gestational history should concentrate on potential exposure to agents that could interfere with normal sexual differentiation. For a female infant with virilized genitalia, these include progestational agents, whereas the mother of a male with incompletely masculinized genitalia may have been exposed to a 5α-reductase inhibitor through her husband's use of such an agent for male pattern baldness or prostate enlargement. It should be determined whether amniocentesis and karyotyping have been performed. A family history should elicit similar cases of genital ambiguity or cases of sudden death, which could raise suspicion of undiagnosed salt-wasting CAH or adrenal hypoplasia congenita.

Physical Examination

The physical examination should document the size of the phallus (clitoris or penis), the degree of chordee (ventral bowing of the phallus), and the extent of fusion of the labioscrotal folds. The urethral meatus should be identified, and there must be careful palpation for gonads in the inguinal canals and labia or scrotum. Bilateral cryptorchidism, even if an isolated finding in a phenotypic male patient, should always lead to evaluation for a possible DSD.

Biochemical Evaluation of the Virilized Female

The minimal diagnostic tests should include measurement of basal serum 17-hydroxyprogesterone, androstenedione, and testosterone. Preferably, a complete profile of adrenocortical hormones is obtained before and 1 hour after stimulation of the adrenal cortex with 125 to 250 μg of cosyntropin ($ACTH_{1\text{-}24,}$). These assays should be deferred until after the first 24 hours of life. They will identify potential defects in adrenal steroidogenesis (i.e., CAH); 21-hydroxylase deficiency is identified by elevations in 17-hydroxyprogesterone, whereas 11-deoxycortisol and 11-deoxycorticosterone are high in 11β-hydroxylase deficiency.

Biochemical Evaluation of the Undervirilized Male

In 46,XY DSD patients, it is necessary to test adrenal and gonadal function as well as extragonadal androgen metabolism. With regard to adrenal defects, 11-deoxycorticosterone and the ratio of pregnenolone to 17-hydroxypregnenolone are high in 17α-hydroxylase deficiency, 17-hydroxypregnenolone and DHEA are high in HSD3B2 deficiency, and all steroids are low in lipoid hyperplasia.

Defects in gonadal steroidogenesis are best evaluated after stimulation with HCG (1500 IU intramuscularly on days 1, 3, and 5, with blood drawn on day 6). However, 17-hydroxylase and HSD3B2 deficiencies affect both the gonads and the adrenal cortex and thus are often diagnosed by cosyntropin stimulation testing. Low levels of all androgen precursors suggest lipoid hyperplasia, 17α-hydroxylase/17,20 lyase deficiency, or a generalized defect in testicular function, such as the vanishing testes syndrome (testicular regression-syndrome) or gonadotropin insensitivity. A high ratio of

androstenedione to testosterone is indicative of 17-ketosteroid reductase (HSD17B3) deficiency, and a high ratio of testosterone to dihydrotestosterone is diagnostic of 5α-reductase deficiency. The diagnosis of androgen insensitivity syndrome is suspected when a 46,XY patient has ambiguous or female-appearing external genitalia despite normal or high circulating levels of testosterone and dihydrotestosterone.

Gonadal Biopsies

Patients with mixed gonadal dysgenesis, true hermaphroditism, or unclear diagnoses should undergo bilateral gonadal biopsies (histology of the two gonads is often not identical). Dysgenetic gonads have a high potential for malignant transformation and usually need to be removed in childhood.

TREATMENT

Rx

Initial Medical Management

Patients with CAH resulting from 21-hydroxylase or HSD3B2 deficiencies or those with lipoid hyperplasia or adrenal hypoplasia congenita require replacement of both glucocorticoids and mineralocorticoids, usually with hydrocortisone (15 to 20 mg/m^2/day in divided doses) and fludrocortisone (usually 0.1 mg/day, but as much as 0.4 mg/day in neonates with salt-wasting crises). Neonates with severe salt losses may require sodium chloride supplementation (≤8 mEq/kg/day). Patients with 11β-hydroxylase or 17α-hydroxylase deficiencies have normal aldosterone biosynthesis and usually require only glucocorticoids. Patients with panhypopituitarism usually require treatment with hydrocortisone, thyroxine, and growth hormone.

All male infants with ambiguous genitalia or micropenis in whom rearing as a boy is contemplated should have a 3- or 4-month therapeutic trial of monthly depot testosterone injections (25 mg) to attempt to increase the size of the phallus during infancy. This treatment may improve social acceptability of the genitalia later in childhood and adolescence and may make reconstructive surgery easier. In cases of suspected partial androgen insensitivity, this treatment also documents the degree to which the patient is androgen responsive and thus may provide useful information about whether rearing as a boy is feasible. Higher doses of testosterone (75 mg every 4 weeks) may be used under these circumstances.

Considerations Related to Sex Assignment

In large medical centers, a team consisting of a neonatologist, a pediatric endocrinologist, a urologist, and preferably an experienced social worker and/or child psychiatrist or psychologist should promptly review the early diagnostic data and make a recommendation to the family as to the sex of rearing and any medical or surgical treatments. These recommendations should be based on both current knowledge of psychosexual development in DSD individuals and the feasibility of surgical treatment (see later).[17]

In general, the recommended sex assignment should be that of the genetic/gonadal sex, if for no other reason than to retain the possibility of reproductive function. This is especially true for female infants with CAH who have normal internal genital structures and the potential for childbearing. An exception may be considered in a genetically female infant with completely male-appearing genitalia, especially if the child has been raised as a boy for more than a few months. Such children need to be castrated at puberty to avoid feminization.

Conversely, genetic male infants with completely female-appearing external genitalia (usually resulting from complete androgen insensitivity syndrome, but also seen with severe testosterone biosynthetic defects) should be raised as female because the potential for reconstruction of male genitalia is poor. They, too, need to be castrated by early adulthood to avoid malignant transformation of the testes. However, male infants with 17-ketosteroid reductase or 5α-reductase deficiency should usually be reared as boys because they have normal levels of androstenedione or testosterone, respectively, and often virilize significantly at puberty. Indeed, many of these patients reassign themselves to the male gender when they are made aware of the diagnosis. The same considerations pertain to male patients with normal testosterone biosynthesis who have penile trauma or anatomic abnormalities such as bladder exstrophy.

Recommendations for sex assignment are to some extent culture specific. In cultures that value boys over girls, parents may strongly resist rearing a female infant with ambiguous genitalia as a girl, and many girls with severely virilized external genitalia will be raised as boys.

Surgical Management

Surgery for Ambiguous Genitalia

Whether, how, and when to intervene surgically in the correction of genital anomalies are the subject of continuing debate. Some adult patients with DSD conditions are unhappy with their gender assignments or surgical outcomes. Some physicians advocate postponing cosmetic genital surgery until the affected individual is able to provide informed consent, thus keeping all the options open if the adult patient wishes to function sexually with abnormal genitalia that nevertheless have sensation undiminished by surgery or chooses to reassign his or her gender. Declining or postponing surgery should not be confused with raising the child with an indeterminate gender, a concept currently well outside the mainstream. The option of deferring surgery should always be presented as part of the informed consent process. Nevertheless, most parents want their child to look as "normal" as possible, and they often resist suggestions to postpone genital surgery.

In addressing this question, it is best to consider the various general types of genital surgery separately. The greatest change in practice over the past few decades probably pertains to male infants with ambiguous (but not completely female) external genitalia. Physicians are far less likely to recommend that such patients be reared as female because it is now recognized that many of these patients reassign themselves as male at puberty. Thus, the ambiguous genitalia in such patients should rarely be "corrected" to female. On the contrary, surgical techniques for hypospadias repair have advanced significantly, and reconstruction of male genitalia is attempted more often, particularly if the infant responds to a course of testosterone with significant phallic growth.

Surgery for female infants with ambiguous genitalia may need to address an enlarged clitoris, the lack of a vaginal introitus, and the presence of a urogenital sinus. The clitoris is normally prominent in many infant girls. Even when enlarged in a girl with virilizing CAH, the clitoris can be prevented from growing larger with adequate suppression of adrenal androgens by glucocorticoids, and it will become less prominent as the patient grows. Thus, mild-to-moderate clitorimegaly is often best managed without surgery. When clitoroplasty is attempted, one must keep in mind the important role of clitoral sensation in the female sexual response. Such surgery must be performed only by experienced operators with scrupulous attention to the preservation of clitoral innervation.

Consensus is still lacking regarding the best age for vaginoplasty. Although many surgeons advocate a first procedure in infancy, it is difficult to maintain a functionally adequate introitus in the absence of estrogen exposure and mechanical dilation (with dilators or through sexual intercourse), and many patients require reoperation as young adults. Conversely, many women with atresia of the upper vagina (owing to complete androgen insensitivity or Mayer-Rokitansky-Küster-Hauser syndromes) can use dilators to lengthen the vagina without the need for surgery.

There is a dearth of large longitudinal studies comparing outcomes in patients who have had early genital surgery versus those who have had no surgery or surgery in adolescence. According to self-assessment surveys among sexually active women with CAH who have had genital surgery, most are able to have satisfactory sexual intercourse. As surgical and medical treatment regimens have improved in recent years, more women with CAH have successfully conceived spontaneously, completed pregnancies, and given birth. Most often, delivery is by cesarean section because of an inadequate introitus, but vaginal delivery is possible in some cases.

Hypospadias repair is usually begun in the first year of life, after testosterone treatment (if necessary to increase phallic size). Depending on the degree of hypospadias, more than one surgical procedure may be required.

Removal of Intra-abdominal Testes in 46,XY Patients with Disorders of Sexual Development

Intra-abdominal testes are at increasing risk for malignant transformation over time. In a boy with cryptorchidism who is being reared as male, orchiopexy should be performed as quickly as possible; this also maximizes the possibility of fertility when the underlying condition does not preclude it. Dysgenetic gonads that cannot be brought into the scrotum should be removed soon after diagnosis because the risk for malignant transformation in childhood is relatively high.

There is a lack of consensus regarding nondysgenetic testes in severely undervirilized genetic male infants in whom rearing as female is planned. In patients with complete androgen insensitivity or complete defects in testosterone biosynthesis, no possibility of fertility exists, and so there seems to be no reason to retain the testes. Conversely, the risk for malignant transformation in such gonads is low before puberty, and patients with complete androgen insensitivity can undergo spontaneous breast development at puberty. At that time, patients themselves can assent or consent to gonadectomy, which can usually be accomplished laparoscopically. This is of particular importance in genetic male patients with partial androgen insensitivity or incomplete defects of testosterone biosynthesis, because such patients may eventually desire a male gender role.

Patients with persistent müllerian duct syndrome have a reduced but still appreciable potential for fertility, and virilization is unaffected. Thus, the testes should be removed only if they cannot be brought into the scrotum. Because the müllerian and wolffian structures are closely approximated in these patients, surgical excision of the uterus and fallopian tubes may result in ischemic and/or traumatic damage to the vas deferens and testes; thus, salpingectomy and hysterectomy are indicated only in patients whose müllerian structures limit intrascrotal placement of the testes.

Space does not permit extensive discussion of surgical management of transgendered adults; options for male-to-female transsexuals include genitoplasty and, for those who did not have hormonal management during adolescence (see the next section), breast augmentation, body contouring, and facial and/or laryngeal surgery to produce a more feminine appearance. Female-to-male transsexuals often desire breast reduction surgery or complete mastectomies.

Treatment of Transgendered Individuals

Children and Adolescents

Transgendered individuals should be treated by multidisciplinary teams that can provide psychosocial evaluation and support.[18,19] Prepubertal children do not require medical management. The majority of such children do not persist in their identification with the opposite sex, although many will be homosexual as adults. Persistently transgendered children may develop significant gender dysphoria (distress at functioning in their natal gender) when puberty commences and are at increased risk for self-injury and suicide as adolescence progresses. If at all possible, such children should be allowed to function in the desired gender role. The current standard of care in many centers for children who have lived in a transgendered role for at least 6 months is to delay pubertal progression until mid-adolescence (~16 years old), with use of gonadotropin-releasing hormone (GnRH) agonists such as leuprolide depot injections or histrelin (Supprelin) implants. This will prevent the development of secondary sexual characteristics that may be distressing to the patient and may present cosmetic barriers to functioning in the desired, non-natal gender. These include breast enlargement, widened hips, and gynecoid adipose distribution in natal females or penile enlargement, facial and body hair, laryngeal enlargement and deep voice, and prominent jaw in natal males.

When the patient is confirmed in the desired gender role (e.g., by living completely in that role for at least 1 year), treatment may begin with the appropriate sex hormones. In high doses, such treatment will itself suppress gonadotropin secretion, and the GnRH agonist may be discontinued. Female-to-male transsexuals can be treated with depot testosterone whereas male-to-female transsexuals can be treated with parental forms of estradiol. Oral estrogen preparations should be avoided because they tend to increase production of clotting factors by the liver and may thus increase the risk for thromboembolism.

Adults

The medical treatment of transgendered adults follows the same principles as for adolescents, except that because secondary sexual characteristics have already developed, prolonged treatment with GnRH agonists is unnecessary. However, continuing such treatment in male-to-female transsexuals permits use of much lower estradiol doses with a concomitant reduction in the risks associated with high dose estrogen treatment. Nevertheless, cost represents a barrier to the long term use of GnRH agonists.

Prenatal Diagnosis and Treatment

Many conditions causing ambiguous genitalia can be detected by karyotyping of chorionic villus samples (for chromosomal abnormalities) or by direct molecular genetic testing. In most cases, this information is useful only for counseling purposes. In the case of virilizing forms of CAH (particularly 21-hydroxylase deficiency), the mother of an affected female fetus can take dexamethasone (20 μg/kg/day), which can cross the placenta and suppress the fetal adrenal gland, thus reducing the secretion of androgens and ameliorating virilization of the external genitalia. To be most effective, this treatment should be started by the sixth week of gestation, before the sex or genotype of the fetus is known. Thus, seven unaffected or male fetuses must be treated with dexamethasone to avoid genital ambiguity in one affected female, until chorionic villus sampling can be performed. Although effective in reducing prenatal virilization, this dose of dexamethasone can cause Cushing syndrome in the mother, and the long-term sequelae in the fetus are not known. Recent consensus statements suggest that this treatment be used only under approved research protocols that allow for case registries and long-term follow-up.

Psychosocial Support

Families of patients with DSD should be assessed for emotional health, initially by the pediatrician and/or pediatric endocrinologist. Parents should be offered psychological counseling soon after the diagnosis is made. Intermittent assessment of family functioning may be a useful tool in predicting future problems. As children mature, they should repeatedly be informed about their condition by parents and physicians in a sensitive and age-appropriate manner. When psychotherapy is undertaken, medical and psychiatric caregivers should communicate with each other so both are aware of the patient's and family's status. Unfortunately, many locales lack mental health professionals with experience in counseling patients with DSD and their families.

Although the psychosexual development of individuals with DSD cannot be predicted with confidence, patients' families should receive anticipatory counseling. For example, counseling of parents of girls affected with CAH should address the high likelihood that such girls will exhibit tomboyish behavior, masculine play preferences, and perhaps, when older, a preference for a career over domestic activities. The endocrinologist and/or mental health professional (depending on inclination and experience) caring for the adolescents with DSDs should address sexual orientation, both fantasized and actual. For example, some women with CAH are most comfortable as homosexuals; such individuals should receive appropriate psychosocial support. Adult patients also should be made aware of relevant patient advocacy groups.

REVIEW QUESTIONS

1. Bilateral inguinal masses are palpated on routine examination of a newborn girl. There is a patent vaginal orifice. A karyotype is 46,XY. Which of the following disorders is *not* a possibility in this child?

A. Complete androgen insensitivity
B. 17-Hydroxylase deficiency
C. 11 β-Hydroxylase deficiency
D. 5α-Reductase deficiency
E. 17-Ketosteroid reductase deficiency

Answer: C This is a genetic male who has testes, with female-appearing external genitalia. The failure of development of normal male external genitalia must be due to failure of biosynthesis (answers B, D, or E) or action (answer A) of the most potent androgen, dihydrotestosterone. Deficiency of 17-hydroxylase (B) prevents synthesis of all androgens; 5α-reductase deficiency (D) prevents conversion of testosterone to dihydrotestosterone, and 17-ketosteroid reductase deficiency (E) prevents conversion of androstenedione to testosterone. In contrast, 11β-hydroxylase deficiency (answer C) is associated with increased secretion of androgen precursors by the fetal adrenal gland, which causes virilization of affected 46,XX female fetuses but no genital abnormality in males.

2. An 8-year-old boy has bilateral inguinal hernias and bilateral cryptorchidism. The penis and scrotum are normal. At operation, a uterus and fallopian tube are noted in the left inguinal canal, following which the surgeon terminates the operation and pages you, the on-call endocrinologist. What gene is *most likely* affected in this patient?

A. AMHR2 (anti-müllerian hormone receptor)
B. CYP21A2 (steroid 21-hydroxylase)
C. SRY (sex-determining region Y)
D. SF1 (steroidogenic factor 1)
E. LHGCR (luteinizing hormone receptor)

Answer: A This boy has persistent müllerian duct syndrome, which can be caused by mutations in either anti-müllerian hormone or (equally likely) in its receptor. Persistence of müllerian structures (uterus and fallopian tubes) in this otherwise normal boy prevents descent of the testes. CYP21A2 mutations (answer B) do not cause any abnormalities of reproductive structures in 46,XY males. Affected 46,XX females might have virilization of the external genitalia that could be severe enough to be mistaken for males and would indeed have a normal uterus and fallopian tubes. However, such individuals almost invariably develop adrenal insufficiency shortly after birth, and all newborns in the United States are screened for this disorder. Moreover, the müllerian structures in females with CYP21A2 mutations are found in their normal positions because there are no testes and spermatic ducts to drag them into the inguinal canals. Mutations of SRY (answer C), SF1 (D), and LHGCR (E) are found in 46,XY phenotypic females.

3. A 15-year-old girl presents for evaluation of primary amenorrhea. She has Tanner 5 breasts and an adult female distribution of pubic and axillary hair. There are no inguinal or labial masses. An ultrasound examination shows ovaries in the normal position but no uterus. The patient's karyotype and diagnosis are *most likely* to be which of the following?

A. 46,XY; complete androgen insensitivity syndrome
B. 45,X/46,XX mosaic; Turner syndrome
C. 46,XY; 17,20-lyase deficiency
D. 46,XX; Mayer-Rokitansky-Küster-Hauser syndrome
E. 46,XX; Kallman's syndrome

Answer: D Patients with Mayer-Rokitansky-Küster-Hauser syndrome have normal ovaries and therefore have normal female secondary sexual characteristics. By definition, they have atresia of the uterus and upper vagina. This phenotypic female has axillary and pubic hair, meaning that she responds normally to androgens secreted by the adrenal glands and (if present) by the ovaries. This rules out complete androgen insensitivity syndrome (answer A); 46,XY males with that condition have absent or sparse axillary and pubic hair. Moreover, they have testes that are often palpable in the inguinal canals or labia. Girls with Turner syndrome (answer B) often have pubic and axillary hair (owing to adrenal androgen secretion) and may have some degree of breast development, owing to local aromatization of adrenal androgens in breast fat and (if mosaic) to some residual ovarian function. But the uterus is normally formed. 46,XY males with 17,20 lyase deficiency (answer C) cannot synthesize androgens and have a phenotype similar to patients with complete androgen insensitivity syndrome. Patients with Kallman's syndrome (answer E) have hypogonadotropic hypogonadism; affected females indeed have primary amenorrhea and may or may not have development of secondary sexual characteristics depending on degree of severity, but they have normal development of the uterus.

4. A 13-year-old boy is brought to your office by his parents because he insists that he is really a girl. He has had this feeling as long as he can remember, but it is causing him increasing distress now that he is in early adolescence. He has insisted on wearing dresses or gender-neutral clothing whenever possible. On examination, he is at the 50th percentile for height and weight for boys for his age. He has downy hair on his upper lip, axillary hair, a normally formed penis with the urethral meatus at the tip of the glans, bilaterally descended 4-mL testes, Tanner stage 2 pubic hair, and 1 cm of firm glandular tissue under each nipple. What would be the single most informative evaluation at this point?

A. Psychology consultation
B. Karyotype
C. Serum levels of dehydroepiandrosterone, androstenedione, and testosterone
D. FSH and LH
E. Estradiol

Answer: A Any patient with gender dysphoria requires psychological evaluation, preferably in the context of evaluation by an experienced multidisciplinary team, before considering any medical management. Transgendered patients rarely have identifiable medical etiologies for their condition unless the history and physical examination raise suspicion for a DSD. This phenotypic boy has palpable testes, strongly suggesting that he is 46,XY (answer B), and a normally formed penis, strongly suggesting intact ability to synthesize androgens (answer C). He has age-appropriate development of secondary sexual characteristics, suggesting that his ability to secrete gonadotropins is intact (answer D). Mild gynecomastia is typical in boys in early to mid-adolescence (owing to aromatization of androgens in breast tissue, in the context of low testosterone levels relative to adults) and is without clinical significance; estradiol levels will not be elevated.

5. You are paged to the intensive care nursery to evaluate a 2300-g term infant for ambiguous genitalia. The baby developed respiratory distress at delivery and is now intubated on a respirator. You are told that a cleft palate was noted on intubation. You hear a grade 3/6 harsh holosystolic murmur. The baby has accessory digits bilaterally. The penis is small and the urethral meatus is at the base of the shaft. There is a bifid scrotum; gonads are palpable bilaterally in the inguinal canals. What laboratory tests are *most likely* to establish the diagnosis?

A. 17-Hydroxyprogesterone and androstenedione
B. Testosterone and dihydrotestosterone
C. Androstenedione and testosterone
D. 11-Deoxycortisol and cortisol
E. 7-Dehydrocholesterol and cholesterol

Answer: E This male infant has Smith-Lemli-Opitz syndrome, owing to an inability to synthesize cholesterol from its immediate precursor. He is small for gestational age and, as a term infant, must have serious cardiorespiratory dysfunction (such as lung hypoplasia) to require ventilator support. The character of the murmur suggests a ventriculoseptal defect. The other physical findings are all typical of this syndrome. Boys with 5α-reductase deficiency are unable to synthesize dihydrotestosterone from testosterone (answer B); they may have female-appearing or ambiguous genitalia, but have no other medical problems. Boys with 17-ketosteroid reductase deficiency cannot synthesize testosterone from androstenedione (answer C); the phenotype is identical to 5α-reductase deficiency. Patients with 11-hydroxylase deficiency cannot synthesize cortisol from 11-deoxycortisol (answer D). Males are phenotypically normal; females may have ambiguous genitalia but no other congenital anomalies.

THE TESTIS AND MALE HYPOGONADISM, INFERTILITY, AND SEXUAL DYSFUNCTION

RONALD S. SWERDLOFF AND CHRISTINA WANG

PHYSIOLOGY

The testis is a bifunctional organ serving as the site of sex steroid (i.e., testosterone) synthesis and sperm production in the male. Androgens and their metabolites (including estrogens) also act on nonreproductive organs and serve essential roles in muscles, adipose tissues, bones, metabolism, and brain functions.

The male reproductive axis consists of six main components: (1) extrahypothalamic central nervous system (CNS), (2) hypothalamus, (3) pituitary, (4) testes, (5) sex steroid–sensitive end organs, and (6) sites of androgen transport and metabolism (Fig. 234-1). The components of this system function in an integrated fashion to control the concentrations of circulating gonadal steroids required for normal male sexual development

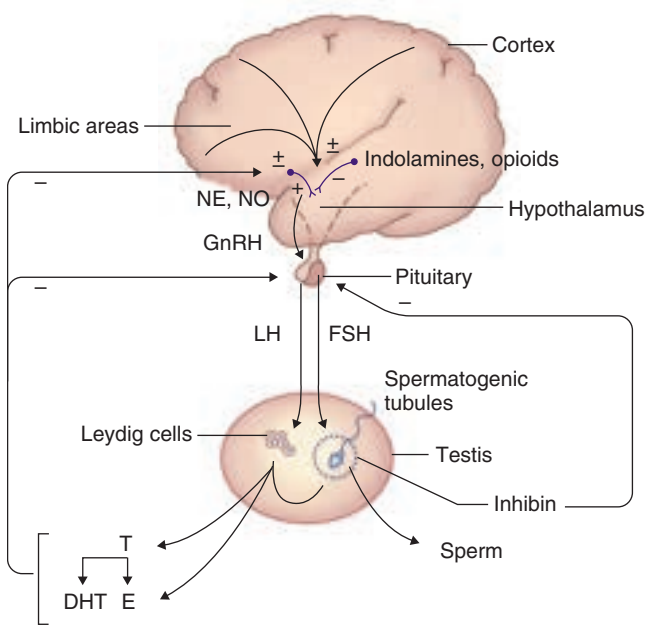

FIGURE 234-1. The hypothalamic-pituitary-gonadal axis in the male. DHT = dihydrotestosterone; E = estrogen; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; NE = norepinephrine; NO = nitric oxide; T = testosterone.

and function and for androgen- and estrogen-mediated metabolic effects on critical end organs. The reproductive axis is also responsible for normal germ cell development and maturation. Accessory sexual organs, including the epididymides, seminal vesicles, and prostate gland, are important for sperm maturation (epididymis) and seminal fluid production. An anatomically functional sperm transport and ejaculatory system are necessary to ensure male fertility.

Hypothalamic-Pituitary Function

The hypothalamus is responsible for the normal pulsatile secretion of gonadotropin-releasing hormone (GnRH) (Chapter 224). The pulsatile release of GnRH provides the signals for the timing of the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which occurs every 60 to 90 minutes in men. The secretion of GnRH is regulated by neuronal input from higher cognitive and sensory centers and by circulating levels of sex steroids and peptide hormones such as prolactin and leptin (Chapter 223). Testosterone or its metabolic products (i.e., estradiol and dihydrotestosterone [DHT]) inhibit the secretion and release of GnRH, LH, and FSH. Prolactin is also a potent inhibitor of GnRH secretion.

Both LH and FSH consist of two subunits (α and β). Both subunits are required for biologic activity; the subunits can be detected in serum and may be increased in certain pathologic conditions (e.g., α-subunit elevations in gonadotropin-secreting pituitary adenomas). LH has a shorter half-life than FSH. Feedback regulation of LH and FSH secretion also occurs at the pituitary, with testosterone, DHT, and estrogens inhibiting the synthesis or release of both gonadotropins. The circulating testicular peptide inhibin, produced by Sertoli cells, also selectively inhibits FSH. LH and FSH act on the testes through specific cell surface receptors on the Leydig and Sertoli cells, respectively.

Testosterone

The testis is a complex organ consisting of (1) seminiferous tubules containing Sertoli cells and germ cells and (2) the interstitium, which contains the steroid-secreting (Leydig) cells. Leydig cells synthesize steroid hormones under the regulation of LH. The LH receptors on the cell surface of the Leydig cells lead to G protein–, adenyl cyclase–, and cyclic adenosine monophosphate–mediated activation of steroid biosynthesis.

Testosterone is the principal male hormone secreted by the testes; approximately 5 to 10 mg/day is produced in adult men. Testosterone synthesis occurs in the human testes through either the Δ^4 or the predominant Δ^5 pathway. The enzymatic rate-limiting steps in the process are the LH-inducible steroid acute regulatory (StAR) protein and the conversion of cholesterol to pregnenolone by the cholesterol side-chain cleavage enzyme P450SCC (Fig. 234-2).

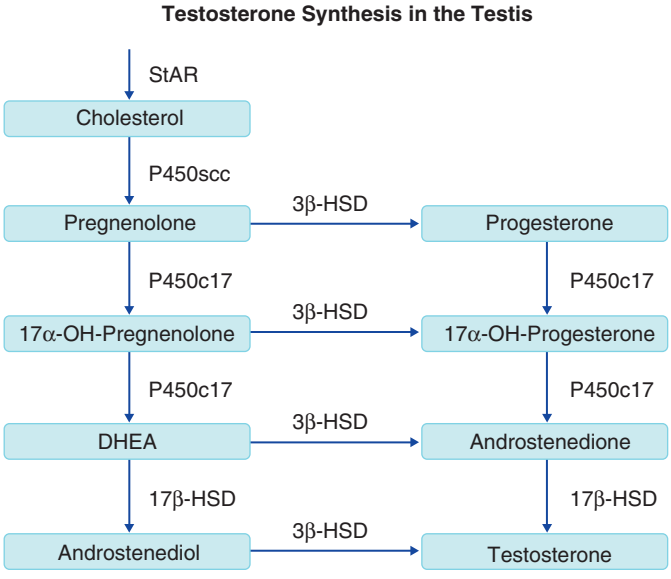

FIGURE 234-2. The steroid acute regulatory (*StAR*) protein mobilizes cholesterol from cellular stores to the mitochondria. Intratesticular steroidogenic pathways for the synthesis of testosterone. Although both the Δ^5 (*left*) and Δ^4 (*right*) pathways exist, the Δ^5 pathway predominates in the testis. DHEA = dehydroepiandrosterone; HSD = hydroxysteroid dehydrogenase.

Testosterone circulates mainly bound to two plasma proteins: sex hormone–binding globulin (SHBG) and albumin. In young adult men, approximately 54% of testosterone is bound to albumin, 44% is bound to SHBG, and 2 to 3% is unbound. Bioavailable testosterone refers to the sum of albumin-bound and free testosterone and is measured by separating SHBG-bound testosterone from total testosterone. Serum SHBG levels are increased in hyperestrogenemic states, hyperthyroidism, aging, phenytoin treatment, anorexia nervosa, and prolonged stress. SHBG levels are lowered in hyperandrogenic states (endogenous and exogenous as in androgen treatment), obesity, acromegaly, and hypothyroidism. In most instances, measurement of serum total testosterone provides biochemical support for the diagnosis of androgen deficiency. In conditions with abnormal SHBG levels, however, the total testosterone measurement may be misleading, and measurement of non–SHBG-bound testosterone may allow better interpretation of the active testosterone levels. This can be done by direct measurement of free testosterone by the equilibrium dialysis method, measurement of bioavailable testosterone, or calculation of the free testosterone by a formula requiring the serum testosterone and SHBG concentrations. Most guidelines recommend against measurement of free testosterone by a "direct" or analogue displacement method because of lack of accuracy traceable to a standard.

Testosterone exerts its effects either through direct action or after conversion to DHT by two separate 5α-reductase isozymes (1 and 2) or to estradiol by the aromatase enzyme (Fig. 234-3). Thus, testosterone can act directly on the androgen receptor or as a precursor for DHT, which also binds efficiently to the androgen receptor. Different tissues have coactivators or coinhibitors that modify the action of the androgen-receptor complex, providing tissue selectivity and amplification. Testosterone also can serve as a precursor for estradiol in some tissues, and after conversion, estrogen binds the estrogen receptors (α or β) to induce its effects. Various end organs differ in their 5α-reductase isoenzyme and aromatase concentrations and/or activity. Congenital and acquired defects in these two enzymes, as well as in the estrogen and androgen receptors, result in distinct syndromes with characteristic phenotypes that are experiments in nature and provide understanding of the actions of specific receptors and enzyme activities (Chapter 233).

Spermatogenesis

The spermatogenic compartment of the testis consists of the Sertoli and germ cells that are intimately interactive with the interstitial compartment. The Sertoli cells bridge the entire space between the basement membrane and the lumen of the tubules. They are the target of androgenic and FSH stimulation of spermatogenesis and also the source of a multitude of paracrine regulators of spermatogenesis (e.g., inhibin, activin, growth factors, cytokines).

Germ cell development and maturation depend on the proper hormonal (FSH) and paracrine (testosterone) milieu. Both testosterone and FSH stimulate progression of spermatogonia to mature spermatozoa, limit the amount of germ cell death (apoptosis), and regulate sperm release from the germinal epithelium.

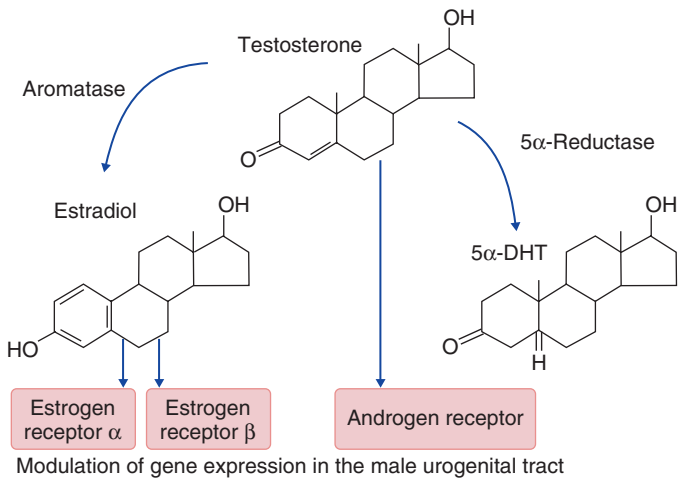

FIGURE 234-3. Testosterone action is mediated directly (androgen receptor), after conversion to estradiol (estrogen receptor α or β), or after conversion to dihydrotestosterone (DHT; androgen receptor). (From Kuiper GCJM, Carlquist M, Gustafsson JA. Estrogen is a male and female hormone. *Sci Med*. 1998;5:36-45.)

After spermatogenesis is completed, mature spermatozoa are released into the excretory system and travel through the rete testes and epididymis, where they become functionally mature and acquire fertilizing capacity before traversing the vas deferens. The seminal fluid gains constituents from the seminal vesicles, prostate, and bulbourethral glands before ejaculation.

Sexual Function and Erectile Physiology

Sexual function in men requires normal sexual desire (libido) and erectile, ejaculatory, and orgasmic capacity. The process is complex, involving cognitive, sensory, hormonal, autonomic neuronal, and penile vascular integrative actions for normal function. Defects can occur at multiple levels.

The brain is the integrative center of the sexual response system. It processes sensory input and hormonal signals to create the hypothalamic neuronal message that traverses the spinal cord to the T9-12 sympathetic and sacral parasympathetic outflow tracts. The nonadrenergic, noncholinergic autonomic plexus nerves initiate vasodilation of the cavernosal arterial and corpora cavernosal sinusoids of the penis through the release of local vasodilators (e.g., nitric oxide and vasoactive intestinal peptide) from the vascular endothelium and the sinusoidal smooth muscle cells of the sinusoids (Fig. 234-4). Nitric oxide produces smooth muscle dilation by the generation of cyclic guanosine monophosphate (cGMP) and the modification of calcium flux. The neurogenic mechanisms leading to vasodilation of the cavernosal arterioles and sinusoids lead to a rapid increase in penile blood flow and expansion of the vascular channels; this, in turn, inhibits venous return through compression of the venous channels against the tunica albuginea and limits venous drainage.

Testosterone's primary effect on erectile function is to enhance libido. Testosterone also increases penile nitric oxide synthase activity and enhances smooth muscle cell growth. Sexual desire and fantasy are highly sensitive to testosterone, explaining the preservation of erectile capacity in many men with partial androgen deficiency.[1]

Physiology in Development and Aging

Reproductive Axis Development during Childhood and Puberty

Adrenarche and Puberty

Adrenarche occurs at approximately 7 or 8 years of age when the zona reticularis of the adrenal gland undergoes maturation, leading to increased secretion of androstenedione, dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEA-S). The process is under the control of adrenocorticotropic hormone, not LH or FSH. Androstenedione and DHEA are technically androgenic prehormones, and the prepubertal growth spurt, as well as the early development of pubic and axillary hair, are mediated to a great extent by the conversion of these precursors to testosterone and DHT in peripheral tissues.

Initiation of puberty is determined by an increase in the pulsatile pattern of hypothalamic GnRH secretion. This is marked by nocturnal bursts of LH secretion. As puberty progresses, feedback sensitivity of the hypothalamus and pituitary to circulating steroids lessens, thus increasing the secretion of gonadotropins. The increasing concentrations of intratesticular testosterone and circulating FSH stimulate the Sertoli cell to produce factors leading to the maturation of spermatogenesis. The majority of the extratesticular end-organ events of puberty are secondary to the increased testosterone and its metabolic products (DHT and estradiol) (Table 234-1). The penis and scrotum grow and become pigmented. As spermatogenesis advances, the testes increase in size from 1 to 2 mL at the outset of puberty to 15 to 35 mL in adulthood. There is a progressive increase in facial, axillary, chest, abdominal, thigh, and pubic hair; frontal scalp hair regresses, and the voice deepens (Fig. 234-5). Genital and sexual hair development and temporal scalp hair regression require DHT. The increased levels of sex steroids result in closure of the epiphysis and achievement of adult height.

Aberrations of Timing of Puberty

Delayed puberty, more common in boys than in girls, is usually defined as a temporary form of hypothalamic hypogonadotropic hypogonadism in which sexual development has not begun by age 13.5 years. Height age (the age

TABLE 234-1 PUBERTAL STAGES IN BOYS

STAGE	PUBIC HAIR	GENITAL
1	Absence of pubic hair	Childlike penis, testes, and scrotum (testes 2 mL)
2	Sparse, lightly pigmented hair mainly at base of penis	Scrotum enlarged with early rugation and pigmentation; testes begin to enlarge (3-5 mL)
3	Hair becomes coarse, darker, more curled, and more extensive	Penis has grown in length and diameter; testes now 8-10 mL; scrotum more rugated
4	Hair adult in quality, but distribution does not include medial aspect of thighs	Penis further enlarged, with development of glans; scrotum and testes (10-13 mL) further enlarged
5	Hair is adult and extends to thighs	Penis and scrotum fully adult; testes ≥ 15 mL

Modified from Marshall WA, Tanner JM. Variation in pattern of pubertal changes in boys. *Arch Dis Child.* 1970;45:13-23.

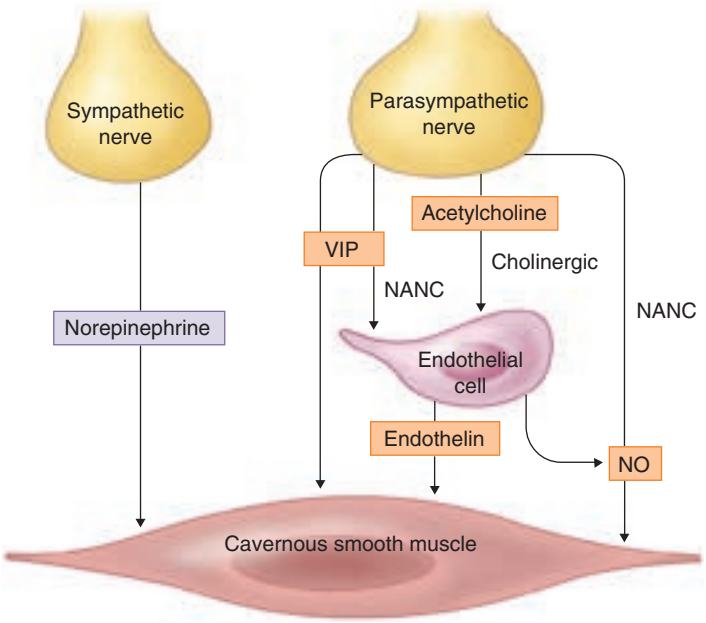

FIGURE 234-4. The interaction among cholinergic, adrenergic, and nonadrenergic, noncholinergic (*NANC*) neuronal pathways and their contribution to penile smooth muscle contraction and dilation (*arrows*). NO = nitric oxide; VIP = vasoactive intestinal polypeptide. (From Lue TF. Physiology of penile erection and pathophysiology of erectile dysfunction and priapism. In: Walsh P, Retick A, Vaughn E, Wein A, eds. *Campbell's Urology,* 7th ed. Philadelphia: WB Saunders; 1998:1164.)

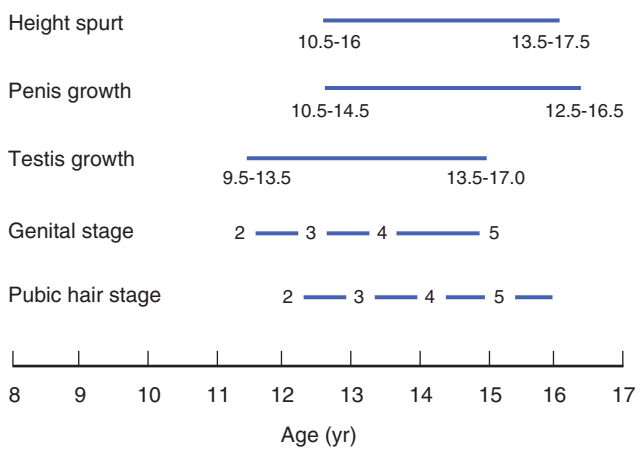

FIGURE 234-5. Diagram of the timing of the various components of puberty. The range of ages at which each parameter begins and is completed is shown for each bar. These data were obtained from European children 40 years ago. Since then, there may be a slight trend for an earlier onset of puberty. (From Marshall WA, Tanner JM. Variations in the pattern of pubertal changes in boys. *Arch Dis Child*. 1970;45:13-23.)

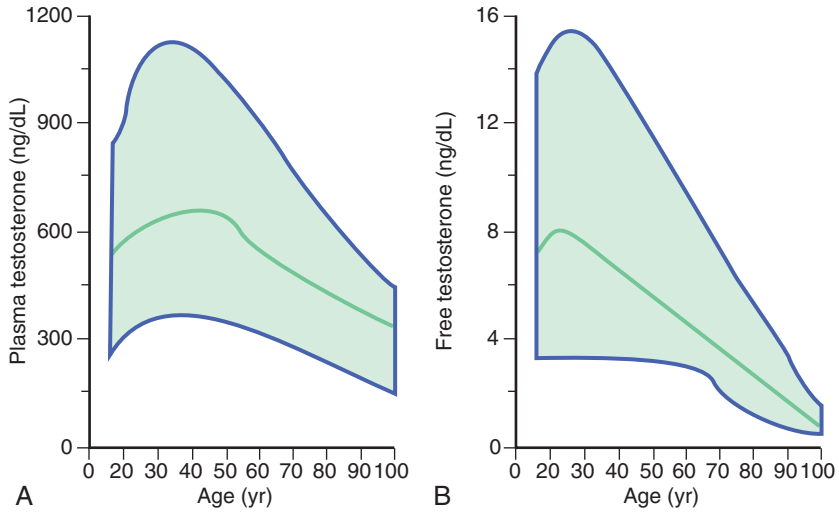

FIGURE 234-6. Relationship between plasma testosterone (A) and free testosterone (B) levels and age in normal males. (From Baker HWG, Berger HG, DeKretser DM, et al. Changes in the pituitary-testicular system with age. *Clin Endocrinol*. 1996;5:349-372.)

representative of 50% of normal children at the patient's height) is delayed with respect to chronologic age, but it is concordant with bone age. Once initiated, puberty is normally completed within 4.5 years. The majority of boys with delayed development eventually attain full sexual adulthood. There is often a family history of a parent or sibling being a "late bloomer." The *GPR54* gene encodes a kisspeptin-responsive G protein–coupled receptor whose absence results in hypogonadotropic hypogonadism resulting from impaired secretion of GnRH. Careful documentation of changing physical findings and measurement of serum LH, FSH, and testosterone concentrations may provide valuable clues to the beginning of puberty. An increase in testicular size to more than 3 mL usually heralds other signs of pubertal onset. Inquiring and testing for hyposmia or anosmia and other midline defects may indicate a common variant of congenital hypogonadotropic hypogonadism (Kallmann's syndrome). The decision to institute early treatment depends on the perceived degree of psychological stress associated with the maturational delay. The major concern is early fusion of the epiphyses induced by treatment with testosterone, which compromises optimal height; however, with proper dosing and monitoring of bone age, this is unusual. In adolescent boys with delayed puberty and low levels of gonadotropins, periodic withdrawal of treatment is used to determine whether spontaneous puberty has occurred. Many adult men diagnosed with and treated as adolescents for a presumed diagnosis of hypogonadotropic hypogonadism achieve normal reproductive function when they discontinue therapy.

Precocious puberty in boys is defined as the onset of pubertal (genital and secondary sexual) development before 9 years of age. Sexual precocity can be subcategorized as true (complete and incomplete) isosexual precocious puberty and pseudo–precocious puberty. The distinction is that true precocious puberty is associated with increases in GnRH-stimulated LH and FSH secretion (hypothalamic-pituitary origin), whereas pseudo–precocious puberty is independent of GnRH stimulation of LH and FSH secretion. True precocious puberty in boys is often associated with CNS disease (two thirds of boys), including hypothalamic tumors, cysts, inflammatory conditions, and seizure disorders. Diagnostic findings include sexual precocity, inappropriately elevated serum LH levels, and associated elevations of testosterone. Magnetic resonance imaging can localize most lesions. Another cause of central precocious puberty is human chorionic gonadotropin secretory germinomas (testicular, hepatic, hypothalamic, or pineal tumors). Pseudo–precocious puberty is characterized by increased testosterone with suppressed LH. Causes of pseudo–precocious puberty include congenital virilizing adrenal hyperplasia, testicular testosterone-secreting neoplasms, and constitutively active LH receptor mutations; the latter condition results in uncontrolled testosterone secretion (testotoxicosis). Treatment of true precocious puberty is removal or correction (with surgery or radiation therapy) of the CNS lesion, if possible, and treatment with GnRH analogues to temporarily suppress LH and FSH secretion. Treatment of pseudo–precocious puberty depends on the cause but includes glucocorticoids for congenital virilizing adrenal hyperplasia and ketoconazole (to suppress steroidogenesis), with or without antiandrogens (e.g., spironolactone, flutamide).

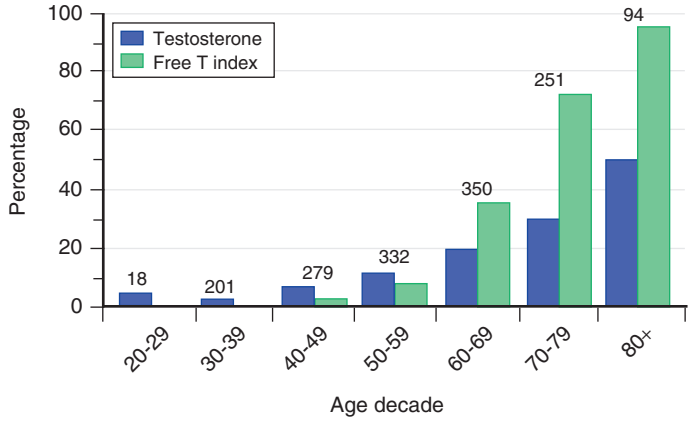

FIGURE 234-7. Hypogonadism in aging men. Bar height indicates the percentage of men in each 10-year interval, from the third to the ninth decades, with at least one testosterone value in the hypogonadal range. The criteria used for these determinations are total testosterone less than 11.3 nmol/L (325 ng/dL) and testosterone and sex hormone–binding globulin (free T index) less than 0.153 nmol/nmol. The numbers above each pair of bars indicate the number of men studied in the corresponding decade. The fraction of men who are hypogonadal increases progressively after age 50 years by either criterion. More men are hypogonadal by free T index than by total testosterone after 50 years, and there seems to be a progressively greater difference, with increasing age, between the two criteria.

Male Senescence: Decreased Testosterone and Other Anabolic Hormones

Testosterone Deficiency in the Elderly

Blood concentrations of testosterone, other anabolic hormones (e.g., growth hormone), and prehormones (e.g., DHEA, DHEA-S) are significantly lower in older men than in young adult men. Both total and bioavailable or free serum testosterone levels progressively decrease with aging (Fig. 234-6). The percentage decline in serum testosterone has been estimated as 1 to 2% per year. Serum SHBG levels also rise with age in men, resulting in a higher percentage of circulating testosterone that is tightly bound and less bioavailable. Between 20 and 80% of men older than 70 years have blood levels of bioavailable or free testosterone below the normal range for young adults (Fig. 234-7). Many older men with serum testosterone below the young adult reference range do not complain of symptoms attributable to low testosterone. In men between 30 and 70 years of age the crude prevalence rate of symptomatic testosterone deficiency has been estimated to be approximately 6%. Low testosterone levels are associated with comorbidities such as obesity, metabolic syndrome, and the commonest symptoms associated with low total or free testosterone in older men are sexual symptoms.[2]

Many of the effects of low testosterone levels in aging men are similar to those observed in younger hypogonadal men. These include decreases in libido, erectile function, muscle mass, muscle strength, bone mass, and impaired mood and sense of well-being. Older men have increased body fat, particularly visceral fat. The benefits of testosterone treatment for symptomatic older men with low serum testosterone levels remain controversial. Recommendations on the diagnosis, investigation, and treatment of late-onset hypogonadism are available but lack evidence from large-scale randomized, controlled national or international intervention studies. A randomized trial of testosterone versus placebo gel application in elderly men with a high prevalence of chronic disease was discontinued early because of an increased risk for cardiovascular events in those receiving testosterone, but the small size of the trial and the unique population prevented broader inferences about the safety of the testosterone therapy.[2] In a more recent study of men in the Veterans Administration health system who underwent coronary angiography and had low serum testosterone levels, the use of the testosterone therapy was found to be associated with increased risk for adverse outcomes.[3] Beneficial effects of testosterone replacement have been demonstrated in elderly men with relatively low serum testosterone levels. Testosterone replacement therapy (up to 3 years) decreases fat mass, increases lean body mass, improves strength, and increases bone mineral density in older men.[2] In larger, more recent studies of treatment with testosterone improved muscle strength and physical function were found in frail elderly men.[2,4] Erectile dysfunction in older men is usually multifactorial (see later), with impaired penile vasodilatory function a predominant factor in many cases. Thus testosterone replacement therapy in older men may enhance libido but often does not improve erectile dysfunction. At present, testosterone treatment is not recommended for men with or suspected of having prostate cancer, moderate-to-severe heart failure, severe and uncorrected sleep apnea, or high red blood cell mass. A digital rectal examination should be performed, prostate-specific antigen level determined, and symptoms of severe urinary tract obstruction evaluated before testosterone treatment is instituted.[5]

Deficiency of Adrenal Androgen in Older Men

A marked decline in the circulating levels of adrenal androgens, especially DHEA and DHEA-S, has been recognized in elderly men and women (Chapter 234). Serum levels of DHEA and DHEA-S peak at approximately the third decade of life and then decline at about 2% per year, resulting in levels 10 to 20% of baseline by 80 years of age. DHEA is a precursor to androgens such as testosterone and DHT. Studies have shown that the oral administration of 50 mg of DHEA to older men raises serum DHEA and DHEA-S concentrations to the levels found in young men without changing serum levels of testosterone, with no beneficial effects on quality of life, sexual function, mood, body composition, or exercise capacity. In the United States, DHEA is available without prescription as a health supplement and is widely used, making large-scale multicenter, prospective, placebo-controlled trials difficult to perform.

MALE HYPOGONADISM

DEFINITION

Hypogonadism (androgen deficiency) is diagnosed in men with consistent symptoms and signs and unequivocally low circulating levels of testosterone.[6] Most men with more severe androgen deficiency have very low intratesticular testosterone concentrations and are infertile. Primary hypogonadism indicates that the abnormality originates in the testis; it is characterized by increased serum LH and FSH levels. Secondary hypogonadism indicates a defect at the hypothalamus or pituitary, resulting in decreased gonadotropins (LH, FSH, or both). Combined primary and secondary hypogonadism occurs in aging and in a number of systemic diseases, such as alcoholism, liver disease, metabolic syndrome, type 2 diabetes mellitus, human immunodeficiency virus (HIV) infection, hemochromatosis, and sickle cell disease. Obesity leads to low total and free testosterone levels. Greater decreases are seen in the total testosterone level because obesity not only decreases testosterone secretion but also lowers SHBG levels. Decreased androgen action with normal or elevated testosterone levels, mimicking androgen deficiency, may occur in patients with androgen receptor defects (androgen resistance), postreceptor signaling abnormalities, and inability to convert testosterone to the active metabolite DHT (5α-reductase abnormalities).

Many of the causes of primary and secondary hypogonadism are listed in Tables 234-2 and 234-3 (see also Chapter 233).

TABLE 234-2 CAUSES OF PRIMARY TESTICULAR FAILURE AND END-ORGAN RESISTANCE

Congenital disorders
Chromosome disorders
Klinefelter's and related syndromes (e.g., XXY, XXY/XY, XYY, XX males)
Testosterone biosynthetic enzyme defects
Myotonic dystrophy
Developmental disorders
Prenatal diethylstilbestrol syndrome
Cryptorchidism
Acquired defects
Orchitis
Mumps and other viruses
Granulomatous disease (e.g., tuberculosis, leprosy)
Human immunodeficiency virus infection
Infiltrative disease (e.g., hemochromatosis, amyloidosis)
Surgical, traumatic injuries, torsion of testis
Irradiation
Toxins (e.g., alcohol, fungicides, insecticides, heavy metals, cottonseed oil, DDT, other environmental "endocrine disruptors")
Drugs
Cytotoxic agents
Inhibitors of testosterone synthesis and antiandrogens (e.g., ketoconazole, cimetidine, flutamide, cyproterone, spironolactone)
Ethanol, opioids, other recreational drugs
Autoimmune testicular failure
Isolated
Associated with other organ-specific disorders (e.g., Addison's disease, Hashimoto's thyroiditis, insulin-dependent diabetes)
Androgen resistance syndromes
5α-Reductase deficiency
Systemic diseases* (e.g., cirrhosis, chronic renal failure, sickle cell disease, acquired immunodeficiency syndrome, amyloidosis)
Aging*

*Systemic diseases and aging produce a mixed pattern of testicular and hypothalamic-pituitary dysfunction.

TABLE 234-3 CAUSES OF HYPOGONADOTROPIC HYPOGONADISM

IDIOPATHIC OR CONGENITAL
Isolated deficiency of gonadotropin-releasing hormone
With anosmia (Kallmann's syndrome)
With other abnormalities (Prader-Willi syndrome, Laurence-Moon-Biedl syndrome, basal encephalocele)
Partial deficiency of gonadotropin-releasing hormone (fertile eunuch syndrome)
Multiple hypothalamic and pituitary hormone deficiency
Pituitary hypoplasia or aplasia
ACQUIRED
Traumatic brain injury, after surgery or irradiation
Neoplastic
Pituitary adenoma (prolactinoma, other functional and nonfunctional tumors)
Craniopharyngioma, germinoma, glioma, leukemia, lymphoma
Pituitary infarction, carotid aneurysm
Infiltrative and infectious diseases of hypothalamus and pituitary (sarcoidosis, tuberculosis, coccidioidomycosis, histoplasmosis, syphilis, abscess, histiocytosis X, hemochromatosis)
Autoimmune hypophysitis
Aging and systemic diseases*
Obesity
Malnutrition
Anorexia nervosa, starvation, renal failure, liver failure
Exogenous hormones and drugs
Antiandrogens, estrogens and antiestrogens, progestogens, glucocorticoids, cimetidine, spironolactone, digoxin, drug-induced hyperprolactinemia (metoclopramide, tranquilizers, antihypertensives)

*Aging and systemic diseases produce a mixed pattern of central and testicular dysfunction.

CLINICAL MANIFESTATIONS

History

The medical history should focus on testicular descent, pubertal development, shaving frequency, changes in body hair, and present and past systemic illnesses. A complete sexual history includes changes in libido, erectile and

ejaculatory functions, frequency of masturbation, coital activity, and fertility (including that of present and previous partners). Information should be obtained on previous orchitis, sinopulmonary complaints, sexually transmitted diseases, human immunodeficiency virus (HIV) status, genitourinary infections, and previous surgical procedures that might affect the reproductive tract (e.g., vasectomy, hernia repair, prostatectomy, varicocele ligation). Social history includes tobacco and alcohol intake. Medication and self-prescribed drug history includes recreational drugs; opioids; anabolic steroids; 5α-reductase inhibitors; and psychiatric, antihypertensive, antiandrogenic, cytotoxic, and alternative medicine therapies; environmental toxins; and exposure to heat (including saunas and Jacuzzis) and irradiation.

Physical Examination

The general physical examination is supplemented by height and span measurements; characterization of facial, pubic, and body hair distribution; presence of acne and facial wrinkling; breast examination for gynecomastia; assessment of muscle mass and adiposity; measurement of penile length and urethral meatus localization; digital rectal prostate examination; and visual field assessment if secondary hypogonadism is suspected. The scrotal examination should include an assessment of midline fusion (e.g., bifid scrotum, hypospadias); testicular size and consistency; presence of intratesticular masses; abnormalities of the epididymis; bilateral presence of vas deferens; and varicoceles, hydroceles, or hernias. Normal testicular size ranges from 3.6 to 5.5 cm in length, 2.1 to 3.2 cm in width, and 15 to 35 mL in volume in white and black men. Asian men have a slightly smaller mean testicular size. A decrease in testicular volume usually implies decreased spermatogenic cells because the seminiferous tubules account for more than 80% of testicular volume.

Laboratory Studies

Because there is a strong diurnal rhythm in testosterone secretion in young men (highest in the morning), testosterone, LH, and FSH are routinely determined from morning blood samples. There is a broad range of reference values of these hormones due partly to measurement variability but also influenced by the selection criteria for the reference population. Most hospital laboratories used immunoassay methods to measure serum testosterone, which may lack precision at low serum testosterone levels. Recent studies suggest that methods using liquid or gas chromatography and mass spectrometry may give more accurate results even at very low serum testosterone levels. Elevated LH and FSH levels distinguish primary from secondary hypogonadism (both have low serum testosterone levels), but many older men with low serum testosterone levels have normal LH concentrations. Serum prolactin levels should be measured in all low testosterone, low LH cases (hypogonadotropic hypogonadism) and in men with known pituitary mass lesions, or galactorrhea. DHT is measured in cases of abnormal differentiation of the genitalia and when 5α-reductase deficiency is suspected. Serum estradiol should be measured in cases of gynecomastia. Assessment of other testosterone precursors and products may be required in special circumstances, including suspected congenital enzyme defects. The semen analysis is the "cornerstone" of the laboratory examination for male infertility.

Primary Testicular Hypogonadism

Primary hypogonadism refers to a condition of androgen deficiency with or without infertility in which the pathologic process lies at the testis level. A list of common causes is given in Table 234-2.

CONGENITAL DEFECTS

The commonest congenital defect is due to chromosomal abnormalities (Klinefelter's syndrome), and other causes are listed in Table 234-2 and described in Chapter 233.

ACQUIRED DEFECTS

Mumps, Orchitis, Leprosy, Human Immunodeficiency Virus Infection, and Hemochromatosis

After puberty, mumps (Chapter 369) is associated with clinical orchitis in 25% of cases, and 60% of those affected become infertile. During acute orchitis, the testes are inflamed, painful, and swollen. This is followed by a gradual decrease in size. The testes may return to normal size and function, or they may atrophy. Spermatogenic defects occur more often and earlier than Leydig cell dysfunction. Thus, patients with postorchitic infertility may have normal testosterone and LH levels with increased serum FSH levels. Over time, elevations in LH and lower serum testosterone levels may appear. Leprosy (Chapter 326) also may cause orchitis and gonadal insufficiency. HIV infection is often associated with hypogonadism, which can be either hypogonadotropic or hypergonadotropic. Hemochromatosis (Chapter 212) may affect the hypothalamus-pituitary, as well as act directly on the testis.

Trauma

The exposed position of the testes in the scrotum makes them particularly susceptible to injury. Surgical injury during scrotal surgery for hernia, varicocele, and vasectomy can result in permanent testicular damage.

Irradiation

Exposure of the testes to irradiation in the treatment of malignant diseases produces testicular germ cell, and less commonly, Leydig cell damage.

DRUGS AND TOXINS

Chemotherapy, in particular alkylating agents such as cyclophosphamide, busulfan, frequently leads to irreversible germ cell damage. Heavy metals (lead, cadmium) and cottonseed oil (gossypol) cause damage to the germ cells. Leydig cells are relatively less susceptible to most chemotherapeutic drugs than are Sertoli and germ cells. Some medications may interfere with testosterone biosynthesis (e.g., ketoconazole, spironolactone) or action (e.g., cyproterone, flutamide). Ethanol, independent of its role in causing liver disease, inhibits testosterone biosynthesis. Marijuana, heroin, methadone, medroxyprogesterone acetate, other progestins, and estrogens lower testosterone, mainly by decreasing LH. Medical treatment with androgens such as testosterone, DHT, and synthetic anabolic steroids or their illicit use (e.g., in athletes, bodybuilders) lowers serum LH and FSH and sperm counts. Serum testosterone levels are low after the use of DHT and synthetic anabolic agents. Environmental toxins such as fungicides and insecticides (e.g., DBCP, metabolites of DDT, vinclozolin) and byproducts of the plastics industry (e.g., phthalates, bisphenol A) are called "endocrine disruptors" because these chemicals may have either weak estrogenic or antiandrogenic effects and have been shown to cause testicular dysgenesis in male offspring when administered in large doses to pregnant female rodents. Data linking "endocrine disruptors" to male reproductive dysfunction in humans are principally associations studies and do not prove causality.[7]

AUTOIMMUNE TESTICULAR FAILURE

Antibodies against the microsomal fraction of the Leydig cells may occur either as an isolated disorder or as part of a multiglandular disorder (Chapter 231) involving, to variable degrees, the thyroid, pituitary, adrenals, pancreas, and other organs.

ANDROGEN RESISTANCE (ANDROGEN-SENSITIVE END-ORGAN DEFICIENCY)

Certain conditions have clinical phenotypes mimicking testosterone deficiency in the absence of lowered testosterone levels. These androgen-resistant states may be drug-induced (antiandrogens) or genetic sensitive defects in the androgen receptor, congenital or acquired post–androgen receptor signaling defects, or 5α-reductase deficiency (Chapter 233).

Hypogonadism Associated with Systemic Diseases

Abnormalities of the hypothalamic-pituitary-testicular axis occur in a number of systemic diseases, including liver failure, renal failure, severe malnutrition, sickle cell anemia, advanced malignant disease, severe obesity, metabolic syndrome, type 2 diabetes, cystic fibrosis, and amyloidosis, as well as in those on chronic hemodialysis. The effects of cirrhosis of the liver on testicular function are complex and may be either independent of or associated with the direct toxic effects of the continued use of alcohol. Gynecomastia, testicular atrophy, and impotence are concomitant signs of cirrhosis. Decreased spermatogenesis with peritubular fibrosis occurs in 50% of cases. Estradiol levels are usually elevated. This results in an increased ratio of serum estradiol to testosterone, often associated with gynecomastia. In sickle cell anemia and thalassemia major, boys may have impaired sexual maturation, and men are often infertile. Diabetes and obesity are two major factors in hypogonadism. Emerging data show that type 2 diabetes is associated with low blood testosterone levels mainly as a result of hypothalamic-pituitary dysfunction; the decrease in serum testosterone correlates with the degree of hyperglycemia.

Secondary Gonadal Insufficiency (Hypogonadotropic Hypogonadism)

CONGENITAL HYPOGONADOTROPIC HYPOGONADISM

Hypogonadotropic hypogonadism represents a deficiency in the secretion of gonadotropins (LH and FSH) because of an intrinsic or functional abnormality in the hypothalamus or pituitary glands (see earlier and Chapter 233). Such disorders result in secondary Leydig cell dysfunction (see Table 234-3). The clinical manifestations depend on the age of the patient at the onset of the disorder.

ACQUIRED HYPOGONADOTROPIC DISORDERS AND FUNCTIONAL DISORDERS

Anorexia Nervosa and Weight Loss

Anorexia nervosa (Chapter 219) and weight loss are examples of functional defects resulting in low serum testosterone levels. Men and women with anorexia nervosa present with manifestations of hypogonadotropic hypogonadism. Starvation also may reduce gonadotropic secretion. Strenuous exercise has minimal effects on testicular function in men.

Stress and Illness

Severe stress (e.g., surgery, trauma) and systemic illness also lower gonadotropin and testosterone levels. Organic hypothalamic-pituitary disorders include neoplastic, granulomatous, infiltrative, and post-traumatic lesions in the region of the hypothalamus and pituitary.

Pituitary Tumors

Prolactinomas manifest differently in men than in women (Chapter 224). In men, these tumors are usually large (>1 cm in diameter; macroadenomas) by the time they are detected. Male patients with prolactin-secreting macroadenomas usually present with hypogonadism, erectile dysfunction, and visual manifestations from suprasellar extension. In small tumors, hypogonadotropic hypogonadism may be due to suppressive effects on GnRH described earlier, but in large tumors, it also may be due to a mass effect damaging the non-neoplastic gonadotrophs.

Large non–prolactin-secreting pituitary tumors (growth hormone, adrenocorticotropic hormone, glycopeptide, and null cell) also may produce gonadotropin insufficiency from damage to the adjacent normal pituitary gland (Chapter 224), resulting in decreased serum LH and testosterone levels.

DIAGNOSIS

The diagnosis is based on clinical symptoms and signs and a reduced serum testosterone level. The normal range of serum total testosterone in a young adult male population varies across different laboratories but should be in the general range of 300 to 1000 ng/dL (10-35 nmol/L). Accurate measurements of testosterone in the severely hypogonadal range are best done by gas or liquid chromatography followed by tandem mass spectrometry. Total testosterone measurements may be misleading indicators of Leydig cell secretory status in conditions in which SHBG levels are abnormal (see earlier section). In these circumstances, a measurement of free testosterone (by an equilibrium dialysis method), bioavailable testosterone (consisting of free plus albumin bound), or calculated free testosterone (by total testosterone and SHBG measurements) may be useful.

The following rules on measurement of serum testosterone apply to most young and middle-aged men thought to have hypogonadism. If a morning serum total testosterone level is repeatedly below 230 ng/dL (8 nmol/L), and he has symptoms or signs compatible with low testosterone state, the patient is probably hypogonadal, and testosterone replacement is indicated. If the serum testosterone level is between 230 and 320 ng/dL with normal serum LH levels, the patient may or may not be clinically hypogonadal and androgen replacement may not improve the symptoms (e.g., sexual dysfunction). Thus, when serum total testosterone is borderline and LH is not increased, one of the measurements of bioactive testosterone is indicated (e.g., free testosterone). The guidelines for men older than 60 years are less certain. Because SHBG levels are often increased, total testosterone levels may overestimate the biologically active forms. A serum total testosterone level above 350 to 400 ng/dL indicates that hypogonadism is very unlikely to be the cause of the symptoms, and the clinician should look for other etiologies for the symptoms.

TREATMENT

Rx

The main medical indication for androgen replacement therapy is male hypogonadism (Table 234-4). In approximately 10% of men with idiopathic hypogonadism reversed by testosterone therapy, the reversal is sustained after therapy is stopped. This suggests that some patients with low serum testosterone may have a transient cause of the deficiency. Administration of testosterone to elderly men with low-normal testosterone concentrations increases lean body mass and decreases fat mass. There are insufficient data to judge whether testosterone treatment will improve functional status or cognition. Carefully designed studies of the efficacy of testosterone treatment in older men are ongoing.

Absolute contraindications to androgen replacement therapy include carcinoma of the prostate and the male breast. Androgens should be used with caution in older men with an enlarged prostate and urinary symptoms, elevated hematocrit, and sleep-related breathing disorders. The various methods of delivering testosterone treatment are shown in Table 234-5.

TABLE 234-4 INDICATIONS FOR ANDROGEN THERAPY

- Androgen deficiency (hypogonadism)
- Microphallus (neonatal)
- Delayed puberty in boys
- Elderly men with low total or bioavailable or free testosterone levels and symptoms
- Angioneurotic edema
- Other possible uses or under investigation
  - Hormonal male contraception
  - Sarcopenia associated with cancer, human immunodeficiency virus infection, chronic infection, frailty in older men and women
  - Hypoactive sexual disorder in postmenopausal women

TABLE 234-5 ANDROGEN PREPARATIONS

ROUTE	PREPARATION	DOSE AND FREQUENCY OF ADMINISTRATION
Oral*	Testosterone undecenoate (not available in United States; available in Canada, Mexico, Europe, Asia)	40-80 mg PO two or three times daily
Buccal	Transbuccal testosterone, mucoadhesive tablets (Striant)	30 mg two times daily
Injection	Testosterone enanthate and cypionate	100 mg/wk IM or 150-200 mg IM every 2-3 wk
	Testosterone undecanoate (not available in United States)	750-1000 mg IM every 10-12 wk
Implant	Testosterone implants	75-mg pellets (in United States), 6-10 inserted once every 4-6 months
Transdermal	Scrotal patch	One patch delivering testosterone 4 or 6/day
	Nonscrotal patch Androderm	Two patches, each delivering testosterone 2.5 mg/day; or one patch delivering testosterone 5 mg/day
	Testoderm TTS	One patch delivering testosterone 5 mg/day
Transdermal gels	AndroGel or Testogel; Testim; Axiron; Fortesta	1 to 2% gel applied once daily delivering 50-100 mg testosterone on skin and 5 to 10 mg to body

*Oral modified 17α-alkylated androgens such as methyltestosterone, fluoxymesterone, oxymetholone, stanozolol, and oxandrolone are not recommended for the treatment of androgen-deficient states because of potential hepatotoxicity and adverse effects on serum lipids.
IM = intramuscularly; PO = orally.

Testosterone esters, such as testosterone enanthate (or cypionate) injections, are widely used in the United States and throughout the world. The recommended dose is 150 to 200 mg administered intramuscularly once every 2 to 3 weeks. Testosterone undecenoate injections administered every 10 to 12 weeks are available in many parts of the world but not yet in the United States.

Modified 17α-alkylated androgens (methyltestosterone and many anabolic steroids), which are available in oral preparations, are not recommended as androgen replacement. These agents may lead to abnormalities in liver function, marked decreases in high-density lipoprotein cholesterol, and increases in total cholesterol levels compared with the testosterone esters. Oral testosterone undecanoate capsules have been available for over 20 years in many parts of the world but not in the United States. Transbuccal delivery of testosterone by mucoadhesive tablets (30 mg applied twice daily) results in physiologic-range testosterone levels through direct absorption into the systemic circulation, thus avoiding first-pass effects on the liver. The tablets may be dislodged from the buccal mucous membrane. Other oral formulations are in clinical trials in the United States.

Implants (pellets) of crystalline testosterone are available for chronic treatment of hypogonadism. Serum testosterone levels are maintained in the physiologic range for 4 to 6 months. Implants are not usually used but are gaining some popularity with urologists in the United States; they are widely used in Australia and the United Kingdom.

Transdermal testosterone delivery through skin patches and gels have been available in the United States for over 15 years. The nonscrotal patches deliver 5 mg/day of testosterone, which is the physiologic production rate. These patches deliver levels of testosterone within the normal range but have a high incidence of skin irritability (redness, swelling, and blisters). Hydroalcoholic and nonalcoholic testosterone gels have been developed for transdermal application and have become the most widely used testosterone formulations in the United States. The usual dosage is 50 to 100 mg of 1, 1.62, and 2% testosterone gel applied daily to the skin, delivering 5 to 10 mg of testosterone to the body. This results in a more consistent serum concentration and causes little skin irritation. Transfer from the user to others is possible during routine use and may be a concern if there is close skin contact with women and children. Protective clothing or a shower is necessary to avoid transferring testosterone through skin-to-skin contact.

Table 234-6 shows the benefits and potential side effects of androgen treatment. In hypogonadal men, androgen replacement leads to the development and maintenance of secondary sexual characteristics. Testosterone has important anabolic effects on muscle and bone and improves libido and sexual dysfunction. It has less effect on erectile dysfunction. It has no major short-term effects on prostate tissue.[8] Epidemiologic studies indicate that lower testosterone is a risk factor for cardiovascular disease. Many small studies have shown benefit or no effect of cardiovascular disease but more recent studies suggest testosterone replacement may increase the risk for cardiovascular events in elderly men, especially those who are frail and have multiple comorbidties.[9]

TABLE 234-6 ANDROGEN THERAPY: RISKS VERSUS BENEFITS

BENEFITS	RISKS
Development or maintenance of secondary sex characteristics	Fluid retention
Improved libido and sexual function	Gynecomastia
Increased muscle mass and strength	Acne, oily skin
Increased bone mineral density	Increased hematocrit
Decreased body and visceral fat	Decreased high-density lipoprotein cholesterol (oral 17α-alkylated agents produce the greatest effect)
Improved mood	Sleep apnea
Effect on cognition (?)	Aggressive behavior (?)
Effect on vitality and quality of life (?)	Prostate disease
Decreased cardiovascular disease risk (epidemiologic studies); clinical study no benefits/risk	Benign prostatic hyperplasia (?)
	Carcinoma of prostate (aggravate existing cancer)
	Increased cardiovascular adverse events in one study in frail elderly men with multiple comorbid conditions

MALE INFERTILITY

DEFINITION

Infertility is defined as the failure of a couple to achieve pregnancy after at least 1 year of frequent unprotected intercourse. If a pregnancy has not occurred after 3 years, infertility will most likely persist without medical treatment.

EPIDEMIOLOGY

Studies in the United States and Europe showed a 1-year prevalence of infertility in 15% of couples. The prevalence in developing countries is likely to be higher because of the higher prevalence of genital tract infection. Of subfertility cases, 30 to 35% can be attributed to predominantly female factors, 25 to 30% to male factors, and 25 to 30% to problems in both partners.

PATHOBIOLOGY

Hypothalamic-pituitary disorders are infrequent causes of male infertility and are discussed in the section on hypogonadism and androgen deficiency. Testicular disorders are the most frequent identifiable cause of infertility (see Table 234-2). Y chromosome microdeletions are increasingly recognized as a genetic cause of azoospermia and severe oligozoospermia. Up to 25% of infertile men have microdeletions in the long arm of the Y chromosome, many of which map to the Yq11 region of the chromosome, which is called the azoospermic factor (AZF). Mutations in the AZF a and b regions are associated with azoospermia, whereas mutations of AFZc region may be associated with oligozoospermia.[10]

DIAGNOSIS

The approach to the diagnosis of an infertile couple includes management of both the male and the female partner (Figs. 234-8 and 234-9).

Examination of the ejaculate is the cornerstone for the investigation of an infertile man (Table 234-7). Semen samples are collected at the physician's office or at home, preferably after 2 to 7 days of abstinence from ejaculatory activity. The generally accepted reference values for a semen analysis are given in Table 234-8. A normal sperm concentration is greater than 15 million/mL, with a total sperm number greater than 39 million per ejaculate; however, men with lower sperm counts can be fertile. More than 40% of the spermatozoa should be motile, and more than 32% should demonstrate a progressive motility pattern. Using strict criteria to assess sperm morphology, the percentage of morphologically normal forms should be above 4%. There is considerable overlap in the semen quality of fertile and subfertile men. Low sperm concentration and/or poor sperm morphology are associated with lower chances of natural conception in the female partner. In patients with abnormal semen analyses, measurements of serum FSH, LH, and testosterone are indicated (see Fig. 234-7). Elevated FSH levels usually indicate severe germinal epithelium damage. A decreased serum inhibin B level also reflects poor Sertoli cell function and may indicate spermatogenic dysfunction. Elevated serum LH and FSH concentrations together with a low serum testosterone level indicate pantesticular failure leading to hypogonadism and infertility. Low serum FSH, LH, and testosterone concentrations suggest hypothalamic-pituitary dysfunction; serum prolactin should be measured, and additional investigations may be required. A low sperm concentration and suppressed LH level with an increased, normal, or low serum testosterone level (without clinical manifestations of androgen deficiency) may suggest exogenous androgen use. The hormonal pattern in androgen insensitivity (an uncommon cause of male infertility) is elevated LH, normal FSH, and high-normal to increased serum testosterone levels. Normal hormonal parameters in azoospermic (no sperm in the ejaculate) men with normal-sized testes may suggest congenital or acquired obstruction in the epididymis or vas deferens.

TREATMENT

Rx

An algorithmic approach to the treatment of male infertility is illustrated in Figures 234-8 and 234-9. The principles of managing male infertility can be summarized as follows. (1) Men with mild-to-moderate oligozoospermia, with or without decreased sperm motility and some impairment of motility, are

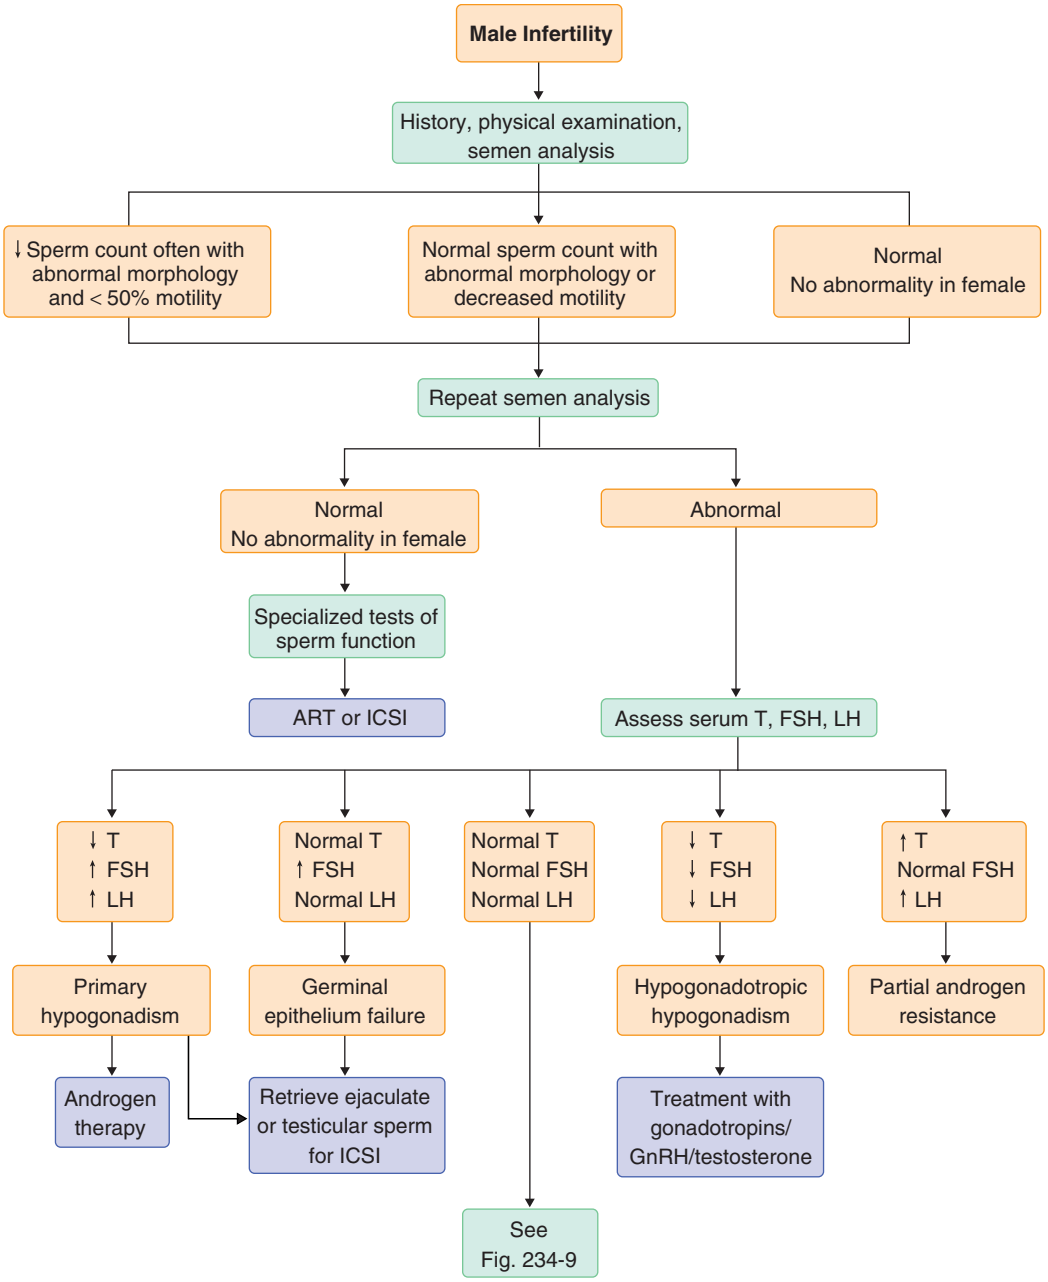

FIGURE 234-8. Algorithmic approach to the diagnosis and treatment of male infertility. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; ICSI = intracytoplasmic sperm injection; LH = serum luteinizing hormone; T = serum testosterone.

subfertile rather than infertile. Spontaneous pregnancies can occur in this group. (2) Reliable pharmaceutical treatment is limited to the 1 to 2% of infertile men with gonadotropin insufficiency. (3) Assisted reproductive technologies, including in vitro fertilization and intracytoplasmic sperm injection, have dramatically improved pregnancy rates. (4) In male factor infertility azoospermia (absence of sperm in the ejaculate) may occur in men with obstruction of the ejaculatory system. In these patients, in vitro fertilization and intracytoplasmic sperm injection after either percutaneous epididymal sperm extraction or microsurgical epididymal sperm extraction are highly successful. (5) Azoospermia resulting from impaired spermatogenesis may not be a sterile state, because sperm may be present within the testes. These sperm can be extracted, and intracytoplasmic sperm injection can be performed with good success, even in patients with Klinefelter's syndrome.

SEXUAL DYSFUNCTION

Sexual dysfunction can be divided into four main categories: (1) loss of desire (libido), (2) erectile dysfunction, (3) ejaculatory insufficiency, and (4) anorgasmic states.

Decreased Libido

Loss of libido refers to a reduction in sexual interest, initiative, and frequency and intensity of responses to internal or external erotic stimuli. Causal factors include psychogenic factors, CNS disease, androgen deficiency and resistance, and side effects from medications (e.g., antihypertensives, psychotropics, alcohol, narcotics, dopamine blockers, antiandrogens, and possibly 5α-reductase inhibitors). Treatment is directed toward the causal mechanism.

Ejaculatory Failure and Impaired Orgasm

Ejaculatory insufficiency refers to absent or reduced seminal emission or impaired ejaculatory contraction. It is usually associated with neurologic conditions and medication therapy. An anorgasmic state is a distressing but relatively uncommon condition in men in which the normal process of erection and ejaculation occurs in the absence of the subjective sensation of pleasure initiated at the time of emission and ejaculation. Premature ejaculation is the most common form of male sexual dysfunction. Estimates of prevalence vary, but 25 to 30% seems to be a reasonable estimate. The recently published *Diagnostic and Statistical Manual of Mental Disorders-5 (2013)* defines premature ejaculation as ejaculation occurring within approximately 1 minute of vaginal penetration before the person wishes it on 75% of occasions for at least 6 months and causing personal distress. The

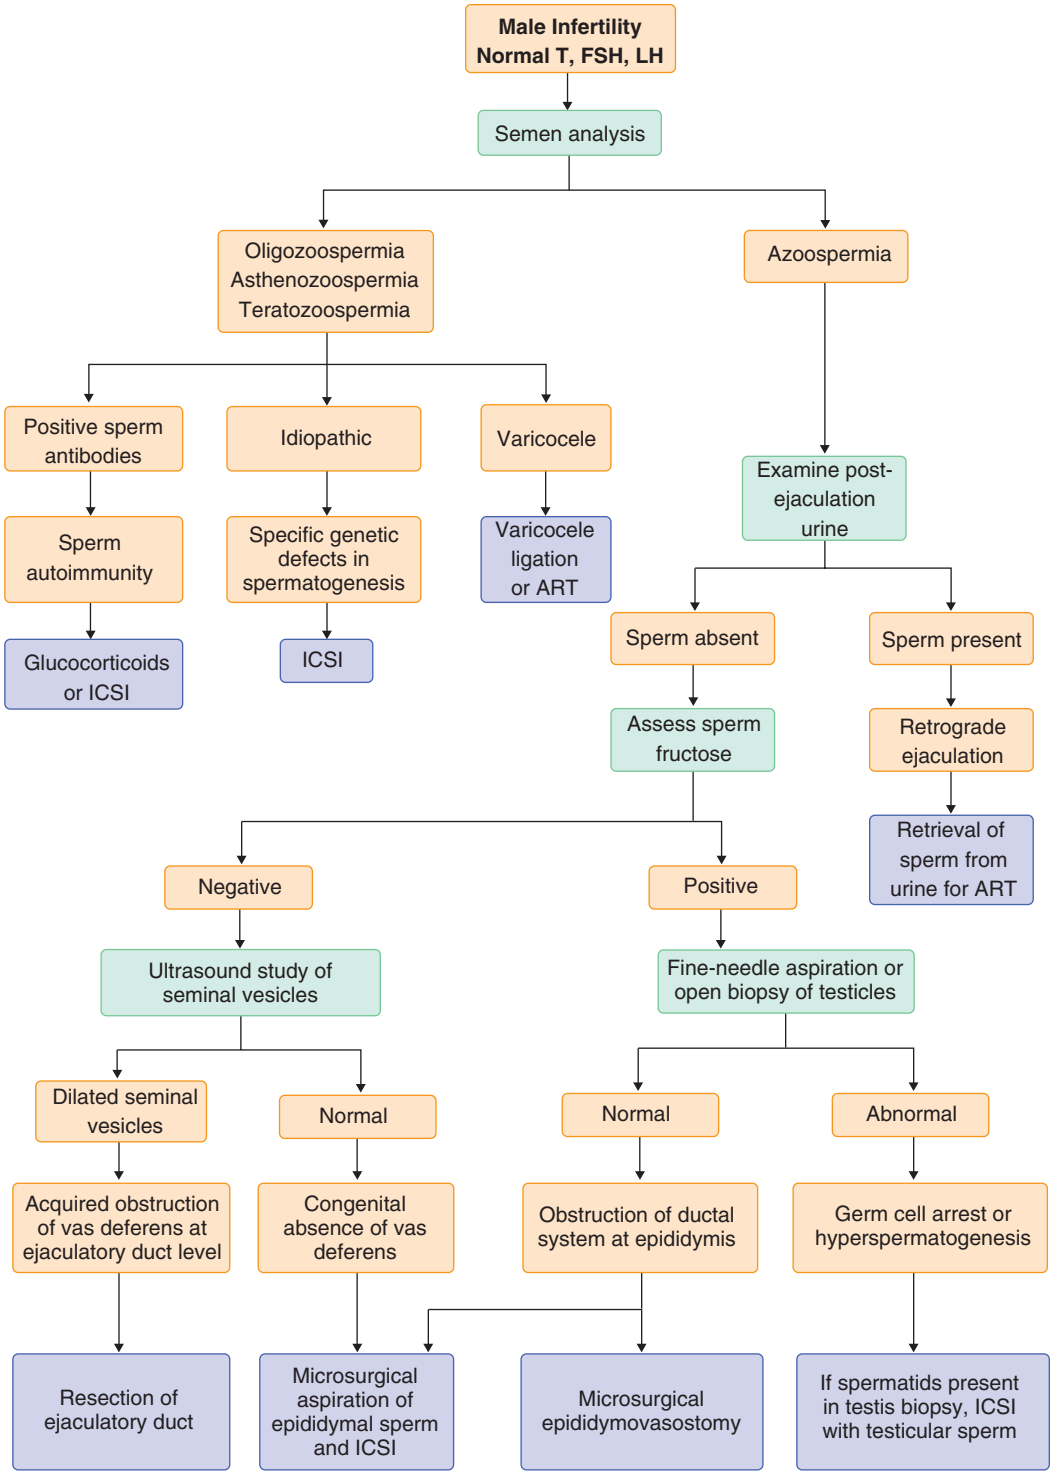

FIGURE 234-9. Algorithmic approach to the diagnosis and treatment of male infertility in patients with normal serum hormone concentrations. ART = assisted reproductive technology; FSH = follicle-stimulating hormone; ICSI = intracytoplasmic sperm injection; LH = serum luteinizing hormone; T = serum testosterone.

pathobiology of premature ejaculation is unknown. It may be associated with marked distress or interpersonal difficulty and is not a direct effect of substance abuse such as opiate withdrawal. The diagnosis is based mainly on sexual history and includes assessment of intravaginal ejaculatory latency time, perceived control, distress, and interpersonal difficulty. The first-line treatment is with selective serotonin reuptake inhibitors or a serotonin transporter inhibitor (e.g., dapoxetine 60 mg as on-demand therapy) together with behavioral therapy and relationship counseling. Topical anesthetic creams can be used as alternatives.[11]

Erectile Dysfunction

DEFINITION

Erectile dysfunction can be defined as a man's inability to obtain rigidity sufficient to permit coitus of adequate duration to satisfy himself and his partner.

EPIDEMIOLOGY

Current estimates suggest that 10 to 15% of all American men suffer from erectile dysfunction, with the incidence progressively increased as men become older. Data from the Massachusetts Aging Study report that 52% of men 40 to 70 years of age experience some degree of erectile dysfunction. The prevalence of erectile dysfunction is even higher in men with type 2 diabetes mellitus and after radical prostatectomy for prostate cancer. Recent epidemiologic studies in the United States and Europe in men between 50 to 80 years indicate that erectile dysfunction is associated with lower urinary tract obstructive symptoms/benign prostatic hyperplasia.

PATHOBIOLOGY

The causes of erectile dysfunction are many, but they can generally be categorized as follows: vasculogenic, psychological, endocrine, neurologic,

TABLE 234-7 MALE INFERTILITY: BASIC LABORATORY TESTS

SEMEN ANALYSES	HORMONE ANALYSES (IN PATIENTS WITH ABNORMAL SEMEN ANALYSES)
Volume, pH	Serum luteinizing hormone and follicle-stimulating hormone
Microscopy: Agglutination, debris	Serum testosterone
Sperm: Concentration, motility, morphology, vitality	If luteinizing hormone and testosterone levels are low, serum prolactin
Leukocytes	
Immature germ cells	
Sperm autoantibodies (sperm and semen biochemistry, sperm function tests)	

TABLE 234-8 SEMEN ANALYSIS: REFERENCE RANGE FROM FERTILE MEN*

PARAMETER	REFERENCE RANGE
Semen volume	>1.5 mL
Sperm	
Concentration	>15 million/mL
Total count	>39 million/ejaculate
Motility	>40% motile
	>32% progressively motile
Morphology	>4% normal†
Vitality (live)	>58%
Leukocytes	<1 million/mL

*Men whose partners had a time-to-pregnancy of ≤12 months were chosen to provide reference distributions for semen parameters.
†This value is based on the strict criteria for assessing sperm morphology in studies using in vitro fertilization as an end point.

iatrogenic (post–radical prostatectomy), drug related, systemic illness, and aging. Erectile dysfunction is common in older men, despite normal serum testosterone levels; this effect appears to be the result of impaired penile vasodilatory capacity as a result of endothelial dysfunction. Decreased nonadrenergic, noncholinergic nerve activity and reduced production of nitric oxide by endothelial cells result in decreased cavernous smooth muscle relaxation, decreased filling of the cavernous sinusoids, and reduced compression of the venous plexus against the tunica lead to failure of erection. Men presenting with erectile dysfunction share common risk factors with cardiovascular disease (smoking, obesity, metabolic syndrome, hyperlipidemia, and type 2 diabetes mellitus).[12] Recent evidence indicates that men presenting with mild erectile dysfunction should be assessed for cardiovascular disease, particularly when other risk factors are present.

DIAGNOSIS

The diagnosis of erectile dysfunction is based mainly on a detailed medical and sexual history of the patient and his partner when available. The history may reveal the underlying cause or other common disorders associated with erectile dysfunction. Physical examination should focus on genitourinary, cardiovascular, endocrine, and neurologic systems. Prostate examination is important because erectile dysfunction is commonly associated with symptomatic benign prostatic hyperplasia. Laboratory tests should include a morning serum testosterone, and, if indicated, prostate-specific antigen, fasting glucose (or hemoglobin A_{1C}), and cholesterol. Specific diagnostic tests are rarely required.

TREATMENT

Rx

The treatment of erectile dysfunction is to find the cause and treat the cause if found.[13] Symptoms can be effectively treated by the oral administration of penile-selective phosphodiesterase-5 inhibitors (sildenafil, vardenafil, tadalafil). A treatment algorithm for erectile dysfunction is given in Fig. 234-10. Lifestyle interventions reduce obesity and improve erectile function.[14] Combined androgen deficiency with decreased libido and decreased penile responsiveness resulting from impaired nitric oxide synthase activity may be common in elderly men. With the availability of effective penile vasodilatory medications to ensure erectile capacity, complaints of diminished libido can be effectively treated with androgen supplementation.

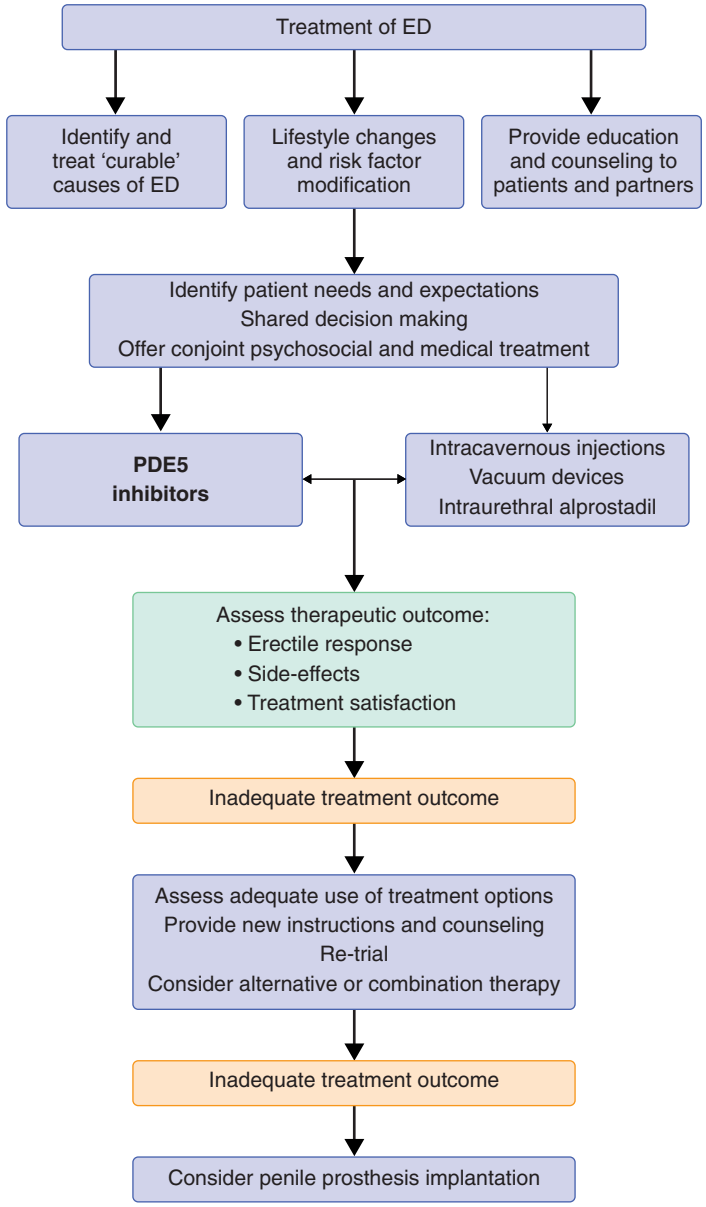

FIGURE 234-10. Treatment algorithm for erectile dysfunction (*ED*). PDE_5 = cyclic GMP phosphodiesterase-5. (Reprinted with permission from Hatzimouratidis K, Amar E, Eardley I, et al. Guidelines on male sexual dysfunction: erectile dysfunction and premature ejaculation. *Eur Urol.* 2010;57:804-814. 2015 update: http://uroweb.org/guideline/male-sexual-dysfunction/. Accessed March 26, 2015.)

Medical Therapy

Oral Medications

Oral and selective inhibitors of cGMP phosphodiesterase-5 (the primary phosphodiesterase in the penile cavernosal tissue) are effective for at least 60% of men. Inhibition of phosphodiesterase-5 causes persistence of normally (sexually) stimulated cGMP in the corpora cavernosa, resulting in protracted cavernosal tumescence and rigidity. Patients with diabetes mellitus, spinal cord injuries, prostatic surgery, and pelvic irradiation also benefit, but with a somewhat lower response rate. The usual starting dose of sildenafil is 50 mg, increasing in 25-mg increments up to 100 mg. Because of its mechanism of action, sildenafil is used on demand with recommended administration 20 to 60 minutes before intercourse. Two other potent phosphodiesterase-5 inhibitors (vardenafil and tadalafil) are widely used for the treatment of erectile dysfunction and appear to be equally effective. Vardenafil (5, 10, and 20 mg) has a relatively longer duration of action (4 to 6 hours), and tadalafil (10 or 20 mg) has an even longer duration of action (up to 36 hours). Randomized controlled trials showed that daily administration of tadalafil (5 mg) improved erectile function compared to on-demand treatment. Daily dosing of tadalafil is well tolerated and effective. Thus, daily dosing starting with 2.5 mg of tadalafil may

be an alternative to on-demand administration if intercourse is expected to be more frequent—for example, more than twice per week. Hypogonadal men with erectile dysfunction and low libido may benefit from combined treatment with testosterone and phosphodiesterase-5 inhibitors (PDE-5). However, the addition of testosterone to sildenafil does not further improve erectile dysfunction.[A6] PDE-5 inhibitors should not be administered with nitrates because the accumulation of cGMP may result in lowering of blood pressure and hypotension. PDE-5 inhibitors also may interact with antihypertensive agents, including α-blockers, resulting in orthostatic hypotension.

Intracavernosal Injection

Second-line treatment of erectile dysfunction involves intracavernosal injection with vasodilators such as prostaglandin E_1 (Alprostadil) alone or with other vasodilators (papaverine, phentolamine) These medications are injected into the cavernosal space with a 27- to 30-gauge needle and may be useful in men who are refractory to oral agents. The main side effects of penile injections are pain and cavernosal fibrosis which usually resolves after discontinuation of injections. Presence of tunica fibrosis may suggest early Peyronie's disease,[15] and injections should be stopped. The intraurethral prostaglandin E_1 suppository alprostadil is believed to work locally on the corpora cavernosa as a vasodilatory agent. The suppository is apparently successful in improving erectile function in 30 to 66% of cases.

Penile Prostheses

Surgical implantation of penile prostheses that include inflatable and malleable devices are the third line of treatment for men who prefer a permanent solution of their problem or for those who do not respond to other therapies.

REVIEW QUESTIONS

1. A 22-year-old man presents to his primary care physician with decreased libido and loss of morning erections. He had a recent low-impact fracture of his right tibia. His height was 185 cm and weight was 230 pounds. Laboratory tests included a serum testosterone of 96 ng/dL on a sample obtained at 4:00 PM and serum LH of 1.0 miU/mL. Which of the following information is *not* necessary in the evaluation of this patient?

A. DEXA scan of the hip and spine
B. Karyotype to evaluate for Klinefelter' syndrome
C. Serum prolactin level
D. Repeat serum testosterone obtained between 7:00 AM and 10:00 AM
E. MRI of the sella with and without gadolinium

Answer: B This patient has a low serum testosterone consistent with his clinical complaints. A DEXA scan is appropriate because he had a low-impact trauma and low serum T is a risk factor for osteoporosis and fractures. The serum testosterone should be repeated even though it is very low because it was collected in the afternoon and serum testosterone declines because of diurnal variation. An MRI and prolactin are appropriate because the low serum testosterone is coupled with a low serum LH, thus raising the possibility that the patient has hypogonadotropic hypogonadism, which could be due to a pituitary mass lesion that might be secreting prolactin (prolactinoma).

2. A 37-year-old man presented to his primary care physician complaining of inability of he and his wife to conceive. They have been married for 3 years. She is 27 years old, is not on contraceptives, and has regular menstrual periods. Neither has had a prior pregnancy. His semen specimen showed no spermatozoa in the ejaculate with a specimen volume of 3 mL. The man has a serum testosterone of 240 ng/dL and serum LH and FSH levels were 2 to 3 times above the upper reference range. A karyotype was XXY. The most appropriate recommendation would be:

A. Referral to a urologist for consideration of testicular sperm extraction and intracytoplasmic sperm injection into eggs obtained from his wife.
B. MRI of the sella.
C. Treatment with HCG and FSH.
D. Treatment with clomiphene.
E. Repeat karyotype.

Answer: A This patient has Klinefelter's syndrome as diagnosed by karyotype. Other than artificial insemination of the partner using donor spermatozoa partner or adoption of a child, the best approach to achieve fertility would be to attempt to extract spermatozoa by testicular sperm extraction and intracytoplasmic sperm injection into oocytes obtained from his female partner. The success rates depend on whether the urologist can find spermatozoa in the testis and the quality of the spermatozoa and the oocyte. There is no need for an MRI of the sella or treatment with HCG or clomiphene, because LH and FSH levels are elevated and a pituitary/hypothalamic lesion is not likely. A repeat karyotype could be done but is not necessary because everything fits the present diagnosis of Klinefelter's syndrome.

3. A 75-year-old man complains of erectile dysfunction (ED). His libido is mildly decreased. He has had two previous myocardial infarctions and is being treated with a calcium channel blocker for hypertension. His morning serum testosterone is 380 ng/dL, with serum LH and FSH in the normal range. The best first-line treatment is:

A. Transdermal testosterone to increase his serum testosterone to over 500 ng/dL.
B. An aromatase inhibitor.
C. A β-blocker to reduce the stress levels of the penis.
D. Phosphodiesterase-5 (PDE-5) inhibitor.
E. Referral to a psychologist to evaluate for psychogenic erectile dysfunction.

Answer: D This elderly man has ED without hypogonadism. The first-line treatment is a PDE-5 inhibitor to increase the vasodilatory functioning in the penis. The other treatments are unnecessary because they are directed toward treatment of primary or secondary hypogonadism (use of testosterone or aromatase inhibitors). A β-blocker is not an effective treatment for ED.

4. An 82-year-old man has decreased libido, decreased muscle strength, and osteopenia on DEXA scan. He has a strong family history of prostate cancer. A serum testosterone level was 300 ng/dL with a free testosterone by equilibrium dialysis that is below the reference range. Serum LH was in the high-normal range. A PSA was 7 ng/mL. The best strategy is to:

A. Treat with a 5α-reductase inhibitor.
B. Treat with testosterone to reverse the manifestation of hypogonadism.
C. Refer to a urologist for assessment of his prostate.
D. Treat with an aromatase inhibitor to reduce estradiol levels.
E. Ignore his complaints because it is normal and acceptable for age

Answer: C The appropriate first-line approach is to refer to a urologist to rule out prostate cancer. The patient is elderly and hypogonadism might be present, but his total testosterone is 300 ng/dL with a low free testosterone that is probably the result of an age-associated increase in SHBG. Even if he were hypogonadal, his PSA is elevated, thus requiring a prostate assessment. Although the clinical symptoms are important to the patient, all treatments (testosterone replacement, use of an aromatase inhibitor to increase endogenous testosterone levels) must be delayed until the prostate risk is assessed. Treatment with a 55α-reductase inhibitor is not appropriate until he has been assessed for possible prostate cancer.

5. A 50-year-old obese man complains of low libido. He had a serum testosterone checked by liquid chromatography tandem mass spectrometry; it was 190 ng/dL. A serum LH level was above the reference range for adult men. The physician decided to treat the patient for hypogonadism with testosterone replacement. Which one of the following adverse events is the most commonly seen?

A. Elevated LDL cholesterol
B. Anemia
C. Hypercalcemia
D. Priapism
E. Erythrocytosis

Answer: E Testosterone increases red blood cell mass by several mechanisms. An increase in both hemoglobin and hematocrit of 5 to 7% from baseline after testosterone is not uncommon. The increase in hemoglobin and hematocrit is dose dependent. Elevation of hematocrit to greater than 54% or hemoglobin greater than 17 g/dL requires either phlebotomy or the withdrawal of testosterone until the hematocrit and hemoglobin decrease into the reference range. Anemia may be seen in testosterone deficiency but not with testosterone treatment. With physiologic replacement of testosterone, LDL cholesterol levels are not elevated. Hypercalcemia does not occur as a result of testosterone therapy. Priapism may occur with PDE-5 inhibitors but not with testosterone treatment.

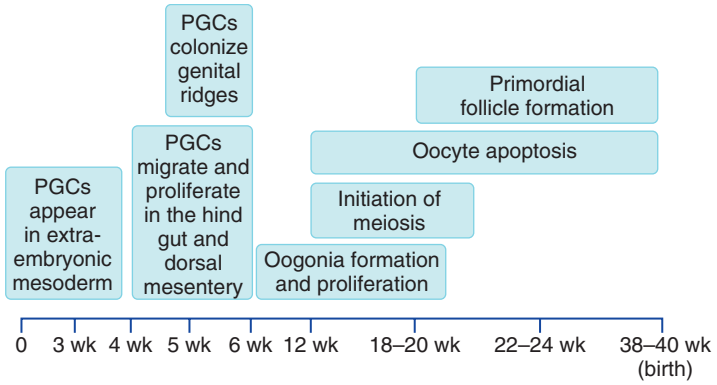

FIGURE 235-1. Diagram illustrating the developmental timetable of the major events that ultimately lead to the formation of primordial follicles during the process of human ovary organogenesis. PGC = primordial germ cell.

235

OVARIES AND PUBERTAL DEVELOPMENT

ROBERT W. REBAR AND WILLIAM H. CATHERINO

DEFINITION

The ovaries or female gonads episodically release female gametes (oocytes or eggs) and secrete sex steroid hormones, principally androstenedione, estradiol, and progesterone. Oocytes are released only during the adult reproductive years, when sex steroid secretion is also greatest, but the ovaries are physiologically active throughout life.

Sex steroids affect the growth, differentiation, and function of a variety of tissues and organs throughout the body; therefore, abnormalities of the ovaries and of sex steroid secretion should be recognized by all physicians. A rational approach to the diagnosis and treatment of reproductive disorders in women requires an understanding of the functions of the ovaries and of their most important unit, the follicle, throughout life.

PHYSIOLOGY

Embryology

Embryogenesis and Differentiation

Organogenesis of the ovaries occurs during fetal life. Ovarian cells are derived from two different sources: (1) primordial germ cells (PGCs) originate at a site outside the prospective gonads, and (2) somatic cells differentiate from the coelomic epithelium and gonadal mesenchyme. In females, PGCs become oocytes, whereas somatic cells differentiate into a variety of cell types, including granulosa, theca, and vascular cells.

PGCs in the human embryo can be distinguished at the gastrula stage (Fig. 235-1). Shortly after formation, PGCs migrate through the dorsal mesentery to the genital ridges. Chemotaxis plays a role in directing PGCs to the gonads. During migration, PGCs proliferate in response to growth factors, most notably Kit ligand. The importance of Kit is demonstrated by the finding that loss-of-function mutations result in a paucity of PGCs, which in turn results in premature ovarian failure.

The genital ridges are characterized by a thickening of the coelomic epithelium and underlying primary mesenchyme. Initially, the gonads are sexually indifferent. Male gonadal differentiation is triggered by the Y chromosome–encoded testis-determining factor SRY. SRY expression results in the differentiation of Sertoli cells and the secretion of müllerian-inhibiting substance, which induces regression of the müllerian ducts. Testicular interstitial cells differentiate into Leydig cells, which secrete testosterone, which in turn stimulates wolffian duct development. In the female, the absence of müllerian-inhibiting substance and testosterone and the activation of the WNT4 pathway leads to the degeneration of the wolffian ducts and the development of the müllerian ducts.[1,2] Thus, the development of the ovaries and female reproductive system is considered a "default" pathway.

When PGCs enter the genital ridges, they begin gametogenesis (see Fig. 235-1). In females, this process is termed *oogenesis* and involves the differentiation of PGCs into oogonia and oocytes. When sex-specific differentiation of the ovary commences, the inactive X chromosome in the PGCs becomes active. This denotes the formation of mitotically active oogonia. The importance of two functional X chromosomes during oogenesis is emphasized by the fact that 45,X females lack oocytes and undergo premature menopause.

After repeated mitosis, oogonia initiate meiosis and become oocytes (see Fig. 235-1). At approximately the same time, granulosa cells differentiate within the gonadal mesenchyme and establish intimate associations with oocytes. Oocytes that become surrounded by granulosa cells stop meiosis after diplotene, and the bivalents enter an interphase state known as dictyotene. If an oocyte is not surrounded by granulosa cells, meiosis continues to diakinesis, and the oocyte dies by apoptosis, although this may not always be true.[3] Granulosa cells, therefore, are critical for oocyte survival. The majority of oocytes die during fetal ovary development (Fig. 235-2), apparently from a lack of contact with granulosa cells.

With further development, the oocyte–granulosa cell complex becomes a primordial follicle. This occurs between the sixth and ninth months of gestation (Fig. 235-3). A primordial follicle consists of a single layer of squamous granulosa cells, a small (about 15 μm in diameter) dictyotene oocyte, and a thin basal lamina (see Fig. 235-3). In the human female, all potential future eggs have entered diplotene of meiosis at the time of birth.

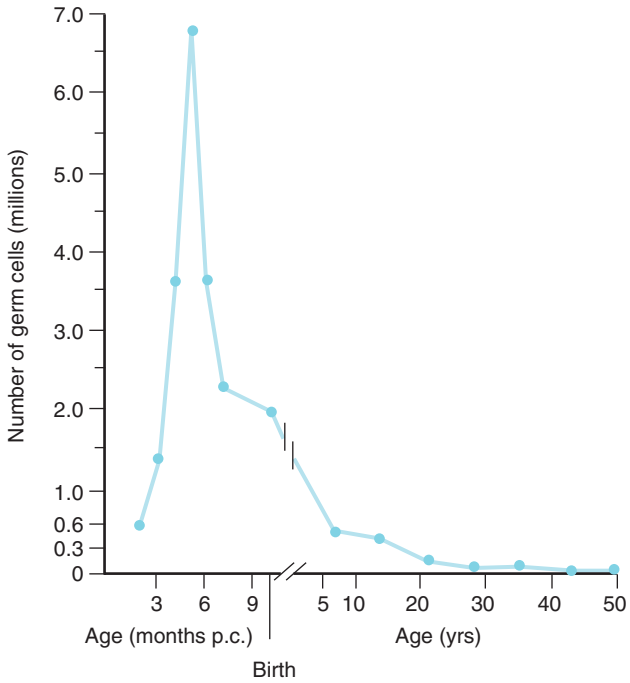

FIGURE 235-2. Changes in the total number of germ cells in the human ovaries during aging. At early to mid-gestation, the number of germ cells increases to almost 7 million; shortly thereafter, the number declines rapidly to about 2 million at birth. The number continues to decline until no oocytes are detected at 50 years of age. p.c. = Post conception. (From Baker TG. Radiosensitivity of mammalian oocytes with particular reference to the human female. *Am J Obstet Gynecol*. 1971;110:746-761.)

Anatomy

The Adult Ovary

The ovaries, which normally measure 2.5 to 5.0 cm long, 1.5 to 3.0 cm wide, and 0.6 to 1.5 cm thick in adults, are organized into two principal parts. A central zone, the medulla, is surrounded by a prominent peripheral zone, the cortex (Fig. 235-4). Growing follicles at different stages of development are present in the cortex. Typically, one follicle per cycle reaches maturity and ovulates its ovum. After ovulation, the follicle transforms into a corpus luteum. The corpus luteum of the cycle lasts for about 14 days, after which it dies and becomes a nodule of dense connective tissue, the corpus albicans (see Fig. 235-4).

The medulla is composed of loose connective tissue with numerous blood vessels and associated nerves. The arterial supply to the ovary originates from two principal sources: the ovarian artery and the uterine artery. These two vessels, which enter the medulla from opposite directions, form an anastomotic trunk and become a common vessel called the ramus ovaricus artery. This artery gives rise to a series of primary branches (spiral arteries) that enter the hilum. In the hilum, numerous secondary and tertiary branches are given off to supply the medulla and the follicles and luteal tissue in the cortex (see Fig. 235-4). The hilum also contains the hilus cells (see Fig. 235-4), which, like the testicular Leydig cells, contain Reinke crystals and secrete testosterone. The physiologic role of the hilus cells is still unknown.

Ovarian Function in Childhood and Puberty

Physical Changes at Puberty

Puberty extends from the earliest signs of sexual maturation until the attainment of physical, mental, and emotional maturity. Pubertal changes in girls result directly or indirectly from maturation of the hypothalamic-pituitary-ovarian (HPO) unit.[4] Human puberty is characterized hormonally by a resetting of the negative gonadal steroid feedback loop, the establishment of new circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the female of a positive estrogen feedback loop controlling the menstrual cycle as interdependent expressions of the gonadotropins and ovarian steroids. In girls, pubertal development generally occurs between 7 and 14 years of age. The age at onset and the rate of progress through puberty are variable and depend on genetic, socioeconomic, nutritional, physical, and psychological factors. It appears that there are racial differences in the onset of pubertal development. In the United States, development begins earlier in African American than in white girls.

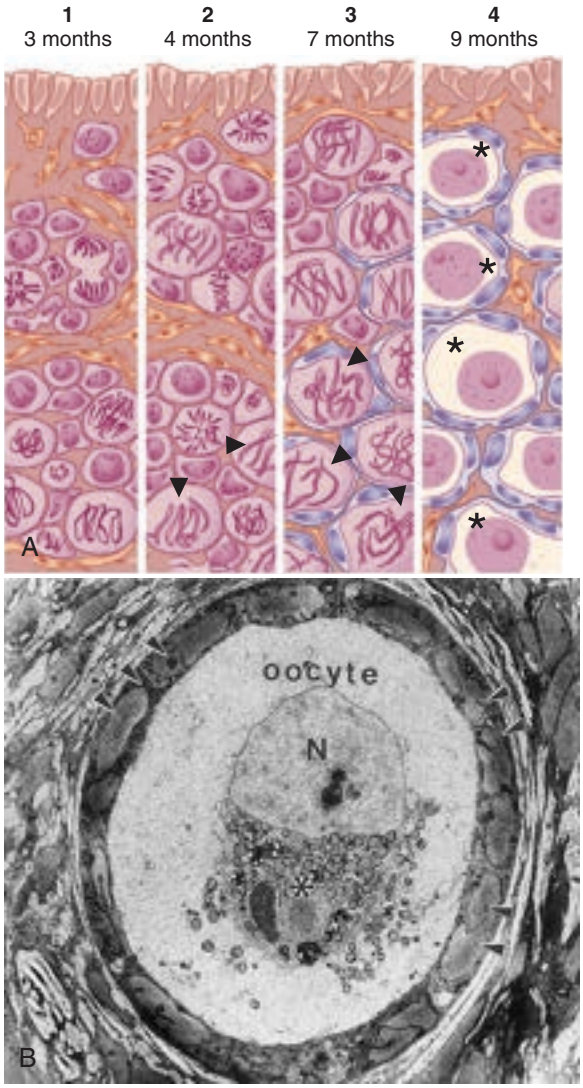

FIGURE 235-3. A, Drawing showing gametogenesis in the human fetal ovary leading to the formation of primordial follicles. At 3 months (1), oogonia divide mitotically. At 4 months (2), some oogonia deep within the cortical cords enter meiosis *(arrowheads)*. At 7 months (3), the cords are no longer distinct, and all germ cells are in meiotic prophase I. At 9 months (4), some oocytes become associated with granulosa cells and appear as primordial follicles *(asterisks)*. **B,** Electron micrograph of human primordial follicle. Granulosa cells *(arrowheads)*, oocyte nucleus (N), and Balbiani's body *(asterisk)* are shown. (From Erickson GF. The ovary: basic principles and concepts. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill; 1995.)

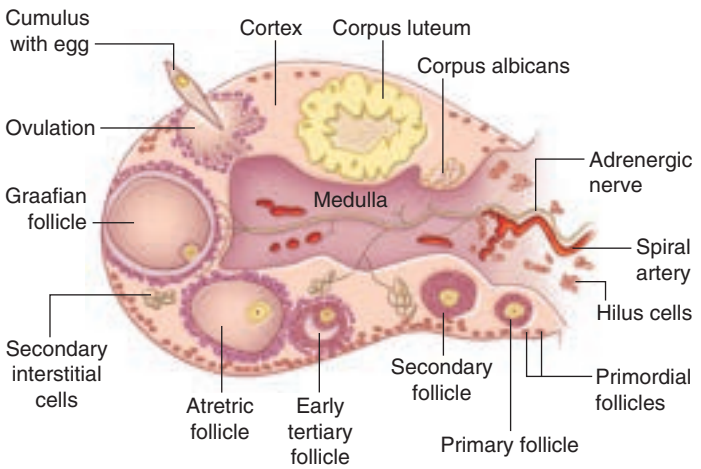

FIGURE 235-4. Diagram showing the anatomy of the human ovary during the reproductive years. Developing follicles and the corpus luteum are located in the cortex; the hilus cells, autonomic nerves, and spiral arteries are present in the medulla. (From Erickson GF. The ovary: basic principles and concepts. In: Felig P, Baxter JD, Broadus AE, et al, eds. *Endocrinology and Metabolism*, 3rd ed. New York: McGraw-Hill; 1995.)

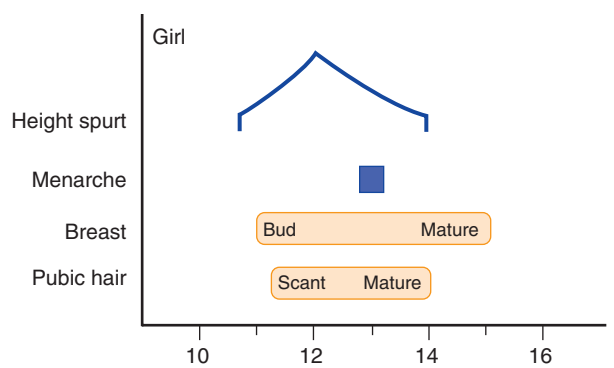

FIGURE 235-5. Temporal sequence of events for the "average" girl during puberty. (From Rebar RW. Practical evaluation of hormonal status. In: Yen SSC, Jaffe RB, Barbieri RL, eds. *Reproductive Endocrinology: Physiology, Pathophysiology, and Clinical Management*, 4th ed. Philadelphia: WB Saunders; 1999:710.)

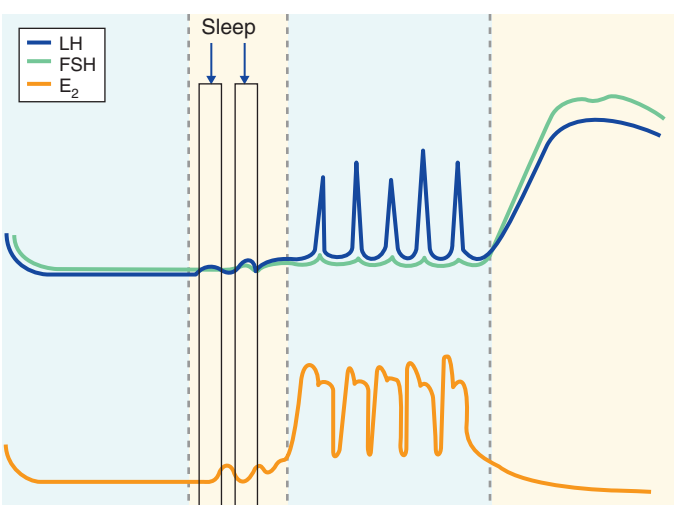

FIGURE 235-6. The changing patterns of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol (E_2) concentrations in peripheral blood throughout the life of a woman. Not shown is the fact that both LH and FSH are secreted in a pulsatile fashion. The pubertal period has been expanded to illustrate the sleep-associated increases in LH and FSH followed by morning increases in E_2 that are observed during puberty. (Reprinted with permission from Endocrine and Metabolism Continuing Education Quality Control Program, 1982. Copyright American Association for Clinical Chemistry Inc.)

Physical changes occur in an orderly sequence during a definite time frame in puberty (Fig. 235-5).[5] Breast budding in girls is usually the first pubertal change, followed shortly by the appearance of pubic hair, with menarche occurring late in pubertal development. The time from breast budding (mean age of 10.0 years in white girls and 8.9 years in African Americans) to menarche is 2 years. Breast development results from increasing ovarian estrogen production, and pubic and axillary hair results from increasing androgen production. Estrogens are required for the growth of pubic hair as well.

The ovarian sex steroids join with growth hormone and adrenal androgens to produce the adolescent growth spurt. Peak growth velocity is achieved relatively early, with little growth observed after menarche. It has been estimated that more than 50 genes play roles in determining final adult height. It is now clear that estrogen, and not testosterone, is the primary hormone mediating pubertal bone growth in both males and females. Lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, but by maturity, women have twice as much body fat as men and less lean body mass and skeletal mass as a result of differences in sex steroid secretion. Estrogens are necessary for the normal formation, mineralization, and maturation of bones. Well-established standards exist for determining whether bone age is appropriate for chronologic age, typically by examining radiographs of the bones of the wrist. Estrogen deficiencies retard, and excesses advance, bone age in relation to chronologic age.

Hormonal Changes

The ovaries function even in early childhood. Low levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are normally present, and these levels increase if the ovaries are removed before puberty, just as they do later in life, indicating the exquisite sensitivity of the hypothalamic-pituitary unit to extremely low circulating sex steroid levels. As puberty nears, there is a progressive decrease in sensitivity of the hypothalamic-pituitary unit to sex steroids, leading to the increased secretion of pituitary gonadotropins, stimulation of sex steroid output, and development of secondary sex characteristics. Increased secretion of both LH and FSH initially occurs at night with sleep and is associated with increased estradiol secretion the next morning (Fig. 235-6). As is true for most hormones, LH and FSH are secreted in an episodic or pulsatile rather than a continuous fashion. Later in puberty, secretion of LH and FSH is increased throughout the 24-hour period, except during the early follicular phase, when nighttime increases still occur. Basal levels of estradiol, the major estrogen secreted by the ovaries, increase throughout puberty. A "critical body mass" may be required for positive estrogen feedback and ovulation. During the first 2 years after menarche, up to 90% of menstrual cycles may be anovulatory because of a delay in synchronization of the HPO axis.

ABERRATIONS IN PUBERTAL DEVELOPMENT

Abnormalities of pubertal development can be divided into four major categories (Table 235-1):

1. Precocious puberty represents any pubertal changes before age 9 years in white girls and before age 8 years in African American girls. This remains controversial. Some clinicians believe evaluation is warranted only if pubertal development begins before age 7 years in white girls and 6 years in African American girls. A compromise may involve careful screening by history and physical examination of girls with early-onset puberty, looking for central nervous system (CNS) symptoms, behavioral concerns, and any other abnormal findings that might warrant further evaluation. The nearer pubertal development begins to the mean age of puberty onset, the less likely it is to have a pathologic basis. Precocious development is isosexual when it is common to the phenotypic sex of the individual and heterosexual when the development is characteristic of the opposite sex. True or central precocious puberty is due to premature maturation of the hypothalamic-pituitary axis. In the absence of increased hypothalamic-pituitary activity, precocious pseudopuberty exists.
2. Delayed (or interrupted) puberty is defined as the absence of any secondary sex characteristics by age 13 years, the absence of menarche by age 16 years, or the passage of 5 years or more from breast budding to menarche.
3. Asynchronous pubertal development occurs when there is deviation from the normal pattern of pubertal development.
4. Heterosexual pubertal development occurs at the appropriate time but has some features characteristic of the opposite sex.

Precocious Puberty

DIAGNOSIS

The overall incidence of precocious puberty has been estimated at 1 in 5000 to 10,000 children. About 10 times as many girls as boys are affected.

Differential Diagnosis

The temporal sequence in which the signs and symptoms of sex steroid hormone excess appear is most important. *Incomplete isosexual precocious puberty* indicates premature development of only a single pubertal feature. If breast budding occurs before age 8 years in the absence of any other development, the diagnosis may be *premature thelarche.* Premature thelarche is believed to be due to transient increases in estrogen secretion or increased breast sensitivity to the small quantities of circulating estrogens present before puberty. Simple ovarian cysts may be present in some girls with this disorder and may be due in some cases to the same genetic abnormality found in girls with McCune-Albright syndrome (Chapters 231 and 248). If pubic or axillary hair develops alone and persists, *premature pubarche* and *adrenarche* must be considered. These abnormalities are associated with slight increases in adrenal androgen secretion but not with clitorimegaly or other signs of virilization. These syndromes require no treatment, and affected girls typically begin true puberty at the usual age. Careful follow-up is required to distinguish these disorders from true precocious puberty.

TABLE 235-1 ABERRATIONS OF PUBERTAL DEVELOPMENT

PRECOCIOUS DEVELOPMENT

- Isosexual precocity
  - Incomplete sexual precocity
    - Premature thelarche
    - Premature pubarche
    - Premature adrenarche
  - True (central) precocious puberty
    - Idiopathic (constitutional)
    - Due to central nervous system lesions
    - Primary hypothyroidism
    - Silver-Russell syndrome
  - Precocious pseudopuberty (of peripheral origin)
    - Ovarian neoplasms
    - Adrenal neoplasms
    - Iatrogenic (estrogen-containing preparations)
    - Human chorionic gonadotropin–secreting neoplasms distinct from central nervous system and ovarian tumors
    - McCune-Albright syndrome
- Heterosexual precocity
  - Ovarian neoplasms
  - Adrenal neoplasms
  - Congenital adrenal hyperplasia
  - Other rare disorders of sexual differentiation

DELAYED PUBERTAL DEVELOPMENT*

- Anatomic abnormalities
  - Mayer-Rokitansky-Küster-Hauser syndrome
  - Distal genital tract obstruction
    - Transverse vaginal septum
    - Imperforate hymen
    - Vaginal agenesis
- Hypergonadotropic hypogonadism (FSH >30-40 mIU/mL)
  - Gonadal dysgenesis
    - With stigmata of Turner syndrome
    - Pure (46,XX or 46,XY)
    - Mixed
  - Ovarian failure with normal ovarian development
    - Genetic disorders
    - Autoimmune disorders
    - Gonadotropin receptor or postreceptor defects (resistant ovary or Savage's syndrome?)
    - Enzymatic defects (17α-hydroxylase deficiency, galactosemia)
    - Physical causes
      - Irradiation
      - Chemotherapeutic agents
      - Viral agents
    - Idiopathic
- Hypogonadotropic or normogonadotropic hypogonadism (LH and FSH <10 mIU/mL, or LH and FSH 6-25 mIU/mL with at least one being <10 mIU/mL)
  - Isolated gonadotropin deficiency
  - In association with midline defects (Kallmann's syndrome)
    - Independent of associated disorders
  - Neoplasms of the hypothalamic-pituitary axis
    - Craniopharyngiomas
    - Pituitary tumors
    - Others
  - Infiltrative processes (Langerhans-type histiocytosis)
  - Idiopathic hypopituitarism
  - "Hypothalamic" forms of amenorrhea
    - Psychogenic
    - Exercise associated
    - Associated with malnutrition
    - Anorexia nervosa
  - Miscellaneous disorders
    - Prader-Labhart-Willi syndrome
    - Laurence-Moon-Bardet-Biedl syndrome
    - Primary hypothyroidism
  - Constitutional delayed puberty

ASYNCHRONOUS PUBERTAL DEVELOPMENT

- Incomplete forms of androgen insensitivity
- Complete forms of androgen insensitivity

HETEROSEXUAL PUBERTAL DEVELOPMENT

- Polycystic ovary syndrome
- Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - 21-Hydroxylase deficiency
  - 11β-Hydroxylase deficiency
  - 3β-ol-Hydroxysteroid dehydrogenase deficiency
- Male pseudohermaphroditism due to 5α-reductase deficiency
- Male pseudohermaphroditism due to partial androgen insensitivity
- Mixed gonadal dysgenesis
- Androgen-producing neoplasms
  - Ovarian
  - Adrenal
- Cushing's syndrome

*No development by age 13 yr, absence of menarche by age 15 yr, or passage of ≥5 yr from breast budding without menarche.
FSH = follicle-stimulating hormone; LH = luteinizing hormone.

When precocious development is isosexual, the purpose of the evaluation is to determine whether the cause is central (true precocious puberty) or peripheral, in which case it is considered gonadotropin-releasing hormone (GnRH)–independent precocious puberty or precocious pseudopuberty. Careful questioning of the patient and her parents may indicate the inadvertent ingestion or absorption of sex steroids (iatrogenic or factitious). As many as 20% of individuals with true precocious puberty have one of several organic brain diseases, including any of several neoplasms, tuberous sclerosis, neurofibromatosis, encephalitis, meningitis, vascular malformations, and hydrocephalus. Because of the seriousness of intracranial lesions, girls with precocious puberty must have radiographic evaluation of the CNS, most effectively by magnetic resonance imaging (MRI). In at least 75% of girls with true precocious puberty, however, no cause is identified (idiopathic or constitutional).

The physical examination may also provide critical information about the cause of the precocious development. Cutaneous café au lait spots, facial asymmetry, polyostotic fibrous dysplasia and other skeletal abnormalities, cranial nerve deficits, and multiple ovarian follicular cysts suggest McCune-Albright syndrome (Chapters 231 and 248) in a girl with precocious development. It is now known that various clones of cells in the endocrine glands of girls with this disorder function autonomously with respect to cyclic adenosine monophosphate production as a consequence of a mutation within exon 8 of the *GNAS* gene, encoding the G_s protein α–subunit. This same mutation probably accounts for the bone lesions and café au lait hyperpigmentation. Other endocrine cells may be similarly affected and lead to pituitary adenomas (usually secreting growth hormone), hyperthyroidism, and, rarely, adrenal hyperplasia.

Studies on the etiologic causes for precocious puberty are ongoing. Heterozygous mutations in the paternal *MKRN3* gene are a diagnosable cause of familial central precocious puberty.[6] Another molecule, kisspeptin, is involved in pubertal development. Kisspeptin and its receptor GPR54 are essential regulators of GnRH-induced gonadotropin secretion and pubertal onset. Activation results in stimulation of the HPO axis, and elevated kisspeptin levels are associated with precocious puberty. Additionally, kisspeptin loss-of-function mutations result in normosmic idiopathic hypogonadotropic hypogonadism.

Abdominal and rectal examination may reveal a mass, suggesting an adrenal or ovarian tumor. Because palpable ovarian cysts may rarely develop before ovulation in true precocious puberty, the presence of a mass does not confirm the diagnosis of precocious pseudopuberty.

When vaginal bleeding is the only sign of development, the diagnosis of sexual precocity should be suspect. Common causes of bleeding in this age group include irritation from a vaginal infection or foreign body, sexual assault, prolapse of the urethral meatus, and ingestion of estrogen-containing medications (most commonly, oral contraceptive preparations). A vaginal or cervical neoplasm is also a rare possibility. Thus, vaginal bleeding requires a vaginal examination, which is often best performed with the patient under anesthesia, before further evaluation is undertaken.

Heterosexual precocity in an apparent prepubertal female is almost always due to congenital adrenal hyperplasia or to an androgen-secreting adrenal or ovarian neoplasm. Only rarely must another disorder of sexual differentiation be considered (Chapter 233). It is important to examine the external genitalia carefully because congenital adrenal hyperplasia is usually associated with some degree of sexual ambiguity.

Excessive androgens produced endogenously by abnormal fetal adrenal glands in utero or diffusing across the placenta to the fetus from the mother can virilize the external genitalia and result in female pseudohermaphroditism. The extent of virilization varies from only an enlarged clitoris to sexual ambiguity sufficient to make gender assignment difficult.

Excessive maternal androgen secretion, typically from an ovarian or adrenal neoplasm, can lead to virilization of a female fetus. This occurs very rarely because of the great capacity of the placenta to aromatize naturally occurring androgens to estrogens. Virilization of a female fetus is much more likely to occur if a pregnant woman has ingested a synthetic steroid preparation with androgenic properties because synthetic compounds generally cannot be aromatized.

Excessive androgen secretion beginning in utero is usually associated with defective cortisol synthesis. As a consequence, pituitary corticotropin secretion is increased, resulting in congenital adrenal hyperplasia and excessive androgen secretion. The three different enzyme defects in the steroidogenic pathway that can lead to virilization of the female fetus are described in Chapter 233. The most common form of congenital adrenal hyperplasia is 21-hydroxylase deficiency, accounting for the disorder in more than 90% of affected individuals. The defect may vary from partial to complete deficiency of the enzyme.

Diagnostic Tests

Measurement of Peptide and Steroid Hormones

Increased levels of immunoreactive human chorionic gonadotropin (HCG) may suggest an HCG-secreting neoplasm, most commonly an ovarian teratoma or dysgerminoma. In such cases, the HCG, which is antigenically and biologically similar to LH, stimulates ovarian steroid secretion and pseudopubertal development. Because even specific LH immunoassays show some cross-reactivity with HCG, values for serum LH may be elevated in individuals with HCG-secreting tumors. Immunoreactive HCG is always elevated in the presence of such tumors. Levels and ratios of FSH and LH typical of pubertal as opposed to prepubertal girls help in the diagnosis of true precocious puberty. Timed urine collections rather than blood samples can be used to measure gonadotropin secretion if necessary. The use of exogenous GnRH to stimulate endogenous LH and FSH secretion can help differentiate gonadotropin-dependent from gonadotropin-independent precocious puberty and is regarded as the "gold standard" in the diagnosis of central precocious puberty.[7] If GnRH is not available, a GnRH analogue can be substituted. Excessively high circulating levels of estrogen (>100 pg estradiol) suggest an estrogen-producing neoplasm or a functioning ovarian cyst. High levels of serum testosterone suggest an ovarian source of excess androgen in girls with heterosexual development, whereas increased levels of dehydroepiandrosterone or its sulfate (the principal precursors of 17-ketosteroids) suggest an adrenal source. High levels of serum 17-hydroxyprogesterone imply congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, whereas high levels of serum 11-deoxycortisol imply an 11β-hydroxylase deficiency (Chapter 233). In congenital adrenal hyperplasia, these hormone levels should decrease promptly after the oral administration of suppressive doses of dexamethasone. Suppression in response to exogenous corticoids occurs much less consistently in individuals with adrenal cortical adenomas and carcinomas (Chapter 227) and rarely in those with ovarian androgen-secreting neoplasms.

Additional Studies

Imaging of the CNS is the most important test if true precocious puberty is present or if there are any neurologic deficits. Ultrasonography of the adrenals and ovaries or computed tomography (CT) of the adrenals may be indicated to confirm clinical suspicions. In girls with ovarian or adrenal neoplasms, the tumor can almost always be localized radiographically. Catheterization of the ovarian and adrenal veins and measurements of the effluent steroids from each gland should be pursued only when CT, ultrasonography, or MRI fails to identify a suspected neoplasm. Radiographic estimation of bone age is also indicated and serves as a useful tool to follow the results of treatment.

TREATMENT

Rx

Treatment of precocious puberty should be initiated promptly so that the patient's ultimate height is not compromised as a result of sex steroid–induced premature epiphyseal closure and to prevent or attenuate emotional disturbances in the patient and her parents.[8]

GnRH analogues are now the preferred therapy for suppressing gonadotropin secretion, and they also may prevent early bone maturation. No randomized trials have been conducted, but there is universal acknowledgment that GnRH analogues increase ultimate adult height in girls presenting before 6 years of age. Two unresolved issues are whether to initiate treatment with GnRH analogues in girls between 6 and 8 years of age and at what age to stop treatment. In addition, some data suggest that metformin may prevent hirsutism and oligomenorrhea in the teenage years when started in 8- to 12-year-old girls with a history of low-normal birth weight and precocious puberty, although these findings have not been confirmed by other groups. The analogues are not effective in children with McCune-Albright syndrome, and ketoconazole and testolactone have been only marginally successful. Aqueous depot medroxyprogesterone acetate (100 to 200 mg intramuscularly every 2 to 4 weeks) also may be used to suppress gonadotropin secretion; however, it does not always prevent premature epiphyseal closure and the resultant short stature. Effective treatment appears to improve fertility in adult life.[9]

Individuals with CNS or steroid-secreting neoplasms must undergo therapy appropriate for the particular lesion. Girls with congenital adrenal hyperplasia are appropriately managed with glucocorticoids (plus mineralocorticoids when indicated), as outlined in Chapter 233.

Delayed Puberty

Girls who have no evidence of thelarche by age 13 years or who fail to undergo menarche by age 15 years have delayed puberty and should be evaluated.[10] Ovarian failure, congenital absence of the uterus and vagina, and constitutional delay constitute about two thirds of cases in large series. Because of the anxiety generated by delayed puberty, some evaluation is always indicated regardless of the age of the patient.

When pubertal development progresses normally but menstruation does not begin, an abnormality in the genital tract should be considered. Congenital malformations of the müllerian ducts are uncommon, occurring in 0.02% of all women. Most do not cause amenorrhea, and many do not impair reproduction. The anomalies associated with amenorrhea vary in severity from an imperforate hymen to complete aplasia of all müllerian duct derivatives, with vaginal atresia. Although aplasia generally involves all the müllerian duct derivatives, defects may involve only a single part of the distal genital tract. Family aggregates of the most common disorders of müllerian differentiation in females—müllerian aplasia and incomplete müllerian fusion—do occur and are best explained by polygenic or multifactorial inheritance. It is clear that the *HOX* genes, a family of regulatory genes that encode transcription factors, are essential for proper development of the müllerian tract.

A müllerian duct anomaly is suggested by (1) normal levels of serum gonadotropins and steroids, (2) an abnormal outflow tract, (3) a history of cyclic abdominal pain with or without a palpable mass, and (4) normal development of secondary sex characteristics. Normal ovarian function still induces endometrial growth and shedding after menarche if the uterus is normal. In the absence of a normal outflow tract, however, the menstrual effluent is retained and may or may not escape into the abdominal cavity. Free in the abdominal cavity, the effluent may cause endometriosis. Constrained to the uterine cavity, the effluent causes hematometra and a large abdominal mass. In the absence of a mass or cyclic pain, karyotyping is indicated in girls with evidence of an abnormal genital tract to rule out disorders of sexual differentiation (Chapter 233). Such disorders, however, almost never occur together with completely normal pubertal development. In girls with a normal karyotype and a genital tract anomaly, examination under anesthesia and diagnostic laparoscopy should be undertaken to delineate the extent of the defect. When the abnormality consists of an imperforate hymen or transverse vaginal septum only, surgical restoration can be accomplished relatively simply. Attempts to provide an outflow tract for the uterus should not be undertaken if there is no cervix because of the high risk for recurrent pelvic infection. Even with a functional cervix, the construction of an outflow tract that permits successful pregnancy is unlikely. A functional vagina can be constructed surgically or by the daily use of ever-larger dilators. To prevent shrinkage and scarring, surgery should be deferred

until the patient is willing to use dilators on a daily basis or she is about to become sexually active.

Other causes of delayed puberty and primary amenorrhea are the same as those that cause amenorrhea in older women (Chapter 236). When no apparent cause of delayed development is found, constitutional delayed puberty must be entertained as a diagnosis of exclusion.[11] A strong family history of delayed maturation supports this presumption. Small doses of estrogen can be administered to induce some pubertal development, but this may obscure a pathologic cause of the delay and may compromise linear growth and ultimate height.[12]

Asynchronous Pubertal Development

Asynchronous pubertal development is characteristic of male pseudohermaphroditism due to androgen insensitivity, especially complete testicular feminization. This syndrome of androgen insensitivity is inherited as either an X-linked recessive trait or a sex-limited autosomal dominant trait. Despite the presence of intra-abdominal or inguinal testes, there is complete failure of virilization. Affected individuals develop breasts (but only to Tanner stage 3) and a typical female habitus with unambiguous female external genitalia, but with the absence of internal female structures and generally only a foreshortened, blind-ending vagina. Little or no pubic and axillary hair develops. The karyotype is 46,XY in these individuals. Circulating testosterone levels are equivalent to or higher than those found in normal men, LH levels are elevated, and FSH levels are normal compared with those in menstruating women. For a more detailed description, see Chapter 233.

Heterosexual Pubertal Development

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS), by far the most common cause of heterosexual pubertal development, is associated with the development of some secondary sex features characteristic of males at the normal age of puberty. Feminization occurs in affected girls, and they develop normal breasts and a typical female habitus, but masculinization also occurs (in contrast, girls with congenital adrenal hyperplasia generally show little if any female development at puberty). A heterogeneous syndrome, PCOS typically begins at or near puberty with hirsutism and irregular menses from the time of menarche. Many girls who develop PCOS are overweight in childhood, and obesity is clearly a risk factor. It now appears that many girls who develop PCOS have alterations in insulin signaling.[13] Menarche may be delayed in a few cases, so young women may present with primary amenorrhea. Basal LH levels tend to be somewhat elevated in perhaps two thirds of cases, and circulating levels of all androgens are moderately elevated. Some degree of insulin resistance is commonly present as well, and hypercholesterolemia may predispose to cardiovascular disease later in life. This is discussed more completely in Chapter 236.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia is generally diagnosed before puberty, and heterosexual precocious pseudopuberty is typical. However, if the defect is mild and changes to the external genitalia are minimal, masculinization may occur at the expected age of puberty. This attenuated or nonclassic form of 21-hydroxylase deficiency seems to occur in families with a strong history of hirsutism. Affected girls generally have some defeminization, with flattening of the breasts, severe hirsutism, relatively short stature, and obesity. For a more detailed description, see Chapter 233.

MIXED GONADAL DYSGENESIS

Mixed gonadal dysgenesis designates asymmetrical gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other. The extent of genital virilization before puberty is variable in this rare disorder. Most individuals are reared as girls, in whom virilization occurs at puberty; some may note breast development as well. Affected individuals generally have a mosaic karyotype, with 45,X/46,XY being most common. Short stature and other stigmata associated with a 45,X karyotype in Turner syndrome are less common in patients with tumors than in patients with testes. Gonadectomy is indicated in all individuals with a Y chromosome to eliminate the increased neoplastic potential of such dysgenetic gonads and in all patients in whom virilization occurs at puberty to remove the source of androgen. Estrogen replacement therapy is warranted after gonadectomy. Other causes of male pseudohermaphroditism associated with heterosexual pubertal development are described in Chapter 233.

OTHER CAUSES

An androgen-producing adrenal neoplasm or Cushing's syndrome may occur rarely during the pubertal years and lead to heterosexual development (Chapter 227).

REVIEW QUESTIONS

1. The testis-determining factor sex-determining region Y (SRY) directly induces differentiation of which one of the following?

A. Sertoli cells
B. Leydig cells
C. Spermatocytes
D. Spermatids
E. Spermatozoa

Answer: A SRY expression leads to the differentiation of Sertoli cells and expression of müllerian-inhibiting substance (or antimüllerian hormone) by these cells. It does not play a role in the differentiation of Leydig cells (which is induced by thyroid hormone and luteinizing hormone, or the various developmental groups of spermatozoa development (which develop in the presence of testosterone). (See Embryogenesis and Differentiation.)

2. In utero, oocyte meiosis arrests at which stage?

A. Prophase
B. Metaphase
C. Anaphase
D. Telophase
E. Interphase

Answer: A During oogenesis, oocytes enter the first phase of meiosis but halt at the diplotene stage of prophase 1. The process of maintaining the prolonged resting state of meiosis is called dictyotene and continues until puberty. Progression beyond the prophase (metaphase, anaphase, telophase, or interphase) involves chromatin condensation and could limit the molecular function of the oocyte DNA. (See Embryogenesis and Differentiation.)

3. Which one of the following is true of precocious puberty in girls?

A. Is diagnosed when pubertal changes occur before 10 years of age
B. Can occur earlier in white girls compared with African American girls
C. Can result in masculine pubertal development
D. Requires premature activation of the hypothalamic-pituitary axis
E. Is less likely to be pathologic if diagnosed at an earlier age

Answer: C Precocious puberty is diagnosed if puberty commences before 9 years of age in white girls and 8 years of age in African American girls. It can result in either isosexual or heterosexual pubertal development. If the cause is central, then the hypothalamic-pituitary-ovarian (HPO) axis is activated; however, noncentral causes (e.g., exogenous gonadal hormone exposure) do not require activation of the HPO axis. The earlier the age of the girl, the more likely it is to be pathologic. (See Precocious Puberty.)

4. Delayed menarche is caused by dysfunction in which one of the following?

A. Hypothalamus
B. Pituitary
C. Ovary
D. Uterus
E. All of the above

Answer: E Delayed menarche can result from the absence of gonadotropin-releasing hormone pulsatility, disruptions in gonadotropin release from the pituitary, loss of functional oocytes, or obstruction of the outflow tract, to name a few. Disruptions at any point along the female reproductive axis can result in disruptions in the orderly transition through puberty. (See Delayed Puberty.)

5. The diagnosis of polycystic ovarian syndrome (PCOS) absolutely requires which one of the following?

A. Evidence of oligo-ovulation or anovulation
B. Evidence of hyperandrogenism
C. Evidence of polycystic-appearing ovaries by imaging
D. Exclusion of other disorders that can cause menstrual irregularity and hyperandrogenism
E. All of the above

Answer: D The diagnosis of PCOS requires two of the following three: evidence of oligo-ovulation/anovulation, hyperandrogenism, and/or polycystic-appearing ovaries. No one of them is absolutely required. However, ruling out other disorders that can appear to be PCOS must be done before PCOS can be diagnosed. (See Polycystic Ovarian Syndrome.)

REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY

ROBERT W. REBAR AND WILLIAM H. CATHERINO

THE NORMAL MENSTRUAL CYCLE

Between menarche and menopause, the reproductive organs of normal women undergo a series of closely coordinated changes at monthly intervals that constitute the normal menstrual cycle. The menstrual cycle is the expression of the coordinated interactions of the hypothalamic-pituitary-ovarian axis, with associated changes in the target tissues (endometrium, cervix, vagina) of the reproductive tract.

A menstrual cycle begins with the first day of genital bleeding (day 1; menses) and ends just before the next menstrual period. The median menstrual cycle length is 28 days but normally ranges from 21 to 35 days. Menstrual cycles vary most in the years immediately after menarche and preceding menopause, partly because of an increase in anovulatory cycles. Irregularities in menstrual cycle length may be caused by changes in diet, exercise, emotional disturbances, parturition, or abortion. The menstrual cycle has three distinct phases: follicular, ovulatory, and luteal.

Follicular (Preovulatory) Phase

The follicular phase begins with the first day of bleeding and extends to the day before the preovulatory luteinizing hormone (LH) surge. A rise in serum follicle-stimulating hormone (FSH) begins in the late luteal phase of the previous menstrual cycle and continues into the early follicular phase. This initiates development of a group of follicles (Fig. 236-1). The preovulatory follicle destined for ovulation is selected from this cohort. After the early follicular phase, FSH levels fall, and LH levels rise slowly. About 7 days before the preovulatory LH surge, estradiol and estrone increase until the day before the LH surge. The divergence in LH and FSH levels may be related to secretion of inhibin B, which inhibits the release of FSH. Several days before the LH surge, plasma androgens begin to increase. They peak on the day of the LH surge. Progesterone does not increase until just before the LH surge onset.

Ovulatory Phase

During this phase, the ovum is released from the mature graafian follicle about 32 to 34 hours after the preovulatory LH surge. The ovulatory phase extends from 1 day before the LH surge to 1 day after the LH surge (see Fig. 236-1). Some women experience unilateral pelvic pain near the time of ovulation, termed *mittelschmerz*, which occurs before or after ovulation. During the ovulatory phase, a rapid rise in plasma LH in response to positive estrogen feedback leads to ovulation. As peak LH levels are reached, estradiol levels drop, but progesterone levels increase.

Luteal (Postovulatory) Phase

The luteal phase is about 14 days in length and ends with the onset of menses (see Fig. 236-1). This phase includes the functional lifespan of the corpus

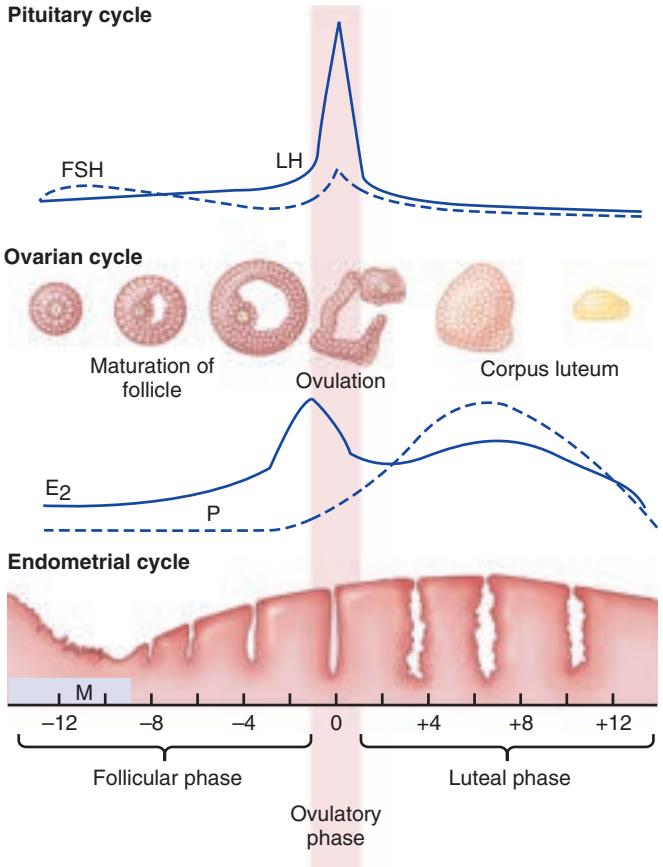

FIGURE 236-1. The idealized cyclic changes observed in gonadotropins, estradiol (E_2), progesterone (P), and uterine endometrium during the normal menstrual cycle. The data are centered on the day of the luteinizing hormone (LH) surge (day 0). Days of menstrual bleeding are indicated by M. FSH = follicle-stimulating hormone; LH = luteinizing hormone. (From Endocrine and Metabolism Continuing Education Quality Control Program, 1982. Copyright American Association for Clinical Chemistry, Inc.)

luteum, which supports the released ovum by secreting progesterone. Progesterone secretion increases up to 8 days after the LH surge. Smaller increases in 17α-hydroxyprogesterone, estradiol, and estrone occur. Progesterone decreases before menses unless the ovum is fertilized and pregnancy results. A serum progesterone level higher than 3 ng/mL 1 week before menses is probably diagnostic of ovulation.

CYCLIC CHANGES IN TARGET ORGANS

Endometrium

The endometrium undergoes histologic and cytologic changes that culminate with menstrual bleeding when the corpus luteum ceases to secrete progesterone (see Fig. 236-1). The basal layer of the endometrium then regenerates the superficial layer of compact epithelial cells lining the uterine cavity and an intermediate layer of spongiosa. Both superficial layers are shed at menstruation. Endometrial glands proliferate under the influence of estrogen, and the mucosa thickens. In the luteal phase, the glands become coiled and secretory, with increased vascularity and edema of the stroma. When estradiol and progesterone decline, the stroma becomes edematous, endometrial and blood vessel necrosis occurs, and bleeding ensues. Local release of prostaglandins may initiate vasospasm with ischemic necrosis and uterine contractions that accompany menstrual flow. Prostaglandin synthetase inhibitors can relieve menstrual cramping. The histologic changes are characteristic; therefore, endometrial biopsies can be used to characterize the stage of the cycle and to assess the tissue response to gonadal steroids.

Cervix and Cervical Mucus

During the follicular phase, cervical vascularity, congestion, and edema increase as a result of estrogen. Cervical mucus increases in quantity (10- to 30-fold) and in elasticity. So-called ferning becomes prominent. Progesterone stimulates cervical mucus thickening and loss of elasticity and ability to fern. These characteristics are useful in evaluating the stage of the cycle and the amount of estrogen present.

Vagina

Low estrogen is associated with pale, thin vaginal epithelium. As estrogens rise, the number of cornified epithelial cells increases. Subsequently, progesterone decreases the percentage of cornified cells and increases the number of precornified intermediate cells. There is also increased cellular debris and clumping of shed desquamated cells. Histologic changes in the vaginal epithelium are sensitive indicators of estrogen status.

Ovary

The ovaries produce a single dominant graafian follicle that grows and develops to the preovulatory stage during the follicular phase. This process is brought about by the combined actions of FSH and LH on the follicle wall to increase estradiol biosynthesis. The LH surge acts on the preovulatory follicle to cause the secretion of the mature fertilizable oocyte. After ovulation, the follicle wall transforms into the corpus luteum, which produces progesterone and estradiol. If implantation does not occur, the corpus luteum undergoes luteolysis and stops hormone production. In the late luteal phase, another dominant follicle develops, and a new menstrual cycle begins.

Chronology of Folliculogenesis

The preovulatory follicle begins its development when a primordial follicle is recruited into the pool of growing follicles. There are two major phases of folliculogenesis: the preantral (gonadotropin-independent) and the antral (gonadotropin-dependent) periods. The first phase is characterized by growth of the oocyte and granulosa proliferation. Preantral folliculogenesis proceeds slowly, requiring at least 300 days. During the second phase, granulosa and theca cells proliferate, and the antrum enlarges. The graafian follicle increases relatively rapidly as it develops. The mature graafian follicle that will ovulate requires 40 to 50 days to complete the antral phase.

Selection

The dominant follicle is selected from a cohort at the end of the luteal phase of the previous menstrual cycle. The selected follicle requires 20 days to develop to the ovulatory stage.

Shortly after the midluteal phase of the cycle, the granulosa cells show a sharp increase in the rate of mitosis. The first indication of selection is that the granulosa cells continue dividing at a high rate. As a consequence of the high and sustained mitotic rate and the progressive accumulation of follicular fluid, the dominant follicle undergoes remarkable growth. The increase in plasma FSH levels that begins at the end of luteal phase and continues through the early follicular phase evokes follicle selection. The concentration of FSH in the follicular fluid of the healthy (dominant) follicle increases but does not increase in the nondominant atretic follicles. The manner in which this selective increase in FSH is controlled is unknown. More than 99.9% of all follicles are not selected and undergo atresia.

Mechanism of Follicle-Stimulating Hormone Action

FSH exerts its influence on follicle growth and development by stimulating granulosa cell mitosis and cytodifferentiation. FSH activates high-affinity receptors on the granulosa cell. The binding event is transduced into an intracellular signal through the cyclic adenosine monophosphate (cAMP)-dependent protein kinase A signal transduction pathway. This leads to an increase in cell number and cytodifferentiation.

The granulosa cells in the chosen follicle continue to divide at a relatively rapid rate throughout the follicular phase of the cycle, increasing from 1×10^6 cells to 50×10^6 cells at ovulation. FSH induces granulosa cytodifferentiation in the dominant follicle. Expression of cytochrome P-450 aromatase (P450arom) is induced by FSH. The temporal pattern of expression of P450arom determines when and how much estradiol is produced. FSH also induces the expression of LH receptors. This is delayed until the dominant follicle is fully differentiated at day 12. The large number of LH receptors in the granulosa cells is essential for the LH surge to trigger ovulation. The terminal differentiation of the granulosa cells is characterized by the accumulation of other FSH-regulated gene products, including inhibin B, activin, and follistatin.

Mechanism of Luteinizing Hormone Action

The primary function of LH in follicle development is to stimulate androgen production by the theca interstitial cells. LH binds to LH-human chorionic gonadotropin (HCG) receptors located on theca cells, which interact with G

proteins and activate adenylate cyclase, leading to the synthesis of cAMP, which stimulates gene expression through protein kinase A. This leads to increased conversion of cholesterol to androstenedione. Theca cells express insulin receptors, and insulin stimulates theca androgen production. The crosstalk between the insulin and LH receptor signaling is clinically relevant because of the relationship between hyperinsulinemia and hyperandrogenism in women.

One of the most important consequences of FSH and LH action on the dominant follicle is the production of estradiol. This physiologically important process is called the *two-gonadotropin, two-cell concept* of follicular estrogen production.

Ovulation

At midpoint in the menstrual cycle, the preovulatory surges of LH and FSH act on the preovulatory follicle to initiate the events leading to ovulation. The LH surge induces meiotic maturation, a process that converts the oocyte into a fertilizable egg arrested at the second meiotic metaphase. During meiotic maturation, the granulosa cells next to the oocyte are stimulated by FSH to undergo cumulus expansion. This is a prerequisite for the oocyte's pickup and transport by the oviduct. The LH surge also stimulates production of proteolytic enzymes in the vicinity of the presumptive stigma. This process requires the LH stimulation of progesterone and prostaglandins, which are obligatory for stigma formation. After 36 hours, the fertilizable egg and surrounding cumulus cells are secreted through the stigma.

Luteogenesis

Ovulation leads to changes in the granulosa and theca cells of the ovulated follicle that result in increased production of progesterone and estradiol during the first week of the luteal phase. This event, termed *luteinization*, is important for the formation and development of a secretory endometrium. Three major physiologic mechanisms are responsible for luteinization: removal of luteinization inhibitors; secretion of LH by the pituitary; and delivery of high levels of cholesterol. The induction of StAR, P450c22, and 3β-hydroxysteroid dehydrogenase in the granulosa lutein cells leads to progesterone production by the corpus luteum. The two-cell, two-gonadotropin mechanism is responsible for estradiol production. If implantation does not occur, the corpus luteum initiates luteolysis, leading to decreases in progesterone, estradiol, and apoptosis. When luteolysis occurs, another dominant follicle is selected, and a new menstrual cycle begins.

Neuroendocrine Regulation of the Ovaries

Neurons containing various peptide hormones that can release or inhibit secretion of the gonadotropins are found in the hypothalamus (Chapter 223). Cells containing gonadotropin-releasing hormone (GnRH) occur in the arcuate nucleus, median eminence, and preoptic area. Axons from these neurons run in the tuberoinfundibular tract and terminate on capillaries within the median eminence, allowing delivery of their products to the anterior pituitary gland. Neurotransmitters, including norepinephrine, dopamine, and serotonin, as well as neuromodulators, such as endogenous opiates and prostaglandins, influence secretion of GnRH. Estrogens and androgens bind to cells in the hypothalamus and the anterior pituitary, and progestins bind to cells in the hypothalamus, to influence hypothalamic-pituitary regulation of ovarian function.

GnRH is secreted in a pulsatile fashion and is responsible for pulsatile release of gonadotropins. Pulsatile gonadotropin release accounts for the pulsatile secretion of sex steroids from the ovaries. The ovarian sex steroids feed back on the hypothalamic-pituitary unit to modulate both the frequency and amplitude of the gonadotropin pulse (Fig. 236-2). Gonadotropin pulses vary throughout the menstrual cycle. Pulses occur at approximately 60- to 90-minute intervals in the follicular phase and at intervals of 180 minutes in the luteal phase.

Gonadal steroids can exert both negative and positive feedback effects on gonadotropin secretion. 17β-Estradiol is the most potent inhibitor of gonadotropin secretion. For women to ovulate, estradiol must also elicit a positive feedback effect on gonadotropin release. The feedback effects are both time and dose dependent. In the normal menstrual cycle, the positive feedback action of estradiol leading to the LH surge is preceded by a period when lower estradiol levels are present.

It appears that the ovary is the "clock" for the timing of ovulation, with the hypothalamus stimulating pulsatile release of the gonadotropins. The follicle complex and corpus luteum develop in response to gonadotropin stimulation. For appropriate ovarian regulation of reproductive function in women, three biologic characteristics are necessary: an appropriate balance and sequence of negative and positive feedback actions; differential feedback effects on the release of LH and FSH; and local intraovarian controls on follicular growth and maturation.

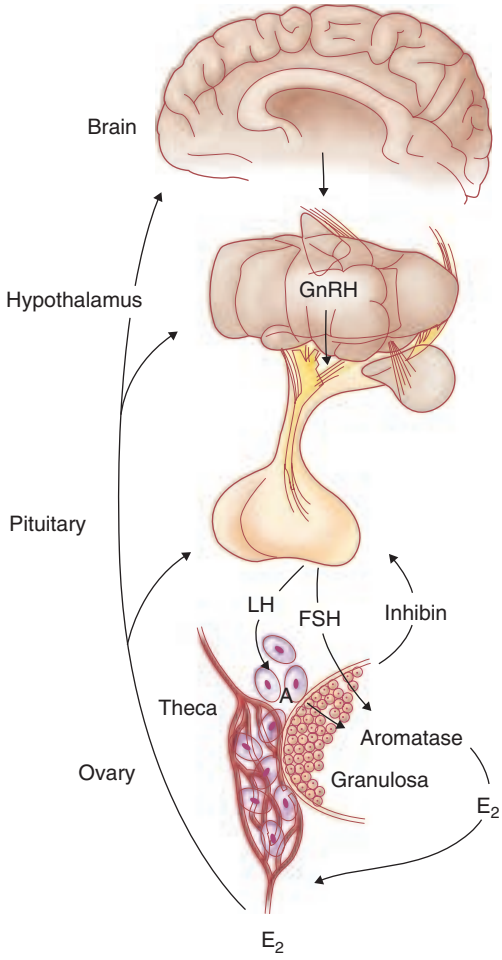

FIGURE 236-2. The hypothalamic-pituitary-ovarian axis in the regulation of follicular maturation and steroidogenesis. A = androgens; E_2 = estradiol; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone. ABNORMALITIES OF THE REPRODUCTIVE YEARS

Dysmenorrhea and Endometriosis

DEFINITION

Dysmenorrhea, defined as painful menstruation, affects about 50% of postpubertal women[1] and can be classified as primary or secondary. *Endometriosis,* which may result in dysmenorrhea, infertility, and dyspareunia (i.e., painful intercourse), is the ectopic occurrence of endometrial tissue, most commonly within the abdominal cavity but sometimes in surgical scars, on the vulva, in the umbilicus, and elsewhere.[2]

PATHOBIOLOGY

Primary dysmenorrhea occurs only in ovulatory cycles. Prostaglandins produce dysmenorrhea by initiating painful, exaggerated uterine contractions and myometrial ischemia. Associated systemic symptoms include nausea, diarrhea, headache, and emotional changes. In secondary dysmenorrhea, there is a pathologic cause, with endometriosis being the most common. Other causes include pelvic inflammatory disease; congenital abnormalities, such as atresia of a portion of the distal genital tract and cystic duplication of the paramesonephric ducts; and cervical stenosis. Recent studies suggest the possibility that the pain of endometriosis is caused by the presence of nerve fibers within ectopic endometrium.

TREATMENT Rx

Prostaglandin synthetase inhibitors (Chapter 37), such as naproxen, ibuprofen, mefenamic acid, and indomethacin, are used to treat primary dysmenorrhea.[3] If the dysmenorrhea persists, addition of an oral contraceptive to inhibit ovulation and limit prostaglandin release is generally effective. In cases in which the pelvic pain remains intractable, additional evaluation is warranted. If thorough evaluation of the gastrointestinal and urinary tracts fails to reveal a definitive cause, examination under anesthesia and diagnostic laparoscopy may be indicated.

If endometriosis is diagnosed at laparoscopy, treatment varies according to the severity of the disease and the goals of the patient regarding fertility.[4] It may be possible to fulgurate implants or to lyse adhesions. Available data do not demonstrate a benefit of excision over ablation at the time of initial diagnosis as the preferred approach to controlling symptoms. From this point onward, efforts should be directed toward treating endometriosis medically, with additional surgery deferred until infertility (if present) becomes manifest. Medical therapy can consist of continuous suppression with oral contraceptives, progestins (oral, injectable, or implantable), or GnRH analogues or danazol for 3 to 6 months. GnRH analogues are currently the most frequently used form of medical suppressive therapy. After a course of treatment, use of oral contraceptive agents should probably be continued until fertility is desired. Conservative surgical resection of endometriotic tissue should almost always be deferred until it is established as the cause of infertility. Surgery may be required, however, for continuing severe pain, severe endometriosis, or large ovarian cysts containing endometriosis (endometriomas). If symptoms continue despite adequate treatment or if psychological overlay is suspected, psychiatric evaluation may be indicated. Medical causes of dysmenorrhea, however, should be eliminated first.

Premenstrual Syndrome

DEFINITION

Premenstrual syndrome (PMS), also known as *premenstrual tension*, is a complex of physical and emotional symptoms that occur repetitively in a cyclic fashion before menstruation and that diminish or disappear with menstruation.[5]

DIAGNOSIS

The cyclic symptoms typically are sufficiently severe to interfere with some aspects of life. More than 150 different symptoms are now thought to vary with the menstrual cycle (Table 236-1). Estimates of the prevalence of PMS range from 25 to 100%. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) classifies severe PMS as premenstrual dysphoric disorder (PMDD). For most women, PMS is merely annoying; severe PMS (or PMDD) causes serious difficulties for 3 to 5% of women of reproductive age. The diagnosis of both PMS and PMDD is best established by requiring patients to keep prospective daily records of symptoms during a 2- to 3-month period. Less than 50% of women complaining of PMS are found to have the syndrome when such records are examined.

TABLE 236-1 COMMON SYMPTOMS OF CYCLIC PREMENSTRUAL SYNDROME

SOMATIC SYMPTOMS	
Abdominal bloating	Constipation or diarrhea
Acne	Headache
Alcohol intolerance	Peripheral edema
Breast engorgement and tenderness	Weight gain
Clumsiness	
EMOTIONAL AND MENTAL SYMPTOMS	
Anxiety	Insomnia
Change in libido	Irritability
Depression	Lethargy
Fatigue	Mood swings
Food cravings (especially salt and sugar)	Panic attacks
Hostility	Paranoia
Inability to concentrate	Violence toward self and others
Increased appetite	Withdrawal from others

Most women seek help for PMS in their 30s after 10 or more years of symptoms. Many report that their symptoms began at menarche; approximately half state that symptoms followed childbirth. Severity and duration of symptoms are often reported to increase after each successive pregnancy and to become more severe with advancing age. Women with severe long-standing PMS almost always describe associated psychological reactions, including social difficulties, such as marital discord, difficulty relating to their children, difficulty maintaining friendships, and withdrawal from social activities.

TREATMENT Rx

General Measures

The cause of PMS is unknown, and patients should be informed that no one therapy has been effective in all women. Women with mild premenstrual symptoms often benefit from simple changes in lifestyle, including daily mild aerobic exercise; reduction in intake of caffeine-containing beverages, salt, and refined sugar, particularly in the luteal phase; stress reduction; and adequate rest.

Medical Therapy

Women with more severe PMS may benefit from symptomatic treatment. Continuous oral contraceptives have inconsistent but generally positive therapeutic benefit.[6] Bromocriptine (generally 2.5 mg twice a day) or danazol (100 to 400 mg/day in two divided doses) may be given continuously for relief of mastalgia (breast pain), although this use is not listed in the manufacturer's directive or approved by the U.S. Food and Drug Administration (FDA), and efficacy has not been documented by rigorous randomized trials. Prostaglandin synthetase inhibitors may help reduce dysmenorrhea and may alleviate headaches. Mild sedatives and tranquilizers may help reduce insomnia and anxiety. Low doses of fluoxetine (20 mg) and other selective serotonin reuptake inhibitors, administered either daily or for the last 2 weeks of each menstrual cycle, are highly effective in reducing the emotional symptoms associated with PMS. Mild diuretics (especially spironolactone at doses up to 100 mg each morning) may benefit cyclic edema.

Natural progesterone, given in the form of vaginal suppositories, has been used, but results of double-blind placebo-controlled trials show no efficacy. Likewise, the value of large quantities of multiple vitamins or of oil of evening primrose, containing the essential fatty acid γ-linolenic acid, a precursor of prostaglandins, is unsubstantiated.

Surgical Therapy

Because PMS requires the occurrence of cyclic ovulation, oophorectomy is occasionally considered for patients with particularly intractable symptoms. However, oophorectomy may create new problems related to estrogen deficiency for women with PMS treated in this permanent fashion. Several trials employing a GnRH agonist together with exogenous steroids have been described as reducing PMS. Whether such therapy can be used in the long term remains to be determined.

Abnormal Uterine Bleeding

DIAGNOSIS

Differential Diagnosis

Because there is considerable confusion about terminology of abnormal uterine bleeding, it is important to determine just what is being included in any term used other than *abnormal uterine bleeding*.[7] Postmenarchal bleeding in adolescents secondary to immaturity of the hypothalamic-pituitary-ovarian axis (resulting in anovulation) accounts for about 20% of cases, and perimenopausal bleeding consequent to incipient ovarian failure constitutes more than half.

The causes of abnormal uterine bleeding in the reproductive years include complications from the use of oral contraceptives; complications of pregnancy, especially threatened, incomplete, or missed miscarriages and ectopic pregnancy; coagulation disorders, most commonly idiopathic thrombocytopenic purpura (Chapter 172) and von Willebrand disease (Chapter 173); and pelvic disease, such as intrauterine polyps, leiomyomas, and tumors of the vagina and cervix. Clear cell adenocarcinoma of the vagina or cervix (Chapter 199) may occur in women exposed to diethylstilbestrol during fetal life. Affected women may also have congenital abnormalities of the upper vagina, cervix, and uterus. Women with a history of diethylstilbestrol exposure should be reassured that the incidence of malignant change is extremely low. Trauma (coital or otherwise), foreign bodies, systemic illnesses including various endocrinopathies (e.g., diabetes mellitus, hypothyroidism and hyperthyroidism, Cushing's syndrome, and Addison's disease), leukemia, and

renal disease may also be associated with abnormal bleeding as the presenting manifestation.

Abnormal uterine bleeding with no demonstrable organic genital or extragenital cause (75% of cases) is most frequently associated with anovulation and is appropriately termed *anovulatory* (sometimes termed *dysfunctional*) *bleeding*. Most anovulatory bleeding is due to either estrogen withdrawal or estrogen breakthrough bleeding. In anovulatory women, estrogen stimulates the endometrium unopposed by progesterone. The endometrium proliferates, becomes thicker, and may shed irregularly. Anovulatory bleeding tends to occur at less frequent intervals, and organic lesions tend to cause bleeding more frequently than cyclic menses.

Clinical Evaluation

All cases of abnormal bleeding should be evaluated, beginning with a thorough history emphasizing the amount and duration of blood loss. Prospective charting of the days on which bleeding occurs may be required to evaluate the bleeding pattern. Complications of pregnancy or a bleeding diathesis must always be ruled out.

The findings on physical examination (including the Papanicolaou smear) are normal in anovulatory bleeding except for signs of anemia in the more severe cases. Laboratory tests should include a complete blood count, platelet count, coagulation studies, thyroid function tests, and fasting blood glucose concentration. Anovulatory bleeding must be a diagnosis of exclusion, with management depending on the age of the patient and the extent of the bleeding. A sample of the endometrium should be obtained by biopsy or by dilation and curettage from all women older than 35 years and from those at increased risk for endometrial carcinoma because of prolonged anovulatory bleeding.

TREATMENT

Even profuse bleeding in hemodynamically stable anovulatory women can almost always be successfully treated by the administration of one combination oral contraceptive pill every 6 hours for 5 to 7 days, although this use is not listed in the manufacturer's directive or approved by the FDA. Bleeding should cease within 24 hours, but patients should be warned to expect heavy bleeding 2 to 4 days after therapy is stopped. If anemia is profound, blood transfusion may be necessary. If the bleeding continues despite therapy, curettage can be carried out. Recurrence can be prevented by giving the patient combination oral contraceptive agents cyclically if pregnancy is not desired. If pregnancy is desired, ovulation can be induced.

Acute episodes of anovulatory bleeding can also be treated with conjugated estrogens administered intravenously (25 mg every 4 hours for up to three doses) until bleeding ceases, although this use is not listed in the manufacturer's directive or approved by the FDA. Progestin therapy (medroxyprogesterone acetate, 5 to 10 mg orally for 10 days) should be started simultaneously. Withdrawal bleeding occurs after cessation of therapy, and the patient can then be treated with oral contraceptive agents for at least three cycles.

For individuals with anovulatory bleeding without an episode of profuse bleeding, treatment with cyclic oral contraceptive agents or progestin can be provided unless pregnancy is desired, in which case ovulation must be induced.

Endometrial ablation by any of several methods is being used increasingly to treat persistent bleeding. However, ablation is not 100% effective, and medical management remains the first line of therapy for most women. Hysterectomy may be an appropriate choice for a small number of women.

Amenorrhea

DEFINITION

Amenorrhea is the absence of menstruation for 3 months or more in women with past menses (secondary amenorrhea) or the absence of menarche by the age of 15 years regardless of the absence or presence of secondary sex characteristics (primary amenorrhea).[8]

PATHOBIOLOGY

If an intact genital outflow tract exists and there is no primary disease of the uterus, amenorrhea is a sign of failure of the hypothalamic-pituitary-ovarian axis to produce cyclically the hormones necessary for menses. Amenorrhea is physiologic in the prepubertal girl, during pregnancy and early in lactation, and after menopause. At any other time, it is pathologic and demands evaluation. Use of the term *postpill amenorrhea* to refer to failure to resume menses within 3 months of discontinuation of oral contraceptives is inappropriate. Women so affected should be evaluated in the same manner as any woman with amenorrhea. Similarly, individuals with menses occurring at infrequent intervals of more than 40 days or having fewer than nine menses per year, termed *oligomenorrhea*, should be evaluated identically to women with amenorrhea.

DIAGNOSIS

Clinical Evaluation

In patients with amenorrhea, even subtle hormonal abnormalities may lead to signs and symptoms. Breast development indicates exposure to estrogens, and the presence of pubic and axillary hair indicates androgenic stimulation.

Patients should be questioned especially closely for evidence of psychological disturbances, dietary and exercise habits, lifestyle, environmental stresses, family history of genetic anomalies, abnormal growth and development, and signs of hyperandrogenism, including hirsutism, temporal balding, deepening of the voice, increased muscle mass, clitorimegaly, and increased libido, and signs of defeminization, including decreasing breast size and vaginal atrophy. Any history of galactorrhea should be determined. A history of symptoms related to thyroid and adrenal dysfunction should also be sought (Chapters 224, 226, and 227).

The physical examination should focus on the evaluation of body dimensions and habitus, extent and distribution of body hair, breast development and secretions, and genitalia. In normal adult women, the arm span is similar to the height; in hypogonadal women, the span is generally more than 5 cm greater than the height. The distribution and quantity of body hair should be considered in view of the family history. The extent of any hirsutism should be recorded, preferably by photographs. Other signs of virilization should be sought carefully. Breast development should be graded according to the method of Tanner (Table 236-2).[9] Breast secretion should be sought by applying pressure to the breasts while the patient is seated. Any secretion should be examined microscopically for the presence of perfectly round fat globules of varying size, which indicate galactorrhea. Finally, the female genitalia should be examined carefully because they are such sensitive indicators of the hormonal milieu. The Tanner stage of pubic hair development should be noted (see Table 236-2).

Because the sensitivity of the genitalia to androgens decreases onward from early in fetal development, the extent of any virilization is important. Fusion of the labia and enlargement of the clitoris with or without formation

TABLE 236-2 CRITERIA FOR DISTINGUISHING TANNER STAGES 1 TO 5 DURING PUBERTAL MATURATION

TANNER STAGE	BREAST	PUBIC HAIR
1 (Prepubertal)	No palpable glandular tissue or pigmentation of areola; elevation of areola only	No pubic hair; short, fine vellus hair only
2	Glandular tissue palpable with elevation of breast and areola together as a small mound; areolar diameter increased	Sparse, long, pigmented terminal hair chiefly along the labia majora
3	Further enlargement without separation of breast and areola; although more darkly pigmented, areola still pale and immature; nipple generally at or above midplane of breast tissue when individual is seated upright	Dark, coarse, curly hair, extending sparsely over mons
4	Secondary mound of areola and papilla above breast	Adult-type hair, abundant but limited to mons and labia
5 (Adult)	Recession of areola to contour of breast; development of Montgomery's glands and ducts on areola; further pigmentation of areola; nipple generally below midplane of breast tissue when individual is seated upright; maturation independent of breast size	Adult-type hair in quantity and distribution; spread to inner aspects of the thighs in most racial groups

Data from Ross GT. Disorders of the ovary and female reproductive tract. In: Wilson JD, Foster DW, eds. *Textbook of Endocrinology*, 7th ed. Philadelphia: WB Saunders; 1985:206; Speroff L, Glass RH, Kase N. *Clinical Gynecologic Endocrinology and Infertility*, 3rd ed. Baltimore: Williams & Wilkins; 1983:377; and Kustin J, Rebar RW. Menstrual disorders in the adolescent age group. *Primary Care*. 1987;14:139-166.

of a penile urethra are observed in women exposed to androgens during the first 3 months of fetal development (Chapter 233). Significant clitorimegaly in the absence of other signs of sexual ambiguity and in the presence of other signs of virilization requires marked androgenic stimulation and strongly implicates an androgen-secreting neoplasm. The development of the labia minora in postpubertal women indicates the influence of estrogens. Overt anomalies of the distal genital tract and any evidence of obstruction to the escape of menstrual blood should be sought. Under the influence of estrogen, the vaginal mucosa changes during sexual maturation from a tissue with a shiny, bright red appearance with sparse, thin secretions to a dull, gray-pink rugated surface with copious, thick secretions.

The history and physical examination quickly differentiate among several causes of amenorrhea (Table 236-3). The various disorders of sexual differentiation and the other anatomic causes are often apparent on inspection. Distal genital tract obstruction should be identified at the time of pelvic examination even if the specific abnormality is not obvious. The physical stigmata of Turner's syndrome, discussed subsequently, generally make the diagnosis simple. Any sexual ambiguity indicates the need for chromosomal analysis and the measurement of 17α-hydroxyprogesterone to rule out congenital adrenal hyperplasia. Pregnancy and gestational trophoblastic disease may be diagnosed by measurement of HCG. The possibility of intrauterine synechiae or adhesions (Asherman's syndrome) must be considered in individuals in whom amenorrhea develops after curettage or endometritis. Tuberculous endometritis, especially in younger women, may also lead to this disorder. Without hormonal measurements, it may be impossible to distinguish between individuals with chronic anovulation, in whom hypothalamic-pituitary-ovarian function is insufficiently coordinated to produce cyclic ovulation, and those with ovarian failure. However, it is generally possible to form a clinical impression about the cause of the amenorrhea. It can be noted whether the patient has absence of, incomplete, or complete development of secondary sex characteristics. The presence of excess body hair or galactorrhea may provide clinical evidence of the pathogenesis of the amenorrhea. Signs and symptoms of adrenal or thyroid dysfunction may be important as well. Administration of a progestin (typically medroxyprogesterone acetate, 5 to 10 mg given orally for 5 to 10 days, or progesterone in oil, 100 mg given intramuscularly) has been advocated to assess the level of endogenous estrogen. This test is of limited value, however, because almost half the young women with premature ovarian failure experience withdrawal bleeding in response to progestin.

To ascertain whether the outflow tract is intact, an orally active estrogen, such as 2.5 mg of conjugated estrogen daily for 21 days, with 5 to 10 mg of oral medroxyprogesterone acetate for the last 5 to 10 days, is administered. Withdrawal bleeding should occur if the endometrium is normal. Still, hysterosalpingography and hysteroscopy may be required for the diagnosis of Asherman's syndrome because some patients with a normal endometrium may not have a withdraw bleed due to obstruction of the cervical os by scar tissue.

TABLE 236-3 CAUSES OF AMENORRHEA

ANATOMIC CAUSES
Pregnancy
Various disorders of sexual differentiation
Distal genital tract obstruction (müllerian agenesis or dysgenesis)
Gonadal dysgenesis*
Ambiguity of external genitalia (male and female pseudohermaphroditism)
Intrauterine adhesions (Asherman's syndrome)
Gestational trophoblastic disease
CHRONIC ANOVULATION
Due to CNS-hypothalamic-pituitary dysfunction
With inappropriate steroid feedback (e.g., polycystic ovary syndrome)
Due to thyroid or adrenal disorders
OVARIAN "FAILURE"
Menopause
Genetic abnormalities
Physical and environmental causes (e.g., chemotherapeutic agents, irradiation)
Autoimmune disorders
Idiopathic

*Gonadal dysgenesis may be viewed as both a disorder of sexual differentiation and a form of gonadal "failure."
CNS = central nervous system.

Laboratory Findings

Basal levels of FSH, prolactin, and thyroid-stimulating hormone (TSH) should be measured in all amenorrheic and oligomenorrheic women to confirm the clinical impression (Fig. 236-3).[10]

Increased TSH levels with or without increased levels of prolactin imply primary hypothyroidism, and further evaluation for this disorder is indicated (Chapter 226). Although hypothyroidism commonly results in anovulation, amenorrhea occurs in only some hypothyroid women. Menorrhagia and oligomenorrhea may occur as well. The sensitive immunoassays for TSH permit identification of women with hyperthyroidism as well because TSH levels are suppressed in those individuals.

If the prolactin concentration is minimally increased and the TSH level is normal, measurement of the prolactin concentration should be repeated before more extensive evaluation is undertaken because prolactin levels are increased by nonspecific stressful stimuli, sleep, and food ingestion. Prolactin levels may be elevated in as many as one third of women with amenorrhea.

Increased FSH levels (generally >30 mIU/mL) imply ovarian failure and require further evaluation. Incipient ovarian failure should be considered in any woman with basal FSH levels of 15 mIU/mL or higher other than during the midcycle LH surge. Many clinicians believe that chromosomal evaluation is indicated in all individuals with elevated FSH levels before age 40 years, and it is certainly indicated if hypergonadotropic amenorrhea begins before age 30 years.

If FSH levels are low or normal, the measurement of total testosterone levels may be helpful whether or not there is any evidence of hirsutism or virilization. Hyperandrogenic women need not be hirsute because some have relative insensitivity of the hair follicles to androgens. Mildly increased levels of testosterone (and perhaps dehydroepiandrosterone sulfate as well) suggest polycystic ovary syndrome (PCOS). However, total circulating androgen levels need not be elevated because of the alterations in metabolic clearance rate and sex hormone–binding globulin that are present in PCOS. Consequently, some clinicians prefer to measure circulating free testosterone levels.

Circulating levels of LH and FSH may aid in differentiation of PCOS from hypothalamic-pituitary dysfunction. LH levels are often elevated in PCOS so that the ratio of LH to FSH is increased; however, LH levels may be identical to those observed in normal women in the follicular phase. In contrast, levels of LH and FSH are normal or slightly reduced in hypothalamic-pituitary dysfunction. There is some overlap between women with "polycystic ovarian–like" disorders and those with hypothalamic-pituitary dysfunction. Radiographic assessment of the sella turcica is indicated in all amenorrheic women in whom both LH and FSH levels are consistently low (both <10 mIU/mL) to exclude a pituitary or parapituitary neoplasm (Chapter 224). Other pituitary functions should be evaluated in any individual with significantly impaired LH and FSH secretion. Both total testosterone and dehydroepiandrosterone sulfate levels should be measured in hirsute or virilized women. Testosterone levels greater than 200 ng/dL should lead to investigation for an androgen-producing neoplasm, most likely of ovarian origin. Dehydroepiandrosterone sulfate levels greater than 7.0 μg/mL should lead to evaluation for an adrenal neoplasm, and levels between 5.0 and 7.0 μg/mL should lead to evaluation for adult-onset congenital adrenal hyperplasia.

Hypergonadotropic Amenorrhea (Presumptive Ovarian Failure, Primary Hypogonadism, Primary Ovarian Insufficiency)

DIAGNOSIS

Differential Diagnosis

Gonadal failure may begin at any time during embryonic or postnatal development and may result from many causes. Normally, the ovaries fail at menopause, when virtually no functioning follicles remain. However, premature loss of oocytes before the age of 40 years may occur and lead to premature ovarian failure. Circulating gonadotropin levels increase whenever ovarian failure occurs because of decreased negative estrogen feedback to the hypothalamic-pituitary unit.

PATHOBIOLOGY

There are several causes for premature ovarian failure, including genetic causes (a growing list that includes karyotypic abnormalities, single gene

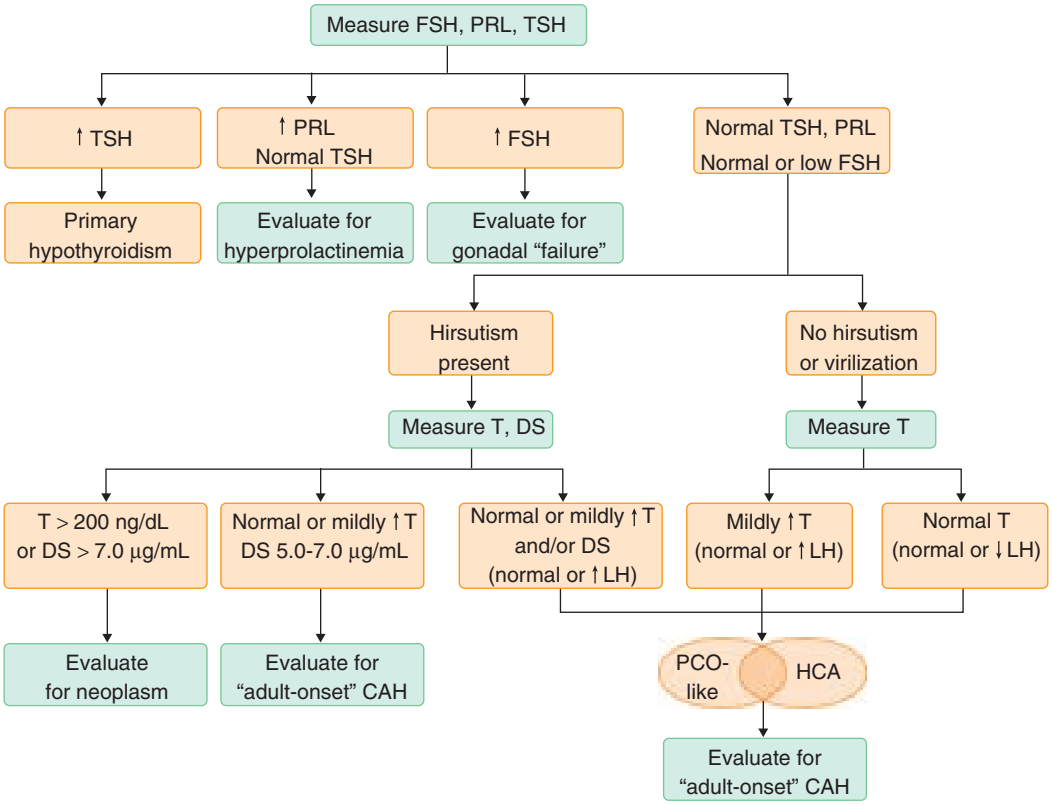

FIGURE 236-3. Biochemical evaluation of amenorrhea. This schema must be considered an adjunct to the clinical evaluation of the patient. See text for details. CAH = congenital adrenal hyperplasia; DS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; HCA = hypothalamic chronic anovulation; LH = luteinizing hormone; PCO-like = polycystic ovarian syndrome–like; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

mutations, and complex multifactorial polygenic inheritance), physical and environmental causes, and autoimmune disturbances. In addition, there may be families in which menopause begins earlier than the expected age without any further pathologic cause.

Genetic Abnormalities

Several pathologic conditions with dysgenetic gonads involve elevated gonadotropin levels and amenorrhea as well as abnormalities of the X chromosome. The term *gonadal dysgenesis* refers to individuals with undifferentiated streak gonads without any association with either extragonadal stigmata or sex chromosome aberrations. Because individuals with gonadal dysgenesis have the normal complement of oocytes at 20 weeks of fetal age but virtually none by birth, this disorder is a form of premature ovarian failure.

Turner's Syndrome

Turner's syndrome (also see Chapter 233) describes patients with streak gonads composed of fibrous stroma and four cardinal features: a female phenotype; sexual infantilism; short stature; and several physical abnormalities, sometimes including webbed neck, low-set ears, multiple pigmented nevi, double eyelashes, micrognathia, epicanthal folds, shieldlike chest with microthelia, short fourth metacarpals, increased carrying angle of the arms, and certain renal and cardiovascular defects (most commonly coarctation of the aorta and aortic stenosis) (Fig. 236-4).[11] The diagnosis can sometimes be made at birth because of unexplained lymphedema of the hands and feet. The syndrome is associated with an abnormality of sex chromosome number, morphology, or both. Most commonly, the second sex chromosome is absent (45,X). Turner's syndrome is the single most common chromosome disorder in humans, but more than 95% of such fetuses are aborted, and the incidence in newborns is approximately 1 in 3000 to 5000. Chromosome breakage and mosaicism occur as well. In mosaic individuals with a normal 46,XX cell line, sufficient follicles may persist postnatally to initiate pubertal changes and to cause ovulation so that pregnancy is possible. Deletions of the X-chromosome-linked *SHOX* gene explain many of the dysmorphic skeletal features that are present, including the short stature. It is believed that the number of phenotypic findings may be related to the percentage of cells that are 45,X. There also may be an effect of imprinting with the variation in phenotype partly explained by the parental origin of the one remaining X chromosome.

Pure Gonadal Dysgenesis

Pure gonadal dysgenesis is the term given to phenotypically female individuals with streak gonads who are of normal stature and have none of the physical stigmata associated with Turner's syndrome. Such individuals have either a 46,XX or 46,XY karyotype. The 46,XX defect may be inherited as an autosomal recessive, with 10% having associated nerve deafness. The 46,XY defect may be inherited as an X-linked recessive, with clitorimegaly occurring in 10 to 15% and gonadal tumors developing in 25% if the gonads are not removed.

Mutations in the X Chromosome Associated with Premature Ovarian Failure

Several regions of the X chromosome are now recognized to contain mutations in genes that may result in premature ovarian failure. Of particular note is the fragile X mental retardation *(FMR1)* gene. More than 5% of women with 46,XX spontaneous premature ovarian failure have mutations of the *FMR1* gene. This risk is increased if there is a family history of premature ovarian failure. A family history of fragile X syndrome, unexplained mental retardation, dementia, developmental delay of a child, or tremor-ataxia syndrome is reason for genetic counseling. Mutations in the *FMR1* gene are known to be associated with a neurodegenerative disorder. Women with mutations in the *FMR1* gene are at risk for having a child with mental retardation, should they be one of the 6 to 8% of women with premature ovarian failure who conceive spontaneously. For *FMR1*, a CGG repeat sequence occurs, with up to 60 repeats being normal. Expansion to more than 200 repeats leads to the fragile X syndrome, with the high level of repeats causing hypermethylation of the gene promoter and silencing of the gene. Female carriers of the permutation have an unstable intermediate number of repeats (i.e., 60 to 199) and the predisposition for premature ovarian failure.

Trisomy X

Trisomy X (46,XXX karyotype) is also associated with premature menopause, although many such individuals have normal reproductive lives. Premature menopause can also occur in mosaic individuals with cell lines with excess X chromosomes. When gonadal abnormalities occur in women with excess X chromosomes, they seem to occur after ovarian differentiation so that some ovarian function is possible. Only later in life do such women develop secondary amenorrhea and premature ovarian failure.

FIGURE 236-4. Adult with Turner's syndrome. This woman was seen at age 56 years by the author of the chapter (Dr. Rebar), and was case number 2, an adolescent at that time, in the original publication of Dr. Henry Turner describing the syndrome.

Known Genetic Alterations of Specific Genes

In girls with the rare syndrome of 17α-hydroxylase deficiency involving *p450c17* who survive until the expected age of puberty, sexual infantilism and primary amenorrhea occur together with elevated levels of gonadotropins (also see Chapter 233). Defects in the 20,22-lyase *(p450scc)* or aromatase *(p450arom)* enzymes may also lead to ovarian failure. Women with galactosemia also experience ovarian failure early in life, even when a galactose-restricted diet is introduced early in infancy.

Mutations of several autosomal genes result in premature ovarian failure. Included in this growing list are mutations involving *FSHR* (the FSH receptor gene), *FOXL2* (a forkhead transcription factor associated with the blepharophimosis-ptosis-epicanthus inversus syndrome), *INHA* (the inhibin-α gene), *E1F2B* (a family of genes associated with central nervous system leukodystrophy and ovarian failure), *PMM2* (the gene for phosphomannomutase), *GALT* (the gene for galactose-1-phosphate uridyltransferase), and *AIRE* (leading to the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome). Myotonic dystrophy (Chapter 421) is caused by an autosomal triple repeat mutation, like the fragile X syndrome, that is similarly associated with premature loss of germ cells from the ovary. The list of mutations associated with early ovarian failure continues to increase as the function of more genes is determined.

Mutations Involving Reproductive Hormones, Their Receptors, and Action

The resistant ovary (Savage's) syndrome occurs in young amenorrheic women who have elevated peripheral gonadotropin concentrations, normal (although immature) follicles present on ovarian biopsy, 46,XX karyotype with no evidence of mosaicism, fully developed secondary sex characteristics, and ovarian resistance to stimulation with human menopausal or pituitary gonadotropins. At least some of these women have mutations in the FSH receptor. It is probably inappropriate to use the term "resistant ovary syndrome" because it is likely that this is a heterogeneous disorder due to various genetic mutations.

Other Causes

Physical and Environmental

Irradiation and chemotherapeutic agents used to treat various malignant diseases may also cause premature ovarian failure. Ovulation and cyclic menses return in some of these patients even after prolonged intervals of hypergonadotropic amenorrhea associated with signs and symptoms of profound hypoestrogenism. In general, the younger the individual at the time of treatment, the less likely is she to have permanent ovarian failure after the completion of therapy. Rarely, mumps affects the ovaries and causes ovarian failure.

Autoimmune Disorders

Premature ovarian failure may occur in conjunction with a variety of autoimmune disorders. The most well-known syndrome (autoimmune polyglandular syndrome type 1) involves hypoadrenalism, hypoparathyroidism, and mucocutaneous candidiasis together with ovarian failure (Chapter 231). Testing for adrenal antibodies by indirect immunofluorescence will identify the 4% of women with spontaneous premature ovarian failure who have steroidogenic cell autoimmunity and are at risk for adrenal insufficiency. Thyroiditis is the most commonly associated abnormality. Antibodies to the FSH receptor have been identified in a few cases. These associations make it mandatory to rule out other potentially life-threatening endocrinopathies in young women with hypergonadotropic amenorrhea.

TREATMENT

Rx

Women with hypergonadotropic amenorrhea and ovarian failure should be treated identically whether or not they have signs of hypoestrogenism or desire pregnancy. Counseling and psychological support are indicated in women in whom the diagnosis of premature ovarian failure is made. Ovarian biopsy is not indicated to document the existence of follicles because only a small portion of each ovary can be sampled and because pregnancies have resulted in patients who had biopsy samples devoid of follicles. Estrogen replacement is warranted to prevent the accelerated bone loss known to occur in affected women (Chapter 243). The estrogen should be given sequentially with a progestin to prevent endometrial hyperplasia. Young women with ovarian failure may require twice as much estrogen as postmenopausal women for relief of signs and symptoms of hypoestrogenism. Inexplicably, women with premature ovarian failure may conceive while taking exogenous estrogen, even in the form of oral contraceptive agents, at the same rate as those not taking estrogen, so barrier contraception should be discussed if pregnancy is not desired.

Women with hypergonadotropic amenorrhea are rarely able to become pregnant. It is not clear why pregnancy may rarely occur in such women, but

the pregnancy and delivery rate is 6 to 8%. Infertility treatment of young women with hypergonadotropic amenorrhea involves hormone replacement to mimic the normal menstrual cycle and embryo transfer by use of donor oocytes. Whether women with gonadal dysgenesis should be offered pregnancy by use of donor oocytes is now the subject of debate because a markedly increased incidence of aortic rupture during pregnancy secondary to medial necrosis has been documented.

Women with Turner's syndrome contemplating pregnancy should be counseled regarding the risks. The coordination of health care of adult women with Turner's syndrome often falls to the endocrinologist because many of the complications of the disease are endocrinologic: hypothyroidism, diabetes, hypertension, obesity, osteoporosis, and hypogonadism. However, guidelines have been published about the surveillance of other multisystem conditions for which Turner's syndrome patients are at risk, including significant psychosocial problems, congenital heart disease, deafness, and gastrointestinal and hepatic disorders.

CHRONIC ANOVULATION

Chronic anovulation, the most frequent form of amenorrhea encountered in women of reproductive age, implies that functional ovarian follicles remain and that cyclic ovulation can be induced with appropriate therapy (Table 236-4). The cause of the anovulation should be determined. The pathophysiologic bases for several forms of anovulation are unknown, but the anovulation can be interrupted transiently by nonspecific induction of ovulation in most affected women. Anovulation can result in either amenorrhea or irregular (generally less frequent) menses.

Hypothalamic Chronic Anovulation

DEFINITION

Hypothalamic chronic anovulation (HCA) represents a heterogeneous group of disorders with similar manifestations. Emotional and physical stress, excessive exercise, nutritional deficiencies, weight loss, reduced body fat, and other unrecognized factors may contribute in varying proportions to the anovulation. Women with HCA have normal neuroanatomic findings.

TABLE 236-4 CAUSES OF CHRONIC ANOVULATION

- Chronic anovulation of hypothalamic-pituitary origin
  - Hypothalamic chronic anovulation
    - Psychogenic
      - Exercise associated
      - Associated with diet, weight loss, or malnutrition
      - Anorexia nervosa and bulimia
      - Pseudocyesis
  - Forms of isolated (idiopathic) hypogonadotropic hypogonadism (including Kallmann's syndrome)
  - Due to hypothalamic-pituitary damage
    - Pituitary and parapituitary tumors
    - Empty sella syndrome
    - Following surgery
    - Following irradiation
    - Following trauma
    - Following infection
    - Following infarction
  - Idiopathic hypopituitarism
  - Hypothalamic-pituitary dysfunction or failure with hyperprolactinemia (multiple causes)
  - Due to systemic diseases
- Chronic anovulation due to inappropriate feedback (i.e., polycystic ovary syndrome)
  - Excessive extraglandular estrogen production (i.e., obesity)
  - Abnormal buffering involving sex hormone–binding globulin (including liver disease)
  - Functional androgen excess (adrenal or ovarian)
  - Neoplasms producing androgens or estrogens
  - Neoplasms producing chorionic gonadotropin
- Chronic anovulation due to other endocrine and metabolic disorders
  - Adrenal hyperfunction
    - Cushing's syndrome
    - Congenital adrenal hyperplasia (female pseudohermaphroditism)
  - Thyroid dysfunction
    - Hyperthyroidism
    - Hypothyroidism
  - Prolactin or growth hormone excess
    - Hypothalamic dysfunction
    - Pituitary dysfunction (microadenomas and macroadenomas)
    - Drug induced
  - Malnutrition

ANOREXIA NERVOSA

Individuals with amenorrhea and significant weight loss should be examined for the possibility of anorexia nervosa (Chapter 219).

ISOLATED HYPOGONADOTROPIC HYPOGONADISM

Affected individuals have absence of spontaneous pubertal development. Most have functional GnRH deficiency, but some have abnormalities of gonadotropin deficiency localized to the pituitary gland.

Kallmann's syndrome is a familial disorder consisting of gonadotropin deficiency, anosmia or hyposmia, and color blindness in men or, more rarely, in women (Chapter 223). Partial or complete agenesis of the olfactory bulb is present on autopsy, accounting for use of the term *olfactogenital dysplasia.* Isolated gonadotropin deficiency in the absence of anosmia occurs as well. Sexual infantilism with a eunuchoid habitus is the clinical hallmark of this disorder, but moderate breast development may occur. Circulating LH and FSH levels are low but almost always detectable. Mutations in *KAL1*, *FGFR1*, *FGF8*, *PROK2*, *ROKR2*, *HS6ST1*, *WDR11*, or *CHD7* have been identified in a minority of patients with Kallmann's syndrome. Ovulation induction requires use of exogenous gonadotropins and HCG or pulsatile GnRH. Estrogen replacement therapy is indicated in these women until pregnancy is desired. It may not be possible to distinguish between partial isolated gonadotropin deficiency and functional HCA in all cases.

HYPOPITUITARISM

Hypopituitarism may be obvious on cursory inspection or sufficiently subtle to require endocrine testing (Chapter 224). The clinical presentation depends on the age at onset, the cause, and the nutritional status of the individual. Failure of development of secondary sex characteristics must always raise the question of hypopituitarism. Ovulation can be induced successfully with exogenous gonadotropins when pregnancy is desired and after the hypopituitarism is treated appropriately. Replacement therapy with estrogen is indicated.

HYPERPROLACTINEMIA

Galactorrhea associated with hyperprolactinemia, whatever the cause, almost always occurs together with amenorrhea caused by hypothalamic-pituitary dysfunction or failure. Many conditions can cause excess prolactin secretion (Chapter 224). A prolactinoma must be excluded. Hirsutism may be observed occasionally in association with amenorrhea-galactorrhea and hyperprolactinemia. Elevated levels of the adrenal androgens dehydroepiandrosterone and dehydroepiandrosterone sulfate may be observed and may account for the polycystic-type ovaries present in some hyperprolactinemic women.

FAILURE OF THE HYPOTHALAMIC-PITUITARY UNIT

The hypothalamic-pituitary unit may also fail to function normally in a number of stressful, debilitating, systemic illnesses that interfere with somatic growth and development. Chronic renal failure, liver disease, and diabetes mellitus are the most prominent examples.

DIAGNOSIS

Abrupt cessation of menses in women younger than 30 years who have no anatomic abnormalities of the hypothalamic-pituitary-ovarian axis and no other endocrine disturbances suggests a diagnosis of HCA. Affected individuals tend to be bright, educated, and engaged in intellectual occupations and may well give a history of psychosexual problems and socioenvironmental trauma. HCA is characterized by low to normal levels of gonadotropins and relative hypoestrogenism. Rarely, however, do affected women present with signs and symptoms of estrogen deficiency. It is important to rule out a central lesion as the cause of the hypogonadotropic hypogonadism in women who appear to have HCA.

TREATMENT

Rx

Psychological counseling or a change in lifestyle, especially for women engaged in strenuous exercise programs, may be effective in inducing cyclic ovulation and menses in women with functional HCA. Cognitive behavior therapy is effective in a proportion of women with functional HCA. For women

desiring pregnancy, ovulation can also be induced with clomiphene citrate (50 to 100 mg/day for 5 days beginning on the third to fifth day of withdrawal bleeding). Treatment with exogenous gonadotropins to induce follicular maturation followed by HCG to induce follicular rupture may be effective in women who do not ovulate in response to clomiphene. Because women with HCA have low circulating levels of leptin, investigators have given recombinant leptin and documented that ovulation may resume in some affected women. Given the heterogeneous nature of the disorder, it is not surprising that exogenous leptin is not effective in all women.

Most physicians advocate the use of exogenous gonadal steroids to prevent osteoporosis. A regimen can consist of daily oral conjugated or esterified estrogens (0.625 to 1.25 mg), ethinyl estradiol (20 μg), or micronized estradiol-17β (1 to 2 mg) or transdermal estradiol-17β (0.05 to 0.10 mg) daily, with oral medroxyprogesterone acetate (5 to 10 mg) added for the first 12 to 14 days of each month. Sexually active women can be given oral contraceptive agents as an alternative. If steroid therapy is administered, patients must be informed that the amenorrhea will probably be present when therapy is discontinued. Other physicians believe that only periodic observation is indicated, with barrier methods of contraception recommended for fertility control. Adequate ingestion of calcium should be ensured regardless of therapy. Contraception is needed for sexually active women with HCA because the functional defect is mild in these disorders and may resolve spontaneously at any time, with ovulation occurring before any episode of menstruation.

Chronic Anovulation Related to Inappropriate Feedback

DEFINITION

PCOS is a heterogeneous disorder in which there is considerable clinical and biochemical variability among affected individuals. (See PCOS as the most common cause of heterosexual pubertal development in Chapter 235.) PCOS is currently considered to exist in women with any two of the following: (1) oligo-ovulation or anovulation, (2) hyperandrogenism, or (3) polycystic ovaries on ultrasound, and in whom other etiologies have been eliminated. PCOS is the classic disorder in which the amenorrhea or oligomenorrhea results from inappropriate feedback of gonadal steroids from the ovaries.

PATHOBIOLOGY

Current evidence suggests that the hypothalamic-pituitary unit is intact and that a functional derangement, perhaps involving insulin-like growth factors (IGFs) such as IGF-I within the ovary, results in abnormal gonadotropin secretion. PCOS is characterized by insulin resistance and compensatory hyperinsulinemia. (See association between PCOS, insulin resistance, and obesity in Chapter 220.) The insulin resistance has been found in affected women of many racial and ethnic groups, implying that it is a universal characteristic and that a common defect may be present. There is increasing evidence of specific genetic abnormalities in some women with PCOS.

CLINICAL MANIFESTATIONS

Although patients usually present with amenorrhea, hirsutism, and obesity, affected women may instead complain of irregular and profuse uterine bleeding, may not have hirsutism, and may be of normal weight (Fig. 236-5). Excess androgen from any source or increased extraglandular conversion of androgens to estrogens can lead to the typical findings of PCOS. Included are such diverse disorders as Cushing's syndrome, mild congenital adrenal hyperplasia, virilizing tumors of adrenal or ovarian origin, hyperthyroidism and hypothyroidism, obesity, and primary PCOS with no other recognizable cause.

In the primary syndrome, the irregular menses, mild obesity, and hirsutism begin during puberty and typically become more severe with time, although there is increasing evidence of improvement in the years just before menopause. Obesity alone can lead to a polycystic ovarian–like syndrome, with the degree of obesity required to cause anovulation varying widely. The increase in the prevalence of obesity is leading to an increased prevalence of PCOS. All such patients are well estrogenized regardless of whether they present with primary or secondary amenorrhea or dysfunctional bleeding. LH concentrations tend to be elevated, with relatively low and constant FSH levels, but both may be in the normal range for the follicular phase of the menstrual cycle. Levels of most circulating androgens, especially testosterone, tend to be mildly elevated.

DIAGNOSIS

After exclusion of other etiologies, two of the following three are required for diagnosis of PCOS: (1) hyperandrogenism (clinical or biochemical); (2) oligo-ovulation or anovulation; (3) polycystic ovaries on ultrasound examination or at surgery.[12]

This definition is confusing to clinicians because it implies that hirsute women with polycystic ovaries on ultrasound examination who ovulate regularly should be considered to have PCOS. Moreover, it is clear that

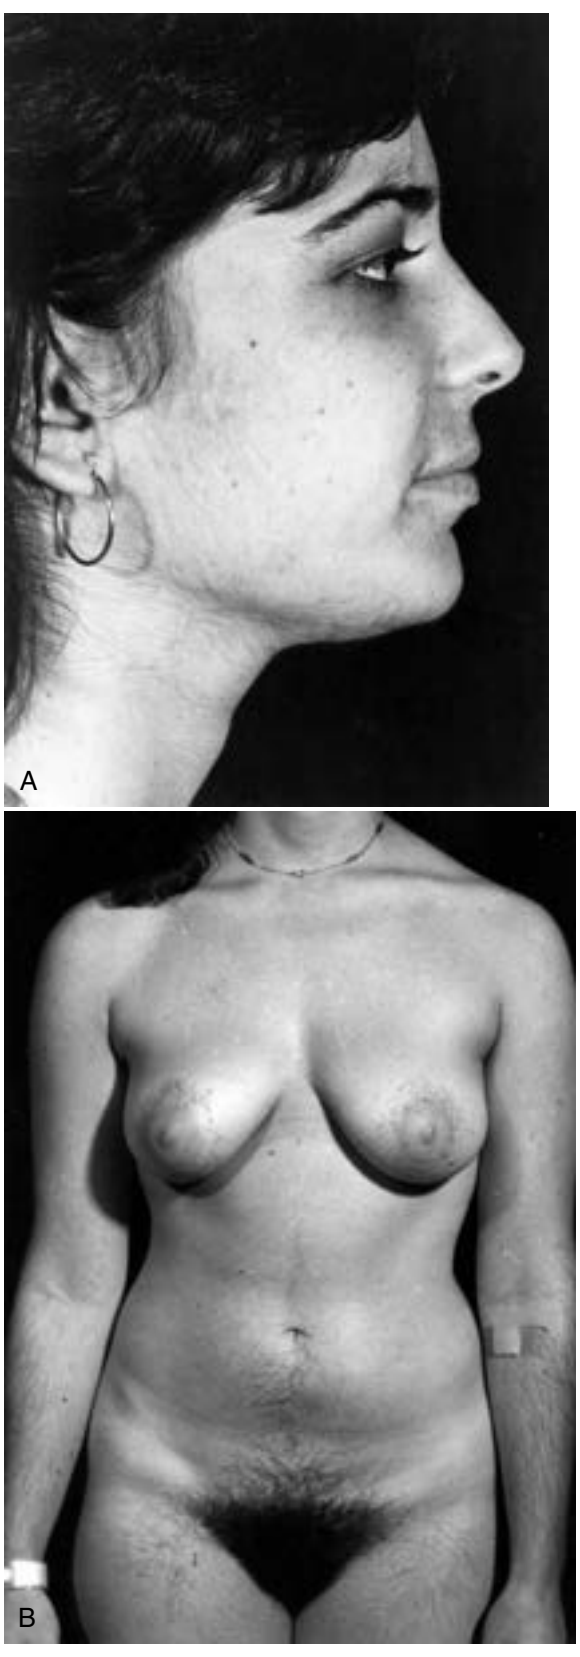

FIGURE 236-5. Adult with polycystic ovary syndrome (PCOS). This 28-year-old woman with documented PCOS had elevated luteinizing hormone levels, irregular menses, and hirsutism since puberty. Note the increased hair in the midline extending up to and above the umbilicus. Other findings (which are not necessarily abnormal) are periareolar hair and hypertrichosis of the arms.

polycystic ovaries may be identified on ultrasound examination in normal women. In any case, the aim of the diagnostic evaluation is to rule out any causes (such as neoplasms) that require definitive therapy. Hirsutism should be evaluated as detailed in Chapter 442.

A particularly severely affected subset of women present with marked obesity, anovulation, mild glucose intolerance with high levels of circulating insulin, acanthosis nigricans, hyperuricemia, severe hirsutism, and elevated circulating androgen levels. These women have hyperthecosis of the ovaries, in which the androgen-producing cells in the stromal, hilar, and thecal regions are increased greatly in number. Hyperthecosis should probably be viewed as a part of the spectrum of disorders constituting PCOS.

TREATMENT

Rx

Patients generally require therapy for hirsutism, for induction of ovulation if pregnancy is desired, and for prevention of estrogen-induced endometrial hyperplasia and cancer. No ideal therapy exists; the therapeutic approach must be individualized. The risks for metabolic syndrome, cardiovascular disease, and diabetes mellitus are increased in women with PCOS, at least in part because of the increased androgens and insulin resistance. Moreover, many women have elevated cholesterol levels.

Medical Therapy

In the anovulatory woman not desiring pregnancy who is not hirsute, therapy with intermittent progestin administration (e.g., medroxyprogesterone acetate, 5 to 10 mg orally for 10 to 14 days each month) or oral contraceptives can be provided to reduce the increased risk for endometrial carcinoma that is present in such a woman with unopposed estrogen. All women using intermittent progestin administration should be cautioned about the need for effective contraception if they are sexually active because these agents do not inhibit ovulation when they are administered intermittently.

Improvements in insulin sensitivity in women with polycystic ovaries, either through lifestyle changes (i.e., exercise and diet) or through pharmacologic intervention, consistently result in improvements in the reproductive and metabolic abnormalities. Resumption of ovulation may occur in up to 60 to 70% of affected women.

The longest and largest published experiences with any agent that improves insulin sensitivity in PCOS is with metformin, a biguanide that functions primarily by suppressing hepatic gluconeogenesis and also improves insulin sensitivity. Its use in PCOS leads to reductions in insulin and androgen levels and resumption of menses in some women. Divided doses of 1500 to 2000 mg/day have proved effective.

Some clinicians advocate giving metformin to all women with polycystic ovaries, whereas others would administer such an agent only to those with documented insulin resistance. Some clinicians also advocate giving metformin first to women who desire pregnancy and then adding an agent to induce ovulation if the metformin proves ineffective. These agents are not approved for use in pregnant women or for the induction of ovulation.

Treatment Considering Pregnancy

Oral contraceptive agents are the first line of therapy for hirsute anovulatory woman not desiring pregnancy and offer protection from endometrial hyperplasia. In women with PCOS desiring pregnancy, clomiphene citrate or letrozole can be used to induce ovulation. Letrozole is not approved for this use by the FDA, but a large multicenter randomized trial has demonstrated its superiority to clomiphene in obese women with PCOS. About 75 to 80% conceive with such therapy. In addition to insulin-sensitizing agents, other possible methods of inducing ovulation include use of exogenous gonadotropins and HCG, and laparoscopic ovarian surgery with multiple punctures of the ovary by diathermy or laser. A large clinical trial documented that clomiphene citrate is more effective than metformin in inducing ovulation and resulting in pregnancy; there was no further improvement when the two agents were used concurrently.

Surgical Treatment

Laparoscopic ovarian surgery can achieve unifollicular ovulation or make it easier for medical ovulation induction but increases the risk for development of ovarian adhesions (themselves leading to infertility). It may be successful in a small subset of women with PCOS who are geographically removed from good medical care.

Chronic Anovulation Related to Other Endocrine and Metabolic Disorders

Adrenal hyperfunction appears to cause chronic anovulation by inducing a polycystic ovarian-like syndrome secondary to increased adrenal androgen secretion. Both hyperthyroidism and hypothyroidism are associated with a variety of menstrual disturbances, including dysfunctional uterine bleeding and amenorrhea as a result of alterations in the metabolism of androgens and estrogens. These metabolic changes in turn result in inappropriate steroid feedback and chronic anovulation.

Luteinized Unruptured Follicle Syndrome

The luteinized unruptured follicle syndrome refers to the development of a dominant follicle without its subsequent disruption and release of the ovum. The abnormality can be diagnosed by ultrasonography or by the absence of evidence of ovulation when the ovary is viewed at laparoscopy. The disorder occurs infrequently and is not a significant cause of infertility. Menstrual cycles in which no ovum is released are characterized by presumptive evidence of ovulation, including biphasic basal body temperatures, secretory endometrium, normal LH surge, and normal progesterone production in the luteal phase.

Luteal Phase Dysfunction

PATHOBIOLOGY

Progesterone secretion in the luteal phase may be reduced in duration (termed *luteal phase insufficiency*) or in amount (termed *luteal phase inadequacy*). More rarely, the endometrium may be unable to respond to secreted progesterone because of the absence of progesterone receptors. These disorders represent causes of infertility (because of inability of fertilized ova to implant) in less than 5% of infertile couples. Abnormalities of the follicular phase, especially in the frequency of gonadotropin pulses, may account for most luteal phase defects. Luteal phase defects may also occur sporadically in normally ovulating women.

DIAGNOSIS

Luteal phase dysfunction may be associated with several clinical entities, including mild or intermittent hyperprolactinemia, strenuous physical exercise, inadequately treated 21-hydroxylase deficiency, and recurrent miscarriage. Luteal dysfunction occurs more commonly at the extremes of reproductive life and in the first menstrual cycles after full-term delivery, abortion, or discontinuation of oral contraceptives. It may also occur during ovulatory cycles induced with clomiphene citrate or exogenous gonadotropins and HCG.

TREATMENT

Rx

Treatment of luteal dysfunction is controversial. Any underlying defect should be treated. If subsequent luteal function depends on prior follicular development, modification of follicular development with either clomiphene citrate (25 to 100 mg daily by mouth for 5 days beginning on cycle day 3 to 5) or FSH (75 to 300 IU intramuscularly for 3 to 5 days beginning on cycle day 3 to 5) can be used; HCG (2500 to 5000 IU intramuscularly at 2- to 3-day intervals beginning with the shift in basal body temperature) or progesterone (12.5 mg intramuscularly in oil daily or 25 mg twice a day as rectal or vaginal suppositories) can be used as well. Bromocriptine may correct the abnormality in individuals with hyperprolactinemia. Synthetic progestational agents should not be used to treat luteal phase defects because of their possible association with congenital anomalies. Furthermore, the synthetic progestins produce an abnormal endometrium. None of these agents has been shown to increase the pregnancy rate.

INFERTILITY

DEFINITION

The World Health Organization (WHO) has defined *infertility* as "a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse." *Sterility* is total inability to reproduce. More than 10% of couples in the United States seek medical assistance for infertility.

The requirements for pregnancy to occur are several:

- The male must produce adequate numbers of normal, motile spermatozoa.
- The male must be capable of ejaculating the sperm through a patent ductal system.
- The sperm must be able to traverse an unobstructed female reproductive tract.
- The female must ovulate and release an ovum.

TABLE 236-5 CAUSES OF INFERTILITY AND THEIR APPROXIMATE INCIDENCE (WHERE AVAILABLE)*

Male factors (40%)
Decreased production of spermatozoa
Varicocele
Testicular failure
Endocrine disorders
Cryptorchidism
Stress, smoking, caffeine, nicotine, recreational drugs
Ductal obstruction
Epididymal (after infection)
Congenital absence of vas deferens
Ejaculatory duct (after infection)
After vasectomy
Inability to deliver sperm into vagina
Ejaculatory disturbances
Hypospadias
Sexual problems (i.e., impotence), medical or psychological
Abnormal semen
Infection
Abnormal volume
Abnormal viscosity
Immunologic factors
Sperm-immobilizing antibodies
Sperm-agglutinating antibodies
Female factors
Fallopian tube disease (20-30%)
Pelvic inflammatory disease or puerperal infection
Congenital anomalies
Endometriosis
Secondary to past peritonitis of nongenital origin
Amenorrhea and anovulation (15%)
Minor ovulatory disturbances (<5%)
Cervical and uterine factors (10%)
Leiomyomas and polyps
Uterine anomalies
Intrauterine synechiae (Asherman's syndrome)
Destroyed endocervical glands (after surgery or after infection)
Vaginal factors (<5%)
Congenital absence of vagina
Imperforate hymen
Vaginismus
Vaginitis
Immunologic factors (<5%)
Sperm-immobilizing antibodies
Sperm-agglutinating antibodies
Nutritional and metabolic factors (5%)
Thyroid disorders
Diabetes mellitus
Severe nutritional disturbances
Idiopathic or unexplained (<10%)

*World Health Organization definition of infertility: ≥12 months of regular unprotected sexual intercourse. In about one third of couples, more than one cause contributes to the infertility.

- The sperm must be able to fertilize the ovum.
- The fertilized ovum must be capable of developing and implanting in appropriately prepared endometrium.

In approximately 40% of cases, infertility is caused by the male (Table 236-5). In one third of couples, more than one cause contributes to the infertility.

Peak age for fertility in the female is 25 years. For nulliparous women of this age, the average time during which unprotected intercourse occurs until conception is 5.3 months. For parous women, the average duration of intercourse until conception is 2.7 months. The reproductive performance of couples is influenced by the ages of the female and male partners, the frequency of intercourse, and the length of time the couple has been attempting to conceive. There is a decline in both female and male reproductive performance after the age of 25 years.

DIAGNOSIS

Couples who complain of infertility merit evaluation regardless of the length of infertility. Evaluation is warranted in all women after 12 months and in women 35 years of age or older after 6 months of regular unprotected intercourse.

The evaluation begins with a detailed history obtained from both partners and physical examinations of both individuals. If possible, the couple should be seen together. Each couple should be questioned together and separately because separate interviews may uncover information that would not be imparted in the presence of the partner.

Initial evaluation for infertility includes assessment of semen; documentation of ovulation by basal body temperature, serum progesterone determination 6 to 8 days before menses, serum thyroid hormone, or (rarely) endometrial biopsy less than 3 days before onset of menses; and evaluation of the female genital tract by hysterosalpingography or sonohysterography. Diagnostic laparoscopy with tubal dye instillation may be performed if results of all previous tests are normal because 30 to 50% of women are found to have endometriosis or tubal disease on surgical evaluation; alternatively, patients with initial normal findings may be merely treated as having idiopathic infertility.

TREATMENT Rx

Treatment must be predicated on the findings of the infertility evaluation. Abnormalities of sperm are difficult disorders to treat. Low sperm count or poor motility is best treated either by donor insemination or in vitro fertilization with intracytoplasmic injection of a single viable sperm into each oocyte. Obstruction of the fallopian tubes may be amenable to surgical intervention, but success rates are often greater with in vitro fertilization. Endometriosis causing infertility may be treated by surgery or various suppressive drugs as indicated; however, here, too, in vitro fertilization may be indicated.

Induction of ovulation is one of the most successful therapies when used in anovulatory women.

Induction of ovulation should never be attempted until serious disorders precluding pregnancy are ruled out or treated. Furthermore, ovulation induction should not be used in women with ovarian failure because they are unresponsive to any form of ovulation induction.

Clomiphene citrate is the agent that usually induces ovulation most easily. Clomiphene should be used in individuals without hyperprolactinemia who have the ability to release LH and FSH. A typical course of clomiphene therapy is begun on the third to fifth days after either spontaneous or induced uterine bleeding. The initial dosage is 50 mg daily for 5 days. Clomiphene appears to act as an antiestrogen and stimulates gonadotropin secretion by the pituitary gland to initiate follicular development. If ovulation is not achieved in the first cycle of treatment, the daily dosage is increased to 100 mg. If ovulation is still not achieved, dosage is increased in a stepwise fashion in 50-mg increments to a maximum of 200 to 250 mg daily for 5 days. The highest dose should be continued for 3 to 6 months before the patient is regarded as unresponsive to clomiphene. The quantity of drug and the length of time that it can be used, as suggested here, are greater than those recommended by the manufacturers and the FDA but conform to published series. Despite absence of FDA approval, letrozole is being used increasingly in place of clomiphene.

The ovulatory surge of LH may occur 5 to 12 days (average, 7 days) after the completion of the last day of clomiphene treatment. Couples are advised to have intercourse every other day during this interval. Ovulation can be documented by monitoring changes in basal body temperature or preferably by measuring serum progesterone 14 days after the last clomiphene dose. Menses should occur after 3 weeks. Withdrawal bleeding with progestin can be induced if the patient fails to bleed within 4 weeks of therapy and if a serum HCG level documents that the patient is not pregnant. Testing the urine for an LH surge may also be useful in timing ovulation.

Some clinicians give 5000 to 10,000 IU of HCG intramuscularly 7 days after the last day of clomiphene therapy to trigger ovulation, but this approach has not been established to increase effectiveness. The administration of HCG, however, does serve to time ovulation and may be helpful in selected couples. Ovulation can be expected to occur approximately 36 hours after HCG administration.

Of appropriately selected patients, 75 to 80% ovulate, and 40 to 50% can be expected to become pregnant. About 15% of pregnancies can be expected with each ovulatory cycle. The multiple pregnancy rate is about 8%, with almost all being twins. The incidence of congenital anomalies is not increased.

Side effects of clomiphene are uncommon and rarely serious. The most serious ones include vasomotor flushes (10%), abdominal discomfort (5%), breast tenderness (2%), nausea and vomiting (2%), visual symptoms (1.5%), and headache (1%). Ovarian enlargement may occur but is rare (5%). Concern has been raised about the potential for clomiphene to increase the risk for epithelial ovarian cancer. The bulk of the evidence now indicates that clomiphene does not increase this risk.

The addition of dexamethasone, 0.5 mg orally at bedtime, to blunt the nighttime secretion of adrenocorticotropic hormone may be useful in hyperandrogenic women who fail to ovulate in response to clomiphene. Other individuals who do not respond to clomiphene typically require exogenous gonadotropins and HCG or perhaps pulsatile GnRH to induce ovulation.

Both bromocriptine and cabergoline are effective in inducing ovulation in hyperprolactinemic women. The drug should be stopped when pregnancy is confirmed. Ovulatory menses and pregnancy are achieved in about 80% of patients with galactorrhea and hyperprolactinemia. Most women with prolactin-secreting pituitary tumors remain asymptomatic during pregnancy. It is rare for a patient with either a microadenoma or a macroadenoma to develop a problem related to the tumor that affects either the mother or the fetus during pregnancy. Monitoring during pregnancy need consist only of questioning the patient about the development of visual symptoms and headaches. Formal assessment of visual fields and computed tomography or magnetic resonance imaging should be carried out in any patient experiencing suggestive symptoms. Symptoms generally abate with institution of therapy with a dopamine agonist. No adverse effects of dopamine agonists on fetuses or pregnancies have been reported. Concerns have been raised that ergot-derived dopamine agonists, in the large doses used in the treatment of Parkinson disease, may increase the risk for cardiac valve regurgitation. Although there is no evidence of risk in women treated with much lower doses for hyperprolactinemia, they should be counseled about this potential side effect.

Several preparations of purified and synthetic biochemically engineered gonadotropins for use for induction of ovulation now exist. Synthetic preparations consist entirely of FSH, whereas most purified preparations contain some LH as well. Each vial typically contains 75 IU of gonadotropin. Individuals with gonadotropin deficiency require a preparation containing some LH. Exogenous gonadotropins are typically administered at doses of two to four vials (intramuscularly or subcutaneously, depending on the preparation) for 5 to 12 days to achieve follicular development as monitored by ultrasonography and serum or urinary estradiol concentrations; HCG, 5000 to 10,000 IU, is administered as a single intramuscular dose when follicular maturation is apparent. The HCG should be withheld if more than three follicles mature together. GnRH analogues are now being used to suppress endogenous follicular activity before initiation of therapy with exogenous gonadotropins and continued until HCG is given in older women and those with poor responses to exogenous gonadotropins. Use of the analogues necessitates administration of larger doses of exogenous gonadotropins. Success rates, however, appear to be somewhat improved with this combined therapy. Because of the expense and the complication rate, thorough evaluation should be carried out to exclude other causes of infertility before exogenous gonadotropins and HCG are used. Ovulation can be induced in almost 100% of patients, but pregnancy occurs in only 50 to 70%. There is no increased risk for congenital anomalies with exogenous gonadotropins and HCG. The rate of multiple pregnancies with exogenous gonadotropins and HCG may approach 30%, with 5% being triplets or more.

Ovarian hyperstimulation (*ovarian hyperstimulation syndrome*, or OHSS) is the major side effect and may be life-threatening. The ovaries enlarge remarkably, and multiple follicle cysts, stromal edema, and multiple corpora lutea are present. There is a shift of fluid from the intravascular space into the abdominal cavity with resultant hypovolemia and hemoconcentration. The cause of the ascites is unknown. The most serious complications of OHSS may include thromboembolism, renal failure, adult respiratory distress syndrome, and hemorrhage from ovarian rupture. Treatment is conservative, with monitoring of fluid and electrolyte status. Pelvic examinations should not be performed for fear of rupturing the ovaries. The hyperstimulation generally resolves slowly during about 7 days but lasts longer if the cycle results in pregnancy.

Clomiphene citrate or exogenous gonadotropins together with intrauterine insemination of spermatozoa may be used in women with unexplained infertility as so-called controlled ovarian hyperstimulation (COH). The intent is to stimulate several oocytes to be ovulated, but multiple (sometimes high-order) gestations are a significant risk. A randomized trial has noted that the risk for multiple gestation and the costs are reduced if COH with gonadotropins is not used and patients are advanced immediately to treatment by in vitro fertilization.

Assisted Reproductive Technologies

The assisted reproductive technologies, in which by definition both eggs and sperm are handled outside of the body, are being used commonly to treat infertile couples with tubal disease, endometriosis, oligospermia and azoospermia, sperm antibodies, and unexplained infertility. The procedure consists of in vitro fertilization and several variants. In vitro fertilization involves ovarian hyperstimulation, oocyte retrieval, fertilization, embryo culture, and embryo transfer. Ovarian hyperstimulation with clomiphene citrate and exogenous gonadotropins, gonadotropins alone, or a GnRH agonist or antagonist plus gonadotropins typically causes 1 to 20 oocytes to mature, depending on the patient's age and ovarian "reserve." After follicular growth is judged sufficient by ultrasound examination, HCG is given to induce final follicular maturation. About 34 hours after HCG administration, the oocytes are retrieved by direct needle puncture of each follicle, usually transvaginally with ultrasound guidance. The oocytes are then inseminated in vitro with washed sperm, or a single sperm is injected directly into a single egg (so-called intracytoplasmic sperm injection). The embryos are cultured for about 40 to 120 hours, after which one or more embryos are transferred to the uterine cavity. Embryos may be cultured to the blastocyst stage (at 120 hours) before transfer. Additional embryos can be frozen in liquid nitrogen for transfer in a subsequent natural cycle. The success rate is most dependent on the age of the woman. In the United States, the percentage of cycles resulting in live births ranges from 40.1% in women younger than 35 years to 12.2% in women aged 41 to 42 years. Approximately 30% are twins and 1% are triplets or higher-order multiples.

It is now possible to test the early embryo for genetic abnormalities by removal of either a single cell (i.e., blastomere) or a polar body from the embryo in vitro and testing it with probes by fluorescent in situ hybridization, with the assistance of polymerase chain reaction, or most recently by comparative genomic hybridization. Identification of normal and abnormal embryos allows only normal embryos to be transferred in families with recognized and testable genetic abnormalities.

SEXUAL FUNCTION AND DYSFUNCTION

Sexual Function

DEFINITION

Sexual responses historically have been divided into four phases: excitement, plateau, orgasm, and resolution. With sexual arousal and excitement, vasocongestion and muscle tension increase progressively, primarily in the genital region, manifested by vaginal lubrication in the female. The lubrication is due to formation of a transudate in the vagina. Sexual excitement is initiated by any of a variety of psychogenic or somatogenic sexual stimuli and must be reinforced to result in orgasm. With continued stimulation, the excitement phase increases in intensity into a plateau phase during which a high state of sexual interest is maintained. The plateau phase may be short or long, and it is from this phase that an individual can shift to orgasm. The orgasmic phase tends to be brief and is characterized by rapid release from the developed vasocongestion and muscle tension. The orgasmic release is also known as the climax because peak psychological and physical intensity is achieved and there is an attendant feeling of satisfaction. Copious secretions and transudate may flow during orgasm in women. Characteristic genital and extragenital responses occur during these phases. Estrogens magnify the sexual responses, but responses may occur in estrogen-deficient women. For women, these changes occur in the breasts and in the pudendal region and are variable from one response cycle to another. For some women, excitement proceeds quickly through plateau to orgasm, and orgasm is explosive and accompanied by vocalization and involuntary contractions of the pelvic skeletal muscles. For other women, the responses are slow in building, controlled in amplitude, and long lasting. For a few women, orgasm never occurs; for many, it is intermittently absent.

The somatic sensate focus enabling orgasmic release is variable and may include stimulation of the breasts, vagina, or clitoris. The psychological aspect of coitus may involve concentration on the current partner or act or fantasies about other times and persons. Although orgasms may vary in physiologic intensity, what is important is psychological satisfaction. Satisfaction for both men and women may be had without orgasm.

Many clinicians have noted several limitations of this traditional human sex response cycle. Many clinicians and researchers see the cycle as circular with stimuli of different types leading to arousal. Clinicians in this field now have extended this theory to include desire and arousal. Women seek sexual experiences for intimacy as well as for sexual gratification. Women may be receptive to or seek out sexual stimuli to enhance intimacy. Biologic and psychological factors contribute to the processing of these stimuli and can enhance arousal and desire simultaneously.

Sexual Dysfunction

Women may seek consultation because of disturbances in normal sexual arousal or orgasm.[13] Such sexual dysfunction may be due to either organic or functional disturbances.

A variety of diseases affecting neurologic function, including diabetes mellitus and multiple sclerosis, may prevent sexual arousal. So, too, may local pelvic disorders, such as endometriosis and vaginitis, which cause dyspareunia and lead to sexual avoidance. Estrogen deficiency causing vaginal atrophy and dyspareunia is a relatively common cause of sexual dysfunction. Debilitating systemic diseases such as malignant disease may also affect sexual function indirectly.

In many cases, the cause of sexual dysfunction is psychological.[14] For instance, vaginismus involves involuntary contractions of the muscles

surrounding the introitus and leads to dyspareunia. It is a conditioned response engendered by a previous real or imagined traumatic sexual experience. Feelings of guilt (caused by incest or rape, as examples), of inadequacy (caused by hysterectomy or mastectomy), or of depression or anxiety may lead to failure to be aroused. Failure to achieve orgasm may be viewed as a dysfunction if the woman is frustrated or dissatisfied.

TREATMENT

Rx

Treatment of sexual dysfunction should eliminate functional causes and provide the patient, often together with her partner, with appropriate psychological counseling.[15] Behavioral modification is effective in treating many women with psychological sexual dysfunction. In one randomized trial, self-reported sexual satisfaction was increased in women treated with testosterone.[16] However, dosing guidelines are not clear, and the therapy cannot be considered standard care based on current evidence.

REVIEW QUESTIONS

1. Which of the following is the main biologic mediator that causes menstrual cramping?

A. Follicle-stimulating hormone (FSH)
B. Prostaglandin
C. Estradiol
D. Inhibin
E. Aromatase

Answer: B Prostaglandins increase in concentration during the luteal phase, and their release results in greater and/or prolonged uterine contraction. This excessive contraction results in ischemic pain. Prostaglandin synthesis inhibitors decrease prostaglandin concentration and thereby alleviate dysmenorrhea. FSH stimulates granulosa cell production of estradiol and is predominant before ovulation. Estradiol is a gonadal hormone involved in the development of female secondary sexual characteristics and reproduction but does not induce menstruation or menstrual pain. Inhibin is released from the follicle to downregulate FSH production by the pituitary. Aromatase converts testosterone to estradiol. (See Cyclic Changes in Target Organs: Endometrium; and Harel Z. Dysmenorrhea in adolescents and young adults: an update on pharmacological treatments and management strategies. *Expert Opin Pharmacother.* 2012;13:2157-2170.)

2. Which of the following directly regulates the secretion of gonadotropin-releasing hormone (GnRH)?

A. Endogenous opiates
B. Follicle-stimulating hormone (FSH)
C. Luteinizing hormone (LH)
D. Follistatin
E. Antimüllerian hormone

Answer: A GnRH secretion is regulated by neurotransmitters and neuromodulators, including endogenous opiates (see Neuroendocrine Regulation of the Ovaries). FSH and LH release are regulated by GnRH, but there is no direct feedback mechanism with these molecules. Instead, FSH and LH act on the ovary to produce gonadal hormones, which can impact GnRH release. Follistatin binds to activin and regulates activin's activity on gonadotropin production but does not itself directly regulate GnRH. Antimüllerian hormone is produced by the follicle and can be used as a marker for ovarian reserve but does not regulate GnRH secretion.

3. Endometriosis is most likely to cause which of the following?

A. Menorrhagia
B. Premenstrual syndrome
C. Dyspareunia
D. Ovarian hyperstimulation
E. Amenorrhea

Answer: C Rationale: Endometriosis is defined as the presence of endometrial glands and stroma outside of the uterine cavity, and typical clinical characteristics are infertility and dysmenorrhea. Endometriosis-related peritoneal scarring can also result in dyspareunia and dyschezia. (See Abnormalities of the Reproductive Years: Dysmenorrhea and Endometriosis: Definition.) Endometriosis does not significantly influence menstrual flow and therefore does not cause menorrhagia or amenorrhea. Premenstrual syndrome occurs before menstruation and has not been demonstrated to by caused by endometrium outside of the uterine cavity. Ovarian hyperstimulation occurs typically with exogenous gonadotropin use, resulting in massive enlargement of the ovaries and ascites. It is not caused by endometriosis.

4. Among women with hypergonadotropic amenorrhea (premature ovarian failure or insufficiency), what is the lifetime likelihood of delivering a live-born progeny using their own oocytes?

A. Same as in normal population
B. 1 in 2
C. 1 in 5
D. 1 in 15
E. Less than 1 in 10,000

Answer: D The lifetime likelihood of delivering a live-born child using their own (e.g., autologous) oocytes is 6 to 8% in this patient population. (See Hypergonadotropic Amenorrhea: Treatment.) As a result, women with this condition should not be managed expectantly, regardless of age. Standard therapies directed at inducing ovulation (clomiphene citrate, letrozole, or gonadotropins) are also not indicated because these women are already exposed to high gonadotropins and are unlikely to respond to exogenous sources. Should such patients desire pregnancy, the most effective intervention requires the use of donor oocytes.

5. Which of the following is the infertility treatment most likely to cause triplet pregnancy?

A. Clomiphene citrate
B. Letrozole
C. Bromocriptine
D. Controlled ovarian stimulation with intrauterine insemination
E. Controlled ovarian stimulation with in vitro fertilization

Answer: D Clomiphene citrate induces ovulation by inhibiting estradiol-mediated feedback, thereby increasing endogenous gonadotropins. Although twinning is common (8%), triplets or more are rare. Letrozole is an aromatase inhibitor that decreases estradiol production and thereby decreases estradiol-mediated negative feedback on gonadotropins in a manner similar to clomiphene. Again, there is minimal evidence of high-order multiple pregnancies. Bromocriptine is used in hyperprolactinemic women to induce normal ovulation, and multiple pregnancies are rare. When exogenous gonadotropins are used without oocyte retrieval, there is a risk for fertilization of multiple mature oocytes, resulting in a twin rate of 30% and a higher order multiple rate of 5%. (See Infertility: Treatment.) When oocytes are retrieved, and the number of embryos transferred to the uterus is limited, the risk for higher order multiples drops to 1%.

237

APPROACH TO WOMEN'S HEALTH

KAREN FREUND

An approach to the care of women must go beyond an understanding of differences in the incidence of disease between men and women. Providers need to consider the impact of sex differences (those based on genetic and hormonal differences) and gender differences (those attributable to the roles men and women are ascribed in society). Therapeutic decisions should take into account both genetic and environmental differences in the presentation of disease and the effectiveness of therapeutic options, the patient's reproductive life stage, comorbidities, and social and cultural contexts of care. Empirical evidence about care for women has expanded since 1994, when the National Institutes of Health required the inclusion of women as research subjects. The increased number of women participating in clinical research, coupled with initiatives through the Office on Research and Women's Health, has led to a broad expansion of knowledge; however, there is a continued need for gender-specific analyses of data to evaluate the impact of any therapeutic intervention.

LIFESPAN GROUPS

Many important women's health issues are linked to the social, psychological, and biologic context at certain ages and stages of life. When considering both preventive care and common causes of mortality and morbidity, these lifespan stages provide a context for organizing care (Table 237-1).

For most women, young adulthood (15 to 44 years) is marked by social transitions in family structure, such as forming one's own family and parenting, and entering the work force. Mortality rates are low, and health visits can focus on behavioral decisions that will influence the risk for future disease, such as those pertaining to sexual behavior, smoking, alcohol and drug use, diet, and exercise. Major sources of morbidity include intentional and unintentional injury, including interpersonal violence (Chapter 241) and motor vehicle crashes. HIV is a leading cause of morbidity and mortality in this age group. Depression and anxiety are common in this and all life stages. Reproductive issues are considered in most therapeutic decisions.

The middle years (ages 45 to 65 years) continue to be influenced by behavioral decisions, especially diet, exercise, and alcohol and substance use. The social context includes role changes as children reach adulthood; caregiving responsibilities are for dependent children and possibly grandchildren, as well as aging parents. The menopausal transition may be accompanied by new symptomatic concerns. Common causes of morbidity, including diabetes and obesity, now reflect earlier behavioral decisions. Cancer is the leading cause of mortality.

Health issues in older women (65+ years) may occur in the context of loss of function and independence, and because women commonly survive their male partners, they are more likely at this stage of life to be single and possibly more isolated. Cardiovascular disease is the major cause of mortality, followed by cancer, cerebrovascular disease, chronic obstructive lung disease, and pneumonia. Loss of independence is related to cognitive decline, osteoarthritis, osteoporotic fractures, and incontinence.

HEALTH DISPARITIES AMONG WOMEN

It is critical to consider the racial and ethnic differences in outcomes for most common causes of mortality and morbidity when addressing the health status of women. American women with a minority racial or ethnic affiliation, including those of African descent (whether born in the United States or abroad), women from many Asian and Pacific Island nations, Native Americans, and women of Latino background, share poorer outcomes for a wide variety of conditions. This broad finding of poorer outcomes across many diverse ethnic and racial groups points away from specific genetic differences in these populations and toward social determinants of health. Minority racial and ethnic affiliation is correlated with lower educational attainment, lower income, residence in neighborhoods with higher crime and more environmental health hazards, less access to comprehensive health insurance, and less access to care even when insured. Common recommendations for health promotion, including a diet low in fats and processed sugars and high in whole grains, fruits, and vegetables, along with regular exercise, such as walking, may be difficult to follow in high-crime neighborhoods or in those without markets offering a variety of affordable, nutritious food options. Barriers to health care access and poor adherence to medical therapy are more common in low-income women. For instance, they may have difficulty scheduling appointments that do not interfere with their work schedules or unpaid time off from clerical or service jobs. The need to care for dependent children or elders may interfere with women's ability to address their own health care needs. Lack of health literacy and cultural barriers can create additional barriers (Chapter 5).

COMMON CAUSES OF MORTALITY IN WOMEN

Cardiovascular Disease

Cardiovascular disease (CVD; Chapter 52) is the overall leading cause of death in women. However, because CVD-related death occurs most often in women older than 65 years, its impact is often under-recognized or underestimated. Racial ethnicity plays a large role in the risk for CVD; African American women have much higher rates of CVD and death from CVD than any other racial or ethnic group, and Latinas and Asian women also have higher rates of CVD and CVD death than white populations.

The incidence rate of CVD in women lags 10 years behind that of men from ages 40 through 70 years; that is, a 65-year-old woman has a similar risk to a 55-year-old man. There is no abrupt increase in CVD risk at menopause in women, suggesting that menopausal changes in estrogen or progesterone do not account for this sex difference. Furthermore, randomized clinical trials have confirmed that hormone therapy in women does not prevent CVD and is not indicated for CVD prevention. Re-analysis of the Women's Health Initiative confirmed the increased risk for CVD *with* hormone therapy, even when treatment is initiated within 10 years of menopause.[1] There has been some controversy about the impact of calcium supplementation for bone and health on increased risk for myocardial infarction, but not CVD deaths. However, most observational studies do not find an association in women, and calcium and vitamin D supplementation are still recommended for women regardless of CVD risk (Chapter 243).[2-4] Other risk factors for CVD in women are the same as those in men: elevated lipids, lack of physical activity, obesity, smoking, hypertension, and diabetes. Women with diabetes have the same risk for CVD as men of the same age with diabetes. Because smoking rates in current cohorts of young women continue to increase, cigarette smoking continues to be an important behavioral risk factor for CVD, especially in younger women, American Indian women, and women with low incomes and low educational attainment. The incidence of many known risk factors, including obesity, hypertension, and hypercholesterolemia, is greater in African American women than in white women. Furthermore, data suggest that women are less likely to receive risk factor reduction therapy, reflecting an inertia caused by misperception by clinicians and patients of heart disease risk.

The presentation of coronary disease in women differs from that in men. Although chest pain is the most common presentation in women, atypical and noncardiac pain is a more common presentation in women than in men, and fewer women have typical chest tightness or pressure as their presenting complaint. For this and other reasons, there are delays in seeking and provision of emergency care at all steps from home to arrival to hospital for women compared with men, which can limit some therapeutic options and increase the severity of disease complications, including congestive heart failure.

The guidelines for the management of lipid disorders (Chapter 206) do not differ per se by gender, but do account for gender differences in the risk models used to guide therapy. The decision to begin statin therapy is based on the absolute low-density lipoprotein (LDL) level as well as age and the presence of diabetes. High intensity statin therapy is recommended for women with clinical vascular disease under age 75 years, for primary prevention when LDL is greater than 190 mg/dL, or for women with a 10 year calculated risk of atherosclerotic cardiovascular disease greater than 7.5%.

Medical management is similar for men and women with acute coronary syndromes, including unstable angina and acute myocardial infarction (Chapter 72). The use of aspirin, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, heparin, and thrombolytic therapy and recommendations for noninvasive testing are the same for women and men. Randomized controlled trial data show that low-risk women with unstable angina or non–ST segment elevation myocardial infarction do not benefit from early revascularization and that medical management is indicated.

TABLE 237-1 IMPORTANT HEALTH ISSUES FOR WOMEN THROUGH THE LIFESPAN

	AGES		
ISSUE	***15-44 yr***	***45-65 yr***	***65+ yr***
Behavioral issues	Risk behaviors Sexual behavior Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Alcohol and drug use Exercise Diet	Risk behaviors Smoking Exercise
Social roles	Entering work force Relationship transitions Parenting	Caregiving to several generations Transitions in family and work environments	Losses and social isolation
Reproductive issues	Reproductive health issues	Menopause transition	
Injury	Intentional and unintentional interpersonal violence Motor vehicle crashes		Falls
Common causes of mortality and morbidity	Depression Anxiety HIV/AIDS	Cancer Obesity Diabetes Depression Anxiety	Cardiovascular disease Cancer Cognitive decline Osteoporosis Osteoarthritis Incontinence Depression Anxiety

Type 2 Diabetes

The rates of type 2 diabetes (Chapter 229) continue to rise, with a greater risk in women who are overweight or obese and physically inactive. Rates are higher in many racial and ethnic groups than among white women, including African Americans, Asians, Native Americans, and Latinas. No randomized clinical trials to date on low- to moderate-risk populations have shown a mortality benefit of screening, and most guidelines do not currently recommend universal screening. Screening women for known risk factors (e.g., hypertension [blood pressure >130/85 mm Hg], obesity, family history) is recommended by some. For women who develop gestational diabetes (Chapter 239), the risk of developing type 2 diabetes later in life increases five-fold; therefore, screening with hemoglobin A_{1C} 6 to 12 weeks postpartum and every 3 years thereafter is recommended by some.

The incidence of diabetes is rising in women at younger ages, with significant perinatal implications. Ongoing discussion of fertility control and family planning is critical in diabetic women with childbearing potential. Tight glycemic control before conception and through the first trimester is critical to reduce the risk for birth anomalies, and it is important later in pregnancy to reduce the risk for adverse fetal events, including macrosomia (large for gestational age) and preterm birth (Chapter 239). Ideally, women planning a pregnancy should switch from oral agents to insulin, with home glucose monitoring for tight control (Table 237-2).

Cancer

Cancer is the leading cause of death in women 40 through 65 years, and it is the leading cause of years of life lost in women younger than 65. Breast cancer (Chapter 198) is the most common type of cancer and the second leading cause of cancer death in women, although most women who develop breast cancer do survive. Studies indicate that many women significantly overestimate their personal risk for the disease. The lack of understanding of the cause of most breast cancers and the limitations of the imaging modalities used as screening tests have hampered efforts at breast cancer control. Recent data suggesting overdiagnosis of breast cancer, especially in women 40 to 50 years of age, has prompted growing interest in joint decision making regarding screening in this age group.[5] After decades of an increasing incidence of breast cancer in the United States, incidence rates have fallen in the past 12 years. The cause of this decline is not understood; reduced use of postmenopausal hormone therapy and recent declines in screening rates have both been implicated.

Lung cancer (Chapter 191) is now the leading cause of cancer death in women, and rates continue to rise, commensurate with the number of women who took up smoking in the 1940s and 1950s and the lower rates of smoking cessation in women compared with men. Most lung cancers are smoking related, although women are more likely than men to have lung cancers that are not tobacco related. Low-dose chest tomography has been shown to reduce death from lung cancer in those with greater than a 30 pack-year smoking history who are current smokers or quit within the previous 15 years; the harms of are false-positive scans and potential overdiagnosis.■ The National Lung Screening Trial enrolled 41% women but has not at this time provided any gender-specific analyses. An analysis based on quintiles of lung cancer risk, including sex, showed female sex associated with a lower risk for cancer. This subanalysis suggests that women may benefit from screening less than men, independent of pack years of smoking. Because of the harms of screening, smoking cessation efforts continue to be recommended as the most effective strategy to prevent lung cancer.

Colorectal cancer (Chapter 193) has a similar incidence in both women and men. Testing for occult blood in the stool using fecal immunochemical test, sigmoidoscopy, and colonoscopy is effective at detecting precancerous lesions and thereby reducing rates of both new cancers and later stage disease.

Ovarian cancer (Chapter 199) is relatively rare, with 21,500 cases in the United States annually, but mortality is high owing to its presentation at late stages in most cases. Lower abdominal or pelvic pain, urinary symptoms, and changes in bowel habits are nonspecific and common in many women, limiting the ability to detect this cancer at an early stage. There is no effective screening test for women at average risk, and screening pelvic examination is no longer recommended in asymptomatic women.[6] CA-125 has both low sensitivity and low specificity, with normal levels in early-stage disease and elevations with nonmalignant ovarian pathology. One randomized clinical trial of average-risk women showed no benefit of mortality and increased harms in terms of false-positive studies and complications due to operative procedures.■ While awaiting the results of another large randomized controlled trial, current recommendations are to consider genetic counseling and testing for women with a family history of ovarian cancer.

The greatest recent advance in cancer prevention is the development of vaccines against the most carcinogenic subtypes of human papillomavirus (HPV) associated with cervical cancer (Chapters 199 and 373) and anal cancer. The vaccine has the potential to reduce significant morbidity caused by the management of premalignant lesions, including the risk for cervical incompetence and preterm labor. Vaccine rates in the United States are low, especially in minority communities. Despite this, there is evidence of reduced HPV prevalence since the vaccine became available. Although concern of tacit approval resulting in increased sexual activity among young adolescents has been cited by parents as a reason to delaying vaccination, evidence does not demonstrate this concern to be founded. Guidelines now suggest delaying Pap test screening in women until age 21 years and increasing the screening interval to every 2 years in women aged 20 to 29 years and to every 3 to 5 years in women aged 30 years and older if previous screening has demonstrated no high-risk subtypes of the HPV and negative HPV serology.[7] Pap tests are not recommended for women after hysterectomy for nonmalignant indications, or for women older than 65 years with adequate recent screening and no high-risk factors.

Osteoporosis

Hip fracture due to osteoporosis (Chapter 243) is one of the major causes of disability, loss of independence, and mortality in older women. Osteoporosis prevention through calcium and vitamin D intake and weight-bearing exercise begins at puberty and extends throughout adulthood. Women require a calcium intake of 1000 mg/day, increasing to 1300 mg in puberty and breastfeeding and 1200 mg after menopause, in order to maintain the structural strength of bone. Vitamin D is a necessary element for the absorption of calcium (Chapter 218), and it is available through direct sun exposure or vitamin D supplementation of milk (not most other dairy products) and some juices. Epidemiologic data suggest widespread vitamin D deficiency in women in the United States. This is attributed to low levels of dietary replacement, decreased sun exposure with the use of sunscreens, and lack of vitamin D production in the skin (even with sun exposure) in northern climates during the winter months. Screening for a single baseline serum 25-hydroxyvitamin D level can provide women with useful information about the adequacy of their diets, with levels above 20 ng/mL considered

TABLE 237-2 PREFERRED MEDICATIONS FOR WOMEN OF REPRODUCTIVE POTENTIAL

COMMON CONDITIONS IN WOMEN OF REPRODUCTIVE POTENTIAL	ISSUES TO BE AWARE OF	PREFERRED MEDICATIONS OR GROUPS OF MEDICATIONS
Depression	Must consider effects of untreated depression on mother and infant	Avoid newer medications when older drugs with more information are available SSRIs are generally considered safe; fluoxetine has most safety data
Anxiety	Commonly associated with depression in women	Benzodiazepines generally considered safe
GERD	No data on harmful effects of either H_2-blockers or PPIs Misoprostol is contraindicated; can cause miscarriage, fetal death, congenital anomalies	Calcium-containing antacids are first-line therapy H_2-blockers preferred over PPIs
Acne	Oral isotretinoin and topical tazarotene are contraindicated owing to congenital defects	Most other topical agents are considered classes B and C
Asthma	Extensive data on safety of common drug categories: benefit ratios far exceed risk in treating women	Cortisone inhalers Systemic prednisone for flares Short- and long-acting bronchodilators
Seizure disorders	Difficult to separate effects of medication from effects of seizure on fetal development All agents associated with some increased risk for fetal abnormality (4-8%, compared with 1-2% in general population). Valproate and phenobarbital with highest risks	Monotherapy at lowest doses recommended Avoid medication changes in first trimester Folate supplementation in preconception period
Hypertension (not preeclampsia)	ACE inhibitors and ARBs are contraindicated in pregnancy; possibly associated with cardiovascular and neurologic anomalies in first trimester; may cause abnormalities in renal hemodynamics in third trimester Most data suggest thiazide diuretics are safe if stable use before pregnancy	β-blockers, especially labetalol, and methyldopa are first-lines choices Calcium-channel blockers are also considered safe
Lipid disorders	Circulating lipid levels are elevated with pregnancy and breast-feeding.	No medications during pregnancy; ideally, stop statins before conception
Analgesics for fever and pain management	Controversy about whether NSAIDs slightly increase risk for miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Headache	Controversy about whether NSAIDs slightly increase risk for miscarriage in first trimester	Acetaminophen preferred; aspirin also considered safe
Diabetes	First-generation sulfonylureas contraindicated in pregnancy; may cause fetal hyperinsulinemia and birth defects	Conversion to insulin during planned preconception period Insulin, metformin, and glyburide preferred in women of childbearing potential
Autoimmune conditions	Must weigh benefits of immunosuppressive use against potential risks to both mother and infant Methotrexate is contraindicated in pregnancy because it induces miscarriage No data on safety or risk for TNF and IL-1 inhibitors	Prednisone generally considered safe in pregnancy Azathioprine, sulfasalazine, cyclosporine, and hydroxychloroquine generally preferred if required
Tobacco control	Cigarette smoking has known harmful effects on fetus In one small randomized controlled trial, nicotine replacement was associated with reduced levels of nicotine and improved birth outcomes Bupropion is linked with reports of some fetal anomalies	Try nonpharmacologic approaches to cessation first Short course of nicotine replacement likely better for fetus than smoking
Polycystic ovarian disease	Metformin can restore ovulatory cycles; use with contraception	
Bacterial infections	Tetracyclines accumulate in fetal bone and teeth Sulfa drugs may increase risk for neural tube defects with use in first trimester and kernicterus with use in third trimester Trimethoprim interferes with folic acid metabolism Streptomycin and kanamycin associated with bilateral deafness	Penicillins, cephalosporins, erythromycin, azithromycin

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; GERD = gastroesophageal reflux disease; IL-1 = interleukin-1; NSAID = nonsteroidal anti-inflammatory drug; PPI = proton pump inhibitor; SSRI = selective serotonin re-uptake inhibitor; TNF = tumor necrosis factor.

sufficient or ideal. Daily replacement of vitamin D of 600 IU is recommended for women, with 800 IU recommended after age 70 years.

Although no long-term outcome data exist on the benefits of dual-energy x-ray absorptiometry (DXA) screening (DEXA bone densitometry), most guidelines recommend DXA screening at age 65 years in women, and in women ages 50 to 65 year who have one risk factor (smoking, family history, body mass index < 22, or alcohol use). An algorithm to assess risk for bone fracture based on DXA and individual risk factors is available through the World Health Organization and can guide decision making on preventive therapy.[8] Long-term estrogen therapy is not recommended for osteoporosis prevention. Complications from bisphosphonate therapy include gastroesophageal erosions, preventable in most women with weekly doses on an empty stomach while sitting upright for 30 minutes. Rare but debilitating jaw osteonecrosis (Chapter 248) has been seen in women with and without risk factors, such as dental disease. Raloxifene, a selective estrogen receptor modulator, has the benefits of preventing osteoporosis while reducing breast cancer risk without increasing the risk for CVD; it has been underused as a preventive agent.

COMMON CAUSES OF MORBIDITY IN WOMEN

Obesity

Obesity rates continue to rise, and the prevalence of obesity is higher in women than men, especially among minority and low-income women (Chapter 220). The rates of increase in obesity in women have doubled from 1976-80, when it was at 17%, to the rate of 35% in 2007-10. Dietary reduction in calories and increased caloric output with aerobic exercise are the short- and long-term strategies for care. Studies suggest that no single diet is superior to others, and many common diet strategies can reduce weight. Increasing activity during the course of one's daily routine is as effective as shorter intervals of more strenuous activity. The most effective programs include a

combination of behavioral therapy, either individually or in groups, to address behavioral patterns in food intake, and with diet and exercise. Weight loss targets of 1 to 2 lb/week and a total loss of up to 5 to 10% of body weight are realistic goals. Even modest changes in weight and modest increases in physical activity reduce morbidity and mortality on a population basis.

Exercise and diet changes are difficult for many people to achieve, for a wide variety of reasons. The physical environment may not be conducive to physical activity owing to the sedentary nature of most workplaces, the lack of safe areas to exercise, and architectural design features, such as the lack of easy access to stairs instead of elevators. The use of prepared foods and the consumption of fast foods, high in fat and calories and low in nutritional content, increase the risk for obesity.

There are currently no evidence-based interventions to support weight reduction in the setting of a brief office visit. Most guidelines focus on assessing body mass index (BMI) in all women and recommending weight reduction with diet restriction and exercise, including behavioral therapy to support these behavioral changes. Orlistat and sibutramine are U.S. Food and Drug Administration (FDA)-approved medications with moderate weight reduction efficacy that should be used in conjunction with an exercise and diet program, and not as sole therapy. For obese women with a BMI greater than 40, or those with a BMI greater than 35 and major comorbidities such as diabetes, sleep apnea, or osteoarthritis, bariatric surgery (Chapter 220) is indicated after other weight loss methods have failed. Bariatric surgery leads to short- and long-term benefits in multiple comorbidities and reduced mortality because of improvements in comorbidities. Critical to the success of this intervention is a team approach, with psychological assessment and diet and exercise programs beginning before and continuing after surgery. Management of obesity in general is discussed in detail in Chapter 220.

Depression

Major depression and other related disorders, including dysthymia, predominate in women (Chapter 434). Multiple short screening tools have been developed to identify depression. Women with depression are highly likely to come to the attention of the health care system. Depression is a significant comorbidity in many chronic medical conditions. Somatic complaints are a common presentation of depressive disorders. All specialties are likely to see patients with unexplained symptoms, such as chest pain, headache, abdominal pain, and other complaints. It is critical to include depression as either a primary or a secondary diagnosis and to treat depression as part of the overall management plan.

Anxiety Disorders

Anxiety disorders also predominate in women. They commonly coexist with depressive disorders. Anxiety disorders, including post-traumatic stress disorder, may be a consequence of violence against women, which often remains unidentified (Chapter 241). Benzodiazepines have been demonstrated to be safe and effective in trials for short-term use. Selective serotonin re-uptake inhibitors (SSRIs) and behavioral therapies are effective for the long-term management of anxiety disorders.

Osteoarthritis

Osteoarthritis (Chapter 262) is one of the most common causes of morbidity and functional status limitation, especially as women age. Assessment of pain and functional status is at the core of management. Physical and occupational therapy to restore functional status is a critical component of care. Joint replacement (Chapter 276) should be considered and recommended when functional status interferes with activities of daily living and supportive care and other symptom management strategies are ineffective.

Smoking

Tobacco use, most commonly cigarette smoking, continues to be one of the major preventable causes of morbidity and mortality in women (Chapter 32). Although there has been much progress in smoking cessation efforts, lower income women and younger women continue to start smoking and fail to quit smoking at high rates. Health care providers can achieve 1 to 2% smoking cessation rates by asking all patients about their smoking status and making a simple statement encouraging smokers to quit. Further gains in smoking cessation are possible with targeted counseling, which involves assessing the patient's stage of readiness to change and providing counseling relevant to that stage.

Nicotine replacement is equally effective in women and men. Smokers with a physiologic addiction to nicotine (those who smoke more than one pack daily or smoke within 20 minutes of awakening) benefit the most from nicotine replacement. Many women report weight gain as a major barrier to smoking cessation. Chapter 32 describes approaches to smoking cessation in detail.

Alcohol Use and Substance Use

Alcohol dependence is estimated in 5% of women; however, this is underrecognized in clinical practice (Chapter 33). It is well established that lower amounts of alcohol cause alcohol-related liver and other disease in women compared with men and increases the risk for breast cancer. Also worrisome is the frequency of binge drinking (defined as four drinks or more at a sitting) by women, with reports that one in eight women drink with this pattern, with risk for poor judgment in personal safety.

Although women in general have lower rates of most substance abuse than men, they have similar rates of nonmedical use of narcotic medications (about 2% of population), a problem that has more than doubled in the past decade, and narcotic overdose deaths have increased five-fold in women in the same timeframe. Current recommendations include specific training for all prescribing physicians; in addition, all nononcology patients who are prescribed more than 30 days of narcotics should be part of a narcotics program, with signed consent on risks and benefits, agreement to obtain medications from a single practice source, and agreement to monitoring, including random pill counts and drug testing, for the presence of the prescribed medication and the absence of other medications.[9]

Alcohol abuse and dependence and drug abuse and dependence are described and discussed in detail in Chapters 33 and 34, respectively.

Incontinence

Urinary incontinence (Chapter 26) is a frequently overlooked cause of major functional status limitations in middle-aged and older women. As many as half of affected women underreport this problem to their physicians and alter their lifestyles to adapt to the problem, including reducing fluid intake, avoiding activities that exacerbate the problem, and restricting travel where access to facilities is uncertain. There are two broad categories of incontinence—stress incontinence and urge incontinence—although women commonly have aspects of both types. Stress incontinence is defined as leaking with increases in intra-abdominal pressure, such as occurs with sneezing or coughing as well as running or walking. The most common reasons are pelvic floor laxity, often from childbirth. Kegel exercises are frequently recommended but are of limited value. A number of surgical procedures are available to address this condition. Less invasive procedures may be tried first, including the fitting of a vaginal pessary or periurethral injections with biodegradable materials such as collagen or with nonbiodegradable materials. Urge incontinence, described as detrusor muscle instability, results in the urge to void with low volumes. Anticholinergic medications and bladder training are both effective. Urodynamic evaluation should be considered if the history does not clearly identify a cause. The problem of incontinence is discussed in more detail in Chapter 26.

HIV Disease

The risk factors for HIV disease in women are heterosexual contact in 80% of new cases and injection drug use in 20%. HIV continues to affect minority women disproportionately, with 61% of incident cases affecting African American women. Incidence rates remain lower in women than in men, with only 27% of incident cases affecting women; in large part, this is due to the fact that male-to-male sexual contact continues to account for 72% of new cases in men. However, the absolute number of new infections from heterosexual contact is twice as high in women as it is in men. Women with HIV/AIDS continue to have poorer survival than men, despite the availability of antiretroviral therapies. There are no data of differential effectiveness of therapy by gender, and there are no gender-specific recommendations regarding timing and type of antiretroviral therapy. Some data suggest that women are less likely than men to adhere to an antiretroviral therapy regimen. The gender difference in therapy adherence was associated with caring for dependent children in one study, suggesting that women's caregiving roles may be a barrier to their own care. Cervical and anal dysplasia and cancer are more common among women with HIV than those without. Therefore, annual Pap tests are recommended for all women with HIV infection, even in the absence of positive HPV testing. There is insufficient evidence to support anal screening for dysplasia, but providers should be aware of the increased risk and perform an external examination for evidence of lesions.

Prophylaxis and management of complications of HIV/AIDS are discussed in detail in Chapter 389, and other aspects of HIV/AIDS are covered in individual chapters in Section XXIV.

REPRODUCTIVE HEALTH ISSUES

All providers caring for women with reproductive potential should consider the reproductive implications of preventive and therapeutic decisions. With half of all pregnancies in the United States unplanned, providers should routinely inquire about contraceptive practices and consider these in their care plans.

All primary care providers should be comfortable counseling patients about contraceptive choices and prescribing oral contraceptives. The absolute contraindications to oral contraceptives are a personal history of CVD, thromboembolic disease, migraine headache with aura, and gynecologic or breast cancer. A family history of cancer is not considered a contraindication; in fact, data suggest that the use of oral contraceptives decreases the risk for both endometrial and ovarian cancer. Smoking while using oral contraceptives increases the risk for thromboembolic events in all women, but especially in those older than 30 years. Oral contraceptive use is considered safe in nonsmoking women until menopause. Although factor V Leiden and other thrombophilias (Chapter 176) have been associated with an increased risk for deep vein thrombosis in those taking oral contraceptives, the absolute risk to any woman is still very low; therefore, screening for this and other genetic thrombophilias is not indicated. Preexisting hypertension is a relative contraindication to oral contraceptive use. Some women develop elevated blood pressures on oral contraceptives; therefore, blood pressure should be monitored at 3 months after starting the drug and then annually.

Providers should consider the reproductive implications of all chronic medications in women of reproductive potential (Chapter 239). Given that the teratogenic effects of medications may occur during the first trimester and before an initial obstetric assessment, the principle when choosing chronic medications for women during their reproductive years is to select those with the greatest safety profile during the first trimester of pregnancy.[10] Table 237-2 outlines common drug categories and recommendations for use in pregnancy.

Antidepressant medications deserve particular attention because of the conflicting data regarding their use in pregnancy.[11] Some initial reports suggested that antidepressants, especially paroxetine, were associated with congenital defects, preterm birth, and neonatology mortality. However, in studies that are able to assess whether prescriptions were filled or not and account for severity of depression and other risk factors of birth defects, specifically smoking, the risks from antidepressants are no greater than in the overall population. For women who wish to take no medication during pregnancy, the recommendation is to gradually reduce the dosage over the course of several weeks and not to abruptly stop taking the medication. The risk for untreated depression during pregnancy and the risk for postpartum depression to the woman and her infant are substantial. Therefore, treatment goals should be to provide adequate and even increased dosing to prevent the worsening of depression during this period and to provide close surveillance of women, whether or not they stop antidepressant medications.

REVIEW QUESTIONS

1. Which of the following is the reason to consider teratogenicity of medication in 30-year-old women who are not currently pregnant?

A. Half of all pregnancies in the United States are unplanned, putting the fetus at risk.
B. Many medications have long half-lives and can affect the fetus even if stopped at the time of conception.
C. Almost all medications are known to be unsafe in the first trimester.
D. Women in their 30s are less likely than younger women to identify that they are pregnant in the first weeks of pregnancy.

Answer: A Half of all pregnancies in the United States are unplanned, including those in women in their 30s and 40s. Most women will not begin prenatal care until 12 weeks' gestation, after which major organogenesis has occurred. It is therefore incumbent on the prescribing physician to consider the impact of the medications they prescribe in any patient of childbearing potential.

2. The decision to undergo screening mammography in women aged 40 to 49 years should be shared decision making because of all except which of the following?

A. Breast cancer is less common than lung cancer is this age group.
B. Overdiagnosis of breast cancer may result in detecting cancers that would not require treatment.
C. Women in their 40s have a higher false-positive rate of screening studies than women older than 50 years.
D. Women tend to overestimate their breast cancer risk and benefit from education and discussion of risks and benefits.

Answer: A U.S. Preventive Services Task Force guidelines recommend shared decision making for women of average risk aged 40 to 49 years for screening mammography, given the potential harms of both a higher false-positive rate and overdiagnosis. Several studies indicate that normal-risk women in this age group tend to overestimate their personal breast cancer risk.

3. Management of a non–ST elevation acute coronary syndrome (ACS) in women should differ from men in which of the following ways?

A. Medical management is preferred over revascularization in women but not in men.
B. Noninvasive testing is not recommended in women.
C. Aspirin is not indicated for emergent treatment of ACS because of bleeding risk.
D. β-Blockers should be avoided because of increased risk for congestive heart failure.
E. Lipid management goals are low-density lipoprotein cholesterol levels of less than 120 mg/dL.

Answer: A Medical management of ACS and non–ST elevation myocardial infarction is the same for men and women, with aspirin, β-blocker, thrombolytic therapy, noninvasive testing, and cardiovascular rehabilitation. Randomized trials suggest that medical management has better outcomes than early revascularization in women with non–ST elevation myocardial infarction (MI) only, but not in men, one place where gender differences in guidelines exist. Early revascularization is recommended for women and men with ST elevation MI.

4. A woman taking fluoxetine for depression is now planning pregnancy. In counseling her, you would advise which of the following?

A. If possible, she should switch to sertraline.
B. She should wait until the pregnancy test is positive, then stop the medication.
C. An increase in dose should be considered if depressive symptoms increase in pregnancy.
D. To avoid fetal abnormalities, she should stop the medication before attempting conception.

Answer: C Although several studies have suggested a possible association between selective serotonin reuptake inhibitor (SSRI) use in pregnancy and fetal anomalies, these associations usually disappear in studies that are able to control for other causes of fetal abnormalities such as smoking, and in those that are able to ascertain that the SSRI is the only prescription used. Fluoxetine appears to have fewer concerns than sertraline in the available studies. Because of drug distribution in pregnancy, increased doses in pregnancy may be required. The benefits of treated depression and the risks for depression to the woman and her child, including evidence of some developmental delays, must be weighed against any small increased risk for fetal anomalies.

5. Screening for problem alcohol use in women should consider all except which of the following?

A. Binge alcohol drinking is common in women.
B. Younger women have an alcohol threshold (amount and duration) for complications that is lower than men.
C. Women develop complications from alcohol abuse with lower intake for shorter time periods.
D. Rates of alcohol dependence in women are about 5%.

Answer: B Although women have lower rates of alcohol dependence (5%) compared with men (10%), they develop complications with lower amounts of alcohol and with short length of abuse. Binge drinking is common not only among young adults but also among those older than 30 years, and it puts women at risk for violence and poor choices, including sexually transmitted diseases and sexual assault.

CONTRACEPTION

BEVERLY WINIKOFF AND DANIEL GROSSMAN

CONTRACEPTIVE USE

Contraception enables men and women to avoid unwanted fertility by preventing pregnancy. Methods can be classified in many different ways. Some classification schemes distinguish among mechanisms (e.g., barriers to the encounter of sperm and ovum versus methods that prevent ovulation); other categories emphasize the timing of use (at the time of intercourse versus ongoing); still other classifications focus on the permanence of the method (sterilization, which is intended as a permanent method, long-acting methods that last for years, and short-term methods that depend on the behavior of the user periodically, every day or at every exposure to pregnancy). There are advantages and disadvantages of each contraceptive method. These advantages and disadvantages should be thoroughly explained so that the individual or couple will choose the most acceptable method that suits their lifestyles and will be used most effectively. Because medical contraindications to individual methods are uncommon among young women, in most cases the choice of contraceptive method depends most on the user's preferences.

In the United States, about 62 million women are in the reproductive age group (15 to 44 years), and about 38 million (62%) are using a method of contraception.[1] Of the remainder, most were either noncontraceptively sterile (about 2%), pregnant or trying to conceive (8%), or never sexually active or had no recent sexual activity (19%). About 8% of women were sexually active in the prior 3 months but were not using a method of contraception. About 50% of U.S. pregnancies are unintended,[2] and more than half of such pregnancies occur in women who are not practicing contraception.[3]

In the United States in 2006 to 2010, the most common methods of fertility prevention were oral contraceptives (OCs) and female sterilization, used by 17.1% and 16.5% of women aged 15 to 44 years, respectively.[4] Next in frequency of use was the male condom (10.2%), followed by male sterilization (6.2%). The injectable progestin was used by 2.4%. However, the intrauterine device (IUD), the most effective method of reversible contraception, was used by only 3.5%, although this is about three times higher than the proportion using an IUD in 2002. Between 1982 and 2006 to 2010, there was a marked decrease in diaphragm use and an increase in condom use.

Contraceptive Effectiveness

Despite an increased use of contraceptive methods by U.S. women since 1982, about half of pregnancies are unintended, meaning they are either mistimed or unwanted. Of the 6.6 million pregnancies that occurred in the United States in 2006 (the most recent data available), 49% were unintended, and 43% of these pregnancies were terminated by elective abortion. Of the women with an unintended pregnancy, 50% stated they were using a method of contraception in the month they conceived. In recent years, teen pregnancy rates have declined, and women aged 18 to 24 years have the highest unintended pregnancy rates. Poor women and those who are unmarried and living with a partner have significantly higher rates of unintended pregnancy compared with women with higher incomes and those who are married or not living with a partner. Research has identified a variety of factors associated with nonuse of contraception or gaps in use, including side effects (both experienced and feared), not liking a method, personal or religious reasons, and barriers to access, including difficulty obtaining a prescription or the method itself, and high cost of a method.

The most pressing need worldwide is that the highly effective contraceptive methods already available should be affordable to most of the population and also that these methods should fulfill the needs of women of different ages and with different reproductive requirements.[5]

Perfect Use versus Typical Use

The terms *perfect use* and *typical use* describe different aspects of the effectiveness of the various contraceptive methods. Perfect use refers to use of the method as intended and covering all acts of exposure to pregnancy. So, for user-dependent methods such as oral pills or condoms, for example, this measure can only be applied to situations in which the user reliably uses the

method every day or at every act of intercourse. Perfect use is a measure of the maximum possible efficacy of the method. *Typical use,* on the other hand, is a measure of how effective methods are when used as a group of people under study actually use them. These rates may be considerably lower than perfect use rates, especially if there is the possibility of not using the method at every intercourse or in other ways not using the method as intended. Methods used at the time of coitus have higher failure rates than OCs, implants, injections, IUDs, and sterilization. IUDs, implants, and sterilization have lower failure rates than pills, patches, and injections because they act over a long period of time, and there is nothing a user needs to do to keep using them. Table 238-1 illustrates the differences in failure rates among the contraception methods under conditions of perfect and typical use.

Cumulative failure rates for use of long-acting methods are low. The effectiveness of long-acting reversible contraception is superior to that of contraceptive pills, patch, or ring and is not altered in adolescents and young women.[6] The cumulative failure rates of all types of tubal sterilization are 1.31% during the first 5 years after the procedure and 1.85% after 10 years; rates are higher for tubal fulguration and lower for segmental resection. The cumulative pregnancy rate for 5 years' use of the levonorgestrel-releasing IUD is 0.5%, and for 10 years' use of the copper T380 IUD, it is 1.7%.

The World Health Organization has developed a chart that nicely represents the actual use (typical) failure rates of most contraceptives, dividing them into three main classes of effectiveness (Figure 238-1).

Contraindications, Risks, and Benefits

Most contraceptives can be used safely by most people, but some conditions or concomitant medications are considered contraindications to use. The U.S. Centers for Disease Control and Prevention have developed evidence-based Medical Eligibility Criteria (MEC) for contraceptive use, based on a similar document developed by the World Health Organization.[7,8] The MEC categorizes conditions or medications into four groups for each contraceptive method: 1—no restriction on use; 2—advantages of use generally outweigh theoretical or proven risks; 3—theoretical or proven risks generally outweigh advantages of using the method; and 4—the condition represents an

*Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason. Estimates of the probability of pregnancy during the first year of typical use for spermicides and the diaphragm are taken from the 1995 National Survey Growth (NSFG) and corrected for underreporting of abortion; estimates for fertility awareness-based methods, withdrawal, the male condom, the pill, and Depo-Provera are taken from the 1995-2002 NSFG corrected for underreporting of abortion.

†Among couples who initiate use of a method (not necessarily for the first time) and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

‡Among couples attempting to avoid pregnancy, the percentage who continues to use a method for 1 year.

§The percentage who become pregnant in the second and third columns are based on data from populations in which contraception is not used and from women who cease using contraception to become pregnant. Among such populations, approximately 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women not relying on reversible methods of contraception if they abandoned contraception altogether.

‖Foams, creams, gels, vaginal suppositories, and vaginal film.

¶The ovulation and 2-day methods are based on evaluation of cervical mucus. The standard-days method avoids intercourse on cycle days 8 to 19. The symptothermal method is a double-check method based on evaluation of cervical mucus to determine the first fertile day and evaluation of cervical mucus and temperature to determine the last fertile day.

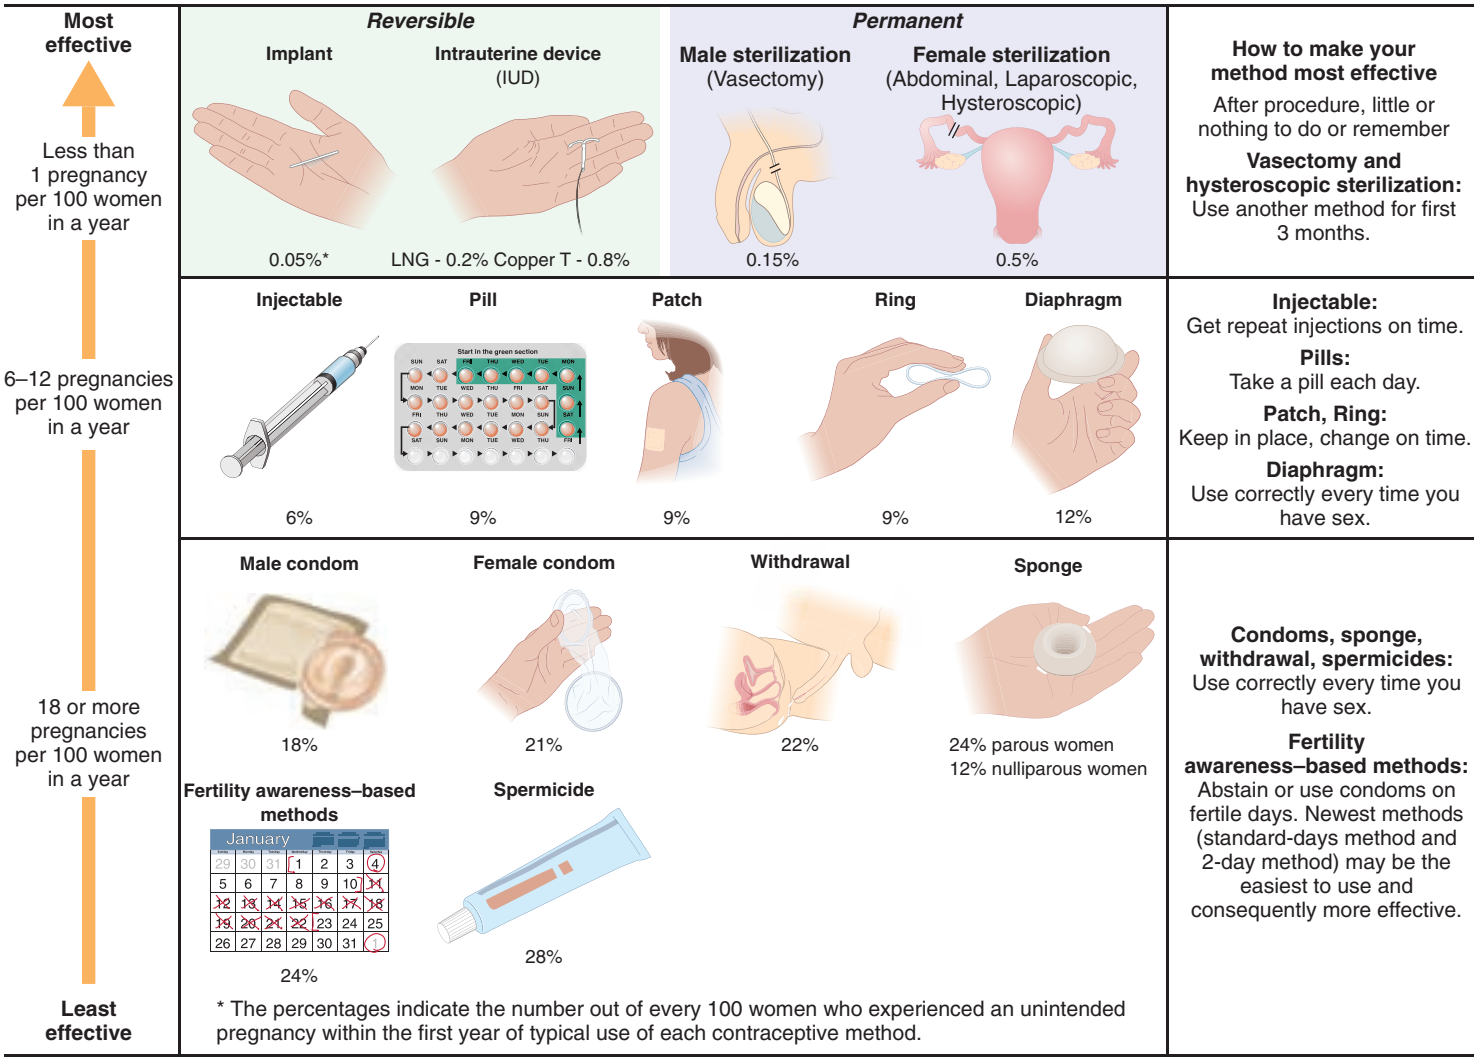
**Without spermicides.

††With spermicidal cream or jelly.

‡‡This is a highly effective, temporary method of contraception. However, to maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency of duration of breast-feeds is reduced, bottle-feeds are introduced, or the baby reaches age 6 months.

Adapted from Trussell J. Contraceptive failure in the United States. *Contraception.* 2011;83:397-404.

Effectiveness of Family Planning Methods



Condoms should always be used to reduce the risk for sexually transmitted infections.

Other Methods of Contraceptions

Lactational Amenorrhea Method: LAM is a highly effective, temporary method of contraception.

Emergency contraception: Emergency contraceptive pills or a copper IUD after unprotected intercourse substantially reduces risk for pregnancy.

FIGURE 238-1. Detailed chart of the effectiveness of family planning methods with instructions for subjects. (Adapted from World Health Organization (WHO) Department of Reproductive Health and Research, Johns Hopkins Bloomberg School of Public Health/Center for Communication Programs (CCP), Knowledge for Health Project. *Family Planning: A Global Handbook for Providers.* 2011 updates. Baltimore, Geneva: CCP and WHO; 2011, and Trussell J. Contraceptive failure in the United States. *Contraception.* 2011;83:397-404.)

unacceptable health risk if the method is used. For conditions that represent relative contraindications (MEC category 3), it is important to recognize that pregnancy may also be risky, and if the method is the best choice to avoid an unintended pregnancy, it may be worth the risk.

In addition to preventing unintended pregnancy, many contraceptive methods have additional benefits. Some of the most significant noncontraceptive benefits include the reduced risk for transmission of HIV and other sexually transmitted infections associated with the use of male and female condoms, as well as the reduction in dysmenorrhea and menorrhagia associated with the use of combined hormonal contraception.

TYPES OF CONTRACEPTIVES

Natural Methods

Methods that rely on the natural infertility of different times in the menstrual or life cycle are often called "natural" methods. These methods are not really more natural than other methods, because they involve disruptions in the "natural" desire for sexual intimacy; however, they do not rely on any specific external technologies to create a state of low fertility potential. Because male sperm can live only 5 days in the female genital tract and female ova have a lifespan of only about 24 hours, the window for fertilization is only 5 to 6 days each month. In theory, if couples avoid unprotected intercourse on those 5 to 6 days, the potential for pregnancy is markedly reduced. The calendar method counts the days of the cycle to predict fertile and infertile days, and the symptothermal method relies on the calendar plus the biologic signals of impending ovulation (changes in vaginal mucus) and of ovulation itself (rise in basal body temperature) to enhance prediction of "safe" days for intercourse. Breast-feeding in the postpartum period also lowers fertility and is considered another natural method of contraception. Exclusive breast-feeding during the first 6 months after a birth provides a good level of protection against pregnancy. However, once a baby is older than 6 months or if foods other than breast milk become part of the infant's diet, then a woman is at much higher risk for ovulation and possible pregnancy.

Withdrawal, or coitus interruptus, when the penis is removed from the vagina before ejaculation, is a commonly used method, with up to 60% of women reporting ever using it. Although the method can be effective with perfect use, with a pregnancy rate of only 4% in the first year of use, failure is much more common in typical use. A recent study reported that among U.S. women aged 15 to 24 years using withdrawal as their primary method, 21% experienced an unintended pregnancy, which was a significantly higher pregnancy rate than that among users of other contraceptive methods.

Barriers

Barrier methods are so called because their mechanism of action is to impose a chemical or physical barrier between ovum and sperm so that fertilization

is not possible. Barrier methods include spermicides, diaphragm, and male and female condoms, among others.

Spermicides

All spermicidal agents contain a surfactant (in U.S. products this chemical is nonoxynol-9) that immobilizes or kills sperm on contact. The spermicidal products are available in foams, creams, and vaginal suppositories that need to be placed into the vagina before each coital act—and reapplied even if coital acts follow immediately after each other. The typical-use effectiveness of spermicides as a sole contraceptive is among the lowest of modern methods (about 28% of women using the method report an unintended pregnancy during 1 year of use.) There is no increased risk for birth defects in the offspring of women who conceive while using spermicides.

Diaphragm

A diaphragm is a dome-shaped latex or silicone device with a flexible rim that seals off the upper genital tract from contact with deposited semen. It is usually used with a spermicide applied inside and around the rim. The device must be fitted by a health care provider using the largest size that does not cause discomfort or undue pressure on the vagina. The woman will need to insert the diaphragm before every act of intercourse. It should be left in place for 6 hours after intercourse, but should not be left in place for more than 24 hours because it may cause ulceration of the vaginal epithelium. In actual use, the diaphragm is more effective than other barrier methods (12% unintended pregnancy rate in first year of use) and provides contraceptive protection almost as well as hormonal pills in actual use. Diaphragm size for any one woman may change after a birth, miscarriage or abortion after 14 weeks, abdominal/pelvic surgery, or a change in weight of more than 20%. The diaphragm may provide some protection against gonorrhea and *Chlamydia* infection, but not against HIV and herpes. A condom is recommended if infection is a concern. Diaphragm users have an increased risk for urinary tract infection.

Male Condom

The male condom is one of the oldest contraceptives known. It is safe, easy to use, and widely available. The modern version is a stretchy latex or plastic sheath that fits over the erect penis and captures the man's ejaculate during intercourse. It is the most effective way to prevent transmission of infections (including HIV) during sex and can be used during vaginal, oral, or anal intercourse. However, natural membrane condoms (made from sheep intestine) do not prevent sexually transmitted infections. Condoms can be used for protection against infection even if another method is used for protection against pregnancy. If the condom is used alone for contraception, in typical use about 18% of women will experience an unintended pregnancy in 1 year. For optimum protection, the condom must be used at every sex act and requires the active participation of the man. Lubricants containing oil-based products may weaken latex condoms and should not be used with them; water-based lubricants (K-Y jelly is one) are safe to use. The male condom causes no side effects except possible irritation or allergy.

Female Condom

The female condom is a soft, loose-fitting prelubricated pouch with two flexible polyurethane rings, one at each end. The smaller ring at the closed end is inserted well into the vagina, creating a barrier to sperm. The larger ring remains outside the vagina, covering the vulva and providing additional protection. The female condom can be inserted before beginning sexual activity and left in place for a longer time than the male condom after ejaculation occurs. Because polyurethane is stronger than the latex used in most male condoms, the female condom is less likely to rupture. Both polyurethane and latex prevent virus transmission and should reduce the risk for acquiring HIV infection.

Hormonal (Steroidal) Contraception

Contraception using steroid hormones has been available since the 1960s. The use of hormones (or derivatives/analogues of hormones) that occur naturally in the female reproductive cycle can alter the reproductive system so that ovulation does not occur or so that physical factors (such as mucus production, tubal motility, and endometrial thickness) that enhance the probability of fertilization or implantation are altered. All modern hormonal formulations are made from synthetic steroids. The hormones are either a combination of an estrogen and a progestin or, in some formulations, a progestin alone. There are two major types of synthetic progestins: derivatives of 19-nortestosterone (which are used in OCs) and derivatives of 17α-acetoxyprogesterone (pregnanes). Pregnanes are structurally related to progesterone and are used in injectable contraceptives, but are not used in pills.

After the discontinuation of hormonal contraceptives, the rate of return of fertility is slightly lower for users of OCs than for users of barrier methods—but faster than for users of Depo-Provera. OCs do not cause permanent infertility or adversely affect pregnancies that occur after their discontinuation. OCs are not teratogenic if they are accidentally ingested during pregnancy.

From the user's point of view, the main differences are route of administration, length of action, how much attention the user needs to pay to the administration of the drug, and side effects. All these methods are very effective, and if used consistently they have very low pregnancy rates. Even with typical use, they are among the more effective methods, although, with the exception of the implants, they are less effective than sterilization or the IUD. The most commonly used of these methods is the OC ("the pill"), which was also the first hormonal contraceptive and the one most widely used globally.

Oral Contraceptives

There are three major types of OC formulations: fixed-dose combination, combination phasic, and daily progestin. The combination formulations are the most widely used and most effective. They consist of tablets containing both an estrogen and a progestin, usually given continuously for 3 weeks. Generally, no steroids are given for the fourth week. Three types of pills provide active tablets for 24 days, with 4 days of inactive tablets. Other types provide active tablets for 84 days followed by 7 days without active tablets or with a low dose of estrogen to allow withdrawal bleeding. The endometrium usually begins to slough 1 to 3 days after steroid ingestion is stopped, causing withdrawal bleeding, which usually lasts 3 to 4 days (and which users interpret as menstrual bleeding). The uterine blood loss with OC use averages about 25 mL per cycle, less than the 35 mL average for ovulatory cycles.

Three estrogens (ethinyl estradiol and its 3-methyl ether, mestranol, as well as one agent with estradiol valerate) are used in combined OCs. They are combined with one of two major types of 19-nortestosterone progestins—estranes and gonanes—both of which have androgenic activity. The estranes currently used in several OCs are norethindrone and its acetates, norethindrone acetate, and ethynodiol diacetate. Gonanes have greater progestational activity per unit weight than estranes, and thus a smaller amount of these progestins is used in OC formulations. One other progestin that is structurally related to spironolactone has been formulated in an OC. This progestin is called drospirenone and has antimineralocorticoid and antiandrogenic actions as well as progestational activity without androgenic activity. There are also daily progestin-only formulations that include norethindrone, levonorgestrel, or desogestrel.

Combined OCs, which contain both estrogen and progestin, consistently inhibit the midcycle gonadotropin surge and thus prevent ovulation. The progestin-only formulation has a lower dose of progestin than the combined agents and does not consistently inhibit ovulation, even though it is ingested every day. Progestin-only pills containing desogestrel appear to more consistently inhibit ovulation than other progestin-only formulations. Both combined OCs and progestin-only formulations also act on the cervical mucus and tubal motility to interfere with sperm transport. Progestins also alter the endometrium so that if fertilization occurs, implantation may be prevented. For contraceptive effectiveness to be maintained with the combination formulations, it is important that the pill-free interval be limited to no more than 7 days. This is made easier to remember by inclusion of placebo pills in the packet for the 7 hormone-free days. Continuous or extended cycle combined OCs seem to be an equally safe option for women who prefer it.

Side Effects

The synthetic steroids in OC formulations have many metabolic effects in addition to their contraceptive actions. These effects can cause the more common, less serious side effects as well as the rare, serious complications. The magnitude of these effects is directly related to the dosage and potency of the steroids in the formulations.

The most frequent symptoms produced by the estrogen component include nausea, breast tenderness, and fluid retention (bloating). The progestins can produce certain androgenic effects, such as weight gain, acne, and depression. But because estrogens decrease sebum production, women who have acne may experience improvement in their symptoms. Insufficient estrogen, too much progestin, or a combination of both may result in unscheduled (breakthrough) bleeding. This problem is more common with

formulations containing 20 μg of estrogen than with those containing 30 to 35 μg and is increased in women who also smoke cigarettes. Shortening the pill-free interval to 3 or 4 days may decrease the incidence of unscheduled bleeding with low-estrogen formulations.

The synthetic estrogens used in OCs cause an increase in the hepatic production of several proteins. Some of the proteins that are increased by ethinyl estradiol, such as factors V, VIII, and X and fibrinogen, have the potential to enhance thrombosis (see later), and an increase in angiotensinogen levels may elevate blood pressure in some users. The incidence of both venous and arterial thrombosis is higher with 50-μg estrogen formulations than with those with 20 to 35 μg of estrogen. Blood pressure should be followed in all users of combined OCs and the drug discontinued if there is a clinically significant increase. The progestins do not affect protein synthesis except to reduce levels of sex hormone–binding globulin.

High-progestin formulations have an adverse effect on the lipid profile. However, estrogen has a beneficial effect on the arterial wall and on serum lipids, so users of these agents do not have an increased risk for cardiovascular disease. The newer combination formulations with less androgenic progestins have a more favorable effect on the lipid profile. The effect of OCs on glucose metabolism is directly related to the dose, potency, and type of progestin. Although high-progestin formulations caused peripheral insulin resistance, the low-progestin formulations in current use do not significantly alter levels of glucose, insulin, or glucagon after a glucose load.

Complications and Risk Factors

Thrombosis

The background rate of venous thrombosis and embolism in women of reproductive age is about 3 per 10,000 woman years. Women of reproductive age who are not pregnant or using OCs experience thrombosis at a rate of 1.9 to 3.7 per 10,000 woman years. Among users of OCs, the relative risk is 3.5 (95% confidence interval, 2.9 to 4.3) compared with nonusers, but less than the rate of 5 to 20 per 10,000 woman years that occurs in association with pregnancy. The risk for venous thrombosis and embolism is higher for women using OCs with 50 μg of ethinyl estradiol than for those using 30 to 35 μg. In the presence of an inherited hypercoagulable state (Chapter 176), the risk for venous thrombosis is increased several-fold. Screening for coagulation deficiencies before women are started on OCs is not recommended unless the individual has a personal or significant family history of thrombotic events. Women with known inherited or acquired thrombogenic conditions should not use estrogen-containing steroid contraceptives in pills, rings, or patches because each of these agents has thrombogenic effects. Some epidemiologic studies have found that the risk for venous thromboembolism is greater in individuals ingesting OCs with the newer, less androgenic progestins than those containing levonorgestrel with the same amount of estrogen. However, other studies have reported that the risk is similar with formulations containing these two types of progestins. These studies are all observational and thus subject to bias.

Myocardial Infarction and Stroke

Myocardial infarction is rare among women of reproductive age, with a rate of 10.1 per 100,000 person years in a recent Danish cohort. Although the absolute risks for myocardial infarction and thrombotic stroke associated with the use of hormonal contraception were found to be low, the risk was increased by a factor of 0.9 to 1.7 with OCs that included ethinyl estradiol at a dose of 20 μg and by a factor of 1.3 to 2.3 with those that included ethinyl estradiol at a dose of 30 to 40 μg, with relatively small differences in risk according to progestin type. The use of high-dose OCs by women who smoke cigarettes increases the risk for myocardial infarction by about 10-fold. Therefore, combination OCs should not be prescribed to women older than 35 years who smoke cigarettes or use alternate forms of nicotine. Epidemiologic studies indicate that use of low-dose OCs by nonsmoking women without hypertension is not associated with a significantly increased incidence of either myocardial infarction or either hemorrhagic or thrombotic stroke.

Cancers of the Reproductive System

An analysis of worldwide epidemiologic data in 1988 showed that the risk for breast cancer diagnosis was increased by about 25% in young women who were currently using OCs, but this increased risk was no longer present 10 years or more after they stopped using OCs. Several studies have reported that use of OCs by women with a family history of breast cancer does not increase their risk for developing breast cancer. A large study of women aged 35 to 64 years in the United States reported that there was no significantly increased risk for breast cancer among current and former OC users compared with women who had not used OCs. A very large cohort study in Great Britain of OC users and aged-matched nonusers was initiated in 1968. Data accumulated until 2004 showed a similar incidence of breast cancer in both groups.

The epidemiologic data are conflicting regarding OC use and the risk for invasive cervical cancer or cervical intraepithelial neoplasia. Most well-controlled studies indicate that there is no change in risk for cervical intraepithelial neoplasia with OC use. The single most comprehensive study now indicates a significant increase in the risk for cervical cancer among OC users that increases with duration of use and declines with interval since last use.

Several studies have shown that the use of OCs has a protective effect against endometrial cancer. Moreover, the decrease in risk persists for many years after OCs are stopped. This protective effect is related to duration of use, increasing from a 20% reduction with 1 year of use to a 60% reduction with 4 years of use. The level of protection declines with time after use is stopped.

In addition, OCs reduce the risk for development of epithelial ovarian cancer as well as cancers with low malignant potential. The magnitude of the decrease in risk is directly related to the duration of OC use, increasing from about a 40% reduction with 4 years of use to a 60% reduction with 12 years of use. The protective effect continues for at least 20 years after the use of OCs ends. As with endometrial cancer, the protective effect occurs only in women of low parity (fewer than four), who are at greatest risk for this type of cancer.

Studies have reported that OCs significantly reduce the risk for development of colorectal cancer by about 20%.

Benign Hepatocellular Adenoma

The development of a benign hepatocellular adenoma was a rare occurrence in long-term users of high-dose OCs containing mestranol, but it is not increased by use of ethinyl estradiol OCs. There is no increased risk for liver cancer associated with OC use.

Contraindications

OCs can be prescribed for most women of reproductive age. According to the MEC, several conditions are considered absolute contraindications to use of combined hormonal contraceptives (category 4), including smoking 15 cigarettes or more per day, at age 35 or older, and severe hypertension, among others. There is no evidence that individuals with asymptomatic mitral valve prolapse should avoid using OCs. The presence of migraine headaches without aura is also not a contraindication to OC use, but if aura is present, combination OCs should not be prescribed because of a possible increased risk for stroke. OC use does not increase the risk for development of malignant melanoma or prolactin-secreting pituitary adenomas.

Management of OC Therapy

If a healthy woman has no contraindications to OC use, it is unnecessary to perform any laboratory tests, including cervical cytology, before she uses them. A pelvic examination is not required. Starting pills on the day of the visit is associated with better long-term use of the method. There is no reason to discontinue OC use unless pregnancy is desired. Intermittent discontinuation is unnecessary and puts women at risk for an unwanted pregnancy.

Although synthetic sex steroids can retard the biotransformation of certain drugs (e.g., phenazone and meperidine) as a result of substrate competition, such interference is usually not important clinically. However, some drugs can interfere clinically with the action of OCs by inducing liver enzymes that convert the steroids to more polar and less biologically active metabolites. These drugs include barbiturates, sulfonamides, cyclophosphamide, griseofulvin, and rifampin. There is a high incidence of OC failure in women ingesting rifampin as well as systemic griseofulvin, and neither should be given concurrently with OCs. Products containing St. John's wort reduce contraceptive effectiveness and cause breakthrough bleeding. Women taking certain medications for epilepsy should be treated with 50-μg estrogen formulations because many antiepileptic medications lower ethinyl estradiol levels and cause breakthrough bleeding, which may cause premature discontinuation of use.

Because of their many health benefits, including reduction in risk for endometrial and ovarian cancer and induction of regular cyclic uterine bleeding, OC use can be continued until menopause in normotensive, nonsmoking women without contraindications.

A common clinical question is what to do if a pill is missed. The standard advice for combined OCs is to take the first missed pill as soon as possible

and take the remaining pills at the usual time, even if it means taking two pills in one day (discarding any additional missed pills). If two or more pills are missed, take the most recent missed pill as soon as possible, continue taking the remaining pills at the usual time, even if it means taking two or more pills on the same day, and use back up contraception (e.g., condoms) or avoid sexual intercourse until pills have been taken for at least 7 consecutive days. If pills were missed in the last week of hormonal pills (third week of cycle), omit the hormone-free interval and start a new pack the next day. Emergency contraception should be considered. Vomiting and diarrhea for up to 48 hours should be considered as one missed pill; vomiting and diarrhea for more than 48 hours should be treated as two or more missed pills. For norethindrone-containing progestin-only pills, a pill is considered "missed" if it is more than 3 hours late.

Emergency Contraception

There is now a way that a women can avoid pregnancy even after unprotected sex acts. The method is termed *emergency contraception* because it should be used as early as possible after the unprotected sex. A formulation of 1500 µg (1.5 mg) levonorgestrel in a single tablet prevents about 85% of expected pregnancies, if used within 72 hours after coitus.[9,10] Another recently approved agent for emergency contraception is the selective progesterone receptor modulator ulipristal acetate given as a single 30-mg dose. This agent is as effective as levonorgestrel and is effective for 5 days after intercourse.

Transdermal and Intravaginal Steroid Contraceptives

Transdermal Patch

In the United States, there is one transdermal contraceptive patch that contains both estrogen and progestin (Ortho Evra). The patch has an area of 20 cm^2 and delivers 150 µg of the progestin norelgestromin, the active metabolite of norgestimate, and 20 µg of ethinyl estradiol daily. It may be applied to the buttocks, lower abdomen, upper arm, or upper torso (but not the breasts). The patch should be removed after 7 days and a new patch applied to a different area of skin. A woman using this method uses three patches sequentially, each for 7 days. After the third patch is removed, she waits 7 days before starting her next patch, thus mimicking the 28-day combined OC cycle (21 hormone days, followed by 7 hormone-free days, during which withdrawal bleeding occurs). Because the patch does not require daily attention, adherence with the patch is somewhat higher than with OCs. Contraceptive efficacy, bleeding patterns, and side effects are similar to those associated with OCs, and the contraindications are similar. Although the effectiveness of the patch may be decreased among women weighing more than 90 kg, there does not appear to be an association between pregnancy risk and body mass index (BMI). For all combined hormonal contraceptives, a BMI of 30 kg/m^2 or greater is considered category 2 (benefits of use outweigh potential risks) by the MEC.

Intravaginal Ring

Another option for nonoral hormonal contraception is the vaginal ring (NuvaRing in the United States). This soft, flexible ring measures 58 mm in diameter and is 4 mm thick. The ring is composed of ethinyl vinyl acetate and contains the progestin etonogestrel, a major metabolite of desogestrel, and ethinyl estradiol. The ring is inserted and removed by the woman herself. There is no "wrong" position or placement of the ring as long as it is inside the vagina. Each ring is left in place for 3 weeks, after which time it is removed for 1 week to allow withdrawal bleeding. Each day, 120 µg of etonogestrel and 15 µg of ethinyl estradiol are released from the ring, and bleeding with the ring in place is uncommon. Contraceptive efficacy and side effects are similar to those of combined OCs, as are contraindications. Women may keep the ring in place during intercourse, or it can be safely removed for up to 3 hours and then reinserted. Tampons may also be used concurrently with the ring without affecting efficacy.

Injectable Steroid Contraceptives

Constituents and Use

Although several types of injectable steroid formulations are in use for contraception throughout the world, currently the only injectable available in the United States is depot medroxyprogesterone acetate (DMPA). The initial formulation of this contraceptive was administered as an intramuscular injection of 1 mL of an aqueous suspension containing 150 mg of crystalline medroxyprogesterone acetate once every 3 months. A recently developed formulation that is administered subcutaneously (DMPA-SC) contains 104 mg of DMPA in 0.65 mL of solution. This lower dose formulation has a lower peak medroxyprogesterone acetate concentration than DMPA and a long duration of action that suppresses ovulation for at least 13 weeks and is not affected by body mass. The formulation for subcutaneous administration allows the possibility for women to self-inject the medication. Other injectable contraceptives include norethindrone enanthate, given in a dose of 200 mg every 2 months, and several once-a-month injections of combinations of different progestins and estrogens.

DMPA has a low failure rate, 0.1% at 1 year and 0.4% at 2 years. The major contraceptive action of DMPA is inhibition of ovulation, and it also impedes sperm transport by thickening cervical mucus. With DMPA and DMPA-SC, serum medroxyprogesterone levels rapidly increase to contraceptively effective blood levels (>0.5 ng/mL) within 24 hours after the injection. With DMPA, medroxyprogesterone levels plateau for about 3 months, after which there is a gradual decline until levels become undetectable 7 to 9 months after the injection. With DMPA-SC, medroxyprogesterone levels steadily decline after the initial peak and reach 0.2 ng/mL 3 to 4 months after the injection.

Side Effects

With both formulations, mean endogenous estradiol levels remain above the postmenopausal range (40 to 60 pg/mL), and symptoms of estrogen deficiency do not occur. Although DMPA may decrease bone mineral density during use, it is unnecessary to measure bone mineral density or to administer bone antiresorptive agents in DMPA users because the bone loss is temporary and reversible after stopping DMPA.

Because of the lag time it takes to clear DMPA from the circulation, resumption of ovulation is delayed for a variable time after the last injection. It may take as long as 1 year for ovulatory cycles to return. After this initial delay, fecundity resumes at a rate similar to that found after discontinuation of a barrier contraceptive.

The major side effect of DMPA is complete disruption of the menstrual cycle. Because this formulation contains only a progestin, without an estrogen, endometrial integrity is not maintained, and usually light uterine bleeding occurs at irregular and unpredictable intervals. As duration of therapy increases, the incidence of frequent bleeding steadily declines and the incidence of amenorrhea steadily increases so that at the end of 2 years, about 70% of users are amenorrheic. Because the major reason for discontinuance of all progestin-injectable contraceptives is menstrual irregularity, several combined progestin-estrogen injectables that are given once monthly and produce regular withdrawal bleeding have been developed, but these are not available in the United States.

Most DMPA users gain between 1.5 and 4 kg in their first year of use and continue to gain weight thereafter. If weight gain occurs, calorie intake should be decreased. Because there is no estrogen in DMPA, its use does not cause hypertension or thromboembolism. DMPA use is associated with a reduction in seizures among women with epilepsy, as well as a reduction in painful crises among women with sickle cell disease.

Subdermal Implants

Constituents and Use

The only subdermal implant currently available in the United States is a single 4-cm by 2-mm ethylene vinyl acetate rod containing 68 µg of etonogestrel, the active metabolite of desogestrel (Implanon or Nexplanon, which is radiopaque). It provides effective contraception for 3 years. The rod is packaged in a disposable metal trocar inserter and does not require a skin incision for insertion, only for removal. Ovulation is inhibited by the circulating etonogestrel levels, and no pregnancies were reported in three large clinical trials. As with other progestin-only implants, irregular bleeding is the most common clinical complaint. Because implants are not user dependent, the typical-use and perfect-use failure rates are identical and very low, making this method essentially as effective as IUDs and sterilization. Another subdermal implant, Jadelle, consists of two 4.3-cm rods each containing 75 mg of levonorgestrel and is approved for 5 years of contraception; it is not yet available in the United States.

Intrauterine Devices

Two options for intrauterine contraception are available in the United States: the copper-containing IUD and the levonorgestrel intrauterine system (LNG-IUS). Both methods are exceedingly effective with perfect- and typical-use failure rates of less than 1%.

The copper T380A IUD is approved for use in the United States for 10 years and maintains its high levels of effectiveness for at least 12 years. The

LNG-IUS is approved for 5 years of use, and it releases a dose of 20 μg of levonorgestrel from the device into the endometrial cavity each day. This causes atrophy of the endometrial lining, which markedly reduces the amount of uterine bleeding, and it is approved to treat menorrhagia. A newer LNG-containing IUD recently became available in the United States that is smaller and designed for use by nulliparous women.

The main mechanism of action for copper IUD is spermicidal. This effect is caused by a local sterile leukocytic response produced by the copper as well as the plastic IUD. The levonorgestrel-releasing IUD acts mainly by preventing transport of spermatozoa through the cervical mucus and thus preventing fertilization of the ovum. In addition, some women do not ovulate because of the systemic absorption of levonorgestrel. After removal of each type of IUD, the inflammatory reaction rapidly disappears, and resumption of fertility is prompt.

The main difference between the two IUDs is the menstrual bleeding pattern. With the copper IUD, women generally continue to have a regular menstrual period, which may be associated with more pain and heavier bleeding. With the LNG-IUS, irregular bleeding is common in the first 4 to 6 months of use, but after that time, most women develop amenorrhea.

Both IUDs can be easily inserted by any clinician who has been trained. No special tests are needed routinely before insertion, and if it is reasonably certain that the woman is not pregnant, the IUD may be inserted on the same day she presents requesting it. It is not necessary to wait for the next menstrual period. Almost all women, including nulliparous and young women, are considered good candidates for the IUD. Uterine perforation is a rare complication of IUD insertion, occurring in less than 0.1% of cases. Spontaneous expulsion of the IUD after insertion is also rare and happens in less than 5% of users. An IUD may be safely inserted immediately after a delivery or abortion, although the expulsion rate may be slightly higher.

Development of acute salpingitis more than 1 month after insertion of the IUD is due to infection with a sexually transmitted pathogen and is unrelated to the presence of the device. All IUD-related upper genital tract infections occur only during the insertion process. If there is clinical suspicion that cervicitis is present, an endocervical test for chlamydia and gonorrhea should be performed and the insertion delayed until negative results are obtained. It is not recommended to administer antibiotics routinely with IUD insertion.

Sterilization

Considering both tubal ligations for women and vasectomy for men, sterilization is the most common contraceptive method used by couples in the United States. Female sterilization may be performed transabdominally, such as at the time of cesarean delivery; through a minilaparotomy incision immediately postpartum; laparoscopically; or hysteroscopically. Both laparoscopic tubal ligation and hysteroscopic sterilization may be performed as outpatient procedures. Hysteroscopic tubal occlusion using the Essure device requires evaluation with a hysterosalpingogram 3 months after the procedure to confirm tubal occlusion.

Vasectomy is a simple outpatient procedure that can be performed under local anesthesia. Although many men are concerned about the possibility, sexual function is not affected by vasectomy. There are often programs that support contraceptive services for low-income women, but it is often more difficult for low-income men to access vasectomy.

REVIEW QUESTIONS

1. A 34-year-old nulliparous woman requesting contraception is found to have a blood pressure of 165/90 mm Hg. Otherwise, her screening for medical contraindications is negative. Which contraceptive methods would *not* be appropriate for her?

A. Progestin-only pills (POPs)
B. Combined oral contraceptives (COCs)
C. Copper-containing IUD
D. Etonogestrel subdermal implant
E. Levonorgestrel-IUS

Answer: B According to the Medical Eligibility Criteria, this level of hypertension is considered a category 4 contraindication for COCs. Hypertension is considered category 2 for POPs and implants, and it is category 1 for the copper IUD. Nulliparity is considered a category 2 condition for the copper IUD.

2. What would you advise a woman who comes seeking protection from one act of unprotected intercourse 60 hours before her visit?

A. Have a copper IUD inserted.
B. Find a regular method of contraception.
C. Fill a prescription for ulipristal emergency contraception (EC).
D. Buy a package of levonorgestrel emergency contraception if other alternatives are not readily available to her.
E. All of the above

Answer: E The clinician should give the woman the choice of how to proceed after explaining the options and their advantages and disadvantages. The IUD works as emergency contraception in this time frame, but there is no large series of data on use of the progestin-containing device as opposed to the copper IUD, largely because it was not available when the earlier studies were done. The time period after exposure is associated with a diminution of efficacy for LNG EC pills, but there is probably still some effect, and they are easy to obtain. Ulipristal works in this time frame, but it must be supplied by prescription and is costly in the United States unless it is covered by insurance. Women who find themselves in need of EC should review their usual contraceptive practices and try to find an effective method that suits them for regular use.

3. A woman calls your office saying that she took her last combined oral contraceptive (COC) pill 3 days ago. She was traveling and lost her pill pack, and she has now returned home. She had sex yesterday and the day before, both times using a male condom, but she thinks the condom broke yesterday. What would you advise her?

A. Start taking a new pack of COC pills immediately.
B. Take two pills today and tomorrow.
C. Use condoms for the next 7 days.
D. Take levonorgestrel emergency contraception.
E. A, C, and D

Answer: E For any scenario with missed pills, women should take a pill as soon as it noticed to be late, and then continue taking one at the usual time. At the most, this would require taking two pills once; repeated days of double-dosing of pills is not recommended. Condoms must be used until the woman is back on COCs for 7 days. Because there is the possibility that the condom broke and she had unprotected sex within the last 24 hours, she should consider taking emergency contraception.

4. What contraceptive method would you recommend for a woman seeking protection from sexually transmitted infection (STI) and pregnancy who wishes to use only one method?

A. Combined oral contraceptives
B. Progestin-containing IUD
C. Female condom
D. Male condom
E. Spermicides

Answer: D Hormonal contraception does not protect against the acquisition of infection. Spermicides, although toxic to infectious organisms in vitro, do not seem to provide protection against STIs in vivo, and the irritation of the genital tract caused by these compounds may create a portal of entry for pathogens. The female condom is also not a proven method to protect against HIV and other sexually transmitted pathogens, but there is a suggestion that it may reduce risk. The only well-studied method that clearly prevents both pregnancy and STI transmission is the male condom.

5. A woman had a copper IUD inserted 3 weeks ago and complains that she cannot feel the strings in her vagina. On speculum examination, the strings are not visible. On pelvic ultrasound, a bright echogenic linear structure is noted within the uterine cavity. Her vital signs and examination are otherwise normal. What is the appropriate diagnosis and next step?

A. The IUD is correctly placed, but the strings have withdrawn into the uterine cavity. Reassure her that the IUD will be effective; no further action is necessary.
B. The IUD has perforated the uterus. The patient must be scheduled for laparoscopic removal of the misplaced IUD.
C. The IUD is misplaced. It must be removed and replaced in order to be effective.

Answer: A The ultrasound confirms that the IUD is correctly placed within the uterus. Even though the strings are not visible, the IUD will be effective. At the time of removal, small forceps may be used to grasp the strings, which are likely in the endocervical canal or lower portion of the uterus. There is no evidence of perforation in this case.

COMMON MEDICAL PROBLEMS IN PREGNANCY

KAREN ROSENE-MONTELLA

There are 62 million women of childbearing age in the United States, 85% of whom will give birth by the age of 44 years. The majority of these women will not have obtained preventive health services in any given year, and more than half the pregnancies will be unplanned or unintended. At least 25% will enter pregnancy with a chronic medical illness, and more than half will be overweight or obese, making the role of the internist paramount in maternal health. In the most recent Confidential Enquiry into maternal mortality in the United Kingdom, more than half of all women who died of direct or indirect causes were overweight or obese, and more than 15% of all deaths were in morbidly obese women. Sixteen percent of pregnant women have depression in the perinatal period, and depression rates are even higher in those with chronic illnesses, such as diabetes and asthma.

By the time pregnant patients are seen by their obstetricians, most major teratogenic abnormalities have already occurred (Fig. 239-1), and the window of opportunity to enter pregnancy in a quiescent disease state, on the safest possible medication profile, may have passed. For this reason, internists caring for women of childbearing age have a unique responsibility to provide preconception care at a time when interventions will be of maximum benefit to both the fetus and the mother. Table 239-1 describes preconception interventions for women with chronic medical illnesses.

The basic principles involved in the care of pregnant patients with medical disorders are reviewed here, followed by a more detailed discussion of certain medical conditions, selected because of their contribution to maternal mortality or because of the frequency with which they occur.

BASIC PRINCIPLES

Pregnancy is associated with significant but normal physiologic changes that have an impact on the diagnosis and management of disease states and the pharmacokinetics of most drugs (Table 239-2).[1] The physiologic changes required during pregnancy may stress the woman's ability to adapt, particularly in the presence of an underlying disease. The mother's response to pregnancy often unmasks diseases or predicts future risk, so pregnancy is an opportunity to identify women at risk for other non–pregnancy-related illnesses. For example, gestational diabetes is predictive of an increased risk for type 2 diabetes; preeclampsia is predictive of increased risk for ischemic heart disease and stroke[2]; and thrombosis, late fetal loss, or preeclampsia may unmask an underlying thrombophilia.

Fetal well-being depends on maternal well-being. Although there is often thought to be a dichotomy between maternal and fetal needs, they are usually one and the same. The fetus is dependent on maternal perfusion, oxygenation, and nutrition. Thus, more harm may be done by withholding necessary treatments and investigations from pregnant women than by providing them. Uninvestigated symptoms lead to the progression of untreated disease, and untreated maternal disease compromises fetal safety, growth, and development. The major cause of asthma exacerbations and seizures during pregnancy is abrupt discontinuation of medications, exposing the fetus to hypoxemia and acidosis in an effort to save the fetus from drug exposure. A population analysis of prescriptions for asthma medications in The Netherlands showed that prescriptions for controller medications decreased by 30% during the first months of pregnancy.[3] In the U.K. Confidential Enquiry, in more than half the cases of maternal death from pulmonary embolism, failure to make the diagnosis was due to the unfounded fear that diagnostic testing would be harmful to the fetus. Most diagnostic imaging can be used safely in pregnancy. The effects of radiation in utero depend on both the gestational age at exposure and the level of exposure. Recommendations on fetal exposure from the National Commission on Radiation Protection are summarized in Table 239-3. Radiation exposure from specific diagnostic tests is provided in Table 239-4.

The effect of contrast agents is related to the bioavailability of iodine, and there is concern about the impact on the fetal thyroid. Iodine availability is extremely low, and single-dose exposures, even if they are high, are unlikely

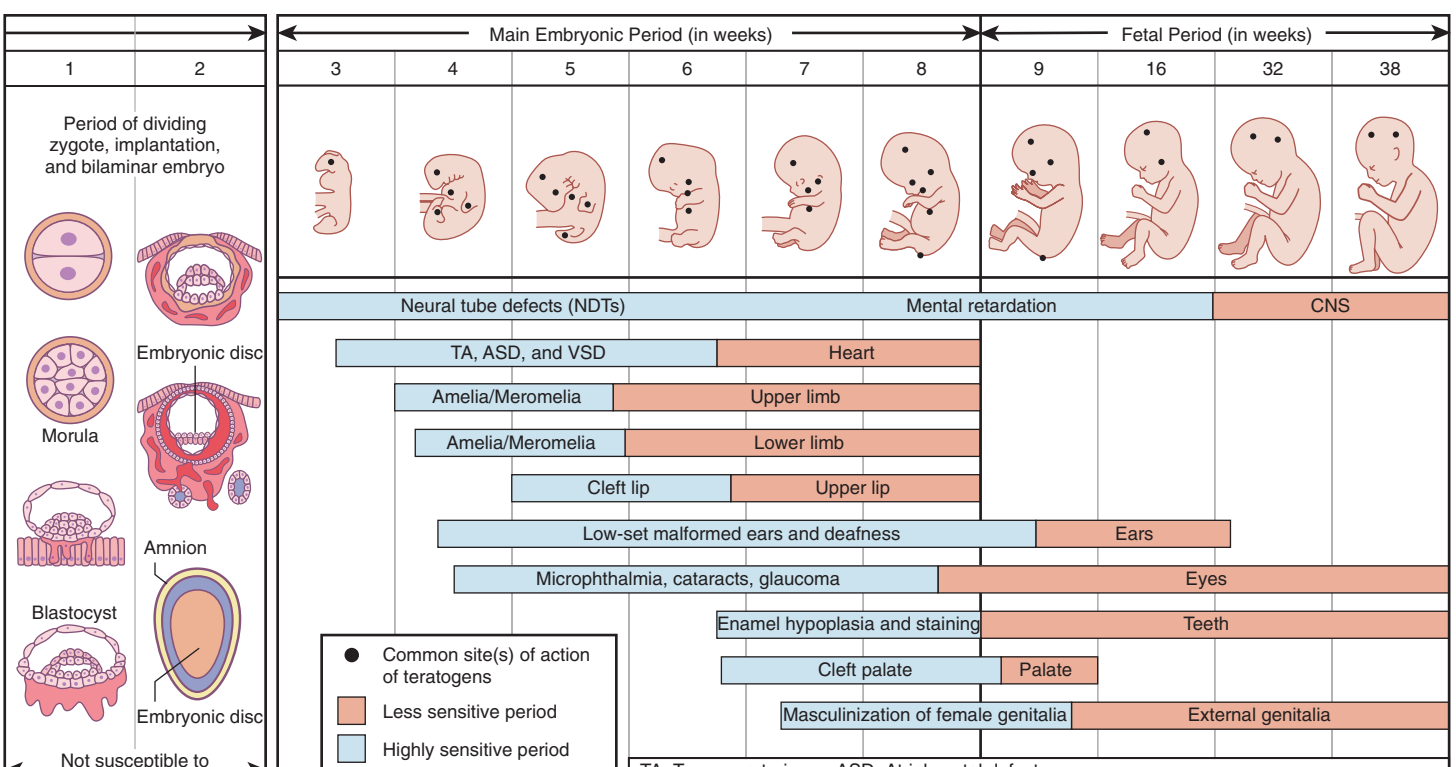

FIGURE 239-1. The developing fetus. CNS = central nervous system. **(From Moore K. The Developing Human: Clinically Oriented Embryology. Philadelphia: WB Saunders; 1982, with permission from Annals of Internal Medicine.)**

to be harmful. Therefore, contrast agents may be used when necessary. There are limited data on gadolinium, so the current recommendation is to avoid gadolinium exposure if possible.

The use of medications to treat pregnant women requires a rational risk-benefit analysis and a good understanding of the maternal indications. It is helpful to view treatment as justifiable or not justifiable rather than as safe or not safe. It is important to consider whether the condition is self-limited or harmless, what the maternal and fetal consequences of discontinuing a medication will be, and the safety data for the drug. U.S. Food and Drug Administration categories may be misleading and often do not include adequate data for a proper risk-benefit analysis. Resources such as the Teratology Information Service, found at http://depts.washington.edu/terisweb/teris, offer more complete information.

The list of known human teratogens is small and includes warfarin, cyclophosphamide, diethylstilbestrol, lithium, thalidomide, penicillamine, isotretinoin, methotrexate, acetazolamide, and the antiepileptic drugs phenytoin, carbamazepine, phenobarbital, and valproic acid. Of the antiepileptic drugs, valproate has the most significant data, and it is the only antiepileptic drug for which discontinuation during pregnancy is recommended if there is an effective alternative.[4] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) should be added to this list on the basis of data confirming that first-trimester exposure is associated with fetal renal agenesis and renal failure. Tetracyclines should be avoided because of later effects on fetal teeth and bone.

HYPERTENSIVE DISORDERS OF PREGNANCY

DEFINITION

Hypertension in pregnancy is defined as a blood pressure (BP) of 140/90 mm Hg or higher. It is defined as chronic hypertension when it predates pregnancy, is diagnosed before 20 weeks' gestation, or persists post partum. Transient late or gestational hypertension occurs toward term and resolves post partum in the absence of any other signs or symptoms of preeclampsia.

EPIDEMIOLOGY

Chronic hypertension is the most common medical condition encountered in women of childbearing age. The incidence is increasing parallel to the increase in obesity, insulin resistance, and pregnancies in women older than 30 years. Hypertension complicates 5 to 8% of pregnancies and is associated with a 20% risk for the development of preeclampsia.

PATHOBIOLOGY

Systemic arterial BP decreases by 10 to 15 mm Hg during normal pregnancy, with a greater fall in diastolic than in systolic pressures, probably because of the decreased sensitivity to angiotensin II that has been demonstrated in pregnant women. BP begins to fall in the first trimester, reaching a nadir toward the end of the second trimester and returning toward baseline at term. This decrease may be exaggerated in women with chronic hypertension, making the diagnosis of chronic hypertension difficult during pregnancy and affecting both diagnostic and therapeutic considerations.

DIAGNOSIS

The diagnosis of hypertension relies simply on a BP measurement, in the sitting position at the level of the heart, of 140/90 mm Hg or higher on two occasions 6 hours apart. Later in pregnancy, inferior vena cava compression by the gravid uterus may lower BP substantially in the supine position, so it is critical to measure maternal BP in the sitting position. The initial evaluation should document target organ damage (such as left ventricular hypertrophy), renal disease (creatinine concentration, urinalysis, and potassium concentration), and retinopathy so that a baseline is established. Consideration of secondary causes is necessary in this young population (Chapter 67), but the diagnosis of secondary causes of hypertension is complicated by normal pregnancy-related changes.[5] The diagnosis of Cushing's syndrome is complicated by increased levels of cortisol and the placental production of adrenocorticotropic hormone and corticotropin-releasing hormone, so the best test is a 24-hour urine free cortisol measurement with higher pregnancy-specific reference ranges. Primary hyperaldosteronism (Chapter 227) may also be

TABLE 239-1 PRECONCEPTION INTERVENTIONS FOR WOMEN WITH MEDICAL ILLNESSES

TYPE 1 AND TYPE 2 DIABETES

Discuss importance of a normal hemoglobin A_{1c} before conception and importance of using contraception until that is achieved
Evaluate for microvascular complications
  Obtain remission for proliferative retinopathy
  Emphasize need to discontinue ACE inhibitor after first missed period
Discontinue thiazolidinediones and statins
Consider change to insulin therapy for type 2 diabetic patients on oral agents unless using metformin for ovulation induction in PCOS
Discuss probable need to reduce insulin dose in first trimester

THYROID DISEASE

Screen for hypothyroidism in women at risk
Normalize TSH and free T_4 before pregnancy
Counsel women taking levothyroxine on probable need to increase dose soon after conception
Diagnose cause of hyperthyroidism and consider ablative therapy for women with Graves' disease requiring high doses of PTU

CHRONIC HYPERTENSION/RENAL DISEASE

Rule out secondary causes of hypertension if appropriate
Evaluate extent of end-organ disease
Quantify GFR and proteinuria
Discuss drugs of choice for hypertension and replace ACE inhibitor
Discuss risk of superimposed preeclampsia and use of low-dose aspirin for women at significant risk of preeclampsia

THROMBOEMBOLIC DISEASE

Consider evaluation for congenital or acquired thrombophilias in women with previous VTE, previous poor obstetric outcome, or family history
Discuss risks of warfarin in pregnancy, need to discontinue warfarin by 4-6 weeks' gestation, and conversion to unfractionated or low-molecular-weight heparin
Discuss options to combined oral contraceptives

EPILEPSY

Determine whether patient is a candidate for withdrawal of antiepileptic drugs
Consider monotherapy with most effective agent at lowest dose possible
Prescribe folate at 1 to 4 mg/day
Discuss possible ineffectiveness of low-dose contraceptives with phenobarbital, phenytoin, and carbamazepine
Consider discontinuing valproate

CARDIAC DISEASE

Obtain baseline echocardiography if congenital disease, stenotic lesion, or pulmonary hypertension suspected
Evaluate for coronary artery disease in women with multiple risk factors

ASTHMA

Verify patient's asthma action plan and peak flowmeter use
Discuss relative safety of all asthma medications except leukotriene modifiers

SYSTEMIC LUPUS ERYTHEMATOSUS AND AUTOIMMUNE DISEASE

Evaluate for renal and cardiopulmonary disease and antiphospholipid, anti-Ro, anti-La antibodies
Avoid pregnancy if disease is active
Discuss relative safety of most immunosuppressants

ACE = angiotensin-converting enzyme; GFR = glomerular filtration rate; PCOS = polycystic ovary syndrome; PTU = propylthiouracil; T_4 = thyroxine; TSH = thyroid-stimulating hormone; VTE = venous thromboembolism.
From Rosene-Montella K, Keely EJ, Lee RV, Barbour LA, eds. *Medical Care of the Pregnant Patient.* 2nd ed. Philadelphia: ACP Press/American College of Physicians; 2008.

difficult to diagnose in the face of normal pregnancy-related elevations in plasma renin activity and aldosterone and because progesterone ameliorates both the hypertensive and the kaliuretic effects of aldosterone. Primary hyperaldosteronism should be strongly considered in any patient with chronic hypertension in whom there is a marked increase in BP toward term or post partum. Pheochromocytoma (Chapter 228) is associated with a high maternal and fetal mortality rate, in large part owing to a delay in diagnosis. Both magnetic resonance imaging and magnetic resonance angiography (which do not require gadolinium) can be used safely in pregnancy to evaluate the adrenal glands and renal arteries.

TABLE 239-2 NORMAL PHYSIOLOGIC CHANGES IN PREGNANCY

CARDIAC

Cardiac output increased 40%
Blood volume increased 30-50%
Heart rate increased 10-20 beats/min
Blood pressure decreased 10-15 mm Hg
ECG changes related to widened thorax, dextrorotation of heart, elevation of diaphragm

PULMONARY

Upper airway hyperemia and glandular hyperactivity leading to increased edema and friability
Nasal congestion, gestational rhinitis, snoring
Difficult airway management and failed intubation
Minute ventilation increased (owing to an increase in tidal volume, *not* respiratory rate, which remains unchanged), which leads to relative respiratory alkalosis (pH 7.4-7.45)
  Normal Pao_2 100-105 mm Hg
  Normal $PaCO_2$ 28-32 mm Hg

RENAL

Increased GFR to 150-180 mL/min/1.73 m^2
Normal serum creatinine concentration <0.8 mg/dL
Increased renal excretion of bicarbonate, limiting buffering capacity in patients who become acidotic
Decreased oncotic pressure

ALTERED PHARMACOKINETICS

Increased renal and hepatic clearance of drugs
Altered absorption
Altered protein binding
Increased volume of distribution

ECG = electrocardiogram; GFR = glomerular filtration rate.
These physiologic changes generally progress throughout gestation.

TABLE 239-3 NATIONAL COMMISSION ON RADIATION PROTECTION (NCRP) RECOMMENDED PREGNANCY EXPOSURES

TOTAL EXPOSURE DURING PREGNANCY (rad)	NCRP RECOMMENDATIONS
≤5	Acceptable; low likelihood of problems
5-10	Low risk for problems
10-15 (at ≤8 wk gestation)	Higher risk; consideration of termination
>15	Termination of pregnancy recommended

CT = computed tomography; IVP = intravenous pyelography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; MRV = magnetic resonance venography.

TREATMENT

Rx

Patients previously receiving drug therapy can often discontinue antihypertensives and restart them when BP gradually rises to prepregnant values toward term. It is difficult to determine whether rising BP represents a normal physiologic return to earlier pressure or the development of preeclampsia. Baseline preeclampsia laboratory tests (see later), very close follow-up, and comanagement with the patient's obstetrician are required. Patients with good BP control may prefer to continue safe medications or switch to another regimen. The drugs for which there is grade A evidence of efficacy and safety are methyldopa and labetalol (Table 67-5). Nifedipine, hydralazine, and other β-blockers, especially those with intrinsic sympathomimetic activity, have also been studied and are acceptable second- and third-line agents.

Dosing should take into consideration the increase in renal and hepatic clearance and the increased volume of distribution, which may require higher doses or narrowed dosing intervals during pregnancy. ACE inhibitors and ARBs should be discontinued at the diagnosis of pregnancy because of their teratogenicity and their association with fetal and neonatal renal agenesis and renal failure even when they are used later in gestation.

The goal of antihypertensive therapy in pregnancy is not clear. Most consensus recommendations, which address fetal concerns and short-term maternal safety only, recommend keeping BP below 160/100 mm Hg. Given the long-term maternal data, most centers prefer to keep maternal BP, particularly in patients with diabetes or renal disease, below 140/90 mm Hg. Consensus recommendations agree that maintaining BP above 120/80 mm Hg is necessary to preserve placental perfusion. There is no evidence that salt restriction or dietary changes improve BP control in pregnancy, and weight loss is not recommended. Likewise, there is no evidence that BP control decreases the risk of preeclampsia. It is important to obtain baseline preeclampsia laboratory tests (complete blood count, platelet count, creatinine concentration, uric acid level, aspartate transaminase level, urinalysis) in all patients with hypertension, given the 20% risk of preeclampsia, and low-dose aspirin and calcium supplementation should be considered to prevent preeclampsia (see later). Fetal monitoring with serial ultrasound for growth and amniotic fluid volume, nonstress testing (fetal heart rate acceleration in response to movement) once or twice a week after 32 weeks, and consideration of Doppler flow velocimetry are recommended.

Most antihypertensives are safe for breast-feeding, which should be encouraged. Hydrochlorothiazides, α-methyldopa, nifedipine, acebutolol, and metoprolol are all approved by the American Academy of Pediatricians. There is no evidence that hydrochlorothiazides affect milk volume. There is evidence that propranolol and atenolol are concentrated in breast milk, so they should be avoided. Enalapril and captopril are the preferred ACE inhibitors in breast-feeding women, but it may be prudent to delay ACE inhibitors for the first few weeks of the baby's life and for mothers of premature babies, given the adverse pregnancy data.

PROGNOSIS

Hypertension may increase the risk of placental abruption, intrauterine growth restriction (IUGR), and low-birthweight babies. The major risk, however, is its contribution to the risk for preeclampsia and the associated increase in perinatal morbidity and mortality. In addition, chronic hypertension in patients with other comorbidities significantly increases the risk for maternal and fetal complications[6] (Table 239-5).

Women who develop hypertension during pregnancy are at increased lifetime risk for the development of chronic hypertension, even if the BP normalizes post partum.[7]

PREECLAMPSIA

DEFINITION

Preeclampsia is a multisystem disorder defined as BP of 140/90 mm Hg or higher, accompanied by proteinuria of more than 300 mg/24 hours after the 20th week of gestation in a previously normotensive patient. When it is diagnosed in a patient with preexisting chronic hypertension, it is referred to as chronic hypertension with superimposed preeclampsia.

A urine protein-creatinine ratio of at least 0.3 may become a criterion for proteinuria, but the American College of Obstetricians and Gynecologists has not yet added this to the definition. Edema and hyperreflexia are no longer considered diagnostic criteria, and the 30 mm Hg increase in systolic pressure or 15 mm Hg increase in diastolic pressure has been dropped from the criteria for hypertension. Severe preeclampsia is defined as the presence of one of the following symptoms or signs with preeclampsia: systolic BP of 160 mm Hg or higher, or diastolic BP of 110 mm Hg or higher, on two occasions at least 6 hours apart; proteinuria of more than 5 g in a 24-hour period; pulmonary edema; oliguria (<400 mL in 24 hours); persistent headaches; epigastric pain or impaired liver function; thrombocytopenia; and IUGR.

EPIDEMIOLOGY

Preeclampsia complicates 6 to 8% of pregnancies worldwide. Preeclampsia/eclampsia is a leading cause of maternal mortality in the developing world and continues to contribute to maternal mortality in the United States despite the availability of antihypertensives and antiseizure medications. In the United States, preeclampsia is believed to be responsible for 15% of premature deliveries and 17.6% of maternal deaths. Worldwide, preeclampsia and eclampsia are estimated to be responsible for approximately 14% of maternal deaths per year (50,000 to 75,000).

Primigravida and multigravida women with new partners are at increased risk, suggesting a role for paternal antigens. Additional risk factors include prior history of preeclampsia, black race, diabetes or insulin resistance, obesity, systemic lupus erythematosus (SLE), renal disease, hypertension, thrombophilia, obesity, molar pregnancy, multiple gestation, and extremes of age (younger than 20 years or older than 40 years).

PATHOBIOLOGY

Preeclampsia is a disorder of abnormal placentation that begins early in gestation, well before its manifestations are clinically apparent. In normal pregnancy, uterine spiral arteries undergo remodeling when they are invaded by fetal cytotrophoblastic cells, resulting in an adhesion receptor switch from cells with characteristics of epithelial cells to cells with the phenotype of endothelial cells. This leads to the transformation of previously narrow, high-resistance maternal uterine blood vessels into dilated, high-capacitance blood vessels. The proximal portions of the spiral arteries are further dilated by the hormonal effects of estrogen and progesterone, resulting in an overall increase in uterine blood flow from 45 mL/minute during menstruation to 750 mL/minute at term. In preeclampsia, this cell switching does not occur, and the fetal cells' only superficial invasion into maternal vasculature results in limited placental perfusion. As the pregnancy progresses, abnormal placentation produces relative hypoxia and ischemia as this compromised uterine blood flow cannot keep up with the growing demands of the fetus and the placenta. The result is diffuse endothelial dysfunction that is manifested as the clinical syndrome of preeclampsia (Fig. 239-2).

Recent work on the potential mechanism of the endothelial dysfunction that underlies this disease state has focused on the imbalance between pro-angiogenic and anti-angiogenic factors, arising from studies showing elevated concentrations of placental soluble film-like tyrosine kinase 1 in the plasma of women with preeclampsia. This protein prevents the interaction of placental growth factor and vascular endothelial growth factor with endothelial receptors, inducing endothelial dysfunction. A placenta-derived soluble transforming growth factor-β coreceptor, soluble endoglin, is elevated in the sera of patients with preeclampsia, inducing vascular permeability and hypertension; the degree of elevation correlates with disease severity, and levels fall after delivery. Additional factors currently being studied include ADAM12 trophoblast and angiogenesis markers, pregnancy-associated plasma protein A, placental protein 13, and placental growth factor.[8] To date, no definitive predictive model has been established. Current studies to address both the cause of and the mechanism linking preeclampsia and the risk of cardiovascular disease are ongoing and focus on endothelial dysfunction.[9]

DIAGNOSIS

The diagnosis of preeclampsia depends on a BP of 140/90 mm Hg or higher and proteinuria of more than 300 mg/24 hours after 20 weeks' gestation. Eclampsia is diagnosed when a patient with preeclampsia has a seizure. Additional abnormalities that contribute to the diagnosis include hyperuricemia, hemoconcentration, elevated creatinine or liver function test results, and thrombocytopenia. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) (Chapter 172) is likely to be a more severe form of preeclampsia. The diagnosis of severe preeclampsia depends on the criteria previously listed.

Diagnostic evaluation should include a careful history, asking about headache, visual complaints, epigastric pain, weight gain, and edema and reviewing the presence of risk factors. The physical examination should include a careful neurologic examination, looking for funduscopic changes (retinal vasospasm, edema, or hemorrhage) or hyperreflexia, and examination for any

For each analysis, reference group was delivery admissions without chronic hypertension and without comorbidity of interest. Admissions with chronic hypertension but without comorbidity of interest were included as a group in each analysis. Because of similarity of estimates of association in these groups to those obtained when analyzing effect of overall chronic hypertension, results are not shown.

focal findings suggestive of mass effect, hepatic tenderness, and edema. Laboratory testing for preeclampsia includes a complete blood count, platelet count, urine protein-creatinine ratio or 24-hour urine protein, liver function tests, creatinine concentration, and uric acid level. Additional evaluation includes fetal testing and close maternal monitoring for life-threatening consequences, such as severe hypertension, seizures, pulmonary edema, cerebral hemorrhage, hepatic infarction or rupture, disseminated intravascular coagulation, and renal failure.

Currently, diagnosis depends on development of the full clinical syndrome, but earlier diagnosis may be possible on the basis of biomarkers. It is likely that a combined model that looks at soluble endoglin, soluble film-like tyrosine kinase 1, pregnancy-associated plasma protein A, ADAM12, and placental growth factor concentrations will be a better prediction instrument before 20 weeks' gestation than any individual marker.

The differential diagnosis of each individual manifestation of preeclampsia is broad, so the diagnosis centers on the constellation of signs and symptoms that suggest preeclampsia. The clinical conditions that can mimic preeclampsia include SLE with nephritis (Chapter 266), thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome (Chapter 172). Differentiation of preeclampsia from a flare of SLE with nephritis (Chapter 266) is difficult because both can cause hypertension, proteinuria, thrombocytopenia, and rises in serum creatinine concentration. The differential diagnostic features that favor SLE include falling serum complement levels, rising anti-DNA antibodies, and extrarenal manifestations of SLE such as rash and arthralgias. The proteinuria and hypertension in preeclampsia are more likely to be of sudden onset.

TREATMENT

Rx

Once it occurs, the only known treatment of preeclampsia is delivery as soon as it is obstetrically feasible. Nevertheless, preeclampsia can be manifested post partum, and both preeclampsia and eclampsia have been reported up to 21 days after delivery. Management of preeclampsia includes treatment of hypertension, seizure prophylaxis, and limitation of fluids due to the risk of pulmonary edema. Treatment of severe hypertension in preeclampsia is reviewed in Table 239-6. Magnesium sulfate is recommended as first-line treatment of eclampsia as well as for prophylaxis against eclampsia in women with

TABLE 239-6 TREATMENT OF SEVERE HYPERTENSION IN PREECLAMPTIC PATIENTS

MEDICATION	ONSET AND DURATION OF ACTION	ACUTE DOSING FOR SEVERE HYPERTENSION	MAINTENANCE DOSE
Labetalol	Begins to work in 5-10 min Lasts 3-6 hr	Given as a series of boluses until BP reaches the desired level: 10 mg IV push; then in 10 min, 20 mg IV push; then in 10 min, 40 mg IV push; then in 10 min, 80 mg IV push; then in 10 min, 80 mg IV push, up to a total dose of no more than 300 mg Follow with PO labetalol or labetalol drip	100-200 mg PO bid-tid (100-600 mg bid-tid; maximum 2400 mg/day) IV infusion 0.5-2.0 mg/min (labetalol comes in vials of 100 mg/20 mL) Put 5 vials (100 mL) labetalol into 150 mL IV fluid (D_5W, LR, or NS) to get a solution of 2 mg/mL; start at 15 mL/hr (0.5 mg/min); titrate up to as high as 60 mL/hr (2 mg/min)
Nifedipine	Begins to work in <30 min Lasts 4-5 hr	10-20 mg PO q30min to a maximum of 50 mg	10-20 mg PO tid of short-acting nifedipine or 30-120 mg once daily of long-acting formulation
Hydralazine	Begins to work in 10-20 min Lasts for 3-6 hr	2.5-10 mg IV q30min	Start at 10 mg PO qid; can be gradually increased to 50 mg PO qid

BP = blood pressure; D_5W= dextrose 5% in water (solution); LR = lactated Ringer's (solution); NS = normal saline.
From Rosene-Montella K, Keely EJ, Lee RV, Barbour LA, eds. *Medical Care of the Pregnant Patient.* 2nd ed. Philadelphia: ACP Press/American College of Physicians; 2008.

severe and nonsevere preeclampsia. Phenytoin and benzodiazepines should not be used for eclampsia prophylaxis or treatment unless there is a contraindication to magnesium sulfate or it is ineffective. There is evidence from two randomized controlled trials that magnesium is superior to phenytoin for the prevention of both primary seizures and recurrent seizures in eclampsia.

Treatment of acute seizures in eclampsia includes airway protection, fetal monitoring, magnesium, BP control, and benzodiazepines as needed to stop seizures acutely. Treatment of severe hypertension is as outlined in Table 239-6.

Severe maternal manifestations of preeclampsia that may warrant early delivery include seizure, renal failure, severe hypertension, severe thrombocytopenia or hemolysis, aspartate transaminase or alanine transaminase elevation of more than two to three times normal, pulmonary edema, retinal hemorrhage, and other symptoms suggestive of end-organ damage (headache, visual disturbance, epigastric or right upper quadrant pain). Fetal indications for delivery may include significant IUGR, oligohydramnios, and nonreassuring fetal testing. Women with preeclampsia before 34 weeks' gestation should receive a corticosteroid that crosses the placenta, such as betamethasone or dexamethasone, to accelerate fetal lung maturation.

PREVENTION

Multiple trials of antihypertensives, antioxidant supplementation with vitamins C and E, magnesium, protein or salt restriction, fish oil, and other dietary changes have failed to prevent preeclampsia. Low-dose aspirin in high-risk populations is the only intervention with data to support a positive effect. Initial trials showed limited effects, but a subsequent meta-analysis found that low-dose aspirin (<100 mg/day) decreases both the risk of preeclampsia and fetal and neonatal deaths. We recommend aspirin 81 mg/day in all patients with risk factors for preeclampsia. Trials of calcium supplementation have shown conflicting results, but given the inverse relationship between dietary calcium intake and BP in the general population, calcium supplementation of at least 1 g/day is recommended for women with a low dietary intake of calcium (<600 mg/day). An alternative to supplementation may be to increase dietary calcium by eating three or four servings per day of dairy products (assuming 250 to 300 mg of calcium per serving).

PROGNOSIS

Women who have had preeclampsia are at increased risk of heart disease, stroke, and cardiovascular death. Preeclampsia is also a marker for increased risk of end-stage renal disease. One year after delivery, preeclampsia patients observed longitudinally by Smith and colleagues had evidence of increased insulin resistance, BP, cholesterol, and triglycerides, which may be the first manifestations of the metabolic syndrome. The same group recently reported on the calculated 10-year, 30-year, and lifetime risk of cardiovascular disease in this cohort.[10] The 10-year, 30-year, and lifetime risk for development of cardiovascular disease was 18.2% versus 1.7%, 31.3% versus 5.1%, and 41.4% versus 17.8% in matched controls who did not have preeclampsia. It is unclear whether there is a shared pathogenesis, an unmasking of already established disease, or a contribution to the development of disease. It is possible that preexisting abnormal endothelial function predisposes to renal and vascular disease later in life and is, in fact, the same abnormality that disturbs implantation, resulting in preeclampsia and fetal loss. It is also possible that preeclampsia itself contributes to the later development of disease.

Continuing care beyond 6 weeks post partum is strongly recommended. Women with a history of severe preeclampsia should be screened for preexisting hypertension, underlying renal disease, thrombophilia, and possibly secondary causes of hypertension. They should also be informed of the risk for preeclampsia in subsequent pregnancies, particularly if the birth interval is less than 2 years or more than 10 years. Women who are overweight should be advised to normalize their body mass index before another pregnancy and to reduce long-term risk. Both women with preexisting hypertension and those whose BP normalizes are likely to benefit from an overall assessment of cardiovascular risk that includes a lipid profile, smoking cessation, and early interventions to reduce risk.

DEEP VENOUS THROMBOSIS, PULMONARY EMBOLISM, AND THROMBOPHILIA
(Chapters 81, 98, and 176)

Pulmonary embolism (PE) is the leading medical cause of maternal mortality in the developed world. It was responsible for 30% of direct maternal deaths in the most recent U.K. Confidential Enquiry. Despite our best efforts, mortality rates from PE in pregnancy have not changed in more than 2 decades, and the incidence of PE in the United States is rising, likely owing to the increase in obesity and cesarean deliveries. Current strategies to reduce risk from PE must address the widespread use of appropriate prophylaxis, early detection of venous thromboembolism (VTE), and prompt, safe, and effective therapy.[11]

EPIDEMIOLOGY

More than half of the VTE events in women younger than 40 years occur in association with pregnancy. VTE is 10 times more common in pregnant than in nonpregnant women of comparable age. It occurs in 5 to 12 of 10,000 pregnancies ante partum and in 3 to 7 of 10,000 post partum. The risk of VTE with pregnancy is increased by the presence of additional risk factors, including prolonged bedrest, cesarean section, preeclampsia, three or more children, smoking, obesity, previous superficial thrombophlebitis, previous VTE, thrombophilia, and family history of VTE.

PATHOBIOLOGY

Pregnancy is a hypercoagulable state (Chapter 176) characterized by venous stasis, maternal prothrombotic imbalance in which activation of the coagulation system exceeds the fibrinolytic response progressively through the course of pregnancy, and endothelial disruption. Venous stasis occurs as a result of progesterone-induced venodilation early in pregnancy and is later increased by the compressive effects of the gravid uterus. Compression of the left iliac vein by the right iliac artery further increases venous stasis on the left, which may explain the finding that more than 90% of cases of deep venous thrombosis (DVT) in pregnancy occur in the left leg. Endothelial damage occurs with preeclampsia and with both vaginal and operative delivery, further contributing to VTE risk.

Genetic and Acquired Thrombophilias

A positive family history for VTE (possibly a marker for thrombophilia) or a known thrombophilia significantly increases the risk for VTE in pregnancy (see Chapter 176). The best-described genetic thrombophilias include deficiencies in protein C, protein S, and antithrombin III, all of which appear to have autosomal dominant inheritance with variable penetrance, and the presence of the single-gene mutations factor V Leiden and prothrombin G202010. Of these, antithrombin-deficient homozygotes (rare) and compound heterozygotes have the highest risk of VTE in pregnancy. The thrombophilias have also been associated with obstetric complications, including IUGR, abruption, both early and late pregnancy loss, and preeclampsia (early, severe, or recurrent). The antiphospholipid antibody syndrome is the major acquired thrombophilia for which there are compelling pregnancy data supporting a link with both thrombosis risk and obstetric complications as well as the use of thromboprophylaxis to prevent poor obstetric outcome (Chapter 176). A large international, multicenter trial, the Thrombophilia in Pregnancy Prophylaxis Study, is currently under way, randomizing patients with thrombophilias and adverse pregnancy outcomes to surveillance versus thromboprophylaxis. Preliminary data analysis has failed to demonstrate efficacy of thromboprophylaxis for the prevention of the adverse pregnancy outcomes described before, and the most recent American College of Obstetricians and Gynecologists technical bulletin recommends against prophylaxis for prevention of adverse pregnancy outcome in patients with thrombophilias other than the antiphospholipid antibody syndrome.[12]

DIAGNOSIS

The diagnosis of VTE during pregnancy is complicated by both normal pregnancy-related physiologic changes and the reluctance to use diagnostic imaging in pregnancy. Clinical signs are unreliable, and leg swelling and complaints of dyspnea are common during pregnancy, making it difficult to decide when to investigate for VTE. The finding that 90% of DVT occurs in the left leg led to the observation that the combination of symptoms in the left leg, calf circumference difference of 2 cm or more, and first-trimester presentation (when leg swelling is less likely) is highly predictive of DVT. Most DVTs occur ante partum, and events are evenly distributed throughout gestation. The majority of fatal PEs in most studies occurred in the postpartum period, so vigilance is required for a prolonged period after delivery. Diagnosis of DVT requires compression ultrasonography that includes the iliac veins and the inferior vena cava at the level of the liver (Chapter 81). It also requires repeated compression ultrasonography if study findings are normal but there is high pretest probability and continuing symptoms. In

patients with suspected iliac or pelvic vein thrombosis and normal findings on ultrasound studies, magnetic resonance imaging or magnetic resonance venography is recommended.

The diagnosis of PE is even more of a problem, given the frequency of dyspnea, the likelihood of normal oxygenation in young patients with no underlying cardiopulmonary disease, and the more invasive nature of diagnostic testing. Arterial blood gas analysis is not helpful; the A-a gradient was normal in 60% of pregnant patients with documented PE in a retrospective review done at two centers.

The radiation exposure from imaging required for the diagnosis of PE is well below that allowed by the National Commission on Radiation Protection (see Table 239-3), so testing should never be withheld out of concern for fetal exposure. Ventilation-perfusion (V/Q) scanning is still the diagnostic test of choice in most centers outside the United States. It is better validated in pregnancy, involves no administration of contrast material, and has good negative predictive value in normal scans and in low-probability scans when it is paired with leg studies. If V/Q is used, it must be understood that there is still a significant risk of PE in patients with scans interpreted to be "intermediate" and "indeterminate," so additional testing is required in those cases. Computed tomography angiography has replaced V/Q scanning in most U.S. centers on the basis of its use in the nonpregnant population. The technique is dependent on cardiac output and plasma volume, both of which are increased during pregnancy. This may lead to poor opacification of the vessels, causing artifacts to be read as filling defects or the failure to visualize clots, so the technique must be adjusted for pregnancy. It is a sensitive, cost-effective test that offers an alternative diagnosis in 25 to 40% of cases, and it is preferred if there is an abnormality on the chest radiograph. It is well tolerated and has a shorter breath-holding time than V/Q scans, so it is also preferred in unstable patients, especially if an alternative diagnosis is suspected. Computed tomography angiography exposes the maternal breast to 2 to 3.5 rad, and exposure of the breast to 1 rad increases the lifetime risk of breast cancer by 13%. The use of breast shields decreases this exposure by about 50% without compromising the integrity of the test, so breast shields are strongly recommended.

The role of D-dimer testing in pregnancy has not yet been elucidated because D-dimer is elevated during normal pregnancy. It may have some use for its negative predictive value, but studies are inadequate to recommend its use at this time.

TREATMENT

Rx

The safety of unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) (Chapter 38) for the fetus is well established, so they are the drugs of choice for both the treatment and the prevention of VTE. Warfarin is a teratogen that crosses the placenta and has been associated with fetal bleeding and central nervous system abnormalities later in gestation, so it is not used for this indication in pregnancy. Initial treatment of VTE in the pregnant patient is either intravenous UFH, followed by subcutaneous UFH or LMWH, or an initial adjusted dose of LMWH that is then continued; both are acceptable.

LMWH causes a lower incidence of heparin-induced thrombocytopenia (Chapter 172) and less osteoporosis, so, given the prolonged exposure during pregnancy, it is the preferred agent. The 2012 American College of Chest Physicians consensus guidelines now recommend LMWH as the preferred agent in pregnancy.[13] The same consensus conference suggests limiting the use of fondaparinux and parenteral direct thrombin inhibitors to patients with severe allergic reactions to heparin (e.g., heparin-induced thrombocytopenia) who cannot receive danaparoid. The use of oral direct thrombin and anti-Xa inhibitors is not recommended (Table 239-7). LMWH has increased bioavailability, but the ease of administration in pregnancy is mitigated by the need for twice-daily dosing and frequent monitoring. Dosing requirements increase with increasing gestation, so it is necessary to follow anti-Xa levels. Because LMWH has limited reversibility with protamine and because it has been associated with epidural hematomas in nonpregnant patients given spinal or epidural anesthesia, most centers recommend a switch to UFH by 34 to 36 weeks. This allows patients the option of epidural anesthesia for delivery, and in the event of an emergent delivery before holding of anticoagulation, UFH can be reversed with protamine. Specific treatment recommendations are outlined in Table 239-8.

PREVENTION

The overall recurrence risk of VTE during pregnancy ranges from 5 to 20%, depending in part on the circumstances of the index clot. Patients with a previous idiopathic VTE (while not pregnant) or a secondary VTE that occurred during a previous pregnancy or while taking oral contraceptives and patients with a positive family history of or identified thrombophilia are at the highest risk. The thrombophilias with the highest recurrence risk are the antiphospholipid antibody syndrome and homozygosity or compound heterozygosity with more than one mutation and antithrombin deficiency. Thromboprophylaxis is required in all these groups, and its intensity is related to the severity of the risk (see Table 239-8). The lowest risk of recurrence, based on retrospective data, appears to be in patients without a family history of thrombophilia in whom the previous VTE occurred in association with a transient risk factor other than pregnancy or oral contraceptive use. The American College of Chest Physicians consensus guidelines now suggest surveillance with postpartum thromboprophylaxis in this group, but many U.S. centers would also offer antepartum thromboprophylaxis. Prophylaxis should be continued for at least 6 to 8 weeks post partum, when the hemostatic changes of pregnancy return to prepregnant values. Additional groups that should be considered for thromboprophylaxis are patients who have undergone cesarean section, particularly if they have an additional risk factor for VTE, and patients on prolonged bedrest. Patients receiving continued prophylactic or treatment doses post partum have the option of switching to warfarin, which is safe in breast-feeding women.

PROGNOSIS

VTE during pregnancy may be the first manifestation of a hypercoagulable state, as pregnancy acts as a "stress test" for thrombophilia. Fifty percent of initial episodes of VTE in women younger than 40 years are manifested in association with pregnancy. A thrombophilia evaluation is indicated in all patients who present with VTE during pregnancy to assess long-term maternal and family risk and to guide future secondary prophylaxis recommendations. Patients with an identified thrombophilia and an adverse pregnancy outcome may be at risk for a similar outcome in a subsequent pregnancy and should be counseled about this risk and considered for thromboprophylaxis.

Patients who have had DVT during pregnancy have a high risk of postphlebitic syndrome and venous insufficiency. Two randomized controlled trials demonstrated a 50% risk reduction in symptoms of post-thrombotic syndrome when compression stockings were used within 1 month of diagnosis and continued for a minimum of 1 year after diagnosis.

ASTHMA (Chapter 87)

Maintaining adequate control of asthma during pregnancy is important for both maternal and fetal outcome. Asthma may be associated with increased perinatal mortality, preterm birth, IUGR, gestational diabetes, and preeclampsia. Well-controlled asthma reduces the likelihood of these adverse outcomes to baseline, so it is safer for both mother and fetus to treat maternal asthma than to allow exacerbations to occur.

EPIDEMIOLOGY

Asthma is the most common respiratory disease in pregnancy. It affects 3.7 to 8.4% of pregnancies in the United States and 12 to 13% of pregnancies in Australia and the United Kingdom. Approximately 10% of U.S. women of reproductive age have asthma, and the rates of asthma reported during labor and delivery have doubled during the last decade.

Effect of Pregnancy on Asthma

The course of asthma in pregnancy is unpredictable, and most studies have found that a third of patients improve, a third worsen, and a third stay the same. The most likely predictor in any individual patient is her course during a previous pregnancy. In most studies, the majority of exacerbations occurred between 17 and 32 weeks, with some improvement reported by 36 weeks' gestation. Patients with mild asthma do well during labor and delivery, but almost 50% of patients with severe asthma worsen during labor and delivery. Risk factors for exacerbations include severe asthma, poor compliance with medications (especially inhaled corticosteroids), obesity, viral infections, rhinitis, gastroesophageal reflux, and poor prenatal care. The highest morbidity and mortality are reported in African American patients.

Effect of Asthma on Pregnancy

Pregnancy and perinatal outcome are improved when asthma is well controlled. Poorly controlled asthma increases the risk of spontaneous abortion,

TABLE 239-7 SAFETY AND PHARMACOKINETICS OF ANTICOAGULANTS IN PREGNANCY

	UFH	LMWH	SEMISYNTHETIC HEPARINOIDS (DANAPAROID)	SYNTHETIC HEPARINS AND FACTOR Xa INHIBITOR (FONDAPARINUX, RIVAROXABAN)	THROMBIN INHIBITORS (RECOMBINANT HIRUDINS)	THROMBIN INHIBITORS (ARGATROBAN, DABIGATRAN)	WARFARIN (COUMADIN)
Monitoring	aPTT	Anti-Xa level	Anti-Xa level	Anti-Xa level	aPTT	aPTT	INR
Half-life	1.5 hr	Enoxaparin: 4.5-7 hr Tinzaparin: 3-4 hr Dalteparin: 3-5 hr All prolonged in renal impairment	24 hr Prolonged in severe renal impairment	17-21 hr Prolonged in severe renal impairment	Lepirudin: 1.3 hr Bivalirudin: 25 min Desirudin: 2 hr All prolonged in renal impairment	Argatroban: 39-51 min Dabigatran: 12-17 hr	20-60 hr
Clearance	Liver, reticuloendothelial system	Liver 40% urine excretion	Plasma Urine excretion	Metabolism unknown Urine excretion	Lepirudin: metabolism unknown; 48% urine excretion Bivalirudin: plasma (80%); urine (20%) excretion Desirudin: kidney	Argatroban: liver; urine and fecal excretion Dabigatran: liver; urine excretion	Liver 92% urine excretion
Safety	Does not cross the placenta No known risk of teratogenicity	Enoxaparin, tinzaparin, and dalteparin: do not appear to cross the placenta and are not believed to increase risk of birth defects on the basis of animal studies and some human studies outcomes.	No longer available in the United States Many case reports of use of danaparoid in pregnancy in various doses and duration have shown successful pregnancy outcomes.	Fondaparinux: on the basis of experimental animal studies, use of fondaparinux in pregnancy is not expected to increase the risk of malformations. Small amounts cross the placenta, but clinical significance of such is unknown. Rivaroxaban: postimplantation pregnancy loss, increased fetal toxicity, and maternal hemorrhagic complications have been observed in animal studies. There are no adequate and well-controlled human studies.	Lepirudin: on the basis of experimental animal studies, it is not expected to increase the risk of congenital malformations, although it is known to cross rat placenta. Case reports of its use during various times of pregnancy did not show adverse events in exposed neonates. Bivalirudin: no epidemiologic studies of congenital anomalies among infants born to women treated with bivalirudin during pregnancy have been reported. Desirudin: teratogenic effects were observed in some animal reproductive studies.	Argatroban: did not produce malformations in rats and rabbits, but dosing was low compared with human therapeutic dose levels. Few case reports describing its use during pregnancy with no adverse newborn outcomes. Dabigatran: adverse events were observed in some animal reproductive studies. There are no adequate and well-controlled studies in pregnant women.	Warfarin crosses the placental barrier. Risk of birth defect with early exposure; potential for fatal hemorrhage to the fetus in utero.
Lactation	Safe	Enoxaparin: excretions in milk unknown Tinzaparin, dalteparin: no data available	Little or no danaparoid appears in breast milk and would likely be inactivated in infant's stomach	Fondaparinux: appears in rat milk. Possible adverse effects of exposure through milk have not been described. Rivaroxaban: no data available	Lepirudin: in one case report, it was used during lactation without adverse events. It was not detectable in milk. Bivalirudin and desirudin: no data available	Argatroban, dabigatran: no data available	Safe
Administration	SC and IV	SC and IV	SC and IV	Fondaparinux: IV Rivaroxaban: PO	IV	Argatroban: IV Dabigatran: PO	PO

aPTT = activated partial thromboplastin time; INR = international normalized ratio; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.

low birthweight, IUGR, and cesarean section. Preterm delivery, gestational diabetes, and preeclampsia have also been associated with poorly controlled asthma, but it is unclear how systemic steroids contribute to these complications. Systemic steroids have been associated with an increased risk of premature rupture of membranes, preeclampsia, prematurity and low birthweight, and gestational diabetes. A retrospective study suggested that some complications may increase even in patients with mild asthma or asthma in good control.

PATHOBIOLOGY

The normal physiologic changes of pregnancy may contribute to variations in asthma severity. Factors contributing to the worsening of asthma include gastroesophageal reflux disease and rhinitis or sinusitis, triggers for asthma that are common during pregnancy. Gastroesophageal reflux may be manifested initially during pregnancy or worsen in patients with preexisting reflux owing to both hormonal and mechanical effects. Progesterone acts as a smooth muscle dilator that reduces lower esophageal sphincter pressure and contributes to delayed gastric emptying. Later in gestation, uterine enlargement further contributes to gastric displacement and increased reflux. Rhinitis and sinusitis clearly contribute to asthma exacerbations in nonpregnant patients. Gestational rhinitis related to hormonal effects is present in most pregnant women, and its behavior seems to parallel that of asthma. Bacterial sinusitis is five to six times more common in pregnancy and should be treated aggressively.

Hormonal effects on the airway may also contribute to asthma status. There is a progressive increase in serum cortisol and estradiol, which affects the quality of mucus production, and in progesterone, which decreases smooth muscle contractility and thereby causes airway dilation and improves minute ventilation. Immunologic factors during normal pregnancy may also contribute to the course of asthma. There is a suppression of cell-mediated immunity, with a predominant T_H2 environment and high interleukin-5 and tumor necrosis factor messenger RNA. In pregnant women with asthma (not receiving inhaled corticosteroid therapy), the T_H2/T_H1 ratio is even higher, possibly contributing to exacerbations.

The mechanism by which asthma exacerbations affect perinatal outcome is probably related to chronic maternal hypoxia, with consequent placental dysfunction and decreased uteroplacental flow, which contributes to decreased fetal growth. Poorly controlled asthma increases low birthweight 2.5-fold. Relative placental ischemia in asthma, particularly in disease that was poorly controlled before conception, is likely the link to an increased risk for preeclampsia. Placentas from women with asthma show a change in response to vasodilators and constrictors in vitro, similar to that seen in preeclampsia.

DIAGNOSIS

The diagnosis of asthma during pregnancy is the same as in the nonpregnant state (Chapter 87): normal forced expiratory volume in 1 second (FEV_1)/forced vital capacity on baseline pulmonary function tests with an obstructive physiology during exacerbations that is reversible either spontaneously or with medications. Airway hyperresponsiveness, as demonstrated by a methacholine challenge causing a 20% drop in FEV_1 from baseline, is also useful for diagnosis in pregnancy. Asthma severity in pregnancy is classified the same as in nonpregnant patients by the new classification of asthma severity that incorporates short-acting β-agonist use. The new classification includes both the level of impairment (daytime and nighttime frequency, quality of life and interference with normal activities, lung function) and the risk of exacerbations based on frequency and severity of prior exacerbations.

Differential Diagnosis

Dyspnea of pregnancy is a benign condition that often occurs later in pregnancy and is characterized by an increased awareness of the work of breathing that is disturbing for many patients. It is not likely to be acute, occurs less with rest, and should not interfere with normal daily activities. Dyspnea of pregnancy should not be accompanied by an increase in respiratory rate, wheezing, or hypoxia. It is important to consider pulmonary edema in any pregnant patient complaining of shortness of breath (Chapter 69). Pregnancy-related causes of pulmonary edema and acute respiratory distress syndrome include tocolytics (drugs that slow contractions), preeclampsia, gastric aspiration, amniotic fluid embolism, sepsis (related to pyelonephritis, chorioamnionitis, endometritis, septic abortion), abruption, and obstetric hemorrhage. Cardiac causes should be suspected when pulmonary edema is manifested at the peak of blood volume (28 to 32 weeks), when occult valvular disease (Chapter 75) is most likely to be unmasked. Additional cardiac considerations are peripartum cardiomyopathy, preeclampsia, and ischemic heart disease, which in pregnancy may also be caused by coronary dissection.

TREATMENT

Rx

Management of asthma during pregnancy does not differ greatly from that of the nonpregnant patient (Chapter 87).[15] However, normal arterial carbon dioxide pressure ($PaCO_2$) in pregnancy is 28 to 32 mm Hg, so a tachypneic pregnant patient with a $PaCO_2$ above this range may be in impending respiratory failure. Minute ventilation in pregnancy increases by an increase in tidal volume, but respiratory rate is unchanged by pregnancy, so tachypnea is always an abnormal finding.

The goal of asthma therapy during pregnancy is to maintain adequate control to ensure maternal and fetal health. It is always safer for pregnant women with asthma to be treated with asthma medications than to experience symptoms and exacerbations. Careful monitoring during all prenatal visits, preferably with spirometry, and stepped-up therapy are required both for maternal asthma control and to ensure appropriate oxygenation of the fetus. Maternal arterial oxygen saturation should be maintained at 95% or more, or the arterial oxygen pressure (PaO_2) should be maintained at 80 mm Hg or more, to maintain fetal oxygenation. E-Figure 239-1 outlines the classification of asthma and care for pregnant patients with asthma. More detailed recommendations for the home management of exacerbations and for hospitalization and emergency care for pregnant patients can be found in the *National Asthma Education and Prevention Program Working Group Report for Managing Asthma During Pregnancy.*

Albuterol is the preferred short-acting β-agonist because it has an excellent safety profile and the most data related to safety during human pregnancy. Inhaled corticosteroids are the preferred medication for long-term control. Budesonide is the preferred inhaled corticosteroid solely because of the amount of reassuring data on its use in pregnant patients. There are, however, no adverse data on the other inhaled corticosteroids. Data on the effectiveness and safety of long-acting β-agonists during pregnancy are limited, although it is reasonable to assume that they have a safety profile similar to that of albuterol. Salmeterol is the preferred agent, based only on its longer availability and lack of reports of adverse outcomes in exposed pregnancies. Cromolyn has an excellent safety profile but has limited effectiveness compared with inhaled corticosteroids.

Minimal published reports are available on the use of leukotriene receptor antagonists during pregnancy; however, animal safety data are reassuring. Current guidelines do not recommend leukotriene receptor antagonists because of the limited data, unless a patient's asthma was well controlled with this type of drug before pregnancy.

Classify Severity: Clinical Features Before Treatment or Adequate Control			Medications Required to Maintain Long-Term Control
	Symptoms/Day / Symptoms/Night	PEF or FEV_1 / PEF Variability	**Daily medications**
Step 4 Severe Persistent	Continual / Frequent	≤60% / >30%	• Preferred treatment: –High-dose inhaled corticosteroid AND –Long-acting inhaled β_2-agonist AND, if needed, –Corticosteroid tablets or syrup long term (2 mg/kg per day, generally not to exceed 60 mg per day). (Make repeat attempts to reduce systemic corticosteroid and maintain control with high-dose inhaled corticosteroid.)
			• Alternative treatment: –High-dose inhaled corticosteroid AND –Sustained-release theophylline to serum concentration of 5–12 μg/mL.
Step 3 Moderate Persistent	Daily / >1 night/week	>60%–<80% / >30%	• Preferred treatment: EITHER –Low-dose inhaled corticosteroid and long-acting inhaled β_2-agonist OR –Medium-dose inhaled corticosteroid If needed (particularly in patients with recurring severe exacerbations): –Medium-dose inhaled corticosteroid and long-acting inhaled β_2-agonist
			• Alternative treatment: –Low-dose inhaled corticosteroid and either theophylline or leukotriene receptor antagonist. If needed: –Medium-dose inhaled corticosteroid and either theophylline or leukotriene receptor antagonist.
Step 2 Mild Persistent	>2 days/week but <daily / >2 nights/month	≥80% / 20%–30%	• Preferred treatment: –Low-dose inhaled corticosteroid
			• Alternative treatment (listed alphabetically): cromolyn, leukotriene receptor antagonist OR sustained-release theophylline to serum concentration of 5–12 μg/mL.
Step 1 Mild Intermittent	≤2 days/week / ≤2 nights/month	≥80% / <20%	No daily medication needed.
			• Severe exacerbations may occur, separated by long periods of normal lung function and no symptoms. A course of systemic corticosteroid is recommended.
Quick Relief All Patients	• Short-acting bronchodilator: 2–4 puffs short-acting inhaled β_2-agonist as needed for symptoms. • Intensity of treatment will depend on severity of exacerbation; up to 3 treatments at 20-minute intervals or a single nebulizer treatment as needed. Course of systemic corticosteroid may be needed. • Use of short-acting inhaled β_2-agonist >2 times a week in intermittent asthma (daily, or increasing use in persistent asthma) may indicate the need to initiate (increase) long-term control therapy.		

E-FIGURE 239-1. Stepwise approach for management of asthma during pregnancy and lactation. FEV_1 = forced expiratory volume in 1 second; PEF = peak expiratory flow. (From National Asthma Education and Prevention Program Working Group Report on Managing Asthma During Pregnancy. *Recommendations for Pharmacologic Treatment—Update 2004. NIH Publication No. 05-5236.* U.S. Department of Health and Human Services; National Institutes of Health; National Heart, Lung, and Blood Institute; March 2005.)

Intranasal corticosteroids are recommended for the treatment of allergic rhinitis (Chapter 251), given the limited systemic effect. The current nonsedating antihistamines of choice are loratadine and cetirizine.

Patients at risk for fatal asthma are those with a large bronchodilator response, overreliance on short-acting bronchodilators, marked circadian variation in lung function, history of hospitalization or intubation, and frequent systemic steroid use. There are specific considerations based on pregnancy physiology in pregnant patients who may require airway intubation. Pregnant patients have a low functional residual capacity and oxygen reserve, a more profound response to sedatives, airway edema, and larger airways. Intubation failure is much higher in pregnant women, so intubation should be performed by the most experienced professional available.

Breast-feeding should be encouraged in all patients with asthma as there is some evidence that it decreases atopy in offspring. Data are conflicting regarding the development of asthma in offspring.

DIABETES (Chapter 229)

Diabetes affects 1.85 million women of reproductive age, and it is estimated that preconception management could reduce the risk for 113,000 births per year. All women of reproductive age with diabetes should be counseled about the relationship between glucose control and congenital anomalies. Hyperglycemia is a teratogen, and the incidence of congenital anomalies is directly related to the hemoglobin A_{1c} level at conception (Fig. 239-3). The anomaly rate was as high as 11% in women without preconception care, including cardiac anomalies, neural tube defects, and sacral agenesis. The single most important contribution an internist can make to the prevention of congenital anomalies is to address pregnancy risk with all women of childbearing age with diabetes. The responsibility to normalize hemoglobin A_{1c} before conception falls to the medical care provider; once pregnancy is diagnosed and the patient is seen by her obstetrician, the teratogenic effects of glucose have already occurred.

DEFINITION

Gestational diabetes mellitus (GDM) is defined as glucose intolerance that first occurs or is first identified during pregnancy. Either type 1 or type 2 diabetes in a pregnant patient is referred to as preexisting or pregestational diabetes.

EPIDEMIOLOGY

The frequency of GDM is rising in the United States; it now occurs in 4 to 14% of all pregnancies, depending on the patient's characteristics. The epidemic of type 2 diabetes has resulted in a higher prevalence at a younger age; in the United States, there has been a 70% increase in the prevalence of diabetes in the 30- to 39-year-old age group versus 33% overall. The proportion of women with type 2 versus type 1 pregestational diabetes has also increased, from 26% in 1980 to 65% in 2000, and it is still increasing. The perinatal morbidity and mortality associated with type 2 diabetes is at least as great as that associated with type 1 during pregnancy.

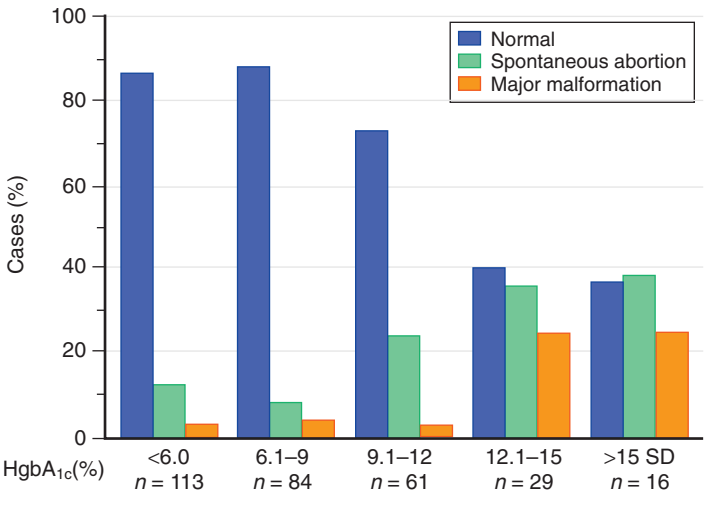

FIGURE 239-3. Relationship of hemoglobin A_{1c} ($HgbA_{1c}$), congenital anomalies, and spontaneous abortion.

PATHOBIOLOGY

Type 1 diabetes is caused by autoimmune destruction of pancreatic beta cells, resulting in an absolute insulin deficiency. Ninety percent of cases are diagnosed before the age of 25 years and are often associated with other autoimmune illnesses or a family history of autoimmune illness, including thyroid disorders, Addison's disease, and celiac disease. Type 2 diabetes is part of the metabolic syndrome, which includes insulin resistance, hyperinsulinemia, dyslipidemia, abdominal obesity, and hypertension with premature atherosclerosis; it probably has a genetic component. GDM may also be a manifestation of the metabolic syndrome, unmasked by the insulin-resistant state of pregnancy. Patients with GDM have a 50% chance for development of type 2 diabetes in the ensuing 5 to 10 years and a long-term risk of approximately 70%.

Pregnancy is a state of accelerated starvation and marked insulin resistance. Lower fasting glucose levels are seen early in the first trimester, and nocturnal hypoglycemia is common. There is blunted hypoglycemic awareness due to decreased epinephrine and norepinephrine release, with falls in blood glucose concentration and increased ketogenesis, resulting in an increased risk for diabetic ketoacidosis. Insulin requirements may decrease 20% in weeks 7 to 12 but then gradually rise later in gestation, such that insulin doses need to be increased by 16 weeks' gestation. Marked insulin resistance is related to the presence of elevated levels of cortisol, prolactin, human placental lactogen, and human placental growth hormone. Insulin sensitivity is decreased by about 50% in the third trimester, resulting in increased serum insulin and postprandial glucose levels, explaining the timing of the onset of GDM.

DIAGNOSIS

The diagnosis of pregestational diabetes is based on the finding of a fasting blood glucose level of more than 125 mg/dL or a 2-hour or random blood glucose level of 200 mg/dL or more. The American Diabetes Association recently added a hemoglobin A_{1c} level of 6.5% or higher as an acceptable alternative diagnostic criterion. GDM is based on the results of a blood glucose screen after a 50-g glucose challenge test (≥140 mg/dL), followed by a 3-hour confirmatory 100-g oral glucose tolerance test. Positive results are any two of the following: fasting, 95 mg/dL or more; 1 hour, 180 mg/dL; 2 hours, 155 mg/dL; and 3 hours, 140 mg/dL. It may be difficult to distinguish between GDM and type 2 diabetes that was not diagnosed before pregnancy. Elevated fasting glucose levels before 24 weeks' gestation and elevated hemoglobin A_{1c} are both suggestive of type 2 diabetes. Any diabetes diagnosed during pregnancy is referred to as GDM; if it persists post partum, it is reclassified as type 2.

TREATMENT

Rx

Dietary recommendations are for 30 kcal/kg, with 40 to 50% carbohydrates, divided into three meals and three snacks. Aerobic exercise may decrease insulin resistance and reduce maternal glucose levels and may be an effective adjunct to diet in patients with GDM. Adjustment of medications should include the discontinuation of ACE inhibitors, ARBs, and statins and the institution of folate and prenatal vitamins. An assessment of baseline disease status in all patients with diabetes should include hemoglobin A_{1c}, ophthalmologic examination, electrocardiogram, assessment of urine protein excretion, serum creatinine concentration, and thyroid-stimulating hormone level. Baseline preeclampsia laboratory studies are also recommended.

The fetal assessment plan includes ultrasound to confirm dates and viability; this is done by the patient's obstetric care provider. There will also be a quad screen, looking for serum markers that suggest neural tube defects or Down syndrome; an ultrasound nuchal translucency and a level 2 ultrasound to assess for congenital anomalies; and a fetal echocardiogram.

Control of Blood Glucose

The goal of treatment for pregestational diabetes is the best hemoglobin A_{1c} level possible, without excessive hypoglycemia. This is achieved by frequent insulin adjustments and self-monitoring of blood glucose level at least four times a day. The specific goals for both GDM and pregestational diabetes are fasting glucose concentration of 65 to 95 mg/dL, 1-hour postprandial glucose concentration of less than 140 mg/dL, and 2-hour glucose concentration of less than 120 mg/dL. This is best achieved by multiple doses of insulin, including basal, intermediate, and long-acting insulin, with preprandial bolus rapid-acting insulin to cover the anticipated carbohydrate load. This regimen requires self-monitoring of blood glucose levels six or seven times a day, so it may be difficult to comply with. Further, the risk of serious

hypoglycemia may limit these glycemic targets, particularly in women with type 1 diabetes. Extreme vigilance is required to avoid serious hypoglycemia, particularly in weeks 7 to 12, when insulin requirements are the lowest during pregnancy.[16] In patients with decreased glycemic awareness, the risk of nighttime hypoglycemia is significant, and patients' partners should be counseled about this risk.

Insulin analogues are being used with increasing frequency. Of the rapid-acting analogues, there are data that lispro does not cross the placenta; there are no data yet on aspart. Although long-acting glargine is being used in pregnancy, its placental transfer is unknown, and there are theoretical concerns about its binding to the insulin-like growth factor receptor and its mitogenic potential.

Of the oral agents for which there are data, glyburide is safe and efficacious in women with GDM, and it is more efficacious than metformin in this setting.[■] Oral agents are less useful with significant insulin resistance and type 2 diabetes, so insulin continues to be the "gold standard" in this group. Metformin does not appear to increase the risk of congenital anomalies or spontaneous abortion, but it does cross the placenta. Women with polycystic ovary syndrome treated with metformin may regain their fertility and should be advised to use contraception. Recent trials support the safety of metformin in the second and third trimesters. In the United States, metformin is not yet recommended for the treatment of type 2 diabetes in pregnancy or for GDM. There are inadequate pregnancy data for the meglitinides and glitazones.

Maternal and Fetal Monitoring

During pregnancy, increased vigilance and continual assessment for the development of complications, including hypertension, preeclampsia, worsening nephropathy, and retinopathy, are required. The incidence of retinopathy in pregnant women with type 1 and type 2 diabetes is 34 to 50% and 3 to 5%, respectively. Nephropathy is found in 4% of diabetic pregnancies and is associated with increased maternal and perinatal morbidity. Most studies agree that pregnancy may accelerate the progression of nephropathy, but the reversibility of this complication is unclear. Most studies show a worsening of retinopathy in pregnant patients similar to that occurring during the same period in nonpregnant patients. The level of severity of retinopathy before pregnancy is most predictive of worsening during pregnancy, and treatment is recommended before conception.

Labor and Delivery

During labor and delivery, tight glucose control is necessary to avoid neonatal hypoglycemia due to hyperinsulinemia at birth. The goal is to maintain serum glucose levels of 72 to 144 mg/dL. The use of an insulin drip with dextrose infusion in active labor is recommended. Immediately after delivery, insulin requirements decrease to prepregnancy levels. Insulin needs should be one half to two thirds prepregnancy requirements, with a further decreased need found in breast-feeding patients.

Postpartum Considerations

Fifteen percent to 25% of type 1 diabetics develop postpartum thyroiditis, so all patients require postpartum measurements of thyroid-stimulating hormone and follow-up for 6 months. Other postpartum recommendations are to restart ACE inhibitors and to monitor closely for infection. It is important to discuss diabetes prevention in the offspring and to address contraception. It is most important to recommend an effective contraceptive method that is acceptable to the patient. Oral estrogens can increase triglycerides, and both oral and injectable progesterone-only contraceptives may increase insulin resistance. Low-dose combined oral contraceptives and the progesterone-releasing intrauterine device appear to have little effect on glucose.

Insulin is acceptable in breast-feeding women, and limited data suggest that glyburide and metformin are safe as well. One small study found that glyburide is not excreted in breast milk and that metformin is excreted in a small amount that is probably not clinically significant.

PROGNOSIS AND COMPLICATIONS

The maternal complications of diabetes may be affected by pregnancy and may affect the course of the pregnancy. Patients with nephropathy experience an increase in proteinuria and a risk for progression of renal disease, especially if the serum creatinine concentration is more than 1.4 mg/dL. There is an increased risk for hypertension, which is seen in 30% of patients during the first trimester and 75% of patients by the third trimester. Autonomic neuropathy may worsen, as manifested by increasing gastroparesis, orthostatic hypotension, and decreased hypoglycemic awareness. Patients with long-standing diabetes may need to be evaluated for ischemic heart disease, which may impair the heart's ability to meet the cardiovascular demands of pregnancy. Pregnant patients are also at risk for hyperlipidemia and for preeclampsia. Diabetes increases the risk for operative delivery and for infections, the most common of which are wound, urinary tract, and respiratory.

Diabetic ketoacidosis may be precipitated by steroid use for fetal lung maturity, hyperemesis, infection, and noncompliance with insulin regimens. Acidosis may occur more quickly and at lower glucose levels in pregnant than in nonpregnant patients. There is a high fetal mortality associated with diabetic ketoacidosis (9 to 10%), and patients should be monitored in an intensive care setting.

Fetal and Neonatal Effects (Fig. 239-4)

There is an increased risk of spontaneous abortion, fetal loss, congenital anomalies, preeclampsia, and preterm delivery in patients with diabetes. Poor

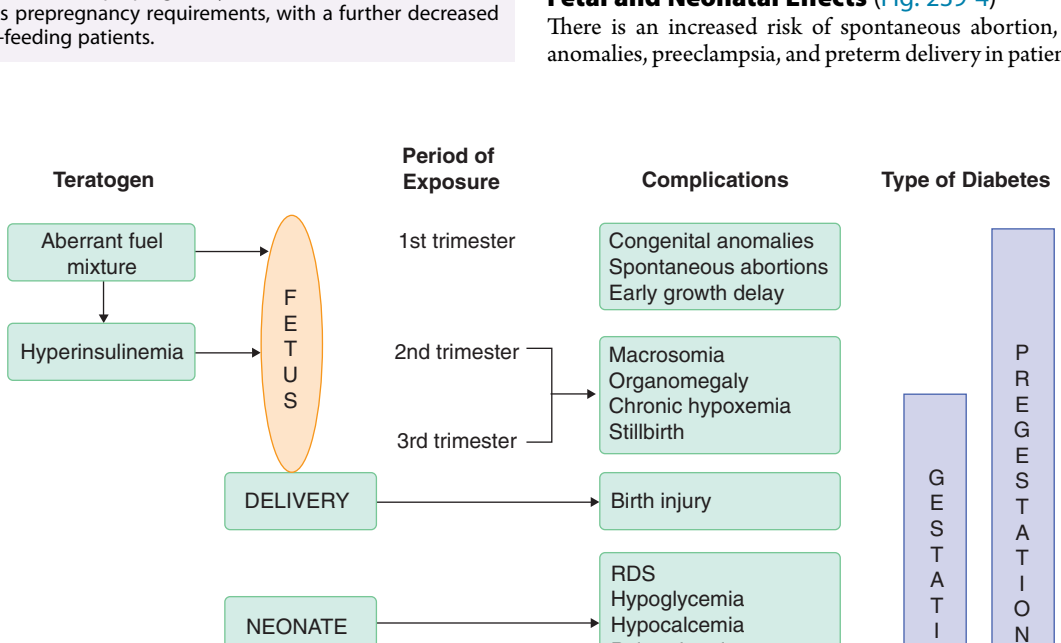

FIGURE 239-4. Fetal, neonatal, and childhood effects of exposure to hyperglycemia. CNS = central nervous system; RDS = respiratory distress syndrome.

glycemic control during pregnancy, especially in type 2 diabetes and GDM, is also associated with macrosomia (baby weighing >4000 g) and fetal intraventricular septal hypertrophy. Poor control is also associated with the effects of maternal vascular and renal disease and ketoacidosis, which include fetal loss, preeclampsia, and low birthweight. A study looking at differences in causes of pregnancy loss in type 1 and type 2 diabetic mothers compared the placental histology of patients with type 1 and type 2 diabetes and found an increase in histologic infarcts in type 2, suggesting a vascular rather than a glycemic cause of pregnancy complications and signs of abnormal development of placentas from patients with type 1 disease.[17]

Neonatal complications include respiratory distress syndrome, hypoglycemia, hypocalcemia, cardiac hypertrophy, hyperbilirubinemia, and polycythemia. The risk of hypoglycemia may be ameliorated by careful control of maternal glucose concentration during labor and delivery. Normalization of maternal glucose concentration prevents hyperinsulinemia in the fetus and mitigates the risk of neonatal hypoglycemia.

Maternal Effects

GDM is a marker for type 2 diabetes; 50% of patients will develop type 2 diabetes within 7 to 10 years, and overall, 70% will develop the disease. Patients who have had GDM need directed testing at their 6-week postpartum visit, annual screening, and recommendations for lifestyle modification and cardiovascular risk reduction. Offspring of patients with GDM and type 2 diabetes are at increased risk for obesity and glucose intolerance.

LIVER DISEASE IN PREGNANCY

Liver disease found during pregnancy may be unique to pregnancy, represent underlying liver disease unmasked during pregnancy, or develop during pregnancy. Most liver function test results are unchanged by pregnancy with the exception of an increase in alkaline phosphatase (which is produced by the placenta), an increase in fibrinogen, and a decrease in serum albumin.

Table 239-9 outlines pregnancy-related liver disease. This discussion focuses on diseases unique to pregnancy and those diseases for which there are specific management considerations during pregnancy.

Liver Diseases Unique to Pregnancy

INTRAHEPATIC CHOLESTASIS OF PREGNANCY (OBSTETRIC CHOLESTASIS)

DIAGNOSIS

Intrahepatic cholestasis of pregnancy (ICP) or obstetric cholestasis affects 0.5 to 2% of pregnant women, although in Bolivia and Chile, rates of 4 to 28% have been observed. ICP is manifested most commonly in the late second or third trimester with intense pruritus accompanied by an increase in serum bile acids and often transaminases and prothrombin time. ICP is likely to be a metabolic disease of multifactorial etiology characterized in most cases by a genetic variation in the biliary transporters and receptors that govern bile acid homeostasis.[18] It is more common in patients with underlying hepatitis C, so it is important to screen all patients with hepatitis C serology. ICP is associated with preterm labor, meconium staining, fetal hypoxia, and sudden fetal demise.

TABLE 239-9 LIVER DISEASE AND PREGNANCY

UNIQUE TO PREGNANCY
Acute fatty liver of pregnancy
HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets)
Hyperemesis gravidarum
Intrahepatic cholestasis of pregnancy
Preeclampsia and eclampsia
INCREASED INCIDENCE DURING PREGNANCY
Budd-Chiari syndrome
Drug-induced hepatotoxicity
Gallstones
Liver transplantation
Sepsis
Viral hepatitis
UNDERLYING CONDITION THAT MAY BE REVEALED
Autoimmune hepatitis
Cirrhosis
Hepatitis B and C
Primary biliary cirrhosis
Primary sclerosing cholangitis
Wilson's disease

Modified from Mufti AR, Reau N. Liver disease in pregnancy. *Clin Liver Dis.* 2012;16:247-269.

TREATMENT Rx

Because no antenatal testing has been able to predict those patients at risk for fetal demise, consensus guidelines recommend delivery at 37 to 38 weeks of gestation in patients with a significant elevation in serum bile acids (≥40 µmol/L). The treatment of choice is ursodeoxycholic acid at 10 to 15 mg/kg, which leads to both symptomatic and biochemical improvement. There are no studies demonstrating a beneficial effect on pregnancy outcome.

PREECLAMPSIA AND ECLAMPSIA

As discussed before, preeclampsia can be associated with liver abnormalities including liver edema and infarction, subcapsular hematoma, liver laceration, and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets).

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum, defined as severe persistent nausea and vomiting of pregnancy with weight loss, ketosis, or dehydration, can be associated with transaminase elevations in 50 to 60% of cases.

TREATMENT Rx

Treatment is supportive with rehydration, antiemetics, and vitamin replacement,[19] often requiring hospitalization. Oral fluid repletion can often be accomplished as indwelling intravenous catheters have been associated with a significant risk of thrombosis and of infections. Hyperemesis gravidarum is usually a reversible condition with no permanent liver damage.

ACUTE FATTY LIVER OF PREGNANCY

DIAGNOSIS

Acute fatty liver of pregnancy is a rare condition that is estimated to occur in 5 per 100,000 pregnancies. It most commonly is manifested in the third trimester and post partum; in its most severe form, it can be associated with fulminant liver failure and the need for liver transplantation. Maternal mortality rates were earlier thought to be as high as 20%, but a more recent U.K. study found a 2% maternal and 11% perinatal mortality rate. The Swansea criteria have recently been validated as a diagnostic tool for the diagnosis of acute fatty liver of pregnancy (Table 239-10).

PROGNOSIS

The maternal mortality rate has been estimated at 18%. Acute fatty liver of pregnancy is associated with an inherited defect in mitochondrial fatty acid B oxidation. The defect results in accumulation of toxic metabolites produced by the fetus and placenta that, after entering the maternal circulation, are deposited in maternal liver. Diagnosis is clinical, based on the constellations of findings described in Table 239-10. Liver function abnormalities can be severe, and hypoglycemia is a poor prognostic sign. Anyone with evidence of liver failure should be seen at a transplant center as early in the course as possible.

TABLE 239-10 SWANSEA DIAGNOSTIC CRITERIA FOR ACUTE FATTY LIVER OF PREGNANCY

Six or more of the following features in the absence of another explanation:

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin
- Hypoglycemia
- Elevated urate
- Leukocytosis
- Ascites or bright liver on ultrasound scan
- Elevated transaminases
- Elevated ammonia
- Renal impairment
- Coagulopathy
- Microvesicular steatosis on liver biopsy

Preexisting or New-Onset Liver Disease during Pregnancy

The major importance of recognition of underlying liver disease in pregnancy is both for maternal health and for those diseases in which lack of treatment results in a high rate of vertical transmission to the fetus or neonate.

VIRAL HEPATITIS

Hepatitis C virus (HCV) infection (Chapter 148) has become an increasingly important and prevalent issue in pregnancy; maternal to child HCV vertical transmission rates are 5 to 10% and as high as 22% with HIV coinfection. New screening guidelines will lead to more universal screening in this age group. The mode of delivery does not have an impact on vertical transmission rates. The higher the viral load and the longer the duration of ruptured membranes, the higher the risk of transmission. Infection with hepatitis E virus and herpes simplex virus is much more likely to be severe in pregnant women. Particularly in the third trimester, it can be associated with fulminant disease and high maternal and perinatal mortality. All pregnant patients with new-onset hepatitis should also be screened for cytomegalovirus and Epstein-Barr virus.

TREATMENT Rx

All pregnant women in the United States are screened for hepatitis B virus (HBV) with hepatitis B surface antigen (Chapter 148). All neonates born to positive mothers are treated with hepatitis B immune globulin within 12 hours of birth and given their first dose of HBV vaccine at birth. This regimen is less effective in mothers with a high viral load or in the presence of hepatitis B e antigen positivity.

Fetal risks involved in the use of interferon during pregnancy outweigh its benefits. All current oral anti-HBV drugs (including lamivudine, entecavir, and adefovir) are categorized as Food and Drug Administration pregnancy category C, except telbivudine and tenofovir, which are pregnancy category B drugs.[20] Vertical transmission of HCV occurs, but data supporting recommendations for prevention are limited. Both ribavirin and interferon are contraindicated during pregnancy.

CHRONIC LIVER DISEASE

Chronic liver disease may be associated with anovulation, amenorrhea, and infertility. Thus, it is unusual to see pregnant patients with significant liver decompensation and cirrhosis. Patients with portal hypertension, autoimmune hepatitis, Wilson's disease, hepatic masses, and successful liver transplantation will be seen during pregnancy.

TREATMENT Rx

The management of these patients requires an understanding of their course in pregnancy and a recognition of the importance of continuing prepregnant treatment.

Portal hypertension (Chapter 153) of any cause will be affected by the increase in blood volume during pregnancy, requiring careful follow-up and management of esophageal varices and splenic artery aneurysm. β-Blockers should be continued, and baseline endoscopy should be done early to consider banding of larger varices.

Autoimmune hepatitis (Chapter 149) improves dramatically with immunosuppression, so many women regain fertility with treatment.[21] Immunosuppression with steroids and azathioprine should be continued to avoid relapse and progression of disease. The cholestasis associated with primary biliary cirrhosis can be treated with ursodeoxycholic acid as outlined for ICP.

Similar to women with autoimmune hepatitis, patients with treated Wilson's disease (Chapter 211) regain fertility. Chelation therapy should be continued as discontinuation is associated with marked rises in copper levels and can lead to fulminant liver failure.

Hepatic masses are most commonly benign adenomas, focal nodular hyperplasia, or hemangiomas in women of childbearing age. Careful follow-up of these estrogen-sensitive masses is important because enlargement and hemorrhage may be complications of pregnancy.

SUMMARY

Women of childbearing age with chronic medical conditions benefit greatly from preconception counseling and interventions that address control of their disease and safety of their medications. Pregnant patients with acute or chronic medical illnesses require a multidisciplinary team that understands the maternal and fetal risks related to both the underlying illness and untreated disease. Pregnancy is a window of opportunity to address maternal health, and the maternal response to pregnancy may be predictive of future risk. The 6-week postpartum visit, rather than being the end of pregnancy care, should represent the beginning of a woman's long-term health care.

REVIEW QUESTIONS

1. A 30-year-old G1P0 at 36 weeks' gestation presents with a complaint of right upper quadrant pain. She denies nausea, vomiting, change in color of urine or stool, or change in the pain with eating. She does state that she has had a dull headache and "floaters" in her vision. Laboratory testing reveals an aspartate aminotransferase level of 82 (upper reference limit = 40), hemoglobin level of 14.3, creatinine concentration of 1.0, and platelet count of 100,000. What is her most likely diagnosis?

A. Cholelithiasis
B. Acute hepatitis
C. Cholestasis of pregnancy
D. Preeclampsia
E. Migraine syndrome

Answer: D This patient is a primigravida who presents in her third trimester with symptoms of preeclampsia, hemoconcentration, elevated creatinine for pregnancy, and thrombocytopenia, all most suggestive of preeclampsia.

2. You are caring for a 36-year-old patient with a 6-year history of type 2 diabetes. She has been erratically controlled with metformin, 500 mg daily, and basal insulin. She has never been pregnant but is considering starting a family. What is the single most important advice you can give her?

A. She is really too old to begin a family.
B. She needs to achieve normoglycemia and normalize her hemoglobin A_{1c} level before conception.
C. She will need to be tightly controlled during pregnancy, so she needs to call you as soon as she has a positive pregnancy test result.
D. She needs an eye examination before pregnancy.
E. She should see a nephrologist to screen her kidney function before pregnancy.

Answer: B This patient is in an ideal circumstance for preconception counseling. Normalization of her glucose concentration and hemoglobin A_{1c} level before conception will lower her risk of fetal congenital anomalies and spontaneous abortion to background risk levels.

3. A 24-year-old G2P1 woman whom you observe for asthma comes in at 14 weeks' gestation. She has had increasing problems with her asthma, needing a rescue inhaler two or three times a day, and has had nocturnal awakening. She denies chest pain, recent upper respiratory infection, gastroesophageal reflux, or new exposures. What is the most likely cause of her asthma exacerbation?

A. The normal effects of pregnancy
B. The increased work load and oxygen consumption associated with pregnancy
C. She has discontinued her steroid inhaler and controller medication because of concern about the drug's effect on the fetus.
D. She has decreased her exercise.
E. The stress of work, pregnancy, and sleep deprivation

Answer: C The most frequent cause of asthma exacerbation in pregnancy is the patient's or physician's discontinuation of controller medication because of the concern about fetal effects. Both maternal and fetal outcome are optimized by good control of her asthma, and there are no data of adverse effects on the fetus associated with her controller medications.

4. A 28-year-old woman currently at 8 weeks' gestation in a first pregnancy presents with left leg pain. She was seen in a local emergency department, having recently returned from a car trip from Boston to Florida. She was advised to use nonsteroidal anti-inflammatory drugs and to elevate her leg. She has had extensive nausea and vomiting during her pregnancy. The findings of your examination are benign, with minimal swelling in the left calf. What should your recommendation be?

A. Radiograph of left knee to ankle
B. Doppler ultrasound of left leg to rule out deep venous thrombosis (DVT)
C. Decrease exercise, especially aerobic classes
D. Examine her for probable restless leg syndrome associated with pregnancy
E. Encourage oral rehydration for her dehydration

Answer: B Pregnant patients are at an increased risk of thrombosis, beginning early in gestation. The hormonal effects leading to venodilation and stasis as well as pregnancy-related increase in coagulation activation are already present in this patient. Her dehydration further increases her hypercoagulability. In addition, more than 90% of DVT during pregnancy and the postpartum period occurs on the left side, so her pretest probability of this being DVT is higher than at baseline.

240

MENOPAUSE

DEBORAH GRADY AND ELIZABETH BARRETT-CONNOR

DEFINITION

All healthy women transition from a reproductive or premenopausal period marked by regular ovulation and cyclic menstrual bleeding to a postmenopausal period marked by infertility and amenorrhea (Fig. 240-1). The onset of the menopausal transition is generally marked by subtle shortening in the length of the menstrual cycle and changes in the duration or amount of menstrual flow. As the menopausal transition progresses, menstrual cycles are missed until complete amenorrhea occurs, but the pattern of missed cycles is not predictable. Amenorrhea for a few months is not a good indicator of menopause because one half to three fourths of middle-aged women who are amenorrheic for 6 months resume cycles. Thus, menopause is typically defined retrospectively after 12 months of amenorrhea.

EPIDEMIOLOGY

The menopausal transition usually begins in the middle to late 40s and lasts approximately 4 years, with menopause occurring at a median age of 51 years and ranging from approximately 45 to 57 years. Age at menopause has not changed significantly during the past century. However, a gradual increase in life expectancy to the low 80s now means that the average woman is postmenopausal for more than one third of her life. Age at menopause does not vary significantly by race or ethnicity, but on average, cigarette smokers experience menopause approximately 2 years earlier than nonsmokers do.

BIOLOGY

During the early menopausal transition, estrogen levels are generally normal (50 to 200 pg/mL, depending on the stage of the menstrual cycle) or even slightly elevated, whereas the levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) begin to increase (see Fig. 240-1). As the menopause transition progresses, estrogen levels fall markedly, and FSH continues to increase. After menopause, women do not ovulate, and their ovaries do not produce estradiol or progesterone. However, a small amount of estrogen may be produced by metabolism of adrenal steroids to estradiol in peripheral fat tissue. In the early postmenopausal period, mean estradiol

Final menstrual period

	Reproductive			Menopause Transition		Postmenopause	
Reproductive stage	Early	Peak	Late	Early	Late	Early	Late
				Perimenopause			
Menstrual cycle	Variable or regular	Regular		Cycle length variable, 1 or 2 missed cycles per year	3 or more missed cycles	None	
Age (duration)	Puberty to mid-40s			Mid-40s to mid-50s (4 yr)		Mean of 51 years to death	
Steroid hormones	Estradiol 50 to 200 pg/mL Testosterone 400 pg/mL			Same or slightly higher Same		40 pg/mL same	0-15 pg/mL same
Pituitary hormones	FSH 10 mIU/mL day 2-4 LH 10 mIU/mL day 2-4			Same or higher Same or higher		>100 mIU/mL >100 mIU/mL	

FIGURE 240-1. Stages of the menopause transition. FSH = follicle-stimulating hormone; LH = luteinizing hormone.

levels average approximately 40 pg/mL, and they fall to less than 15 pg/mL in the late postmenopausal period. Depending on the measurement method, estradiol is unmeasurable in approximately 15 to 30% of older postmenopausal women. After menopause, testosterone levels may fall slightly but are generally similar to premenopausal levels.

It is not clear what causes menopause, but two leading theories have been proposed.[1] Age-related depletion of ovarian follicles may lead to decreased production of estrogen and inhibin and may thus cause altered hypothalamic-pituitary feedback that results in menopause. Alternatively, age-related changes in hypothalamic production of gonadotropin-releasing hormone and subsequent effects on FSH and LH may be responsible for the increased rate of loss of ovarian follicles, declining ovarian function, and menopause.

MENOPAUSAL SYMPTOMS

Menopause is a positive occurrence in the life of many women. It marks the end of cyclic bleeding and the need for birth control. It occurs at an age when children generally have become independent adults, thereby reducing family and child care responsibilities. Conversely, menopause is a notable sign of aging in cultures that value youth. In addition, it often occurs with other stresses, such as caring for elderly or ill parents. Women in the menopausal transition commonly report a wide variety of symptoms, including hot flushes, night sweats, vaginal dryness, trouble sleeping, sexual dysfunction, depression, anxiety, labile mood, memory loss, fatigue, headache, joint pains, weight gain, and urinary incontinence.

Only vasomotor symptoms, vaginal dryness, and sleep disturbance are consistently associated with the menopausal transition. Other reported symptoms may result from aging or stress associated with menopause. Some symptoms, such as depression, anxiety, memory loss, and fatigue, may be the consequence of frequent hot flushes or poor sleep.

Vasomotor Symptoms

DEFINITION

Vasomotor symptoms include hot flushes, chills, and sweats.[2] A hot flush is a sudden feeling of warmth, generally most intense over the face, neck, and chest. The duration is variable, but it averages approximately 4 minutes. It is often accompanied by sweating that can be profuse and followed by a chill.

EPIDEMIOLOGY

The prevalence of hot flushes is maximal in the late menopausal transition, occurring in approximately 50% of women (Fig. 240-2).[3] However, prevalence varies markedly, depending on the definition of flushing (any flushing, daily flushing, troublesome flushing) and the population studied. Lower prevalence is reported among women in China, Japan, and other Asian countries. The reason for this variation is not clear, but investigators have suggested that it may result from differences in biology, cultural influences on

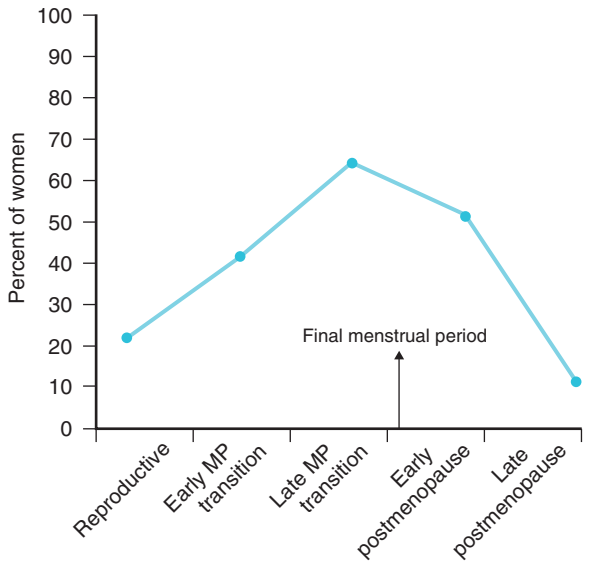

FIGURE 240-2. Prevalence of hot flushes during the menopause (MP) transition.

experiencing or reporting flushes, or diet and lifestyle. In the United States, flushes are more common in African American and Latina women and less common in Chinese and Japanese women compared with white women. Approximately 15% of women with menopausal symptoms consult a physician.

Cigarette smoking increases the likelihood of flushing, but other potential risk factors, including surgical menopause, physical activity, body mass index, alcohol consumption, and socioeconomic status, have been inconsistently associated with hot flushes. Currently, there is no way to predict whether an individual woman will suffer from hot flushes.

In most women, hot flushes are transient. Approximately 50% of women report resolution of symptoms within a few years, and symptoms resolve in about 90% within 8 years. However, some women continue to have frequent and severe flushes many years after menopause. Approximately 10% of women in their middle to late 60s report significant flushing. It is not clear why flushes persist for many years in some women and resolve in others.

PATHOBIOLOGY

Thermoregulation is abnormal in menopausal women with hot flushes. Body temperature is regulated by inducing vasodilation and sweating to release heat and vasoconstriction and shivering to conserve heat. Thermoregulation

is complex and depends on central stimuli from the anterior hypothalamus and local changes in cutaneous vasoconstriction or dilation (Chapters 223 and 418). A hot flush is similar to a heat dissipation response because both result in vasodilation, sweating, and reduction in core body temperature. The mechanism of altered thermoregulation is not clear. The acute vasodilation associated with hot flushes is preceded by a marked increase in skin sympathetic activity, which mediates vasodilation by a number of substances including nitric oxide, vasoactive intestinal peptide, prostaglandins, and substance P. Local blockade of skin sympathetic activity prevents vasodilation, as does local blockade of nitric oxide.

One theory suggests that abnormalities in central nervous system adrenergic neurotransmission cause hot flushes. This theory is supported by studies showing that systemic administration of yohimbine, an α_2-adrenergic antagonist that increases norepinephrine release, provokes hot flushes, whereas administration of clonidine, an α_2-adrenergic agonist that decreases norepinephrine release, reduces the frequency of hot flushes. Alternatively, some evidence indicates that changes in serotonergic neurotransmission could cause hot flushes. Lower estrogen levels are associated with lower levels of serotonin (5-hydroxytryptamine) in blood, resulting in increased sensitivity of 5-hydroxytryptamine type 2A receptors in the hypothalamus. Stimulation of these receptors can alter the thermoregulatory set point in animals. Mild stressors, such as heat and anxiety, cause a brief release of 5-hydroxytryptamine that may stimulate central 5-hydroxytryptamine type 2A receptors, lower the thermoregulatory set point, and cause flushing. This hypothesis is supported by the finding that drugs that increase central serotonin levels are modestly effective in the treatment of hot flushes.

Estrogen treatment effectively relieves hot flushes, but the exact role of estrogen in flushing is not clear. Fluctuations in estrogen levels in an individual woman do not correlate with the onset of flushes. Prepubertal girls with very low levels of endogenous estrogen, premenopausal women with marked fluctuations in estrogen during the menstrual cycle, and most postmenopausal women with low, constant levels of estradiol do not experience flushing. However, women with gonadal dysgenesis (Chapter 233) who are treated with estrogen for several months experience flushing when treatment is discontinued. Thus, withdrawal of estrogen, rather than the absolute estrogen level, appears to play a key role in the etiology of hot flushes.

In addition to changes in estradiol, menopause is associated with multiple other hormonal changes. In the Study of Women's Health Across the Nation, a large cohort study in the United States, lower estradiol was associated with flushing in middle-aged women in univariate models. However, higher FSH was the only measure independently associated with flushing after multivariate adjustment for other hormone levels. Hot flushes correlate with pulsatile increases in LH, but suppression of LH with gonadotropin-releasing hormone agonists does not eliminate flushing. Androgens may also play a role because men who are treated with androgen deprivation therapy for prostate cancer frequently report flushing.

DIAGNOSIS

Vasomotor symptoms are classic manifestations of the menopause transition, and the diagnosis is generally obvious from a woman's age and description of the symptoms. No abnormal physical findings are associated with hot flushes. Estradiol, FSH, and LH levels may be in the normal premenopausal range during the menopausal transition (see Fig. 240-1). A woman in her middle 40s to middle 50s who complains of classic hot flushes does not require any specific physical or laboratory evaluation unless there is good reason to suspect another cause of flushing (Table 240-1). However, an FSH determination may be helpful in assessing the risk for pregnancy. A woman in her middle 40s to middle 50s with an FSH level obtained on the third day after menses that is higher than 20 IU/L is at very low risk of becoming pregnant.

TABLE 240-1 DIFFERENTIAL DIAGNOSIS OF HOT FLUSHES

Alcohol consumption
Carcinoid syndrome
Dumping syndrome
Hyperthyroidism
Narcotic withdrawal
Pheochromocytoma
Medications
Aromatase inhibitors
Gonadotropin-releasing hormone agonists or antagonists
Nicotinic acid
Nitrates
Selective estrogen receptor modulators (tamoxifen and raloxifene)

TREATMENT

Rx

Because self-reported frequency and severity of hot flushes improve markedly with placebo, conclusive evidence of efficacy of treatments requires randomized, blinded trials.

General Measures

Behavioral and Alternative Therapies

Many women have mild flushes and obtain adequate relief with simple measures such as lowering ambient temperature and wearing lighter clothing. Weight loss has been shown to improve hot flashes, but moderate exercise does not alleviate flushing.

There is no convincing evidence that acupuncture, yoga, Chinese herbs, dong quai, evening primrose oil, ginseng, kava, omega-3 fatty acids, or red clover extract improves hot flushes, although a more recent trial found that, among health sedentary menopausal women, yoga appears to improve menopausal quality of lie. Evidence regarding black cohosh is mixed but primarily negative. Multiple trials have been performed with different phytoestrogen preparations. Although some of these studies have reported benefit, the weight of evidence, especially from good-quality trials with blinded comparisons, suggests little benefit. One trial of vitamin E supplementation found an improvement in flushes, but the decrease was only one hot flush per day. Many women prefer alternative medications because they believe that these treatments are harmless, but phytoestrogens and possibly black cohosh bind estrogen receptors and theoretically could cause adverse outcomes similar to those observed with estrogen. No studies of these preparations have been of adequate size or duration to document safety.

Medical Therapy

Estrogens

Multiple randomized trials have demonstrated that estrogen markedly improves the frequency and severity of hot flushes.[4,5] All types, preparations, and routes of administration of estrogen are effective, reducing the frequency of hot flushes 60 to 95%, depending on the dose. Higher doses of estrogen may control symptoms more rapidly but are also associated with a higher rate of side effects, including uterine bleeding, breast tenderness, and headache.

At similar biologically active doses, oral and transdermal estrogens are approximately equally effective for treatment of vasomotor symptoms. Oral estrogens undergo first-pass metabolism in the liver that results in changes in hepatic proteins and enzymes. Hepatic effects are responsible for the beneficial effects of estrogen on lipoproteins (reduced low-density lipoprotein cholesterol and increased high-density lipoprotein cholesterol) but may also cause adverse effects, such as increases in clotting factors. The transdermal route may be safer because it minimizes these changes.

Many estrogen preparations are approved for treatment of vasomotor symptoms (Table 240-2).[6] To individualize treatment, physicians should become familiar with several of these preparations.

Treatment with estrogen alone markedly increases the risk for uterine hyperplasia and cancer. The risk for endometrial abnormalities appears not to be increased with the use of vaginal estrogens that deliver low systemic doses, especially if they are used only a few times per week, as is generally recommended (Table 240-3).

Adding a progestin to the estrogen regimen prevents the increased risk for uterine cancer. For this reason, a woman with a uterus who takes estrogen should also be given a progestin.[7] There is no reason to add progestins to the hormone regimen in women who have had a hysterectomy. Several progestins are approved by the U.S. Food and Drug Administration (FDA) for this purpose and are available either to add to estrogen or in preparations combined with estrogen (see Table 240-2). Two general approaches are used in prescribing progestins to protect the endometrium. Sequential therapy (estrogen given daily with a progestin added on the last 10 to 14 days of a 28-day cycle) results in endometrial shedding and cyclic bleeding resembling a menstrual period in approximately 80% of women. To avoid monthly menstruation-like bleeding, the progestin may be added to estrogen every 3 to 6 months. However, data regarding the safety of this "long cycle" approach to prevent endometrial hyperplasia are mixed, and women using this regimen should undergo vaginal ultrasound or endometrial biopsy if they experience abnormal vaginal bleeding.

Alternatively, the progestin can be added to the estrogen every day. This continuous regimen results in endometrial atrophy and unpredictable uterine spotting or bleeding that can be difficult for the woman to anticipate and manage. Bleeding occurs in approximately 80% of women in the first 6 months of continuous treatment. Amenorrhea becomes common with prolonged use, but some women continue to bleed or spot for many years.

The most commonly used progestins in sequential regimens in women using standard doses of estrogens (0.625 mg oral conjugated estrogens, 1 mg

Hip fracture	0.66 (0.45-0.98)	0.61 (0.41-0.91)
Dementia	2.05 (1.21-3.48)	1.49 (0.83-2.66)
Death	0.98 (0.82-1.18)	1.04 (0.88-1.22)

*Results of the Women's Health Initiative estrogen plus progestin randomized trial: 16,608 postmenopausal women without hysterectomy randomized to 0.625 mg conjugated estrogen plus 2.5 mg medroxyprogesterone acetate per day or identical placebo and observed for 5.2 years.
†Results of the Women's Health Initiative estrogen-only randomized trial: 10,739 postmenopausal women with hysterectomy randomized to 0.625 mg conjugated estrogen per day or identical placebo and observed for 6.8 years.

oral estradiol, or 0.05 mg transdermal estradiol) are medroxyprogesterone acetate 5 mg and micronized progesterone 200 mg for 10 to 14 days per month. Continuous regimens generally include about half these progestin doses given daily. In some situations, it may be slightly less costly to prescribe estrogen and progestins separately, but the convenience of taking a single pill and the assurance that the estrogen is adequately opposed by progestin make combination preparations preferable.

A combination of conjugated equine estrogens (0.45 mg) and bazedoxifene (20 mg) has been approved by the FDA for treatment of hot flashes in women with a uterus. Bazedoxifene is a selective estrogen receptor modulator that, like progestin, appears to block the carcinogenic effects of estrogen on the uterus. In clinical trials, conjugated estrogens plus bazedoxifene reduced the frequency of hot flashes about 80%, improved dyspareunia, and increased bone density with few side effects. Studies of up to 2 years have not identified other important adverse effects, such as endometrial cancer, breast cancer, venous thromboembolic events, or stroke, but experience with this preparation is limited.

The use of "bioidentical hormones" is based on the concept that estrogens (estradiol, estrone, and estriol) and progestins (progesterone) made from plant products are identical to women's endogenous hormones and therefore more natural, safe, and effective than FDA-approved hormone preparations. Bioidentical hormone therapy often uses doses and combinations of steroid hormones guided by the patient's symptoms or serum hormone levels, and prescriptions are generally filled by Internet-based compounding pharmacies. There is little scientific rationale for the mixtures and ratios of hormones employed, and there are no adequate clinical trial data to support the safety or efficacy of these regimens, some of which include very large doses of estradiol. Bioidentical hormones are not approved by the FDA for treatment of menopausal symptoms.

Side Effects and Risks of Postmenopausal Hormone Therapy

Estrogen is generally well tolerated, but it may cause headache (especially in women with a history of migraine) and breast tenderness. Added progestins tend to make these side effects more severe and also cause uterine bleeding.

The effects of hormone therapy on disease outcomes have been evaluated among postmenopausal women in the Women's Health Initiative (WHI) randomized trials (Table 240-4). Both estrogen and estrogen in combination with progestin reduced the risk for hip fracture by 35 to 40%. Neither estrogen alone nor estrogen with a progestin reduced the risk for coronary events, and both increased the risk for stroke by approximately 40%.

Compared with estrogen alone, added progestin appears to increase the risk for coronary events, pulmonary embolism, breast cancer, and dementia (Table 240-4). This finding suggests that adding a progestin should be avoided, but treatment with unopposed estrogen in women with a uterus markedly increases the risk for uterine hyperplasia and cancer as well as the rate of gynecologic procedures and hysterectomy. Replacing progestins with the selective estrogen receptor modulator bazedoxifene is a novel approach to blocking the carcinogenic effects of estrogen on the uterus, but at this time bazedoxifene has not been proved to be safer than progestins.

The excess risk of any one of the adverse events listed in Table 240-4 in the WHI trials was about 2 per 1000 women treated for 1 year with estrogen in combination with progestin (about 4 per 1000 per year in women older than

65 years if dementia is included) and 1 stroke per 1000 women treated with unopposed estrogen. These risks are relatively small, but they cumulate such that treatment for 5 years is associated with an excess risk of 1 event per 100 women treated with estrogen in combination with progestin and 3 strokes per 1000 women treated with unopposed estrogen. Given these potential harms and the availability of other effective and safe drugs for prevention of osteoporotic fractures, postmenopausal hormone therapy currently has no role for prevention of disease, especially in older women.

The average age of women enrolled in the WHI trials was 63 years. In contrast, most women who take hormone therapy for treatment of hot flashes are generally in their 50s. Subgroup analyses by age from the WHI trials that include women who took hormone therapy for 5 to 7 years show that the *relative* risk for any adverse event among women who took estrogen plus progestin was similar for younger (50 to 59 years) and older (70 to 79 years) women; but given the lower rate of events in younger women, the *absolute* increase in the rate of any major adverse event in the younger women was about 1 per 1000 per year, compared with 4 per 1000 per year for older women. Among women who took estrogen alone, the *relative* risk was lower in younger women than in older women, and the *absolute* rate of adverse events was decreased by 2 per 1000 per year in the younger women compared with an increase of 5 per 1000 per year in the older women. These data suggest that the risk for women in their 50s taking estrogen plus progestin for a few years for the treatment of hot flashes is very low, and there may be no risk associated with taking estrogen alone.

Despite these findings, hormone therapy is relatively contraindicated in women with a history of stroke, breast cancer, or venous thromboembolic events and should be avoided in women at high risk for these conditions.

Stopping Hormone Therapy

Given the possible adverse effects of hormone therapy, current guidelines recommend that women use the lowest effective dose for the shortest time necessary. Vasomotor symptoms improve or resolve spontaneously within a few years of onset in most women, suggesting that most should be able to discontinue hormone therapy within a few years of starting. Women using hormone therapy for treatment of symptoms should stop every 6 to 12 months to determine whether symptoms have improved to the point that treatment is no longer needed. A small percentage of women are unable to stop hormone therapy because vasomotor symptoms persist for many years.

Women experiencing intolerable symptoms after stopping hormone treatment can be told to resume therapy and either to begin a slow taper or to wait 6 months before trying again to stop. Tapering can be accomplished by decreasing the dose of hormone therapy, but it may be easier to decrease the number of days per week that hormone therapy is used. The *dose taper* involves progressively reducing the dose of hormone therapy, for example, by reducing the dose of conjugated estrogens from 0.625 mg/day to 0.45 to 0.3 mg/day and then discontinuing therapy. If changing to a lower dose is associated with tolerable symptoms, the next reduction in dose should not occur until symptoms improve, which may require 3 to 6 months in some women. The *day taper* involves decreasing the number of days per week of hormone therapy use and effectively decreasing the weekly dose. For example, therapy with the same dose may be continued, but only Monday through Friday. If this reduced weekly dose is tolerated, therapy may be discontinued on Friday, and so on. As with the dose taper, if symptoms develop, the weekly dose should be maintained until symptoms improve. Both these approaches to tapering can require many months or even years until therapy is discontinued. The day taper has the advantages of allowing smaller reductions in weekly dose, ensuring that the estrogen dose is appropriately opposed by a progestin in women using continuous therapy, and does not require multiple new prescriptions for different doses of hormone therapy. For women who cannot tolerate even a slow taper, the value of symptom relief likely outweighs the risks of hormone therapy.

Other Prescription Drugs

The progestins megestrol and medroxyprogesterone acetate are effective for the treatment of hot flushes, but they have frequent side effects, and progestin use was associated with increased risk for adverse effects in the WHI trials. Several selective serotonin and serotonin-norepinephrine reuptake inhibitors and gabapentin have been studied (Table 240-5). Paroxetine and escitalopram reduce the frequency of hot flashes by about 0.5 to 1 hot flash per day more than placebo; these drugs have side effects typical of selective serotonin reuptake inhibitors. Low-dose paroxetine mesylate (7.5 mg/day) reduces hot flash frequency by about 1 hot flash per day more than placebo, and side effects were uncommon. This is the only nonhormonal drug currently approved by the FDA for the treatment of hot flashes. In a randomized, double-blinded trial, the efficacy of low-dose oral estradiol (0.5 mg daily) was found to be only slightly superior to that of the serotonin-norepinephrine reuptake inhibitor venlafaxine (extended release, 75 mg daily) in alleviating vasomotor symptoms. Gabapentin also has only modest efficacy (reducing the frequency of hot flashes by 0.5 to 1 hot flash per day more than placebo) but is associated with dizziness, somnolence, headache, and nausea. Extended-release gabapentin has been studied in three phase III randomized trials, but results have not been published and the drug was not approved by the FDA for treatment of hot flashes. Clinical trials of these prescription drugs have generally lasted only 3 months and have not been adequately large or prolonged to detect uncommon adverse effects.

Summary of Approach to Treatment of Vasomotor Symptoms

Women with mild vasomotor symptoms may find adequate relief by wearing layered clothing and keeping the home and bedroom cool. Women with moderate symptoms may choose a low dose of estrogen or a nonestrogen therapy. Low-dose paroxetine is modestly effective, has the best side effect profile of the nonhormonal drugs, and is approved by the FDA for this indication. For women with severe symptoms, hormone therapy is the most effective treatment.

Vaginal Symptoms

EPIDEMIOLOGY

The prevalence of vaginal dryness, discomfort, itching, and dyspareunia increases as women transition through the menopause. Up to 30% of perimenopausal and early postmenopausal women and a higher proportion of older menopausal women express these complaints. Urologic symptoms, including urgency, frequency, dysuria, and incontinence, are not clearly correlated with the menopause transition.

PATHOBIOLOGY

Vaginal symptoms generally correlate with findings (often called vaginal atrophy) including pallor, dryness, friability, and decreased rugosity of the vaginal mucosa. Vaginal fluid in premenopausal women is acidic, ranging from a pH of approximately 4.5 to 5.5 with mild alkalinization to approximately 6.0 before ovulation. Acidity is produced by proton excretion from the vaginal epithelial cells and by metabolism of glycogen stored in vaginal epithelial cells by *Lactobacillus* species, the normal vaginal flora. The acid environment of the vagina inhibits growth of *Escherichia coli* and other enteric gram-negative bacteria that are a potential cause of urinary tract infections. Vaginal pH can easily be measured from lateral vaginal wall fluid.

In postmenopausal women, vaginal pH is generally neutral, and the predominant flora are often *E. coli* and other gram-negative bacteria. This appears to occur because estrogen deficiency associated with menopause causes vaginal epithelial cell dysfunction, including decreased storage of glycogen, less ability to acidify the vaginal fluid, and lowered production of vaginal lubrication. Vaginal epithelial cells, which are primarily superficial and intermediate cells in premenopausal women, shift to predominantly immature parabasal cells in postmenopausal women. Treatment with estrogen improves or relieves vaginal dryness, lowers vaginal pH, and increases the proportion of superficial cells in the vaginal epithelium.

DIAGNOSIS

Diagnosis is primarily based on typical complaints of vaginal dryness, discomfort, itching, or dyspareunia in women undergoing the menopause transition or older postmenopausal women. Pelvic examination should be performed to exclude other causes of symptoms, including infections, lesions, and trauma. Physical findings of vaginal dryness, pallor, friability, and vaginal pH above 5.5 support the diagnosis. Cytologic examination of the proportion of superficial, intermediate, and parabasal cells from a scraping of the lateral vaginal wall (vaginal maturation index) showing primarily parabasal cells also supports the diagnosis. In clinical practice, measurement of pH and vaginal maturation index are not necessary to make the diagnosis.

TREATMENT

Rx

Some women with mild dyspareunia may obtain adequate relief with over-the-counter vaginal lubricants used as needed for sexual intercourse.[8] Over-the-counter vaginal moisturizers, such as Replens (a bioadhesive polycarbophil vaginal gel used daily or three times per week), have been shown to improve vaginal symptoms and findings. Estrogen therapy is highly effective.[9] Topical therapy is efficacious[10] and is preferred because it generally results in smaller increases in systemic estrogen levels than with oral or transdermal therapy. Estrogen vaginal creams, tablets, and rings approved for treatment of vaginal dryness are listed in Table 240-3.

Most clinicians do not add a progestin to protect the uterus in women treated with vaginal estrogen, but evidence to support the uterine safety of vaginal estrogen is limited to short-term studies. Low-dose, intermittent

TABLE 240-5 EVIDENCE FROM RANDOMIZED, CONTROLLED CLINICAL TRIALS OF THE EFFICACY OF NONESTROGEN DRUGS FOR TREATMENT OF MENOPAUSAL HOT FLUSHES

TREATMENT	EVIDENCE OF BENEFIT	COMMENTS	REFERENCES	SIDE EFFECTS*
ANTIDEPRESSANTS				
Citalopram	No	No benefit of 30 mg citalopram compared with placebo	Suvanto-Luukkonen E, Koivunen R, Sundstrom H, et al. *Menopause.* 2005;12:18-26.	Selective serotonin reuptake inhibitors citalopram, escitalopram, fluoxetine, paroxetine, and sertraline: nausea, vomiting, diarrhea, insomnia or somnolence, anxiety, decreased libido, dry mouth, worsening depression, mania, suicidality, serotonin syndrome, withdrawal syndrome, and possible decreased tamoxifen effectiveness
Escitalopram	Yes	Among generally healthy women, frequency of hot flushes reduced 47% with escitalopram 10 to 20 mg/day compared with 33% with placebo	Freeman EW, Guthrie KA, Caan B, et al. *JAMA.* 2011;305:267-274.	
Fluoxetine	Mixed	Among breast cancer survivors, frequency of hot flushes reduced 50% with fluoxetine 20 mg/day compared with 36% with placebo No benefit among women with breast cancer treated with 30 mg fluoxetine compared with placebo	Loprinzi CL, Sloan JA, Perez EA, et al. *J Clin Oncol.* 2002:20:1578-1583. Suvanto-Luukkonen E, Koivunen R, Sundstrom H, et al. *Menopause.* 2005;12:18-26.	
Paroxetine	Yes	Among generally healthy women, frequency of hot flushes reduced 62% with 12.5 mg and 65% with 25 mg paroxetine CR compared with 38% in placebo In a crossover trial in which 81% of participants had a history of breast cancer, paroxetine 10 mg reduced hot flush frequency by 41% compared with 14% with placebo, and paroxetine 20 mg reduced hot flush frequency by 52% compared with 27% placebo In 2 similarly designed trials of 7.5 mg of paroxetine mesylate daily compared with placebo, paroxetine reduced the frequency of hot flashes by about 1 hot flash per day more than placebo	Steans V, Beebe KL, Lyengar M, et al. *JAMA.* 2003;289:2827-2834. Stearns V, Slack R, Greep N, et al. *J Clin Oncol.* 2005;23:6919-6930. Simon JA, Portman DJ, Kaunitz AM, et al. *Menopause.* 2013;20:1027-1035.	
Sertraline	No	Among women with a history of breast cancer, no benefit of treatment with 50 mg of sertraline compared with placebo Among generally healthy women, no benefit of 100 mg of sertraline compared with placebo	Kimmick GG, Lovato J, McQuellon R, et al. *Breast J.* 2006;12:114-122. Grady D, Cohen B, Tice J, et al. *Obstet Gynecol.* 2007;109:823-830.	
Venlafaxine	Mixed	Among breast cancer survivors, frequency of hot flushes reduced 61% with 75 or 150 mg venlafaxine compared with 27% placebo Among women without breast cancer, no effect on frequency of flushes with 75 mg venlafaxine, but women treated with venlafaxine were more likely to report that flushes improved compared with placebo	Loprinzi CL, Kugler JW, Sloan JA, et al. *Lancet.* 2003;356:2059-2063. Evans ML, Pritts E, Vittinghoff E, et al. *Obstet Gynecol.* 2005;105:161-166.	In addition to the side effects noted above, the selective serotonin-norepinephrine reuptake inhibitors venlafaxine and desvenlafaxine can also cause hypertension.
Desvenlafaxine	Yes	Meta-analysis of the results of 6 randomized trials showed that treatment with 100 to 150 mg of desvenlafaxine per day reduces the frequency of hot flashes by 0.3 to 0.5 more than with placebo	Umland EM, Falconieri L. *Int J Womens Health.* 2012;4:305-319.	
ANTIHYPERTENSIVES				
Clonidine	Mixed	Small trials suggest little or no benefit	Nelson HD, Haney E, Humphrey L, et al. AHRQ Publication No. 05-E016-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005. Goldberg RM, Loprinzi CL, O'Fallon JR, et al. *J Clin Oncol.* 1994;12:155-158. Pandya KJ, Raubertas RF, Flynn PJ, et al. *Ann Intern Med.* 2000;132:78-93.	α-Adrenergic antagonists clonidine and methyldopa: dry mouth, drowsiness, dizziness, hypotension, rebound hypertension
Methyldopa	No		Nelson HD, Haney E, Humphrey L, et al. AHRQ Publication No. 05-E016-2. Rockville, MD: Agency for Healthcare Research and Quality; 2005.	

TABLE 240-5 EVIDENCE FROM RANDOMIZED, CONTROLLED CLINICAL TRIALS OF THE EFFICACY OF NONESTROGEN DRUGS FOR TREATMENT OF MENOPAUSAL HOT FLUSHES—cont'd

TREATMENT	EVIDENCE OF BENEFIT	COMMENTS	REFERENCES	SIDE EFFECTS*
HORMONES				
Medroxyprogesterone acetate	Yes	Frequency of hot flushes was reduced 74% with 20 mg medroxyprogesterone acetate compared with 26% with placebo	Schiff I, Tulchinsky D, Cramer D, et al. *JAMA*. 1980;244:1443-1445.	Progestins medroxyprogesterone and megestrol: nausea, vomiting, constipation, somnolence, depression, breast tenderness, uterine bleeding; possible increased risk for venous thromboembolism, cardiovascular events, and breast cancer
Megestrol	Yes	Among breast cancer survivors, frequency of hot flushes reduced 74% with 20 mg megestrol twice a day compared with 27% with placebo	Loprinzi CL, Michalak JC, Quella SK, et al. *N Engl J Med*. 1994;331:347-352.	
OTHER DRUGS				
Gabapentin	Yes	Among healthy women, frequency of hot flushes was reduced 45% with gabapentin 300 mg three times/day compared with 29% with placebo Frequency of hot flushes was reduced 31% more than with placebo among breast cancer survivors	Guttuso TJ, Kurlan R, McDermott MP, et al. *Obstet Gynecol*. 2003;101:337-345. Pandya JK, Morrow GR, Rosco JA, et al. *Lancet*. 2005;366:818-824.	Nausea, vomiting, somnolence, dizziness, rash, ataxia, fatigue, leukopenia

*Side effects were reported in clinical trials of the therapy or from Epocrates RX drug reference (available at http://www.epocrates.com).

treatment (e.g., 1 to 2 g conjugated estrogen cream or 0.025 mg estradiol tablet twice a week) results in small increases in systemic estrogen levels that appear not to cause endometrial stimulation. However, full-dose daily treatment has been shown to increase estradiol levels to 50 pg/mL or higher in approximately half of treated women and has been associated with uterine bleeding and hyperplasia.

Ospemifene, an oral selective estrogen receptor modulator, is approved by the FDA for the treatment of menopausal vaginal dryness and dyspareunia. Treatment with 60 mg once daily reduces the bothersomeness of vaginal symptoms about 10 to 15% more than placebo does, but it is associated with hot flashes, urinary tract infection, and vaginal infections. Small studies of up to 1 year have not shown increased risk of endometrial cancer, breast cancer, venous thromboembolic events, or stroke, but because ospemifene is a selective estrogen agonist, these potential adverse effects are of concern.

Sleep Disturbance

The prevalence of self-reported sleep disturbance increases from about 40% of premenopausal women to approximately 60% of postmenopausal women. Sleep disturbances, including trouble falling asleep and early awakening, are reported by menopausal women, but awakening during the night appears to be most bothersome.

The etiology of sleep disturbance associated with menopause is unclear. Postmenopausal women with hot flushes are more likely to report sleep disturbance than are those without flushes, and women commonly report that they are awakened by hot flushes. However, studies using polysomnography find that nocturnal hot flushes do not consistently occur at the same time as sleep disturbance. Thus, disturbed sleep appears to be part of a menopausal syndrome, but it may not be caused by flushing.

Menopause-related sleep disturbance can be treated by standard approaches to sleep hygiene and prescription medications. Both oral and transdermal estrogen preparations improve sleep in perimenopausal and postmenopausal women with hot flushes.

REVIEW QUESTIONS

1. Which of the following case histories documents that the woman is in the early menopause transition?

A. A 50-year-old woman complains of labile mood, forgetfulness, and loss of libido and reports that she missed a menstrual period last month.
B. A 54-year-old woman reports that she has not had a menstrual period for a year and is having hot flashes.
C. A 48-year-old smoker complains that she is having hot flashes and trouble sleeping and reports that she has missed three menstrual periods in the past year.
D. A 48-year-old woman who is taking birth control pills reports gaining 10 pounds in the past year.
E. A 60-year-old woman complains that she has been having hot flashes for 10 years since her menstrual periods stopped, and the hot flashes recur every time she tries to stop her estrogen treatment.

Answer: C A woman in her mid-40s to mid-50s who complains of classic hot flashes is likely to be in the menopause transition. The fact that the woman in C has missed three menstrual periods in the last year suggests that she is in the early menopause transition. The symptoms reported by the women described in A and D are not associated with the menopause transition. The women described in B and E have undergone menopause or are in the late menopause transition because they have not had a menstrual period for a year.

2. What evaluation is required for a 52-year-old woman who has missed six menstrual periods in the previous year and complains of hot flashes?

A. Lateral vaginal wall pH
B. A careful pelvic examination to evaluate for vaginal atrophy
C. Serum follicle-stimulating hormone (FSH) level
D. Review of medications and prior medical history
E. Serum thyroid-stimulating hormone level

Answer: D A clear history of appropriate age (mid-40s to mid-50s), missing menstrual periods, and classic description of hot flashes with no other medical problems that might cause flushing (see Table 240-1) is diagnostic of menopause-related hot flashes, and no further evaluation is needed. There are no associated physical findings, and FSH levels may be normal in the early menopause transition. If the woman is not complaining of vaginal symptoms, a pelvic examination or vaginal wall pH measurement is not helpful.

3. What treatment would you recommend for a 50-year-old woman with mild hot flashes?

A. Reassure her that the symptoms are likely to resolve in a few years.
B. Suggest that she dress in layers and keep her bedroom cool.
C. If there are no contraindications, offer low-dose (7.5 mg/day) paroxetine.
D. If there are no contraindications, offer low-dose hormone therapy.
E. All of the above

Answer: E Many women with mild hot flashes want to be reassured that they are indeed in the menopause transition and that this is a normal stage of reproductive life. These women are often not bothered enough by hot flashes to want treatment. However, some women are bothered and would like to try treatment to alleviate the hot flashes. In this situation, a nonhormonal drug such as paroxetine, 7.5 mg daily, or a low-dose estrogen, such as 0.025 mg estradiol (combined with a progestin if she has a uterus), is likely to provide adequate relief.

4. What treatment would you recommend for a 50-year-old woman with severe hot flashes that are interfering with her ability to work? She has not had a hysterectomy, and her only other medical problem is osteoarthritis, for which she takes a nonsteroidal anti-inflammatory drug.

A. Reassurance that the symptoms are likely to resolve in a few years
B. A nonhormonal drug, such as low-dose paroxetine 7.5 mg daily
C. Bioidentical hormone therapy
D. Standard-dose estrogen given daily, combined with a progestin given on the last 10 to 14 days of the month or half-dose progestin given daily
E. Estradiol 0.5 mg given daily

Answer: D A woman with severe hot flashes is unlikely to obtain adequate relief with nonhormonal treatments. However, if she wishes to try these treatments before taking hormone therapy or there is a contraindication to hormone therapy, it would appropriate to try a nonhormonal treatment such as paroxetine or escitalopram. A woman with a uterus should have a progestin added to estrogen therapy to avoid the increased risk of endometrial hyperplasia and cancer associated with unopposed estrogen therapy. This can be done by adding standard-dose progestin on days 10 to 14 of the month (or by using a sequential combination estrogen plus progestin pill) or by adding half-dose progestin daily (or using a combination estrogen plus progestin pill or transdermal patch). Hormone therapy options are provided in Table 240-2. The various types of estrogen and progestins are equally effective at equivalent doses. Some women prefer a patch, whereas others prefer a pill; both the oral and transdermal routes are effective.

5. What treatment would you recommend for a 65-year-old woman with severe vaginal dryness, itching, and dyspareunia?

A. Reassurance that the symptoms are likely to resolve in a few years
B. Use of a vaginal lubricant as needed for sexual intercourse
C. Use of a vaginal moisturizer daily or three times per week
D. Estrogen vaginal cream
E. Estrogen vaginal ring

Answer: D or E The best answers are D and E. Reassurance is inappropriate, as unlike hot flashes, menopause-related vaginal symptoms generally do not resolve over time. The woman could try vaginal lubricants for sexual intercourse and a vaginal moisturizer such as Replens, but these are unlikely to provide adequate relief of symptoms. Low-dose topical estrogen applied to the vagina is the most effective treatment. Estrogen can be provided as a cream, vaginal tablet, or slow-release ring. Treatment options are provided in Table 240-3. If topical estrogens are used at low doses (two or three times per week as described in Table 240-3), added progestins are not required for women with a uterus.

241

INTIMATE PARTNER VIOLENCE

GENE FEDER AND HARRIET L. MACMILLAN

DEFINITION

Intimate partner violence (IPV) is defined as any behavior within an intimate relationship or ex-relationship that causes physical, psychological, or sexual harm. This includes physical aggression, such as hitting, kicking, and beating; psychological violence, such as intimidation and constant humiliation; various controlling behaviors, such as isolation from family and friends, monitoring of movements, financial control, and restricting access to services; and sexual violence, including forced intercourse and other sexual coercion. Lifetime prevalence of isolated violent acts within relationships is comparable for men and women, but repeated coercive, sexual, or severe physical violence is perpetrated largely against women by men. Although IPV also occurs in same-sex relationships, research evidence on the health consequences of IPV and the care of survivors is largely confined to women in heterosexual relationships.

Historically, there has been the stereotype of a male batterer as one who uses severe, repeated, and unilateral violence against a nonviolent female

victim. It is now recognized that *bilateral violence* is a common form of IPV, even though the overwhelming burden of morbidity and mortality related to IPV is experienced by women. Bilateral violence, sometimes referred to as *common couple violence,* is considered less severe than the pattern of abuse known as *battering* or *intimate terrorism,* a severe and escalating form of IPV characterized by threats, terrorization, multiple forms of abuse, and controlling behavior on the part of the abuser. Current research suggests that women rarely subject men to battering.

IPV is a risk factor for a wide range of medical and psychiatric conditions and therefore can be understood as an epidemiologic exposure. Yet violence perpetrated by an intimate partner or ex-partner is essentially a violation of human rights and a preventable psychosocial issue that needs to be addressed through social and educational policies.

EPIDEMIOLOGY

The prevalence of IPV against women varies internationally but is universally high, comparable to that of chronic conditions like diabetes and asthma. The most robust comparative study (24,097 women from 15 sites in 10 countries), conducted by the World Health Organization, found a lifetime prevalence of physical violence, sexual violence, or both ranging from 15 to 71%.[1] Prevalence of physical or sexual violence during the past year ranged from 15 to 54%. In all sites but one, women were more at risk for violence from a partner or ex-partner than from violence by other people. A systematic review that included data from 66 countries found that one in seven homicides globally are committed by an intimate partner; this figure is six times higher for female homicides compared with male homicides.[2]

Causation

Several theories about the causes of IPV have been proposed over the years. Social learning theory suggests that IPV is a learned behavior. The fact that male perpetrators and female victims are more likely to report histories of exposure to violence in childhood supports this theory. However, most individuals exposed to violence in childhood do not go on to commit violence as adults, and not all abusers have violent upbringings. Furthermore, the link between poor parenting generally, including neglect, and subsequent IPV in adulthood suggests that the effect is not simply one of modeling abusive behavior. Exposure to rejecting or neglectful parenting is associated with adverse effects on intrapersonal (e.g., poor self-worth) and interpersonal development that are associated with IPV.

A feminist perspective views IPV against women as a form of social control that results from society's patriarchal structure leading to inequality in power relationships between men and women. Lending support to this perspective is the finding that IPV appears to be less common in more democratic and less economically polarized societies. Although IPV occurs more often in contexts in which there is support for male authority in the family and women have less access to economic security, it is not clear why some individuals are more likely than others to be violent under such conditions.

With regard to psychological theory, there are conflicting views about the association between IPV and psychopathology. Some researchers argue that abusive males have deficits in one or more coping mechanisms, anger control, and communication skills, whereas others suggest that IPV results from dysfunctional interactional patterns between partners. Because types of IPV are not the same for all couples, there are likely to be multiple causes for its occurrence. Most of the research has focused on factors associated with increased risk of men abusing women (Table 241-1)[3]; however, whether these factors are "causal" is unknown.

TABLE 241-1 FACTORS ASSOCIATED WITH A MAN'S RISK FOR ABUSING HIS PARTNER

INDIVIDUAL	RELATIONSHIP	COMMUNITY	SOCIETAL
Young age	Poor family functioning	Weak community sanctions against intimate partner violence	Traditional gender norms
Heavy drinking	Marital instability	Poverty	Social norms supportive of violence
Depression	Marital conflict	Economic inequality	
Personality disorders	Male dominance	Low social capital	
Low academic achievement	Economic stress		
Low income			
Exposure to violence in childhood			

Modified from World Health Organization: World Report on Violence and Health. Geneva: World Health Organization; 2002.

CLINICAL MANIFESTATIONS

The information in this section pertains to female patients because most of the research examining clinical manifestations associated with IPV exposure has focused on women. However, studies of male victims suggest that they also experience increased risk for poor health as well as chronic physical and emotional health problems and injuries.[4]

Patients seldom present with a chief complaint of IPV. Injuries are the most obvious manifestation; a clinician should have increased suspicion for IPV if there are multiple injuries, the presenting history of injuries is not consistent with the physical examination, and there is a delay in seeking medical care for injuries. Patients exposed to physical violence may present with injuries that vary from minor abrasions to life-threatening trauma. Although there can be overlap between injuries resulting from IPV and injuries from other causes, the former typically involve trauma to the head, face, and neck, whereas the latter are more typically injuries of the extremities.[5] Multiple facial injuries are suggestive of IPV rather than of other causes, and those that are more specific for IPV include zygomatic complex fractures, orbital blowout fractures, and perforated tympanic membrane. Although facial injuries are the most common injuries associated with IPV, they have low specificity. Musculoskeletal injuries are considered the second most common type of injuries, including sprains, fractures, and dislocations.[6] Blunt-force trauma to the forearms should raise suspicion of IPV because these can occur when trying to block being struck.

Victims of IPV often experience multiple mechanisms of injury; being struck by a hand is the most common, followed by use of a household object. Injuries from weapons such as knives and guns are far less common (<1%) but are associated with higher risk for mortality. Strangulation also occurs frequently,[7] but less is known about the types of clinical manifestations that result from this form of IPV. Other injuries that raise suspicion of IPV include fractures of the spine or trunk, bites, hair pulling, and open wounds. Those exposed to sexual abuse may show signs of trauma to the genital area, but sexual assault is associated with signs of injury in less than one third of cases.

Most victims of IPV presenting to health care settings do not have signs of obvious trauma but rather have a constellation of overlapping physical and mental health problems. A patient presenting with vague signs and symptoms or chronic somatic complaints, including pain, suggests the possibility of IPV. Other behaviors that suggest IPV include delay in seeking medical care, multiple cancellations of medical appointments, and noncompliance with vital medications (e.g., insulin).

There are no systematic reviews of studies on the overall physical health consequences of IPV, but an overview of studies reported increased rates of chronic physical conditions, particularly gynecologic, gastrointestinal, and nervous system disorders, as well as increased cardiovascular risk, although most of the studies were small and poorly adjusted for other risk factors. The overview also found that women with a history of abuse, particularly physical and sexual violence, were more likely to experience chronic pain and nonspecific symptoms, although an association between abuse and number of physical symptoms is also found in women who experience emotional abuse without any physical abuse. The World Health Organization study reported significant associations between women's lifetime experiences of partner violence and self-reported poor health and specific health problems in the previous 4 weeks, such as difficulty in walking, difficulty with daily activities, pain, memory loss, dizziness, and vaginal discharge. Other physical conditions that should raise suspicion of IPV include chronic gynecologic or gastrointestinal symptoms, such as irritable bowel syndrome and chronic pelvic pain. It should not be assumed, however, that there is a specific association of functional disorders, such as irritable bowel syndrome and fibromyalgia, over and above the greater reporting of physical syndromes in general. IPV exposure is associated with an increased risk for sexually transmitted infections, including human papillomavirus.

Exposure to any type of IPV can be associated with a wide range of emotional and behavioral symptoms[8]; depression and post-traumatic stress disorder (PTSD) are the two most commonly associated emotional conditions, but other anxiety disorders and substance abuse are also associated with IPV exposure. In the World Health Organization study, women who reported IPV at least once in their life reported three to four times more emotional distress, suicidal thoughts, and suicide attempts than nonabused women. There is strong evidence of increased risk for depression, anxiety, substance abuse, and PTSD, with longitudinal studies reporting increased morbidity after

violence. A recent meta-analysis examining the association between IPV against adult women and depressive conditions found a 2- to 3-fold increase in risk of major depressive disorder and a 1.5- to 2-fold increased risk of postpartum depression and elevated depressive symptoms.[9] The cross-sectional design of most studies examining associated impairment precludes conclusions about the causal role of IPV in these conditions, but the few published longitudinal studies show the onset or worsening of depression, PTSD, and substance abuse *after* exposure to IPV.

Pregnant women deserve special mention because IPV can threaten the health of both mother and fetus. Injury patterns during pregnancy are more likely to be central, including blunt trauma to the head, torso, abdomen, breasts, and genitalia. Abuse directed to the abdomen may lead to poor pregnancy outcomes and perinatal death. Although the evidence regarding a direct association between IPV in pregnancy and low birthweight has been conflicting, the increased risk for preterm birth as well as other factors, such as psychosocial stress, may play a role in adverse outcomes for infants, but more investigation is required.

Although it is beyond the scope of this chapter, there is increasing recognition that children's exposure to IPV shows a significant association with children's internalizing and externalizing problems, including trauma symptoms, developmental delay, educational problems, and long-term mental health conditions.[10]

Identification

Despite some guidelines recommending universal screening for IPV, randomized controlled trials have shown that although such screening increases the identification of women with IPV, it has not been shown to improve women's health outcomes or to reduce the occurrence of IPV. Consistent with the World Health Organization guidelines referred to before, IPV screening is not recommended for women of any age group.[11] However, it is important to be alert to the signs and symptoms associated with IPV, including those associated with the broad range of physical and mental health conditions referred to previously, and for clinicians to have a low threshold for asking about abuse. Indicators that suggest a higher likelihood of IPV include symptoms of depression, somatization, and PTSD in the female patient and a history of alcohol or drug abuse and unemployment in the male partner (or ex-partner). It is important, when asking about exposure to IPV, to do so privately, with no one else present, including a child (beyond infancy) or partner. If the inquiry or response is overheard, it could put the patient at risk for further IPV. A meta-analysis of qualitative studies of women's expectations and experiences reported that when the topic of IPV is raised, patients want questioning that is nonjudgmental, compassionate, and caring.[11] Women want to be asked about IPV with confidentiality ensured but do not want to be pressured to disclose. In some jurisdictions, however, disclosure of IPV when a patient has children in the home can lead to mandatory reporting to child protection services. It is important that patients be advised about the limits of confidentiality before being asked about IPV exposure.

Possible questions to ask if IPV is suspected include the following:

Sometimes partners or ex-partners use physical force. Has this ever happened to you?

Have you felt humiliated or emotionally harmed by your partner or ex-partner?

Are you now or have you ever been afraid of your partner or ex-partner?

Have you ever been physically threatened or hurt by your partner or ex-partner?

Have you been forced to have any kind of sexual activity by your partner or ex-partner?

Has your partner or ex-partner ever tried to control your behavior, for example, control where you go or whom you see?

The initial clinical response when IPV is identified should include validation of the experience (e.g., everyone deserves to feel safe at home), affirmation that violence is unacceptable, and expression of support. The clinician needs to acknowledge the complexity of IPV and respect the patient's individual concerns and decisions. The assessment should include an evaluation of safety; the patient should be asked if it is safe for her (or him or any children) to return home. The following are examples of safety considerations:

Has the frequency or severity of the violence increased?

Is the partner or ex-partner obsessed with the patient?

How safe does she (he) feel?

Does the partner or ex-partner have a weapon or access to one?

Has she (he) been threatened with a weapon?

Although a general discussion of gun violence is beyond the scope of this chapter, having firearms in the home is associated with an increased risk for homicide associated with IPV. Another predictor of domestic homicide is threats of deadly violence.

TREATMENT

Inquiry and Disclosure

The initial response of clinicians to the disclosure of IPV by female patients, whether the disclosure is spontaneous or the result of clinical inquiry, is crucial in gaining trust and is the basis of further management. IPV is a highly stigmatized condition, akin to sexually transmitted infection or substance abuse, with the added dimension of risk for further harm from breach of confidentiality. A number of qualitative studies of women's expectations and experiences (847 informants) reported consistent messages about how clinicians can respond appropriately to disclosure. *Before disclosure or questioning,* they should understand the problem, including knowing about the available community services and appropriate referral systems; ensure that the clinical environment is supportive, welcoming, and nonthreatening; place brochures and posters in the clinical setting; try to ensure continuity of care; assure abused women about matters of privacy, safety, and confidentiality; be alert to the signs of abuse and raise the matter when indicated; use verbal and nonverbal communication skills to develop trust; and be compassionate, supportive, and respectful toward abused women. *When the topic of IPV is raised,* they should be nonjudgmental, compassionate, and caring when questioning about abuse; be confident and comfortable asking about domestic violence; not pressure women to disclose abuse because simply raising the topic may be helpful to women; ask about abuse during the course of several interviews because a woman may disclose abuse at a later date; ensure that the environment is private and confidential; and provide time. *Immediate response to disclosure* should be nonjudgmental, with compassion, support, and belief of experiences; acknowledge the complexity of the problem and respect the woman's unique concerns and decisions; put the needs identified by the woman first and help ensure that social and psychological needs are met; take time to listen, to provide information, and to offer referrals to specialist help; validate her experiences, challenge assumptions, and provide encouragement; and respond to any concerns about safety. *Response in later interactions* should be patient and supportive, allowing her to progress at her own therapeutic pace; understand the chronicity of the problem and provide follow-up and continued support; respect the woman's wishes and not pressure her into making any decisions; be nonjudgmental if a woman does not follow up with referrals immediately; and give abused women an opportunity to disclose abuse at a later date.

Referral Services and Advocacy

Beyond their initial response and managing the medical sequelae of abuse, most generalists have neither the expertise nor the capacity to meet the specific needs of women experiencing IPV, which include legal, financial, housing, and safety needs. A key step, particularly in the context of current or recent violence, is an offer of referral to some sort of specialist support. Two main types of services have been evaluated: advocacy programs and psychological interventions (individual or group based). In general, advocates engage with individual clients who are being abused, aiming to empower them and linking them to community services. Core activities of advocacy include provision of legal, housing, and financial advice; facilitation of access to and use of community resources, such as refuges (shelters, safe houses) and emergency housing; and provision of safety planning advice. Advocates can also provide ongoing support and informal counseling. A Cochrane review of 10 randomized controlled trials (1527 participants) of domestic violence advocacy concluded that there was equivocal evidence that advocacy for women recruited in domestic violence shelters (refuges) had a beneficial effect on their physical and psychosocial well-being and was unable to draw any conclusions for women receiving advocacy in or referred from health care settings. A broader systematic review that included all controlled studies of domestic violence advocacy concluded that most showed a reduction in abuse, increased social support, and improved quality of life as well as increased use of safety behaviors and accessing of community resources. Only two of the studies had participants referred from health care settings. Clinicians should be able to refer patients to specialist IPV advocacy and are more likely to ask about abuse if they have the support of these services. If such services are not immediately available, shelters and refuges often provide these kinds of services for women both in residences and on an outreach basis.

Individual and Group Psychological Interventions

A systematic review of controlled studies of psychological interventions for survivors of IPV identified 17 studies, 7 of individual and 10 of group interventions. There was a wide range of individual psychological interventions that

TABLE 241-2 SUMMARY OF SELECT INTIMATE PARTNER VIOLENCE RECOMMENDATIONS FROM THE WORLD HEALTH ORGANIZATION

CATEGORY	RECOMMENDATION	QUALITY OF EVIDENCE	STRENGTH OF RECOMMENDATION
Woman-centered care	Women who disclose any form of violence by an intimate partner (or other family member) should be offered immediate support by clinicians, at a minimum. If clinicians are unable to provide this first-line support, they should ensure that someone else (within their health care setting or another that is easily accessible) is immediately available to do so.	Indirect	Strong
Identification of survivors	Universal screening is not recommended.	Low-moderate	Conditional
	Ask about exposure to IPV when assessing conditions that may be caused or complicated by abuse.	Indirect	Strong
	Written information about IPV should be available in all health care settings.	No relevant evidence	Conditional
Care for survivors	Women with preexisting diagnosed or IPV-related mental disorders should receive mental health delivered by health care professionals with a good understanding of violence against women.	Indirect	Strong
	Cognitive-behavioral therapy or eye movement desensitization and reprocessing interventions, delivered by health care professionals with a good understanding of violence against women, should be offered to women with post-traumatic stress disorder who are no longer experiencing violence.	Low-moderate	Strong
	Women who have spent at least 1 night in a shelter, refuge, or safe house should be offered a structured program of advocacy, support, and/or empowerment.	Low	Conditional
	For children who are exposed to IPV at home, a psychotherapeutic intervention should be offered.	Moderate	Conditional
Training of clinicians	Training at prequalification level in first-line support for women who have experienced IPV should be given to clinicians (in particular physicians, nurses, and midwives).	Very low	Strong
	Clinicians offering care to women should receive in-service training integrated with training on managing sexual assault.	Low-moderate	Strong
Health care policy	Care for women experiencing IPV should be integrated into existing health services rather than as a stand-alone service.	Very low	Strong
Mandatory reporting	Mandatory reporting to the police by clinicians is not recommended; clinicians should offer to report the incident to the appropriate authorities (including the police) if the woman wants this and is aware of her rights.	Very low	Strong

IPV = intimate partner violence. (From Feder G, Wathen CN, MacMillan HL. An evidence-based response to intimate partner violence: WHO guidelines. *JAMA* 2013;310:479-480.)

demonstrated improvements in psychological outcomes, including depression, PTSD, and self-esteem. Well-executed trials of individual cognitive therapy–based interventions for women with PTSD who were no longer experiencing violence provided reasonable evidence for this intervention, but this cannot be extrapolated to women still in an abusive relationship.[■■] All the studies of group psychological interventions showed improvement in one or more psychological or mental health outcomes, but with the exception of one study, they were poorly conducted. Consequently, the effectiveness of this type of intervention remains uncertain, particularly for women who are still experiencing IPV.

Treatment of Abuser and Couple Therapy

Although the assessment and treatment of the abuser should be carried out by mental health professionals with expertise in this area, it can be helpful for general clinicians to have some awareness of the effects of treatment. The evidence for batterer treatment is mixed, with the better-designed studies generally indicating little or no benefit or potential harm (i.e., increased recidivism).[■] To date, there is insufficient evidence to recommend specific treatment for those committing IPV. The evidence for couple therapy is mixed, with trial-level evidence indicating no benefit in a military sample.[■] Most authors caution that these couple therapy programs are not safe for many abused women, particularly those experiencing "intimate terrorism." Furthermore, when abusers are enrolled in treatment programs, it is important that women be provided with concurrent advocacy and support. There is some evidence to suggest that permanent, but not temporary, civil protection orders may be effective in reducing future violence.

PREVENTION

From a public health perspective, primary prevention of IPV is desirable, although most of the available research focuses on the health care response to the survivors of IPV, both while a woman is still exposed to abuse (secondary prevention) and when she is experiencing the long-term health problems associated with IPV (tertiary prevention).

Efforts aimed at primary prevention of IPV through educational programs have generally focused on changes in attitude, knowledge, skills, or self-reports of dating (relationship) violence. No studies to date have measured physical or emotional health outcomes. A meta-analysis assessed the efficacy of interventions aimed at preventing dating or relationship violence in adolescents and young adults; such violence is often considered a precursor to IPV in adulthood.[■] The authors concluded that there was no evidence that the interventions were effective in improving attitudes, behaviors, or skills related to relationship violence or in reducing episodes of relationship violence; there was a small improvement in knowledge about relationships. However, given that there was substantial heterogeneity between the studies, and that when those studies considered at high risk of selection bias were excluded, the only remaining study showed no effect on knowledge, the overall conclusion was no evidence of effect for the interventions.

There is no clinical trial evidence for the effectiveness of interventions provided in general medical settings with the aim of secondary prevention. A systematic review concluded that there is insufficient evidence to determine the effectiveness of interventions in preventing IPV against pregnant women.[■] However, an advocacy and empowerment program in antenatal clinics reduced psychological and minor physical violence,[■] and a program for pregnant African American women based on individual counseling sessions reduced violence and improved pregnancy outcomes.[■] Within an Australian family medicine setting, there was equivocal benefit in terms of mental health and safety of a brief counseling intervention delivered by physicians.[■] Outside of health care settings, intensive advocacy (12 hours or more duration) may reduce physical abuse among women leaving shelters or refuges after 12 to 24 months of follow-up, but not for shorter or longer follow-up. There is evidence that a training and support program for primary care clinicians improves identification of women experiencing abuse and referral to advocacy services.[■] The World Health Organization has published guidelines for the health care response to IPV with recommendations linked to the current evidence base. Table 241-2 outlines the key recommendations related to prevention of IPV and treatment of conditions associated with exposure to IPV. Particularly noteworthy are the recommendation on training for clinicians in first-line support to women who have disclosed IPV and the recommendations against screening and mandatory reporting.

PROGNOSIS

The prognosis of IPV with and without intervention is uncertain. Trials of interventions have small samples and short follow-up, and most have substantial attrition of participants. As far as the "natural history" of the condition is concerned, cohort studies are rare, and cross-sectional studies are potentially misleading. In a 3-year follow-up of participants who received an advocacy intervention after leaving a shelter, 36% had been assaulted by their original partner or a new partner in the 6 months before the interview. The difference

in re-victimization at 2 years between intervention and control arms did not persist, but there was still a significant difference in quality of life and social support among women receiving advocacy. In a U.S. cohort study, 44% of participants were still being abused after 3½ years.

REVIEW QUESTIONS

1. A 25-year-old woman comes to the emergency department with a bruise to her left eye. She is accompanied by a woman whom she refers to as a friend. The patient explains that she was hit in the eye while playing baseball. The friend insists on remaining with the patient while the initial history is taken by the nurse. Which of the following is the most appropriate recommendation?

A. The friend should be asked politely to leave during the history taking, which should include exploration about the possibility of intimate partner violence (IPV).
B. The patient should first be asked if she wants her friend to stay, and if she agrees, the patient can be asked about IPV.
C. The patient should be asked if the friend is a partner; if not, it is acceptable to proceed with exploration of IPV in the presence of the friend.
D. Because the patient is accompanied by a friend, it is important not to inquire about exposure to IPV because of confidentiality.
E. Because the patient has given a plausible explanation for the bruise to her eye and there is no evidence for universal screening, she should not be asked about exposure to IPV.

Answer: A The patient has an injury that is suggestive of exposure to IPV. It is important that she be asked privately about the nature of the injury. Such inquiry is a form of case finding, not universal screening.

2. A 17-year-old pregnant woman comes to the family physician's office to discuss her plans for the pregnancy. During the visit, she discloses that her 20-year-old boyfriend has twice threatened to hit her before she became pregnant. Which of the following is the most appropriate approach by the family physician?

A. Ask the patient whether she has ever experienced any physical injury from her boyfriend; if not, advise her that they should attend couple counseling together.
B. Advise the patient that the risk will likely escalate during the pregnancy and she should leave the partner.
C. Give the patient the opportunity to discuss her concerns at a pace that is comfortable for her.
D. Advise the patient that this creates significant risk for her infant in the future, and it is not safe for her to remain in the relationship.
E. Explain to the patient that it is best to return another day when the appointment can be set aside to discuss the issue in more detail.

Answer: C The patient needs to be given the opportunity to discuss her concerns at a pace that is comfortable for her. The other responses could put the patient at risk (A) or are too directive (B and D) or not sufficiently responsive to the patient's needs (E).

3. A 56-year-old woman is a new patient in a family medicine practice. In her first consultation, she presents with a 16-year history of recurrent depression. In taking a comprehensive history, the family physician asks about any experience of abuse. She discloses that she has been frightened of her husband for years. He is extremely controlling and occasionally physically violent. What is the most appropriate initial response from the physician to this disclosure?

A. Have you ever thought about packing your bags and leaving him?
B. Have you ever thought about going to couple counseling?
C. Is there something you could do differently so that he becomes less angry?
D. That must be very difficult for you; I can help you find support.
E. That sounds frightening; do you want me to have a word with him?

Answer: D The priority must be initial validation, empathizing with the patient and signaling that support is available. The other responses are too directive (A) or could increase risk to the patient (B and F) or are victim blaming (C).

4. A clinical team is developing a policy on IPV. It should include which of the following?

A. A protocol for annual screening of all women patients for current abuse
B. A mandatory reporting requirement ensuring that the police are informed in all cases of serious assault
C. Recording of abuse in the medical record of the victim and the perpetrator
D. A training program on IPV for all clinical staff that includes a referral pathway to IPV advocacy support

Answer: D Training of clinicians is a prerequisite for an appropriate response to patients experiencing IPV, and a referral pathway to advocacy removes one of the barriers to the clinician's asking about abuse. The other responses are not based on evidence of effectiveness (A) or could increase the risk to the patient (B and C), also reducing the likelihood of disclosure to health care providers.

APPROACH TO THE PATIENT WITH METABOLIC BONE DISEASE

THOMAS J. WEBER

DIAGNOSIS

History

Patients with metabolic bone disease may present to the clinician in a number of ways, ranging from no symptoms to disabling musculoskeletal pain, depending on the nature of the underlying disorder. The most common conditions, osteoporosis and primary hyperparathyroidism, encompass a clinical spectrum that ranges from asymptomatic (diagnosed by low bone density and an elevated serum calcium, respectively)[1] to severe disease (fractures and bone pain). Less common conditions, such as osteomalacia, have more predictable presentations. In osteoporosis, fractures of the long bones (humerus, distal forearm, femur, and tibia) are clearly evident, whereas fractures at other sites (vertebrae, ribs, pelvis) may not be (see later and Chapter 243).[2] Patients with osteomalacia may complain of deep bone pain or aches, although often it is difficult for them to distinguish such pain from muscular pain. They may also report proximal muscle weakness that impairs their ability to ascend stairs. Vitamin D deficiency, the most common cause of osteomalacia, may confer similar bone and muscle complaints as well. In hyperparathyroidism, either self-reported or elicited fatigue may be a common complaint, along with mildly impaired cognition and memory. A history of recurrent nephrolithiasis is a hallmark of symptomatic primary hyperparathyroidism.

Physical Examination

Patients may exhibit physical clues to their skeletal condition. Height loss of more than 2 inches from a self-reported maximum, measured accurately with a calibrated stadiometer, may suggest the presence of vertebral compression fractures, which are clinically silent in up to three fourths of patients. Corresponding thoracic kyphosis may be present, and tenderness to palpation or percussion over the spinous process may suggest a recent vertebral fracture. Thoracic kyphosis will also impart quantifiable physical characteristics, including decreased and increased rib-pelvis and wall-occiput distances, respectively, which may be followed clinically in patients and significantly predict the presence of vertebral fractures. The method for the rib-pelvis distance measurement is illustrated in Figure 242-1. The wall-occiput distance is the space between the wall and the occiput of the head when a patient stands straight with the heel, buttocks, and back against the wall: it reflects the degree of kyphosis. Patients may also exhibit signs of secondary causes of osteoporosis (e.g., blue sclerae with osteogenesis imperfecta, goiter and proptosis with hyperthyroidism, facial plethora and purple striae with Cushing's syndrome). Patients with Paget's disease may have a skeletal deformity and warmth over the affected sites. Patients with osteomalacia often have tenderness to palpation over the tibia or other long bones due to expansion of the subperiosteal space by undermineralized osteoid with nerve irritation. These patients may also have a wide-based, "waddling" gait due to pain. Hyperparathyroid patients may have flank tenderness if active nephrolithiasis is present and can rarely have corneal calcification if hypercalcemia is severe and longstanding. Such patients rarely have a palpable parathyroid adenoma. If present, however, a diagnosis of parathyroid carcinoma should be entertained.

FIGURE 242-1. Method of assessing rib-pelvis distance. While standing behind the subject, the examiner holds his or her hands vertically and places them into the space between the inferior margin of the ribs and the superior surface of the pelvis in the mid-axillary line. The vertical distance is then measured in fingerbreadths.

Laboratory and Radiologic Investigations

Laboratory studies are a useful adjunct in the evaluation of metabolic bone disease, although their specificity depends somewhat on the disease in question. In particular, studies performed in the work-up of osteoporosis are generally not solely diagnostic but rather are supportive of secondary etiologies that may contribute to bone loss. Examples include thyroid-stimulating hormone, 25(OH)D, and testosterone levels (Table 242-1). In addition to a cursory work-up as detailed, additional investigations may also be indicated as clinically indicated and in individuals with a greater dual-energy x-ray absorptiometry (DXA) bone density deficit than expected for age (see later and Chapter 243).[3] In contrast, the diagnosis of other conditions is more securely based on abnormal studies, such as alkaline phosphatase (elevated in Pagets disease and depressed in hypophosphatasia) and parathyroid hormone (elevated in hyperparathyroidism). More sophisticated studies that target a specific diagnosis should be based on the history and examination (i.e., genetic testing for osteogenesis imperfecta). Bone turnover markers, which are cellular products of bone formation and resorption that can be measured in the blood and urine of patients, may provide noninvasive information on skeletal turnover (i.e., high or low) but cannot be used for diagnosis. They also have unacceptable biologic and measurement variability that precludes their clinical usefulness at this time.

Radiologic studies are critical to the diagnosis and management of these patients. Because the most common clinical event is fracture, plain radiographs of the involved skeletal sites are often indicated.[4] It is important to note that radiographs are relatively insensitive in identifying stress fractures and may also lag behind a frank fracture by hours or days. As such, additional, more sensitive modalities may be employed, including computed tomography and magnetic resonance imaging, to confirm a fracture. These studies also reveal characteristic patterns of skeletal involvement in certain conditions (i.e., Paget's disease). Whole body bone scintigraphy with the radioisotope techneticum-99m is the most sensitive tool to identify an active skeletal process but is nonspecific as to the nature of the underlying process (e.g., fracture, infection, malignancy). Perhaps most widely used and critical to management of osteoporosis is bone mineral density (BMD) testing, generally by DXA. As detailed in Chapter 243, DXA is a low-radiation, noninvasive examination of the spine, proximal femur, and distal forearm that may be used to identify and subsequently follow the treatment response to pharmacologic or conservative therapies. Finally, although rarely needed, tetracycline-labeled, transcortical bone biopsy of the iliac crest, with subsequent histomorphometic analysis, may be useful in the management of patients. Bone biopsy, which is generally performed by an orthopedic surgeon under conscious sedation, may be indicated to best guide management in patients with excessive bone fragility that cannot be adequately characterized by noninvasive means (e.g., patients with renal osteodystrophy, suspected osteomalacia, fractures with normal BMD by DXA).

TABLE 242-1 LABORATORY WORK-UP OF OSTEOPOROSIS

ALL OSTEOPOROSIS/OSTEOPENIA PATIENTS	AS CLINICALLY INDICATED
Serum creatinine, calcium, total protein, albumin, phosphorus, alkaline phosphatase, liver function tests	Serum and urine protein electrophoresis (SPEP and UPEP) (if total protein-to-albumin ratio is >2.0)
Complete blood count	Intact parathyroid hormone
Thyroid-stimulating hormone	24-Hour urine cortisol
24-Hour urine calcium and creatinine	Celiac panel (antigliadin/antiendomyseal antibodies)
Serum 25(OH)D	Fasting morning testosterone (men)

TREATMENT

Rx

Management of patients with metabolic bone disease is generally directed by the disease process, although there are some unifying aspects of treatment. Adequate intake of calcium and vitamin D, usually through a combination of diet and supplements, is recommended for patients with osteoporosis. High-dose vitamin D is indicated for low-vitamin D–related osteomalacia, and phosphorus in combination with vitamin D analogues (i.e., calcitriol) is necessary to heal osteomalacia and facilitate normal longitudinal growth in children and adolescents with certain osteomalacic conditions (e.g., X-linked hypophosphatemic rickets or X-linked hypophosphatemia). Weight bearing and resistive exercise are also advisable for osteoporotic patients, although physical therapy consultation may be indicated in patients at high risk for fracture (previous fractures, frequent falls). Pharmacotherapy with oral and parenteral bisphosphonates is frontline therapy for patients with both osteoporosis and Paget's disease because of the anticatabolic effect on excessive osteoclastic bone resorption that underlies these diseases. In addition, other antiresorptive drugs, such as raloxifene and denosumab, are approved for the treatment of osteoporosis. Parenteral bisphosphonates and denosumab also are effective in combating malignancy-related bone disease (e.g., metastatic breast cancer, multiple myeloma). Finally, the anabolic bone agent teriparatide, a recombinant parathyroid hormone analogue, is useful in "building" bone density and reducing fracture risk in patients with severe osteoporosis, defined as very low BMD, high fracture risk, and/or multiple fractures. Newer drugs in development that target more recently identified aspects of bone physiology (e.g., the Wnt pathway in bone formation), as well as specific derangements in less common diseases (e.g. FGF-23 antibody in X-linked hypophosphatemia), will necessarily further improve the management of patients with metabolic bone disease.

243

OSTEOPOROSIS

THOMAS J. WEBER

DEFINITION

Osteoporosis is defined as a skeletal disorder characterized by compromised bone strength predisposing to an increased risk for fracture. The pertinent clinical outcomes of this disease include fractures, bone pain, height loss, and physical deformity. This definition was developed by the National Institutes of Health in 2000 to help clinicians better diagnose and treat patients with the disease. The concept of bone strength is central to understanding the disorder because patients who suffer an osteoporotic or fragility fracture may or may not have osteoporosis by bone mineral density (BMD) criteria. The World Health Organization defines osteoporosis as a BMD that is equal to or greater than 2 standard deviations (SD) below that of an average individual at peak bone mass (generally age 20 to 30 years, depending on the measured skeletal site). However, it is well established that most fragility fractures, which are defined as fractures occurring from the energy imparted from a fall from a standing height or less, occur in individuals who have low (osteopenia) or even normal BMD. (Osteopenia, or low bone density, is defined as a BMD between −1.0 and −2.5 SD below young average normal.) This observation is consistent with the lack of a specific BMD threshold for fracture. Given these observations, it is clear that other factors must also significantly influence fracture risk. Certainly, falls and traumatic injuries are a significant, independent risk factor for fractures. Excluding falls and trauma, however, studies to date have also identified qualitative factors that are integral to bone strength, including skeletal microarchitecture, bone turnover, damage accumulation (e.g., microfractures), and pattern or degree of mineralization. Newer technologies are currently in development to improve our understanding of how these qualitative changes in bone compromise skeletal strength, including high-resolution peripheral quantitative computed tomography (HR-pQCT) and high-resolution magnetic resonance imagine (MRI) (Fig. 243-1).[1] Although promising, these newer techniques are not widely available. More important, they have not enhanced fracture prediction to date over known risk factors and BMD. Indeed, the availability and widespread application of Internet-based fracture prediction tools such as FRAX, which incorporate independent, additive clinical risk factors for fracture with or without hip BMD, are currently the best approach for identifying individuals at risk for and most likely to benefit from treatment to prevent fragility fractures.

EPIDEMIOLOGY

Approximately half of white women will develop an osteoporosis-related fracture in their lifetime, which is greater than their risk for breast cancer, heart attack, and stroke combined. In addition, one in five men will also fracture.[2] More than 2 million fractures occur annually in the United States, at an estimated total direct cost of $17 billion. Nearly three fourths of them occur in women, with most occurring in white women. Nonetheless, there are no ethnic exclusions to developing the disorder. The most common site of osteoporotic fracture is the spine, accounting for more than 750,000 fractures annually. Fractures of the proximal femur, which disproportionately confer a greater cost than other osteoporotic fractures, account for 14% of incident fractures but nearly three fourths of costs. Additional sites of fracture include the distal forearm, proximal humerus, and pelvis, with the latter two more commonly occurring in elderly people. The risk for fracture increases markedly with age, although the pattern of fracture risk does differ by skeletal site. The risk of Colles fractures increases until the mid-60s and then plateaus, whereas the risk for hip fractures increases exponentially in woman after the age of 65 years. Vertebral fracture risk rises earlier than that of hip, although many spine fractures are not clinically apparent and only identified through radiographic assessment. Although clinically silent, such fractures do confer a significant independent risk for future fractures, particularly if they are of recent occurrence.[3] Men also ascribe to an age-independent increase in fracture risk, although the increase in incidence generally lags at least 5 to 10 years behind that of women (Fig. 243-2). The reason for the gender-based difference in fracture incidence is likely related to anatomic differences because although men and woman have similar volumetric bone density at a given skeletal site, bone size is larger in men than in women and confers an independent mechanical protection against fracture. Nonetheless, the independent contribution of age to fracture risk necessarily predicts a higher morbidity and cost related to osteoporosis in men as well as women, with an increase in the United States alone by the year 2025 to greater than 3 million fractures with an associated annual cost of $25.3 billion.

There are also significant ethnic and geographic differences in the rate of osteoporotic fractures. African Americans have a lower lifetime risk for osteoporotic fracture, approximately roughly half that of whites. Differences in bone size, bone microarchitecture (thicker trabeculae in blacks), body composition, calcium absorption in youth, and life expectancy are potential reasons for this observation. Asian Americans and Hispanics have a fracture risk that is intermediate between that of whites and blacks, despite the fact that the former have a BMD that generally approximates that of whites.

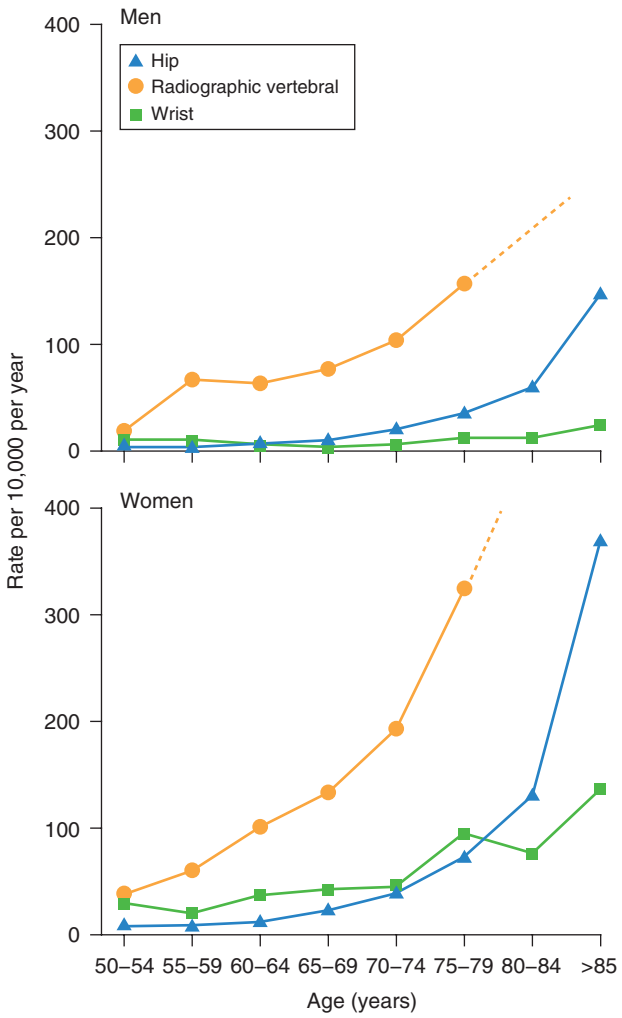

FIGURE 243-2. Age-specific and sex-specific incidence of radiographic vertebral, hip, and distal forearm fractures. (Data derived from European Prospective Osteoporosis Study and General Practice Research Database; from Sambrook P, Cooper C. Osteoporosis. *Lancet.* 2006;367:2010-2018.)

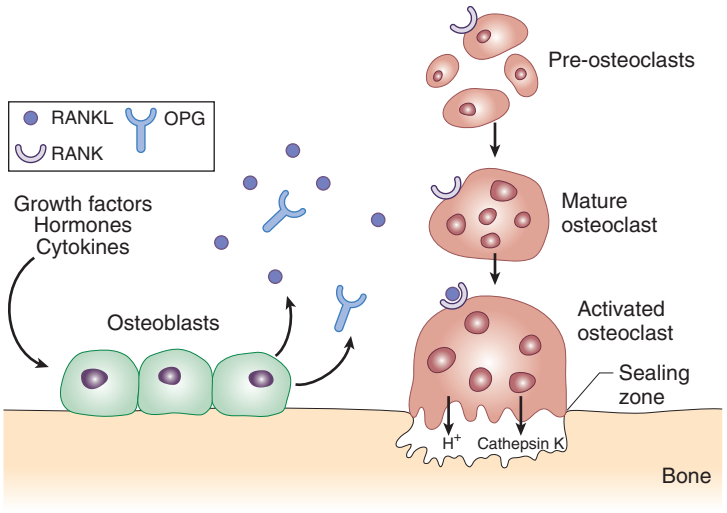

FIGURE 243-3. RANKL expressed by osteoblast lineage cells binds to RANK on the surface of pre-osteoclasts and mature osteoclasts, resulting in increased bone resorption through an increase in osteoclast differentiation, activity, and survival. Osteoprotogerin (OPG) is a "decoy receptor," also produced by osteoblasts, that binds to RANKL, preventing RANKL binding to RANK and thereby inhibiting osteoclastic bone resorption. It is the balance of RANKL and OPG that determines the ultimate rate of bone resorption. (Adapted from Lewiecki EM. New targets for intervention in the treatment of postmenopausal osteoporosis. *Nat Rev Rheumatol.* 2011;7:631-638.)

Indeed, the risk for hip fracture in U.S. Asian men and women is actually equal to or lower than that of U.S. blacks. The U.S. data are consistent with the global experience as well because hip fracture rates in China are lower than those observed in the United States, despite similar bone density at the hip. Differences in hip geometry, physical activity, and diet have been proposed as possible explanations. Despite this, rates of hip fracture have actually been increasing in the Far East, while declining in the United States for unclear reasons. Changing patterns of nutrition and physical activity could be responsible for the former, although the latter observation remains heretofore unexplained.

PATHOBIOLOGY

Normal Bone Biology

BMD in adults is determined by the magnitude of bone acquisition during adolescence and young adulthood, and the rate of bone loss that ensues thereafter. These processes are generally referred to as bone modeling and remodeling. Heritable factors, including gender and ethnicity, account for 60 to 80% of the variability in skeletal development, including peak bone mass, bone size, and bone geometry, although nutrition, lifestyle, and other factors also have a significant impact. Peak bone mass is achieved in most individuals by the early to late 20s and differs in timing by skeletal site (age 18 to 20 years for proximal femur, 25 to 30 years for spine). Modeling of the skeleton occurs during this time and represents a true increase in bone mass and bone size through endochondral ossification of the axial skeleton and periosteal apposition of the appendicular skeleton.

To best understand the underlying pathophysiology of osteoporosis, one must first appreciate the concept of bone remodeling. Skeletal remodeling is a finely orchestrated process of bone resorption and subsequent formation. It is a necessary physiologic function that results in repair of damaged bone and redistribution of the skeleton to adapt to changes in mechanical stress and to provide calcium to the systemic circulation for critical cellular processes. Recent evidence suggests that the osteocyte, which accounts for 90 to 95% of all bone cells, is the critical cell that regulates both resorption and formation. Osteocytes are derived from osteoblasts that are embedded within the bone matrix. During this maturation phase, this "osteoid-osteocyte" cell actively secretes and calcifies bone matrix material. In addition, mature osteocytes within bone contain dendritic processes that may directly regulate osteoblast recruitment and bone formation. Recent studies also suggest that mature osteocytes may form new bone within their lacunae. In addition, osteocytes produce proteins that regulate mineralization, including positive (PHEX, DMP-1) and negative (FGF-23) factors.

Osteocytes also regulate bone resorption, both directly through apoptosis proximate to skeletal microcracks or fatigue damage in need of repair and indirectly through enhancement of pre-osteoblast or mesenchymal stromal cell (MSC) development. (MSCs may also develop into adipocytes, chondrocytes, and muscle cells, depending on developmental stimuli.) These events result in the production, expression, and release of cytokines critical to osteoclast recruitment and development, including interleukin-1 (IL-1), interleukin-6 (IL-6), osteoprotogerin (OPG), and receptor activator of nuclear factor-κB ligand (RANKL). The cognate receptor for RANKL, RANK, is expressed on the surface of the developing and mature osteoclast, which itself is a derivative of cells of the monocyte-macrophage lineage. RANKL is a critical determinant of osteoclast recruitment, development, and survival, such that disruption of RANKL signaling results in high bone density fragility disorders (e.g., osteopetrosis). OPG, which is also produced by pre-osteoblasts, is a decoy receptor for RANK that binds to RANKL, preventing RANKL binding to RANK and thereby serving as an endogenous suppresser of osteoclast function. In essence, RANKL/OPG represent a "yin/yang" paradigm in which osteoclast biology and bone resorption are intricately regulated and controlled (Fig. 243-3).

Factors Affecting Peak Bone Mass and Remodeling

As mentioned, peak bone mass is achieved by the third decade. Longitudinal studies in children and adolescents suggest that hormonal, physical activity, nutritional, and genetic factors are all important in this process. Hereditary influence is the most important determinant and to date the least well understood. Growth hormone and sex hormones play critical roles in growth of the appendicular (long bones) and axial (vertebrae) skeleton, with the former maturing earlier than the latter (end of puberty vs. young adulthood). Males

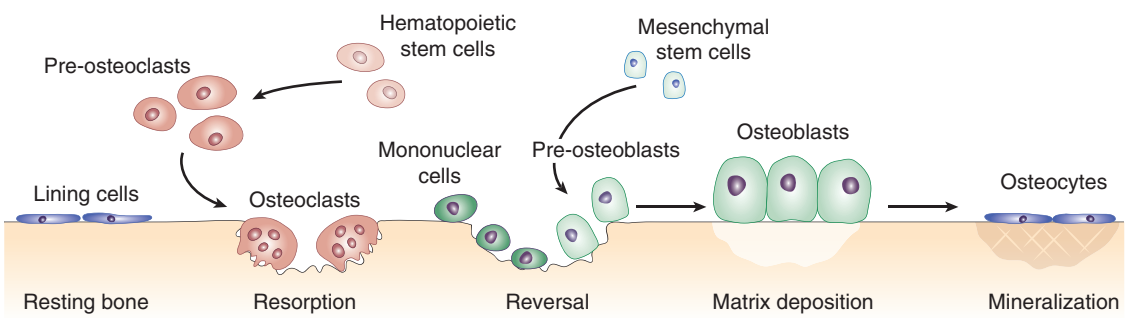

FIGURE 243-4. The basic multicellular unit (BMU) moving across the bone tissue. First, 10 to 20 osteoclasts resorb old or damaged tissue; then they recruit 1000 to 2000 osteoblasts, which produce new bone matrix. The BMU moves at a speed of 20 to 40 µm/day and survives for up to 6 months. (From Kapinas K, Delany AM. MicroRNA biogenesis and regulation of bone remodeling. *Arthritis Res Ther.* 2011;13:220.)

have larger bones as a result of greater periosteal (outer surface of bone) expansion of bone than occurs in females. Current evidence supports a positive effect of exercise and loading on bone size and mineral density, although a subsequent potential antifracture benefit later in adult life is not proved. Poor nutrition and concomitant disease may also affect bone accrual, primarily through delayed pubertal onset and progression, although studies do support a potential for "catch-up" growth, which depends on the degree of insult and timing of resolution.

Although these factors are all important, genetic factors appear to account for 60 to 80% of the variance in peak BMD. Genome-wide association studies have identified 62 distinct loci that are significantly associated with BMD.[4] Three known obligatory pathways of bone metabolism were identified by genome-wide association studies, namely Wnt, RANK-RANKL-OPG, and endochondral ossification. The RANK pathway was discussed previously. The Wnt signaling pathway is obligatory for bone formation, owing to its role in osteoblast proliferation and differentiation. It was initially discovered through study on kindreds with high bone mass and the osteoporosis pseudoganglioma syndrome, who have, respectively, activating and inactivating mutations in the Wnt pathway receptor LRP5. Endochondral ossification, a process that involves the cartilage growth plate and subsequent ossification of the cartilaginous skeleton, is dependent on transcription factors (SOX6, RUNX2) and proteins (parathyroid hormone–related peptide, bone sialoprotein 2, and osteopontin) that are necessary for the development of the cartilage growth plate, bone matrix mineralization, and osteoblast differentiation. Indeed, the first two pathways are already the target of existing and developing therapies for osteoporosis. Despite these advances, our understanding of the relationship between genes and bone mass accrual remains poor, as evidenced by the fact that less than 6% of the variance in femoral neck BMD is explained by the loci identified in genome-wide association studies.

In adults, bone remodeling is a physiologic process through which skeletal repair and adaption to changes in biomechanical stress occur. The basic multicellular unit (BMU), which is composed of bone-resorbing osteoclasts, bone-forming osteoblasts, bone lining cells, and embedded osteocytes, is the cellular apparatus that facilitates remodeling (Fig. 243-4). After the age of 30 years, this process is reasonably matched, resulting in rates of bone loss of only 0.3 to 0.5% per year from the third through fifth decades of life. As individuals age, mismatches in bone remodeling, either due to reduced formation, increased resorption, or a combination of both, result in greater rates of bone loss. Biologic changes, such as menopause and aging, systemic disease, personal vices, and medications (most notably glucocorticoids), may contribute to this imbalance. In addition, there is evidence that genetic factors also influence rates of bone loss and fracture. Although not as robust an influence as on peak BMD, twin and family-based studies suggest that genetic factors contribute roughly 30 to 50% of the variance in rates of bone loss at the spine, hip, and forearm. However, studies attempting to identify specific genes that are associated with accelerated rates of bone loss have been inconsistent to date, including ones that have identified the collagen gene (*COL1A1*), vitamin D receptor gene (*VDR*), estrogen receptor-1 gene (*ESR1*), interleukin-6 (IL-6), and the apoprotein AOE*4 allele as potential candidates. This inconsistency may be due to insufficient data sets that do not have repeated measures of bone density. Interestingly, there is a fairly robust heritability of menarche and menopausal onset, perhaps paralleling the observations on *ESR1* and IL-6 (whose production is suppressed by estrogen) and supporting hormonal pathways as a potential target of genetically mediated bone loss.

Although a better understanding of the genetic influences on bone mass accrual and subsequent loss is critically needed, it is perhaps more important to extend these analyses to the pertinent clinical outcome in this disease—fracture. This is further supported given the previously described significant unexplained variance between BMD and fracture risk. Unfortunately, such work to date has yielded disappointing results, likely in part because the heritability of fracture risk diminishes significantly with aging. In addition, the contributions of individual genetic variants to fracture risk are quite small and potentially falsely negative when studied. Nonetheless, there is preliminary evidence that simulated genetic profiling using a large number of variants could increase the discriminatory value of existing fracture prediction models and significantly re-stratify individuals in need of or not requiring antifracture therapies.[5]

Mechanisms of Bone Loss

"Natural" and Aging-Related Bone Loss

As noted previously, net bone loss during adult life is expected, although the rate of bone loss accelerates during the latter decades because of a number of factors. Perhaps most important for women, rates of bone loss increase substantially in the perimenopausal and early postmenopausal years, amounting to losses of 1 to 5% per year. Unfortunately, there are currently no biologic markers that help determine which women a priori are "rapid losers." Bone loss is slower in obese women, likely because of higher estrogen levels afforded by production through aromatization in adipose tissue. A decline in circulating estrogen is primarily responsible for bone loss following both natural and surgical menopause, which is mediated primarily through upregulation of cytokines (most notably RANKL) and a resultant increase in the number, activity, and depth of osteoclast-mediated bone resorption sites. In addition, OPG production is diminished, further amplifying bone resorption, although estrogen replacement can restore OPG production while reducing RANKL expression and thereby help mitigate bone loss during this period. Although bone resorption and formation do occur sequentially during this period, resorption outpaces formation because of potentiation of the former aided by the release of soluble cytokines, resulting in a significant uncoupling of bone remodeling and accelerated bone loss. Fortunately, this phase of rapid bone loss is typically limited to 5 to 7 years in most women.

Current evidence supports a key role in bone loss for reduced estrogen levels in men, perhaps owing to reduced aromatase activity in fat tissue. Decline in circulating insulin-like growth factor-I levels also occurs with aging, which may inhibit the production of MSCs and pre-osteoblasts, in addition to limiting periosteal bone expansion. The latter is a normal adaptive process to aging that increases bone size, more so in men than in women, somewhat attenuating the observed increase in fracture risk with aging. Bone loss in later decades also is caused by lower 25-hydroxy vitamin D (25[OH]D) levels, related to restricted sun exposure and a reduced capacity to generate pre–vitamin D in the skin with aging, as well as limited intake of vitamin D and calcium. Indeed, more than 75% in individuals in the United States are either vitamin D deficient or insufficient (25[OH]D < 30 ng/mL). Low vitamin D results in secondary hyperparathyroidism, which accelerates cortical bone loss, as well as likely increasing the risk for falls. Increase in bone

marrow adiposity is also inversely and significantly correlated with aging-related bone loss. This process likely reduces bone formation through the production of fewer osteoblast precursors, which share a common mesenchymal stem cell lineage with adipocytes. It is also likely the result of increased activation of the nuclear receptor peroxisome proliferator activator receptor-γ (PPARG), which commits stem cells toward adipocyte and away from osteoblast differentiation. Additionally, fat-derived adipokines (adiponectin and leptin) may negatively affect bone remodeling through a "bone-fat" connection by reducing bone formation, further exacerbating bone loss.[6] Finally, loss of weight and muscle mass (sarcopenia) is associated with bone loss, with evidence of a recently identified common factor (myostatin) that may provide insights on this muscle-bone interaction.[7]

Secondary Causes and Clinical Impact of Bone Loss

Bone loss also occurs as a result of secondary processes, such as diseases and medications. In fact, such processes are identifiable in more than one fourth of individuals with osteoporosis and may be more likely with greater degrees of skeletal deficit. A list of secondary causes of osteoporosis, based on a systems-based approach, is detailed in Table 243-1. As expected, endocrine disorders, including hypogonadism and Cushing's syndrome, predominate. Nonetheless, bone loss in several conditions is mediated indirectly through attendant effects on vitamin D metabolism (e.g., malabsorption, chronic liver disease) and is the case with certain medications as well (antiepileptic drugs phenytoin and phenobarbital). In the case of vitamin D deficiency, undermineralization of bone may confound the clinical picture of bone loss and should be considered first before initiation of bone active medications (see later). Rarely, malignancies can be the principal cause of osteoporosis, with the best example being multiple myeloma (Chapter 187). Myeloma causes bone loss through uncoupling of bone resorption and formation, the latter occurring through Wnt inhibition by the protein Dickopf. Medications also cause bone loss through both osteoclastic activation and osteoblastic inhibition. Reduced bone formation is the mechanism by which glucocorticoids cause bone loss, both through exogenous administration and exogenous overproduction. Previous work has confirmed reduced osteoblast and osteocyte function and survival as the principal mechanism of glucocorticoid-induced osteoporosis. Anorexia nervosa likely interferes with the anabolic effect of insulin-like growth factor-I on bone. Alcohol excess appears to suppress osteoblast function, perhaps both directly and indirectly through associated malnutrition, but it may also possibly cause bone loss through hypogonadism, which results in accelerated turnover. Finally, relatively rare connective tissue disorders, such as osteogenesis imperfecta and Marfan syndrome, increase skeletal fragility by means of disturbances in the skeletal matrix and mechanical integrity rather than altered bone remodeling.

TABLE 243-1 SECONDARY CAUSES OF OSTEOPOROSIS

ENDOCRINE DISORDERS
Hypogonadism: female and male
Hypercortisolism: endogenous and exogenous
Hyperthyroidism
Hyperparathyroidism
Idiopathic hypercalciuria
Diabetes mellitus: type 1 and type 2
NUTRITIONAL AND GASTROINTESTINAL DISORDERS
Malabsorption: celiac disease, gastrointestinal bypass
Vitamin D deficiency
Cirrhosis (including primary biliary cirrhosis)
Pancreatic insufficiency
Inflammatory bowel disease
Cystic fibrosis
Anorexia nervosa, bulimia
HEMATOLOGIC AND ONCOLOGIC DISORDERS
Multiple myeloma
Hemolytic anemia
Hemoglobinopathies: thalassemia, sickle cell
Myeloproliferative neoplasms
Skeletal metastases
Pompe's disease
Mastocytosis
CONNECTIVE TISSUE AND METABOLIC DISORDERS
Osteogenesis imperfecta
Ehlers-Danlos syndrome
Marfan syndrome
Homocystinuria
Gaucher's disease
Pompe's disease
MEDICATIONS
Glucocorticoids
Thyroxine (excessive)
Antiepileptics
Heparin
Gonadotropin-releasing hormone agonists
Depo-Provera
Immunosuppressants: tacrolimus, cyclosporine
Chemotherapy
Selective serotonin reuptake inhibitors*
Proton pump inhibitors*
Thiazolidinediones*
Alcohol
MISCELLANEOUS
Rheumatoid arthritis
Immobilization
Juvenile osteoporosis
Pregnancy-associated osteoporosis

*Association based.

The resulting clinical impact of bone loss and the persistence of effect depend on a number of factors, both potentially modifiable and nonmodifiable. The age at which bone loss occurs (e.g., young adult vs. 80-year-old) affects the ability to recover BMD with resolution or treatment of the condition (younger people have more robust recovery than elderly people) and also appears to hold for conditions of accelerated bone resorption (e.g., immobilization) or reduced bone formation (e.g., glucocorticoids). Predicated on and paralleling this observation, BMD response to treatment is generally more pronounced in individuals with higher rates of bone turnover, likely reflecting to some extent a "filling in" of bone remodeling space. Menopausal stage in women also influences rate of bone loss as described previously, with greater rates of decline occurring within the first 5 to 7 years of cessation of menses (Chapter 240). Concomitant vitamin D deficiency and resulting secondary hyperparathyroidism also potentiate rates of BMD loss, particularly in elderly people; it is thought to be a major contributing factor to the increase in hip fracture incidence in this group. Tobacco and alcohol overuse may also accelerate bone loss, owing to global effects that include reduced sex hormones, altered calcium metabolism, and weight loss and frailty, resulting in uncoupled bone remodeling. Therefore, a distinct appreciation of the clinical context is critical to defining an appropriate diagnostic and treatment approach to patients with osteoporosis.

CLINICAL MANIFESTATIONS

Historically, osteoporosis was diagnosed in an individual presenting with a low trauma or fragility fracture, typically of the vertebrae or hips. Classic representations of women with the so-called dowager's hump or kyphotic deformity were common depictions of the disease. Currently, however, the disease is appreciated both for its clinical and subclinical manifestations, because of both the advent of bone density testing and the appreciation that many vertebral fractures are clinically silent. This approach is akin to paradigms that identify a surrogate marker for both diagnosis and risk stratification, such as hypertension for stroke and hyperlipidemia for myocardial infarction.

A history of fragility fracture is strongly suggestive of osteoporosis, although there is evidence that a history of high trauma fractures also identifies persons with low BMD and those at higher risk for low-trauma fractures. The National Osteoporosis Foundation considers fractures of the spine, proximal femur, distal forearm, and proximal humerus "major" osteoporotic fractures, although other skeletal sites are also prone to fragility fractures. These include the pelvis, ribs, and proximal tibia, although there is controversy about whether ankle fractures should be considered as such. Fractures of the spine are generally from the mid-thoracic region through the lower lumbar region, with the greatest frequency at T11 through L2.[8] Patient often present after a fall or a spinal flexion-loading event in which they may hear a "pop" and complain of sharp midline back pain that may radiate to the flanks. Patients may also present with complaints of back "tiredness," which is improved with sitting or lying down. This symptom is likely related to paraspinal weakness or spasm from abnormal spinal curvature that occurs with

chronic vertebral compression. Back pain may commonly be related to other pathology, such as degenerative disc and spine disease that is concomitantly present. This is important to note because low bone mass in and of itself does not cause pain, unless it is due to osteomalacia (see later). Vertebral fractures may occur without acute symptoms as well, as noted later. In contrast, nonvertebral fracture events are always clinically evident. Hip fractures generally occur with falls, although they may rarely occur with limited force such as twisting.

Physical examination may also indicate the presence of osteoporosis and associated fractures, as well as potentially identifying underlying secondary processes contributing to the disease. Measured height loss, best confirmed using a calibrated device such as a stadiometer, of greater than 4 cm since young adult maximum height is suggestive of prior vertebral fractures. Height loss also occurs with scoliosis and aging (approximately ⅓ inch of height is lost per decade after age 50 years). A kyphotic deformity of the upper thoracic spine may be present, although it is important to distinguish it from accentuated cervical lordosis with associated prominence of T1. Spinal tenderness to palpation and percussion can occur with an acute vertebral compression fracture. Palpable tenderness of the long bones may suggest underlying osteomalacia instead, due to periosteal expansion and nerve irritation. Reduced rib-pelvis and increased wall-occiput distances are correlated with vertebral fractures as well.

In addition to the history and physical examination, radiologic findings may identify the presence of osteoporosis, sometimes somewhat surreptitiously. Plain films can detect bone loss by means of accentuation of vertical striations on spine radiographs that represent loss of horizontal trabeculae, although this generally indicates BMD loss of at least 25% or more. Kyphosis and compression fractures may be present, and patients often are unaware of the deformities because nearly three fourths of such fractures occur without acute pain. Furthermore, radiologic reporting of these fractures is inconsistent, suggesting that, if possible, the clinician review available digitized lateral chest radiographs and even lateral scout films often available from computed tomography (CT) to identify such fractures (Fig. 243-5). This is critical for optimal management, given the aforementioned risk conferred by previous fractures on future fracture events. The degree of compression fracture is also important because more severe fractures (>25% vertebral height loss) appear to better predict future fractures, as do nonvertebral fractures. When fractures are suspected, CT and MRI may be used, given that plain radiographs have a lower sensitivity acutely and with stress fractures. MRI also can be used to define a vertebral fracture with persistent swelling and edema based on T2 characteristics, potentially identifying patients who could benefit from vertebroplasty or kyphoplasty (see later). Finally, whole body bone scintigraphy is the most sensitive test for fracture but can be falsely positive because of inflammation, infection, or tumor and usually is positive for 6 to 12 months after a fracture event.

FIGURE 243-5. Incidental vertebral compression fractures on chest radiograph. Lateral radiograph of the chest of a 74-year-old man studied for cough. No relevant pulmonary abnormality was noted on the frontal radiograph (not shown). Examination of the thoracic spine shows the presence of a mild anterior wedge compression fracture of T9 (*thick arrow*) and moderate anterior wedge fracture of T6 (*thin arrow*). Neither fracture was reported on the radiographic report.

DIAGNOSIS

Although a recent fragility fracture is a reasonable basis for diagnosis of osteoporosis, other skeletal conditions should also be entertained, including inherited and acquired osteomalacias and pathologic fracture due to malignancy. These disorders can often be distinguished by history and physical examination, although additional investigations may be required. This distinction is critical because therapies may differ greatly between disorders. Most patients with osteoporosis are diagnosed on the basis of BMD measurement, generally by dual-energy x-ray absorptiometry (DXA). DXA is a low-radiation-based radiologic measurement of the areal bone density (g/cm^2) of the lumbar spine, proximal femur, and distal radius. Osteoporosis can be diagnosed if the BMD of a postmenopausal woman or man older than 50 years is more than 2.5 SD below young average normal (T score ≤ −2.5). A T score between −1.0 and −2.5 is considered low bone density or osteopenia, and a Z score (age-matched BMD) in premenopausal women and men younger than 50 years that is more than 2 SD below that of an a average age-matched individual is considered low bone density for age. BMD is an independent predictor of fracture risk, such that the relative risk for fracture increases by 1.5- to 2-fold for each 1 SD decrease in T score. In addition, fracture risk increases exponentially below a T score of −2.5. Furthermore, BMD of the femoral neck may be used in fracture prediction models such as FRAX to better define an individual's risk for subsequent fracture (see later). In addition to DXA, other modalities are also used to diagnose osteoporosis, including quantitative CT of the spine (QCT) and wrist and tibia (pQCT), finger DXA, and ultrasound of the calcaneus or wrist. Measurement of BMD by all of these techniques has been shown to globally predict fractures, akin to DXA. QCT and pQCT provide additional information on cortical and trabecular bone compartments but are accompanied by higher radiation exposure and poorer reproducibility compared with DXA. Ultrasound is radiation free and easy to operate but is less sensitive in diagnosing osteoporosis and does not measure change in a reliable fashion in response to age or treatment, making it useful as a screening modality but not for longitudinal care.

Although DXA is an effective diagnostic tool, several potential limitations and caveats need to be considered by the clinician. First, DXA cannot distinguish between low bone density and undermineralized bone matrix, the latter of which occurs in osteomalacia (Chapter 244). BMD may also be quite disparate between regions, perhaps in more than one third of individuals. This inconsistency results from a number of factors, including differences in bone composition (predominantly trabecular bone in the spine and cortical bone in the one-third radius) with resultant variations in rates of bone loss due to aging and disease (vertebral bone loss with menopause and glucocorticoid use versus cortical bone loss in hyperparathyroidism). Degenerative changes due to aging, such as facet osteoarthritis and aortic calcification, may artifactually raise spine BMD value. Given these considerations, the lowest skeletal site should be used for diagnosis. Finally, BMD should be measured longitudinally on the same DXA machine if possible, because of intermachine and intermanufacturer differences that may confound the ability to validly measure change over time. Despite these caveats, DXA remains the best method to diagnose and manage osteoporosis by bone density testing.

Despite its utility, bone density has been limited historically in optimally predicting fracture risk in individual patients. In addition, BMD does not take into account clinical factors that independently predict fracture. Under this premise, fracture prediction models have been developed that combine BMD and risk factors to better stratify fracture risk. The best known and most widely used of these prediction models is FRAX. FRAX was developed by the World Health Organization in collaboration with national and international osteoporosis foundations as an Internet-based computer algorithm that defines a person's 10-year risk for hip and major osteoporotic fracture (hip, clinical spine, forearm, and proximal humerus all combined). The model uses country-specific data on clinical risk factors and femoral neck BMD to calculate fracture probability and is available as a web-based tool that can be used by clinicians with their patients to assist in making informed decisions on osteoporosis management (http://www.shef.ac.uk/FRAX/). FRAX can be also be used to define country-specific recommended diagnostic and treatment thresholds. An example of this is the National Osteoporosis Foundation guidance that 10-year risks equal to or exceeding 3 and 20% for hip and major fracture risk, respectively, warrant consideration of pharmacologic treatment, which is based on cost-effective analyses in the United States. Furthermore, the number needed to treat (NNT) can be determined to best

inform patients of their expected risk and benefit of treatment (e.g., bisphosphonate use roughly reduces hip fracture risk by half, or from 10 to 5%, with NNT of 1/0.05, or 20 patients treated to prevent one hip fracture). Despite its utility and ease of use, FRAX does have limitations. These include inability to use patients who are not treatment naïve, underestimation of fracture risk in those with disparately lower BMD in the spine than hip, absence of fall history/fall risk in the model, and the use of fixed clinical risk factors. Modifications have been suggested for the latest guidelines, including adjusting FRAX score up or down based on glucocorticoid dose. In addition, although fracture risk calculators that incorporate fall risk are available (e.g., from the Garvan Institute), they do not include the competing risk of mortality as FRAX does. As such, FRAX should be viewed, not as a perfect, but rather as a complementary tool to BMD in best defining a person's risk for fracture and candidacy for pharmacologic intervention.

Finally, all patients presenting with osteoporosis require an assessment for secondary causes of bone loss, given that 20 to 25% of women and perhaps an even greater portion of men will have identifiable additional etiologies that may contribute to bone loss (see Table 243-1). Most patients will have had routine chemistry, hematology, and thyroid studies as part of their annual examination. The 25(OH)D level should be measured in all patients for multiple reasons, as previously discussed. Additional investigations may also be considered, as directed by the clinical history and physical examination. In addition, a greater degree of BMD deficit (i.e., lower Z score) indicates a need for more extensive testing, given the greater likelihood of secondary causes being present. Bone turnover markers (BTMs) are serum and urinary products of bone formation or resorption that can also be used to assist in management. Available tests include bone-specific alkaline phosphatase, osteocalcin, type I procollagen amino-terminal propeptide, and type I procollagen carboxy-terminal propeptide as formation markers, and serum and urine C- and N-terminal peptides of type I collagen as resorption markers, among others. Their use is predicated on studies showing that high bone turnover increases fracture risk independent of BMD. In addition, fracture risk reduction correlates well with reduction in bone turnover based on clinical trials with anticatabolic agents. Nonetheless, their clinical utility has been tempered to date by several issues. First, there is significant biologic variability due to nonmodifiable (e.g., age, gender, underlying comorbid disease, medications) and modifiable (e.g., time of day, food intake, presence of fracture) factors that limit the ability to detect meaningful change over time in an individual patient. Second, optimal specimen processing is required for valid results and interpretation. Finally, and perhaps in part secondary to these issues and others, evidence to date does not demonstrate significant benefit of BTMs in individual patients in securely predicting bone density increase, fracture risk reduction, or cost effectiveness through patient feedback and improved adherence. Therefore, at present, BTMs should not be used in routine clinical practice, although they could help inform management in more complicated cases of metabolic bone disease.[9]

PREVENTION AND TREATMENT

Calcium

Adequate intake of calcium is critical to the optimal accumulation and maintenance of bone mineral density. Calcium supplementation has meaningful impact on BMD and fracture risk reduction, although the latter is much less certain. BMD is modestly improved by 1 to 2%, although evidence of a definitive reduction in hip and nonvertebral fracture risk when given without vitamin D is lacking at present, although previous studies have suggested a trend toward vertebral fracture risk reduction. Given the established increase in rate of nephrolithiasis and a possible, albeit unproven, potential increase in nonfatal cardiac events with higher dose calcium supplementation, it would seem prudent to recommend that adults with osteoporosis obtain 1200 to 1500 mg of calcium from a combination of supplements and dietary sources.

Vitamin D

Appropriate circulating levels of 25(OH)D are necessary for optimal intestinal absorption of calcium and skeletal accrual and maintenance. Despite this, a significant proportion of children and adults have vitamin D levels that would be deemed insufficient (i.e., 25[OH]D < 20 ng/mL). Data in adults with osteoporosis confirm a benefit of vitamin D supplementation for fracture risk reduction, although the effect is dependent on the patient population and the amount of supplementation. Doses of 400 to 800 IU of vitamin D combined with 1000 mg of calcium reduce the risk for hip fracture in postmenopausal women and men aged 65 years and older, although the benefit is less certain for community-dwelling individuals than for those in assisted living centers. In addition, it appears that a 25(OH)D level of at least 30 ng/mL is needed to reduce the risk for hip fracture, although there is some controversy over this recommendation based on the results of other meta-analyses with likely different methodologies. In addition, a daily vitamin D intake of at least 800 IU also reduces the risk for falls, likely by improving muscle strength and reducing body sway. It should be noted that the recent U.S. Preventive Services Task Force recommendation against the use of calcium and vitamin D[10] was based on the general U.S. population and does not pertain to patients with osteoporosis. Finally, although activated vitamin D analogues such as calcitriol and α-calcidiol have been shown to reduce fracture risk, they are generally not indicated based on unacceptable risk for hypercalcemia. The exception to use of vitamin D analogues is possibly patients with stage 3 and 4 chronic kidney disease, wherein treatment of secondary hyperparathyroidism could provide skeletal benefit.

Exercise and Lifestyle

Physical activity is also a critical element of osteoporosis management, which can be indirectly inferred based on the known profound effects of decreased gravitational force (i.e., immobilization, paraplegia, weightlessness in space) on inducing bone loss. Physical activity likely also confers additional benefits through enhanced muscle strength, improved cardiovascular status, and reduction in fall risk. Meta-analysis confirmed a modest benefit of exercise on lumbar spine (mean difference = 0.85%) and trochanteric BMD (mean difference = 1.03%) in postmenopausal women compared with placebo, although it did not show significant changes in femoral neck or total hip BMD. However, studies to date have not confirmed an improvement in bone strength with exercise in this patient group. Studies concerning middle-aged and older men are much more limited in number and quality, although preliminary evidence suggests that resistance training with or without impact-loading activities has the greatest BMD benefit. Importantly, although none of the aforementioned studies have demonstrated a clear antifracture benefit from exercise, there are abundant data that multiple targeted exercise interventions do reduce either the risk for falling (Tai Chi) or both the rate and risk for falling (group and home-based exercise programs), which is most likely an inciting event in older patients incurring an osteoporotic fracture. Finally, modification of aberrant lifestyles is also indicated in patients with osteoporosis, especially tobacco cessation and moderation of caffeine, carbonated beverage, and alcohol intake. Data are lacking, however, on whether these reduce overall fracture risk.

Medications

There is robust evidence that pharmacologic therapy significantly reduces the risk for osteoporotic fracture in a clinically meaningful and cost-effective manner.[11] Medications approved for osteoporosis can be classified based on their mechanism of action: anticatabolic (i.e., antiresorptive) and anabolic (i.e., bone building).

Anticatabolic Agents

Anticatabolic medications, or antiresorptive as they were more commonly known, inhibit osteoclast recruitment, function, and/or survival, resulting in reductions in skeletal turnover and bone loss. These agents, depending on the potency and persistence of bone effect, reduce the number of new activation sites (BMUs) and the bone remodeling space, thereby improving BMD while strengthening the skeletal microstructure and reducing fracture risk.

Bisphosphonates

Bisphosphonates (BPs) are the most widely prescribed and used medications for the treatment of osteoporosis, owing in large part to good tolerability and an ability to dose them infrequently (from once weekly to once yearly, depending on the drug). BPs are chemically engineered analogues of the naturally occurring molecule pyrophosphate in which a carbon is substituted for an oxygen. As a result, BPs have an extremely high affinity for hydroxyapatite crystals within bone. After incorporation into bone, BPs are taken up by osteoclasts and thereafter inhibit cellular attachment, function, and survival. The carbon side-chain molecules largely determine skeletal affinity and potency of BP effect. The first-generation BP etidronate, which is not approved in the United States for treatment of osteoporosis, is the least potent agent of the class. It must also be given in an interrupted fashion for 2 weeks every 3 months owing to the potential to cause focal osteomalacia, and it may cause lower gastrointestinal symptoms (i.e., abdominal pain and diarrhea). Nonetheless, it is has been shown to reduce the risk for vertebral but not nonvertebral nor hip fractures.

Three oral bisphosphonates are approved by the U.S. Food and Drug Administration (FDA) and currently available in the United States: alendronate, risedronate, and ibandronate, in order of time since initial FDA approval. All three drugs are also available as generic preparations, although some differences do exist between the brand name and generic drugs in regard to the

(Adapted with permission from Levis S, Theodore G. Summary of AHRQ's comparative effectiveness review of treatment to prevent fractures in men and women with low bone density or osteoporosis: update of the 2007 report. *J Manag Care Pharm.* 2012;18[4 Suppl B]:S1-S15, discussion S13.)

inactive excipients. The oral BPS may be administered once weekly (alendronate and risedronate) or once monthly (risedronate and ibandronate), fasting in the morning with water only, and the patient must remain fasting in a sitting or standing position for 30 to 60 minutes after the dose. Recently, a delayed-release formulation of risedronate (Atelvia) was approved that may be taken immediately after breakfast. The most common side effect is precipitation or aggravation of gastroesophageal reflux, although most patients tolerate the drugs without difficulty. In light of this side effect and a potential risk for esophageal irritation and ulceration, these drugs are contraindicated in patients with functional or anatomic disorders of esophageal transit (i.e., esophageal stricture, achalasia). All three drugs significantly reduce the risk for vertebral fractures, although high-strength evidence for hip and nonvertebral fracture risk reduction exists for alendronate and risedronate but not ibandronate (Table 243-2). In addition, studies confirm a persistent BMD and likely antifracture benefit after 5 years of therapy.

Parenteral BPs are also approved and available for osteoporosis treatment, although they should be considered second line to oral BPs based on overall risk-benefit assessment in most osteoporotic patients. They may be considered for use in patients with contraindications to oral BPs (e.g., esophageal disease, inability to sit upright and/or fast after dose), documented or expected poor adherence to oral BPs, or failure to respond to oral BPs or other FDA-approved therapies (recurrent fractures, declining BMD). Zoledronic acid, 5 mg once yearly, and ibandronate, 3 mg quarterly, may be given, although high-strength evidence would favor the use of zoledronic acid, given its unequivocal effect on spine, hip, and nonvertebral fracture risk reduction. Intriguingly, zoledronic acid has also been shown to reduce mortality in women and men following a low-trauma hip fracture, although the mechanism of the mortality benefit is unknown. Finally, BMD remains stable and the antifracture effect likely persists for 3 years after three annual doses of zoledronic acid. Both drugs are associated with an approximately 15 to 20% likelihood of a flu-like reaction, typically consisting of fever, arthralgias, and myalgias, usually limited to the first infusion, and generally lasting 24 to 48 hours, although symptoms lasting weeks to months have rarely been reported to the FDA. Both drugs confer a higher risk as well for delayed healing of exposed bone in the oral cavity compared with oral BPs (see later).

Rare, considerably more serious adverse effects have been associated with both oral and intravenous BPs. Osteonecrosis of the jaw, which is defined as exposed bone within the oral cavity for more than 8 weeks following an invasive dental procedure (e.g., tooth extraction, dental implant) or spontaneous tooth loss, occurs in roughly 1 in 10,000 to 100,000 patients treated with oral BPs, although it likely occurs in 1 in 1000 to 10,000 in intravenous BP–treated patients with osteoporosis. Current evidence suggests that microbial biofilm formation on an acellular bone surface, perhaps facilitated by BPs and the non-BP drug denosumab (see later), may be operative in the development of this disorder. As such, patients on intravenous BPs should maintain optimal oral hygiene and consider a BP holiday or delay in dose if invasive oral procedures are planned. Atypical femoral fractures have also been recently described in patients on long-term bisphosphonate therapy, generally after 5 years or more of treatment. Patients will typically have prodromal thigh or groin pain, which is referable to a stress fracture of a thickened lateral femoral cortex, inferior to the greater trochanter. These fractures can be bilateral in nature and may be identified radiographically with plain films, MRI, or CT. These patients are at risk for low-trauma, severe, oblique, "chalk-stick" fractures, which often represent orthopedic repair and healing challenges. Fortunately, the estimated prevalence of atypical femoral fractures is low (~1 in 5,000 to 10,000). Nonetheless, the severe manifestations of osteonecrosis of the jaw and atypical femoral fractures make it prudent for clinicians to consider a BP drug holiday, particularly given strong evidence of continued benefit on discontinuation.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) are compounds that bind to the estrogen receptor and thereby influence bone and reproductive biology. As with estrogen (see later), SERMs are anticatabolic agents in bone, acting through a reduction in cytokines (RANKL, tumor necrosis factor-α) that engender osteoclast activation and function. Raloxifene is the only FDA-approved drug for prevention and treatment of osteoporosis in menopausal women, although the breast cancer drug tamoxifen likely has skeletal benefits as well. Both drugs have antiestrogenic effects in the breast and are FDA approved for the prevention of breast cancer in high-risk patients. Raloxifene does reduce the risk for vertebral fractures by approximately 30 to 50% but does not reduce the risk for hip and nonvertebral fractures. This antifracture profile positions it as an alternative to bisphosphonates in postmenopausal women with osteopenia and a relatively low risk for hip and other nonspine fractures. The most common side effects include hot flushes and leg cramps in about 10 to 15% and about 5% of patients, respectively. SERMs also increase the risk for deep vein thrombosis, with an absolute risk of roughly 1 in 400, akin to that seen with oral estrogen replacement therapy (ERT). Raloxifene has also been associated with an increased risk for fatal stroke in women at higher baseline risk for stroke, likely precluding its general consideration in women older than 65 years.

Estrogen

ERT, either alone or in combination with a progestin in women with an intact uterus, had historically been a frontline agent in the management of osteoporosis in postmenopausal women (Chapter 240). ERT prevents bone loss if administered to women at menopause and significantly increases BMD by approximately 3 to 5% in woman who are well into their menopausal years. Although lower doses of estrogen may have skeletal benefits, more standard doses of estrogen (0.625 mg of conjugated equine estrogen and 1.0 mg of ethinyl estradiol) have been proved efficacious. Long-term estrogen therapy reduces the risk for all clinical fractures by about 27%, based on the available moderate-quality evidence. ERT is also the most efficacious agent available for treatment of vasomotor symptoms. These data notwithstanding, ERT is associated with an increased risk for stroke (34% increase), and the use of continuous combined hormone replacement therapy (HRT) confers an unacceptable greater global risk than benefit in woman initiating HRT, based on the results of the Woman's Health Initiative. These results, however, may not be applicable to the younger postmenopausal population, based on differences in cardiovascular risk, although data confirming this are currently lacking. Both ERT and HRT are also associated with a two- to three-fold increase in the risk for venous thromboembolic disease. Therefore, ERT/HRT is recommended only for postmenopausal women at significant risk for fracture for whom other antifracture therapies are unsuitable.

Denosumab

As detailed previously, increased osteoclast activation through the RANKL pathway is a key mechanism through which bone loss occurs in menopause and other osteoporotic conditions. Intuitively, a therapy that targets this process directly would be desirable. Denosumab is a fully human monoclonal antibody to RANKL that is FDA approved for the treatment of osteoporosis in postmenopausal women and in men, as well as for individuals with breast and prostate cancer to reduce bone loss associated with hormonal deprivation therapy. It is administered twice yearly as a subcutaneous injection in the clinic and clearly reduces the risk for spine, hip, and nonvertebral fractures. Denosumab does not undergo hepatic or renal metabolism and thus can potentially be used in patients with more advanced renal dysfunction, unlike BPs. In contrast to BPs, it is reversible, such that robust bone loss ensues once the medication is stopped. Denosumab is well tolerated in clinical studies, although a higher incidence of skin conditions (eczema and erysipelas) and infections, including serious infections that required hospitalization, were observed in drug- versus placebo-treated subjects. Therefore, the drug is likely not suitable for patients on immunosuppressant therapy who are at higher baseline risk for infection.

Anabolic Agents

Although anticatabolic drugs are effective at retarding bone loss and reducing fracture risk, anabolic or "bone-building" drugs would be preferred. Teriparatide (TPTD) is a recombinant human parathyroid hormone analogue that encompasses amino acids 1 to 34 and was approved by the FDA in 2002. Given

as a self-administered once-daily subcutaneous injection, TPTD is truly anabolic based on robust increases in bone density (~10% over 2 years in the lumbar spine) and bone formation as determined by bone biopsies and other sophisticated imaging studies. More important, TPTD significantly reduces the risk for vertebral and nonvertebral fractures by approximately two thirds and one half, respectively. Because bone resorption increases along with bone formation, bone loss generally ensues on cessation of therapy, necessitating the initiation of an anticatabolic bone drug to preserve the increase in BMD facilitated by TPTD. Finally, although it is plausible to consider that a combination of TPTD and an anticatabolic drug is more beneficial than either drug alone, evidence from randomized controlled trials to date has failed to confirm this. Recent studies, however, suggest that the combination of TPTD and denosumab may have a truly synergistic effect on BMD.

TPTD is more expensive than other treatments for osteoporosis, although it is generally covered by insurance in patients who have severe osteoporosis (based on BMD and/or fracture risk) and who cannot tolerate or have contraindications to other antifracture agents. The drug is generally well tolerated, with the most common adverse effects being dizziness and leg cramps. TPTD has a black box warning, based on the fact that toxicology studies in rats revealed an increase in risk for osteosarcoma in animals treated with supratherapeutic doses of the drug, particularly in growing animals. Given this, the drug is contra-indicated for patients who are at a higher baseline risk for osteosarcoma, including patients with Paget disease and previous therapeutic radiotherapy, as well as younger individuals with open epiphyses. Fortunately, there has not been an observed increase in the rate of osteosarcoma in teriparatide treated patients above that expected in the general population to date.

Other Therapies and Treatment Considerations

Currently Available and Emerging Therapies

Nasal calcitonin is FDA approved and available at the time of this writing for treatment of postmenopausal osteoporosis, although it is widely considered the weakest antifracture agent based on marginal vertebral fracture benefit. In addition, recent human studies have suggested a possible link to cancer, potentially further limiting its clinical utility and future availability in the United States. Strontium ranelate is approved in Europe for the treatment of osteoporosis and may have a dual proformation-anticatabolic effect on bone. It has been shown to reduce the risk for vertebral and nonvertebral fractures, as well as clinical osteoporotic fractures. It is not available for use in the United States, and alternative forms of strontium salts cannot be assumed to be effective as well. In addition, BMD by DXA cannot be followed in patients on strontium because of artifactual increases in BMD related to the incorporation into bone of the strontium salt.

Emerging therapies on the horizon will likely provide additional tools to treat this debilitating disease, including new anticatabolic agents (e.g., cathepsin K inhibitors) and new anabolic therapies (e.g., sclerostin antibody). Odanacatib is an oral, small molecule that reversibly inhibits cathepsin K, which is produced by activated osteoclasts and primarily is responsible for the breakdown of type 1 collagen. Odanacatib also does not significantly suppress bone formation, perhaps "uncoupling" bone turnover in a favorable fashion to potentiate improvements in BMD. Sclerostin is a naturally occurring inhibitor of the Wnt pathway and bone formation, and preliminary clinical studies do confirm a significant anabolic effect and BMD increase with intermittent administration of a monoclonal antibody to sclerostin. Interestingly, unlike TPTD, inhibition of sclerostin does not appear to stimulate bone resorption, potentially affording greater and more persistent gains in BMD. Ongoing and future clinical studies are needed to confirm an antifracture benefit of this compound.

Glucocorticoid-Induced and Male Osteoporosis

As detailed previously, glucocorticoids are a major cause of and the most common etiology of medication-related secondary osteoporosis. Glucocorticoids are prescribed for a number of common inflammatory conditions, often in a chronic, long-term manner. They are potent suppressors of bone formation and at higher doses likely increase bone resorption, principally through central suppression of sex steroid production. This resultant "uncoupling" of bone turnover can result in dramatic declines in BMD within the first 6 months of starting therapy. In addition to bone loss, there is good evidence to support that individuals on glucocorticoids may fracture at a higher level on BMD compared with non-glucocorticoid-treated patients. Fracture rates are increased as well with doses of prednisone as low as 2.5 mg per day, although the increase in risk appears to attenuate with glucocorticoid discontinuation. The treatment approach to glucocorticoid-induced osteoporosis is similar to osteoporosis in general, with the exception that attempts should be made to reduce the steroid dose to as low as the underlying treated disease will permit.[12] Calcium and vitamin D are important adjuncts but are insufficient to prevent bone loss or fractures. Although not clearly evidence-based, replacement of deficient sex steroids is a reasonable strategy in younger individuals who are at lower risk for fracture. The BPs alendronate, risedronate, and zoledronic acid are FDA approved for glucocorticoid-induced osteoporosis in women and men, although the established benefit is based primarily on BMD improvement. A more logical and indeed superior treatment of glucocorticoid-induced osteoporosis is TPTD, which as an anabolic drug more directly addresses the primary mechanism of bone loss in glucocorticoid-induced osteoporosis: osteoblast inhibition. TPTD is FDA approved for treatment of glucocorticoid-induced osteoporosis in women and men and is superior to alendronate in improving BMD and vertebral fracture risk reduction. Although the drug was used for 36 months in this head-to-head trial, treatment is advised for no more than 24 months based on previously mentioned safety considerations.

Male osteoporosis historically has been under-recognized and underappreciated by primary care clinicians and patients alike, although the current data support a significantly more prevalent and clinically significant disorder. More than 2 million men in the United States have osteoporosis, and one in four men older than 50 years will suffer a fragility fracture in their remaining lifetime. Roughly 30% of vertebral and hip fractures combined occur in men, and these are the more common fractures in older men. In addition, men have a substantially higher mortality after hip fracture compared with women. As in women, aging, low body weight, and prior fragility fractures are independent predictors of fracture. In some contradistinction to women, however, osteoporosis in men is more commonly multifactorial in etiology, with the most common secondary causes being excess glucocorticoids, hypogonadism, and alcohol overuse. Despite these associations and others (current smoking, history of falls), there is not at present sufficient evidence to warrant use of a specific testing or screening strategy to identify men at higher risk for fracture. The laboratory work-up of male osteoporosis is similar to that for women, with the exception of a morning fasting testosterone level. Idiopathic osteoporosis may also occur, particularly in younger men with no discernable cause. Genetic factors may well be important in these men, with studies suggesting an association with lower production and circulating levels of estrogen. As in women, primary treatment of male osteoporosis is targeted at lifestyle changes, adequate nutrition (calcium and vitamin D), and exercise. Bisphosphonates (oral and intravenous), denosumab, and TPTD are all effective at improving BMD in men. Although more limited in scope, antifracture efficacy is evident for denosumab in men with prostate cancer on androgen deprivation therapy. True antifracture efficacy for the other agents is either less convincing or absent, based on the paucity of randomized controlled trial data, although this should not be construed as a reason not to treat. Testosterone replacement of men with significant biochemical hypogonadism (total T score < 200 ng/dL) does improve bone density, although data on fracture risk reduction are lacking. In older men (>50 years) at a substantial risk for fracture based on history and risk factors, androgen replacement should be considered second line behind the aforementioned other therapies, based on overall risk-benefit and lack-of-fracture data.

Vertebroplasty and Kyphoplasty and Low-Intensity Vibration

Although often clinically silent, vertebral fractures may cause acute and severe back pain. In addition, up to one third of vertebral fractures remain chronically painful, perhaps related to incomplete healing or instability of the fracture. Over the past decade, vertebroplasty and kyphoplasty have been developed and advanced to reduce the morbidity associated with acute spine fractures. These invasive procedures introduce, through the spinal pedicles, a cement-like substance (polymethylmethacrylate) to the compressed vertebral body, with (kyphoplasty) or without (vertebroplasty) use of saline-infused balloon tamps that permit a few millimeters of elevation of the vertebral end plates. Initial randomized trials suggested a benefit of vertebroplasty over conservative management in patients with acute vertebral fractures, although a recent meta-analysis of patient-level data from two randomized controlled trials did not confirm this finding. Additionally, there may be a concern about fracture of adjacent vertebrae following the procedure, reinforcing the need for further, adequately powered and designed clinical trials.

Low-intensity vibration is also under active investigation as an anticatabolic and possibly anabolic intervention for osteoporosis. Animal studies using low-intensity vibration appears to show enhanced osteoblast and hindered osteoclast development, thereby "coupling" bone remodeling. Clinical studies suggest a modest but significant BMD benefit in postmenopausal women and other groups (children with cerebral palsy, adults on prolonged bed rest), although further studies are needed to confirm a true clinical and ideally antifracture benefit of this intervention.

PROGNOSIS

It stands to reason that, based on the information and data discussed previously, the burden incurred by individual patients and society as a whole can be significantly lessened through a combination of diagnostic, preventive, and therapeutic interventions. Although there is no true "cure" for osteoporosis, current pharmacotherapies reduce the risk for fracture roughly by half.

This reduction is critical because there is robust evidence to suggest an independent increase in mortality after an osteoporotic fracture, including fractures of the spine, humerus, tibia, and pelvis, as well as the proximal femur. Moreover, available data, primarily from randomized controlled trials with bisphosphonates, confirm a statistically significant reduction in death with pharmacologic treatment of osteoporosis, although the mechanism of this effect is not known.[13] These data further underscore the importance of identifying and treating patients with osteoporosis.

REVIEW QUESTIONS

1. A 60-year-old woman presents to her physician to discuss her recent bone density results and management options. She has treated hypertension and a history of atrial fibrillation, as well as rheumatoid arthritis, for which she takes infliximab. Family history is notable for a hip fracture in her mother after a fall at age 65 years. She drinks socially and does not smoke. Her physical examination is unremarkable, including only 1 inch of height loss from her young adult maximum. Her spine examination reveals normal curvature, no kyphosis, normal rib-pelvis distance of 3 fingerbreadths, and 0 fingerbreadth wall-occiput distance. Laboratory studies are normal, including 25(OH)D level. Duel-energy x-ray absorptiometry (DXA) bone density reveals lumbar spine, femoral neck, and total hip T scores of −2.5, −3.0, and −2.7, respectively. Her FRAX 10-year estimates of hip and major osteoporotic fracture are 5.6 and 29%, respectively. What is the best management recommendation for this woman?

A. Calcium and vitamin D supplementation alone
B. Hormone replacement therapy
C. Raloxifene
D. Oral bisphosphonate
E. Denosumab

Answer: D This patient has osteoporosis based on T score at the lumbar spine and proximal femur. In addition, she has an absolute fracture risk that supports pharmacologic intervention on a cost-effectiveness basis. Oral bisphosphonates are effective and generally frontline therapy. Active use of immunosuppressive therapy increases her risk for infection, which was seen more frequently in denosumab-treated patients in randomized controlled trials. Her cardiovascular history increases her risk for stroke, which has been observed more frequently in raloxifene- and estrogen-treated patients. Finally, calcium and vitamin D are important adjuncts to her management but should not be considered adequate alone for fracture risk reduction in this woman.

2. A 65-year-old woman presents with 6 months of progressive lower extremity pain and describes difficulty ascending stairs because of pain and weakness. She also brings a recent outside DXA bone density test, which shows total hip T and Z scores of −4.5 and −2.5, respectively. She does not have a history of fragility fractures. Past medical history is notable for hypertension and long-standing irritable bowel syndrome. She takes 600 mg of calcium and 400 IU of vitamin D daily, but no other medications. Family history is negative for osteoporosis or parental hip fracture. She does not smoke or drink alcohol. Physical examination is notable for tenderness to palpation over the mid-tibia bilaterally. She also has a wide-based, nonantalgic gait. What is the next best choice for her skeletal management?

A. Double her calcium and vitamin D daily intake.
B. Measure serum 25(OH)D level.
C. Start an oral bisphosphonate.
D. Measure fasting serum C telopeptide level (CTx)
E. Start teriparatide therapy.

Answer: B This patient has lower bone density than expected for age based on Z score of −2.0 or less. This suggests a secondary cause for low bone mineral density (BMD) besides menopause. Her clinical presentation is consistent with osteomalacia, which cannot be distinguished from osteoporosis based solely on BMD. In addition, the prevalence of vitamin D deficiency or insufficiency and established hip fracture efficacy warrant its identification and treatment as the next best step in patient management. The recommended increase in calcium and vitamin D would be insufficient to treat vitamin D deficiency–related osteomalacia in this woman, and bisphosphonate and teriparatide therapy would be inappropriate until the vitamin D deficiency is corrected. Finally, bone turnover markers cannot be used independently for diagnosis in patients with metabolic bone disease.

3. An 81-year-old man is admitted after a fall and low-impact fracture of the proximal femur. His history is notable for Parkinson's disease treated with dopamine agonist therapy. On physical examination, patient has a mild resting tremor while lying in bed. Laboratory investigations do not reveal secondary causes of osteoporosis, including a 25(OH)D level of 30 ng/mL and testosterone of 300 ng/dL. The patient has normal renal function and calcium. The patient undergoes successful operative repair. After discharge, the patient undergoes 4 weeks of inpatient rehabilitation. What is the most definitive choice for this patient's metabolic bone management?

A. Start calcium and vitamin D supplementation.
B. Increase dopamine agonist therapy for Parkinson's disease.
C. Give zoledronic acid, 5 mg intravenously.
D. Start testosterone replacement therapy.
E. Prescribe ergocalciferol 50,000 IU once weekly.

Answer: C This gentleman has incurred a low trauma femur fracture, which greatly increases his risk for subsequent fractures. Furthermore, the fracture confers a mortality rate up to 30% within 1 year of the event. Zoledronic acid has been proved not only to reduce the risk for subsequent fracture but also to reduce mortality by 27% Calcium and vitamin D are important adjuncts to treatment but not definitive. Given his level of 25(OH)D, additional antifracture and/or fall risk reduction would not be anticipated from pharmacologic vitamin D treatment. There is no evidence that testosterone treatment of either eugonadal or hypogonadal men reduces fracture risk. Finally, optimal management of his Parkinson's disease, which does not appear undertreated in this patient, might reduce his risk for falls but not his risk for fracture.

4. A 55-year-old white woman presents to her physician with intense midback pain after a fall onto her backside while walking. Her history is notable for a recent diagnosis of polymyalgia rheumatica, for which she has taken prednisone 10 mg daily for the last 6 months. She does have known osteopenia, with lumbar spine, femoral neck, and total hip T scores of −1.5, −1.2, and −0.8, respectively. Physical examination is notable for tenderness to palpation and percussion over the lower thoracic spine. Plain films of the thoracolumbar spine reveal a new moderate (35%) anterior compression fracture at T11. Laboratory work-up, including 25(OH), is within normal limits. Other than continuing the calcium and vitamin D that the patient is currently taking, what is the most appropriate pharmacologic choice for treatment at this time?

A. Vitamin D 50,000 IU once weekly
B. Alendronate 70 mg once weekly
C. Risedronate 150 mg once monthly
D. Teriparatide 20 mcg subcutaneously daily
E. Denosumab 60 mg subcutaneously every 6 months

Answer: D This woman presents with an acute vertebral fracture following a low trauma event. Her level of BMD is not osteoporotic, underscoring the independent contribution of glucocorticoids to fracture risk such that fractures may occur at a higher (i.e., better) level of BMD. The recent nature of her fracture further underscores the need for initiation of treatment now. There is no evidence that increasing this patient's vitamin D level will further reduce her risk for fracture. Denosumab will likely reduce her risk for subsequent fracture, although the association with infection and use of concurrent prednisone in this woman preclude its consideration at present. Alendronate and risedronate are approved for the prevention and treatment of glucocorticoid-induced osteoporosis (GIO). Despite this, teriparatide has been proved more effective that bisphosphonates in patients with GIO and is indicated for this woman, assuming she has no contraindications to treatment.

5. A 70-year-old man presents with acute, mid-back pain after lifting a bag of topsoil while gardening 1 week ago. His medical history is notable for known male hypogonadism due to mumps orchitis in his 20s, although he does not take testosterone because of severe benign prostatic hypertrophy. He does take 600 mg of calcium twice daily and 1000 IU of vitamin D once daily. On physical examination, he has tenderness to palpation and percussion over his mid-thoracic spine. Laboratory investigations are unrevealing, including a 25(OH) level of 45 ng/mL. DXA bone density study confirms osteoporosis with lumbar spine T score of −3.0, although femoral neck and total hip T scores are normal. Radiographs of the thoracic spine reveal a new severe (50%) biconcave compression fracture at T8 without apparent widening of the pedicles. In addition to prescribing alendronate, which of the following is best adjunct management for this patient?

A. Analgesic therapy and referral to physical therapy for post-fracture consultation
B. Prescription for a spinal brace that patient should wear fro 6 months
C. Percutaneous vertebroplasty
D. Nasal calcitonin use for 1 year
E. No additional interventions are required at this time.

Answer: A This gentleman has osteoporosis secondary to long-standing hypogonadism, exhibited by predominantly great bone density loss and deficit in cancellous bone (i.e., spine). He has incurred by definition a low-trauma fracture and is in need of a pharmacologic antifracture therapy (i.e., alendronate). Although he has significant pain that must be addressed, there is no evidence that conservative therapy with analgesics is inferior to vertebroplasty in regard to pain management. In addition, his radiographic findings do not suggest fracture instability that might benefit from vertebroplasty. Physical therapy is also helpful both short term as an adjunct to pain management and long term regarding modification of lifestyle and exercise to maximally reduce future fracture risk. A supportive spine brace may be used, although its use should be limited to only 4 to 6 weeks because of the necessary induction of paraspinal muscle weakness associated with long-term use. Similarly, nasal calcitonin may have some analgesic benefit in the acute, post-fracture period based on limited data, although there is no evidence of a long-term analgesic benefit with continued use of the drug.

OSTEOMALACIA AND RICKETS

ROBERT S. WEINSTEIN

DEFINITION

Rickets refers to impaired mineralization of the cartilaginous growth plate and abnormal endochondral bone formation and therefore cannot occur in adults after epiphyseal closure.[1] Osteomalacia, literally meaning softening of bone, refers to defective or delayed mineralization of the organic matrix of bone, or osteoid, at the interface between calcified bone and osteoid, and may occur at any age. Both rickets and osteomalacia may be present in a growing child, but defective mineralization can cause only osteomalacia in adults; therefore, this chapter will focus on osteomalacia. Despite advances in our understanding of vitamin D metabolism and the increased sensitivity of measurements of serum 25-hydroxyvitamin D, osteomalacia remains a common and frequently overlooked disorder in the world. Optimal therapy requires precise identification of the etiology of the abnormal mineralization, which may present a problem because there are numerous causes (Table 244-1). However, after a correct diagnosis is made, therapy is usually gratifying and often spectacular. Early recognition of osteomalacia depends on familiarity with the typical clinical manifestations and settings. It is helpful to appreciate that the bone disease almost always manifests in the same manner regardless of the cause of the osteomalacia.

EPIDEMIOLOGY

About 20% of North American women receiving treatment for osteoporosis have 25-hydroxyvitamin D levels below 20 ng/mL (adequate values are greater than 30 ng/mL), and 8% have levels below 15 ng/mL. This indicates that, at the least, impaired bone mineralization could be a confounding factor in their osteoporosis treatment and, at worst, osteomalacia is the correct diagnosis (a defect in mineralization) rather than osteoporosis (a reduced amount of normally mineralized bone). An inadequate response to the bisphosphonate treatment commonly used for postmenopausal osteoporosis is four times more likely when 25-hydroxyvitamin D levels are subnormal than when the levels are above 30 ng/mL.[2] Vitamin D deficiency is more common in elderly people, especially in nonaffluent people during the winter, at higher latitudes, and with low sun exposure. Vitamin D deficiency is also commonly found in medical inpatients, institutionalized patients, and postmenopausal women with acute hip fracture.[3]

The prevalence of osteomalacia due to vitamin D deficiency varies with the referral source. The disorder is far more frequent when patients are referred from geriatricians, gastroenterologists (osteomalacia may be found in up to 30% of patients with gastric surgery or bypass for obesity), nursing homes, or orthopedists concerned about symmetrical or nonhealing fractures. The most common hypophosphatemic osteomalacia is the inherited disease X-linked hypophosphatemia (XLH), but affected adults infrequently present to internists and then only when troubled by severe bone pain or nonunion of fractures.

PATHOBIOLOGY

A review of normal bone remodeling and the mineralization of osteoid (bone matrix) serves as a background to understand the abnormal mineralization characteristic of osteomalacia. Bone remodeling or turnover is carried out by teams of juxtaposed osteoclasts and osteoblasts, comprising temporary anatomical structures known as basic multicellular units (BMUs). In cortical bone, the BMUs drill tunnels or "cutting cones" through the compact tissue; whereas in spongy, cancellous bone, they gouge across the trabecular surface, forming serpiginous trenches. Bone turnover begins by conversion of a quiescent skeletal surface to a remodeling site, a process referred to as *activation.* Activation involves proliferation of new blood vessels needed to bring recruited osteoclast progenitors to the remodeling site and retraction of the flat, pavement-like bone-lining cells that cover the quiescent surfaces to expose the mineralized bone surface. The recruited cells become multinucleated osteoclasts, which attach to the newly exposed bone surface with a ring of contractile proteins sealing off a subosteoclastic resorption compartment. Lysosomal enzymes, hydrogen ions, and collagenase are secreted through the microvilli of the ruffled underside border of the osteoclasts, and these chemicals begin to excavate a resorption cavity. The osteoclasts remove both the bone mineral and matrix. It is a misunderstanding to attribute to these cells or to metabolic acidosis the ability to remove only the mineral, leaving behind demineralized osteoid. Demineralized bone in vivo is a misnomer. Demineralized or decalcified bone only occurs when bones are placed in acid (1N HCl) or chelating solutions (ethylenediaminetetraacetate, or EDTA). Osteoclasts are motile cells, capable of resorbing more than just the cavity within which they are identified. After an osteoclast digs a cavity, it may detach from bone and move on to a new resorption site or die by apoptosis and be quickly removed by phagocytes. When the osteoclasts have moved on, osteoblasts assemble to reconstitute the previously resorbed cavity with new bone. In any established BMU, both events are happening at the same time; bone formation begins to occur while bone resorption advances.

Between the end of bone resorption and the beginning of bone formation is the reversal phase, when mononuclear phagocytes smooth out the jagged erosion bays. During this phase, the old bone is coated by a thin layer of cement substance, a collagen- and mineral-poor matrix rich in glycosaminoglycans, glycoproteins, and acid phosphatase, to which the new osteoblasts attach. In adults, new osteoblasts assemble only at sites where osteoclasts have recently been eroding bone; a phenomenon referred to as *coupling.* The arrival of the osteoblasts in the right place at the right time and in sufficient numbers to reconstitute the cavity is referred to as *remodeling balance* and is likely due to proportional production of osteoblasts and osteoclasts in the bone marrow, release of osteoblast-recruiting substances from the resorbed bone, and chemotaxis by the cement substances. As osteoblasts complete their bone matrix synthesis and move away from the cement line, they gradually flatten. Some osteoblasts become bone-lining cells, and some become osteocytes, but as many as 65% of the osteoblasts that originally assembled at the remodeling site die by apoptosis. It is the balance between cell proliferation and apoptosis that determines the amount of work performed by these cells.

Normally, up to 70% of the mineralization of the osteoid deposited by the osteoblasts starts within 4 to 12 days and proceeds at about 1 µm per day; but in osteomalacia, mineral deposition in the osteoid slows or stops completely, while the osteoblasts continue to make osteoid, which then accumulates in excessive amounts. Therefore, normal osteoid width is about 4 to 12 µm, but in osteomalacia, the osteoid width may become dramatically augmented. Depending on the extent of the delay in mineralization, overt osteomalacia may take many years to develop. In normal subjects, further mineralization proceeds slowly over months to years and at the cost of displacement of the water in the hydroxyapatite crystals, resulting in a modest increase in brittleness and the eventual need for another round of remodeling. Even though 1 million BMUs are undergoing remodeling every day, bone mass in a healthy adult is preserved thanks to a remarkably tight balance between the amount of bone resorbed and the amount formed during each cycle of remodeling. By this means, the adult skeleton is almost completely regenerated every 10 years.

Mineralization requires the availability of sufficient calcium and phosphorus at the remodeling site, the presence of a normal bone collagen matrix, the absence of inhibitors of mineralization, and an adequate amount of skeletal alkaline phosphatase activity. Defects in these requirements are the cause of most forms of osteomalacia. Deficiency of vitamin D per se has traditionally been incriminated as the cause of the osteomalacia, but today, considerable evidence indicates that the abnormal mineralization associated with vitamin D deficiency depends more on the deficiency of calcium and phosphorus than the absence of a direct effect of vitamin D on bone cells. The primary function of vitamin D is to provide adequate levels of calcium and phosphorus by increasing their intestinal absorption. Chronic metabolic acidosis has also been identified as a cause of osteomalacia, but evidence suggests that the bone disease associated with chronic metabolic acidosis is primarily due to the associated hypophosphatemia.

CLINICAL MANIFESTATIONS

The clinical presentation of osteomalacia depends on three overlapping manifestations: those due to the underlying disorder, such as gastrointestinal disease or surgery (especially troublesome are gastric resection, stapling or bypass for obesity, and intestinal malabsorption); those due to hypocalcemia or hypophosphatemia; and those directly due to the bone disease. The most common symptoms and signs are bone pain, muscle weakness, and bone tenderness. The bone pain is usually nonspecific and poorly localized. Because of the paucity of findings, the pain is often attributed to rheumatism or neurosis. It may be worse at night and after sudden movements such as turning in bed or the change from sitting to standing. Most often, the pain is in the lower back, pelvis and legs and is worse on weight bearing, resulting in a characteristic flat-footed, springless, waddling gait made worse by proximal muscle weakness. The gait has been referred to as "mother penguin's walk." Patients may complain that they can only climb stairs by pulling themselves up with the hand rail or rise from sitting in a chair or on the toilet by using their hands to push off. The decrease in strength is usually far greater than the degree of muscle wasting. Fasciculations are absent, and both reflexes and sensation remain normal. The bulbar, facial, and ocular muscles are always spared. However, muscle weakness is conspicuously absent when the osteomalacia is due to X-linked hypophosphatemia (see Table 244-1). Often, bone tenderness can be elicited by rib cage compression or pressing on the tibiae, wrists, pubic rami, or iliac crests. Hypocalcemia is usually mild to moderate but, rarely, can be severe enough to present with paresthesias, muscle cramps, a positive Chvostek's sign, or seizures. If the osteomalacia is mistaken for osteoporosis and treatment is started with a bisphosphonate, the patient may experience new-onset paresthesias, muscle cramps, and palpitations. This not uncommon scenario occurs because the antiresorptive treatment interferes with the compensatory secondary hyperparathyroidism and aggravates the hypocalcemia.

DIAGNOSIS

Biochemical changes depend on the stage of the disease and its etiology. In vitamin D deficiency, hypophosphatemia precedes and is more severe than the hypocalcemia because of the secondary or compensatory hyperparathyroidism (Chapter 245) that almost invariably accompanies the disorder by the time that osteomalacia has occurred. In malabsorption, hypomagnesemia may contribute to the hypocalcemia, and hypoalbuminemia may lead to a spurious diagnosis of hypocalcemia. Increased serum alkaline phosphatase activity is classically associated with osteomalacia due to vitamin D deficiency but is not an early or reliable clue because some patients may have normal or borderline levels. The serum 25-hydroxyvitamin D levels are often less than 10 to 15 ng/mL. In contrast, serum 1,25-dihydroxyvitamin D levels are usually elevated because of the concomitant hyperparathyroidism and do not contribute to the diagnosis of osteomalacia except in the rare abnormalities of vitamin D resistance (when 1,25-dihydroxyvitamin D levels may be extraordinarily high) or when 1-hydroxylation is defective (and 1,25-dihydroxyvitamin D levels are low). Quite a different pattern occurs with the inherited disease hypophosphatasia: serum 25-hydroxyvitamin D and calcium are normal, phosphorus and vitamin B_6 levels are high normal or frankly elevated, and alkaline phosphatase activity is below the normal range.[4]

Radiographic findings may be absent with early osteomalacia, and only blurred margins of the cancellous bone with thin cortices may be noted. The presence of bilateral, thin (2 to 3 mm), radiolucent bands known as *pseudofractures* (Fig. 244-1) found perpendicular to the periosteal surface in ribs, pubic and ischial rami, the neck of the femur, and metatarsals and below the glenoid fossa on the outer border of the scapulae are generally considered to be pathognomonic of osteomalacia, but this classical radiographic sign is infrequent today. Rarely, it may be seen in disorders lacking excessive osteoid. These pseudofractures (sometimes called *Looser's zones* or *Milkman's fractures*) show increased uptake on bone scans (Fig. 244-2) and may lead to an inappropriate search for a primary malignancy. Bone mineral density T scores are often −3 or −4, with the radial diaphyseal density lower than that of the lumbar spine or total proximal femur.

FIGURE 244-1. Radiographic evidence of a pseudofracture of the femoral neck is suspicious for osteomalacia *(arrow)*.

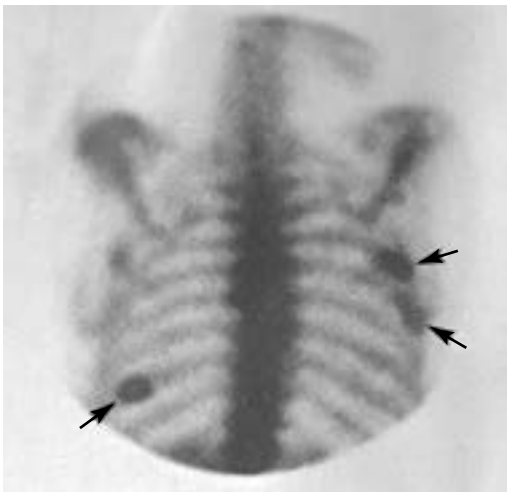

FIGURE 244-2. In osteomalacia, focal increased uptake of radionuclide on a bone scan may erroneously suggest metastatic disease *(arrows)*.

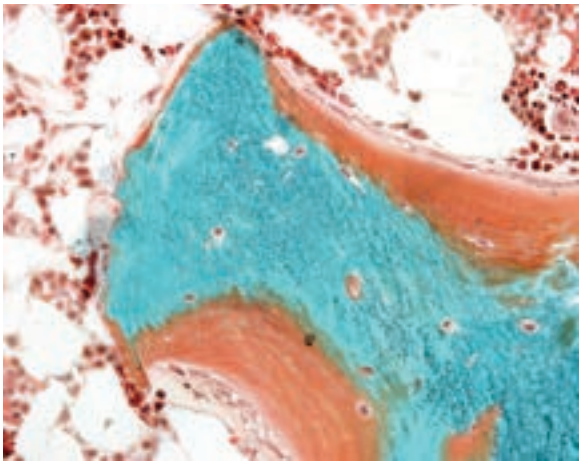

FIGURE 244-3. An undecalcified bone biopsy specimen shows the characteristic abundant osteoid and flattened osteoblasts of osteomalacia (normally mineralized bone is *blue* and osteoid is *red*).

Although characteristic clinical, radiographic, and biochemical findings may suggest osteomalacia, the absence of these findings cannot exclude the diagnosis. Quantitative histologic examination of undecalcified bone is, therefore, required to establish the unequivocal presence of osteomalacia (Fig. 244-3). Rigorous kinetic criteria for the histologic recognition of osteomalacia are necessary to preserve the traditional clinical, biochemical, and therapeutic connotations of the term. Therefore, a review of the quantitative bone histologic findings or histomorphometry in osteomalacia is useful.[5] The histomorphometric diagnosis of osteomalacia requires the simultaneous presence of three findings: (1) excessive osteoid (osteoid area >10% of the cancellous bone area; normal is <4%), (2) augmentation of the osteoid width (>15 μm; normal is 4 to 12 μm), (3) and prolongation of the mineralization lag time (>100 days; normal is 9 to 20 days), as determined by the osteoid width divided by the distance between and linear extent of double tetracycline labels observed in the bone after the patient receives two time-spaced courses of oral tetracycline. Tetracycline is deposited early in the course of hydroxyapatite crystal formation and generates bright stripes at the interface of mineralized bone and osteoid when viewed with fluorescent microscopy. If the two time-spaced courses of tetracycline (1 g/day for 3 days) are separated by a 14-day interval, the rate of mineralization (μm/day) can be calculated by measuring the average distance between the double labels divided by the number of days between the two courses. When the double labels are numerous and widely spaced, mineralization is intact and excess osteoid must be due to increased bone turnover. A paucity of tetracycline labels that are narrowly spaced indicates that if excessive osteoid is present, it must be due to the delayed or ceased mineralization of osteomalacia (Fig. 244-4).

Therefore, it follows that excessive osteoid can occur from two distinct mechanisms. Osteomalacia is the consequence of defective mineralization, while osteoid production continues. However, osteoid will also accumulate with accelerated bone formation if the rate of osteoid deposition exceeds the rate of mineralization, as occurs in states of greatly increased bone turnover, such as hyperparathyroidism (Chapter 245), Paget's disease (Chapter 247), or thyrotoxicosis (Chapter 226). Even though osteoblasts in osteomalacia are usually sparse and flattened, whereas they are numerous, plump, and cuboidal with high bone turnover, these two groups of disorders can only be reliably distinguished with the use of tetracycline markers. The treatment of increased bone turnover and of defective mineralization is completely different, which is why the three histomorphometric criteria are necessary. Additionally, evaluation of each of the criteria in isolation has limitations. Regarding the first requirement, a small increase in the osteoid area relative to the total bone area may occur in osteoporosis, with a decrease in the amount of mineralized bone. In the second requirement, wide osteoid seams may be seen in some specimens obtained from patients with severe secondary hyperparathyroidism, such as those on maintenance hemodialysis therapy (Chapter 131). In the third requirement, reduced mineral appositional rate and increased mineralization lag time are nonspecific indices of impaired matrix synthesis by osteoblasts, as is often found in patients with involutional osteoporosis. Only when all three requirements are fulfilled is the diagnosis of osteomalacia irrefutable.

Several presumed causes of osteomalacia (anticonvulsant drugs, metabolic acidosis without hypophosphatemia, pseudohypoparathyroidism, and chronic renal failure) have not fulfilled all of these requirements and primarily represent secondary hyperparathyroidism. Patients with the nephrotic syndrome lose albumin and vitamin D metabolites in the urine, but evidence indicates that serum ionized calcium and parathyroid hormone levels are normal and metabolic bone disease in adults with the nephrotic syndrome is absent. Muscle weakness and bone pain are significantly more common in patients in whom the rigorous histologic diagnosis of osteomalacia has been proved. However, bone biopsy is not always necessary to be reasonably certain of the diagnosis. When biopsy is necessary, the local pathologist must be familiar with the processing of undecalcified bone specimens and plastic embedding; otherwise, the best solution is to refer the patient to a histomorphometry center for biopsy. This ensures satisfactory communication between the clinician, operator, and pathologist and is the best insurance against the incomplete, broken, fragmented, or accidentally decalcified bone specimens. Such referral may be indispensable in the evaluation of a patient with unusually painful disease or progressive loss of bone mineral density, particularly when the results of the physical examination, radiographs, and biochemical findings are ambiguous. Biopsy may also be indicated in patients with unexplained chronic hypophosphatemia.

The best approach is to avoid overlooking the diagnosis of osteomalacia by maintaining a high degree of suspicion in the typical clinical settings.[6] This is especially important because osteomalacia can usually be successfully

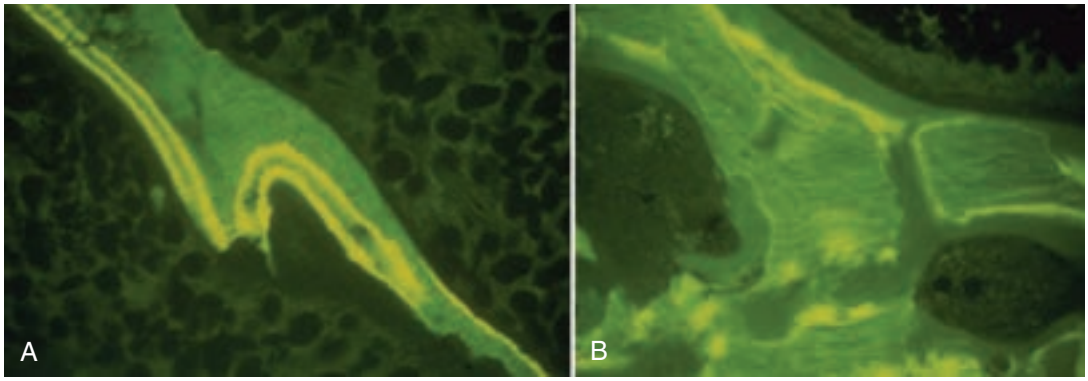

FIGURE 244-4. Histomorphometric diagnosis of osteomalacia by fluorescence imaging of double tetracycline labeling. **A,** Tetracycline double labels are numerous, discrete, and widely spaced, as is typical of intact mineralization. **B,** The tetracycline labels are mostly single despite the administration of two time-spaced doses of oral tetracycline, indicating that mineralization must be delayed or ceased, as is typical of osteomalacia.

treated. An investigation for osteomalacia is indicated in elderly patients with bone pain and muscle weakness, in patients with gastric surgery and low bone mineral density or bone pain, and in patients with persistent hypophosphatemia. Unexplained elevations of the serum alkaline phosphatase activity are usually due to drugs (e.g., anticonvulsants, anabolic steroids, phenothiazines, or antibiotics) or Paget's disease of bone (Chapter 247) but rarely may be the only biochemical clue to osteomalacia in a patient with variable skeletal discomfort. Bilateral or slowly healing fractures also warrant an investigation for osteomalacia.

TREATMENT

Rx

Understanding of the treatment of osteomalacia is facilitated by dividing the disease into four subgroups. The *first subgroup* is osteomalacia due to disorders of vitamin D absorption or metabolism; the *second* is osteomalacia due to chronic hypophosphatemia. Most patients with osteomalacia will be in these first two subgroups. Treatment of osteomalacia caused by these two subgroups is discussed in detail in the next two sections. The *third subgroup* includes osteomalacia caused by inhibitors of mineralization, such as etidronate (the first oral bisphosphonate, now rarely used in North America); high doses of fluoride; accumulation of a skeletal burden of aluminum from water used for dialysis or as a contaminate in solutions used for parenteral nutrition (now rarely seen); iron overload as in thalassemia; and cadmium, which induces the proximal tubular lesion of Fanconi's syndrome and causes osteomalacia due to the resultant hypophosphatemia. The *fourth subgroup* includes miscellaneous causes of osteomalacia that lack specific therapy but are fortunately quite rare. This last subgroup includes the variable forms of the heritable disorder hypophosphatasia, caused by a deficiency of the tissue-nonspecific (liver, bone, kidney) isoenzyme of alkaline phosphatase (although, therapeutic trials have shown that enzyme replacement is effective); axial osteomalacia, a sporadic osteosclerotic disorder primarily affecting middle-aged men and presenting with mild to moderate pain in the spine and pelvis (but without fractures), apparently due to the production of an abnormal and poorly mineralized bone matrix by osteoblasts; and fibrogenesis imperfecta ossium, another sporadic disorder presenting with intractable bone pain and fractures, mainly in middle-aged men and women and apparently also due to production of an abnormal bone matrix lacking the normal collagen birefringence by osteoblasts. In axial osteomalacia and fibrogenesis imperfecta ossium, serum calcium, phosphorus, and vitamin D levels are normal, but serum alkaline phosphates activity may be increased. General measures for this last subgroup include routine nutritional advice and avoidance of further bone loss due to postmenopausal or involutional osteoporosis. High-dose vitamin D therapy in these disorders has caused nephrocalcinosis, nephrolithiasis, and renal insufficiency and must be avoided.

Osteomalacia Due to Vitamin D Disorders

Iron deficiency anemia, hypocalcemia, weight loss, glossitis, or pruritic rash and bone discomfort in a patient with low bone mineral density point to celiac disease even without gastrointestinal symptoms. These signs suggest the need to test for immunoglobulin A antiendomysial and antitissue transglutaminase antibodies. Cholestyramine therapy for cholestatic liver disease may increase malabsorption of vitamin D by binding bile salts. Laxative abuse may cause osteomalacia and severe resistance to vitamin D supplementation, including treatment with calcitriol. Advice on nutrition and sun exposure, discontinuation of offending drugs, adherence to a gluten-free diet, and pancreatic enzyme replacement may cure the mineralization defect in mild cases without the need for additional treatment.

Patients with severe disease will usually require vitamin D and calcium supplementation. Replacement doses depend on the serum 25-hydroxyvitamin D level, as shown in Table 244-2. Because pharmacologic doses of any vitamin D preparation carry the risk for vitamin D intoxication, increases in the dose must be made carefully. The interval between increments in dosage should be at least the time required to reach maximal effects plus about 50%. However, experience with the doses given in Table 244-2 indicates that serum 25-hydroxyvitamin D levels rarely reach 80 to 100 ng/mL. Vitamin D intoxication is unlikely even with of levels of 200 to 250 ng/mL. The goal is to raise the serum 25-hydoxyvitamin D level well above 30 ng/mL and restore the elevated parathyroid hormone concentration to normal without hypercalcemia or hypercalciuria. Urinary calcium excretion should be monitored when treatment has normalized the serum calcium level. The urinary calcium-to-creatinine ratio (mg/mg) should be kept below 0.22. Approximately 1 to 1.5 g/day of oral elemental calcium is a reasonable initial dose. Frequent small doses (three times a day) are more effective and tolerable than fewer larger ones, and the absorbability of calcium supplements is enhanced with meals. Most patient do well using the calcium preparations used for osteoporosis, such as calcium carbonate (40% calcium as in Os-Cal or the equivalent) or calcium citrate (21% calcium as in Caltrate or the equivalent). Some patients who cannot tolerate calcium carbonate or citrate experience fewer adverse gastrointestinal symptoms with the use of the chocolate or coffee-flavored formulations known as Viactiv (500 mg calcium per tablet). The vitamin D content of these calcium supplements is trivial in the treatment of osteomalacia.

TABLE 244-2 VITAMIN D PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

	VITAMIN D_3 (CHOLECALCIFEROL)	CALCITRIOL ($1,25[OH]_2D_3$)
Trade names	Calciferol, BIOTECH†	Calcitriol
Dosage form	Caps: 50,000 units = 1.25 mg	Caps: 0.25 and 0.50 µg
Dosage:		0.50-2.0 µg/day
If serum 25(OH)D = 20 to 30 ng/mL	50,000 units once a week × 10 weeks* and once a month thereafter	
If serum 25(OH)D = 10 to 20 ng/mL	50,000 units twice a week × 10 weeks* and twice a month thereafter	
If serum 25(OH)D = less than 10 ng/mL	50,000 units three times a week × 10 weeks* and three times a month thereafter	
Dosage in resistant cases	Up to 50,000 units per day	5-20 µg/day
Time to reach maximum effects	4-10 weeks	3-7 days
Persistence of effects after cessation	6-30 weeks	3-7 days
Cost in U.S.	$40/100 capsules of 50,000 units	$130/100 capsules of 0.25 µg $150/100 capsules of 0.5 µg

*If not >30 ng/mL after 10 weeks, exclude malabsorption, gluten enteropathy, and noncompliance. High-quality cholecalciferol, free from gluten, dairy, egg, fish nuts, soy, or artificial colors can be obtained from †BIOTECH at 1-800-345-1199. Weekly tanning bed treatments may be used if oral vitamin therapy fails or a switch to the more costly calcitriol may be necessary.
25(OH)D = 25-hydroxyvitamin D.

In patients with malabsorption, vitamin D requirements may increase during periods of increased diarrhea, and calcitriol may be easier for these patients to absorb. Its rapid onset of action and disappearance after cessation add to the safety of treatment, albeit at far greater cost. Calcium, phosphorus, potassium, magnesium, multivitamins, and gonadal steroids may also be beneficial in patients with malabsorption. Some patients do not tolerate any form of oral vitamin D, and the parenteral ergocalciferol preparations in North America are ineffective. These patients can be improved, although not restored to normal, by the use of weekly tanning bed treatments to areas of their bodies not normally exposed to the sun, an attempt to minimize solar-induced skin cancer. Calcitriol is the drug of choice in patients with the autosomal recessive disease, vitamin D–dependent rickets type I, in which the 1α-hydoxylase enzyme necessary to convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D is deficient. In vitamin D–dependent rickets type II, another rare autosomal recessive disease presenting with alopecia, diminished target sensitivity to 1,25-dihydroxyvitamin D may require extraordinarily high doses of calcitriol. If oral treatment fails, nocturnal infusions of calcium and phosphorus have been successful, providing additional evidence that the osteomalacia is due to inadequate calcium and phosphorus rather than the defect in vitamin D metabolism.

An increase in the serum alkaline phosphatase activity (the healing "flare") and a small increase in the serum and urine calcium levels are the earliest signs of effective treatment. Thereafter, the serum alkaline phosphatase activity level falls progressively as healing occurs. At the start of therapy, serum calcium levels should be measured at weekly intervals. If hypoalbuminemia is present, serum ionized calcium determinations are more useful. When therapy appears stabilized, biweekly or monthly intervals are usually sufficient for the first 3 or 4 months, but even with long-term therapy, measurements should be at least two to three times a year. In some patients with severe osteomalacia, bone pain and paresthesias may increase and the serum calcium levels decrease during the first few weeks of therapy. This is due to the increased skeletal avidity for mineral during healing and indicates the need for additional calcium supplementation.

Osteomalacia Due to Hypophosphatemia

Therapy of chronic hypophosphatemia is aimed at maintaining normal concentrations of serum phosphorus without inducing secondary hyperparathyroidism or nephrocalcinosis. This considerably difficult task requires divided doses of phosphorus supplements (1 to 3 g/day) and calcitriol (1 to 4 μg/day) to increase the absorption of phosphorus and try to prevent the increase in parathyroid hormone (Tables 244-2 and 244-3). If phosphorus-induced secondary hyperparathyroidism develops, the phosphorus supplements are rapidly excreted, and therapy thus is not only futile but also causes the additional bone disease of hyperparathyroidism. Baseline and yearly renal ultrasound examinations are necessary to recognize early nephrocalcinosis or nephrolithiasis.

X-linked hypophosphatemia (XLH) is the most common cause of chronic hypophosphatemia, and the presence of a positive family history, pediatric onset, and bowed legs usually substantiates the diagnosis. Treatment with an anti-FG23 antibody can raise serum phosphorus and 1,25 vitamin D levels,[A1] although the long-term benefits are not yet known. However, some hypophosphatemic patients have an autosomal dominant family history and present in adulthood with osteomalacia but without lower extremity deformities. Like patients affected with XLH, these patients may present with bone pain, pseudofractures, and high-normal or frankly elevated levels of fibroblast growth factor 23 (FGF23), a phosphaturic protein that interferes with 1-hydroxylation of 25-hydroxyvitamin D.[7] Patients with autosomal dominant hypophosphatemic osteomalacia (ADHR) appear to acquire the renal phosphate losses in adolescence or adulthood, whereas other patients with ADHR may lose the defect as they age. A diagnostic problem arises when a patient with chronic hypophosphatemia presents without a positive family history or bowed legs because this presentation resembles that of patients with oncogenic osteomalacia. This disorder is associated with a variety of small, hard to find, benign mesenchymal tumors that secrete FGF23.[8,9] The muscle pain, weakness, fractures, and osteomalacia characteristic of this syndrome are due to hypophosphatemia made worse by inappropriately low levels of 1,25-dihydroxy vitamin D. Oncogenic osteomalacia is also treated with phosphorus supplementation and calcitriol until the offending tumor can be located and resected. Improved tumor localization has been reported with positron emission tomography and computed tomography.[9-11] Surgical correction of deformities should be postponed until medical management achieves persistently normal levels of calcium, phosphorus, and alkaline phosphatase activity. An exception to this rule is an acute fracture of the femoral neck. Prompt surgical repair may be essential to avoid osteonecrosis. Oncogenic osteomalacia rarely occurs with malignant tumors that secrete FGF23, but unless surgical resection is complete, the osteomalacia will persist. Recent evidence suggests that tumors in surgically difficult locations may be treated by radiofrequency ablation.[12] Antacid-induced hypophosphatemia due to the ingestion of large quantities of phosphate-binding antacids has become rare with the increased availability of proton pump inhibitors but still occurs occasionally.

TABLE 244-3 PHOSPHATE PREPARATIONS FOR TREATMENT OF OSTEOMALACIA

PREPARATION	TABLET MARKINGS AND SHAPE	SODIUM CONTENT (mEq)	POTASSIUM CONTENT (mEq)	AMOUNT THAT CONTAINS 1 GRAM OF ELEMENTAL PHOSPHORUS
Neutra-Phos	0	28.5	28.5	4 unit dose caps*
Neutra-Phos-K	0	0	57.0	4 unit dose caps*
K-Phos Neutral	"Beach 11-25" oblong	50.4	4.6	4 tabs
K-Phos Original	"Beach 1111" round	0	33.0	9 tabs

*Each unit dose cap is reconstituted with 75 mL of water, fruit juice, or cola, and this formulation is preferred by children. The unit dose cap contains the powder concentrate and is not to be swallowed undiluted. Adults prefer the K-Phos Neutral tablets.

PREVENTION

Advice about vitamin D supplementation should help to prevent osteomalacia caused by vitamin D deficiency, but this has proved to be difficult because routine supplements may be inadequate and compliance with nutritional supplements is poor. The optimal vitamin D supplementation dosage is not clear, but most bone and mineral problems are avoided by 50,000 units of ergocalciferol given once monthly. Notable exceptions occur in patients with celiac disease, gastric surgery, or bypass for obesity, who often require much larger amounts (see Table 244-2). In patients with osteomalacia due to hypophosphatemia, the need for phosphorus supplementation may be lifelong. Rare exceptions occur in oncogenic osteomalacia if complete surgical removal or destruction of the tumor is accomplished.

PROGNOSIS

The response to appropriate treatment in most forms of osteomalacia is usually excellent. Improvements in bone pain and muscle weakness usually occur within 2 or 3 months, and healing of skeletal lesions occurs within 6 to 18 months. Depending on the quantity of excess osteoid, repeat bone mineral density determinations may show as much as 20% gains at the lumbar spine and total proximal femur. However, bone density at the radial diaphysis may not improve because of the irreversible loss of cortical bone resulting from prolonged secondary hyperparathyroidism. Furthermore, if decreased bone volume is present in addition to excess osteoid, skeletal recovery may be incomplete, and the risk for fractures may remain increased.

REVIEW QUESTIONS

1. Defective mineralization in osteomalacia is due to lack of one or more of the following except which one?

A. Adequate calcium and phosphorus at the remodeling site
B. Adequate amount of skeletal alkaline phosphatase
C. Normal pH at the site of calcification
D. Presence of a normal bone collagen matrix
E. Adequate level of fluoride

Answer: E Fluoride is an inhibitor of mineralization. See Pathobiology.

2. The correct sequence of steps involving bone remodeling is represented by which one of the following?

A. Reversal, activation, bone resorption by osteoclasts, osteoblast assembly and new bone formation
B. Activation, bone resorption by osteoclasts, reversal phase, osteoblast assembly and new bone formation
C. Bone resorption by osteoclasts, activation, osteoblast assembly and new bone formation, reversal
D. Activation, osteoblast assembly and new bone formation, bone resorption by osteoclasts, reversal
E. None of the above

Answer: B See Pathobiology.

3. All of the following may be signs or symptoms of osteomalacia except which one?

A. Nonspecific and poorly localized bone pain
B. Bone pain after sudden movements
C. Fasciculations and absent reflexes
D. Flat-footed waddling gait
E. Muscle weakness

Answer: C See Clinical Manifestations.

4. Excessive osteoid due to osteomalacia can be reliably distinguished from that caused by increased bone turnover by which one of the following?

A. Serum alkaline phosphatase
B. Presence of pseudofractures
C. Increased radionuclide on a bone scan
D. Phosphate level
E. Bone histomorphometry using tetracycline labels

Answer: E See Diagnosis.

5. A 30-year-old woman presents to her primary care physician with fatigue, generalized bone pains, weight loss, and a pruritic rash on her elbows and back. Laboratory studies show: hemoglobin 10 (male, 14-17 g/dL; female, 12-16 g/dL); serum iron 20 (60-160 µg/dL); serum calcium 8 (9-10.5 mg/dL). What is the next appropriate diagnostic test?

A. Bone mineral density scan
B. Hemoglobin electrophoresis
C. Colonoscopy
D. Antiendomysial immunoglobulin A antibodies
E. Skin biopsy

Answer: D The patient has gluten enteropathy, which may occur even without gastrointestinal symptoms. See Treatment.

THE PARATHYROID GLANDS, HYPERCALCEMIA AND HYPOCALCEMIA

RAJESH V. THAKKER

CALCIUM METABOLISM

A healthy adult body has a total of 1 kg of calcium; about 99% of this is present within the crystal structure of bone mineral, and less than 1% is in soluble form in the extracellular and intracellular fluid compartments. In the extracellular fluid compartment (ECF), about half of the total calcium is

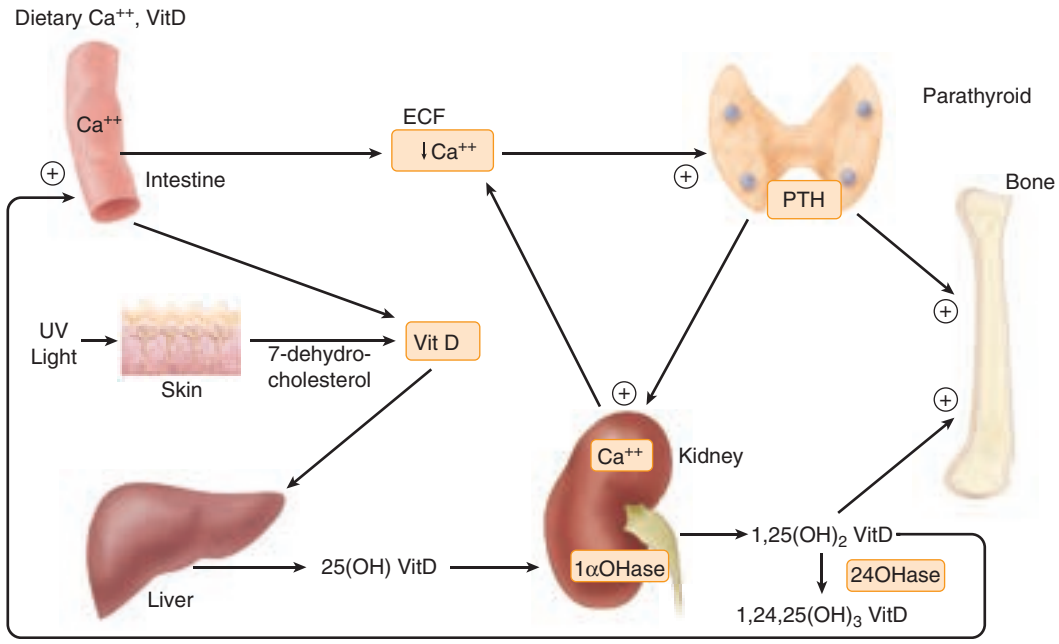

FIGURE 245-1. Regulation of extracellular fluid (ECF) calcium (Ca^{2+}) by parathyroid hormone (PTH) action on kidney, bone, and intestine. A decrease in ECF Ca^{2+} is sensed by the calcium-sensing receptor (see Fig. 245-2), and this leads to an increase in PTH secretion and a reduction in PTH degradation. The increased circulating PTH predominantly acts directly on kidney and bone that possess the PTH receptor (PTHR, Fig. 245-2). The skeletal effects of PTH are to increase (+) osteoclastic bone reabsorption. However, because osteoclasts do not have PTHRs, this action is mediated by the osteoblasts, which do have PTHRs and in response release cytokines and factors in turn that activate osteoclasts. In the kidney, PTH stimulates (+) the 1α-hydroxylase (1αOHase) to increase the conversion of 25-hydroxyvitamin D [25(OH)VitD] to the active metabolite 1,25-dihydroxyvitamin D [1,25$(OH)_2$VitD]. In addition, PTH increases (+) the reabsorption of Ca^{2+} from the renal distal tubule and inhibits the reabsorption of phosphate from the proximal tubule, thereby leading to hypercalcemia and hypophosphatemia. PTH also inhibits Na^+, H^+ antiporter activity and bicarbonate reabsorption, thereby causing a mild hyperchloremic acidosis. The elevated 1,25$(OH)_2$VitD acts on the intestine to increase (+) absorption of dietary calcium and phosphate. It is important to note that PTH does not appear to have a direct action on the gut. Thus, in response to hypocalcemia and the increase in PTH secretion, all of these direct and indirect actions of PTH on the kidney, bone, and intestine will help to increase ECF Ca^{2+}, which in turn will act through the calcium-sensing receptor to decrease PTH secretion. (From Thakker RV, Bringhurst FR, Jüppner HH. Regulation of calcium homeostasis and genetic disorders that affect calcium metabolism. In: Jameson JL, De Groot LJ, giudice LC, et al., eds. *Endocrinology: Adult & Pediatric.* 7th ed. Philadelphia: Saunders; 2016.)

ionized, and the rest is principally bound to albumin or complexed with counter-ions. Ionized calcium in the ECF plays an important role in many physiologic pathways, including muscle contraction, secretion of neurotransmitters and hormones, and coagulation pathways. Ionized serum calcium concentrations range from 4.65 to 5.25 mg/dL (1.16 to 1.31 mmol/L), and the total serum calcium concentration ranges from 8.5 to 10.5 mg/dL (2.12 to 2.62 mmol/L).[1] However, the usual 2 : 1 ratio of total to ionized calcium may be disturbed by disorders such as metabolic acidosis, which reduces calcium binding by proteins, or by changes in protein concentration, caused by cirrhosis, dehydration, venous stasis, or multiple myeloma1. In view of this, total serum calcium concentrations are adjusted, or "corrected," to a reference albumin concentration: the actual total serum calcium value is adjusted by adding or subtracting 0.8 mg/dL (0.016 mmol/L) for every 1 g/dL (1 g/L) of albumin below or above a reference albumin concentration of 4 g/dL (40 g/L), respectively.

The control of body calcium involves a balance between the amounts that are absorbed from the gut, deposited into bone and into cells, and excreted from the kidney (Fig. 245-1).[2] This fine balance, involving three organs, is chiefly under the control of parathyroid hormone (PTH), which is synthesized and secreted by the parathyroid glands. Hypocalcemia leads to an increased secretion of PTH, whereas hypercalcemia results in diminished PTH secretion. Regulation of extracellular calcium takes place through complex interactions (Fig. 245-2) at the target organs of the major calcium-regulating hormone, PTH, and vitamin D and its active metabolites, 1,25-dihydroxyvitamin D (1,25$[OH]_2$D).

PARATHYROID GLANDS, PARATHYROID HORMONE, *PTH* GENE, AND PARATHYROID HORMONE ACTIONS

Parathyroid Glands

There are usually four parathyroid glands, which are located in close proximity to the superior and inferior poles of the lobes of the thyroid gland. The superior parathyroids are derived from the endoderm of the embryonic fourth pharyngeal pouches, and the inferior parathyroids are derived with the thymus from the endoderm of the third pharyngeal pouches. Extra parathyroid glands are commonly found in aberrant locations along this migrating path and also within the thymus and thyroid. Parathyroid cells express a G protein–coupled receptor (GPCR), referred to as the *calcium-sensing receptor* (CaSR), that detects changes in extracellular calcium and leads to alterations in PTH secretions.[3] For example, activation of the CaSR, which is also expressed in renal tubular cells, as a result of elevated extracellular calcium concentrations causes G protein–dependent stimulation of phospholipase C activity through Gαq and Gα11, which leads to accumulation of inositol 1,4,5-trisphosphate and an increase in intracellular calcium concentrations.[4] These changes, in turn, lead to reduced circulating PTH concentrations and increased urinary calcium excretion. Disorders of the parathyroid glands may cause hypercalcemia or hypocalcemia, and these can be classified according to whether they arise from an excess of PTH, its deficiency, or insensitivity to its effects (Table 245-1; see Fig. 245-2).

Parathyroid Hormone and *PTH* Gene

The mature PTH peptide is encoded by the *PTH* gene and secreted from the parathyroid chief cells as an 84–amino acid peptide; however, when the *PTH* mRNA is first translated, it is as pre-proPTH peptide. The "pre" sequence consists of a 25–amino acid signal peptide (leader sequence) that is responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell. The "pro" sequence is 6 amino acids in length and, although its function is less well defined than that of the "pre" sequence, is also essential for correct PTH processing and secretion. After the 84–amino acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of about 2 minutes, by nonsaturable hepatic uptake and renal excretion.

Parathyroid Hormone Actions

PTH shares a receptor with PTH-related peptide (PTHrP); this PTH/PTHrP receptor (see Fig. 245-2) is a member of a subgroup of the G protein–coupled receptor family.[5] PTH/PTHrP receptors are expressed in kidney and bone, where PTH is its predominant agonist, and thus PTH acts directly on kidney and bone cells and indirectly on intestinal cells (see Fig. 245-1) to enhance renal calcium reabsorption, release stored calcium in bones into the ECF, and increase gut calcium absorption, respectively. Expression of the PTH/PTHrP receptor also occurs in the brain, heart, skin, lung, liver, and testis, where it mediates the actions of PTHrP. Mutations

PTH is an 84–amino acid peptide encoded by the *PTH* gene, which is located on chromosome 11p15 and consists of three exons (transcribed regions) that are separated by two introns. Exon 1 of the *PTH* gene is 85 base pairs (bp) in length and is untranslated, whereas exons 2 and 3 code for the 115–amino acid pre-proPTH peptide. Exon 2 is 90 bp in length and encodes the initiation (ATG) codon, the prehormone sequence, and part of the prohormone sequence. Exon 3 is 612 bp and encodes the remainder of the prohormone sequence, the mature PTH peptide, and the 3′ untranslated region. The 5′ regulatory sequence of the human *PTH* gene contains a vitamin D response element 125 bp upstream of the transcription start site, which downregulates *PTH* messenger RNA (mRNA) transcription in response to vitamin D receptor binding. *PTH* gene transcription (as well as PTH peptide secretion) is also dependent on the extracellular calcium concentration, although the presence of a specific upstream "calcium response element" has not yet been demonstrated.

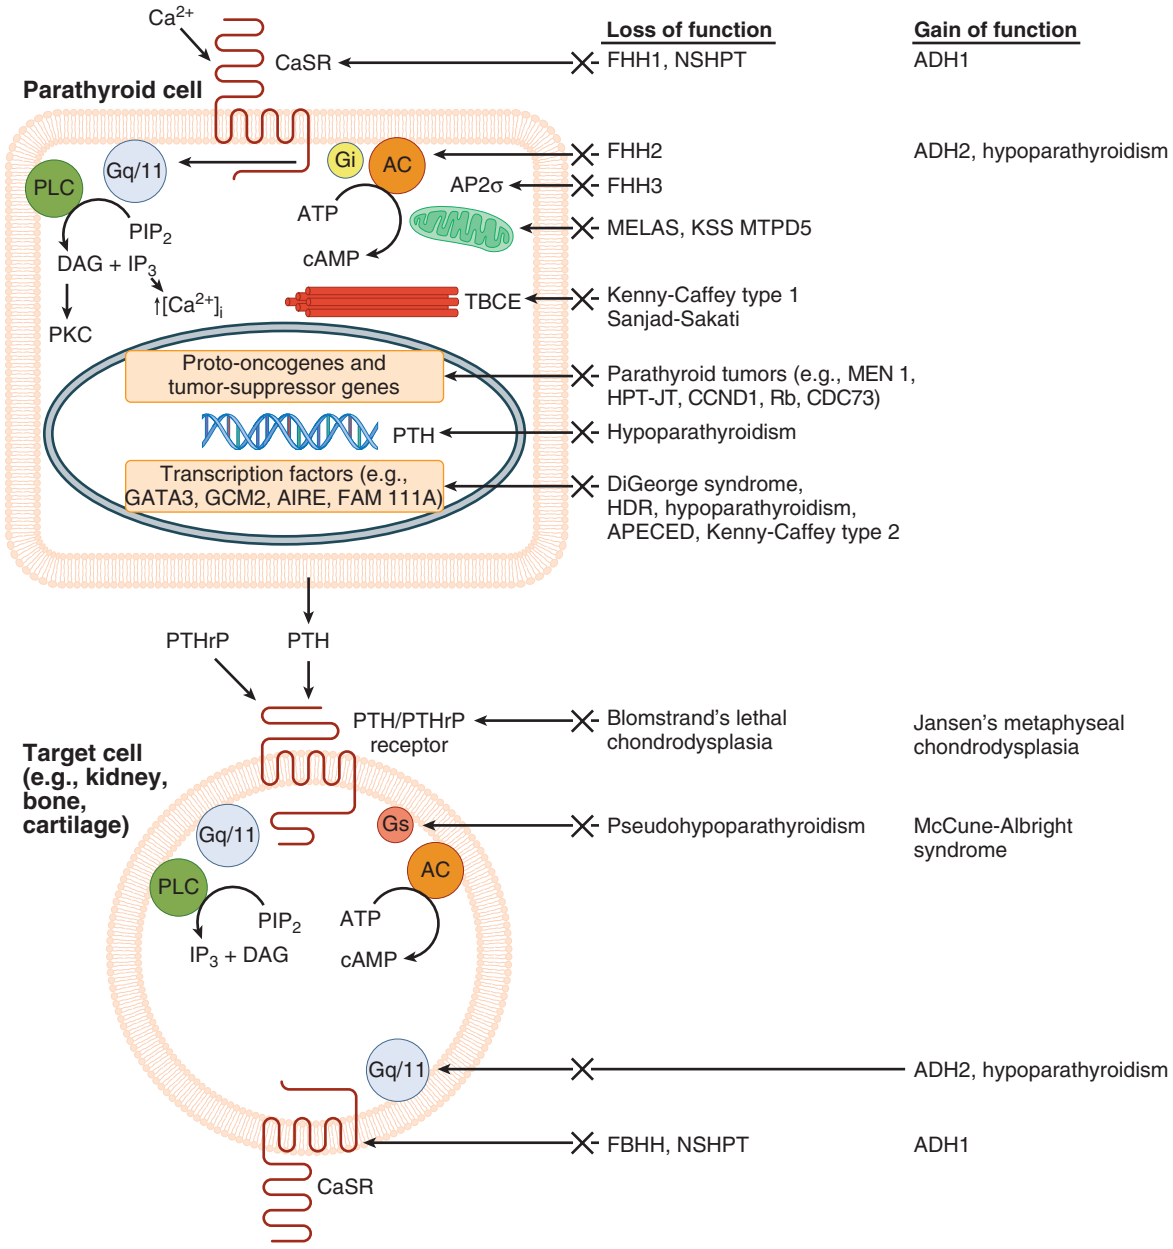

FIGURE 245-2. Schematic representation of some of the components involved in calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (CaSR), which is a 1078–amino acid G protein–coupled receptor. The PTH/PTHrP receptor, which mediates the actions of PTH and PTHrP, is also a G protein–coupled receptor. Thus, Ca^{2+}, PTH, and PTHrP involve G protein–coupled signaling pathways, and interaction with their specific receptors can lead to activation of Gs, Gi, and Gq, respectively. Gs stimulates adenylcyclase (AC), which catalyzes the formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). Gi inhibits AC activity. cAMP stimulates protein kinase A (PKA), which phosphorylates cell-specific substrates. Activation of Gq stimulates phospholipase C (PLC), which catalyzes the hydrolysis of the phosphoinositide (PIP_2) to inositol triphosphate (IP_3), which then increases intracellular calcium, and diacylglycerol (DAG), activating protein kinase C (PKC). These proximal signals modulate downstream pathways, which result in specific physiologic effects. Loss of function in several genes, shown with their respective sites of action on the right, has been identified in specific disorders of calcium homeostasis (also see Table 245-1). (From Thakker RV, Bringhurst FR, Jüppner H. Regulation of calcium homeostasis and genetic disorders that affect calcium metabolism. In: Jameson JL, De Groot LJ, giudice LC, et al., eds. *Endocrinology: Adult & Pediatric.* 7th ed. Philadelphia: Saunders; 2016.)

involving the genes that encode these proteins and receptors in this calcium-regulating pathway (see Fig. 245-2) are associated with hypercalcemic and hypocalcemic disorders (see Table 245-1).

Renal Actions

Calcium is absorbed at multiple sites and by different mechanisms, which include passive paracellular or active transcellular transport, along the renal tubule.[2] The renal actions of PTH are to (1) stimulate activity of the proximal tubular cell 1α-hydroxylase; (2) increase reabsorption of calcium by the cells of the distal tubule, connecting tubules and the thick ascending loop of Henle (TAL); and (3) inhibit phosphate reabsorption by proximal tubular cells (see Fig. 245-1). PTH increases the formation of biologically active $1,25(OH)_2D$ from its precursor 25-OH-D by stimulating the activity of the renal 1α-hydroxylase and inhibiting the 24-hydroxylase, which metabolizes $1,25(OH)_2D$ to the inactive $24,25(OH)_2D$ form (see Fig. 245-1). PTH regulates calcium reabsorption by distal tubular cells by upregulating expression of the transient receptor potential vanilloid 5 (TRPV5), thereby promoting calcium entry into the cell, and increasing calbindin-D28K expression to enhance transcellular calcium reabsorption by increased buffering of subapical Ca^{2+} ions. In the TAL, PTH may increase active transcellular transport of calcium, as well as paracellular calcium transport, by augmenting the transepithelial voltage gradient. Phosphate transport in proximal tubular cells is mediated by the luminal membrane sodium-phosphate cotransporters 2a and 2c (NPT2a and NPT2c), and PTH actions lead to internalization and degradation of NPT2a and NPT2c, thereby resulting in decreased reabsorption of phosphate.

Skeletal Actions

PTH acts directly on osteoblasts and indirectly on osteoclasts to increase their numbers and activity, thereby enhancing bone turnover and release of stored calcium. Thus, PTH increases the size of the osteoblast precursor pool, increases the bone-forming activity of mature osteoblasts, and stimulates

TABLE 245-1 PARATHYROID DISEASES AND THEIR CHROMOSOMAL LOCATIONS

METABOLIC ABNORMALITY	DISEASE	INHERITANCE	GENE/GENE PRODUCT	CHROMOSOMAL LOCATION
HYPERCALCEMIA

*Mutations of PTH gene are identified only in some families.
†Most likely inheritance.

osteoblasts to release cytokines such as colony-stimulating factor 1 and receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), which stimulate the formation of new osteoclasts and activate mature osteoclasts. PTH also inhibits osteoblast production of osteoprotegrin (OPG), which is a soluble decoy receptor for RANKL that inhibits osteoclast development. Calcium transport involves TRPV4 and TRPV5 in bone cells; TRPV4 regulates intracellular calcium concentrations in osteoblasts and osteoclasts, whereas TRPV5, expressed in osteoclasts, participates to remove the mineral bone matrix.[2] The net result of persistent elevations of PTH is linked to an increase in osteoclast activity more than osteoblast activity, hence liberating the stores of calcium to the ECF (see Fig. 245-1).

Intestinal Actions

Calcium is absorbed throughout the intestine by passive paracellular routes and active transcellular routes, which involve TRPV6 and calbindin D9K. PTH exerts indirect actions on intestinal calcium absorption by increasing the circulating $1,25(OH)_2D$ concentrations (see Fig. 245-1). The increased $1,25(OH)_2D$ concentrations increase TRPV6 expression, which facilitates enhanced calcium entry into the cell from the lumen, and cytosolic calbindin D9K expression, which facilitates transcellular transport of calcium.

HYPERCALCEMIA

DEFINITION

Hypercalcemia is defined as a serum calcium concentration greater than 2 standard deviations above the normal mean, and this is usually a total serum calcium above 10.5 mg/dL (2.62 mmol/L) and an ionized serum calcium of above 5.25 mg/dL (1.31 mmol/L). There is no formal grading system for defining the severity of hypercalcemia, but mild, moderate, and severe hypercalcemia is generally considered for total serum calcium concentrations less than 12 mg/dL (3 mmol/L), between 12 and 14 mg/dL (3 to 3.5 mmol/L), and greater than 14 mg/dL (3.50 mmol/L), respectively.

PATHOBIOLOGY

Hypercalcemia may arise through one of three mechanisms: increased bone resorption, increased gastrointestinal absorption of calcium, and decreased renal calcium excretion (see Fig. 245-1). For example, lytic bone metastases cause increased bone resorption; thiazide diuretics lead to a decrease in calcium excretion; and excessive PTH will either directly or indirectly, by increasing $1,25(OH)_2D$ production, stimulate bone resorption and calcium

absorption from the gut and renal tubules.[6] The causes of hypercalcemia may be classified according to whether serum PTH concentrations are elevated (i.e., primary or tertiary hyperparathyroidism due to parathyroid tumors) or reduced (i.e., not due to parathyroid tumors but instead to an excessive production of PTHrP by a cancer; a defect in the PTH receptor, for example, the PTH/PTHrP receptor; an excess production of downstream mediators, for example, $1,25(OH)_2D$; or an altered set point in the calcium-sensing receptor) (Table 245-2; see Fig. 245-2). Primary hyperparathyroidism and malignancy are the most common causes and account for more than 90% of patients with hypercalcemia. Detailed clinical history and examination will usually help to differentiate between these two diagnoses. In primary hyperparathyroidism, the hypercalcemia is often less than 12 mg/dL (3 mmol/L), asymptomatic, and may have been present for months or years. If symptoms, such as nephrolithiasis, are present, then they have usually been present for several months. However, in malignancy, the patients are usually acutely ill, often with neurologic symptoms; the hypercalcemia is more than 12 mg/dL (3 mmol/L); and the cancer (e.g., lung, breast, or myeloma) is often readily apparent. Hypercalcemia from causes other than primary hyperparathyroidism or malignancy may also occur (see Table 245-2), and a careful history (e.g., for vitamin D ingestion, drugs, renal disease) and examination (e.g., for thyrotoxicosis, adrenal disease, granulomatous diseases), together with appropriate investigations (Table 245-3; Fig. 245-3), are essential for establishing the diagnosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of hypercalcemia varies from a mild, asymptomatic, biochemical abnormality detected during routine screening to a life-threatening medical emergency. In general, the presence or absence of symptoms correlates with the severity and rapidity of onset of the hypercalcemia. Thus, symptoms do not usually develop when serum calcium is below 12 mg/dL (3 mmol/L) and are invariably present when the hypercalcemia exceeds 14 mg/dL (3.5 mmol/L). However, there is a considerable variability, and some patients may be symptomatic with mild hypercalcemia. Although there are many causes of hypercalcemia (see Table 245-2), the signs and symptoms of hypercalcemia are similar, regardless of etiology. Indeed, the clinical manifestations of hypercalcemia involve several organ systems that include the renal, musculoskeletal, gastrointestinal, neurologic, and cardiac systems (Table 245-4), and many of these have been referred to as "moans, groans, pains, and stones." Investigations should be directed at confirming the presence of hypercalcemia and establishing the cause (Table 245-5; see Table 245-3).

TABLE 245-2 CAUSES OF HYPERCALCEMIA

HIGH PARATHYROID HORMONE LEVELS

Primary hyperparathyroidism* (adenoma, hyperplasia, or carcinoma): nonfamilial or familial, e.g., MEN 1, MEN 2, HPT-JT, FIHP
Tertiary hyperparathyroidism (hyperplasia or adenoma in chronic renal failure)

LOW PARATHYROID HORMONE LEVELS

Malignancy*
- Primary
  - Parathyroid hormone–related peptide (PTHrP): carcinoma of lung, esophagus, renal cell, ovary, and bladder
  - Excess production of $1,25(OH)_2D$ (lymphoma)
- Secondary
  - Lytic bone metastases* (multiple myeloma* and breast carcinoma*)
  - Other location, ectopic factors (e.g., cytokines)

Excess vitamin D
- Exogenous vitamin D toxicity by parent D compound, 25(OH) vitamin D_3, or $1,25(OH)_2$ vitamin D_3 in vitamin preparations, cod liver oil, herbal medicines
- Endogenous production of 25(OH) vitamin D_3—Williams syndrome
- Endogenous production of $1,25(OH)_2$ vitamin D_3, e.g., granulomatous disorders (sarcoidosis, HIV, TB, histoplasmosis, coccidioidomycosis, leprosy), lymphoma, and infantile hypercalcemia

Drugs
- Thiazide diuretics
- Lithium
- Total parenteral nutrition
- Estrogens/antiestrogens, testosterone
- Milk-alkali syndrome
- Vitamin A toxicity
- Aluminum intoxication (in chronic renal failure)
- Aminophylline

Nonparathyroid endocrine disorders
- Thyrotoxicosis
- Pheochromocytoma
- Acute adrenal insufficiency
- Vasoactive intestinal polypeptide hormone producing tumor (VIPoma)
- Immobilization

INAPPROPRIATE PARATHYROID HORMONE LEVELS DUE TO ALTERED SET POINT

Familial benign hypocalciuric hypercalcemia (FBH or FHH)

*Most common causes.
FIHP = familial isolated hyperparathyroidism; HIV = human immunodeficiency virus; HPT-JT = hyperparathyroidism with jaw tumors; MEN = multiple endocrine neoplasia; TB = tuberculosis.

TABLE 245-3 PRELIMINARY INVESTIGATIONS FOR HYPERCALCEMIA

BLOOD

× 2-3 estimations of serum calcium, phosphate, albumin, urea and electrolytes, creatinine, alkaline phosphatase, liver function tests
Parathyroid hormone
Complete blood count
Electrophoretic protein strip or serum protein electrophoresis
25-OH-D_3 (and if indicated, $1,25[OH]_2D_3$)
Thyroid function tests
Magnesium
Parathyroid hormone–related peptide (if malignancy suspected)

URINE

× 2-3 estimations of 24-hr urinary calcium and creatinine clearance, and clearance ratios

Imaging
- Chest radiograph
- Radiograph of hands
- Ultrasound of kidneys

TABLE 245-4 CLINICAL FEATURES OF HYPERCALCEMIA

Renal
- Stones (nephrolithiasis) and nephrocalcinosis, polyuria, polydipsia

Musculoskeletal
- Bone pain, osteopenia, fractures, muscular weakness, especially proximal myopathy

Gastrointestinal
- Nausea, vomiting, lack of appetite, constipation, peptic ulcers, and pancreatitis

Neurologic
- Tiredness, lethargy, inability to concentrate, increased sleepiness, depression, confusion, coma

Cardiac
- Bradycardia, first-degree atrioventricular block, arrhythmias, shortened QT interval

TABLE 245-5 SUMMARY OF GUIDELINES FOR PARATHYROID SURGERY IN PRIMARY HYPERPARATHYROIDISM PATIENTS

Surgery* recommended if patient meets any one of the following criteria:
- Serum calcium >1 mg/dL (0.25 mmol/L) above upper limit of normal
- Any complication of primary hyperparathyroidism (e.g., nephrolithiasis† or bone erosions of osteitis fibrosa cystica)
- An episode of acute primary hyperparathyroidism with life-threatening hypercalcemia
- Significant reduction in creatinine clearance (i.e., <60 mL/min)
- Reduction in bone mineral density (i.e., T score <–2.5, and/or previous fracture fragility)
- Age <50 years

*Surgery is also indicated in patients for whom medical surveillance is neither desired nor possible.
†Some physicians still regard marked hypercalciuria (>9 mmol/L per 24 hr or >400 mg/24 hr) as an indication for surgery.
Adapted from Bilezikian JP, Khan AA, Potts JT Jr. Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the third international workshop. *J Clin Endocrinol Metab.* 2009;94:335-339.

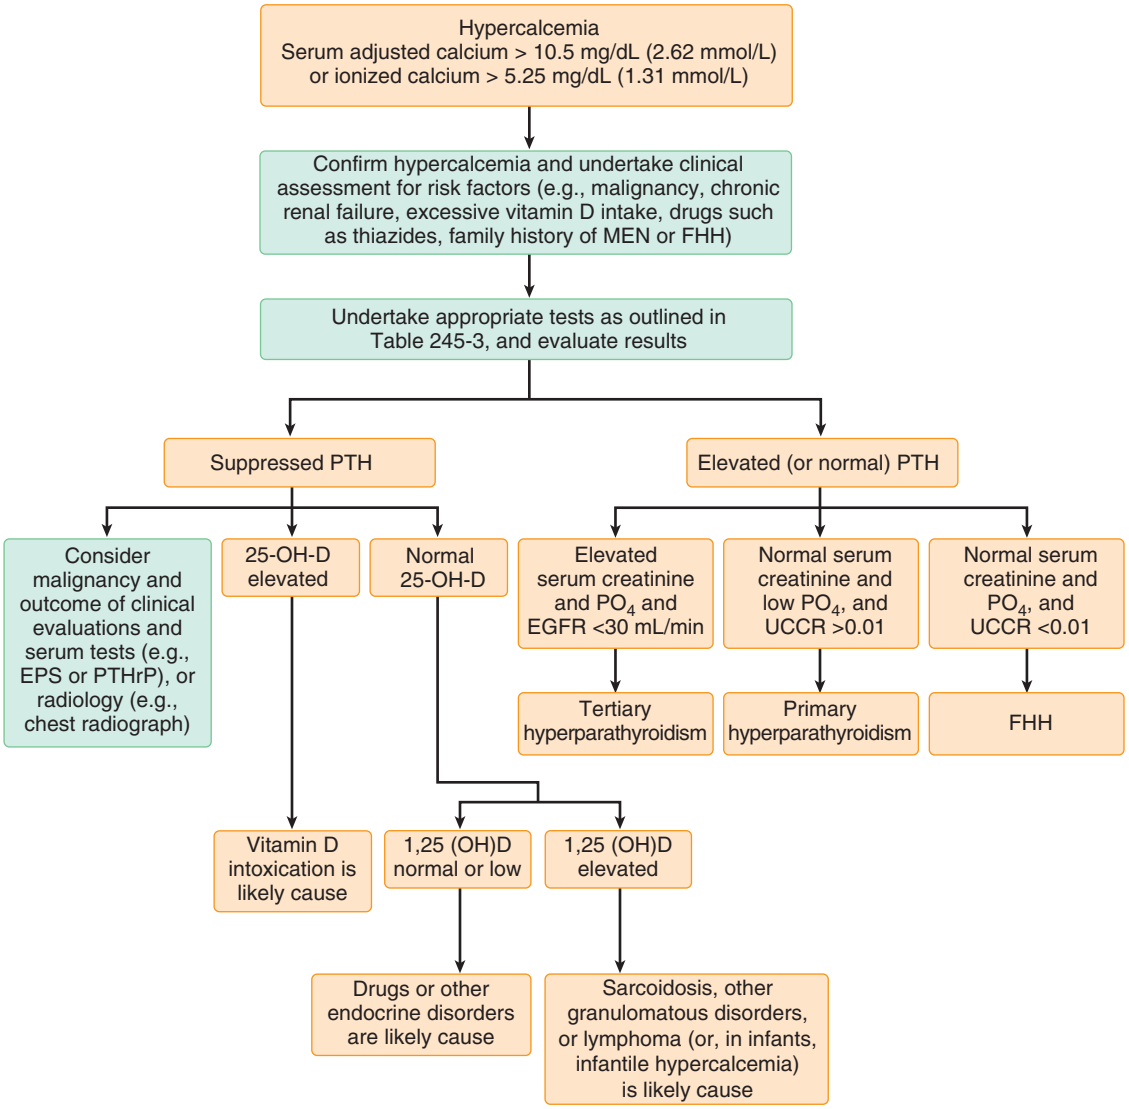

FIGURE 245-3. **Clinical approach to the investigation of causes of hypercalcemia. $1,25(OH)_2D$ = 1,25-dihyroxyvitamin D; 25-OH-D = 25-hydroxyvitamin D; EGFR = estimated glomerular filtration rate; EPS = electrophoretic strip (serum protein electrophoresis); FHH = familial hypocalciuric hypercalcemia; MEN = multiple endocrine neoplasia; PTH = parathyroid hormone; PTHrP = parathyroid hormone–related peptide; UCCR = 24-hour urinary calcium clearance–to–creatinine clearance ratio.**

TREATMENT

Rx

The treatment of hypercalcemia depends on the severity of the hypercalcemia and the presence of symptoms. Thus, asymptomatic patients with mild hypercalcemia do not usually need urgent treatment, whereas patients with severe hypercalcemia would require treatment regardless of symptoms, and patients with moderate hypercalcemia would require urgent treatment if symptomatic. Before instituting treatment, it is always important to consider the underlying causes (see Table 245-2) and to initiate investigations (see Table 245-3). In addition, drugs such as thiazides and vitamin D compounds, which cause hypercalcemia, should be discontinued and, if appropriate, dietary calcium restricted.

The acute management of hypercalcemia involves general measures to enhance hydration and diuresis and specific measures using drugs to lower serum calcium. Dehydration due to hypercalcemic symptoms, such as anorexia, nausea, vomiting, and polyuria because of defective urinary concentration, is very common, and patients may require 5 to 10 liters of 0.9% sodium chloride over a 24- to 48-hour period. This vigorous hydration with normal saline may lower serum calcium by 1 to 3 mg/dL (0.25 to 0.75 mmol/L); it enhances urinary calcium excretion by increasing glomerular filtration and reducing proximal and distal renal tubular reabsorption of calcium and sodium. This saline diuresis may need adjuvant therapy with a loop diuretic (e.g., furosemide, 10 to 20 mg), as necessary to control complications due to volume overload, especially in elderly patients and those with impaired cardiovascular and renal function. Note that excessive use of furosemide before intravascular volume has been restored may worsen the hypercalcemia by exacerbating volume depletion. Saline diuresis may lead to hypokalemia, hypomagnesemia, and electrolyte imbalance, which will need correction.

If saline diuresis is not successful, particularly if the hypercalcemia is very severe, then more specific measures, such dialysis and/or drugs, will be required. The drugs of choice are pamidronate and zoledronic acid, which are potent bisphosphonates, but these should not be used if the hypercalcemia is due to primary or tertiary hyperparathyroidism. Recommended treatments are to administer pamidronate (15-60 mg, depending on serum calcium concentration, in a single IV infusion or in divided doses, depending upon renal function and responses, over 2-4 days; maximum of 90 mg per treatment course) or zoledronic acid (4 mg as single IV infusion). Other bisphosphonates (e.g., etidronate and clodronate) and other agents, such as mithramycin, calcitonin, and gallium nitrate, have also been used in the past. Glucocorticoid therapy (e.g., hydrocortisone, 120 mg/day in three divided doses, in adults) is particularly effective when the hypercalcemia is mediated by the actions of $1,25(OH)_2D$, for example in granulomatous disease or lymphoma, or myeloma. Dialysis using a low or zero calcium dialysate should be considered if these treatments are not effective or if the patient has renal failure. When the acute management of hypercalcemia has been completed, appropriate treatment for the underlying cause needs to be undertaken.

HYPERPARATHYROIDISM

DEFINITION

Hyperparathyroidism is characterized by high concentrations of serum immunoreactive PTH, and three types, referred to as primary, secondary, and tertiary, are recognized. Primary and tertiary hyperparathyroidism are associated with hypercalcemia (see Table 245-2), whereas secondary

hyperparathyroidism is associated with hypocalcemia (see later). Primary hyperparathyroidism usually occurs as an isolated nonsyndromic endocrinopathy and less commonly as part of complex syndromic disorders such as the multiple endocrine neoplasia (MEN)[7] and hyperparathyroidism with jaw tumors (HPT-JT). Syndromic and nonsyndromic forms of primary hyperparathyroidism may also occur as hereditary (i.e., familial), usually autosomal dominant disorders, or they may occur as nonfamilial (i.e., sporadic) diseases. Tertiary hyperparathyroidism usually arises in association with chronic renal failure.

Primary Hyperparathyroidism

EPIDEMIOLOGY

Primary hyperparathyroidism, which affects 3 in 1000 adults, is one of the two most common causes of hypercalcemia and is due to an excessive secretion of PTH from one or more parathyroid tumors. Studies have estimated that the global prevalence of parathyroid tumors is 4 million. Primary hyperparathyroidism usually occurs as a nonsyndromic isolated endocrinopathy, between the ages of 40 and 65 years, and is three times more common in females than males.

PATHOBIOLOGY

Eighty percent of patients with primary hyperparathyroidism will have a solitary parathyroid adenoma, and 15 to 20% of patients will have hyperplasia involving all four parathyroid glands. Parathyroid carcinoma occurs in less than 0.5% of patients with primary hyperparathyroidism. The underlying causes of primary hyperparathyroidism are largely unknown. However, more than 10% of patients with clinically nonfamilial primary hyperparathyroidism occurring before 45 years of age have a germline mutation in 1 of 11 genes, including those of MEN 1 (*MEN1*), cell division cycle 73 (*CDC73*), and *CaSR*. In addition, studies of nonfamilial sporadic parathyroid adenomas have shown that 35% to 50% have somatic mutation of the *MEN1* gene; 15% have overexpression of cyclin D1; and more than 85% have an abnormality of the Wnt/β-catenin pathway.[8,9]

CLINICAL MANIFESTATIONS

Many patients with primary hyperparathyroidism are asymptomatic, and the hypercalcemia, which is usually mild, is detected by chance at the time of biochemical screening for other reasons.[10,11] However, it is important to note that nearly half the patients have subtle neuromuscular symptoms such as fatigue and weakness, and this becomes apparent only in retrospect after a successful parathyroidectomy.

Symptomatic hypercalcemia (see Table 245-4) predominantly affects the skeletal, renal, and gastrointestinal systems; peptic ulcers and pancreatitis may develop. The skeletal changes of osteitis fibrosa cystica due to subperiosteal resorption of the distal phalanges, tapering of the distal clavicles, a salt-and-pepper appearance of the skull, bone cysts, and brown tumors of the long bones are now identified in less than 5% of patients. However, osteopenia, as assessed by bone mineral density, occurs in 25% of patients. Renal stone disease (nephrolithiasis and nephrocalcinosis) occurs in 20% of patients, and hypercalciuria occurs in 30% of patients; renal impairment may complicate this disease.

DIAGNOSIS

In the presence of hypercalcemia, the finding of elevated circulating PTH concentrations establishes the diagnosis because PTH is elevated in approximately 90% of patients with primary hyperparathyroidism, who invariably have hypercalcemia (see Fig. 245-3). However, it is important to make sure that the immunoradiometric (IRMA) and immunochemiluminometric (ICMA) assays for PTH are being used to measure the intact molecule, rather than the older radioimmunoassays, which were not as reliable. The only other hypercalcemic disorders in which PTH may occasionally be elevated are those related to familial benign hypocalciuric hypercalcemia (FBH or FHH), immobilization, or lithium or thiazide use (see Table 245-2), and a careful history and a cessation of drug use helps to exclude these possibilities.[12,13] The hypercalcemia of primary hyperparathyroidism, unlike that of malignancy or granulomatous disease, is usually not suppressible by a 10-day course of oral hydrocortisone (120 mg/day given in three divided doses). This test, referred to as the *steroid suppression test,* was previously used to differentiate primary hyperparathyroidism from other causes of hypercalcemia; however, with the advent of more reliable PTH assays, this test is rarely used now. About one third of patients with primary hyperparathyroidism have a low serum phosphate level (see Fig. 245-3), and in the others, it is in the lower range of normal. In addition, some patients have a small increase in serum chloride concentration and a concomitant decrease in bicarbonate concentration. Serum alkaline phosphatase activity may be elevated in some patients, and urinary calcium excretion is increased in 30% of patients. The circulating $1,25(OH)_2D$ concentration is elevated in some patients with primary hyperparathyroidism, although it is not of diagnostic value because it is also elevated in other hypercalcemic disorders such as sarcoidosis and lymphomas (see Fig. 245-3). The serum 25-OH-D concentration is within the normal range. Densitometric scanning is of use in detecting early skeletal changes. Patients with primary hyperparathyroidism develop reduced bone mineral densities (osteopenia) primarily of the cortical bone (e.g., distal third of forearm) rather than the cancellous bone (e.g., lumbar spine). The hip bones, which are an equal mixture of cortical and cancellous bone, show intermediate reductions in bone mineral density. Overall, the risk for bone fractures in patients with mild primary hyperparathyroidism is similar to those in matched, normal controls. However, successful parathyoidectomy does lead to an increase in bone mineral density over a 6- to 12-month period, and this continues for up to 10 years. Indeed, bone mineral density measurements are used in the evaluation of patients with primary hyperparathyroidism and in deciding on conservative as opposed to surgical management (see Table 245-5).

Preoperative localization to define the sites of the parathyroid tumors may be undertaken.[14] The noninvasive tests consist of ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy with technetium-99m sestamibi. Sestamibi scintigraphy has now become established as the best and most convenient localization test; this can be performed with CT techniques (e.g., single-photon emission computed tomography [SPECT]) to give a three-dimensional image with greater anatomic resolution. It is important to note that there is an appreciable incidence of false-positive rates with all the noninvasive localization procedures, so a confirmation using two methods is preferable. Invasive localization tests consist of arteriography and selective venous sampling for PTH in the veins draining the thyroidal region. These tests are time consuming, expensive, difficult, and dependent on the skill of the radiologist. It is generally accepted that these preoperative localization tests are indicated in those patients who have had previous neck surgery. However, their role in patients who have not had prior surgery remains to be established, and at present, the preferences and expertise of the local medical, radiology, and surgery teams usually determine the use of venous sampling procedures.

TREATMENT

Rx

Parathyroidectomy, which is the definitive cure, is a generally successful and safe procedure if undertaken by an experienced surgeon. There have also been major advances in surgery that have facilitated a surgical approach to be undertaken under local, as opposed to general, anesthesia. An example of this is the use of minimally invasive parathyroidectomy (MIP) in the patient with single gland disease that has been successfully localized by the combined use of sestamibi scintigraphy and ultrasonography. Surgery is recommended for symptomatic patients and for those who have skeletal and renal complications (see Table 245-5). Complications of parathyroid surgery include damage to the recurrent laryngeal nerve and permanent hypoparathyroidism. However, the decision to recommend surgery may be difficult in asymptomatic patients, who may constitute more than 50% of patients with primary hyperparathyroidism. The natural history of primary hyperparathyroidism in most patients is to progress slowly or not at all. For example, among asymptomatic patients, only 25% have progressive disease, which is usually manifested as a decrease in bone mineral density during a 10-year period. This has led to a controversy regarding the indications for surgery, and guidelines have been provided by the Third International Workshop (2008) on the Management of Asymptomatic Primary Hyperparathyroidism (see Table 245-5). However, these guidelines may not exclusively influence the decision for or against surgery, and a careful evaluation and assessment of the risks and benefits is considered by most medical and surgical teams in conjunction with the patient. Clearly, some patients will not wish to continue living with a curable disease and will prefer surgery despite the guidelines (see Table 245-5), whereas other patients will decline surgery, despite having guideline indications for surgery, because they may have coexisting medical conditions that make them feel that the risks for surgery are too great.

Patients who do not undergo parathyroidectomy should be evaluated clinically and also monitored for serum calcium, creatinine, and PTH at 12-month intervals, and for bone mineral density at 12- to 24-month intervals. In addition, the following medical guidelines are recommended. First, they should avoid dehydration and remain ambulant. Second, the dietary intake of calcium should be moderate, that is, at or below 1000 mg/day, and thiazide diuretics

should be avoided. Finally, they should avoid herbal and tonic remedies that may contain vitamin D or vitamin A. Drugs that have been used for the treatment of primary hyperparathyroidism include oral phosphate, estrogens, or selective estrogen receptor modulators (SERMs) in postmenopausal women; bisphosphonates; and the calcimimetic, cinacalcet. Phosphate is not used because of concerns related to soft tissue ectopic calcification. Estrogens and SERMs (e.g., raloxifene) do increase bone density in postmenopausal women with primary hyperparathyroidism, but they have only small effects on the serum calcium and PTH concentrations. The bisphosphonates (e.g., alendronate and zoledronic acid) inhibit bone resorption and reduce serum calcium. However, these effects are not sustained. In a randomized, double-blind, placebo-controlled clinical trial, cinacalcet was effective in lowering serum calcium concentrations to normal values and reducing PTH levels in patients with primary hyperparathyroidism.[E] These effects were maintained with long-term treatment without major adverse effects. Bone mineral density in the treated patients remained unchanged, but there was a reduction in biochemical markers for bone resorption and formation. Cinacalcet may therefore represent an effective nonsurgical treatment for the management of primary hyperparathyroidism. Daily high dose (70 mg or 2800U) cholecalciferol also can decrease PTH and improve bone density when used for 6 months before and after parathyroidectomy.[E]

FAMILIAL PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is most frequently encountered as a nonfamilial (sporadic) disorder. However, approximately 10% of patients with primary hyperparathyroidism have a hereditary form that may either be part of the MEN 1, MEN 2, MEN 3, and MEN 4 syndromes or part of the HPT-JT syndrome. In addition, hereditary primary hyperparathyroidism may develop as a solitary endocrinopathy, and this has also been referred to as familial isolated hyperparathyroidism (FIHP). Patients with these familial forms of primary hyperparathyroidism, including the MEN syndromes, have important differences from those developing nonfamilial forms; these include an earlier age of onset (20 to 25 years versus 55 years) and an equal male-to-female ratio (1 : 1 versus 1 : 3). In addition, MEN syndromes are associated with the occurrence of multiple parathyroid tumors, rather than the solitary parathyroid adenomas typically found in the sporadic form; and HPT-JT is associated with occurrence of parathyroid carcinoma in 15% of patients. This has implications for the treatment of parathyroid tumors in patients with these disorders. Thus, minimally invasive parathyroidectomy is an unsuitable approach in MEN patients because of multigland disease, and patients with HPT-JT are likely to require earlier surgery because of the higher risk for parathyroid carcinoma. Investigations of the hereditary and sporadic forms of primary HPT have helped to identify some of the genes and chromosomal regions that are involved in the etiology of parathyroid tumors (see Table 245-1 and Fig. 245-2). FIHP has been reported in several kindreds, and some have been shown to harbor mutations of the *MEN1*, *CDC73*, or *CaSR* genes. The familial syndromes associated with parathyroid tumors include MEN 1, MEN 2, MEN 3, and MEN 4. They are reviewed in detail in Chapter 231.

HYPERPARATHYROIDISM–JAW TUMOR SYNDROME

The HPT-JT syndrome is an autosomal dominant disorder characterized by the occurrence of parathyroid tumors, which may be carcinomas in approximately 15% of patients, and ossifying fibromas that usually affect the maxilla or mandible. In addition, some patients may also develop Wilms' tumors, renal cysts, renal hamartomas, renal cortical adenomas, papillary renal cell carcinomas, uterine tumors that may be malignant, pancreatic adenocarcinomas, testicular mixed germ cell tumors with a major seminoma component, and Hurthle cell thyroid adenomas. Mutations of the *CDC73* gene, which is located on chromosome 1q31.2 and encodes a 531–amino acid protein, parafibromin, cause HPT-JT. Parafibromin has been shown to be associated with the human homologue of the Paf1 protein complex, which interacts with RNA polymerase II, and as part of this protein complex, parafibromin may regulate post-transcriptional events and histone modification. Patients with nonfamilial parathyroid carcinomas frequently harbor germline *CDC73* mutations.

UREMIC HYPERPARATHYROIDISM

PATHOBIOLOGY

Serum PTH levels rise in response to hypocalcemia, and this secondary hyperparathyroidism usually resolves with treatment of the underlying cause of hypocalcemia (Table 245-6). However, in chronic renal failure (Chapter 130), the secondary hyperparathyroidism may persist for a longer time, and eventually the parathyroid cells gain an autonomous function, secreting excessive PTH despite hypercalcemia; this state is referred to as tertiary hyperparathyroidism (see Table 245-2). The cause of progression from the early, presumably polyclonal, secondary hyperplasia of the parathyroids to the later, presumably monoclonal, tumors is not understood and appears to involve genes other than those involved in the etiologies of the sporadic and familial forms of primary hyperparathyroidism (see Table 245-2).

TABLE 245-6 CAUSES OF HYPOCALCEMIA

LOW PARATHYROID HORMONE LEVELS (HYPOPARATHYROIDISM)
Parathyroid agenesis
Isolated or part of complex developmental anomaly (e.g., DiGeorge syndrome)
Parathyroid destruction
Surgery*
Radiation
Infiltration by metastases or systemic disease (e.g., hemochromatosis, amyloidosis, sarcoidosis, Wilson's disease, thalassemia)
Autoimmune
Isolated
Polyglandular (type 1)
Reduced parathyroid function (i.e., parathyroid hormone secretion)
Parathyroid hormone gene defects
Hypomagnesemia*
Neonatal hypocalcemia (may be associated with maternal hypercalcemia)
Hungry bone disease (postparathyroidectomy)
Calcium-sensing receptor or Gα11 mutations
HIGH PARATHYROID HORMONE LEVELS (SECONDARY HYPERPARATHYROIDISM)
Vitamin D deficiency*
As a result of nutritional lack,* malabsorption,* liver disease, or vitamin D receptor defects
Inadequate production of active vitamin D ($1,25[OH]_2D$) as a result of chronic renal failure*
Vitamin D resistance (rickets)
As a result of renal tubular dysfunction (Fanconi's syndrome) or vitamin D receptor defects
Parathyroid hormone resistance
(e.g., pseudohypoparathyroidism, hypomagnesemia)
Drugs
Calcium chelators (e.g., citrated blood transfusions, phosphate—cow's milk is rich in phosphate)
Inhibitors of bone resorption (e.g., bisphosphonates, calcitonin, plicamycin)
Altered vitamin D metabolism (e.g., phenytoin, ketoconazole)
Foscarnet
Miscellaneous
Acute pancreatitis
Acute rhabdomyolysis
Massive tumor lysis
Osteoblastic metastases (e.g., from prostate or breast carcinoma)
Toxic shock syndrome
Hyperventilation

*Most common causes.

CLINICAL MANIFESTATIONS AND TREATMENT

Rx

In chronic renal failure, the ensuing phosphate retention and decreased production of $1,25(OH)_2D$ result in hypocalcemia and secondary hyperparathyroidism. This combination of biochemical abnormalities results in a severe bone disease that shows combined features of hyperparathyroidism and vitamin D deficiency (i.e., osteomalacia). Thus, in renal osteodystrophy, bone erosions and osteomalacia are simultaneously observed. Treatment is based on correcting the hypocalcemia, for example, with oral administration of calcium salts, which also ameliorates the hyperphosphatemia by chelating phosphate in the intestines, and with calcitriol ($1,25[OH]_2D$). The use of the most appropriate phosphate binder is not well established, but it is clear that aluminum-containing compounds are to be avoided. Aluminum in these preparations and as a contaminant of dialysis solutions contributed in the recent past to the osteomalacic osseous disease and other aspects of metal toxicity in patients with renal failure (e.g., hypochromic anemia and encephalopathy). Early treatment of the metabolic disturbance will prevent or delay

the onset of severe secondary hyperparathyroidism and tertiary hyperparathyroidism, which requires parathyroidectomy. For patients who have end-stage renal failure and are on dialysis, cinacalcet, the allosteric activator of the CaSR, can be used to treat the severe secondary hyperparathyroidism. Cinacalcet will reduce the PTH concentrations and may also have an antiproliferative effect.

DISORDERS AND SYNDROMES ASSOCIATED WITH HYPERCALCEMIA

Endocrine Causes of Hypercalcemia Other than Hyperparathyroidism

Several nonparathyroid disorders (see Table 245-2) are associated with hypercalcemia, and these include thyrotoxicosis, pheochromocytoma, Addison's disease, vasoactive intestinal polypeptide hormone producing tumor (VIPomas), familial benign hypocalciuric hypercalcemia, Jansen's disease, and Williams syndrome.

THYROTOXICOSIS

Mild hypercalcemia (<12 mg/dL, or 3 mmol/L)) frequently accompanies thyrotoxicosis, which leads to increased bone turnover and resorption. The hypercalcemia may respond to treatment with β-adrenergic blockers.

FAMILIAL BENIGN HYPOCALCIURIC HYPERCALCEMIA

Familial benign hypercalcemia (FBH), which is also referred to as familial hypocalciuric hypercalcemia (FHH), is an autosomal dominant disorder characterized by lifelong asymptomatic hypercalcemia in association with an inappropriately low urinary calcium excretion (i.e., calcium clearance–to–creatinine clearance ratio (CCR) <0.01), and normal circulating PTH concentrations in 80% of patients. Hypermagnesemia is also typically present. Although most patients with FBH are asymptomatic, chondrocalcinosis and acute pancreatitis have occasionally been observed. Patients with FHH have been misdiagnosed as having primary hyperparathyroidism because 20% of FHH patients may have elevated plasma PTH concentrations. In addition, 20% of FHH patients may have a CCR greater than 0.01 and therefore be indistinguishable from patients with primary hyperparathyroidism. Moreover, low CCRs are observed in patients with primary hyperparathyroidism who have vitamin D deficiency or renal insufficiency or are of African American origin. It is important to distinguish FHH patients from those with primary hyperparathyroidism because the hypercalcemia in FHH is generally benign and does not result in sequelae (see Table 245-4). Moreover, parathyroidectomy does not correct the hypercalcemia in FHH. Mutational analysis may help in identifying FHH patients from those with primary hyperparathyroidism.

FHH is genetically heterogenous, with three reported variants—FHH1, FHH2 and FHH3—whose loci are on chromosomes 3q21.1, 19p, and 19q13, respectively (see Table 245-1). FHH1 is due to heterozygous loss-of-function mutations of the CaSR, which is a GPCR that signals through Gαq and Gα11. The human CaSR, a 1078–amino acid cell surface GPCR encoded by the *CaSR* gene located on chromosome 3q21.1, is expressed in parathyroid cells, thyroid cells, and kidney (see Fig. 245-2). Approximately two thirds of FHH kindreds have unique heterozygous mutations of the CaSR, and expression studies of these mutations have demonstrated a loss of CaSR function whereby there is an increase in the calcium ion–dependent set point for PTH release from the parathyroid cell. FHH2 is due to loss-of-function mutations in the G-protein subunit α11 (Gα11) (see Fig. 245-2), which decrease the sensitivity of cells expressing the CaSR, probably by impairing the release of guanosine diphosphate. Such Gα11 loss-of-function mutations may occur in less than 5% of FHH patients.

FHH3 is due to loss-of-function mutations of the adaptor protein 2 (AP2) sigma subunit (AP2σ) (see Fig. 245-2). AP2 is a central component of clathrin-coated vesicles (CCVs) and is pivotal in clathrin-mediated endocytosis, which internalizes plasma membrane constituents such as GPCRs. AP2 is a heterotetramer of α, β, μ, and σ subunits and links clathrin to vesicle membranes and binds to tyrosine- and dileucine-based motifs of membrane-associated cargo proteins. The FHH3-associated AP2σ mutations, which all involve an Arg15 residue that forms key contacts with the dileucine-based motifs of CCV cargo proteins, result in a decreased sensitivity of CaSR-expressing cells to extracellular calcium and reduced CaSR endocytosis, probably through loss of interaction with a C-terminal CaSR dileucine-based motif, whose disruption also decreases intracellular signaling. Such AP2σ loss-of-function mutations occur in more than 5% of FHH patients. FHH1, FHH2, and FHH3 have similar clinical features, and thus genetic analysis is required to identify the relevant mutations.

AUTOIMMUNE HYPOCALCIURIC HYPERCALCEMIA

Some patients, who have the clinical features of FHH1, but not CaSR mutations, may have autoimmune hypocalciuric hypercalcemia (AHH). Such patients may have multiple clinical autoimmune manifestations, including antithyroid, antigliadin, or antiendomyseal antibodies. These patients were shown to have circulating antibodies to the extracellular domain of the CaSR, and these antibodies stimulated PTH release from dispersed human parathyroid cells in vitro, probably by inhibiting the activation of the CaSR by extracellular calcium. The effects of treatment with glucocorticoids have been variable, with the hypercalcemia responding in one patient but not in another. Thus, AHH is a condition of extracellular calcium-sensing that should be considered in FHH1 patients who do not have CaSR mutations.

NEONATAL SEVERE PRIMARY HYPERPARATHYROIDISM

Neonatal severe primary hyperparathyroidism (NSHPT) is defined as symptomatic hypercalcemia with skeletal manifestations of hyperparathyroidism in the first 6 months of life.[5] NSHPT children often present in the first few days or weeks of life with failure to thrive, dehydration, hypotonia, constipation, rib cage deformities, and multiple fractures due to bony undermineralization. Children with NSHPT often have life-threatening hypercalcemia and require urgent parathyroidectomy, which corrects the PTH-dependent hypercalcemia and bone demineralization. FBH or FHH is due to heterozygous inactivating mutations of the CaSR, and NSHPT is often associated with inactivating homozygous CaSR mutations when the children are from consanguineous parents with FHH1 (see Fig. 245-2). However, NSHPT has also been observed in children for whom one parent had clinically apparent FBH, and many other NSHPT patients appear to be sporadic; that is, both parents have normal serum calcium concentrations. In such NSHPT patients with heterozygous CaSR mutations, the mutant CaSR may exert a dominant negative action on the normal CaSR.

JANSEN'S DISEASE

Jansen's disease is an autosomal dominant disease that is characterized by short-limbed dwarfism due to metaphyseal chondrodysplasia and severe hypercalcemia and hypophosphatemia despite normal or undetectable serum levels of PTH. These abnormalities are associated with activating mutations of the PTH receptor (see Fig. 245-2), and thus this represents a PTH-independent activation of the PTH receptor (PTHR).

WILLIAMS SYNDROME

Williams syndrome is an autosomal dominant disorder characterized by supravalvular aortic stenosis, elfin-like facies, psychomotor retardation, and infantile hypercalcemia. The underlying abnormality causing hypercalcemia, which affects 5 to 50% of patients, remains unknown, but abnormal $1,25(OH)_2D_3$ metabolism and decreased calcitonin production have been implicated, although no abnormality has been consistently demonstrated. Hemizygosity due to a microdeletion of chromosome 7q11.23 involving the *ELASTIN* and *LIM-KINASE* genes, which may explain the respective cardiovascular and neurologic features, have been reported in Williams syndrome patients. However, the calcitonin receptor gene, located on chromosome 7q21 and close to the region deleted in Williams syndrome, was not involved in the deletion found in four patients with Williams syndrome, indicating that it is unlikely to be implicated in the hypercalcemia of such children. Another, as yet uncharacterized gene that is within this contiguously deleted region is likely to be involved to explain the abnormalities of calcium metabolism.

INFANTILE HYPERCALCEMIA

Infantile hypercalcemia is associated with failure to thrive and is characterized by severe hypercalcemia, hypercalciuria, and nephrocalcinosis and elevated circulating $1,25(OH)_2D$ concentrations. Some infants with this disorder have homozygous or compound heterozygous mutations of the gene encoding the 24-hydroxylase (CYP24A1) enzyme, which metabolizes the active $1,25(OH)_2D$ to the inactive $1,24,25(OH)_3D$ form (see Fig. 245-1).

Malignancy

Hypercalcemia may occur in 20 to 30% of patients with a malignancy, and this is usually due to increased bone resorption, which may either be directly

due to skeletal metastases or indirectly due to tumor production of a humoral factor that stimulates osteoclastic bone resorption (Chapter 179). The cancers that typically metastasize to produce lytic bone lesions are from the breast, lymphomas, or multiple myeloma (see Table 245-2). The associated osteolysis, mediated by recruitment and activation of osteoclasts, involves cytokines. Denosumab, a humanized neutralizing monoclonal antibody to RANKL, may be used to prevent the recruitment and activation of osteoclasts. The cancers that are typically associated with the humoral hypercalcemia of malignancy (HHM) are squamous carcinomas of the lung, esophagus, cervix, vulva, skin, head, or neck, but other types from the kidney, bladder, ovary, and breast may also occur. HHM accounts for up to 80% of patients with malignancy-associated hypercalcemia. The most common factor causing HHM is PTHrP, which can be measured in the serum by immunoassay. However, these assays are relatively insensitive, and the failure to detect serum PTHrP does not exclude the diagnosis of HHM. Patients with HHM generally have hypercalcemia associated with lower or undetectable serum PTH levels, marked hypercalcemia, and a reduced plasma $1,25(OH)_2D$ level. Therapy of HHM is aimed at (1) reducing the tumor load by surgery, radiotherapy, and/or chemotherapy; (2) reducing osteoclastic bone resorption by use of bisphosphonates (e.g., zoledronate) calcitonin or denosumab; and (3) increasing renal calcium clearance by a saline diuresis.

Granulomatous Disorders

Several granulomatous disorders are associated with hypercalcemia (see Table 245-2), and this is invariably associated with elevated circulating concentrations of $1,25(OH)_2D$, which is due to extrarenal synthesis. Sarcoidosis is the most frequently encountered granulomatous disorder associated with hypercalcemia; 10% of patients with sarcoidosis have hypercalcemia, and about half become hypercalciuric. The finding of raised serum angiotensin-converting enzyme (ACE) activity may help confirm the diagnosis. Glucocorticoids (e.g., 40 to 60 mg of prednisolone) decrease $1,25(OH)_2D$ production and restore the calcium concentration to normal. Failure to achieve normal serum calcium concentrations within 10 days of glucocorticoid therapy (e.g., hydrocortisone, 40 mg three times per day), the steroid suppression test, should suggest the coexistence of another cause for the hypercalcemia, such as primary hyperparathyroidism or malignancy.

Drugs

Several drugs (see Table 245-2) can cause hypercalcemia by different mechanisms. Compounds containing vitamins D and A are common and frequently associated with hypercalcemia. The use of thiazide diuretics is often associated with hypercalcemia. The hypercalcemia appears to be largely renal in origin because thiazides enhance distal renal tubular calcium reabsorption. Hypercalcemia reverses rapidly with discontinuation of the drug.

The milk-alkali syndrome was first described in the 1930s, generally in the context of ulcer treatment with large quantities of milk together with sodium bicarbonate. Today, the responsible agent is usually calcium carbonate, although consumption of large quantities of dairy products (milk, cheese, and yogurt) may still contribute. Classic features include moderate to severe hypercalcemia with alkalosis and renal impairment. The amount of calcium ingested by patients with this syndrome is usually 5 to 15 g/day. Treatment consists of (1) discontinuing the ingestion of the calcium containing compounds and antacids; (2) rehydration; and (3) saline diuresis.

HYPOCALCEMIA

DEFINITION

Hypocalcemia is defined as a serum calcium concentration below the lower limit of normal range, and this is usually an ionized serum calcium below 4.65 mg/dL (1.16 mmol/L) and a total serum calcium below 8.5 mg/dL (2.12 mmol/L). Mild hypocalcemia is defined as a total serum calcium of 8 to 8.5 mg/dL (2 to 2.12 mmol/L) and severe hypocalcemia as a total serum calcium below 7.6 mg/dL (1.9 mmol/L).

PATHOBIOLOGY

Hypocalcemia (see Table 245-6) can be classified by cause, according to whether serum PTH concentrations are low (i.e., hypoparathyroid disorders) or high (i.e., disorders associated with secondary hyperparathyroidism). Hypocalcemia is most commonly caused by hypoparathyroidism, a deficiency or abnormal metabolism of vitamin D, acute or chronic renal failure, or hypomagnesemia. Hypocalcemic diseases (see Table 245-6) may arise because of a destruction of the parathyroid glands, failure of parathyroid gland development, or reduced PTH secretion or PTH-mediated actions in target tissues. Thus, these diseases may be classified as being due to a deficiency of PTH, a defect in the PTH receptor (i.e., the PTH/PTHrP receptor), or insensitivity to PTH caused by defects downstream of the PTH/PTHrP receptor (see Fig. 245-2). The diseases may also be classified as being part of the hypoparathyroid disorders, of the CaSR abnormalities, or of the pseudohypoparathyroid disorders.

TABLE 245-7 HYPOCALCEMIC CLINICAL FEATURES OF NEUROMUSCULAR IRRITABILITY

Paresthesia, usually of fingers, toes, and circumoral regions
Tetany, carpopedal spasm, muscle cramps
Chvostek's sign*
Trousseau's sign†
Seizures of all types (i.e., focal or petit mal, grand mal, or syncope)
Prolonged QT interval on electrocardiogram
Laryngospasm
Bronchospasm

*Chvostek's sign is twitching of the circumoral muscles in response to gentle tapping of the facial nerve just anterior to the ear; it may be present in 10% of normal individuals.
†Trousseau's sign is carpal spasm elicited by inflation of a blood pressure cuff to 20 mm Hg above the patient's systolic blood pressure for 3 minute.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical presentation of hypocalcemia ranges from an asymptomatic biochemical abnormality to a severe, life-threatening condition. In mild hypocalcemia, patients may be asymptomatic. Those with more severe and long-term hypocalcemia may develop acute symptoms of neuromuscular irritability (Table 245-7), ectopic calcification (e.g., in the basal ganglia, which may be associated with extrapyramidal neurological symptoms), subcapsular cataract, papilledema, and abnormal dentition. Investigations should be directed at confirming the presence of hypocalcemia and establishing the cause (Fig. 245-4).

In hypoparathyroidism, serum calcium is low, phosphate is high, and PTH is undetectable; renal function and concentrations of the 25-hydroxy and 1,25-dihydroxy metabolites of vitamin D are usually normal (see Fig. 245-4). The features of pseudohypoparathyroidism are similar to those of hypoparathyroidism except for PTH, which is markedly increased.[15] In chronic renal failure, which is the most common cause of hypocalcemia, phosphate is high, and alkaline phosphatase, creatinine, and PTH are elevated; 25-OH-D_3 is normal, and $1,25(OH)_2D_3$ is low (see Fig. 245-1). In vitamin D deficiency osteomalacia, serum calcium and phosphate are low, alkaline phosphatase and PTH are elevated, renal function is normal, and 25-OH-D_3 is low (see Fig. 245-4). The most frequent artifactual cause of hypocalcemia is hypoalbuminemia, such as occurs in liver disease or the nephrotic syndrome.

TREATMENT

Rx

Acute Hypocalcemia

The management of acute hypocalcemia depends on the severity of the hypocalcemia, the rapidity with which it developed, and the degree of neuromuscular irritability (see Table 245-7). Treatment should be given to symptomatic patients (e.g., with seizures or tetany) and asymptomatic patients with a serum calcium of less than 7.6 mg/dL (1.90 mmol/L) who are at high risk for developing complications. The preferred treatment for acute symptomatic hypocalcemia is calcium gluconate, 10 mL 10% w/v (2.20 mmol of calcium) intravenous, diluted in 50 mL of 5% dextrose or 0.9% sodium chloride and given by slow injection (>5 minutes); this can be repeated as required to control symptoms. Serum calcium concentrations should be assessed regularly. Continuing hypocalcemia may be managed acutely by administration of a calcium gluconate infusion; for example, dilute 10 ampules of calcium gluconate, 10 mL 10% w/v (22 mmol of calcium), in 1 liter of 5% dextrose or 0.9% sodium chloride, start infusion at 50 mL/hour, and titrate to maintain serum calcium concentrations in the normal range. Generally, 1.2 to 1.6 mg/kg (0.3 to 0.4 mmol/kg) of elemental calcium infused over 4 to 6 hours increases serum calcium by 2 to 3 mg/dL (0.5 to 0.75 mmol/L). If hypocalcemia is likely to persist, oral vitamin D therapy (see later) should also be administered. In hypocalcemic patients who are also hypomagnesemic, the hypomagnesemia must be corrected before the hypocalcemia will resolve. This may occur in the postparathyroidectomy period or in patients with severe malabsorption, for example, those with established celiac disease (Chapter 140).

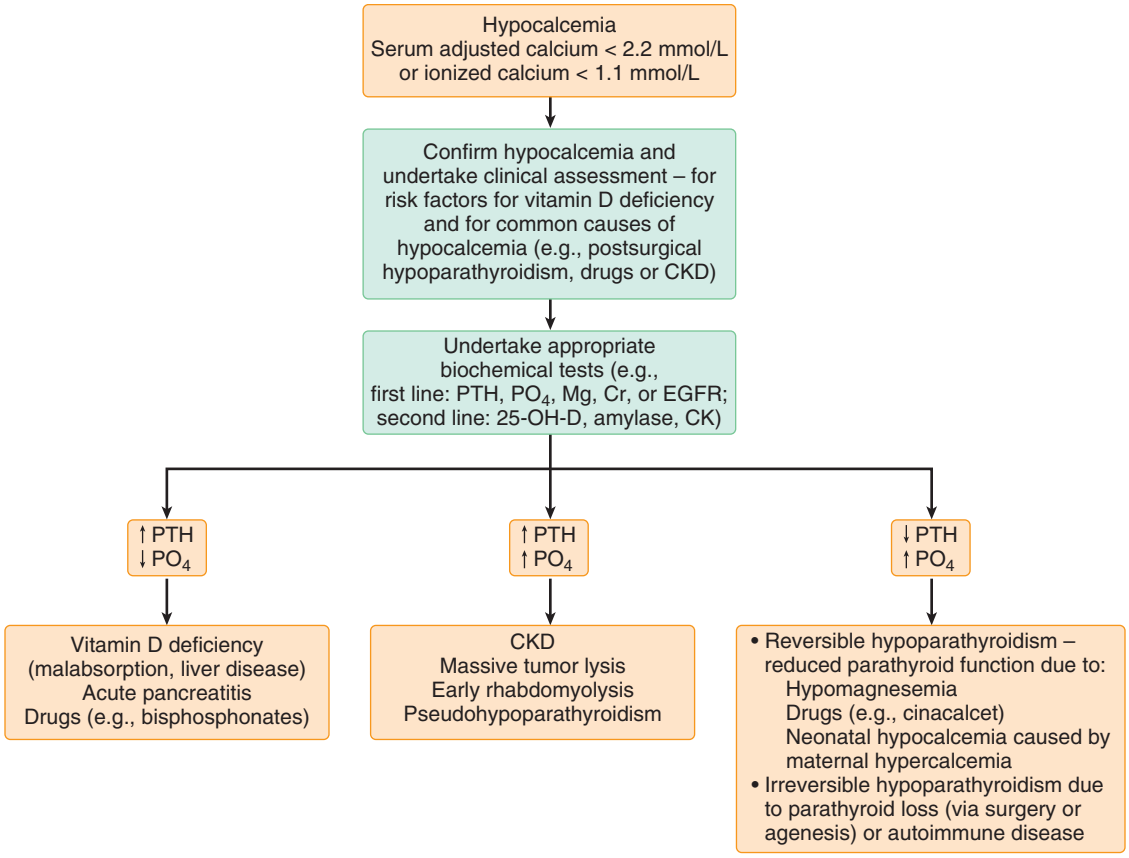

FIGURE 245-4. Clinical approach to investigation of causes of hypocalcemia. 25-OH-D = 25-hydroxyvitamin D; CK = creatinine kinase ; CKD = chronic kidney disease; Cr = creatinine; EGFR = estimated glomerular filtration rate; PTH = parathyroid hormone.

Chronic Hypocalcemia

The two main agents available for the treatment of chronic (long-term) hypocalcemia are supplemental calcium, about 10 to 20 mmol calcium every 6 to 12 hours, and vitamin D preparations. Patients with hypoparathyroidism seldom require calcium supplements after the early stages of stabilization with vitamin D. A variety of vitamin D preparations have been used. These include vitamin D_3 (cholecalciferol) or vitamin D_2 (ergocalciferol), 10,000 to 50,000 units (0.25 to 1.25 mg/day); dihydrotachysterol (now seldom used), 0.25 to 1.25 mg/day; alfacalcidol (1α-hydroxycholecalciferol), 0.25 to 1 μg/day; and calcitriol (1,25-dihydroxy cholecalciferol), 0.25 to 2 μg/day. In children, these preparations are prescribed in doses based on body weight. Cholecalciferol and ergocalciferol are the least expensive preparations but have the longest durations of action and may result in prolonged toxicity; however, they are the preparations of choice for treating hypocalcemia associated with vitamin D deficiency (see Table 245-6). The other preparations, which do not require renal 1α-hydroxylation, have the advantage of shorter half-lives and thereby minimize the risk for prolonged toxicity. For treatment of hypocalcemia due to hypoparathyroidism or chronic renal failure, calcitriol is the drug of choice because it is the active metabolite and, unlike alfacalcidol, does not require hepatic 25-hydroxylation. Close monitoring (at about 1- to 2-week intervals) of the patient's serum and urine calcium concentrations are required initially, and 3- to 6-month intervals are appropriate once stabilization is achieved. The aim is to avoid hypercalcemia, hypercalciuria, nephrolithiasis, and renal failure. It should be noted that hypercalciuria may occur in the absence of hypercalcemia. The use of PTH (1-84) in hypoparathyroid patients has been reported to be associated with improvement in the biochemical and skeletal indices, as well as in mental and physical health.[16]

HYPOPARATHYROIDISM

DEFINITION

Hypoparathyroidism is characterized by hypocalcemia and hyperphosphatemia, which are the result of a deficiency in PTH secretion or action.[17] Serum concentrations of immunoreactive PTH are low or undetectable, and the concentrations of $1,25(OH)_2D_3$ are usually in the low-normal to low range, but alkaline phosphatase activity is unchanged (see Fig. 245-4). The daily urinary excretion of calcium is reduced, although the fractional excretion of calcium is increased. Nephrogenous cyclic adenosine monophosphate (cAMP) excretion is low, and renal tubular reabsorption of phosphate is elevated. Urinary cAMP, plasma cAMP, and urinary phosphate excretion increase markedly after administration of exogenous bioactive PTH (Chase-Aurbach and Ellsworth-Howard tests).

PATHOBIOLOGY

Hypoparathyroidism may result from agenesis (e.g., DiGeorge syndrome) or destruction of the parathyroid glands (e.g., following neck surgery, in autoimmune diseases), from reduced secretion of PTH (e.g., neonatal hypocalcemia or hypomagnesemia), or from resistance to PTH (which may occur as a primary disorder (e.g., pseudohypoparathyroidism or secondary to hypomagnesemia) (see Table 245-6). In addition, hypoparathyroidism may occur as an inherited syndromic disorder (see Table 245-1) that may either be part of a complex congenital defect (e.g., DiGeorge syndrome) or part of a polyglandular autoimmune disorder (see Table 245-6 and Fig. 245-2). Hypoparathyroidism may also occur as a nonsyndromic solitary endocrinopathy, which has been referred to as isolated or idiopathic hypoparathyroidism. Familial occurrences of isolated hypoparathyroidism with autosomal dominant, autosomal recessive, and X-linked recessive inheritances have been established.

Isolated Hypoparathyroidism

Isolated hypoparathyroidism may either be inherited or acquired by damage to the parathyroids at surgery, by infiltrating metastases, or by systemic disease (see Table 245-6).

ACQUIRED FORMS OF HYPOPARATHYROIDISM

Hypoparathyroidism may occur after neck surgery, after irradiation, or because of infiltration by metastases or systemic disease, for example, hemochromatosis, amyloidosis, sarcoidosis, Wilson's disease, or thalassemia (see Table 245-6). Surgical damage to the parathyroids occurs most commonly after a radical neck dissection, such as for laryngeal or esophageal carcinoma treatment, after a total thyroid resection, or after repeated parathyroidectomies for polyglandular disease (e.g., in MEN 1 or MEN 2, discussed

previously). Hypocalcemic symptoms begin 12 to 24 hours after surgery and may need treatment with oral or intravenous calcium. Parathyroid function often returns, but persistent hypocalcemia requires treatment with vitamin D preparations.

Neonatal hypoparathyroidism resulting in hypocalcemia may occur in the infant of a mother with hypercalcemia caused by primary hyperparathyroidism (see Table 245-6). Maternal hypercalcemia results in increased calcium delivery to the fetus, and this fetal hypercalcemia suppresses fetal PTH secretion. Postpartum, the infant's suppressed parathyroids are unable to maintain normocalcemia. The disorder is usually self-limited, but occasionally therapy may be required. In addition, the feeding of cow's milk, which has a high phosphate content, to infants may result in hypocalcemia in some children.

Functional hypoparathyroidism may result from severe hypomagnesemia (<0.4 mmol/L), which may be due to a severe intestinal malabsorption disorder (e.g., Crohn's disease) or a renal tubular disorder (see Table 245-6). It is associated with hypoparathyroidism because magnesium is required for the release of PTH from the parathyroid gland and also for PTH action through adenyl cyclase. Magnesium chloride, 35 to 50 mmol intravenously in 1 liter of 5% glucose or other isotonic solution given over 12 to 24 hours, may be repeatedly required to restore normomagnesemia.

INHERITED HYPOPARATHYROIDISM

Patients with inherited forms of hypoparathyroidism may develop hypocalcemic seizures in the neonatal or infantile periods and require lifelong treatment with oral vitamin D preparations, such as calcitriol. Autosomal dominant, autosomal recessive, and X-linked recessive inheritances for hypoparathyroidism have been observed (see Table 245-1). Some of the autosomal forms are due to mutations of the *PTH* gene, the CaSR (see later), the Gα11 subunit (see later), and the transcriptional factor *GCMB* (glial cells missing B). The X-linked forms likely alter regulation of SOX3 (see Fig. 245-4).

Autosomal Dominant Hypocalcemia Type 1 and Type 2

Autosomal dominant hypocalcemia type 1 (ADH1) is characterized by lifelong mild or severe hypocalcemia in association with normal serum PTH concentrations in about 40% of patients or low serum PTH concentrations in about 60% of patients. Serum phosphate and magnesium concentrations may be elevated or low, respectively. Approximately 50% of ADH1 patients have asymptomatic hypocalcemia, and the remaining 50% may experience paresthesia, muscle cramps, carpopedal spasms, and seizures, which may be associated with a febrile illness. In addition, about 10% of ADH1 patients may have absolute hypercalciuria, which may be associated with nephrocalcinosis and kidney stones in 35% of patients. Vitamin D preparations and calcium supplementation to correct the hypocalcemia may worsen the hypercalciuria and lead to renal impairment. Basal ganglia or ectopic calcification may be found in more than 35% of patients. About 20% of ADH1 patients do not have a previously reported family history because they have de novo mutations. ADH1 is due to gain-of-function mutations of the CaSR (see Table 245-1 and Fig. 245-2). ADH2 is due to gain-of-function mutations of the Gα11 subunit, and ADH2 patients appear to have clinical features that are similar to those in ADH1 patients.

Complex Syndromes Associated with Hypoparathyroidism

Hypoparathyroidism may occur as part of a complex syndrome that may be associated with either a congenital developmental anomaly or an autoimmune syndrome. The congenital developmental anomalies associated with hypoparathyroidism, which occurs in 1 in 4000 live births, include DiGeorge syndrome, hypoparathyroidism, deafness, and renal anomalies (HDR) syndrome, Kenney-Caffey and Barakat syndromes, and also syndromes associated with either lymphedema or dysmorphic features and growth failure (see Table 245-1 and Fig. 245-2).

POLYGLANDULAR AUTOIMMUNE HYPOPARATHYROIDISM

Polyglandular autoimmune hypoparathyroidism comprises hypoparathyroidism, Addison's disease, candidiasis, and two or three of the following: type 1 diabetes mellitus, primary hypogonadism, autoimmune thyroid disease, pernicious anemia, chronic active hepatitis, steatorrhoea (malabsorption), alopecia (totalis or areata), and vitiligo. The disorder has also been referred to as either the autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome or the polyglandular autoimmune type 1 syndrome (see Table 245-1). Antibodies directed against the adrenal, thyroid, and parathyroid glands are detected in the sera of some patients. The polyglandular autoimmune type 2 syndrome is characterized by adrenal insufficiency, type 1 diabetes mellitus, and thyroid disease and does not involve hypoparathyroidism. APECED, which has an autosomal recessive inheritance, has a high incidence in Finland and among Iranian Jews. The *APECED* gene, which has been located to chromosome 21q22.3, encodes a 545–amino acid protein that contains motifs associated with a transcriptional factor and includes two zinc-finger motifs, a proline-rich region, and three LXXLL motifs. The gene is referred to as *AIRE* (autoimmune regulator) (see Fig. 245-2). Four *AIRE* mutations are commonly found in APECED families, and these likely abolish the E3 ubiquitin ligase activity of the AIRE1 protein. AIRE1 has been shown to regulate the elimination of organ-specific T cells in the thymus, and APECED is likely to be caused by a failure of this specialized mechanism for deleting forbidden T cells and establishing immunologic tolerance.

AUTOIMMUNE ACQUIRED HYPOPARATHYROIDISM

Twenty percent of patients who had acquired hypoparathyroidism (AH) in association with autoimmune hypothyroidism were found to have autoantibodies to the extracellular domain of the CaSR (see Table 245-1 and Fig. 245-2). The CaSR autoantibodies did not persist for long; 72% of patients who had AH for less than 5 years had detectable CaSR autoantibodies, whereas only 14% of patients with AH for more than 5 years had such autoantibodies. The majority of the patients who had CaSR autoantibodies were female, a finding that is similar to that found in other autoantibody-mediated diseases. Indeed, a few acquired hypoparathyroidism patients have also had features of autoimmune polyglandular syndrome type 1. The epitopes for the anti-CaSR antibodies were localized to the N terminal of the extracellular domain of the receptor. These findings establish that the CaSR is an autoantigen in acquired hypoparathyroidism.

DIGEORGE SYNDROME

Patients with the DiGeorge syndrome suffer from neonatal hypoparathyroidism, T-cell immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth (e.g., cleft lip and/or palate). Children with DiGeorge syndrome often die from infections related to the immunodeficiency. The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroids and thymus. Most cases are sporadic, but an autosomal dominant inheritance of DiGeorge syndrome has been observed, and an association between the syndrome and an unbalanced translocation and deletions involving chromosome 22q11.2 has also been reported (see Table 245-1). In some patients, deletions of another locus on chromosome 10p13-p14 have been observed in association with DiGeorge syndrome, and this is referred to as DGS2, whereas patients with the 22q11.2 deletions are referred to as having DGS1. Studies of the DGS1 deleted region on chromosome 22q11.2 have revealed four genes (*RNEX40*, *NEX2.2-NEX3*, *UDFIL*, and *TBX1*) to be involved. However, point mutations in DGS1 patients have been detected only in the *TBX1* gene, and *TBX1* is now considered to be the gene causing DGS1 (see Table 245-1 and Fig. 245-2). *TBX1* encodes a DNA-binding transcriptional factor, of the T-BOX family, that is known to have an important role in vertebrate and invertebrate organogenesis and pattern formation. The *TBX1* gene is deleted in approximately 96% of all DGS1 patients, and some of those without deletions have been shown to harbor mutations of *TBX1*.

HYPOPARATHYROIDISM, DEAFNESS, AND RENAL ANOMALIES SYNDROME

HDR syndrome is an autosomal dominant disorder in which patients often have asymptomatic hypocalcemia with undetectable or inappropriately normal serum concentrations of PTH. Bilateral, symmetrical, sensorineural deafness involving all frequencies occurs, and the renal abnormalities consist mainly of bilateral cysts that compress the glomeruli and tubules and lead to renal impairment. Cytogenetic abnormalities involving chromosome 10p14-10pter were identified in HDR patients, and HDR patients have deletions or mutations of the zinc-finger transcription factor *GATA3* (see Table 245-1 and Fig. 245-2).

MITOCHONDRIAL DISORDERS ASSOCIATED WITH HYPOPARATHYROIDISM

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: Kearns-Sayre syndrome, MELAS syndrome, and a mitochondrial trifunctional protein deficiency syndrome (MTPDS) (see Table 245-1 and Fig. 245-2). Kearns-Sayre syndrome is characterized by progressive external ophthalmoplegia and pigmentary

TABLE 245-8 CLINICAL, BIOCHEMICAL, AND GENETIC FEATURES OF HYPOPARATHYROID AND PSEUDOHYPOPARATHYROID DISORDERS

		PSEUDOHYPOPARATHYROIDISM				
	HYPOPARATHYROIDISM	*PHP 1a*	*PPHP*	*PHP 1b*	*PHP 1c*	*PHP 2*

Other hormonal resistance	No	Yes	No	No	Yes	No

↓ = decreased; ↑ = increased; ? = presumed, but not proved; AD = autosomal dominant; AHO = Albright's hereditary osteodystrophy; AR = autosomal recessive; N = normal; PHP = pseudoparathyroidism; PPHP = pseudopseudoparathyroidism; PTH = parathyroid hormone; X = X-linked.
*Plasma cyclic adenosine monophosphate (cAMP) responses are similar to those of urinary cAMP.
†Involves deletions that are located upstream of GNAS1.

retinopathy before the age of 20 years and is often associated with heart block or cardiomyopathy. MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both Kearns-Sayre and MELAS syndromes have been reported to occur with type 1 diabetes mellitus and hypoparathyroidism, and mitochondrial gene abnormalities have been identified in some patients. Mitochondrial trifunctional protein deficiency is a disorder of fatty acid oxidation that is associated with peripheral neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed in one patient with trifunctional protein deficiency.

KENNEY-CAFFEY, SANJAD-SAKATI, AND KIRK-RICHARDSON SYNDROMES

Hypoparathyroidism has been reported to occur in more than 50% of patients with Kenney-Caffey syndrome, which is associated with short stature, osteosclerosis, cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia. Parathyroid tissue could not be found in a detailed postmortem examination of one patient, and this suggests that hypoparathyroidism may be due to an embryologic defect of parathyroid development. In Kirk-Richardson and Sanjad-Sakati syndromes, which are similar, hypoparathyroidism is associated with severe growth failure and dysmorphic features. This has been reported in patients of Middle Eastern origin whose parents were consanguineous, indicating that these are autosomal recessive disorders. Molecular genetic investigations have identified mutations of the tubulin-specific chaperone (*TBCE*), located on chromosome 1q42-q43, to be associated with the Kenney-Caffey type 1 and Sanjad-Sakati syndromes (see Table 245-1 and Fig. 245-2). *TBCE* encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of αβ-tubulin heterodimers. Kenney-Caffey type 2 syndrome is due to mutations of a member of the family with sequence similarity 111 of gene (*FAM111A*), located on chromosome 11q12.1.

PSEUDOHYPOPARATHYROIDISM

Patients with pseudohypoparathyroidism (PHP), which may be inherited as an autosomal dominant disorder, are characterized by hypocalcemia and hyperphosphatemia due to PTH resistance rather than PTH deficiency (see Table 245-6). Five variants are recognized on the basis of biochemical and somatic features (Table 245-8), and three of these—PHP type 1a (PHP 1a), PHP type 1b (PHP 1b), and pseudopseudohypoparathyroidism (PPHP)—will be reviewed in further detail. Patients with PHP 1a exhibit PTH resistance (hypocalcemia, hyperphosphatemia, elevated serum PTH, and an absence of an increase in serum and urinary cAMP and urinary phosphate following intravenous human PTH infusion), together with the features of Albright's hereditary osteodystrophy (AHO), which includes short stature, obesity, subcutaneous calcification, mental retardation, round faces, dental hypoplasia, and brachydactyly (i.e., shortening of the metacarpals, particularly the third, fourth, and fifth). In addition to brachydactyly, other skeletal abnormalities of the long bones and shortening of the metatarsals may occur. Patients with PHP 1b exhibit PTH resistance only and do not have the somatic features of AHO, whereas patients with PPHP exhibit the somatic features of AHO in the absence of PTH resistance. The absence of a normal rise in urinary excretion of cAMP after an infusion of PTH in PHP 1a indicated a defect at some site of the PTH receptor–adenyl cyclase system (see Fig. 245-2). This receptor system is regulated by at least two G proteins, one of which stimulates (Gsα) and another of which inhibits (Giα) the activity of the membrane-bound enzyme that catalyses the formation of the intracellular second messenger cAMP. Patients with PHP 1a may also show resistance to other hormones, such as thyroid-stimulating hormone, follicle-stimulating hormone, and luteinizing hormone, that act through GPCRs. Inactivating mutations of the Gsα gene (referred to as *GNAS1*), which is located on chromosome 20q13.2, have been identified in PHP 1a and PPHP patients (see Table 245-1 and Fig. 245-2). However, *GNAS1* mutations do not fully explain the PHP 1a or PPHP phenotypes, and studies of PHP 1a and PPHP that occurred within the same kindred revealed that the hormonal resistance is parentally imprinted. Thus, PHP 1a occurs in a child only when the mutation is inherited from a mother affected with either PHP 1a or PPHP; and PPHP occurs in a child only when the mutation is inherited from a father affected with either PHP 1a or PPHP. PHP 1b is due to deletions that are located upstream of the *GNAS1* gene. Moreover, in affected individuals, the deletion involved the maternal allele, whereas its occurrence on the paternal allele resulted in unaffected healthy carriers. This is consistent with parental imprinting of the *GNAS1* abnormality causing PHP 1b.

Additional Familial Syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported (see Table 245-1). Thus, an association of hypoparathyroidism, renal insufficiency, and developmental delay has been reported in an Asian family in whom autosomal recessive inheritance of the disorder was established. The occurrence of hypoparathyroidism, nerve deafness, and a steroid-resistant nephrosis leading to renal failure, which has been referred to as Barakat syndrome, has been reported in four brothers from one family, and an association of hypoparathyroidism with congenital lymphedema, nephropathy, mitral valve prolapse, and brachytelephalangy has been observed in two brothers from another family. Molecular genetic studies have not been reported from these two families as of this time.

BLOMSTRAND'S DISEASE

Blomstrand's chondrodysplasia is an autosomal recessive disorder characterized by early lethality, dramatically advanced bone maturation, and accelerated chondrocyte differentiation. Affected infants, who usually have consanguineous unaffected parents, develop pronounced hyperdensity of the entire skeleton with markedly advanced ossification, which results in extremely short and poorly modeled long bones. Mutations of the PTH/PTHrP receptor that impair its function are associated with Blomstrand's disease (see Table 245-1 and Fig. 245-2). Thus, it seems likely that affected infants will, in addition to the skeletal defects, have abnormalities in other organs, including secondary hyperplasia of the parathyroid glands, presumably due to hypocalcemia.

REVIEW QUESTIONS

1. Which one of the following statements is true for the actions of parathyroid hormone (PTH)?

A. Acts directly on renal, bone, and intestinal cells
B. Acts directly on renal cells and indirectly on bone and intestinal cells
C. Acts directly on renal and bone cells and indirectly on intestinal cells
D. Has no direct actions on renal, bone, and intestinal cells
E. Acts via a tyrosine kinase receptor

Answer: C PTH shares a receptor with PTH-related peptide (PTHrP), and this receptor is a member of the G protein–coupled receptor (GPCR) family. PTH/PTHrP receptors are expressed by kidney and bone cells, and PTH acts directly on renal and bone cells. PTH acts indirectly on intestinal cells to enhance calcium absorption as follows: PTH stimulates renal 1α-hydroxylase activity to promote synthesis of the active form of vitamin D (1,25-dihydroxyvitamin D), which then acts on the intestine to enhance calcium absorption.

2. Which of the following is not a cause of hypercalcemia?

A. Granulomatous disorders
B. PTH receptor loss-of-function mutation
C. Autoimmunity
D. Renal 1α-hydroxylase overactivity
E. Myeloma

Answer: B PTH receptor loss-of-function mutations result in Blomstrand's chondrodysplasia, which is not associated with hypercalcemia. Instead, PTH receptor gain-of-function mutations that lead to Jansen's metaphyseal chondroplasia are associated with severe hypercalcemia. Granulomatous disorders, autoimmunity (e.g., autoantibodies to the calcium-sensing receptor), renal 1α-hydroxylase overactivity, and myeloma may all be associated with hypercalcemia.

3. Which of the following statements is not included as a recommendation for parathyroid surgery in asymptomatic primary hyperparathyroid patients?

A. Serum calcium >10.mg/dL (0.25 mmol/L) above upper limit of normal
B. Reduction in bone mineral density by T score <–2.5
C. Reduction in creatinine clearance below 60 mL/min
D. Marked hypercalciuria (>400 mg per 24 hr, >9 mmol/L per 24 hr))
E. Age <50 years

Answer: D Marked hypercalciuria (>400 mg per 24 hr, >9 mmol/L per 24 hr) was included as a recommendation for parathyroid surgery in asymptomatic primary hyperparathyroidism by the Second International Conference (2002), but not by the Third International Conference (2008). However, some physicians still regard marked hypercalciuria as an indication for parathyroid surgery.

4. Which of the following statements regarding parathyroid tumors in multiple endocrine neoplasia (MEN) syndrome is *false*?

A. In MEN 1, parathyroid tumors occur with equal frequency in men and women.
B. In MEN 2b and MEN 3, parathyroid tumors are a rare occurrence.
C. In MEN 1, minimally invasive surgery is not a suitable approach because of the high occurrence of multiple parathyroid tumors.
D. Patients with MEN 2a have a higher risk for developing parathyroid carcinomas.
E. Parathyroid tumors occur in more than 95% of MEN 1 patients.

Answer: D MEN 1 is an autosomal dominant disorder, and this generally affects men and women equally. Parathyroid tumors are found in more than 95% of patients with MEN 1, who usually have multiple parathyroid tumors, and hence minimally invasive surgery is not recommended. Parathyroid tumors rarely occur in patients with MEN 2b or MEN 3, and about 20% of MEN 2a patients will usually have parathyroid hyperplasia and not parathyroid carcinoma. However, patients with hyperparathyroidism with jaw tumors are at high risk for developing parathyroid carcinomas.

5. Which of the following is not a cause of hypocalcemia?

A. Vitamin D–resistance disorders
B. Secondary hyperparathyroidism
C. Adrenal insufficiency
D. Autoimmunity
E. Acute pancreatitis

Answer: C Acute adrenal insufficiency is associated with hypercalcemia, not hypocalcemia. Hypocalcemia typically occurs in patients with secondary hyperparathyroidism and in those with vitamin D–resistance disorders, and it may be found in patients with acute pancreatitis. In addition, autoimmune destruction of the parathyroids, resulting in hypoparathyroidism, or autoantibodies to the calcium-sensing receptor may be associated with hypocalcemia.

246 MEDULLARY THYROID CARCINOMA

SAMUEL A. WELLS, JR.

MEDULLARY THYROID CARCINOMA

DEFINITION

Medullary thyroid carcinoma (MTC) is an uncommon cancer that arises from the neural crest—derived C cells of the thyroid gland.

EPIDEMIOLOGY

MTC accounts for 5% of thyroid cancers, and there will be approximately 3000 new cases in the United States in 2015. MTC occurs either sporadically (75% of cases) or as part of the multiple endocrine neoplasia (MEN) syndromes, MEN 2A (Online Mendelian Inheritance in Man [OMIM] #171400) or MEN 2B (OMIM #162300), or the related syndrome familial medullary thyroid carcinoma (FMTC) (OMIM #155240).[1] The incidence of MEN 2A and FMTC combined is approximately 1 in 100,000 live births, whereas the incidence of MEN 2B is approximately 1 in 2,000,000 live births.

PATHOBIOLOGY

As the lateral thyroid complex closes during embryogenesis, the C cells are incorporated within the middle and upper portions of the thyroid lobes. Because of its anatomic location, MTC is classified as a thyroid tumor; however, considering its origin from the neural crest rather than the thyroid follicular cells, it is a neuroendocrine tumor. Sporadic MTC occurs as a solitary tumor in one thyroid lobe, whereas hereditary MTC develops in both thyroid lobes and is multicentric. In patients with hereditary MTC, the first manifestation of a C-cell disorder is C-cell hyperplasia (CCH) that progresses over time to microinvasive MTC and then to invasive MTC.[2]

The C-cell mass is much greater in the thyroid glands of men than in women, which accounts for the higher serum calcitonin levels seen in men compared with women.

The C cells have diverse biosynthetic activity and secrete calcitonin (CTN) and carcinoembryonic antigen (CEA), which are excellent serum markers for the presence of a C-cell disorder. CTN was once thought to be important in calcium homeostasis; however, its physiologic importance has been called into question. The *RET* protooncogene encodes a single-pass transmembrane receptor of the tyrosine kinase family of proteins. At several stages of development, it is expressed in cells derived from the branchial arches (parathyroids), the neural crest (brain, parasympathetic and sympathetic ganglia, thyroid C cells, adrenal medulla, and enteric ganglia), and the urogenital system. Activating, germline point mutations in *RET* are present in virtually all hereditary MTCs, and somatic *RET* mutations are present in approximately half of sporadic MTCs.[3,4] Recently, it was discovered that somatic mutations in *HRAS*, *KRAS*, and rarely *NRAS* are present in sporadic MTCs and are almost always mutually exclusive with the presence of somatic *RET* mutations.[5]

Approximately 75 *RET* mutations have been reported in association with MEN 2A, MEN 2B, and FMTC. The mutations for MEN 2A and FMTC are located in exons 5, 8, 10, 11, 13, 14, 15, and 16. The mutations for MEN 2A are mostly located in the extracellular, cysteine-rich region of exon 10 (including codons 609, 611, 618, and 620) and exon 11 (including codons 630 and 634). Approximately 85% of the mutations associated with MEN 2A involve *RET* codon 634, about half of which are *C634R RET* mutations. The *RET* mutations in MEN 2B cause constitutive activation, which alters substrate specificity, presumably owing to a conformational change in the binding pocket of the kinase. Approximately 95% of mutations causing MEN 2B are in codon M918T, and 5% are in codon A883F. Rare cases of MEN 2B are caused by double somatic *RET* mutations involving codon V804M and either codon Y806C, S904C, or E805K.

In 50% of patients with MEN 2B and 10% of patients with MEN 2A and FMTC, the disease arises de novo. In such founder cases, the de novo mutation almost always derives from the paternal allele.[6]

CLINICAL MANIFESTATIONS

The peak incidence of sporadic MTC is in the fifth decade of life, and most patients present with a solitary thyroid nodule and lymph node metastases. Clinically, the tumors are more aggressive than papillary thyroid carcinoma and follicular thyroid carcinoma but less aggressive than anaplastic thyroid carcinoma (Chapter 226). The 10-year survival rate is 75%. In the expectation of detecting MTC at any early stage, clinicians in Europe evaluate serum CTN levels in patients with thyroid nodules who have no history of hereditary MTC. The detection rate of MTC is less than 0.5%, however, and clinicians in the United States have not adopted this practice. The clinical manifestations of MEN 2A, MEN 2B, and FMTC are listed in Table 246-1.

TABLE 246-1 CLINICAL MANIFESTATIONS OF MULTIPLE ENDOCRINE NEOPLASIA 2A, 2B, AND FAMILIAL MEDULLARY THYROID CARCINOMA

MULTIPLE ENDOCRINE NEOPLASIA (MEN) 2A
Medullary thyroid carcinoma (~100%) Pheochromocytoma (incidence of 50% in families with a *RET* codon 634 germline mutation but less in families with other *RET* codon mutations) Hyperparathyroidism (incidence of 30% in families with a *RET* codon 634 germline mutation but less in families with other *RET* codon mutations.)
VARIANTS OF MEN 2A
MEN 2A with cutaneous lichen amyloidosis (almost always associated with a *RET* codon 634 germline mutation.) MEN 2A with Hirschsprung disease (most common in families with *RET* germline mutation most commonly involving codon 620)
FAMILIAL MEDULLARY THYROID CARCINOMA (FMTC)
Since the original description of this syndrome, there has been confusion about the designation FMTC. Most clinicians now consider it a variant of MEN 2A.
MEN 2B
Medullary thyroid carcinoma (~100%) Pheochromocytoma (50%) Mucosal neuroma, ganglioneuromatosis, marfanoid habitus, colonic abnormalities, characteristic physical appearance (~100%)

MEN 2A (80% of cases), MEN 2B (5% of cases), and FMTC (15% of cases) are inherited as autosomal dominant traits with near-complete penetrance and, in the cases of MEN 2A and MEN 2B, variable expressivity. Approximately 50% of patients with MEN 2A (and a codon 634 mutation) develop pheochromocytomas (Chapters 228 and 231), the frequency being much lower in association with mutations in codons 609, 611, 618, and 620.[7] Before the availability of biochemical and genetic screening in families with MEN 2A, the most frequent cause of death was pheochromocytoma, not MTC. The deaths occurred most often in patients during childbirth or interventional procedures. Thus, pheochromocytoma must be excluded in patients with a confirmed or presumptive diagnosis of hereditary MTC (Chapter 228). With rare exceptions, the pheochromocytoma should be excised first in patients who also have MTC.

Parathyroid hyperplasia occurs in up to 30% of patients with MEN 2A and is usually associated with a *RET* codon 634 mutation. The disease is frequently asymptomatic, with the only abnormality being an elevated serum calcium concentration.[8]

Patients with MEN 2A may also develop cutaneous lichen amyloidosis (CLA) or Hirschsprung disease (HD).[9] CLA occurs in about 25% of patients and involves the interscapular region of the back, corresponding to dermatomes T2 through T6. Pruritus, the dominant symptom, leads to repetitive scratching and secondary skin changes characterized by the deposition of amyloid. The lesion may be evident in infancy, thus serving as a precursor marker of MEN 2A. Cutaneous lichen amyloidosis is almost always associated with a *RET* codon 634 mutation.

HD, manifested by the absence of intrinsic ganglion cells in the distal gastrointestinal tract, has been reported in 30 or more families with MEN 2A or FMTC and is associated with mutations in *RET* exon 10 involving codons 609 (15%), 611 (4%), 618 (30%), and 620 (50%). In functional studies, the cell surface expression of *RET* with these codon mutations is lower than that found with a codon 634 mutation. This suggests a novel mechanism whereby the specified *RET* mutations have low transforming activity, which is sufficient to trigger the development of MTC and pheochromocytoma, yet is insufficient to stimulate differentiation of intestinal ganglion cells. It is also of interest that 50% of patients with familial HD and 30% of patients with sporadic HD have germline *RET* mutations.

Patients with MEN 2B develop mucosal neuromas, ganglioneuromatosis throughout the aerodigestive tract, hypotonia, skeletal malformations, and medullated corneal nerves. They also develop colonic dysfunction manifested by abdominal pain and occasionally intestinal obstruction. Patients

have a characteristic physical appearance, which may not be evident early in life. The failure to diagnose MEN 2B at a young age can be catastrophic because MTC is often evident soon after birth, and regional or distant metastases occur soon thereafter. The MTC associated with MEN 2B is much more aggressive than that occurring with MEN 2A or FMTC. The primary basis for the difference is that MEN 2B mutations are associated with significantly higher basal kinase activity compared with mutations in MEN 2A and FMTC. Patients with FMTC develop only MTC, which, relative to the tumors in patients with MEN 2A and MEN 2B, is slow growing. Many clinicians consider FMTC a variant of MEN 2A.

DIAGNOSIS

The measurement of serum levels of CTN, either in the basal state or following the intravenous administration of the secretagogues calcium, pentagastrin, or both, was initially the primary method of establishing the diagnosis of a C-cell disorder. With the discovery that MEN 2A, MEN 2B, and FMTC are caused by mutations in the *RET* protooncogene, direct DNA analysis became the method of choice for identifying affected family members who had inherited a mutated *RET* allele. At present, the determination of CTN is primarily used to detect persistent or recurrent MTC following thyroidectomy or to evaluate response to therapy in patients with regional or metastatic disease. As we have learned more about the variable clinical expression of MEN 2A in families with the identical *RET* mutation, however, the measurement of basal and stimulated serum CTN levels has assumed importance in timing early thyroidectomy in young family members with *RET* mutations.[10] The two-site, two-step, chemiluminescent, immunometric assay that is highly specific for monomeric CTN is the preferred method for quantitating serum CTN levels.

At present, direct DNA analysis of RET has become the preferred method of detecting *RET* mutations in families with hereditary MTC. The Gene Tests directory currently lists 63 laboratories that perform DNA analysis for *RET* mutations (http://www.genetests.org). Almost all laboratories use direct sequence analysis to evaluate mutations in exons 10, 11, 13, 14, 15, and 16, and some laboratories include exon 8. If no mutations are found in these exons, the entire coding region of *RET* can be sequenced. It is important to perform direct DNA analysis for *RET* mutations in all patients with presumed sporadic MTC because approximately 7% of them will have hereditary MTC. A diagnosis of hereditary MTC in this setting mandates a different treatment strategy for the patient, as well as his family members, who should be offered the opportunity for clinical evaluation and genetic testing.

TREATMENT

Rx

The primary treatment for patients with MTC, whether sporadic or hereditary, is total thyroidectomy. Resection of lymph nodes in the central compartment is included in all adults and in children with MEN 2B but is excluded in outwardly normal youngsters with MEN 2A and FMTC who are undergoing early thyroidectomy based on directed DNA analysis. If enlarged cervical lymph nodes are evident on preoperative ultrasound examination or at the time of thyroidectomy, the involved anatomic nodal compartment should also be resected. During the thyroidectomy, great care must be taken to preserve the parathyroid glands, the recurrent laryngeal nerves, and the external branch of the superior laryngeal nerve. Postoperatively, serum calcitonin is normal in only 10% of patients with node-positive disease compared with 60% of patients with node-negative disease. Many patients with regional lymph node metastases have a good prognosis, however, with 5- and 10-year survival rates of 80 and 70%, respectively.

Repeat neck operation following initial thyroidectomy is indicated in patients with complications from recurrent tumor compressing or invading vital structures, such as the spinal cord, airway, or esophagus. Also, patients who have intractable diarrhea due to markedly elevated tumor hormone secretions, presumably CTN, may obtain symptom relief by tumor debulking. Patients who develop persistent or recurrent MTC following thyroidectomy, as indicated by elevated serum levels of CTN or CEA, are also candidates for reoperation; however, the benefit of such surgical procedures is open to question because there are no long-term data on quality of life and survival. Rarely, patients with MTC develop Cushing syndrome (Chapter 227) due to the inappropriate secretion of adrenocorticotrophic hormone (ACTH) or corticotropin-releasing hormone. Such patients have advanced disease, and bilateral adrenalectomy may be required if steroidogenesis inhibitors are ineffective. Inappropriate secretion of ACTH is a poor prognostic sign, associated with an average survival of 2 years.

The treatment of pheochromocytoma is adrenalectomy, as described in Chapter 228. Hyperparathyroidism (Chapter 245) is managed by either subtotal parathyroidectomy or total parathyroidectomy with heterotopic autotransplantation.

For patients with locally advanced or metastatic MTC, single-agent or combined chemotherapeutic regimens have been minimally effective, being characterized by low response rates of short duration. External beam radiotherapy is indicated primarily for the treatment of localized metastases, primarily of the central nervous system or bone.

With the demonstration that the tyrosine kinase inhibitor imatinib induced remissions in patients with chronic myelogenous leukemia and gastrointestinal stromal tumors, there was hope that similar molecular targeted therapeutics (MTTs) would be developed for other solid tumors, including MTC. In a recent prospective, randomized, placebo-controlled, double-blind, phase III trial, patients treated with the MTT vandetanib had a significantly prolonged progression-free survival compared with placebo.[A1] On the basis of this study, the U.S. Food and Drug Administration (FDA) approved vandetanib for the treatment of patients with advanced MTC.[11] The FDA also recently approved a second MTT, cabozantinib,[12] based on similar results of a phase III trial.[A2] Thus, effective systemic therapies are available for patients with advanced MTC, and additional studies of other MTTs have recently been initiated.

PREVENTION

In patients with a hereditary cancer syndrome, the removal of an organ destined to become malignant should be considered in the light of five factors. There should be (1) near-complete penetrance of the mutated gene, (2) a reliable method of detecting family members who have inherited a mutated allele, (3) minimal morbidity associated with removal of the organ at risk, (4) excellent replacement therapy for the function of the removed organ, and (5) a reliable method for determining whether the operative procedure has been curative. Few hereditary malignancies meet all of these criteria; fortunately, MEN 2A, MEN 2B, and FMTC meet each of them. Young members of kindred with hereditary MTC who are found to have a mutated *RET* allele on genetic screening have the greatest likelihood of being cured by early thyroidectomy. Surgeons in several countries have reported success with this operative procedure, and the question is no longer should it be done but at what age.

The Consensus Committee of the 7th International Workshop on MEN, the National Comprehensive Cancer Network, and the American Thyroid Association have all proposed guidelines for the timing of prophylactic thyroidectomy in patients with MEN 2A, MEN 2B, and FMTC[13]. The recommendations of the three groups are similar, in that children with MEN 2B (or with mutations in codons 918 or 882) should have thyroidectomy at the time of diagnosis, even during the first months of life. Children with MEN 2A and mutations in codons 611, 618, 620, or 634 should have the thyroid removed at or before 5 years of age. In children with mutations in other *RET* codons, the recommended timing of thyroidectomy is less clear but is generally between 5 and 10 years of age.

PROGNOSIS

Several factors portend an adverse outcome in patients with MTC.[14] Poor prognosis is associated with older age, advanced disease at the time of diagnosis of a large primary tumor, lymph node metastases, markedly elevated serum levels of CTN and CEA preoperatively, extrathyroidal invasion of the trachea or soft tissues, and distant metastases. Patients with MEN 2B and patients with MEN 2A who have *RET* mutations in codon 634 have a poorer prognosis than those with *RET* mutations in other codons. Also, in patients with sporadic MTC, the presence of a *RET M918T* mutation, compared with other codon mutations, is associated with a more aggressive tumor and a poor prognosis. Patients apparently cured by thyroidectomy are followed at 6-month intervals with measurement of serum levels of CTN and CEA. The doubling times of serum CTN are especially useful in predicting the course of the disease. CTN doubling times of less than 6 months (compared with those greater than 24 months) are associated with a very poor prognosis.

REVIEW QUESTIONS

1. Sporadic medullary thyroid carcinomas (MTCs) without somatic *RET* mutations most commonly have which of the following?

A. Somatic *RAS* mutations
B. Germline *RET* mutations
C. Somatic *BRAF* mutations
D. No additional genetic mutations
E. Gene fusions involving the *RET* protooncogene

Answer: A About half of patients with sporadic MTC have somatic *RET* mutations, and about 70% of sporadic MTCs with no somatic *RET* mutations have *HRAS, KRAS*, or rarely *NRAS* mutations. (Moura MM, Cavaco BM, Pinto AE, Leite V. High prevalence of RAS mutations in RET-negative sporadic medullary thyroid carcinomas. *J Clin Endocrinol Metab.* 2011;96: E863-868.)

2. Patients with MEN 2A who develop pheochromocytomas and hyperparathyroidism, in addition to MTC, most commonly have mutations in which codon?

A. *RET* codon 620.
B. *RET* codon 918
C. *RET* codon 634
E. *RET* codon 791
E. *RET* codon 804

Answer: C There is a clear relationship between genotype and phenotype in patients with MEN 2A. Virtually all patients with this syndrome develop MTC, but the development of pheochromocytoma and hyperparathyroidism is highly variable, occurring much more often in patients with *RET* 634 codon mutations and much less frequently in patients with other *RET* codons mutations. (Wells SA Jr, Pacini F, Robinson BG, Santoro M. Multiple endocrine neoplasia type 2 and familial medullary thyroid carcinoma: an update. *J Clin Endocrinol Metab.* 2013;98:3149-3164.)

3. After thyroidectomy, the most reliable indicator of prognosis is which of the following?

A. The specific *RET* or *RAS* mutation associated with the MTC
B. The serum levels of calcitonin (CTN) and carcinoembryonic antigen (CEA) immediately postoperatively
C. The rate at which serum CTN and CEA double
D. The completeness of the thyroidectomy
E. The gender of the patient

Answer: C The presence of an elevated serum CTN or CEA in the immediate postoperative period or soon thereafter is diagnostic of persistent or recurrent MTC. Although this determination is valuable, it is not as significant an indicator of prognosis as the rate at which serum levels of CTN and CEA double. Doubling times of less than 6 months for either CTN or CEA are a very poor prognostic sign. (Meijer JA, le Cessie S, van den Hout WB, et al. Calcitonin and carcinoembryonic antigen doubling times as prognostic factors in medullary thyroid carcinoma: a structured meta-analysis. *Clin Endocrinol.* 2010;72:534-542.)

4. In patients with MEN 2B where the *RET* mutation arises de novo,the mutated allele comes from which parent(s)?

A. The mother
B. The father
C. Either parent
D. Neither parent

Answer: B In patients with de novo MEN 2B, where neither parent expresses the characteristic phenotype associated with the disease, the mutated *RET* allele is virtually always inherited from the father. The average age of males who transmit the disease is significantly greater than the average age of all fathers. This appears to be due to a selective advantage acquired by the testis stem cells, which increases the mutation's frequency in the testis. (Choi SK, Yoon SR, Calabrese P, Arnheim N. Positive selection for new disease mutations in the human germline: evidence from the heritable cancer syndrome multiple endocrine neoplasia type 2B. *PLoS Genet.* 2012;8:e1002420.)

5. In patients with hereditary MTC, thyroidectomy should be performed within the first 5 years of life in which cases?

A. All patients with a germline *RET* codon mutation
B. Only patients with MEN 2B
C. Patients with MEN 2A who have a germline *RET* codon 634 mutation and patients with MEN 2B
D. Patients with a germline *RAS* mutation
E. Patients who only have an elevated serum calcitonin level

Answer: C The published guidelines for managing patients with hereditary MTC all discuss the timing of thyroidectomy in children who have inherited a mutated *RET* allele. There is uniform agreement that thyroidectomy should be performed before 5 years of age in patients with *RET* mutations in codon 634, and as soon as the diagnosis is made in patients with MEN 2B, even in the first months of life. (Kloos RT, Eng C, Evans DB, et al. Medullary thyroid cancer: management guidelines of the American Thyroid Association. *Thyroid.* 2009;19:565-612.)

247

PAGET DISEASE OF BONE

STUART H. RALSTON

DEFINITION

Paget disease of bone is a disorder of skeleton characterized by increased and disorganized bone remodeling affecting one or more skeletal sites. Affected bones enlarge, become deformed, and are at increased risk for pathologic fractures

EPIDEMIOLOGY

The population prevalence of Paget disease is about 1% in the United States and 2% in the United Kingdom. It is also common in Western Europe and in people of European descent who have migrated to other parts of the world. Paget disease is rare in Scandinavians, Africans, and Asians. These differences are thought to have a genetic basis and to be caused by founder mutations that occurred in Europeans many centuries ago with subsequent spread to the rest of the world through emigration. Paget disease is strongly related to age; in the United Kingdom, the incidence is 0.3 to 0.5 per 10,000 person years in those aged 55 to 59 years but doubles in frequency each decade thereafter to reach an incidence of 5.4 per 10,000 person years in women and 7.6 per 10,000 person years in men in those 85 years and older. The prevalence and severity of Paget disease have diminished in most countries over the past 25 years.[1] The causes are unclear, but suggested explanations include influx of migrants from low prevalence areas in some populations, improved nutrition, a more sedentary lifestyle with a reduction in skeletal injuries, and reduced exposure to infections.[2]

PATHOBIOLOGY

Susceptibility to Paget disease seems to be genetically determined, but environmental factors also play a key role in regulating onset and severity of the disease. The importance of genetics is emphasized by the fact that between 15 and 40% of patients have a positive family history and that the risk for developing Paget disease in a first-degree relative of a patient is about sevenfold higher than in the general population.[3] In many families, the disease is transmitted in an autosomal dominant manner, although penetrance is incomplete. The most important susceptibility gene for classical Paget disease is *SQSTM1*. Mutations of *SQSTM1* are present in up to 40% of patients with a family history and 5 to 10% of people with sporadic disease. The *SQSTM1* gene encodes a protein called p62 that is involved in regulating signal transduction downstream of the receptor activator of nuclear factor κB (RANK), which plays a critical role in regulating osteoclastogenesis when activated by RANK ligand (RANKL) (Fig. 247-1). The disease-causing mutations cluster in the ubiquitin-associated domain and have the effect of upregulating nuclear factor κB (NFκB) signaling and stimulating osteoclastogenesis by complex mechanisms that are reviewed in detail elsewhere. Genome-wide association

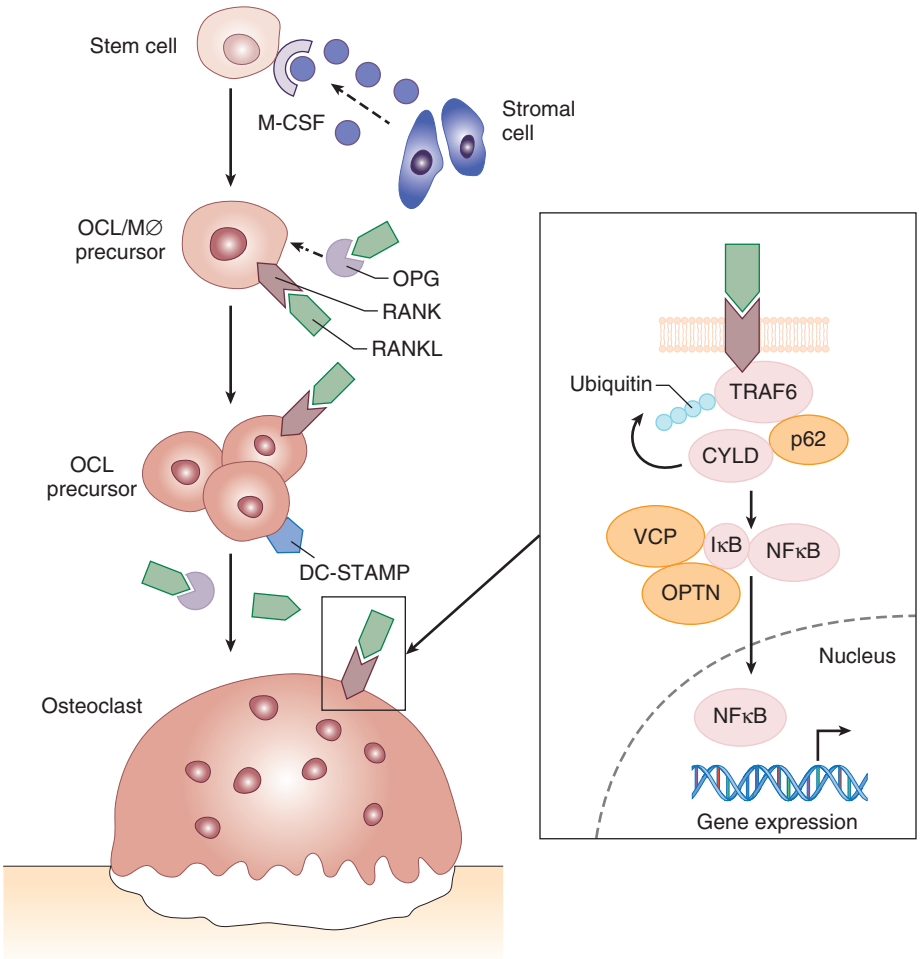

FIGURE 247-1. Regulators of osteoclast dysfunction in Paget disease. Some of the key molecules that have been implicated in the pathogenesis of Paget disease are illustrated. Macrophage colony-stimulating factor (M-CSF) encoded by *CSF1* is required for differentiation of stem cells to the osteoclast/macrophage (OCL/MØ) lineage. Osteoclast differentiation and activity are enhanced when RANK (encoded by *TNFRSF11A*) is activated by RANKL but inhibited by OPG (encoded by *TNFRSF11B*). Fusion of osteoclast precursors to form mature osteoclasts requires DC-STAMP (encoded by *TM7SF4*). Within the cell *(inset),* p62 (encoded by *SQSTM1*) is required for signal transduction downstream of the RANK receptor and is also involved in regulating autophagy. Both VCP (encoded by *VCP*) and OPTN (encoded by *OPTN*) also play a role in regulating NFκB signaling and autophagy.

TABLE 247-1 GENES THAT PREDISPOSE TO PAGET DISEASE–LIKE SYNDROMES

SYNDROME	GENE (PROTEIN)	GENE FUNCTION	INHERITANCE/MUTATION	CLINICAL FEATURES
Familial expansile osteolysis Early-onset familial Paget disease of bone Expansile skeletal hyperplasia	*TNFRSF11A* (RANK)	Enhances osteoclast differentiation and bone resorption	Autosomal dominant Insertion mutations exon 1	Onset during adolescence, extensive bone lesions, deafness, tooth loss.
Juvenile Paget disease	*TNFRSF11B* (OPG)	Inhibits osteoclast differentiation and bone resorption	Autosomal recessive Various loss of function mutations	Onset during childhood, extensive bone lesions, deafness, fractures, deformity, premature cardiovascular disease
Inclusion body myopathy, Paget disease, and frontotemporal dementia	*VCP* (p97)	Multiple cellular functions, including roles in NFκB signaling and autophagy	Autosomal dominant Loss of function mutations in UBA domain	Onset during 3rd-4th decades, with myopathy, Paget disease, and dementia occurring during 5th-6th decades

studies have identified seven other loci that predispose to Paget disease, which individually increase the risk between 1.4 and 1.7 fold.[4,5] These loci have additive effects such that individuals who carry several predisposing alleles have a substantially increased risk for developing Paget disease. Many of these loci lie close to genes that play key roles in osteoclast function, including *CSF1*, which encodes macrophage colony-stimulating factor (M-CSF); *TNFRSF11A*, which encodes RANK; *TM7SF4*, which encodes DC-STAMP; and *OPTN*, which encodes optineurin (see Fig. 247-1). Several inherited diseases with clinical features overlapping with those of Paget disease have also been described (Table 247-1). These syndromes are also caused by mutations in genes that regulate osteoclast function.

Under normal circumstances, bone is renewed and repaired in an orderly and tightly regulated fashion through the process of bone remodeling. The bone remodeling process is highly abnormal in Paget disease. Osteoclasts are increased in number, larger than normal, and hypernucleated. Some contain nuclear inclusion bodies. These were originally thought to be paramyxovirus nucleocapsids, but it has been suggested more recently that they may be aggregates of un-degraded proteins caused by defects in the autophagy pathway. Bone formation is also markedly increased, but the amount of new bone that is formed greatly exceeds that which has been removed by osteoclast activity, leading to enlargement and deformity of affected bones (Fig. 247-2). The bone that is formed is laid down in a disorganized fashion (woven bone) and has impaired mechanical strength. Other features include increased vascularity and marrow fibrosis. The focal nature of Paget disease remains a puzzle. Suggested explanations include the occurrence of somatic mutations in affected bones, which locally increase osteoclast activity, or excessive mechanical loading or skeletal injuries early in life, which by causing microdamage act as a focus for localized increases in bone remodeling.

CLINICAL MANIFESTATIONS

It has been estimated that between 7 and 16% of patients with Paget disease come to medical attention, and the presentation is highly variable.[6] Many patients are asymptomatic, and Paget disease is detected as the result of a raised serum alkaline phosphatase (ALP) or an abnormal radiograph in patients who are being investigated for another reason. In those that do present clinically, symptoms that are attributable to Paget disease are observed in about 75% of cases. The most common is pain, which can be due to either increased bone turnover or a complication such as osteoarthritis, spinal stenosis, pseudofractures, or nerve compression syndromes. Deafness may occur in patients with skull involvement, but this is usually conductive rather than due to auditory nerve compression. Osteosarcoma occurs in less than 0.5% of cases but should be suspected in patients who experience a sudden increase in bone pain or swelling of an affected site. Other, rare complications include obstructive hydrocephalus, high-output cardiac failure, and hypercalcemia in patients who are immobilized. The risk for cardiovascular disease is increased in patients with Paget disease compared with age- and gender-matched controls, probably owing to an increased prevalence of vascular calcification. Most patients have no clinical signs but some present with bone deformity (see Fig. 247-2) or warmth of the skin overlying an affected bone.

DIAGNOSIS

The diagnosis can usually be made by radiograph, which shows the typical features of focal osteolysis with coarsening of the trabecular pattern, bone expansion, and cortical thickening (see Fig. 247-2). Occasionally, the disease may be predominantly lytic in nature (see Fig. 247-2). The most sensitive way of defining the extent of Paget disease is a radionuclide bone scan in which tracer uptake is intensely increased at affected sites (see Fig. 247-2). Imaging with magnetic resonance imaging and computed tomography is not usually required unless complications such as spinal stenosis or osteosarcoma are suspected. Laboratory testing should include assessment of renal function, calcium, albumin, alkaline phosphatase (ALP), and 25(OH)D levels; liver function should be assessed to rule out the possibility that elevations in ALP are of hepatic origin. Typically, Paget disease presents with an elevation in ALP with otherwise normal biochemistries, but normal levels of ALP do not exclude the diagnosis. Vitamin D deficiency is a common finding but most likely reflects the fact that Paget disease predominantly affects older people in whom vitamin D deficiency is prevalent. Specialized markers such as bone-specific ALP or procollagen type 1 N-terminal propeptide can be useful in patients with coexisting liver disease but otherwise offer no advantage over total ALP in diagnosis and assessing treatment response. Susceptibility to Paget disease can be assessed in relatives of affected patients by genetic testing for *SQSTM1* mutations, although this is not commonly performed in routine clinical practice.

The differential diagnosis includes hyperostosis frontalis interna (a benign condition characterized by osteosclerosis of the frontal bones of the skull), fibrous dysplasia, pustulotic arthro-osteitis (which can present with mixed osteosclerotic and osteolytic lesions of the clavicle and ribs),[7] and osteosclerotic metastases, particularly from carcinoma of the prostate. Usually, Paget disease can be distinguished from these conditions biochemically and through imaging, but occasionally, biopsy of an affected site may be required.

Treatment

The most common indication for medical treatment of Paget disease is bone pain localized to an affected site.[8] Although such pain may be caused by increased metabolic activity, other causes may also be operative, including nerve compression syndromes, pseudofractures, secondary osteoarthritis, and other musculoskeletal conditions. Careful assessment of the patient is therefore necessary to decide on the most appropriate treatment. Bone pain caused by increased metabolic activity is localized to the affected site and is usually accompanied by a raised ALP level. It is common to encounter patients in whom pain occurs in the presence of coexisting osteoarthritis, bone deformity, or other musculoskeletal conditions. In such cases, it can be difficult to be sure about the origin of the pain, and many clinicians give a therapeutic trial of bisphosphonates. If the pain responds, then one can assume it was due to increased metabolic activity; if it does not, further evaluation should be undertaken to identify the cause and treat the patient appropriately. Pseudofractures represent a distinct management problem. These are areas of focal osteolysis that traverse the lateral cortex of weight-bearing bones of the lower limbs. Some remain stable for prolonged periods without causing symptoms; others regress spontaneously; and others progress to pathologic fracture, often in association with a localized increase in pain at the affected site.[9]

Bisphosphonates

Bisphosphonates are the drugs of first choice for the treatment of pain that is thought to be due to increased metabolic activity. Nowadays, nitrogen-containing bisphosphonates (aminobisphosphonates) are used in preference to older bisphosphonates because of their greater potency (Table 247-2).

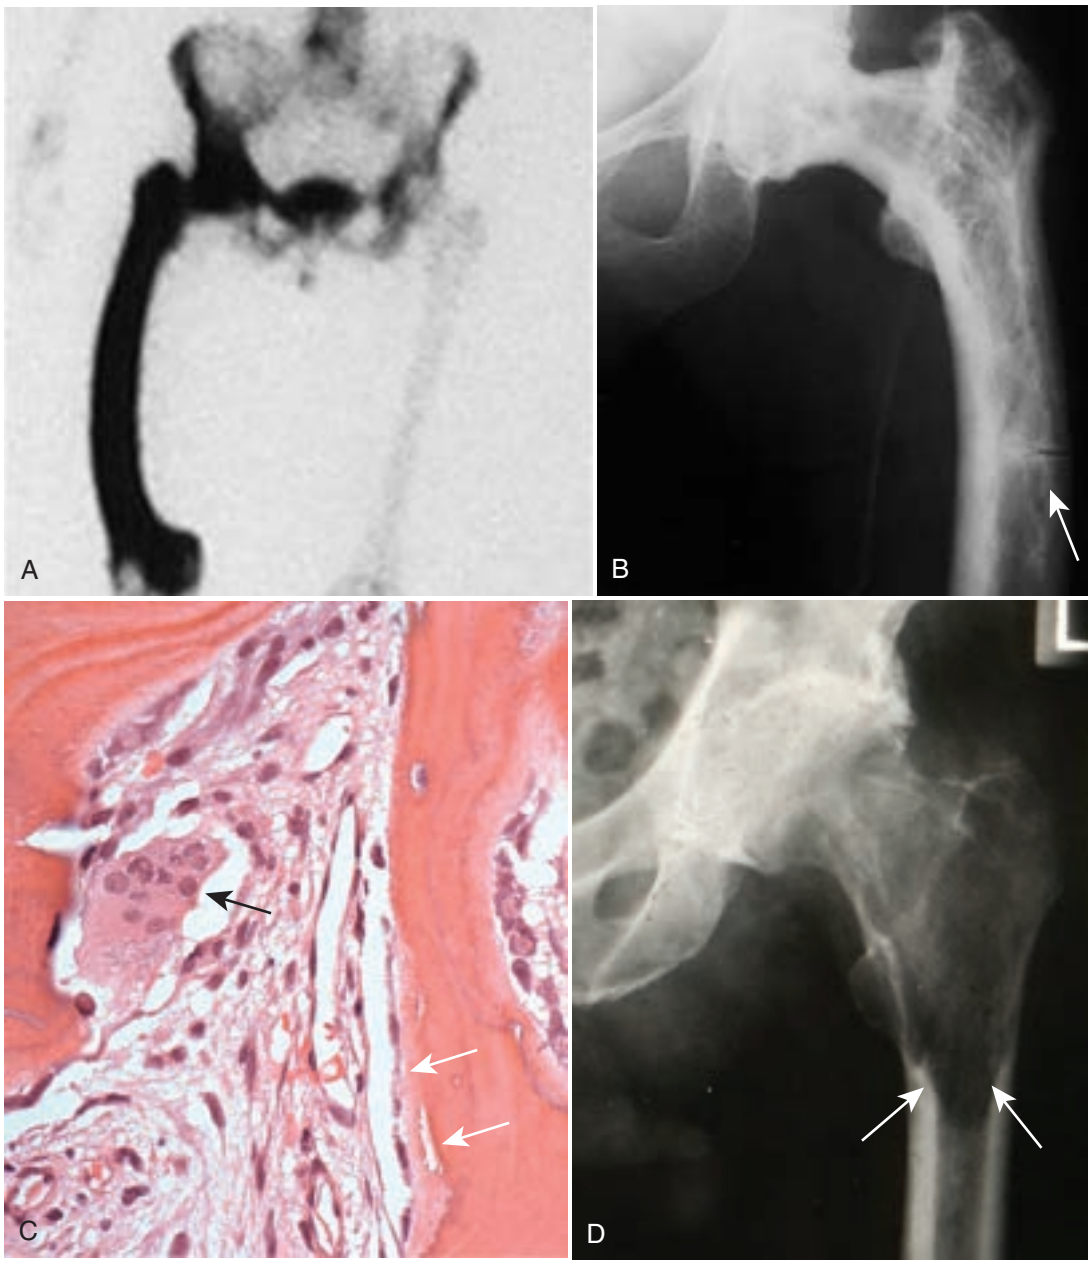

FIGURE 247-2. Radiographic and histologic features of Paget disease. A, Radionuclide bone scan image showing intense tracer uptake, typical of Paget disease of bone (PDB) in the right femur. **B,** Radiograph of an affected left femur showing bone expansion with mixed osteolytic/osteosclerotic areas and loss of normal trabecular pattern. A pseudofracture is visible in the lateral cortex *(arrow).* **C,** Histologic features from a hematoxylin and eosin stained section. A large osteoclast is visible *(black arrow)* close to an area of new bone formation *(white arrows).* There is extensive marrow fibrosis. Irregular cement lines typical of woven bone are apparent to the right of section. **D,** Predominantly lytic Paget disease of the left femur. The lytic area involves the intertrochanteric region and extends down the femoral shaft *(white arrows).*

Placebo controlled trials have shown that most bisphosphonates are effective at improving bone pain in Paget disease. Superiority of aminobisphosphonates over etidronate and tiludronate at suppressing ALP levels has been demonstrated, but with little difference in the response of pain. There are limited data comparing different aminobisphosphonates. In an open-label study comparing pamidronate 180 mg intravenously in unit doses of 30 mg weekly or 60 mg alternate weeks to oral alendronate 40 mg daily given in 3-monthly blocks over a 2-year period, there were no significant differences in the proportion of patients who achieved normal levels of ALP (86 and 91% respectively) or in symptomatic response.[■] Another study that compared a single infusion of 5 mg zoledronic acid with oral risedronate 30 mg daily for 2 months showed significant superiority of zoledronic acid in lowering ALP. Those randomized to zoledronic acid had greater improvement in some domains of health-related quality of life, but the differences between groups were small (1 to 2 points) and below the threshold of 5 points, which is considered clinically significant.[■] Another randomized trial compared the effects of giving repeated course of bisphosphonates (mainly risedronate) with the aim of normalizing ALP (intensive treatment), with therapy primarily aimed at controlling symptoms (symptomatic therapy) in Paget disease.[■] This showed no difference in response of pain, quality of life, or complications between the groups, indicating that trying to restore ALP to normal confers no clinical advantage in most patients with Paget disease.

After initiation of bisphosphonate therapy, levels of ALP start to fall within about 10 days and reach a nadir between 3 and 6 months. Levels of ALP can remain suppressed for many months or years thereafter, particularly with zoledronic acid. Symptoms can improve while ALP levels are still falling, and good clinical responses are often observed in patients whose ALP levels are not restored to normal.

Intravenous bisphosphonates can cause transient bone pain, myalgia, headache, nausea, pyrexia, and fatigue within 1 to 3 days of the infusion in about 25% of cases (acute phase response). These symptoms can be ameliorated by acetaminophen given before and for a few days after the infusion, but they almost always subside within 7 days even without treatment. The acute phase response is much less common after second and subsequent infusions. Hypocalcemia may occur, particularly in patients with substantial elevations in bone turnover and vitamin D deficiency. The risk can be

TABLE 247-2 BISPHOSPHONATES USED IN THE TREATMENT OF PAGET DISEASE

DRUG	DOSE	COMMON ADVERSE EFFECTS
Oral		
Etidronate*	400 mg/day orally for 3-6 mo	Diarrhea, nausea, abdominal pain
Tiludronate	400 mg/day orally for 3 mo	Diarrhea, nausea, dyspepsia
Risedronate	30 mg/day orally for 2 mo	Dyspepsia, esophagitis
Alendronic acid†	40 mg/day orally for 6 mo	Dyspepsia, esophagitis
Intravenous		
Pamidronate	180 mg IV in unit doses of 30 mg weekly or 60 mg alternate weeks	Acute phase response, hypocalcemia
Zoledronic acid	5 mg IV	Acute phase response, hypocalcemia

*Now seldom used.
†Not licensed in the United Kingdom or Europe for Paget disease. Etidronate, pamidronate, tiludronate, and risedronate should be avoided if estimated glomerular filtration rate (eGFR) <30; zoledronic acid and alendronic acid should be avoided if eGFR <35.

minimized by correcting vitamin D deficiency before treatment and providing calcium and vitamin D supplements for the first 1 or 2 weeks after the infusion.

Patients taking oral bisphosphonates must fast for 30 minutes (risedronate, alendronate) or 120 minutes (etidronate, tiludronate) before and after dosing to achieve adequate absorption. The most common adverse effects are dyspepsia (risedronate and alendronic acid) and diarrhea (tiludronate and etidronate). Other rare side effects of bisphosphonates include uveitis, skin rashes, atrial fibrillation, and osteonecrosis of the jaw, as well as atypical subtrochanteric fractures. Bisphosphonates can cause kidney injury and are contraindicated in patients with significant renal impairment.

Other Drug Treatments

Analgesics, anti-inflammatory drugs, and antineuropathic agents are often required in patients with Paget disease, particularly when there is coexisting osteoarthritis or a nerve compression syndrome. Calcitonin can improve bone pain due to metabolic activity in Paget disease but is seldom used except in patients for whom bisphosphonates are contraindicated. Adverse effects such as nausea and flushing can be problematic, and resistance may develop owing to the formation of neutralizing antibodies. Anecdotal reports suggest that the osteoclast inhibitor denosumab may also be effective at reducing ALP levels in Paget disease of bone, but it is not licensed for this indication.

Nonpharmacologic Treatments

Nonpharmacologic approaches (acupuncture, physiotherapy, hydrotherapy, and transcutaneous electrical nerve stimulation) are often used to control pain, but their effectiveness has not been specifically investigated in controlled trials. Clinical experience suggests that specific problems such as limb shortening and deformity can be helped by aids and devices such as walking sticks and shoe raises.

Monitoring Disease Activity and the Effects of Treatment

Metabolic activity and the response to treatment is typically assessed by measuring ALP, although levels can be normal in patients with localized disease that is metabolically active. Further courses of treatment should be considered in patients with recurrent or persistent pain in whom ALP levels remain or become elevated.

Surgery

Orthopedic surgery may be required for the management of coexisting osteoarthritis, pseudofractures, fractures, bone deformity, and spinal stenosis. Osteotomy is performed infrequently, but analyses of small cases series have reported good results in about 60% of patients. Surgery is much more frequently required to repair fractures and to replace joints that are affected by osteoarthritis. Surgical treatment of Paget disease can be technically challenging because of deformity, osteosclerosis, and increased vascularity, but evidence from case series indicate that fractures through pagetic bone heal normally and that joint replacement surgery has a good outcome. It has been suggested that a bisphosphonate should be given before orthopedic and spinal surgery with the aim of reducing operative blood loss, but the effectiveness of this has not been studied. There is a theoretical concern that previous bisphosphonate therapy might impair fracture union and bone repair, but there is little evidence to suggest that this is a problem in clinical practice.[10] Orthopedic surgery may also be required in patients who develop osteosarcoma, but the prognosis is poor even with aggressive operative treatment.

PROGNOSIS

The prognosis of Paget disease is highly variable. Some patients remain completely asymptomatic throughout life, but those that present clinically frequently have complications and have a significant reduction in quality of life. Although modern bisphosphonates are highly effective at suppressing bone turnover in Paget disease,[11] they have not as yet been shown to alter the natural history of the disease or prevent complications. Disease severity and extent can be predicted by genotyping for *SQSTM1* mutations and other risk alleles, and studies are currently in progress to determine whether genetic testing can be combined with prophylactic bisphosphonate therapy to prevent or delay the onset of disease.

REVIEW QUESTIONS

1. A previously healthy 75-year-old man presents to his primary care physician with pain in the left hip that is worse on walking. Systematic enquiry is unremarkable, but examination reveals pain and a reduction in range of movement of the left hip. Radiography shows mixed osteosclerotic-osteolytic lesions in the right hemipelvis with expansion of the iliac bone. Osteophytes and joint space narrowing are observed in the left hip. Routine hematology, urea and electrolytes, calcium and phosphate, and liver function tests are normal, but alkaline phosphatase is raised at 200 μ/L (reference range, 40 to 125). Serum 25(OH)D is 35 nmol/L, parathyroid hormone is 7ng/L (normal, 2 to 12). What is the most likely cause of the hip pain?

A. Paget disease of the pelvis
B. Osteoarthritis of the hip
C. Osteomalacia
D. Osteoporosis
E. Prostate cancer

Answer: B Osteoarthritis of the hip. Although the blood test results are consistent with Paget disease, the pain is localized to the noninvolved side of the pelvis. Although serum 25(OH)D is slightly reduced, osteomalacia is unlikely because this does not usually present with localized pain, and parathyroid is normal. Prostate cancer with bone metastases can cause osteosclerotic metastases, which can look similar to Paget disease on radiography, but the fact that he is clinically well makes this less likely.

2. A 47-year-old man with known Paget disease of the left tibia presents with pain localized to the anterior aspect of the affected tibia. On examination, there is mild deformity of the tibia on the left side, with warmth of the skin overlying the tibia. Hematology and biochemistry are normal, including alkaline phosphatase, which is 105 (reference range, 40 to 125). What is the most appropriate treatment?

A. Paracetamol
B. Surgical osteotomy of the tibia to correct the deformity
C. Amitriptyline
D. Intravenous zoledronic acid, 5 mg IV annually for 3 years
E. Intravenous zoledronic acid, 5 mg IV

Answer: E A single infusion of zoledronic acid would be the most appropriate option. The pain is clearly localized to an affected site and is likely due to Paget disease, even though the alkaline phosphatase is normal, because there is warmth of the overlying skin. To give three infusions would be unnecessary and would represent overtreatment because the clinical effects of zoledronic acid usually last for several years in Paget disease. Osteotomy can be used to correct significant deformity but would not be indicated to treat pain in a patient with mild deformity. Both paracetamol and amitriptyline can be used to help pain control in Paget disease, but in this case it would be appropriate to first assess the response to bisphosphonate before progressing to other treatments.

3. A 62-year-old women presents with a 5-year history of musculoskeletal pain affecting the low back region, both shoulders, and both hips, neck, and head. She reports that her father and older brother have a history of Paget disease. Routine hematology, urea and electrolytes, calcium and phosphate, and liver function tests are normal, but alkaline phosphatase is raised at 2350 μ/L (reference range, 40 to 125). A radiograph of the pelvis shows typical changes of Paget disease. What would be the most appropriate investigation to determine the extent of the disease?

A. Magnetic resonance imaging (MRI) of the spine
B. Computed tomography (CT) of the abdomen, chest, and pelvis
C. Serum bone specific alkaline phosphatase
D. Radionuclide bone scan.
E. Radiograph of the skull, shoulders, and cervical spine

Answer: D Radionuclide bone scan. Bones that are affected by Paget disease typically show intense tracer uptake, allowing one to delineate the extent of involvement in a single test. Imaging with MRI or CT can be useful if complications of Paget disease are suspected, such as spinal stenosis or osteosarcoma, but are not as useful in determining the extent of the disease. Bone-specific alkaline phosphatase will provide information on whether the elevated alkaline phosphatase is of bony origin but will not provide information on disease extent. Although radiographs can detect Paget disease with reasonable sensitivity, one would need to perform a whole skeletal survey to evaluate the extent of the disease.

4. A 75-year-old man develops pain in the low back region that is gradually worsening and has started to radiate into the buttocks on walking. A lateral radiograph of the lumbar spine shows mixed osteosclerotic-osteolytic lesions in lumbar vertebrae 2, 3, and 4, with expansion of all three vertebrae. Routine hematology, urea and electrolytes, calcium and phosphate, and liver function tests are normal, but alkaline phosphatase is raised at 350 μ/L (reference range, 40 to 125). What further investigations would be useful in determining the cause of the pain?

A. MRI of the lumbar spine
B. Anteroposterior radiograph of the spine
C. Radionuclide bone scan
D. Serum procollagen 1N peptide (PINP)
E. CT scan of the lumbar spine

Answer: A MRI of the lumbar spine would be the most appropriate test because the symptoms are suspicious of spinal stenosis, which is a known complication of Paget disease of the lumbar spine and caused by expansion of the affected bones with encroachment on the cauda equina. The anteroposterior radiograph would not be useful in identifying spinal stenosis. Although the CT scan could give information on narrowing of the lumbar canal, it does not provide detail on the soft tissues, which would be necessary to determine whether the cauda equina is being compromised. The bone scan may show evidence of Paget disease in the spine but would not provide information on cauda equina compression. Measurement of PINP would provide information on bone formation but would not be helpful in defining the cause of the pain.

5. A 54-year-old man falls and sustains an injury to his right ankle. A radiograph is taken to exclude a fracture. No evidence of fracture is found, but changes consistent with early Paget disease are noted affecting the upper part of the right tibia. On clinic review 6 weeks after the injury, the patient has fully recovered and is asymptomatic. Routine biochemistry and hematology are normal. What would be the most appropriate evidence-based treatment option for this patient?
