The goal of tumor staging is to define the extent of a patient's disease. Tumor stage provides critical prognostic information that will inform the therapeutic approach that is most appropriate. Accurate staging involves delineating the magnitude of the tumor determined by imaging procedures, as well as confirming the pathologic limits of disease spread from tissues removed at surgery. In essence, for most solid tumor patients, the tumor stage will establish whether the treatment will focus on a local (usually confined to an organ), regional, or disseminated pattern of malignancy and can determine whether the expected outcome of therapy is curative or palliative. On the other hand, hematopoietic malignancies are often disseminated at diagnosis and demand their own prognostic classifiers.

The focus of the staging work-up is to identify potential sites of metastases and to establish indicator lesions with which to monitor therapy. For most solid tumors, CT scans can accomplish both goals; however, in some circumstances, other imaging modalities are more appropriate for therapeutic monitoring (e.g., MRI when central nervous system [CNS] metastases are likely [small cell lung cancer], or combined PET/CT imaging to establish that a given lesion is likely to be malignant, or in diseases where early metabolic responses to treatment can be confirmed (such as for gastrointestinal stromal tumors). In patients with established advanced disease, indicator lesions for therapeutic monitoring should be carefully chosen prior to the initiation of treatment, be well documented in the medical record, and should be evaluated with the minimum frequency of imaging procedures required for accurate follow-up, consistent with evidence-based medical practice or the clinical protocol on which the patient is entered.

The consulting medical oncologist may often be advised by a local tumor board composed of other medical, surgical, and radiation oncologists,

TABLE 179-1 KARNOFSKY AND ZUBROD PERFORMANCE SCALES

KARNOFSKY PERFORMANCE STATUS SCALE

VALUE	LEVEL OF FUNCTIONAL CAPACITY
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity, minor signs or symptoms of disease
80	Normal activity with effort, some signs or symptoms of disease
70	Cares for self, unable to carry on normal activity or to do active work
60	Requires occasional assistance but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled; hospitalization is indicated, although death is not imminent
20	Hospitalization is necessary; very sick, active supportive treatment necessary
10	Moribund; fatal processes progressing rapidly
0	Dead

EASTERN COOPERATIVE ONCOLOGY GROUP (ZUBROD) PERFORMANCE SCALE

PERFORMANCE STATUS	DEFINITION
0	Asymptomatic
1	Symptomatic; fully ambulatory
2	Symptomatic; in bed < 50% of day
3	Symptomatic; in bed > 50% of day
4	Bedridden

pathologists, radiologists, and members of the cancer care team (oncology nurses, social workers, and palliative care specialists). In such a multidisciplinary environment, the patient's overall prognosis can be reviewed and alternatives for care, including standard therapy, possible clinical trials, a second opinion, or no treatment, can be considered. The outcome of such an evaluation is usually viewed by patients and families as an important component in the coordinated development of an overall plan for either further diagnostic procedures or therapy. Finally, many oncologists actively participate in clinical trials that may make investigational drugs or other investigational procedures available for patients, or they may suggest referral to a tertiary cancer center where disease-specific clinical trials are available, as appropriate.

TREATMENT

Therapeutic Plan

Intention of Treatment

Based on the multidisciplinary evaluation of an accurately staged patient, it should be possible to define whether the intent of treatment is curative or palliative. Whether or not this is done during a formal tumor board or multidisciplinary case conference, clarity must be reached regarding the specific choice of therapeutic options (and their potential risks and benefits, overall goals, and alternatives) when considered in the context of the wishes of the patient and family. This is particularly true when the side effects of treatment are substantial (such as for the multidisciplinary management of non–small cell lung cancer or esophageal cancer). For cancers amenable to surgery, resection is often an initial alternative if the patient is a suitable candidate for anesthesia (Chapter 432) and is otherwise in acceptable condition in terms of concomitant or comorbid illnesses. Determination of the patient's performance score (see Table 179-1) is a simple means of assessing functional status. If life expectancy is limited or if the patient is not a good candidate for surgery, more limited approaches to palliative radiation or systemic therapy may be appropriate. There are now substantial data suggesting that the extent of surgery required for an optimal long-term outcome may be reduced for certain solid tumors through the use of presurgical neoadjuvant chemotherapy, often as part of an "organ-sparing" approach. Concomitant and/or sequential multimodality treatments also have the potential to produce long-term disease-free remissions. When the best therapeutic outcomes require the combined skills of surgical, radiation, and medical oncologists, the need for coordination of care among a variety of specialists becomes paramount, and the use of predefined treatment regimens critical.

Therapeutic Paradigm and Therapeutic Index

The therapeutic paradigm in oncology, although still directed at improving the multidisciplinary care model, has begun to change from one focused on delivering treatments at the "maximally tolerated dose" for normal tissues, to therapy that is personalized based on both the molecular characteristics of the patient's tumor as well as any individual germline features that could modify treatment tolerance (Chapter 181). Based on the rapid expansion of our understanding of somatic mutations in human malignancies, and the ability to produce therapeutic molecules that can target specific deficiencies in tumoral DNA repair, growth factor signaling, or energy balance, for example, the currently developing approach to cancer therapeutics involves the employment of predictive molecular markers to guide all modalities of cancer care for the benefit of unique cancer patients. Hence, the focus of oncologists today is on the elaboration of treatments that can be administered with a high therapeutic index, defined as the comparison of the amount of treatment that is effective to the amount that causes toxicity; in this era of personalized cancer medicine, the goal of cancer therapy is to minimize normal tissue toxicity while preserving quality of life by advancing therapies or procedures that are targeted only to specific molecular dependencies in tumors.

Surgical Therapy

Surgery is used to biopsy a suspected lesion, remove the primary tumor, bypass obstructions, provide palliation, and prevent cancers in patients at very high risk because of genetic predispositions or chronic inflammatory states. Surgical staging also establishes the extent of disease. For example, patients with ovarian cancer (Chapter 199) benefit from surgical "debulking" to remove all visible disease, leaving minimal residual tumor, a process that may enhance the effectiveness of systemic treatment. Placement of a venous access device at the time of surgery, if considered proactively, may eliminate the need for a second surgical anesthesia.

Surgery remains the most common method to cure localized cancers such as breast cancer (Chapter 198), colorectal cancer (Chapter 193), and lung cancer (Chapter 191), but it is limited by the location of the tumor, its extension, and distant metastases. Even if a tumor cannot be removed, surgical biopsy provides confirmation of the diagnosis and additional tissue for molecular analysis. Occasionally, an obstructing lesion can be bypassed to provide palliation.

In specific circumstances when the primary tumor has been controlled, removal of a single metastasis (metastasectomy) can result in long-term survival; an example is resection of a solitary liver metastasis found at the time of colectomy for colorectal cancer. A variety of surgical techniques, such as radiofrequency ablation or cryoablation, can also be used to treat hepatic metastases in carefully selected patients. Adjuvant chemotherapy is often given after surgery in this situation to treat microscopic metastases.

The careful application of reconstructive surgery after a disfiguring procedure is critical to long-term physical and emotional well-being. Examples include postmastectomy breast reconstruction (Chapter 198) and plastic surgical procedures to correct deformities following head and neck surgery (Chapter 190).

Radiation Therapy

Ionizing radiation (Chapter 20) can be delivered using beams of high-energy rays, known as *teletherapy*, via a linear accelerator; by brachytherapy, through the application of sealed radioactive implants, seeds, wires, or plaques; and intravenously by using radioisotopes, either directly or attached to antibodies or other targeting molecules. Radiation interacts with water molecules to induce free radical species, including hydroxyl radicals, which damage DNA, proteins, and lipid membranes, leading to cell death. Like chemotherapy, radiation therapy is most effective against rapidly dividing cells that are well oxygenated.

The utility of radiation therapy is limited by the inapparent extension of disease outside a local treatment field, by the location of tumors next to normal structures that must be preserved, and by the presence of distant metastases. Normal tissue tolerance, which varies across different organs and tissues, often prevents the use of radiation doses that could uniformly eradicate cancers. Radiation therapy is also limited by tumor hypoxia: large, bulky tumors are frequently relatively radioresistant, whereas well-oxygenated tumors can be more effectively treated at lower doses. In addition to acute radiation-related toxicities (Chapter 20), late effects of radiation therapy include second malignancies, such as breast cancers that may occur decades after administering thoracic radiation fields during curative treatment for Hodgkin disease.

Radiation therapy can be used as primary treatment, as part of multimodality therapy, in the adjuvant setting, and for palliation. As a single modality, radiation therapy can be curative for early-stage malignancies such as laryngeal cancer (Chapter 190), cervical cancer (Chapter 199), and prostate cancer

(Chapter 201). Breast-conserving surgery (Chapter 198) requires the use of radiation to treat the remaining breast. Partial irradiation techniques using three-dimensional planning with external beam radiation have recently been developed and used in selected patients with appropriately placed and sized breast cancers. For localized prostate cancer (Chapter 201), implanted radioactive seeds of gold or palladium offer an alternative to surgery or external beam radiation therapy in certain patients.

Newer techniques, such as intensity-modulated radiation therapy (IMRT), permit more exact tailoring of the dose to the target, thereby reducing damage to the surrounding normal tissues. Stereotactic radiation therapy or gamma knife techniques allow the treatment of primary or metastatic brain tumors (Chapter 189) measuring up to 3 cm with enhanced accuracy, minimizing damage to normal brain. Particle-based treatment with protons has expanded in use, particularly for limited-stage prostate cancer, based on the potential to deliver higher radiation doses locally. However, there are no randomized studies demonstrating its superiority over other approaches using computational techniques to improve the specificity of radiation delivery (such as IMRT); it is also used for some uveal melanomas, base-of-skull tumors, and a few pediatric malignancies.

Low- to moderate-dose palliative radiation is used to ameliorate symptomatic cancer when cure is no longer the goal. For instance, radiation therapy can improve symptoms from brain metastases (Chapter 189), relieve pain from bone lesions, relieve some obstructing lesions, and sometimes improve hemoptysis caused by lung cancer (Chapter 191) or bleeding from a gynecologic malignancy (Chapter 199). Bone-seeking radioisotopes of samarium, strontium, or radium may relieve pain from bone metastases in prostate cancer (Chapter 201) or breast cancer (Chapter 198).

Systemic Therapy

Cancer Pharmacology

Principles

The fundamental goal of cancer pharmacology is the development of treatments that can be matched to the intrinsic sensitivity of specific tumors, and that can be delivered in concentrations that affect the molecular target of interest with an acceptable therapeutic index. Three properties of all cancer therapeutic agents underlie their clinical utility: (1) pharmacogenetics of the drug (how the germline or somatic expression of genes alters normal tissue toxicity or antitumor efficacy); (2) action of the drug (pharmacodynamics, or what the drug does to the tumor/body); and (3) delivery of the drug (pharmacokinetics, or what the body does to the drug).

Pharmacogenetics

Pharmacogenetics, the study of inherited interindividual differences in drug disposition and effects, is important in cancer therapy because genetic polymorphisms in drug-metabolizing enzymes may be responsible for variations in efficacy and toxicity observed with many chemotherapeutic agents. Drugs potentially affected by polymorphisms identified to date include the thiopurines, 5-fluorouracil, irinotecan, taxanes, and the platinum agents. In patients who are heterozygous or homozygous for deficiencies in metabolizing enzymes, toxicity can be dramatically enhanced. Testing for pharmacogenetic variations that predict for altered normal tissue tolerance is currently available for thiopurines and irinotecan.

Molecular Targeting and Pharmacodynamics

Molecular diagnostic testing to predict antitumor activity for hormonal and anti-HER2 therapeutics has been part of routine oncologic practice for the past two decades, but the recent past has witnessed a remarkable increase in the use of molecular diagnostic testing in cancer drug development and a consequent increase in the number of molecularly targeted anticancer agents that are prescribed only after demonstration of specific molecular abnormalities (predictive of response) in primary or metastatic tumor tissues.[1,2] Examples of such diagnostic/drug pairs include: EGFR mutations in lung adenocarcinomas and erlotinib; ALK tyrosine kinase translocations in lung adenocarcinomas and crizotinib; and $BRAF^{V600E}$ mutations in melanoma and vemurafenib. Recent advances in the process of cancer drug discovery, furthermore, have focused on demonstrating engagement of presumed molecular targets of drug action early in the development process (e.g., evidence of enzyme inhibition, protein dephosphorylation, or DNA damage) as the first step toward implementation of a predictive molecular test for the drug in clinical practice.

Pharmacokinetics and Drug Delivery

Dose selection in oncology is a critical issue primarily because anticancer agents have among the smallest therapeutic ratios in all of medicine. When tumors are responsive to treatment, higher doses may or may not be more effective but are likely to be more toxic to normal tissues. The clearance of a drug from both the systemic circulation and, potentially, from specific physiologic compartments (CNS, thoracic, or peritoneal effusions) is the most important determinant of the dose chosen for a particular patient. It is a composite of all the routes and mechanisms by which the drug can be eliminated from the body and thus determines dose and dose adjustments in the face of changes in drug metabolism, transport, or altered organ function. Although it is important to develop a clear understanding of drug half-lives to establish initial dosing schedules, drug clearance will be the actual determinant of the dose of drug that can be safely administered. Another aspect of drug delivery is the use of body surface area dosing versus flat dosing (using fixed amounts of a drug) in oncologic practice. Although dosing based on body surface area has a long history in oncology (unlike other areas of internal medicine), very little data support this approach; for most agents in common use, empirically determined pharmacokinetic variability from patient to patient is far greater than that which could reasonably be ameliorated by dosing based on weight or surface area.

Routes of Drug Dosing

Prior to the approval of imatinib (administered orally) for the treatment of chronic myelogenous leukemia in 2001, most anticancer agents were developed for parenteral use. However, although intravenous administration remains important, most new anticancer agents are developed for oral use; 7 of the 11 cancer drugs approved by the U.S. Food and Drug Administration (FDA) in 2012 are given by mouth. This change in the route of administration for new drugs brings to the forefront many drug delivery issues that had previously not been routinely considered in the oncology clinic, such as: treatment adherence (does the patient take his/her medication), variability in absorption due to food effects, emesis prior to drug absorption, first-pass metabolism in the liver or intestine, and difficulties in swallowing. For example, whether the orally administered anti-HER1/2 drug lapatinib is taken with food or on an empty stomach can alter its absorption by as much as 10-fold.

In addition to intravenous or oral dosing, anticancer drugs may be used: for intrathecal delivery (to overcome the blood-brain barrier) for the treatment or prevention of meningeal spread of leukemia; for intravesicle therapy of early-stage bladder cancer; for intra-arterial delivery of fluoropyrimidines or other agents to treat hepatic metastases from colon cancer or hepatocellular carcinoma; and for intraperitoneal administration of drugs such as platinum agents for ovarian cancer therapy, which provides a survival advantage for these agents compared with intravenous treatment. In almost all cases, administration of anticancer agents by other than the oral or intravenous routes requires intimate involvement of an oncologic specialist.

Clinical Trials

Clinical trials in oncology are defined by the steps in which new diagnostic approaches, therapeutic agents, or procedures are tested to determine whether they will become part of the standard care for cancer patients. During interventional (rather than observational) clinical trials, specific treatments or procedures are assigned to participants, and the effects of the interventions are measured. For trials of new oncologic drugs, the FDA recognizes several states in the drug development process. Exploratory studies of new drugs examined for the first time in humans (phase 0 trials) may be conducted in on a limited number of patients to define a drug's mechanism of action or biodistribution and to guide subsequent dosing in larger studies. Phase 1 trials define, using a variety of dose-escalation strategies, the maximum dose that can be safely administered to humans and the most appropriate schedule for drug administration, as well as the pharmacokinetic (and more recently pharmacodynamics) profile of the drug. Phase 2 trials often enroll 50 to 150 subjects and focus on testing the drug to determine its effectiveness and side-effect profile in a specific malignancy (or for a specific cancer-related molecular abnormality). If a drug demonstrates anticancer activity in a phase 2 study, phase 3 trials are performed to compare the usefulness of an investigational treatment to a control group receiving the standard of care; patients in most phase 3 studies are randomly assigned to the new or standard treatment to avoid a biased assessment of the results of the study. Finally, after approval of a new drug by the FDA, usually based on the results of phase 3 studies, phase 4 trials may be performed to collect safety information on larger patient populations to define the prevalence of side effects that may be rare but serious.

Drug Interactions

Many drug interactions affect the toxicity profile of anticancer agents, for the most part because concomitant administration of a second drug changes the clearance of the cancer therapeutic, potentially enhancing side effects if the clearance is decreased or diminishing efficacy because of reduced drug exposure. Most often these interactions occur because one drug affects the metabolism of the other by inhibiting or enhancing the activity of cytochrome P-450 isoforms (such as CYP3A) in the liver. This is particularly true for agents administered orally, such as imatinib, crizotinib, enzalutamide, pazopanib, and lapatinib. Concomitant drug-related as well as pharmacogenetic variations in proteins that affect the transport of anticancer agents across tumor and normal cell membranes, such as efflux pumps, also affect the sensitivity or resistance of many classes of cancer drugs. For example, certain drugs that are well-known inducers of hepatic metabolism (phenytoin and rifampin) also induce the expression of drug transport proteins.

Combination Therapy

Virtually all curative chemotherapy regimens developed for hematologic malignancies or solid tumors use combinations of active agents. Combination

chemotherapy is usually superior to the use of single agents in adjuvant and neoadjuvant therapy as well. The improved results achieved by combination chemotherapy can be explained in several ways. Mechanisms of resistance to any particular single agent are almost always present in the tumor genome at diagnosis, even in clinically responsive tumors.[3,4] Tumors that are initially "sensitive" to systemic therapy rapidly acquire resistance to single agents, either as a result of selection of a preexisting clone of resistant tumor cells or because of a variety of potential acquired molecular changes (e.g., increased drug efflux, enhanced DNA repair, insensitivity to apoptosis) leading to clinical drug resistance. Combination therapy may address these phenomena by providing a broader range of mechanisms of drug action against initially resistant tumor cells, preventing or slowing the selection of resistant clones.

The development of combination systemic therapy regimens follows a set of principles (Table 179-2). For standard cytotoxic agents, each drug in the combination must be active against the tumor, and all drugs must be given at an optimal dose and on an appropriate schedule. The drugs should have different mechanisms of antitumor activity as well as different toxicity profiles, and the drugs should be given at consistent intervals for the shortest possible treatment time. The use of molecularly targeted agents in combination requires that each agent engages its specific target and that dual target inhibition produces a complementary enhancement of tumor growth inhibition. Toxicities of targeted agents should be moderate to allow prolonged administration and maximum target inhibition.

Therapeutic Settings

Systemic therapy is used in a variety of settings with or without and before, during, or after surgery and radiation therapy (Table 179-3). Considerable experimental evidence suggests that cancers are most sensitive to chemotherapy during early stages of growth because of higher growth fractions and shorter cell cycle times. Thus, a given dose of a cytotoxic drug may exert a greater therapeutic effect against a rapidly growing tumor than against a larger quiescent tumor.

Neoadjuvant therapy, also called primary or induction systemic therapy, is used before surgery or radiation therapy to decrease the size of locally advanced cancers, thereby permitting a more complete surgical resection or eradicating undetectable metastases. It also affords an opportunity to evaluate the effectiveness of treatment by histologic and molecular analysis of resected tissue. This approach is most often used for locally advanced breast cancer (Chapter 198).

TABLE 179-2 PRINCIPLES OF COMBINATION THERAPY

CYTOTOXIC AGENTS	MOLECULARLY TARGETED DRUGS
Drugs are each active against the tumor	Agent has therapeutic effect on molecular pathway in vivo
Drugs have different mechanisms of action	Agents have complementary effects on the same target or other targets in the same pathway or pathways that cross-talk to control tumor growth
Drugs have different clinical toxicities to allow full doses of each to be administered	Toxicities do not overlap with cytotoxics and are moderate to low to allow prolonged administration. Consider physiologic consequences of target engagement in relation to toxicity profile
Intermittent intensive therapy preferred to continuous treatment for cytoreduction and to reduce immunosuppression	Schedule chosen to maximize target inhibition

TABLE 179-3 COMMON EXAMPLES OF THERAPEUTIC SETTINGS

ADJUVANT THERAPY	NEOADJUVANT THERAPY	ORGAN-SPARING THERAPY	COMBINATION CHEMOTHERAPY
Stage I and II breast cancer Stage III colorectal cancer Stage II lung cancer	Stage III breast cancer	Anal cancer Laryngeal cancer Esophageal cancer	Metastatic solid tumors* Hematologic malignancies

*Usually palliative.

Organ-sparing therapy is another use of chemotherapy, radiation therapy, or both, to salvage organs that would have been surgically removed if cure were the intended result. This technique is often effective in patients with cancers of the larynx (Chapter 190), esophagus (Chapter 192), and anus (Chapter 193).

Adjuvant chemotherapy is used in patients whose primary tumor and all evidence of cancer (e.g., regional lymph nodes) have been surgically removed or treated definitively with radiation, but in whom the risk of recurrence is high because of involved lymph nodes or certain morphologic or biologic characteristics of the cancer. Common examples include cancers of the breast (Chapter 198) and colon (Chapter 193). The typical end points of chemotherapy, such as shrinkage of measurable tumor on serial radiographic studies, are not available in this situation; instead, relapse-free survival and overall survival are the principal measures of treatment effect. For an individual patient receiving adjuvant therapy, there is no way to determine whether such therapy is beneficial; hence, decisions are generally based on evidence from clinical trials.

Assessment of Response

Assessment of the response to therapy (usually performed using RECIST [Response Evaluation Criteria in Solid Tumors]) depends largely on tumor size, determined by either direct measurement or diagnostic imaging studies, using predefined categories. The categories of response are "complete response," with total absence of tumor and correction of tumor-associated changes measured twice at least 4 weeks apart; "partial response," defined as 30% or greater reduction in the sum of the longest diameters of up to 5 target lesions per organ confirmed by repeat measurement 4 weeks later; "progressive disease," characterized by either 20% or greater increase over the smallest sum of the longest diameters of target lesions or the development of new tumors; and "stable disease," defined as meeting criteria for neither partial response nor progressive disease. Leukemias are assessed by bone marrow biopsies and molecular diagnostic tests for residual disease, and multiple myeloma is typically assessed by the measurement of monoclonal proteins, peripheral blood counts, and percentages of malignant plasma cells in bone marrow samples, as well as imaging of bone lesions. Accurate assessment of response following systemic therapy is essential because of the tight relationship between the degree of response and the duration of disease control.

Classes of Therapeutic Agents

Cytotoxic Agents, Targeted Small Molecules, and Antibodies

The pharmacologic properties of the most commonly used cytotoxic and molecularly targeted chemotherapeutic agents approved by the FDA are described in Table 179-4, as well as their most common therapeutic indications. In all cases, current information from the manufacturer should be sought before therapy is initiated.

Administration of chemotherapy is best done by specifically trained individuals because of the dual acute risks of hypersensitivity reactions and extravasation. No doses or schedules are suggested in Table 179-4 because these agents are often used in combination, and the doses of each drug may need to be reduced when the compounds are combined. The treatment of special populations, including patients with significant obesity, during pregnancy, the elderly, and those with abnormal end-organ function, are addressed later in this chapter.

Unless otherwise specified, most cytotoxic chemotherapeutic agents are capable of producing some degree of nausea and vomiting, myelosuppression, alopecia, mucositis, and/or diarrhea after treatment; many agents are also teratogenic, mutagenic, and carcinogenic. Drugs used routinely to prevent agent-specific toxicities are also included in Table 179-4.

Over the past decade, several dozen small molecule anticancer agents with more precisely targeted mechanisms of action have become a standard part of oncologic practice (see Table 179-4). Although the molecular dependencies within tumor cells against which these drugs are targeted are broad in scope, including tyrosine kinase growth factors or their receptors, they are functionally much more specific than prior generations of systemic cancer therapies. This allows for a better appreciation of the clinical situations wherein certain drugs might be beneficial, as well as the possibility of developing agents for use in specific tumors based on their genetic susceptibilities. It is also noteworthy that the toxicity profiles of molecular targeted agents most often reflect alterations produced in biochemical pathways that control normal organ function, rather than a general pattern of toxicity consistent with injury to rapidly growing tissues, such as the bone marrow or gastrointestinal tract. Current research aims to clarify specific mutational profiles in the clinic that can be used to prospectively select patients for therapy (Chapter 181).

The development of monoclonal antibodies directed against antigens found on cancer cells represents an additional approach to molecular targeting of systemic therapy. Examples include cetuximab (targeting the epidermal growth factor receptor), rituximab (targeting the B-cell CD20 surface antigen), and trastuzumab (which blocks HER2). These monoclonal antibodies can be used alone, or labeled with a radioactive molecule, or conjugated to another

Text continued on p. 1218

TABLE 179-4 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER

DRUG NAME	DRUG CLASS AND MECHANISM OF ACTION	PHARMACOKINETICS AND METABOLISM	TOXICITY	INDICATIONS
ALKYLATING AGENTS				
Bendamustine (Treanda)	Alkylating agent; bifunctional, with both alkylating and purine-like antimetabolite action	Biotransformation in liver; decrease dose for hematologic toxicity	Nausea, vomiting, and bone marrow suppression	CLL and B-cell non-Hodgkin lymphoma
Carboplatin (Paraplatin)	Platinum coordination compound; produces intrastrand and interstrand DNA cross-links leading to introduction of DNA breaks during replication	Rapidly cleared largely unchanged by kidney; patients with decreased CrCl experience greater thrombocytopenia	Thrombocytopenia; nephrotoxicity substantially less than cisplatin	Ovarian cancer, testicular cancer, lung cancer, head and neck cancer, breast cancer
Chlorambucil (Leukeran)	Bifunctional alkyl forms interstrand DNA cross-links with resultant inactivation of DNA; cell cycle nonspecific acting agent	Highly orally bioavailable; hepatic biotransformation	Dose-limiting myelosuppression; mucosal toxicity mild	CLL, Waldenström macroglobulinemia, non-Hodgkin lymphomas
Cisplatin (Platinol)	Platinum coordination compound; produces interstrand and intrastrand DNA cross-links leading to DNA breaks; cell cycle nonspecific	Rapid distribution and DNA binding to tissues; over 90% of drug is protein bound	Nephrotoxicity is dose-limiting; significant nausea and vomiting require expert management; ototoxicity; peripheral neuropathy; hypomagnesemia and potassium wasting	Testicular cancer, other germ cell tumors, ovarian cancer, bladder cancer, lung cancer, sarcomas, cervical cancer, endometrial cancer, gastric cancer, breast cancer, head and neck cancer
Cyclophosphamide (Cytoxan, Neosar)	Alkylating agent; cross links DNA, decreasing macromolecular synthesis; immunosuppressive	Hepatic biotransformation of parental pro-drug to alkylating species; metabolites excreted in urine	Bone marrow suppression moderate at standard doses; alopecia; hemorrhagic cystitis, SIADH, and pulmonary fibrosis infrequent	Breast cancer, Hodgkin and non-Hodgkin lymphomas, leukemias, neuroblastoma, retinoblastoma, other sarcomas, osteogenic sarcoma, Wilms tumor
Ifosfamide (Ifex)	Alkylating agent; alkylated metabolites interact with DNA; cell cycle nonspecific	Hepatic biotransformation; renal elimination	Myelosuppression; hemorrhagic cystitis (requires co-administration of the uroprotector mesna); nephrotoxicity; CNS toxicity (lethargy, stupor)	Germ cell tumors, sarcomas, non-Hodgkin lymphomas
Melphalan (Alkeran)	Alkylating agent; forms interstrand, intrastrand, or DNA protein cross-links; cell cycle nonspecific	Unpredictable absorption by GI tract; highly protein bound; hydrolyzed in plasma; partially eliminated by kidney	Myelosuppression; vomiting when used at high dose; associated with secondary leukemias when used chronically	Multiple myeloma, rhabdomyosarcoma, bone marrow ablation for stem cell transplantation
Oxaliplatin (Eloxatin)	Platinum coordination compound; produces interstrand DNA cross-links; not identical to other platins	Renal elimination following active metabolism; no excretion by liver and safe to use in face of liver dysfunction	Cumulative sensory neuropathy is dose-limiting and worse in the cold; fatigue and nausea common	Colorectal cancer
Temozolomide (Temodar)	Nonclassic alkylating agent that is affected by DNA methylation status	Oral bioavailability good; penetrates blood-brain barrier	Myelosuppression may be cumulative; treatable nausea; fatigue	Melanoma, brain tumors
ANTIMETABOLITES				
5-Azacitidine (Vidaza)	Antimetabolite; pyrimidine nucleoside analogue of cytidine; hypomethylates DNA, producing gene activation; directly incorporated into DNA, with cytotoxicity at higher doses	Hepatic metabolism; renal excretion	Dose-limiting myelosuppression; transient liver function abnormalities; nausea, vomiting, abdominal pain	Myelodysplastic syndrome
Capecitabine (Xeloda)	Pyrimidine antimetabolite; pro-drug form of 5-fluorouracil; inhibits DNA and RNA synthesis	Well absorbed after oral administration; metabolized to 5-fluorouracil in liver and in tumor	Myelosuppression, hand-foot syndrome, diarrhea, stomatitis, fatigue	Breast cancer, colorectal cancer
Cladribine (Leustatin), 2-chloro-2-deoxy-D-adenosine	Purine nucleoside antimetabolite; inhibits DNA synthesis and repair	Excreted primarily in urine as unchanged parent drug; excellent oral bioavailability	Bone marrow suppression, fever	Hairy cell leukemia, CLL, non-Hodgkin lymphoma
Clofarabine (Clofar)	Purine nucleoside antimetabolite; inhibits DNA synthesis and repair; activates apoptosis	Excreted in urine	Bone marrow suppression, hepatotoxicity, capillary leak syndrome	Relapsed acute lymphoblastic leukemia
Cytarabine* (Cytosar-U, Tarabine PFS)	Antimetabolite activated to cytarabine triphosphate in tissues; inhibits DNA synthesis; cell cycle specific, S phase	Deaminated in blood and tissues, with short terminal half-life	Bone marrow suppression, stomatitis, pancreatitis; with high doses, cerebral dysfunction, GI damage, hepatotoxicity, pulmonary edema, corneal damage, Ara-C syndrome	Acute myelocytic leukemia

Decitabine (Dacogen)	Antimetabolite that inhibits DNA methyltransferase, producing hypomethylation and gene activation	Deaminated in liver, blood, and GI tract; short half-life	Bone marrow suppression, nausea and vomiting, fatigue, abnormal liver function and blood sugar	Myelodysplastic syndrome
Fludarabine phosphate (Fludara)	Purine nucleotide antimetabolite; 2-fluoro-ara-ATP inhibits DNA synthesis by inhibition of ribonucleotide reductase and DNA polymerases	After IV dosing, 2-fluoro-ara-A widely taken up by tissues; drug and metabolites excreted by kidney	Neurotoxicity, including somnolence and demyelinating lesions, dose-limiting; myelosuppression (lymphopenia)	CLL; also used for low-grade non-Hodgkin lymphomas
Fluorouracil (5-FU, Adrucil)	Pyrimidine antimetabolite; inhibitor of thymidylate synthase; also alters RNA synthesis	Primarily metabolized by dyhydropyrimidine dehydrogenase in liver; remainder metabolized in tumor and other tissues to active species; renal excretion of remaining drug	Mucositis and diarrhea, myelosuppression; hand-foot syndrome when used as an IV infusion; rare cerebellar ataxia or cardiac ischemia	Colorectal cancer, other GI cancers, breast cancer, head and neck cancer
Gemcitabine (Gemzar)	Nucleoside analogue antimetabolite that inhibits ribonucleotide reductase and is incorporated into DNA following intracellular metabolism, leading to DNA synthesis inhibition	Metabolized by deamination in a variety of tissues and excreted both as parent drug and metabolites by the kidneys; elevated bilirubin requires dose reduction; increased creatinine enhances drug toxicity	Myelosuppression, nausea and vomiting, elevated transaminases, fever	Pancreatic cancer, breast cancer, non–small cell lung cancer, bladder cancer, ovarian cancer
Methotrexate (Folex, Mexate)	Folic acid analogue antimetabolite; inhibition of dihydrofolate reductase blocks nucleotide synthesis	Mainly renal excretion with minimal hepatic metabolism; strict attention to renal function required for dosing; third-space accumulation, including pleural effusions and ascites, with prolonged release and associated toxicity	Myelosuppression is dose-limiting; stomatitis and diarrhea common, especially if delayed excretion; renal toxicity can also be severe if drug elimination impaired	Acute leukemias, especially in children; non-Hodgkin lymphoma, breast cancer, head and neck cancer, sarcomas
Pemetrexed (Alimta)	Folic acid analogue antimetabolite; inhibits multiple enzymes in folate pathway, leading to altered DNA and RNA synthesis	Excreted as unchanged drug by kidney	Myelosuppression, nausea, diarrhea, rash, fatigue; must be given with folic acid and vitamin B_{12} to reduce toxicity	Mesothelioma, non–small cell lung cancer
Pralatrexate (Fotolyn)	Folic acid analogue antimetabolite	Renal excretion	Myelosuppression, mucositis, pyrexia; must be given with folic acid and vitamin B_{12} to reduce toxicity	Relapsed peripheral T-cell lymphoma
DIFFERENTIATING AGENTS				
All-*trans*-retinoic acid (ATRA)	Retinoid; induces cellular differentiation and/or apoptosis	Conjugated to glucuronic acid, with subsequent biliary excretion and enterohepatic circulation	Mucocutaneous, ocular, musculoskeletal, neurologic, hepatic toxicity; hyperlipidemia	Acute promyelocytic leukemia
Arsenic trioxide (Trisenox)	Arsenical differentiating agent	Hepatic metabolism; excreted in urine	Prolonged QT interval; acute promyelocytic leukemia differentiation syndrome (leukocytosis, fever, dyspnea, chest pain, hypoxia) that can be treated with corticosteroids; peripheral neuropathy	Acute promyelocytic leukemia
ENZYMES				
L-Asparaginase (Elspar)	Enzyme that hydrolyzes 1-asparagine to aspartic acid and ammonia, resulting in cellular deficiency of 1-asparagine, critical for tumor cells that lack asparagine synthetase; interferes with protein, DNA, and RNA synthesis	Metabolized in the vasculature by proteolysis	Hypersensitivity reactions; inhibitory effects on protein synthesis, with resultant decreases in hepatic synthesis of coagulation factors, pancreatitis, hyperglycemia, CNS depression, hepatotoxicity, transient renal dysfunction	Acute lymphoblastic leukemia
DNA-ACTIVE DRUGS WITH PLEIOTROPIC MECHANISMS OF ACTION				
Bleomycin (Blenoxane)	Antitumor antibiotic; produces free radical–related DNA strand breaks	Metabolized partially by intracellular aminopeptidases; renal excretion	Dose-related pulmonary fibrosis, fever, hypersensitivity reactions, skin toxicity, including Raynaud phenomenon	Testicular cancer and other germ cell tumors, Hodgkin and non- Hodgkin lymphomas; sclerosing agent for pleural effusions
Carmustine (BiCNU, BCNU)	Nitrosourea-class alkylating agent; alkylates DNA and may affect carbamoylation of amino acids	Taken up by CNS; metabolized in liver and excreted by kidney	Myelosuppression may be slow in onset and cumulative; severe nausea and vomiting, renal toxicity, interstitial lung disease	Glioblastoma
Daunorubicin (Cerubidine)	Anthracycline antibiotic; pleiotropic effects, including free radical formation, inhibition of topoisomerase II, altered mitochondrial metabolism, activation of pro-apoptotic signal transduction	Hepatic metabolism with biliary excretion; small amount of renal excretion leads to "orange-red" urine	Myelosuppression and mucositis are dose-limiting; alopecia, cumulative dose-related cardiotoxicity, extravasation injury	Acute myelocytic leukemia, acute lymphoblastic leukemia

TABLE 179-4 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER—cont'd

DRUG NAME	DRUG CLASS AND MECHANISM OF ACTION	PHARMACOKINETICS AND METABOLISM	TOXICITY	INDICATIONS
Doxorubicin (Adriamycin, Rubex)	Anthracycline antibiotic; pleiotropic effects, including free radical formation, inhibition of topoisomerase II and DNA strand breaks, altered mitochondrial metabolism, activation of pro-apoptotic signal transduction	Hepatic metabolism to both active and inactive species, with 50% biliary excretion; "orange-red" urine	Myelosuppression and mucosal injury are dose-limiting; alopecia, cumulative dose-related cardiotoxicity (cardiomyopathy), nausea and vomiting, severe extravasation injury risk, secondary AML	Acute myelocytic leukemia, acute lymphoblastic leukemia, breast cancer, small cell lung cancer, Hodgkin and non-Hodgkin lymphomas, sarcomas, endometrial cancer, Wilms tumor, neuroblastoma
Doxorubicin liposomal (Doxil)	Anthracycline antibiotic with pleiotropic mechanisms of action	Liver	Myelosuppression, dose-related cardiotoxicity, extravasation injury, hand-foot syndrome	Ovarian cancer, breast cancer, Kaposi sarcoma
Epirubicin (Ellence)	Anthracycline antibiotic with pleiotropic mechanisms of action similar to others in class	Liver	Similar to doxorubicin; modestly less cardiotoxic; extravasation	Breast cancer adjuvant therapy
Etoposide (VP-16, VePesid)	Epipodophyllotoxin plant alkaloid; inhibits topoisomerase II, leading to decreased DNA synthesis	Extensively protein bound; hepatic metabolism; excreted as metabolites in bile and unchanged in urine	Dose-limiting myelosuppression, nausea and vomiting, stomatitis when used at high dose, secondary AML	Small cell lung cancer, germ cell tumors, lymphomas; high-dose therapy conditioning regimens
Idarubicin (Idamycin)	Anthracycline antibiotic with pleiotropic mechanisms of action similar to others in class	Hepatic metabolism with biliary excretion	Similar to doxorubicin; modestly less cardiotoxic; extravasation	Acute myelocytic leukemia
Irinotecan (Camptosar)	Semisynthetic camptothecin analogue that poisons DNA topoisomerase I, preventing religation of replication-related single-strand breaks	Partially inactivated in plasma; metabolized by esterases to active species SN-38, which is excreted into bile; patients with elevated bilirubin have increased toxicity	Myelosuppression; early and late diarrhea may be severe; flushing, alopecia	Colorectal cancer
Topotecan (Hycamtin)	Semisynthetic camptothecin analogue that inhibits DNA topoisomerase I, inhibiting transcription	Excreted primarily unchanged in urine	Severe myelosuppression is dose-limiting (both granulocytes and platelets); mild nausea, fatigue, diarrhea	Relapsed ovarian and small cell lung cancer
INHIBITORS OF MITOTIC FUNCTION				
Docetaxel (Taxotere)	Mitotic spindle poison that stabilizes tubulin polymers, leading to mitotic tumor cell death	Biliary excretion	Myelosuppression and alopecia, hypersensitivity reactions, fluid retention syndrome, peripheral sensorimotor neuropathy	Breast cancer, non–small cell lung cancer, ovarian cancer, gastric cancer, head and neck cancer
Eribulin mesylate (Halaven)	Semisynthetic natural product; microtubule inhibitor	Excreted primarily as unchanged parent compound in feces	Neutropenia, peripheral neuropathy, QT prolongation, fatigue, nausea	Metastatic breast cancer
Ixabepilone (Ixempra)	Microtubule inhibitor; analogue of epothilone B that binds to β-tubulin, suppressing function of microtubules and causing mitotic cell death	Metabolized by liver and excreted in feces; dose reduction required in face of liver dysfunction	Cumulative peripheral neuropathy, neutropenia, hypersensitivity reactions, fatigue, myalgias, stomatitis	Breast cancer
Paclitaxel (Taxol)	Taxane natural product; mitotic spindle poison that inhibits tubulin depolymerization	Hepatic metabolism, biliary excretion	Myelosuppression, mucositis, hypersensitivity reactions, cumulative peripheral neuromyopathy with arthralgias, cardiovascular toxicity with hypotension, arrhythmias	Non–small cell lung cancer, ovarian cancer, breast cancer, esophageal cancer, gastric cancer, head and neck cancer
Paclitaxel protein-bound particles (Abraxane)	Albumin nanoparticle-bound form of paclitaxel; same mechanism of action	Hepatic metabolism, biliary excretion	Hypersensitivity reactions, myelosuppression, neuropathy, arthralgias/myalgias, cardiotoxicity	Metastatic breast cancer, pancreatic cancer, non–small cell lung cancer
Vincristine (Oncovin)	Vinca alkaloid natural product; inhibits tubulin polymerization, arresting cells in metaphase	Hepatic metabolism, biliary excretion	Extravasation injury, dose-limiting peripheral neurotoxicity, constipation	Acute lymphocytic leukemia, neuroblastoma, Wilms tumor, Hodgkin and non-Hodgkin lymphomas, rhabdomyosarcoma
Vinorelbine (Navelbine)	Semisynthetic vinca alkaloid; inhibits tubulin polymerization during mitosis	Hepatic metabolism, biliary excretion	Myelosuppression, extravasation, milder neurotoxicity than other vincas	Non–small cell lung cancer, breast cancer

HORMONAL AGENTS				
Abiraterone acetate (Zytiga)	Inhibitor of androgen biosynthesis	Parent drug and metabolites excreted in stool; systemic clearance decreased in patients with liver dysfunction	Joint swelling, edema, hepatotoxicity	Castration-resistant metastatic prostate cancer
Anastrozole (Arimidex)	Nonsteroidal aromatase inhibitor; inhibits conversion of adrenal androgens to estrogens	Metabolized in liver, excreted into bile and urine	Hot flashes, headache, arthralgias	Adjuvant and metastatic breast cancer in postmenopausal women
Bicalutamide (Casodex)	Nonsteroidal antiandrogen that binds to prostatic androgen receptor	Hepatic metabolism	Worsening bone pain, hot flashes, gynecomastia	Prostate cancer (usually in conjunction with LHRH antagonist)
Degarelix (Firmagon)	GnRH receptor antagonist; binds to GnRH receptors in pituitary, decreasing gonadotropin release	Biliary excretion of parent and metabolites; lesser renal excretion of unchanged parent drug	Injection site reactions, hot flashes, weight gain, increased LFTs, QT prolongation	Prostate cancer
Enzalutamide (Xtandi)	Nonsteroidal antiandrogen; inhibits androgen receptor-mediated signal transduction	Hepatic metabolism, eliminated primarily in urine	Fatigue, arthralgias, dizziness, bone pain	Metastatic castration-resistant prostate cancer
Exemestane (Aromasin)	Steroidal aromatase inhibitor; binds and irreversibly inhibits aromatase, inhibits synthesis of estrogens by preventing conversion of adrenal androgens to estrogens	Metabolized in liver	Hot flashes, fatigue, arthralgias	Metastatic breast cancer in postmenopausal women
Flutamide (Eulexin)	Nonsteroidal antiandrogen; inhibition of nuclear binding of androgen in target tissues; its interference with testosterone at cellular level complements "medical castration" produced by LHRH analogues	Metabolized to active and inactive metabolites in liver	Worsening bone pain, hot flashes, gynecomastia, impotence	Prostate cancer (usually in conjunction with LHRH antagonist)
Fulvestrant (Faslodex)	Estrogen receptor antagonist; binds to estrogen receptor, causing degradation of estrogen receptor protein	Metabolized by liver, excreted in bile	Hot flashes, nausea, peripheral edema and weight gain, fatigue, arthralgias	Recurrent breast cancer in postmenopausal women
Goserelin (Zoladex)	Synthetic decapeptide analogue of LHRH; suppresses pituitary gonadotropins, with fall of serum testosterone into castrate range	Slowly released from depot injection site; not extensively metabolized; urinary excretion	Worsening bone pain, hot flashes, impotence, gynecomastia, breakthrough vaginal bleeding	Prostate cancer, breast cancer
Letrozole (Femara)	Nonsteroidal competitive inhibitor of aromatase; inhibits estrogen synthesis by blocking conversion of adrenal androgens to estrogens	Metabolized in liver, excreted by kidney	Hot flashes, fatigue, arthralgias	Adjuvant and metastatic breast cancer in postmenopausal women
Leuprolide (Lupron, Lupron Depot)	Synthetic LHRH analogue; suppresses secretion of GnRH, with resultant fall in testosterone secretion, producing "medical castration"	Metabolized to inactive peptide fragments; minor renal excretion	Increased bone pain, hot flashes, gynecomastia, lethargy, thromboembolic phenomena	Prostate cancer, breast cancer
Octreotide (Sandostatin)	Synthetic octapeptide analogue of somatostatin; suppresses secretion of serotonin and GI peptides; blocks carcinoid flush, decreases serum 5-HIAA, and controls other symptoms associated with carcinoid syndrome	Hepatic metabolism; renal excretion following hydrolysis in plasma	Hyper/hypoglycemia, hepatic dysfunction, diarrhea	Palliative treatment of carcinoid tumors and vasoactive intestinal peptide tumors (VIPomas)
Tamoxifen (Nolvadex)	Nonsteroidal antiestrogen; competes with estradiol for estrogen receptor protein; also has non–estrogen receptor–dependent effects on tumor cells	Metabolized in liver but not excreted in bile or urine	Hot flashes, nausea/vomiting, vaginal bleeding or discharge, endometrial hyperplasia, thrombophlebitis, hypercalcemia, visual disturbances	Adjuvant and metastatic estrogen receptor–positive breast cancer; also approved for chemoprevention of breast cancer in high-risk individuals

TABLE 179-4 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER—cont'd

DRUG NAME	DRUG CLASS AND MECHANISM OF ACTION	PHARMACOKINETICS AND METABOLISM	TOXICITY	INDICATIONS
BIOLOGIC AND IMMUNOLOGIC MODIFIERS				
Aldesleukin (Human Recombinant IL-2, Proleukin)	Cytokine that supports T-cell proliferation, augments natural killer cell cytotoxicity, induces lymphokine-activated killer (LAK) cell development, and participates in activation of monocytes and B cells	Catabolized by proteolysis in many tissues; minimal renal or biliary excretion	Toxicities associated with continuous infusion (and to a lesser extent with bolus dosing) include: capillary leak syndrome, fever and chills, hypotension, edema, arrhythmias, nephrotoxicity, pulmonary edema, abnormal liver function, endocrinopathies, dermatologic complications, CNS toxicity, myelosuppression, sepsis	Renal cancer, melanoma
Erythropoietin (Aranesp, Epogen, Procrit)[†]	Hematopoietic growth factor; stimulates division and differentiation of committed erythroid progenitors in bone marrow	Proteolytically degraded in vasculature, with minimal excretion of intact peptide	Increased risk of thrombosis, stroke, myocardial infarction; headache, hypertension, and possible seizures; allergic reactions; can produce iron deficiency with prolonged use—concomitant iron dosing may enhance efficacy	Correction of anemia due to chronic renal failure or HIV-related infection, and symptomatic chemotherapy-induced anemia (however, risk of tumor progression limits use for patients being treated with chemotherapy for cure)
Filgrastim (G-CSF, Neupogen)	Hematopoietic growth factor; binds to specific cell surface receptors on progenitor cells to stimulate proliferation and differentiation of neutrophils	Elimination by proteolysis in vasculature and by the kidney	Pain at site of subcutaneous injection, allergic reactions, bone pain, low-grade fever, myalgia, arthralgia	Decreases incidence of infection after myelosuppressive chemotherapy; enhances myeloid engraftment after BMT; enhances peripheral progenitor cell yield prior to BMT
Interferon-α (Intron-A, Roferon)[‡]	Interferon antiviral immunostimulant with both antiproliferative and immunomodulatory properties	Catabolized in renal tubules	Fever and flulike symptoms, fatigue, myelosuppression, cardiotoxicity, depression, neurotoxicity	Hairy cell leukemia, Kaposi sarcoma
Ipilimumab (Yervoy)	CTLA-4-blocking monoclonal antibody that enhances the anticancer effect of activated T cells	No clear pharmacokinetic effects of altered renal or hepatic function	Fatigue, diarrhea and immune-mediated colitis, hepatitis, rash, pruritus, endocrinopathy	Metastatic melanoma
Sargramostim (GM-CSF, Leukine, Prokine)	Hematopoietic growth factor; binds to specific cell surface receptors to stimulate proliferation and differentiation of granulocytes and macrophages; not lineage specific	Metabolized in liver and kidney	Fever and capillary leak syndrome, pain at site of subcutaneous injection, allergic reactions, arthralgias, bone pain	Decreases incidence of infection after myelosuppressive chemotherapy; enhances myeloid engraftment after BMT; enhances peripheral progenitor cell yield
MOLECULARLY TARGETED AGENTS				
Aflibercept (Zaltrap)	VEGF inhibitor; decoy receptor that binds circulating VEGF thus inhibiting activation of VEGFR	Metabolized by proteolysis	Hemorrhage, GI fistulas and perforation, hypertension, altered wound healing, stomatitis, fatigue, myelosuppression	Colon cancer in combination with chemotherapy
Axitinib (Inlyta)	Multikinase inhibitor, including VEGFR1, 2, and 3; inhibits angiogenesis	Metabolized by hepatic P-450 enzymes; excreted in feces>urine; multiple interactions with CYP 3A4/5 inducers	Hypertension, hand-foot syndrome, fatigue, asthenia, stomatitis, hypothyroidism	Advanced renal cancer
Bevacizumab (Avastin)	Recombinant humanized monoclonal antibody against VEGF; inhibits angiogenesis by binding to VEGF, blocking receptor binding and subsequent stimulation of blood vessel growth	Prolonged (20-day) half-life after IV infusion	Fatigue, nausea, delayed wound healing, hypertension, proteinuria, thromboembolic phenomena and hemorrhage	Metastatic colorectal cancer, lung cancer, kidney cancer, breast cancer, ovarian cancer
Bortezomib (Velcade)	Reversible inhibitor of 26S proteasome; blocks breakdown of ubiquitinated intracellular proteins and disrupts ubiquitin-proteasome pathway	Undergoes oxidative metabolism (deboronation) as well as cytochrome P-450-dependent metabolism; dose reduction to 0.7 mg/m^2 required in face of moderate to severe liver dysfunction; adverse event profile unchanged in myeloma patients with CrCl < 50 mL/min	Myelosuppression, peripheral neuropathy, asthenia, diarrhea, hypotension	Multiple myeloma, non-Hodgkin lymphoma

Cetuximab (Erbitux)	Chimeric monoclonal antibody targeted against EGFR; blocks growth factor binding to EGFR, preventing cell signaling by tyrosine kinase phosphorylation	Half-life 5-7 days, with minimal renal or hepatic clearance	Hypersensitivity reactions (fever, dyspnea), acneiform rash, diarrhea, hypomagnesemia	Metastatic colorectal cancer (*K-Ras* wild-type); head and neck cancer in combination with radiation
Carbozantanib (Cometriq)	Multikinase inhibitor that targets RET, MET, VEGFR1-3, KIT, AXL, TIE-2, and FLT-3	Metabolized by hepatic CYP 3A4 and subject to interactions related to CYP3A4 substrates; excreted into urine and feces	Hypertension, GI perforation, diarrhea, stomatitis, hemorrhage, fatigue	Metastatic medullary thyroid cancer, prostate cancer, bone metastases
Crizotanib (Xalkori)	Tyrosine kinase inhibitor active against ALK, ROS, MET	Hepatic P-450-mediated metabolism; excreted in feces and urine	Hepatotoxicity, pneumonitis, QT prolongation, vision disturbance, nausea, fatigue	Non–small cell lung cancer positive for anaplastic lymphoma kinase (ALK) rearrangement
Dasatinib (Sprycel)	Multitargeted tyrosine kinase inhibitor; inhibits BCR-ABL, SRC, and multiple other kinases	Metabolized in liver by P-450 CYP3A4; multiple interactions with CYP3A4 inducers or inhibitors	Myelosuppression, fluid retention, diarrhea, rash, musculoskeletal pain	Resistant/refractory CML
Denosumab (Prolia)	IgG2 monoclonal antibody that targets RANKL, a ligand for the RANK receptor on osteoclasts, and decreases bone resorption	Prolonged elimination (>20 days) typical of monoclonal antibodies	Musculoskeletal and bone pain, arthralgias, abdominal pain, peripheral edema, hypersensitivity, hypocalcemia	Prevention of malignant bone fractures
Erlotinib (Tarceva)	Small molecule inhibitor of tyrosine kinase domain of EGFR	Hepatic metabolism with excretion in feces; CYP3A4 inducers and inhibitors may alter metabolism, and dose should be reduced by 50% in patients with hepatic dysfunction; renal dysfunction does not alter drug tolerability	Acneiform rash, fatigue, diarrhea, interstitial lung disease, weight gain, hepatic toxicity	Non–small cell lung cancer; pancreatic cancer in combination with gemcitabine
Everolimus (Affinitor)	mTOR inhibitor that inhibits signal transduction through PTEN/AKT pathway	Metabolized by CYP3A4 in liver	Pneumonitis, stomatitis, renal dysfunction, myelosuppression, hyperglycemia, altered lipids	Renal cell carcinoma; hormone receptor–positive breast cancer in combination with exemestane; neuroendocrine tumors
Ibrutinib (Imbruvica)	Oral inhibitor of Bruton tyrosine kinase; blocks signaling through the B-cell antigen receptor important for B-cell chemotaxis and adhesion	Metabolized in the liver by CYP3A (avoid use with strong CYP3A inhibitors such as ketoconazole or grapefruit); primarily eliminated unchanged in feces	Myelosuppression, renal dysfunction, bleeding	Mantle cell lymphoma
Imatinib (Gleevec)	Inhibits BCR-ABL tyrosine kinase	Hepatic metabolism, excreted in feces; inhibits CYP3A4 and CYP2D6; mild hepatic dysfunction requires dose reduction to 500 mg/day; mild to moderate renal dysfunction alters kinetics but does not affect drug tolerance	Myelosuppression, hypophosphatemia, fluid retention, nausea, fatigue, hemorrhage, myelosuppression, hepatotoxicity	CML; GIST
Lapatinib (Tykerb)	Inhibitor of both EGFR and HER2 tyrosine kinases	Metabolized by CYP3A4 in liver	Diarrhea, hand-foot syndrome, hepatotoxicity, decreased cardiac function	HER2-positive breast cancer in combination with capecitabine
Lenalidomide[§] (Revlimid)	Immunomodulatory and antiangiogenic agent, in part through downregulation of VEGF, TNF-α, and IL-6, and T-cell and NK cell activation	Renal excretion	Neutropenia, thrombocytopenia, diarrhea, pruritus, rash, fatigue, leg cramps	Myelodysplasia, multiple myeloma
Nilotinib (Tasigna)	Inhibits ATP site of BCR-ABL kinase	Metabolized in liver	Prolonged QT interval, rash, fatigue, myalgias, nausea, myelosuppression	Resistant/intolerant CML
Ofatumumab (Arzerra)	Monoclonal antibody against CD-20	Not known if dose requires modification for patients with renal impairment	Infusion reactions, tumor lysis syndrome, myelosuppression, hepatitis B reactivation, infection	Resistant CLL
Pazopanib (Votrient)	Inhibits multiple tyrosine kinases including VEGFR-1, VEGFR-2, PDGFR, FGF, Kit, Lck, and cFms	Hepatic P-450 metabolism; excreted in feces	Hepatotoxicity, QT prolongation, hypertension, fatigue, nausea, decreased cardiac function	Renal cell cancer, soft tissue sarcoma
Panitumumab (Vectibix)	Monoclonal antibody that binds EGFR, inhibiting ligand interaction	Prolonged (7-day) half-life	Acneiform rash (may be severe), diarrhea, infusion reaction, hypomagnesemia, pulmonary fibrosis	EGFR-expressing colorectal cancer

TABLE 179-4 U.S. FDA-APPROVED DRUGS COMMONLY USED FOR THE SYSTEMIC TREATMENT OF CANCER—cont'd

DRUG NAME	DRUG CLASS AND MECHANISM OF ACTION	PHARMACOKINETICS AND METABOLISM	TOXICITY	INDICATIONS
Pertuzumab (Perjeta)	Monoclonal antibody against HER2; blocks HER2-mediated signaling; associated with antibody-dependent cell-mediated cytotoxicity	Prolonged half-life	Decreased cardiac ejection fraction (particularly in patients previously exposed to anthracyclines), hypersensitivity reactions, nausea, diarrhea, rash	HER2-positive metastatic breast cancer in combination with trastuzumab and docetaxel for patients without prior anti-HER2 therapy
Ponatinib (Iclusig)	BCR-ABL kinase inhibitor; also inhibits BCR-ABL carrying the T315I resistance mutation; also inhibits other tyrosine kinases including VEGFR, FGFR, SRC, PDGFR, and FLT3	Hepatic metabolism with fecal excretion	Significant risk of arterial thrombosis, stroke, myocardial infarction; myelosuppression, hypertension, hepatotoxicity, fatigue, rash	Because of thrombotic risk, usage limited to patients with CML resistant to or intolerant of first- or second-line BCR-ABL inhibitors
Romidepsin (Istodax)	Histone deacetylase inhibitor; catalyzes removal of acetyl groups from lysines on histone proteins, enhancing transcription from less condensed chromatin	Metabolized by hepatic P-450 system	Nausea and vomiting, T-wave changes and QT prolongation on ECG, diarrhea, infections, hypomagnesemia, hypotension, myelosuppression, hypersensitivity reactions	Cutaneous T-cell lymphoma
Rituximab (Rituxan)	Chimeric antibody targeting B-cell CD20 surface antigen on lymphocytes	Proteolysis without substantial excretion	Hypersensitivity reactions, lymphopenia	Relapsed low-grade CD20-positive non-Hodgkin lymphomas
Rogorafenib (Stivarga)	Multikinase inhibitor; targets VEGFR2, TIE-2; inhibits angiogenesis	Hepatic metabolism with excretion into feces>urine	Hypertension, hepatotoxicity, fatigue, abdominal pain	Colorectal cancer, GIST
Ruxolitinib (Jakafi)	JAK1 and 2 kinase inhibitor; blocks JAK-dependent immune and hematopoietic signal transduction pathways	Hepatic metabolism with excretion into urine >feces	Myelosuppression, bruising, headache, weight gain, liver function abnormalities	Myelofibrosis
Sorafenib (Nexavar)	Multikinase inhibitor; inhibits RAF kinase, as well as VEGF and PDGF receptors; antiangiogenic	Metabolized in liver, excreted in feces; patients with severe liver or kidney dysfunction do not tolerate drug well	Rash, hand-foot syndrome, fatigue, diarrhea, hair loss, hypertension, arthralgias, myelosuppression, cardiac ischemia and QT prolongation	Renal cell carcinoma, hepatocellular carcinoma, thyroid cancer
Sunitinib maleate (Sutent)	Multitargeted tyrosine kinase inhibitor with activity against VEGFR1-3, FLT-3, PDGFR; antiangiogenic	Metabolized by P-450's in liver, with excretion in feces	Bleeding, decreased cardiac function, prolonged QT interval, hypertension, myelosuppression, nausea, rash, liver function abnormalities	Renal cell cancer, GIST, pancreatic neuroendocrine tumors
Temosirolimus (Torisel)	Inhibits mTOR kinase-dependent cell signaling	Metabolized in liver	Hypersensitivity reaction, bowel perforation, interstitial lung disease	Renal cell cancer
Thalidomide (Thalomid)	Immunomodulatory and antiangiogenic agent; inhibits TNF-α production; alters endothelial cell proliferation and cytokine production	Nonenzymatic hydrolysis; eliminated in urine	Teratogenicity, sedation, constipation, peripheral neuropathy, rash	Multiple myeloma
Trastuzumab (Herceptin)	Recombinant monoclonal antibody against HER2; downregulates expression of HER2 pathways; immune-mediated effects	Minimal renal or hepatic clearance	Hypersensitivity reactions, fever, and chills; nausea; enhances anthracycline cardiac toxicity	Metastatic or adjuvant HER2-expressing breast cancer or HER2-positive gastric cancer

Vemurafenib (Zelboraf)	Inhibits B-RAF kinase carrying V600E mutation	Metabolized by liver, excreted into feces	QT prolongation, liver function abnormalities, photosensitivity, alopecia, arthralgias, fever, rash, hyperkeratosis and skin papillomas	Malignant melanoma carrying B-RAF V600E mutation
Vismodegib (Erivedge)	Hedgehog pathway inhibitor; binds and inhibits Smoothened, a transmembrane G-protein receptor important for signal transduction in the hedgehog pathway	Hepatic metabolism, excretion in feces	Muscle spasms, fatigue, alopecia, weight loss, diarrhea	Advanced basal cell carcinoma
Vorinostat (Zolinza)	Histone deacetylase inhibitor; catalyzes removal of acetyl groups from lysines on histone proteins, enhancing transcription from less condensed chromatin	Metabolized in liver, eliminated in urine	Deep venous thrombosis, diarrhea, fatigue, alopecia, myelosuppression,	Cutaneous T-cell lymphoma
Zoledronic acid (Zometa)	Bisphosphonate inhibitor of osteoclastic bone resorption	Renal elimination	Bone pain, arthralgias and muscle pain, fever, fatigue, abnormal renal function, osteonecrosis of jaw, atypical subtrochanteric femoral fractures	Hypercalcemia of malignancy, multiple myeloma; prevention of bone fractures for patients with advanced breast and prostate cancer in concert with standard systemic therapy
DRUGS THAT AMELIORATE CHEMOTHERAPY SIDE EFFECTS				
Dexrazoxane (Zinecard)	Anthracycline protective agent that chelates iron and protects the heart by inhibiting formation of anthracycline-induced reactive oxygen species	Hepatic metabolism, excreted in urine	Myelosuppression, nausea and vomiting, stomatitis	Reduces cumulative cardiotoxicity when administered with anthracyclines; also ameliorates anthracycline-induced extravasation injury
Leucovorin (folinic acid, citrovorum factor, Wellcovorin)	Water-soluble folate vitamin; increases body and tumor pool of reduced folates; enhances 5-FU metabolite-mediated inhibition of thymidylate synthase	Renal excretion	Well tolerated by itself; occasional nausea	Prophylaxis and treatment of hematopoietic side effects of folic acid antagonists; enhanced efficacy of 5-FU for colon cancer and other GI malignancies
Mesna (Mesnex)	Synthetic sulfhydryl compound; metabolite, mesna disulfide, reacts chemically with urotoxic ifosfamide metabolites, resulting in their detoxification	Renal	Bad taste, diarrhea	Prophylaxis of cyclophosphamide/ifosfamide-induced hemorrhagic cystitis

*An intrathecal formulation, DepoCyt, is used for the treatment of carcinomatous meningitis.
†Dosing differs among agents.
‡Dosages differ among brands.
§An analogue of thalidomide, which is a severe human teratogen; restricted prescribing.
AML = acute myelogenous leukemia, ATP = adenosine triphosphate; bFGF, basic fibroblast growth factor; BMT = bone marrow transplantation; CrCe = creatine clearance, CHF = congestive heart failure; CLL = chronic lymphocytic leukemia; CML = chronic myelogenous leukemia; CNS = central nervous system; CSF = colony-stimulating factor; CTLA-4 = cytotoxic T-lymphocyte-associated protein 4; EGFR = epidermal growth factor receptor; ERBB2 = HER2/neu; FDA = U.S. Food and Drug Administration; FSH = follicle-stimulating hormone; G-CSF = granulocyte colony-stimulating factor; GM-CSF = granulocyte-macrophage colony-stimulating factor; GI = gastrointestinal; GIST = gastrointestinal stromal tumor; GnRH = gonadotropin-releasing hormone; 5-HIAA = 5-hydroxyindolacetic acid; HIV = human immunodeficiency virus; IL = interleukin; LFT = liver function test; LH = luteinizing hormone; LHRH = luteinizing hormone–releasing hormone; MAO = monoamine oxidase; mTOR = mammalian target of rapamycin; NSAID = nonsteroidal anti-inflammatory drug; PDGF = platelet-derived growth factor; SIADH = syndrome of inappropriate secretion of antidiuretic hormone; TKI = tyrosine kinase inhibitor; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor.

cytotoxin to enhance cell killing.[■] Radioimmunoconjugate approaches have been most effective in the treatment of non-Hodgkin lymphoma (Chapter 185) and chronic lymphocytic leukemia (Chapter 184). The effectiveness of monoclonal antibodies in specific tumor types is not identical to small molecules developed against the same target, in part because of the induction of immunologically mediated mechanisms of tumor cell killing that are unique to antibodies.

Hormonal Therapies

Endocrine or hormonal therapy for cancer, the earliest form of systemic therapy, is almost entirely limited to breast cancer (Chapter 198) and prostate cancer (Chapter 201). Many premenopausal breast cancers are thought to be under the influence of estrogens, and hormonal deprivation (ablation) may produce long-term responses in properly selected patients (those with estrogen and/or progesterone receptor positivity who have predominantly soft tissue or bone disease). The antiestrogen tamoxifen is effective against breast cancer, and it may decrease the incidence of contralateral breast cancers in both premenopausal and postmenopausal women with breast cancer. It also has an estrogen-like activity that is responsible for an increased rate of endometrial cancers. Postmenopausal women who are candidates for hormonal therapy may also respond to tamoxifen; however, aromatase inhibitors (e.g., anastrozole, letrozole, exemestane), which decrease the conversion of metabolites in fat and muscle into estrogen, have been found to be more effective than tamoxifen as first-line therapy in both the adjuvant and metastatic settings.

Prostate cancer (Chapter 201) is usually androgen dependent, and androgen deprivation can produce meaningful responses. The recent introduction of more potent inhibitors of androgen biosynthesis (abiraterone) and androgen receptor-mediated signal transduction (enzalutamide)[■] has further enhanced the range and effectiveness of androgen deprivation therapy for this disease.

The corticosteroids (Chapter 35), typically prednisone or dexamethasone, are widely used in the treatment of hematologic and oncologic cancers. In Hodgkin disease (Chapter 186), the non-Hodgkin lymphomas (Chapter 185), and multiple myeloma (Chapter 187), corticosteroids have antitumor activity. In solid tumor patients, they are used as antiemetics and for symptomatic relief of cerebral edema in cases of CNS metastases (Chapter 189), or as an adjunct to radiation therapy for spinal cord metastases.

Immunotherapy

Recently, several new approaches to improving cancer immunotherapy by blocking the negative effects on the immune system produced by tumors have yielded dramatic clinical benefits for patients with a variety of advanced cancers, including melanoma, kidney, and lung cancers. The survival of men and women with metastatic melanoma (Chapter 203) was significantly increased following treatment with an antibody (ipilumumab, anti-CTLA-4) that neutralizes proteins that protect tumor cells against destruction by the immune system.[■] Additional antibodies that target other immunologic checkpoints (anti-PD-1 and anti-PD-L1) are in advanced stages of clinical investigation and are likely to provide substantive clinical benefits for patients with melanoma, renal cancer (Chapter 197), and non–small cell lung cancer.

Drugs for Prevention of Toxicity

In addition to the hematopoietic growth factors used to reduce the adverse effects of systemic cancer therapies on the bone marrow (discussed later under Management of Complications), there are drugs that have been developed to ameliorate important side effects of cytotoxic chemotherapy (see Table 179-4). These include dexrazoxane, an iron chelating agent that can prevent the cardiac toxicity of the anthracyclines (doxorubicin and daunorubicin); leucovorin, which can diminish the hematologic side effects of folic acid antagonists; and mesna, a thiol-containing compound that blocks damage to the bladder mucosa from metabolites of cyclophosphamide.

Bone Marrow or Hematopoietic Stem Cell Transplantation

Because the major dose-limiting toxicity of most chemotherapeutic agents is myelosuppression, approaches have been developed to harvest the pluripotent stem cells found in bone marrow, peripheral blood, or, less often, cord blood before marrow-damaging chemotherapy so that the stem cells can be reinfused later (Chapter 178). This technique is most effective for acute leukemias (Chapter 183), relapsed lymphomas (Chapter 185), and germ cell tumors (Chapter 200). The effectiveness of the approach is limited more by the inability to eradicate cancer cells than by the inability to achieve engraftment. Transplants may be syngeneic (from an identical twin), autologous (from oneself), allogeneic (from a matched donor such as a sibling or parent), or from a matched unrelated donor. Nonablative hematopoietic transplants that do not completely abolish myelopoiesis reduce toxicity and allow the treatment of older and medically infirm patients. Hematopoietic stem cell transplantation is discussed in detail in Chapter 178.

Special Treatment Populations

Obesity

Studies of practice patterns indicate that up to 40% of obese patients receive limited doses of chemotherapy that are not based on actual body weight. Concerns about toxicity or overdosing based on the use of actual body weight in obese patients with cancer are unfounded. The American Society of Clinical Oncology (ASCO) has published evidence-based practice guidelines that recommend that full cytotoxic chemotherapy doses be used to treat obese patients with cancer, especially when the goal of treatment is cure.[5]

Pregnancy

Cancer during pregnancy is not uncommon, with breast, cervical, ovarian, and thyroid cancers, melanoma, and hematologic malignancies being most common. This is an emotionally charged time, and clinical decision making is complicated by ethical, moral, cultural, and religious issues. If surgery can be safely accomplished, this may be the best course, even if it is only a temporizing measure. Radiation therapy carries the very real risk of radiation exposure to the fetus, and staging is almost always suboptimal and confined to ultrasound examinations. When the disease requires chemotherapy, changes in both the mother and fetus must be taken into account; for instance, there are major changes in drug clearance during pregnancy, along with gastrointestinal absorption and placental transfer, not to mention fetal pharmacokinetics and placental excretion. Many commonly used chemotherapeutic drugs are classified by the FDA as category D (positive human fetal risk, but the benefits in pregnant women may be acceptable despite the risk) or category X (studies in humans and animal have shown fetal malformations or there is evidence of fetal risk based on human evidence). If the mother's condition permits, it is advisable to defer chemotherapy (including anthracyclines and taxanes) during the first trimester and to treat life-threatening situations during the third trimester after extensive counseling with the parents.

Geriatrics

An increasing proportion of cancers occur in the older population. The physiologic changes that develop with age include: decreased excretion of drugs and metabolites from the kidneys, decreased volume of distribution of water-soluble drugs, and increased susceptibility to myelosuppression, cardiomyopathy, and neuropathy, related in part to comorbid conditions. As a general rule, the suitability of an older patient for therapy can be determined by a comprehensive geriatric assessment (CGA) that evaluates the patient's function, comorbidity, nutrition, medications, and resources. Geriatric assessment is discussed in detail in Chapter 24. By itself, age is not a barrier to surgery; rather, the patient's performance status and the CGA should determine the likelihood of a good recovery. Tolerance of radiation therapy seems to remain largely intact with increasing age. Chemotherapy decisions are also based on the performance status and CGA. Dosage adjustments are also made for individual glomerular filtration rates for patients aged 65 and older, where appropriate. The use of lower chemotherapy doses based on age alone is not advisable and may result in ineffective treatment.

Organ Dysfunction

Alterations in drug clearance play a critical role in the safe administration of anticancer agents. Over the past decade, pharmacokinetic studies have begun to detail the landscape of how specific levels of carefully defined renal or hepatic dysfunction alter the clearance and tolerance of many of the most commonly used drugs for the systemic treatment of cancer. For each new agent, prospective investigations are required to define usage parameters for each clinically defined level of organ dysfunction. It should be pointed out that alterations in pharmacokinetic parameters per se may occur with or without important changes in toxicity. Where evidence exists, applicable recommendations for chemotherapeutic drug use in the setting of renal or hepatic dysfunction are outlined in Table 179-4.

Management of Complications

Supportive Care

Nutritional Support

Nutrition is always a concern for patients newly diagnosed with cancer, even if they have not experienced weight loss. In fact, significant weight loss is an adverse prognostic factor for several cancers, especially lung cancer. Patients are often concerned about whether their diet contributed to development of the cancer and whether diet can influence the results of therapy. In most settings, neither of these scenarios is the case. Malnourished patients should be evaluated by a dietitian to determine whether they are ingesting sufficient calories and whether dietary supplements might be needed. Nutritional assessment is discussed in detail in Chapter 214. Some patients, such as those with head and neck cancers (Chapter 190) or esophageal cancers (Chapter 192), may require parenteral nutrition through a percutaneous gastrostomy tube. Total parenteral nutrition (Chapter 217) is rarely indicated. Larger-than-recommended doses of vitamins are also not helpful and may be toxic. It is important to determine whether over-the-counter and/or

alternative medications (Chapter 39) are being contemplated or used by the patient because of the potential for drug interactions.

Psychosocial Support

Patients with a recent cancer diagnosis have increased risks of death from cardiovascular causes, especially during the first week after diagnosis. The need for continuing psychosocial support in the face of ongoing cancer treatment, and the associated anxiety, depression, and fear experienced by many patients, is substantive and may be beyond the ability of the immediate family to fulfill. In this setting, patients often benefit from participation in support groups or from direct one-on-one counseling, and from efforts to improve communication across all levels of care and support systems.

Hematopoietic Growth Factors

Growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), speed recovery from white blood cell count depression, permitting chemotherapy to be given on schedule, without reducing the dosage in many cases (Chapter 156). However, such therapy does not decrease hospitalizations or improve survival. It is possible to determine which individuals are at greatest risk for febrile neutropenia (Chapter 167) and to treat them in advance, based on published guidelines.[6] Correction of anemia with erythropoiesis-stimulating agents (ESAs) (Epoetin alfa and Darbepoietin alfa), while possible, may be associated with complications of adverse cardiovascular events and even potentially tumor progression (Chapter 158).[7]

Prevention of Pathologic Bone Fractures

The bisphosphonates pamidronate and zoledronate are very effective not only for the treatment of tumor-induced hypercalcemia but also to reduce pathologic fractures in bones with metastatic lesions, particularly from breast cancer (Chapter 198), prostate cancer (Chapter 201), and myeloma (Chapter 187). They are also used to treat osteoporosis caused by chemotherapy-induced premature menopause in young women with breast cancer (Chapter 243). Denosumab is a human monoclonal antibody that binds to RANK ligand, a protein found on osteoclasts that is involved in bone breakdown. Some clinical trials have found denosumab to be superior to zoledronic acid for the prevention of skeletal-related events in cancer patients with bone metastases.

Symptom Management

Effective management of symptoms is critical to successful delivery of either curative or palliative treatment and maintenance of a patient's quality of life.

Nausea and Vomiting

Patients continue to fear chemotherapy because of the risk of nausea and vomiting. New antiemetics, used in combination, have made this side effect much less debilitating. Chemotherapeutic drugs can be ranked according to their probability of causing nausea and vomiting, with prophylactic treatment given accordingly. The availability of the serotonin 5-hydroxytryptamine type 3 (5-HT_3) receptor antagonists (dolasetron, granisetron, ondansetron) has dramatically improved our ability to completely control nausea and vomiting. More emetogenic regimens require combination therapy with a corticosteroid (usually dexamethasone), a 5-HT_3 antagonist, and a benzodiazepine (e.g., lorazepam) or the neurokinin-1 receptor antagonist, aprepitant. Aprepitant is particularly useful for the treatment/prevention of delayed nausea and vomiting. A double-blind randomized clinical trial of four combination regimens for controlling delayed nausea concluded that the addition of dexamethasone on days 2 and 3 was particularly effective.

Pain Control

Pain control[8] (Chapter 30) can be accomplished with a variety of analgesics, both non-narcotic and narcotic. Oncologists use a variety of scales for the evaluation of pain and start treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and acetaminophen, progress through ibuprofen and related drugs, and then through combinations of NSAIDs and narcotics to stronger narcotics. Newer narcotics are available in both short-duration and long-duration forms; some dermal patches last 72 hours, which is ideal for patients who have severe pain and are unable to take oral medications. Oral transmucosal fentanyl is more effective than standard-release morphine in this setting. Painful oral mucositis, a common complication of intensive therapy for hematologic malignancies, can be treated with local measures or with recombinant human keratinocyte growth factor. Oral anti-*Candida* drugs that are absorbed or partially absorbed from the gastrointestinal tract can help prevent pain from oral candidiasis. American Pain Society standards for pain management in cancer recommend both pharmacologic[9] and psychosocial[10] interventions as complementary approaches. A recently published meta-analysis of randomized controlled studies of various psychosocial interventions among adult cancer patients (e.g., relaxation training, cognitive behavioral therapy, and other education- and skills-based approaches) demonstrated medium-sized effects on both pain severity and interference with daily activities.

Malignant Effusions

Accumulations of fluid and malignant cells in the pleural, peritoneal, or pericardial spaces are common complications of epithelial and hematopoietic malignancies that frequently produce a significant array of symptoms, either at the time of diagnosis or accompanying tumor progression. Malignant pleural effusions (Chapter 99) are most commonly associated with cancers of the lung and breast or lymphomas, may be the result of lymphatic obstruction or direct invasion of pleural membranes, and can produce significant degrees of dyspnea, cough, or pain that require therapy. Diagnostic thoracentesis of sufficient volume (>60 mL), with cytologic analysis of the pleural effusion, has a reasonably high diagnostic yield for malignancy (60 to 90%). In patients with previously untreated lymphoma, breast cancer, or small cell lung cancer, objective response to the initiation of systemic chemotherapy may provide long-term symptomatic relief. However, in patients with recurrent lung or breast cancer, for example, pleural effusions that are confirmed to contain malignant cells may present difficult ongoing therapeutic challenges. For symptomatic patients, therapeutic thoracentesis, usually under ultrasound guidance, is required and may need to be repeated to reduce dyspnea. When frequent thoracenteses over short intervals are needed, a pleurodesis procedure is often performed, encompassing drainage of the pleural space with a chest thoracostomy and the instillation of a sclerosing compound (talc, doxycycline) that will initiate an inflammatory response of sufficient magnitude to obliterate the pleural space. Pleurodesis is at least temporarily successful in preventing fluid recurrence in most patients; when it is not, placement of an indwelling pleural catheter may provide long-term symptomatic relief of dyspnea.

Malignant ascites (peritoneal effusion) occurs most frequently in patients with intra-abdominal malignancies (gastric, ovarian, pancreatic, and primary peritoneal cancers) but can be observed as well in patients with advanced breast and lung cancers or lymphoma. Malignant ascites may be caused in part by increased permeability of the tumor vasculature that is a result of vascular endothelial growth factor overexpression, by inflammatory cytokine overproduction in the peritoneal space, or by lymphatic blockade secondary to carcinomatosis. Ultrasound-guided paracentesis provides relief of bloating, dyspnea, and the pain of abdominal distension, but will often need to be repeated, which carries the risk of dehydration, protein loss, electrolyte imbalance, bleeding, infection, and kidney dysfunction. A requirement for paracentesis at frequencies less than 1 week should prompt consideration of placement of a permanent catheter to allow self-drainage, although these devices carry a significant risk of infection.

Malignant pericardial effusions (Chapter 77) are most commonly related to direct extension or metastatic spread from lung or breast cancers, melanomas, and hematologic malignancies. As is the case for other malignant effusions, image-guided pericardiocentesis with cytologic examination of the fluid that has been evacuated will frequently provide diagnostic confirmation of malignancy; furthermore, even the removal of a relatively modest amount of fluid (<50 mL) may, at least partially, relieve the hemodynamic compromise produced by the effusion. The approach to a patient with malignant pericardial effusions is dictated by hemodynamic status (which can drive the choice between emergency pericardiocentesis or elective pericardiostomy) and by the predicted sensitivity of the inciting tumor to systemic therapy (untreated lymphoma versus chemotherapy-resistant lung cancer, for example).

ENDOCRINE MANIFESTATIONS OF CANCER

Clinical syndromes associated with ectopic hormone production may pose special diagnostic dilemmas, can produce a significant degree of morbidity or even death in cancer patients, and may be difficult to treat (Table 179-5). Management of these syndromes involves the simultaneous treatment of both the cancer and the syndrome caused by excessive hormone production. Many of the endocrine manifestations of cancer are caused by the production of small polypeptide hormones by tumors, some of which are derived from specific types of neuroendocrine cells. These cells are widely dispersed in a wide variety of organs, are often of neural crest origin, and can produce biogenic amines. The hormones produced from these tumors include adrenocorticotropic hormones (corticotropin, ACTH), calcitonin, vasoactive intestinal peptide, growth hormone–releasing hormone, corticotropin-releasing hormone (CRH), somatostatin, and other peptides. A second group of tumors, generally derived from squamous epithelium, produces parathyroid hormone–related proteins (PTHrP) and vasopressin.

Hypercalcemia of Malignancy

Humoral hypercalcemia is one of the most common endocrine syndromes related to an underlying malignancy. There are several different underlying mechanisms related to this pathophysiologic process, including ectopic production of PTHrP with activation of the PTH receptor to increase osteoclast

TABLE 179-5 SOME CLINICAL SYNDROMES OF ECTOPIC HORMONE PRODUCTION

Humoral hypercalcemia
Parathyroid hormone–related protein
Squamous cell carcinoma
Breast cancer
Neuroendocrine tumors
Renal cell cancer
Melanoma
Prostate cancer
Increased calcitriol
Lymphoma
Benign conditions: sarcoid, berylliosis, tuberculosis, fungal infections
Corticotropin
Proopiomelanocortin
Small cell lung cancer
Pulmonary carcinoid
Medullary thyroid cancer
Islet cell tumor
Pheochromocytoma
Ganglioneuroma
Corticotropin-releasing hormone
Medullary thyroid cancer
Paraganglioma
Prostate cancer
Islet cell tumors
Human chorionic gonadotropin
Choriocarcinoma
Testicular embryonal cell carcinoma
Seminoma
Hypoglycemia
Insulinoma
Sarcomas or large retroperitoneal tumors
Inappropriate antidiuretic hormone secretion
Small cell lung cancer
Squamous cell head and neck cancer
Erythropoietin
Renal cell cancer
Hepatoma
Pheochromocytoma
Benign conditions: cerebellar hemangioblastoma, uterine fibroids

TABLE 179-6 EVALUATION AND DIAGNOSIS OF PARANEOPLASTIC SYNDROMES

Characterize abnormality; obtain laboratory studies and biopsy as necessary.
Carefully elicit any additional symptoms and signs.
Eliminate common causes.
If there is no obvious etiology, consider a paraneoplastic syndrome.
If findings are consistent with a known syndrome, screen for underlying malignancy.
If signs and symptoms are consistent with a known paraneoplastic syndrome, undertake a search for an unknown primary cancer or recurrence or progression of a known primary tumor.
Screening should include a careful physical examination with breast, gynecologic, and prostate evaluations; basic hematology, chemistry, and urine studies; chest radiograph; and mammogram.
Computed tomography (CT) of the abdomen and pelvis or positron emission tomography (PET) scan is indicated if there are any suspicious symptoms, signs, or laboratory abnormalities.
Antibody testing for paraneoplastic neurologic syndromes and/or skin biopsy should be performed as indicated.
Consider treatment of cancer and/or appropriate palliative treatment, including immunosuppressive therapy for paraneoplastic symptoms when possible.

differentiation and bone resorption, with consequent hypercalcemia. Ectopic PTHrP (rather than PTH) production by several different types of cancer, most characteristically in squamous cell, breast, renal cell, and prostate cancer, as well as neuroendocrine tumors and melanoma (see Table 179-5), is one of the most common causes of hypercalcemia of malignancy.[11] Increased production of calcitriol, which increases calcium absorption with suppression of serum PTH levels, is another cause of malignant hypercalcemia that is most commonly observed in patients with lymphoma. Bone metastases, particularly in patients with breast cancer and myeloma, may produce hypercalcemia due to increased local production of PTHrP or other cytokines that increase bone resorption.

The treatment of malignant hypercalcemia is similar to that caused by hyperparathyroidism (Chapter 245) in that reversal of dehydration and the initiation of a saline diuresis should begin early; patients with a serum calcium in excess of 13 mg/dL should be treated with a bisphosphonate initially, with extended use of the bisphosphonate, as described earlier, for the prevention of bone fractures and recurrence of hypercalcemia (Chapter 245).

Other Ectopic Hormone Syndromes

Inappropriate secretion of ACTH is rare but resembles pituitary Cushing disease (Chapter 224); tumors that produce CRH include medullary thyroid cancer, prostate cancer, and islet cell neoplasms. Ectopic ACTH syndrome may become manifest as classic Cushing syndrome, with easy bruisability, centripetal obesity, muscle wasting, hypertension, diabetes, and metabolic alkalosis, although many patients with ectopic ACTH-producing cancers progress too quickly to develop prominent cushingoid manifestation clinically. Profound hypokalemia may predominate without all the classic features of Cushing syndrome in patients with small cell lung cancer.

Tumor-associated hypoglycemia, although uncommon, may be the result of: insulin overproduction by islet cell tumors; insufficient hepatic gluconeogenesis related to loss of functional hepatic mass by metastatic disease; and overexpression of insulin-like growth factor II, which can activate the insulin receptor in patients with large retroperitoneal sarcomas or hepatocellular carcinomas. In each of these cases, treatment with frequent small feedings can be prescribed; however, successful symptomatic management of hypoglycemia may be difficult without control of the primary tumor mass or metastases.

The clinical syndrome of inappropriate secretion of antidiuretic hormone is caused by ectopic production of vasopressin, primarily in patients with small cell lung cancer or squamous cancers of the head and neck, and occasionally in those with primary brain tumors. It is characterized by hyponatremia, hypo-osmolality, excessive urine sodium excretion, an inappropriately high urine osmolality for the low serum osmolality, and normal kidney, adrenal, and thyroid function (Chapter 116). Fluid (free water) restriction can provide adequate short-term management of symptomatic hyponatremia; however, treatment with demeclocycline, which blocks the effects of vasopressin on the kidney, provides more effective long-term therapy.

PARANEOPLASTIC SYNDROMES

The term *paraneoplasia*, which means "alongside cancer," has been commonly used to denote remote effects of cancer that cannot be attributed either to direct invasion or to distant metastases. These syndromes may be the first sign of a malignancy and affect up to 15% of patients with cancer (Table 179-6). However, if patients with cachexia are excluded, the incidence probably drops to only a few percent. Paraneoplastic syndromes may be the initial presenting sign or symptom of an underlying malignancy. Up to two thirds of paraneoplastic syndromes arise before an associated malignancy is diagnosed. In some cases, the paraneoplastic syndrome may be associated with relatively small tumors; recognition of these associations may lead to earlier diagnosis and possibly more effective therapy. Furthermore, one of the hallmarks in defining a paraneoplastic syndrome is that the course of the syndrome generally parallels the course of the tumor. Therefore, effective treatment of the underlying malignancy is often accompanied by improvement or resolution of the syndrome. Conversely, recurrence of the cancer may be heralded by the return of systemic symptoms. The numerous neurologic paraneoplastic syndromes[12] are reviewed in Chapter 411.

Dermatologic Paraneoplastic Syndromes

Associations between cutaneous syndromes and underlying malignancies may be difficult to confirm. Generally, the skin condition and cancer follow a parallel course, and the two diagnoses should be made at about the same time. Some skin lesions are almost always associated with malignancy. Others, however, are nonspecific and are most commonly seen with nonmalignant conditions, making it difficult or impossible to connect the skin disease with the underlying malignancy. In addition, biopsies of the skin lesion are usually nonspecific, showing features identical to those when the same lesion is seen without a malignant condition. The formation of tumor-related autoantibodies has rarely been associated with dermatologic paraneoplastic syndromes, although inflammatory cell infiltration may be seen.

Recognition of cutaneous manifestations of malignancy can be critical for the early diagnosis and successful treatment of cancer, but some syndromes

are seen only with advanced, incurable disease. Cutaneous manifestations include direct involvement of the skin with tumor as well as the remote effects of cancer.[13,14] Both specific and nonspecific dermatologic adverse effects are also seen with cytotoxic chemotherapeutic agents, including alkylating agents, antimetabolites, anthracyclines, and antitumor antibiotics.

One of the best-known paraneoplastic syndromes is acanthosis nigricans, the pathogenesis of which is unclear. The tumor may produce factors that activate insulin-like growth factors or the insulin receptor in skin. Many tumors are known to produce transforming growth factor-α (TGF-α), which might activate epidermal growth factor receptors in skin, causing hyperpigmentation and thickening. The skin lesions arise as velvety, verrucous hyperpigmentation of the neck, axilla, groin, and mucosal membranes, including the lips, periocular area, and anus. Although acanthosis nigricans clearly occurs as a benign entity associated with obesity and endocrinopathy, its appearance in older adults, especially when it includes mucosal lesions, has been highly associated with malignancies of the gastrointestinal tract as well as other adenocarcinomas. The lesions often regress with successful treatment of the underlying tumor.

Rheumatologic Paraneoplastic Syndromes

In patients who have rheumatic disorders with atypical clinical presentation—particularly older patients, those with coexisting systemic symptoms, and patients who respond unexpectedly poorly to usual antirheumatic treatments—the possibility of an underlying occult malignancy should be considered.[15] Chemotherapeutic agents can also cause rheumatic adverse effects.[16]

One of the more common and specific rheumatologic paraneoplastic syndromes is hypertrophic osteoarthropathy, which arises as an oligoarthritis or polyarthritis of the distal joints, with clubbing, tender periostitis of the distal long bones, and noninflammatory synovial effusions (also see Chapter 275). Hypertrophic osteoarthropathy may affect up to 10% of patients with adenocarcinoma of the lung. It is also seen with a variety of other pulmonary malignancies, including lung metastases from other primary sites. The etiology is unknown. Laboratory studies often reveal an elevation in the erythrocyte sedimentation rate; bone radiographs show linear ossification of the distal long bones separated by a radiolucent zone from the underlying cortex (Fig. 179-1). Treatment is symptomatic with anti-inflammatory agents; successful treatment of the underlying tumor may also improve the signs and symptoms of this syndrome.

FIGURE 179-1 Hypertrophic pulmonary osteoarthropathy characterized by periosteal elevation of the tibia (*arrow*). (Courtesy Dr. Lynne S. Steinbach.)

Fever and Cachexia

Fever (Chapter 280), night sweats, and cachexia are nonspecific symptoms that, when seen in the absence of infection or a known disorder, suggest the diagnosis of an underlying malignancy. Cytokines clearly play a pathogenetic role in inducing both fever and cachexia. TNF-α, interleukins (particularly IL-1 and IL-6), and interferon-γ are produced directly by the tumor or by tumor-associated host inflammatory cells, such as macrophages, which results in a catabolic state. Cytokines may produce fever directly by acting at the level of the hypothalamic thermoregulatory center. In addition to the burden of tumor and the production of cytokines, cachexia may be caused or worsened by the side effects of cancer treatment, by intestinal blockage or malabsorption caused by tumor infiltration, and by depression.

Fever is generally cyclic and may be associated with drenching night sweats. Symptoms resolve with successful treatment of the underlying tumor, and return of fever usually heralds relapse. When treatment of the tumor is not possible or is ineffective, NSAIDs or steroids given around the clock significantly improve quality of life. Although cancer-related fever is most commonly seen in association with malignant lymphoproliferative disease (Chapters 185 and 186), renal cell carcinoma (Chapter 197), and leukemias (Chapters 183 and 184), it may also occur with other cancers, particularly in the face of extensive hepatic metastases.

Cachexia, or the cancer wasting syndrome, is probably the single most common paraneoplastic syndrome, eventually affecting up to 80% of patients with cancer. This syndrome is characterized by anorexia, muscle wasting, loss of subcutaneous fat, and fatigue. It appears to be caused by a combination of protein wasting, malabsorption, immune dysregulation, and increased glucose turnover in the setting of tumor-induced increases in energy expenditure. Successful treatment of the underlying tumor reverses the process; symptomatic treatment for patients with advanced disease is modestly successful at best. Megestrol acetate given in high concentrations in liquid form (400 to 800 mg/day) can improve appetite and result in weight gain, but at the cost of fluid retention.

SURVIVORSHIP AND FOLLOW-UP

Approximately 4% of the United States population (≈14 million people) is living with a history of cancer; about 60% of cancer survivors are age 65 or older.[17] Thus, there is a large and increasing number of individuals who are living longer during the period of cancer survivorship—from the end of active treatment to the point of recurrence or death from another condition. There has been a growing appreciation of the specific care needs of these patients, including: a defined program of surveillance to detect recurrence or second cancers and the late effects of cancer treatment; intervention to treat the consequences of the cancer and its treatment (such as lymphedema, fatigue, and psychosocial distress); prevention of new cancers through changes in diet, behavior, and physical activity; and the institution of a coordinated program of care for cancer survivors that may require a variety of specialty services. Long-term follow-up can be optimized by the provision of a survivorship care plan for patients that provides a comprehensive summary of all diagnostic and therapeutic procedures undergone, toxicities experienced, and therapeutic outcomes, as well as a specific program of individualized follow-up care. Although definitive follow-up regimens do not exist for most cancers, evidence-based templates for common malignancies have been developed by the American Society of Clinical Oncology and the National Comprehensive Cancer Network. Lastly, it must be remembered that issues of survivorship affect caregivers, who often experience a high degree of psychological distress, along with the patient, during and after the period of active treatment.

REVIEW QUESTIONS

1. A 65-year-old man reports symptoms of fatigue and loss of appetite. Physical examination demonstrates jaundice and an abdominal mass. CT scan of the abdomen reveals a mass at the head of the pancreas, with surrounding nodal involvement. The most appropriate next step in this patient's care is:

A. Examination of serum biomarker studies including CEA and α-fetoprotein
B. Image-guided biopsy of the abdominal mass
C. Initiation of combination chemotherapy for advanced pancreatic cancer
D. Referral for surgical resection and subsequent pathologic staging

Answer: B The diagnosis of locally advanced pancreatic cancer can often be made by CT-guided biopsy. In this patient with regionally advanced disease, surgery is unlikely to be beneficial; neither are serum biomarkers of use in making a tissue diagnosis, which is the first step in planning further treatment.

2. An 82-year-old woman is found to have a stage III left-sided invasive ductal carcinoma of the breast. She has well-controlled inflammatory bowel disease and adult-onset diabetes, lives alone, and has no immediate family. The most important factor in choosing a program for further diagnostic evaluation and treatment is her:

A. Age
B. Comorbid illnesses
C. ECOG performance score
D. Lack of family support

Answer: C A patient's performance status on the ECOG scale has been demonstrated to correlate well with tolerance of treatment and long-term outcome across a wide variety of malignancies to a much greater degree than age or individual comorbid illnesses.

3. In choosing a therapeutic regimen for systemic administration, of the following, which is the most important consideration for an adult cancer patient?

A. Drug pharmacokinetics
B. The ratio of the amount of treatment that can be delivered to the toxicity expected at that dose
C. Route of drug administration
D. The range of potential toxicities that might accompany drug administration

Answer: B Pharmacokinetic profiles and routes of administration are important factors in early drug development; however, the "therapeutic index" relating efficacy to toxicity is of paramount consideration in deciding which treatment should be employed.

4. Altered hepatic function would require substantive dose reduction of which one of the following anticancer agents?

A. 5-Fluorouracil
B. Imatinib
C. Oxaliplatin
D. Carboplatin

Answer: B Only imatinib, which unlike the other three drugs is metabolized by the hepatic cytochrome P-450 system, requires significant dose reduction for liver dysfunction.

5. A 52-year-old man with chronic hepatitis C develops a multifocal hepatocellular carcinoma, accompanied by malignant ascites and thrombocytopenia. The most appropriate approach to the control of the patient's malignant effusion is:

A. Fluid restriction and diuresis
B. Regular large-volume paracentesis in the clinic
C. Cryosurgery for the major hepatic lesions
D. Insertion of a permanent catheter for self-drainage

Answer: D This patient's tumor is not curable surgically; fluid restriction will lead to hyponatremia without producing symptomatic benefit; and large-volume paracentesis without ultrasound guidance in this patient carries an excessive risk of bleeding.

180 EPIDEMIOLOGY OF CANCER

DAVID J. HUNTER

EPIDEMIOLOGY

Overview

The International Agency for Research on Cancer (IARC) estimates that over 14.1 million new incident cases of cancer (excluding non-melanoma skin cancer) occurred in 2012, of which over 8 million (57%) occurred in less developed regions (defined as Africa, Asia [excluding Japan], Latin America, and the Caribbean, plus Melanesia, Micronesia, and Polynesia in Oceania). Over 8.2 million deaths occurred, with over 5.3 million (65%) in less developed regions.[1] This is predicted to increase to 21.7 million incident cases and 13 million deaths by 2030 (Fig. 180-1), with the majority of this increase being due to the aging of populations, as well as increased total population.

The 10 most common cancers diagnosed worldwide in 2012 were lung (13%), breast (12%), colon/rectum (10%), prostate (8%), stomach (7%), liver (6%), cervix (4%), esophagus (3%), bladder (3%), and non-Hodgkin lymphoma (3%) (Fig. 180-2A), with 8 of these being among the 10 most common causes of cancer death: lung (19%), stomach (9%), liver (9%), colon/rectum (9%), breast (6%), esophagus (5%), prostate (4%), pancreas (4%), cervix (3%), and leukemia (3%) (Fig. 180-2B). These global estimates mask very large differences in regional incidence rates of specific cancers, with age-standardized incidence rates varying over five-fold between low- and high-incidence regions (Fig. 180-3); for some cancers there is a 20-fold difference between the lowest and highest incidence rates in individual countries. The burden of cancer on individual countries is a function of age-specific rates and population size. Thus, the country with the largest population in the world faces the largest number of cases of cancer, but the United States, with the world's third largest population, has the second largest number of cases of cancer, owing to high age-specific rates, and a high proportion of people in older age groups (Fig. 180-4).

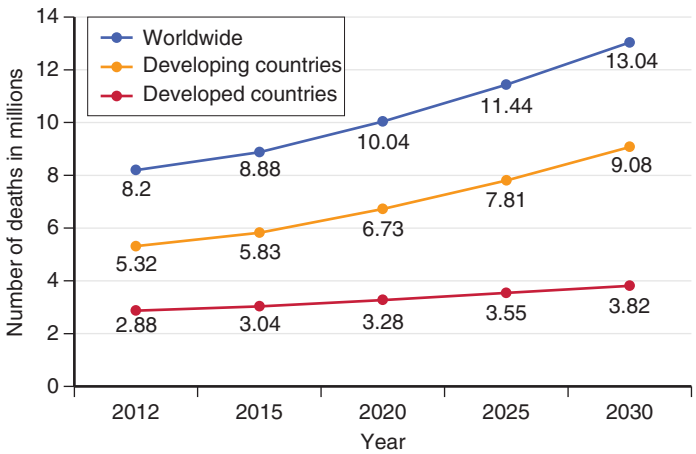

FIGURE 180-1. Projected Number of Cancer Deaths Worldwide, 2012-2030. (Data from Ferlay J, Soerjomataram I, Ervik M, et al. GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11 [Internet]. Lyon, France: International Agency for Research on Cancer; 2013. Available from: http://globocan.iarc.fr. Accessed February 18, 2015.)

In the United States, the most common cancers predicted for 2014 for men are prostate, (27%), lung (14%), colorectal (8%), bladder (7%), melanoma (5%), renal (5%), non-Hodgkin lymphoma (4%), oropharyngeal (4%), leukemia (4%), and liver (3%), with 8 of these being among the 10 most common causes of cancer death: lung (28%), prostate (10%), colorectal (8%), pancreas (7%), liver (5%), leukemia (5%), esophagus (4%), bladder (4%), non-Hodgkin lymphoma (3%), and renal (3%), with the addition of pancreas (7%) and esophagus (4%). For women, these are breast cancer (20%), lung (13%), colorectal (8%), uterine (6%), thyroid (6%), non-Hodgkin lymphoma (4%), melanoma (4%), renal (3%), pancreas (3%), and leukemia (3%), with 7 of these being the among the top 10 causes of mortality: lung (26%), breast (15%), colon/rectum (9%), pancreas (7%), leukemia (4%), uterine (3%), and non-Hodgkin lymphoma (3%), with the addition of ovary (5%), liver (3%), and brain and other nervous system (2%).[2]

Demographic Factors

Age

The rates of most cancers increase with age, often in a log-linear (exponential) fashion; any population that experiences increases in life expectancy in the proportion of the population in older age groups will almost inevitably see an increase in the numbers of cases of cancer. Some cancers have different age-incidence curves, notably cancers that occur mostly in the first few years of life, such as retinoblastoma and neuroblastoma, or in young adulthood, such as testicular cancer. Hodgkin lymphoma has a bimodal age incidence curve with peaks in younger and older adults. Breast cancer rates increase with age in premenopausal women but plateau or increase more slowly postmenopausally.

Sex

Male breast cancer occurs at less than 1% of the rate of female breast cancer in most countries. For cancers that occur in both sexes, age-specific rates are often two- to three-fold higher in men than women; for smoking-related cancers, this is often due to higher prevalence and duration of smoking among men.

Causes of Cancer

People who migrate from low to high organ-specific cancer incidence countries tend to acquire the cancer incidence profile of their new country within one to three generations; for example, breast cancer risk among Asian American women with grandparents born in the United States is actually higher than for white U.S. women. These data suggest that the large international differences in cancer incidence rates are caused by environment and lifestyle differences between countries, rather than ethnic-specific differences in genetic susceptibility. Substantial changes in cancer incidence within countries over time, such as the rise in U.S. lung cancer incidence in the last 50 years (while stomach cancer incidence has fallen steadily) also suggest changes in the environmental determinants of these diseases. Thus, a high proportion of cancer cases are due to environment and lifestyle, and cancer epidemiologists have tried to establish these causative factors over the last 60 years.

Smoking

Smoking is the major modifiable cause of cancer in many countries, estimated to cause one third of cancer deaths in the United States and 21% of cancer deaths worldwide. While smoking prevalence has fallen in the United States over the past several decades, it has increased in many other countries, including the world's largest, China[3]; the number of cancer deaths from tobacco is likely to be much higher in the 21st century than in the 20th century. Although lung cancer dominates the spectrum of smoking-related cancers, cancers at many other anatomic sites have been convincingly related to smoking, including those of the oropharynx, larynx, esophagus, stomach, liver, pancreas, kidney and ureter, cervix, bladder, and colon/rectum, as well as acute myeloid leukemia.[4] Second-hand (or passive) smoking has been associated with lung cancer. Smoking cessation results in rapidly reduced rates of lung cancer; cessation before age 30 reduces lifetime risk by more than 90% compared with continuing tobacco smoking. However, the latency between smoking initiation and cancer occurrence is several decades, so the emergence of large numbers of smoking-related cancers occurs decades after smoking prevalence increases.

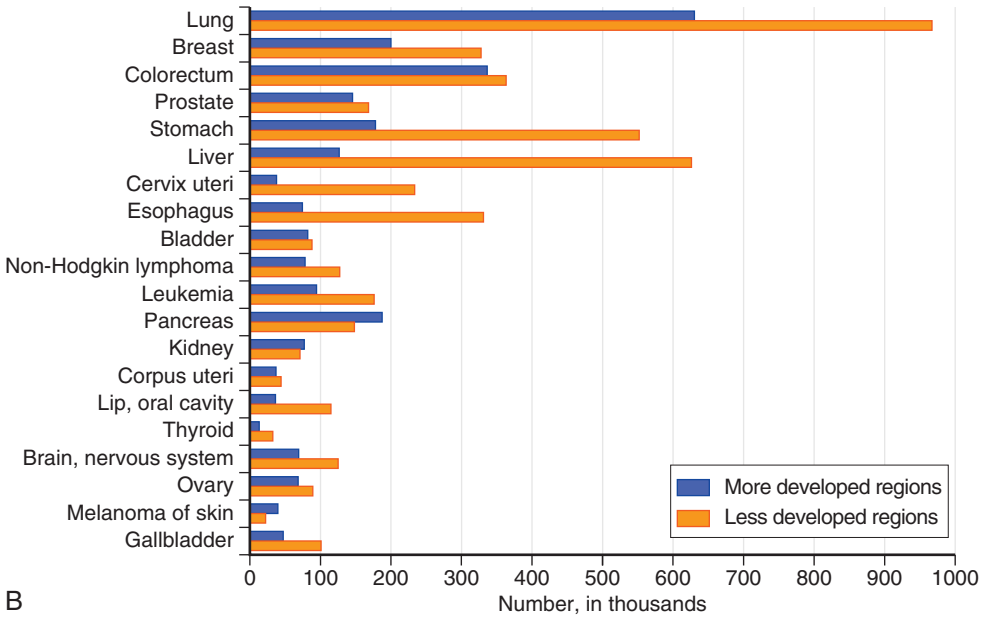

FIGURE 180-2B. Global Annual Cancer Mortality, Both sexes, All ages. (Data from Ferlay J, Soerjomataram I, Ervik M, Dikshit R, Eser S, Mathers C, Rebelo M, Parkin DM, Forman D, Bray, F. GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11 [Internet]. Lyon, France: International Agency for Research on Cancer; 2013. Available from: http://globocan.iarc.fr. Accessed February 18, 2015.)

Infections

A substantial fraction of cancers, estimated to be about 16% globally, are caused by infectious agents, particularly in less developed countries (estimated to be ≈ 23%).[5] On the other hand, only 3% of cancers were estimated to be due to infections in the United Kingdom.[6] The major infectious agents are *Helicobacter pylori* (stomach cancer), human papillomavirus (HPV [cervical cancer]), and hepatitis B and C viruses (liver cancer).

Diet

Perhaps no field of epidemiology has been as complex and controversial as the relationship between diet and cancer. Authoritative sources have estimated that a large fraction of cancer incidence is associated with dietary factors; however, a definitive understanding of the mechanisms involved has been difficult, mainly because of difficulties in obtaining valid estimates of intake of specific foods and nutrients and dietary patterns. Foods or nutrients associated with one type of cancer may not be associated with other types of cancer; it is also difficult to distinguish between true etiologic differences between cancer at different sites and false-positive results for a specific cancer type. The World Cancer Research Fund has issued two large-scale summaries of the evidence, most recently in 2007,[7] and the critical recommendations on diet were to: (1) limit consumption of energy-dense foods (avoid sugary drinks); (2) eat mostly foods of plant origin; (3) limit intake of red meat, and avoid processed meat; and (4) limit consumption of salt, and avoid moldy cereals (grains) and legumes.

Part of the difficulty in making generalizations about the percent of cancer attributable to diet is the relationship between diet and body size, and whether to "count" this influence as a "dietary" or "anthropometric" factor. Well-nourished, more affluent societies tend to have taller and heavier populations, both factors positively related to risk of cancer at several sites.

Body Weight and Height

The role of overweight and obesity as risk factors for a wide variety of cancers has become more apparent in the last decade. Even this relationship can be

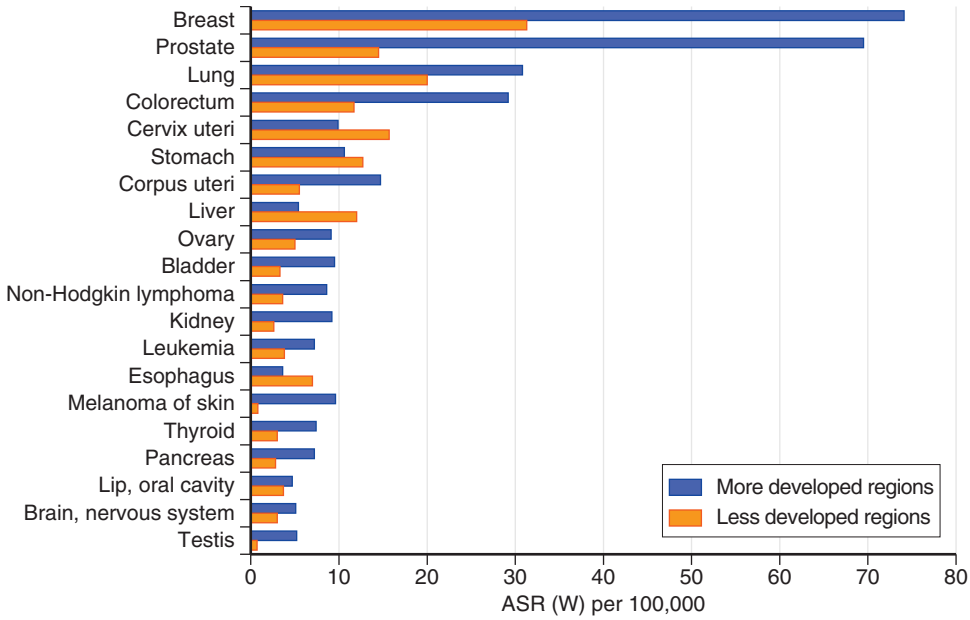

FIGURE 180-3. Age-standardized Rate of Cancer Incidence, Both Sexes, All ages. (Data from Bray F, Ren JS, Masuyer E, Ferlay J. Estimates of global cancer prevalence for 27 sites in the adult population in 2008. Int J Cancer. 2013 Mar 1;132(5):1133-45. doi: 10.1002/ijc.27711. Epub 2012 Jul 26. Available from: http://globocan.iarc.fr. Accessed February 18, 2015.)

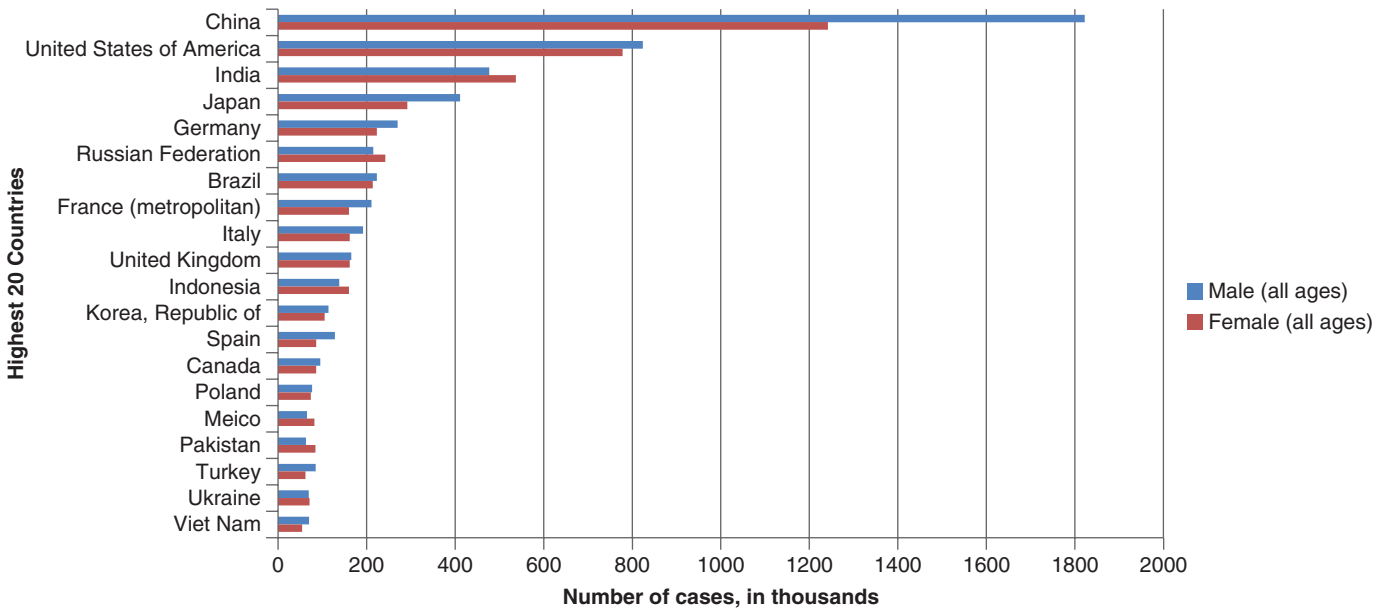

FIGURE 180-4. Annual cancer incidence (excluding non-melanoma skin cancer) by number of cases, highest 20 countries. (Data from Ferlay J, Soerjomataram I, Ervik M, Dikshit R, Eser S, Mathers C, Rebelo M, Parkin DM, Forman D, Bray, F. GLOBOCAN 2012 v1.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11 [Internet]. Lyon, France: International Agency for Research on Cancer; 2013. Available from: http://globocan.iarc.fr. Accessed February 18, 2015.)

complex. For example, obesity is inversely related to the incidence of premenopausal breast cancer but positively related to postmenopausal breast cancer. Greater height is associated with modest increases in the risk of cancer at many sites. The secular trends of increasing height and weight in more affluent societies explain a substantial fraction of the increases in cancer rates over time.

Physical Inactivity

An independent role for physical activity in cancer causation is difficult to dissect from the fact that sedentary lifestyles are associated with overweight and obesity. Physical activity has occupational, recreational, and activities of daily living components and can be difficult to measure in epidemiologic studies. A majority of studies suggest that higher levels of physical activity are associated with lower colorectal cancer risk, independent of body weight, and many studies have also reported an inverse relationship with breast cancer. Whether or not this is due to uncontrolled confounding by body weight, a more active lifestyle is a key component of prevention of weight gain, and thus is recommended for prevention of at least these two types of cancer.

Alcohol

Consumption of alcohol is associated with cancer at several sites, notably cancers of the mouth, pharynx and larynx, esophagus, liver, breast, and rectum. Globally, about 5% of cancers were estimated to be due to alcohol, and for the United Kingdom the estimate is 4%. For breast cancer, the risk appears to increase linearly with increasing alcohol consumption, whereas for the aerodigestive cancers, such as esophageal cancer, the risk is most apparent for heavy drinking. Most authorities recommend no more than one alcoholic drink per day for women, and two for men.

Ionizing Radiation

Ionizing radiation is a clear cause of leukemia and thyroid cancer; however, minimization of exposure means that it is a relatively infrequent cause of cancer, estimated to account for about 2% of cancers in Western societies.

Ultraviolet Radiation

Ultraviolet radiation is the major cause of non-melanoma skin cancers and melanoma, and is estimated to account for 3 to 4% of cancers in the Western world. Avoidance of sunburns in early life may be particularly important for reducing the risk of melanoma.

Occupational Exposures

Starting with the work of Sir Perceval Potts on scrotal cancer in chimney sweeps, it has been appreciated that cancer at certain sites is more frequent in specific occupations. A wide variety of industrial chemicals, more common in certain occupations, are associated with risk of specific cancers. In advanced economies, efforts to minimize exposure usually ensure that risks are minimal, although it was estimated that almost 4% of cancers in the United Kingdom are still due to occupational exposures. In less developed economies, risks may be higher, owing to migration of "dirty" industries to less regulated environments, and a lower level of appreciation of the risks and need to protect workers from carcinogenic exposures.

Exogenous Hormones

Use of oral contraceptives increases the relative risk of breast cancer by about 30% while women are taking them; however, since most women taking oral contraceptives are in the 15- to 40-year age group, when breast cancer incidence rates are low, the absolute number of additional cases is small.[8] Ten or more years of use of oral contraceptives reduces ovarian cancer risk by more than 50%, as well as reducing risk of endometrial cancer.[9]

Use of postmenopausal hormones, particularly those combining estrogen and progestins, increases risk of breast cancer, although risk declines quickly after cessation[10] and decreases risk of colon cancer.[11] After the publication of the Women's Health Initiative findings of a positive association, use of postmenopausal hormones declined dramatically, and the incidence rate of breast cancer (mostly estrogen receptor positive) declined over the next few years, one of the few examples in which a rapid change in prevalence of a risk factor can be linked to a short-term change in cancer incidence.

Reproductive Factors

A variety of reproductive factors have been associated with risk of cancer in women. These include early age at menarche, late age at first birth, nulliparity or low parity, and late age at menopause, short duration of lactation (all increase risk of breast cancer), and nulliparity or low parity (increased risk of ovarian and endometrial cancer).

PREVENTION

Definitions of what risk factors are modifiable vary, but consensus estimates in the 1980s, 1990s, and the 2000s[12] agree that the majority of cancers are theoretically preventable by various combinations of risk factor reduction, and immunization against cancer-causing infectious agents.

Primary Prevention

Primary prevention refers to the strategy of reducing risk factor prevalence, and thus reducing the incidence of cancer. Reducing the prevalence of smoking and the use of other tobacco products is the single factor with the greatest potential for reducing cancer risk. Unfortunately, while per capita consumption of cigarettes has approximately halved in several high-income countries since the 1970s, global consumption is still increasing, fueled by younger age population structures in less developed countries, as well as the tobacco industry's marketing in countries where cigarette consumption was previously low.

Next to smoking, there is consensus that a diet that minimizes weight gain through the course of life is the next major potentially preventive factor. Although the precise content of the diet that is preventive remains unclear, consensus panels stress diets high in fruits and vegetables and low in meat and processed meat products. Minimal to moderate alcohol exposure reduces cancer risk.

Avoidance of sunburns and long periods of ultraviolet exposure will reduce risk of skin cancers. Hepatitis B and HPV vaccination are underused strategies globally; clinical interventions against *H. pylori* would probably reduce risk of stomach cancer, but this is unproven. Occupational health regulations and enforcement are needed to reduce risk of exposure to ionizing radiation and workplace carcinogens. Reduction in use of postmenopausal hormones has already been shown to reduce rates of estrogen-positive breast cancer. Reproductive factors such as age at menarche, parity, and age at first birth, although theoretically modifiable, are difficult to change (e.g., extreme physical activity delays menarche) or are socially determined in a way that tends to supersede concerns about future cancer risk.

Secondary Prevention

Secondary prevention aims to prevent cancer death in those diagnosed with cancer or a premalignant lesion, usually by treating at an early stage. The major success in cancer screening has been organized cervical cancer screening, which is responsible for dramatic reduction in cervical cancer deaths in countries such as the United States, where most cases occur in women with a history of suboptimal screening.[13] A decline in U.S. colorectal cancer incidence is at least partly due to screening for early cancers and premalignant colorectal adenomas, with fecal occult blood testing, sigmoidoscopy, and colonoscopy having different tradeoffs in terms of patient acceptance and test performance. The use of PSA screening for prostate cancer and mammography for breast cancer remains controversial. In both cases, there is plausibly a reduction in the death rate from each cancer in men or women screened, respectively. However, better appreciation of the harms of screening and "overdiagnosis" (i.e., detection and treatment of lesions that might never have come to clinical attention) has meant that recommendations have been changed in recent years. In the case of breast cancer, better treatment of the disease and better awareness by women of the need to seek early assessment of any lumps or changes in the breast may mean that the effectiveness of mammography in reducing death rates has changed over time.[14] A report for the U.S. Preventive Services Taskforce describes the evidence as "strong" that low-dose computed tomography screening reduces risk of lung cancer and lung cancer death, although the evidence is based on a single, large, good-quality study.[15]

Although many cancers can be cured if detected early enough, the sheer volume of cancers in less developed countries with limited infrastructure, plus the cost of frequent screening, means that organized screening activities will take time to develop. The exception may be cervical screening, for which HPV testing combined with gynecologic follow-up may provide a means of screening large numbers of women relatively rapidly, although this is by no means a trivial endeavor. Greater awareness of cancer symptoms and signs, combined with appropriate and prompt follow-up, will remain a mainstay of attempts to downstage cancers in less developed regions, and developing adequate diagnostic and treatment services may be required before instituting screening services.

TREATMENT

Rx

Once cancer is diagnosed, appropriate treatment is not available to many in less developed countries, resulting in substantially higher case-fatality rates. Many of the most efficacious chemotherapy drugs are off-patent and relatively inexpensive; other modalities such as radiation can be offered at low cost per patient once a facility has been built and staff trained to use it. It is estimated that 80% of patients in the world have no access to opiates at the end of life,[16] a situation that could be remedied at low cost if international treaties that limit opiate export, as well as concerns about their abuse, could be addressed.

FUTURE DIRECTIONS

As for other non-communicable diseases, a broad range of actions need to be taken to prevent, detect, and treat cancers as incidence rates of many cancers increase and absolute rates increase faster because of the aging of populations around the world. Fortunately, several non-communicable diseases share similar risk factors,[17] particularly tobacco use and sedentary lifestyles/obesity; hence, efforts to limit the spread of these risk factors may be important in the control of cardiovascular disease, diabetes, and respiratory diseases, as well as cancer.[18] Access to even low-cost treatments requires major investments in health systems, but without these investments the human and economic costs of cancer will be greater still.

REVIEW QUESTIONS

1. Which of the following types of cancer is not related to smoking?

A. Bladder
B. Esophagus
C. Pancreas
D. Acute lymphocytic leukemia
E. Head and neck

Answer: D Acute lymphocytic leukemia is primarily a disease of children, and even in adults, it appears to be unrelated to smoking.

2. Excessive alcohol intake is associated with which one of the following malignancies?

A. Laryngeal cancer
B. Soft tissue sarcoma
C. Neuroblastoma
D. Melanoma
E. Basal cell skin cancer

Answer: A Cancers of the head and neck, aerodigestive tract, and liver are well known to be associated with excessive alcohol consumption; no such association exists for pediatric malignancies or melanoma or for non-melanoma skin cancers. (See section on "Alcohol" under "Causes of Cancer.")

3. Which of the following malignancies is not associated with exposure to an infectious agent?

A. Cervical cancer
B. Hepatocellular cancer
C. Head and neck cancer
D. Chronic lymphocytic leukemia
E. Gastric cancer

Answer: D Cervical and head and neck cancers are associated with the human papillomavirus, and hepatocellular cancer with chronic hepatitis B and/or C infection. Gastric cancer is associated with *Helicobacter pylori* infection. Chronic lymphocytic leukemia is not associated with exposure to an infectious agent. (See section on "Infections" under "Causes of Cancer.")

4. "Overdiagnosis" in the context of cancer screening efforts can be defined as:

A. The excessive use of noninvasive imaging tests for asymptomatic patients
B. The detection and treatment of lesions that might never have come to clinical attention
C. The use of clinical algorithms for cancer diagnosis that have not been validated
D. Use of plasma biomarkers of cancer to justify initiation of systemic treatment

Answer: B Treating tumors that are of no clinical significance (e.g., asymptomatic prostate cancers in men > 80 years of age) can produce morbidity with no therapeutic benefit.

5. The factor that is not related to cancer incidence is:

A. age
B. physical inactivity
C. diet
D. exposure to cold weather

Answer: D Although excessive sun (and concomitant UV) exposure is a well-known risk for the development of melanoma, no such relationship exists for exposure to colder climates. The rates of most cancers increase with age, often in a nonlinear (exponential) fashion. Physical inactivity is indirectly (if not directly) linked to cancer causation by its association with obesity. A large fraction of cancer incidence is acknowledged to be associated with dietary factors, although a definitive understanding of the mechanisms involved has been challenging. (See section on "Causes of Cancer.")

181 CANCER BIOLOGY AND GENETICS

ADRIAN R. BLACK AND KENNETH H. COWAN

CANCER AS A GENETIC DISEASE

Cancer Development Is Driven by Random Mutations

Cancer develops from mutations in genes that regulate normal cellular processes; thus, cancer can be thought of as a genetic disease. Mutations that lead to cancer involve two types of genes: mutant genes that enhance the development of cancer are known as oncogenes, whereas genes that inhibit tumorigenesis are known as tumor suppressor genes. Alterations in the function of oncogenes and tumor suppressors allow cells to escape the normal controls that regulate tissue homeostasis, leading to the outgrowth of mutant cells and the subsequent development of cancer. Except in rare cases, such as seen with the *BCR-ABL* fusion gene in chronic myelogenous leukemia (CML), a single mutation is not sufficient to lead to cancer. Instead, cancer develops in a multistep process that requires accumulation of mutations that drive progression of normal tissues through benign precancerous lesions to aggressive malignant disease.[1]

The acquisition of these mutations is random, and tumor evolution follows a model of natural selection where mutations that bestow a growth and/or survival advantage allow for clonal expansion of the population of cells that carry the mutation. During this process, many mutations occur that are disadvantageous, and cells that carry these mutations die out. The timing of mutations is also a factor in the evolution of cancer. Some mutations that help drive cancer development are deleterious to normal cells but can provide a growth/survival advantage in cells in which other mutations have occurred. For example, activation of oncogenes in normal cells can lead to cell death through apoptosis (see later) or induce a permanent growth arrest known as senescence, and their oncogenic activity is only manifested if mutations that negate these effects have already occurred in the cell. The need for mutations to occur in the correct order represents an important brake on cancer progression. The sequential multistep nature of cancer is reflected in the preferential association of specific mutations with different stages of tumor progression, as has been elegantly demonstrated for the development of colon cancer (Fig. 181-1).[2]

Mutation Rate and Cancer Risk Factors

Because mutations occur randomly within the genome, it is impossible to predict who will get cancer or to know definitively why it developed in any particular patient. However, factors that increase the rate of mutation increase the risk of tumorigenesis. For example, exposure to environmental chemicals that damage DNA (mutagens) has long been recognized as a major risk for developing cancer, as exemplified by the association of exposure to tobacco smoke—which contains multiple mutagenic compounds—with lung, oral, and other cancers. Similarly, ionizing radiation, which causes DNA strand breaks and crosslinks, is also closely associated with cancer risk. This is seen in the high risk of leukemia in survivors of the nuclear bombs in Hiroshima and Nagasaki and in the association of exposure to ultraviolet radiation in sunlight and on tanning beds with melanoma and other skin cancers. Physiologically, increased cell proliferation also increases the risk of cancer because it enhances the rate at which mutations from DNA damage become fixed in the genome during replication, increases replication-associated mutations and chromosomal rearrangements, and accelerates expansion of the pool of mutated cells. This effect is seen in the association of endometrial cancer with hormone replacement therapy, tamoxifen therapy, and obesity, which are all mitogenic in the endometrium owing to increases in estrogenic signaling.

Another major risk factor for cancer is chronic inflammation[3], such as that found in the increased risk of colon cancer for patients with inflammatory bowel disease and of stomach cancer for patients harboring *Helicobacter pylori* infections. Inflammatory cells increase the mutation rate by producing reactive oxygen species and other immune effectors that damage DNA, as well as through mitogenic cytokines that can directly increase tumor cell proliferation. Because mutations accumulate over time, increasing age itself is a major risk factor for most cancer types.

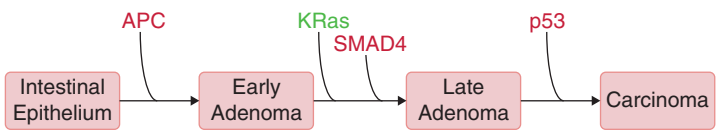

FIGURE 181-1. Genetic changes associated with different stages of colon cancer development. Scheme for accumulation of genetic changes in colon cancer in familial adenomatous polyposis patients, adapted from that originally proposed by Dr. Burt Vogelstein and colleagues at the Johns Hopkins University. Proto-oncogenes/oncogenes are indicated in green; tumor suppressor genes are indicated in red.

Genomic Instability and Cancer Development

Although the genome is continuously being damaged, cells have efficient mechanisms that keep the overall mutation rate low. Mechanisms for repair of replication errors and damaged nucleotides include mismatch repair, base-excision repair, and nucleotide-excision repair, whereas more severe damage and double strand breaks can be repaired by homologous recombination and non-homologous end joining. Mutations that disrupt these mechanisms dramatically increase the rate of mutation. Because cancer development requires ordered mutation of selected genes, efficient DNA repair means that the chances that appropriate mutation will accumulate in a cell to produce cancer within the lifetime of an individual are very low. Thus, it is not surprising that mutations that disrupt DNA repair are almost universally seen in cancer cells. Although these mutations do not directly provide an advantage to cells (and may even decrease survival), they dramatically increase the chance that cells will accumulate appropriate mutations for cancer development.

The contribution of DNA repair defects to cancer development[4] can be seen in the number of inherited cancer susceptibility syndromes that are due to mutations in DNA repair genes (Table 181-1). These mutations are also found in corresponding sporadic cancers. Mutations in mismatch repair genes (e.g., *MLH1*, *MSH2*) that cause the Lynch syndromes (also known as hereditary nonpolyposis colon cancer [HNPCC]) are commonly found in sporadic colon cancer. Mutations in *BRCA1* (involved in homologous recombination repair, non-homologous end joining, and nucleotide excision repair) or *BRCA2* (homologous recombination repair) that lead to familial breast and ovarian cancer are also common in sporadic disease.

DNA repair is essential for cell survival, and mutations in DNA repair genes can thus predispose to "synthetic lethality" in cancer cells. For example, inhibition of poly-ADP ribose polymerase (PARP) induces double strand breaks in cells with *BRCA1* or *BRCA2* mutations, but not in BRCA1/2 wild-type cells. The potential clinical relevance of this finding is supported by results from clinical trials.

Two Types of Cancer Genes

As mentioned, genes whose mutation contributes to the development of cancer are traditionally divided into two groups, oncogenes and tumor suppressor genes. The products of oncogenes, which are generally proteins referred to as oncoproteins, are positive drivers of cancer development. In contrast, tumor suppressor genes help to prevent the development of cancer in normal tissues and often counter the effects of oncogenes. Because mutations in oncogenes are activating, only one copy of the gene needs to be affected for the phenotype to be manifested; thus, oncogene mutations are dominant. The presence of two copies of tumor suppressor genes in the normal diploid genome means that both copies of these genes have to be inactivated to remove tumor suppressive activity. Thus, tumor suppressor mutations are recessive. This need for two "hits" for inactivation of tumor suppressors represents another brake on cancer development.

Familial Cancer Susceptibility Syndromes

Although most tumors are sporadic, there are a number of inherited syndromes that are associated with the risk of cancer. The vast majority of these syndromes are due to a germline mutation in one copy of a tumor suppressor gene (see Table 181-1). Because tumor suppressor genes are recessive, they remain phenotypically silent until the wild-type copy of the gene is mutated. However, the germline mutations provide the first "hit" for the loss of a tumor suppressor and vastly increase the risk of developing cancer. The dominant nature of mutations in oncogenes means that they are generally incompatible with normal development. Thus, although some familial syndromes are associated with oncogenes, these are relatively rare (see Table 181-1). Individuals with family histories of cancers that point to the possibility of an inherited disease should be offered genetic screening and counseling.

TABLE 181-1 HEREDITARY CANCER RISK SYNDROMES

SYNDROME	GENE	ASSOCIATED TUMORS
TUMOR SUPPRESSOR MUTATIONS		
Cowden	*PTEN*	Breast, thyroid, endometrial, colorectal, kidney, melanoma
Familial adenomatous polyposis	*APC*	Colorectal, stomach, intestinal, hepatoblastoma, thyroid, pancreatic, adrenal, bile duct, medulloblastoma
Familial gastric carcinoma	*CDH1* (E-Cadherin)	Stomach, breast
Familial malignant melanoma	*CDKN2* ($p16^{INK4A}$ and $p14^{ARF}$), *CDK4*	Melanoma, pancreatic
Familial Wilms tumor	*WT1*	Wilms (kidney)
Hereditary retinoblastoma	*RB1* (pRB)	Retinoblastoma
Hereditary paraganglioma	*SDHA, SDHB, SDHC, SDHD* or *SDHAF2* (succinate dehydrogenase)	Paraganglioma, pheochromocytoma
Li-Fraumeni	*TP53* (p53)	Osteosarcoma, soft tissue sarcoma, leukemia, breast, brain, adrenal, melanoma, Wilms, stomach, colorectal, pancreatic, esophageal, lung, gonadal germ cells
Multiple endocrine neoplasia type 1	*MEN1*	Parathyroid, pituitary, islet cell, adrenal, carcinoid
Neurofibromatosis type 1	*NF1*	Neurofibroma, glioma, leukemia, breast, rhabdomyosarcoma, gastrointestinal stromal
Neurofibromatosis type 2	*NF2*	Neuromas, schwannomas, meningiomas, astrocytomas, gliomas
Peutz-Jeghers syndrome	*LKB1*	Colon, intestine, stomach, pancreas, cervix, ovary, testis, breast, thyroid
Von Hippel-Lindau	*VHL*	Kidney, adrenal, pheochromocytoma
DNA REPAIR GENE MUTATIONS		
Ataxia telangiectasia	*ATM*	Leukemia, lymphoma
Bloom	*BLM*	Leukemia, multiple solid tumors
Fanconi anemia	*FANCA, FANCC, FANCD2, FANCE, FANCF or FANCG*	Leukemia, multiple solid tumors
Hereditary breast and ovarian cancer	*BRCA1*or *BRCA2*	Breast, ovary, pancreatic, fallopian tube
Lynch (hereditary nonpolyposis colon cancer)	*MLH1, MSH2, MSH6 or PMS2*	Colorectal, endometrial, stomach, breast, ovarian, intestinal, pancreatic, prostate, urinary tract, liver, kidney
MYH-associated polyposis	*MUTYH*	Colorectal, intestinal
Xeroderma pigmentosum	*XPA, XPC, ERCC2, ERCC3, ERCC4, ERCC5,* or *DDB2*	Skin (basal cells, squamous), melanoma, tongue, eye
ONCOGENE MUTATIONS		
Costello	*HRAS*	Papilloma, rhabdomyosarcoma, neuroblastoma
Noonan	*PTPN11, SOS1, KRAS, NRAS, RAF1 or BRAF* (Ras-Erk pathway regulators)	Leukemia, rhabdomyosarcoma, neuroblastoma
Familial malignant melanoma	*CDK4*	Melanoma
Multiple endocrine neoplasia type 2	*RET*	Thyroid, parathyroid, pheochromocytoma

Oncogenes and Proto-oncogenes

Oncogenes are activated forms of normal cellular genes that are termed *proto-oncogenes*. The products of proto-oncogenes are involved in the regulation of multiple aspects of physiology, including proliferation, survival, and cell migration, and play an important role in development and tissue homeostasis. Mutations that activate oncogenes lead to loss of the normal control that governs the activity of proto-oncogenes and gives a growth or survival advantage to the cell. A single oncogene can affect multiple aspects of tumor progression and in rare cases may be all that is needed to support oncogenic transformation (e.g., the *BCR-ABL* oncogene in CML). In keeping with their diverse roles, proto-oncogenes perform diverse functions in the cell. They commonly function as signal transduction molecules, acting as extracellular ligands/growth factors (e.g., KGF, SIS, INT-2, WNT1), growth factor receptors (e.g., EGFR, HER2, FGFR), and signaling intermediates (e.g., the PI-3 kinase [PI-3K] catalytic subunit *PIK3CA*, PKCι, B-Raf, and the Ras proteins K-Ras, N-Ras, and H-Ras). They can also be involved in direct regulation of gene expression, acting as transcription factors (e.g., myc, fos, jun, myb), translation factors (e.g., eIF4E), or regulators of protein degradation (e.g., MDM2, Cbl). Other common roles are in promoting cell survival (e.g., Bcl2, MCL1) and cell cycle progression (e.g., cyclin D1, CDK4, cyclin E).

Oncogenes can be activated by multiple mechanisms, and a single oncogene can be activated by different mechanisms. Activation can result from mutations that lead to a qualitative change that affects the activity or regulation of the encoded oncoprotein, or by a quantitative effect that increases the levels of an oncoprotein in the cell (through increased gene expression or reduced protein turnover). Qualitative effects are generally due to point mutations that lead to loss of negative regulatory domains or, more commonly, to single amino acid changes that affect the activity or interactions of an oncoprotein. These mutations can (1) directly increase kinase activity (e.g., *B-Raf* mutations in melanoma and colon cancer, or *PIK3CA* mutations in colorectal, brain, and gastric cancers), (2) decrease negative regulation (e.g., C-terminal truncation of Src), (3) alter autoregulation (e.g., K-Ras, H-Ras, and N-Ras, seen in 50% of colon cancers), and (4) reduce protein degradation (e.g., phosphorylation site mutations of β-catenin, seen in colon cancer). These mutations often occur at a single site or limited region of the gene, so-called hot spots that localize to important functional regions of the protein encoded by the oncogene. For example, oncogenic mutations of *B-Raf* are commonly missense mutations of the valine residue in its activation loop (V600).

In addition to point mutations, gross chromosomal abnormalities can lead to activation of oncogenes. Increased gene copy number through gene amplification is a mechanism by which oncogenes become overexpressed. Gene amplification is extremely common in cancer and represents a major mechanism by which oncogenes are activated. Amplifications are detected histologically by karyotypic abnormalities such as double-minute chromosomes (DMs) and homogeneous staining regions (HSRs). Chromosomal translocations can also lead to overexpression of oncogenes by locating the gene next to a strong transcriptional element. For example, the t(8;14) translocation in Burkitt lymphoma transcriptionally activates the *MYC* oncogene by placing it in the immunoglobulin heavy chain locus. In many cases, translocations not only lead to increased expression of an oncoprotein but can also alter the

protein itself. The t(7;9) translocation in T-cell acute lymphoblastic leukemia (ALL) places the *NOTCH1* gene (*TAN1*) next to the T-cell receptor promoter. However, the translocation is only partial and leads to overexpression of the transcriptionally active NOTCH1-IC fragment, and thus constitutively activates Notch signaling. Translocations can also lead to the production of fusion proteins that have distinct properties from the original proto-oncogene. For example, the t(9;22) translocation seen in CML fuses the B-cell receptor gene with *Abl* tyrosine kinase genes. The resultant BCR-ABL fusion protein is not only overexpressed and a constitutively active kinase, it is also aberrantly localized to the cytoplasm and thus phosphorylates different substrates from Abl. Although oncogenic chromosomal translocations are particularly prevalent in leukemias and lymphomas, they are also seen in solid tumors such as Ewing sarcoma, papillary thyroid cancer, and rhabdomyosarcoma (producing the *EWS-FLI*, *RET-PCP*, and *PAX3-FKHR* gene fusions, respectively).

Viral Infection and Cancer

Viral infection has been associated with up to 20% of cancers worldwide and is thus a major concern in oncology (Chapter 180). Known oncoviruses include: human papillomaviruses HPV-16 and HPV-18 (the main causative factors for cervical cancer), hepatitis B and hepatitis C viruses (linked to hepatocellular carcinoma), Epstein-Barr virus (linked to lymphomas and nasopharyngeal carcinoma), HTLV-I (linked to T-cell leukemia), Kaposi sarcoma herpesvirus (Kaposi sarcoma), and Merkel cell polyomavirus (Merkel cell carcinoma). Viral reproduction requires replication of viral DNA in the host cell. Oncoviruses achieve this by enlisting the host replicative machinery through expression of oncogenes (e.g., E6 and E7 of human papillomavirus and LMP1 and BARF1 of Epstein-Barr virus), which results in an increased risk of cancer in the infected tissue.

Tumor Suppressors

Whereas the term *oncogene* refers to a mutated version of a proto-oncogene, tumor suppressor genes are normal cellular genes whose inactivation contributes to the development of cancer. Although mutations of tumor suppressors are almost always recessive, occasionally mutation in a tumor suppressor gene can give rise to a "dominant negative" protein that can block the activity of the wild-type protein; such mutated forms of the tumor suppressor act as an oncogene (e.g., some c-cbl and p53 mutations).

As with proto-oncogenes, tumor suppressors are involved in multiple aspects of cellular physiology. They can be cell surface receptors and downstream mediators of growth inhibitory signaling [e.g., TGFβ receptor II (*TGFBR2*), SMAD4 (*DPC4*)], negative regulators of mitogenic signaling [e.g., APC, NF1, PTEN], negative regulators of the cell cycle [e.g., the retinoblastoma protein (pRB, *RB1*), $p16^{INK4a}$ (*CDKN2A*), p53 (*TP53*)], promoters of apoptosis (p53, *RASSF1A*), regulators of cell adhesion [e.g., E-cadherin (*CDH1*)], transcription factors [e.g., p53, pRB, Wilms tumor suppressor 1 (*WT1*)] or regulators of protein degradation (e.g., Von Hippel-Lindau protein (*VHL*)]. Genes involved in DNA damage repair and maintenance of genome stability are also considered tumor suppressors (see Table 181-1). As discussed earlier, although DNA repair defects do not directly contribute to the transformed phenotype, they greatly increase the chances that cancer will develop.

Inactivation of tumor suppressors can occur through point mutations in the gene. These can be missense mutations that lead to alterations in amino acid sequences (hot spots) that are critical for the activity of a tumor suppressive protein (e.g., Trp248 and His273 mutations in p53) or nonsense mutations that lead to a truncated protein (e.g., APC truncations in colon cancer). Tumor suppressor genes can also be inactivated by chromosomal deletion or rearrangement (e.g., inactivation of PML by the t[15;17] translocation in acute promyelocytic leukemia, which results in the RAR-PML fusion protein).

In addition to genetic changes, tumor suppressor genes can be inactivated epigenetically.[5] DNA methylation of the promoter region of genes, which results in transcriptional repression, is a normal regulatory mechanism that ensures correct gene expression and stable silencing during development. Aberrant promoter methylation of tumor suppressor genes is very common in cancer and represents a major mechanism by which these genes are inactivated. Reversal of this transcriptional repression allows for reexpression of the tumor promoters and forms the rationale for the use of drugs that inhibit DNA methylation, such as decitabine.

Once one copy of a tumor suppressor gene is disrupted, the most common mechanism for inactivation of the remaining wild-type copy is through loss of heterozygosity (LOH). LOH can occur when the wild-type gene is lost through deletion, chromosomal loss, or unequal recombination, which results in a single mutant copy remaining in the cell. Alternatively, copy neutral LOH can occur, in which the wild-type gene is replaced by the mutant gene through loss and reduplication or mitotic recombination.

miRNAs as Oncogenes and Tumor Suppressors

Although most of our knowledge of tumor suppressors and oncogenes is concentrated on genes that encode for protein, an important role for non-coding RNAs is rapidly emerging.[6] microRNAs (miRNAs) regulate the expression of other genes by binding to their mRNAs in a sequence specific manner and causing their degradation or inhibiting their translation. miRNAs that inhibit the expression of oncogenes act as tumor suppressors, whereas those that inhibit the expression of tumor suppressors have oncogenic properties and are known as oncomirs. Recent research is identifying miRNA profiles that are associated with particular cancer types, underlining the importance of these non-coding RNAs in tumor development.

Activities of Oncogenes and Tumor Suppressors Are Interrelated

Oncogenes and tumor suppressors are commonly part of signal transduction pathways (Fig. 181-2). A pathway that is activated in many cancers is the Ras/Raf/Erk signaling cascade. In addition to the Ras and Raf proteins (e.g., K-Ras, B-Raf), growth factor receptors that activate Ras (e.g., EGFR, HER2, PGDF, KIT) and downstream targets of the pathway (e.g., the transcription factors Fos and Jun) also act as oncoproteins to activate this pathway. In contrast, the NF1 tumor suppressor (see Table 181-1) negatively regulates the pathway by inactivating Ras. Another pathway that is activated in cancer is the PI-3K/AKT/mTOR pathway, in which growth factor receptors activate the Akt protein kinase through PI-3K-mediated phosphorylation of phosphatidylinositol (see Fig. 181-2). Although both PI-3K (PIK3A) and Akt can act as oncogenes in this pathway, the PTEN tumor suppressor negatively regulates the pathway by dephosphorylating phosphatidylinositol-(3,4,5) triphosphate. Thus, in addition to activation by direct mutation, proto-oncogenes can be activated indirectly through mutation of upstream oncogenes or tumor suppressors. Because only one oncogene or tumor suppressor needs to be mutated to activate a pathway, it is rare that two mutations are seen in the same pathway. An example can be seen in the APC/β-catenin pathway: although mutations in either APC or β-catenin are commonly found in colon cancer, mutation of these genes is mutually exclusive.

Signal transduction pathways in a cell do not act simply as linear pathways but participate in interlinked networks. Oncogenes and tumor suppressors

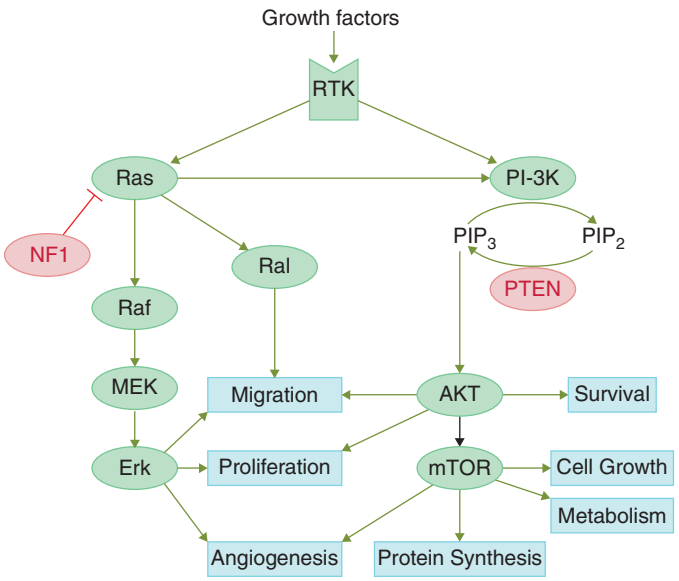

FIGURE 181-2. Ras/Erk and PI-3K/Akt pathways. Schematic diagram of the relationship between critical components of the Ras/Erk and PI-3K/Akt pathways are shown, along with downstream effects of pathway activation. Proto-oncogenes/oncogenes are indicated in green; tumor suppressors are indicated in red. Green arrows indicate activation, and the red T indicates inhibition. NOTE: mutations that affect oncogenes or tumor suppressors at any point along a signaling pathway can stimulate the pathway and have similar effects on downstream targets. RTK = receptor tyrosine kinase (e.g., EGFR, HER2, PDGFR). For details see section on "Activities of Oncogenes and Tumor Suppressors Are Interrelated"

are involved in this signaling crosstalk. For example, Ras activates both the Raf-Erk and the PI-3K/Akt pathways, and Ras-Erk signaling inactivates the *LKB1* tumor suppressor that is a negative regulator of AMPK signaling (see Table 181-1).

Oncogenes and Tumor Suppressors Are Not Restricted by Disease Site

Certain oncogenes and tumor suppressors are associated with particular cancer types, as can be seen in many familial syndromes. This often reflects the roles of particular signaling pathways in the normal tissue from which the cancer arises. For example, in keeping with the critical role of the Wnt/APC/β-catenin signaling pathway in regulating proliferation and stem cell maintenance in the normal intestinal epithelium, activation of this pathway through loss of *APC* or activation of β-catenin is found in the vast majority of colon cancers. Because the same signaling pathways can be important in multiple tissues, cancers in different disease sites can have mutations in the same oncogenes and tumor suppressors. For example, in addition to colon cancer, disruption of the Wnt/APC/β-catenin pathway is found in other cancer types including those arising in the pancreas, breast, and thyroid. This lack of disease site specificity for tumor suppressors can clearly be seen in the array of cancers that are associated with familial cancer susceptibility syndromes (see Table 181-1).

There are two pathways that appear to be of universal importance and are disrupted in most, if not all, cancers. These involve the tumor suppressor genes *RB1*, encoding the retinoblastoma protein (pRB), and *TP53*, encoding p53 (Fig. 181-3). pRB was the first tumor suppressor to be identified and is responsible for hereditary retinoblastoma. It is a central player in a pathway that senses the extracellular growth environment and controls whether or not a cell will proliferate. Disruption of this pathway in cancer cells thus divorces proliferation from the normal controls that maintain tissue homeostasis. pRB inhibits proliferation by repressing transcription of growth-related genes through binding to E2F transcription factors. The activity of pRB is regulated by cyclin-dependent kinases (cdks). When bound to cyclins, cdks phosphorylate pRB, and this blocks its ability to bind E2Fs and allows for transcription of E2F-regulated genes, many of which are proto-oncogenes. Expression of D-type cyclins (e.g., cyclin D1), regulatory molecules whose binding to cdks initiates the phosphorylation of pRB, is regulated by extracellular signaling and thus provides a link between cell proliferation and the extracellular growth environment. Activity of this pathway is negatively regulated by a number of cdk inhibitory proteins, including $p21^{CIP1}$, $p27^{KIP1}$, and $p16^{INK4A}$. Although mutations in pRB itself are relatively rare, mutations in multiple members of the pathway that mediate inactivation of pRB are a common feature of cancer (Table 181-2). In addition, oncogenes and tumor suppressors feed into this pathway through regulation of cyclins and cdk inhibitory protein.

p53 is the most commonly mutated tumor suppressor gene, with mutations seen in about 50% of all human cancers. Germline mutations in p53 are responsible for Li-Fraumeni syndrome (see Table 181-1). p53 is known as "the guardian of the genome" because it is a central player in the system that assesses DNA damage and the internal fitness of the cell to divide. DNA damage leads to transcriptional activation p53, which has two major effects dependent on the severity of the damage. If DNA damage is not too severe, p53 can induce cell cycle arrest by increasing expression of the cdk inhibitor $p21^{CIP1}$, which activates the pRB growth inhibitory pathway. This allows time for DNA to be repaired prior to the initiation of replication. With more severe DNA damage, p53 induces apoptosis through upregulation of proapoptotic proteins such as PUMA and Bax. In addition to p53 mutations, activation of oncogenes such as *MDM2* or loss of tumor suppressors like $p14^{ARF}$ can disrupt p53 activity in the cancer cell (see Fig. 181-3).

The importance of the p53 and the pRB-E2F pathway to cancer development can be seen in the targeting of these pathways by DNA tumor viruses. For example, the E6 and E7 oncogenes of human papillomavirus target p53 for degradation and prevent pRB binding to E2F, respectively.

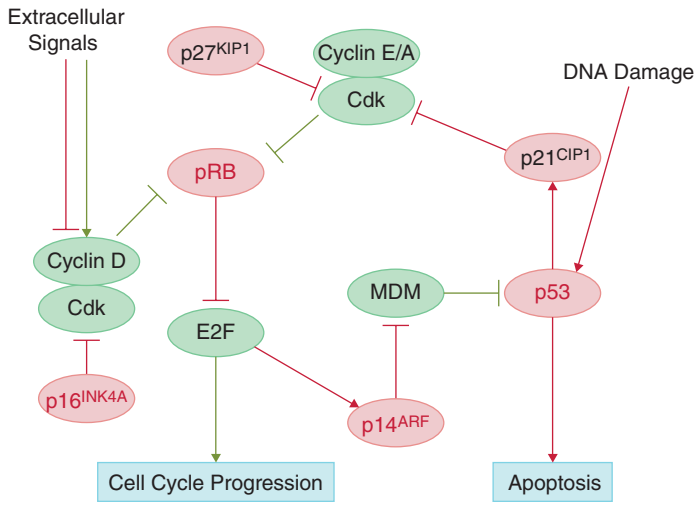

FIGURE 181-3. Interaction of the pRB/E2F and p53 pathways. Proto-oncogenes/oncogenes are indicated in green; tumor suppressors are indicated in red. Green and red connectors indicate growth/survival promoting and inhibitory effects, respectively. For details, see section on "Oncogenes and Tumors Are Not Restricted by Disease Site."

CRITICAL FEATURES OF THE CANCER PHENOTYPE

As cells accumulate oncogenic mutations, they progressively gain the ability to circumvent the normal mechanisms that control tissue homeostasis. Although diverse sets of mutations can lead to cancer, there are a set of general characteristics that must be acquired for tumors to develop. These phenotypic changes have been termed "hallmarks of cancer" and include the ability to sustain growth and resist growth inhibitory signals, resist apoptosis, stimulate angiogenesis, acquire replicative immortality, metastasize, deregulate cellular energetics, and avoid immune destruction (Table 181-3). These core characteristics, along with other factors that have a direct impact on cancer development and its clinical management, are discussed below.

Sustained Cell Proliferation

Normal tissue homeostasis is regulated by the balance between signals that promote proliferation and those that inhibit proliferation and induce differentiation. Multiple oncogenic mutations free cancer cells from this regulation by lessening their dependence on growth factors and weakening their sensitivity to negative signals. As noted earlier, direct disruption of cell

TABLE 181-2 pRB-E2F PATHWAY DISRUPTION IN CANCER

PROTEIN	GENE	COMMON CHANGES IN CANCER
pRB	*RB1* (tumor suppressor)	Mutation, deletion, methylation
p130	*RB2* (tumor suppressor)	Mutation
Cyclin D1	*CCND1* (oncogene)	Transcriptional activation, amplification, chromosome rearrangement
Cyclin E	*CCNE1* (oncogene)	Amplification
Cdk4	*CDK4* (oncogene)	Amplification, mutation
$p16^{INK4a}$	*CDKN2A* (tumor suppressor)	Deletion, methylation
$p27^{KIP1}$	*CDKN1B* (tumor suppressor)	Post-transcriptional downregulation

TABLE 181-3 THE HALLMARKS OF CANCER

- Sustaining proliferative signaling
- Evading growth suppressors
- Activating invasion and metastasis
- Enabling replicative immortality
- Inducing angiogenesis
- Resisting cell death
- Deregulating cellular energetics
- Avoiding immune destruction

The "hallmarks of cancer" comprise these biological capabilities acquired during the multistep development of human tumors. Underlying these hallmarks are "enabling characteristics," including genome instability and mutation and tumor-promoting inflammation. In addition to the cancer cells themselves, tumors recruit a repertoire of ostensibly normal cells that contribute to the acquisition of hallmark traits by creating a "tumor microenvironment."

Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. *Cell.* 2011;144:646-674.

cycle regulation through the pRB-E2F pathway, and activation of growth promoting signaling pathways through oncogene activation and tumor suppressor inactivation, isolates cancer cells from the requirement for growth factors and the effects of negative growth signals. Similarly, loss of p53 contributes to continued proliferation in the presence of genetic damage that would normally cause growth arrest.

Replicative Immortality

Even in the presence of continuous positive growth signals, the majority of cells in normal tissues have a limited replicative potential. Once this limit is reached, cells either enter senescence or die through apoptosis (see later). Therefore, for a cancer to grow to a size where it becomes clinically relevant, this limit must be overcome. One of the major factors that limit replicative potential is the shortening of chromosomes during replication. Genetic material at the end of chromosomes is protected from this loss by repetitive DNA sequences known as telomeres. Telomeres also form specialized structures that protect chromosomes from cellular exonucleases and from fusion due to non-homologous end joining. Germline cells and some stem cells express an enzyme, telomerase, that is able to lengthen their telomeres following replication. However, for most cells in the body, replication leads to a progressive shortening of telomeres until they become unable to protect the chromosomes; the DNA ends are then recognized as DNA damage, and the cell becomes senescent or enters apoptosis. Tumor cells evade this fate by acquiring mechanisms to maintain telomere length above the critical minimum. This is mainly by reexpression of telomerase or, less commonly, through a recombination-based mechanism. Loss of telomeres can also contribute to genetic instability, because defects in the DNA damage response can allow continued replication in the presence of chromosomal fusions associated with telomere loss.

Apoptosis

Apoptosis is a physiologic mechanism of programmed cell death that involves a protease cascade, leading to activation of executioner caspases. It is induced by both external and internal signals and is integral to development and control of tissue damage. Many of the alterations that lead to cancer also trigger apoptosis, mainly through the intrinsic pathway. These include oncogene activation, uncontrolled E2F activity due to inactivation of the pRB pathway, and DNA damage. Thus, cancer progression requires mechanisms to overcome these apoptotic responses. A major mechanism of apoptosis that results from intrinsic cellular abnormalities involves the release of cytochrome c from mitochondria, which leads to activation of cytoplasmic caspases. The tumor suppressors Bax and Bim mediate the release of cytochrome c, whereas the oncogene *Bcl2* inhibits its release. Another mechanism by which apoptosis is reduced in cancer cells involves upregulation of inhibitors of apoptotic proteins (e.g., survivin, XIAP, cIAP) that can directly suppress caspase activity. Changes in the expression of survival proteins can result from mutation of oncogenes and tumor suppressors, or from oncogenic activation of prosurvival signaling pathways such as those involving Akt and the NF-κB transcription factors. As noted, loss of p53 activity is a major contributor to apoptosis resistance in cancer cells.

Although these changes help to reduce the effect of pro-apoptotic changes associated with tumor development, apoptosis is prevalent in many tumors, and cancer cells remain susceptible to apoptotic signals. This susceptibility forms much of the basis for the selectivity of cytotoxic chemotherapeutic agents, and changes affecting apoptosis represent a mechanism of drug resistance in cancer.

Stress Responses

The accumulation of genetic damage and mutations, along with the hostile environment in which tumors develop, places significant stress on cancer cells. Cells respond to stress by eliciting a stress response characterized by upregulation of chaperone proteins. Chaperones, such as the heat shock proteins hsp90 and hsp70, play a central role in regulation of protein folding and are expressed at low levels under normal conditions. Under stress, these proteins become limiting, and their upregulation protects cells from the deleterious effects of protein denaturation and reduces apoptosis. Cancer cells characteristically have a constitutive stress response and are dependent on elevated levels of chaperone proteins for survival. Notably, many oncogenes are highly dependent on chaperones for their activity, making these proteins potential targets for cancer therapy. While no antichaperone therapies have been approved to date, several—especially those targeting hsp90—have shown promise in clinical trials.

Angiogenesis

Without an ability to recruit new blood vessels through angiogenesis, tumors are reliant on diffusion of oxygen and nutrients from surrounding tissue and can only grow to a few millimeters in diameter. Angiogenesis is a normal physiologic response that is essential for normal development and wound healing but is dormant in most adult tissues. It is regulated by a balance of pro-angiogenic and anti-angiogenic signals; several factors switch this balance toward angiogenesis in cancers. Hypoxia, which develops in tumors as they outgrow the diffusion limit of oxygen, is a major physiologic inducer of angiogenesis. In addition, activation of oncogenic signaling and loss of tumor suppressors directly leads to secretion of angiogenic factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), and to downregulation of anti-angiogenic factors such as Tsp-1. Many tumors also recruit significant numbers of inflammatory cells that secrete pro-angiogenic factors. Angiogenesis in tumors differs from that in normal tissues; the tumor vasculature is not properly organized. Blood vessels in tumors are leaky to both water and macromolecules, which leads to an increase in intratumoral pressure. These vessels are also prone to collapse, leading to large areas of tumors that remain hypoxic. The properties of tumor vessels can present a problem for cancer therapy, particularly for those that require oxygen (e.g., ionizing radiation).

Angiogenesis is an attractive target for cancer treatment, and agents that target this process have entered the clinic. Bevacizumab, a monoclonal antibody that inhibits angiogenesis by binding VEGF-A, has been approved for treatment of refractory glioblastoma. Several approved multitargeted kinase inhibitors that block VEGF receptors, such as pazopanib, sorafenib, and sunitinib, may also partially act through effects on angiogenesis.

Invasion and Metastasis

For most solid tumors, the main clinical threat comes from their ability to metastasize. Metastasis is a complex multistep process that involves local invasion, intravasation, survival in the circulatory system, extravasation, and colonization. A key mechanism underlying this process is epithelial-to-mesenchymal transition (EMT), characterized by the loss of cell-cell junctions and polarity, together with the gain of mesenchymal markers such as vimentin. EMT, which is normally involved in developmental cell dispersal and tissue regeneration, is subverted in cancer cells, allowing them to gain enhanced migratory capacity, invasiveness, and increased resistance to apoptosis. EMT has also been linked to the acquisition of stem cell characteristics (see later) and may thus contribute to the population of the metastatic site. Multiple transcription factors, including Snail, Slug and Zeb1, as well as miRNAs, cooperate with oncogenic signaling changes to induce EMT in cancer cells. In addition to cell-inherent changes, environmental factors including hypoxia and tissue interactions modulate EMT.

A major change that drives EMT is downregulation of E-cadherin, a component of adherens junctions and a tumor suppressor in the Wnt/β-catenin pathway. In many cases, tumor cells only undergo partial EMT, with the degree of EMT varying both within a tumor and between different tumors. Furthermore, EMT is reversible, and cells can undergo mesenchymal-to-epithelial transition (MET), which contributes to the establishment of tumors at metastatic sites.

Tumor Microenvironment

A tumor does not solely consist of transformed cancer cells but represents a complex tissue that also includes a wide array of stromal cells. The importance of stromal components in tumor phenotype is highlighted by the fact that four out of the seven genes in the genetic profile used by the recently developed Oncotype DX Colon Cancer Assay to predict the risk of recurrence in colon cancer are stromal factors. Cancer progression occurs within the context of complex interactions between multiple cell types, which can be major drivers of the evolution of tumor cells. For example, the ability to recruit immune cells can engender a significant advantage to tumor cells because intratumoral inflammatory cells secrete cytokines and growth factors that promote tumor cell proliferation and survival as well as angiogenesis. Recruitment of immune suppressor cells also helps tumors evade immune surveillance (see later). As a result, many cancers evolve to recruit inflammatory cells, and infiltration by these cells is often seen in tumor biopsies.

Other cellular components of the stroma, such as fibroblasts, can also secrete growth factors that support survival and proliferation of cancer cells. Direct interaction of integrins on cancer cells with the extracellular matrix

and other cells also enhances tumorigenesis by activation of focal adhesion kinase (FAK) and several oncogenic signaling pathways, including Mek/Erk and PI-3K/Akt signaling (see Fig. 181-2).

The Immune Response to Cancer

Accumulating evidence indicates that immune surveillance and removal of immunogenic transformed cells presents a physiologic barrier to cancer development. Cancer cells can evolve a number of mechanisms to evade the immune system. They can reduce immune recognition by downregulation of major histocompatibility complex (MHC) class I antigens or by expressing immune suppressive proteins such as PD-L1. Cancer cells also have direct effects on the immune system. They secrete factors such as TGF-β, VEGF, and IL-10 that reduce the immune response, potentiate immune checkpoints, and recruit T_{reg} cells and other immune suppressor cells. Exploitation of the immune response for cancer therapy is gaining momentum in the clinic.[7] A major strategy in immune therapy is to boost the antitumor response by targeting immune checkpoints. Ipilimumab, a humanized antibody approved for the treatment of melanoma, enhances T-cell activation through blockade of CTLA-4-mediated co-inhibition. Similar therapies targeting PD-1/PD-L1–mediated checkpoints have also recently demonstrated substantial clinical effectiveness. Cancer cells also express antigens that can be used in vaccine therapies. These include cancer-testis antigens that are normally only expressed on germline cells (e.g., NY-ESO-1) and tissue-specific antigens. Sipuleucel-T is a cancer vaccine against prostatic acid phosphatase (PAP); it is approved for metastatic hormone-refractory prostate cancer. Evidence indicates that immune responses may also play a role in the therapeutic effect of antibodies designed to target specific oncogenes (see following and Table 181-4).

Energy Metabolism

Cancer cells evolve changes in energy metabolism known as the Warburg effect. This is characterized by a vast increase in the uptake of glucose, which is preferentially channeled to glycolysis rather than aerobic respiration. Oncogenic alterations that underlie these changes in glucose uptake and metabolism include increased PI-3K/Akt/mTor signaling, as well as upregulation of c-Myc and hypoxia-inducible factor-1α (HIF-1α). A direct role for altered metabolism in carcinogenesis[8] is supported by mutations affecting succinate dehydrogenase in hereditary paraganglioma (see Table 181-1), succinate dehydrogenase or fumarate hydratase in some renal cell carcinomas, and isocitrate dehydrogenase-1 and -2 (*IDH1*, *IDH2*) in glioma. Although the exact advantage conferred by the Warburg effect remains to be established, a likely rationale is that increased glycolysis provides many of the intermediates required for macromolecular synthesis, and thus may be required to sustain tumor growth. In some cases, it may also reflect an adaptation to hypoxia in tumors. Altered energy metabolism has attracted attention as a potential biomarker and target for cancer therapy, with 2-deoxyglucose and inhibitors of 6-phosphofructo-2-kinase, and pyruvate kinase M2 already being tested in clinical trials. The increased glucose uptake in cancer cells also underlies the use of positron emission tomography for visualizing tumors in vivo.

Cancer Stem Cells

Normal proliferating tissues contain pluripotent self-renewing stem cells that have high proliferative potential and can differentiate into all of the cell types in the tissue. Stem cell division gives rise to daughter stem cells and to more differentiated, transit-amplifying progenitor cells. Transit amplifying cells then continue to divide and progressively differentiate to give rise to the full spectrum of a tissue's cellular components. Stem cells are rare within tissues and usually divide very slowly, with the bulk of the proliferation responsible for tissue renewal carried out by the transit-amplifying population. Stem cells can also be found in tissues that are traditionally considered to be nonproliferative, where they remain quiescent until required for tissue repair.

Increasing evidence indicates that cancer cells are not phenotypically identical cells but are organized similarly to proliferative tissues. Analysis of solid tumors and hematopoietic cancers has revealed the presence of populations of cells that have a high potential to regenerate cancers, whereas the bulk of cancer cells have a negligible regenerative potential. Moreover, these cells can regenerate tumors that recapitulate the heterogeneity of the original malignancy. Such cells are analogous to normal tissue stem cells with regard to their capacity for self-renewal and "tissue" regeneration, and are thus referred to as cancer stem cells. This analogy is strengthened by the fact that cancer stem cells express many of the markers that differentiate stem cells in the tissues from which the cancer arose. In addition to their ability for self-renewal, cancer stem cells differ from the bulk of cancer cells in that they are slowly dividing and relatively resistant to chemotherapy. Despite these differences, the precise relationship between the different populations of cancer cells remains to be established. For example, EMT can induce a cancer stem cell–like phenotype, opening the possibility that acquisition of "stemness" in cancer cells is a dynamic process, with cells able to enter and exit a stem cell state in response to microenvironmental cues or other stimuli.

Whatever the nature of cancer stem cells, the presence of a population of drug-resistant cells with self-renewing capacity has required a reevaluation of the criteria by which cancer treatments are assessed. Treatments that do not kill the cancer stem cell population are destined to result in relapse, no matter how efficiently they debulk the cancer. Future development of treatment regimens will have to consider efficacy against the minor population of cancer stem cells that may be difficult to detect after treatment.

Tumor Heterogeneity

In addition to the phenotypic heterogeneity associated with the presence of stem cells, cancers show considerable genetic and morphologic heterogeneity both within and between patients.[9] The genetic instability associated with cancer development, together with the stochastic nature of oncogenic mutations, supports genetic drift and the coevolution of cancer cells with different genetic lesions within a tumor. Morphologic heterogeneity within tumors is particularly noticeable in the stroma, which is affected not only by the ability of cancers to recruit different cell types but also by random factors such as tumor depth, variations in vascularization, and differences in the surrounding tissue. The resultant variation in microenvironment produces different evolutionary pressures that select for regional heterogeneity within the cancer cells of a tumor. Even in apparently homogeneous cancers that arise from clonal expansion of genetically identical cells, small variations in the microenvironment may allow for the survival of subpopulations of genetically distinct cells.

Heterogeneity across tumors has implications for therapy that are analogous to those seen with stem cells. Genetically distinct populations in different microenvironments would be expected to differ in their susceptibility to treatment. Thus, heterogeneous cancers are likely to have subpopulations of resistant cells that may evade therapy and lead to relapse. This is a particular concern for metastases, which are exposed to environmental pressures that are distinct from those of the original tumor.

EXPLOITATION OF TUMOR BIOLOGY FOR TARGETED THERAPIES

Targeted Therapies

Knowledge of the biology that underlies cancer development is being leveraged in the clinic,[10] with an increasing number of drugs that target molecular changes in cancer being evaluated in patients (Table 181-4). The promise of these therapies is that by targeting changes specific to cancer, highly effective treatments can be developed that do not have the side effects associated with traditional cytotoxic chemotherapy. The majority of agents in the clinic directly target oncogenic pathways, with most approved agents being either small molecules that target protein kinases or antibodies that disrupt signaling from cell surface receptors (see Table 181-4). Another strategy is to exploit the potential "synthetic lethality" that results from oncogenic changes, as seen with the susceptibility of cells with BRCA1 or BRCA2 mutations to inhibitors of PARP (see "Genome Instability and Cancer Development" section).

By their nature, targeted therapies are only effective in tumors with relevant mutations. Specific mutations may be common in tumors from a particular disease site, leading to targeted therapies being associated with specific cancer types (e.g., HER2 inhibitors and breast cancer, EGFR inhibitors in lung and colon cancer); however, only a subpopulation of tumors at a specific disease site will be susceptible to any given targeted therapy. For example, although breast cancers with overexpression of HER2 are responsive to trastuzumab (see Table 181-4), they represent only 20 to 25% of all breast cancers; furthermore, the majority of these HER2-expressing breast tumors do not respond to HER2 inhibitors. Tumors can also have mutations in downstream components of a signaling pathway that negate the action of a drug. For example, B-Raf is downstream of EGFR, and thus EGFR inhibitors are ineffective for tumors carrying mutations activating B-Raf, even if they overexpress EGFR. As a result, application of targeted therapies requires testing of tumors to determine if they have the correct genomic profile to respond to any given treatment. Optimal use of targeted agents requires that

TABLE 181-4 TARGETED CANCER THERAPIES

THERAPEUTIC AGENT	TYPE	TARGET	DISEASE	INDICATION	COMPANION TEST
Imatinib Dasatinib Nilotinib	Small molecule	BCR-ABL	CML, ALL	Philadelphia chromosome positive	Cytogenetic analysis, FISH, PCR
Ponatinib Bosutinib	Small molecule		CML and AML resistant to prior tyrosine kinase inhibitor therapy	Philadelphia chromosome positive	Cytogenetic analysis, FISH, RT-PCR
Imatinib	Small molecule	c-Kit	Gastrointestinal stromal tumors	CD117 (c-Kit) positive	Immunohistochemistry (c-Kit PharmDx)
Cetuximab Panitumumab	Monoclonal antibody	EGFR	Colorectal cancer, head and neck	*KRAS* wild-type in colon cancer	PCR (*therascreen* KRAS RGQ Kit)
Gefitinib Erlotinib	Small molecule	EGFR	NSCLC	Mutant EGFR	PCR (*therascreen* EGFR RGQ PCR Kit, cobas EGFR Mutation Test)
Tramatenib Dabrafenib Vemurafenib	Small molecule	B-Raf	Melanoma	V600 mutant BRAF	PCR (THxID, cobas 4800 BRAF V600 Mutation Test)
Trastuzumab	Monoclonal antibody	Her2	Breast, stomach, gastroesophageal	Her2 positive	Immunohistochemistry (PATHWAY, InSite, Bond Oracle, HercepTest), FISH (Inform, PathVysion, SPOT-Light, HER2 CISH PharmDx)
Lapatinib	Small molecule	Her2, EGFR	Breast	Her2 positive, trastuzumab resistant	
Everolimus	Small molecule	mTOR	Breast, pancreatic, renal cell, astrocytoma		
Bevacizumab	Monoclonal antibody	VEGF	NSCLC, metastatic colorectal, metastatic kidney, glioblastoma		
Ipilimumab	Monoclonal antibody	CTLA-4	Melanoma		

Companion tests in parentheses are U.S. Food and Drug Administration–stipulated tests for certain uses of the corresponding drug.
ALL = acute lymphoblastic leukemia; CML = chronic myelogenous leukemia; FISH = fluorescence in situ hybridization; NSCLC = non–small cell lung cancer; PCR = polymerase chain reaction.

the appropriate mutation or other molecular abnormality be present (see Table 181-4). Many new targeted drugs are being approved by the U.S. Food and Drug Administration, together with a companion diagnostic test for identification of relevant therapeutic targets.

Use of genetic testing and targeted therapies is blurring the classification of cancer based on disease site. The fact that similar genetic changes can occur in cancers from different organs means the same drug may be appropriately used to target the same molecular change in cancers originating from different histologies (see Table 181-4). This, together with the observation that only a subset of cancers respond to a targeted treatment, suggests that in the future the classification of tumors based on the genetic abnormalities they contain may be more relevant for the choice of therapy than the tissues from which they arise.

Efficacy and Resistance Associated with Targeted Therapies

When appropriate genetic changes are present, targeted therapies can be remarkably effective, particularly in homogeneous cancers that are driven by a single well-defined genetic lesion. This can be seen with Philadelphia chromosome–positive CML, which arises because of the aberrant tyrosine kinase activity of the *BCR-ABL* oncogene (Chapter 184). Imatinib, an inhibitor of Abl (along with PDGFRα and c-Kit) is highly effective in treating chronic-phase CML patients, turning it from a uniformly fatal disease to one with a 7-year survival of about 90%. It is important to note that despite its clinical efficacy, the majority of patients treated with imatinib harbor residual disease, and recurrence is observed when treatment is stopped. This is true for most targeted therapies which are labeled for continuous treatment until disease recurrence. Thus, even successful targeted therapies may not cure cancer but turn it into a chronic condition that requires ongoing treatment for continuing patient benefit.

Because of their specificity, most targeted therapies are particularly vulnerable to the development of resistance resulting from mutations that produce changes in the target protein. Mutations that affect drug binding or induce overexpression (such as amplification) can render a targeted therapy ineffective. The genetic instability present in tumors, along with the need for chronic treatment with these agents, exacerbates this problem. Resistance arising from mutation of the target can be overcome by use of agents that are insensitive to the mutation. For example, tyrosine kinase inhibitors such as dasatinib, nilotinib, or ponatinib can be effective against imatinib-resistant BCR-ABL. Where resistance is the result of mutations in another protein that reduces reliance on a particular target, the other proteins can be targeted if known. For example, the B-Raf inhibitor dabrafenib (see Table 181-4) is being tested in combination with EGFR inhibitors for treatment of tumors that are resistant to EGFR inhibitors owing to the V600-activating mutation of B-Raf (see Fig. 181-2).

Although targeted therapies have proven highly effective for homogeneous cancers, they have more limited efficacy in the majority of more heterogeneous tumors. This can be seen with CML, where imatinib has limited efficacy in patients experiencing blast crisis where additional molecular lesions have accumulated (Chapter 184). Targeted therapies are available that prolong survival of appropriately selected patients, but in most cases these treatments give rise to transient responses with rapid emergence of resistant disease. Treatment failure may arise from de novo mutations or from preexisting subpopulation(s) of resistant cells present in heterogeneous tumors. The rapid emergence of resistant tumors indicates that tumor heterogeneity is a particular concern. Use of combination therapies, where targeted agents are combined with either conventional chemotherapy or with other targeted therapies, is one strategy that can increase the efficacy of these agents (e.g., pertuzumab, a monoclonal antibody that targets HER2, has been approved for combined therapy with trastuzumab and docetaxel in breast cancer).

Side Effects of Targeted Therapies

Although targeted therapeutics may lack the systemic toxicity of traditional chemotherapy, they are not without side effects. With traditional chemotherapies, the therapeutic window is based on the increased susceptibility of cancer cells to their cytotoxic effects, and treatment is limited by their maximum tolerated dose (MTD). However, the concept of MTD is less appropriate for targeted therapies where side effects are a direct consequence of the intended action of the drug. Most oncogenes have normal cellular equivalents (proto-oncogenes) that regulate homeostasis in non-tumor tissues. Since proto-oncogenes can be inhibited by the targeted agents, disruption of normal tissue homeostasis may, in some cases, be an unavoidable consequence of targeted therapies. In many situations, such as the rash seen with EGFR inhibitors, side effects can provide an indication of whether the drug is altering its target. Severe side effects of targeted therapeutics, such as cardiac problems associated with HER2 inhibitors, are rare and generally reverse upon cessation of treatment.

Genetic Profiling and Personalized Medicine

Development of molecularly targeted cancer therapies opens the possibility that treatment could be tailored to the specific defect in the cancer of an individual patient. Such a personalized approach to cancer therapy has become feasible with recent technologic advances in DNA sequencing that allow mutational profiles of individual tumors to be determined over a short time interval. Technologies currently under development include array-based platforms for analysis of mutations in genes of interest, deep sequencing of known drivers of tumorigenesis (i.e., repeated reads of the sequence of interest), and whole genome or exome sequencing (Chapter 43). Each approach has its advantages and disadvantages. For example, deep sequencing can identify mutations in subpopulations of cells that may be missed by other methods, but this approach is more costly and time consuming. Approaches that rapidly test a limited number of genes, on the other hand, may miss changes that would be identified in whole genome/exome sequencing. Thus, the best strategy for personalized medicine remains to be determined. Because analysis is normally performed on biopsies of primary tumors, the problem of regional heterogeneity in tumors and potential genetic differences in metastases also needs to be addressed for successful implementation of more personalized treatments.

Genetic profiling of tumors can also be used to gain prognostic information. Our increasing knowledge of the biology and genetics of cancer has led to the development of mutation and expression signatures that are associated with various cancer phenotypes. As a result, several commercial tests that use the mutational status of a panel of genes to predict the risk of recurrence and/or aggressiveness for breast (e.g., MammaPrint, Oncotype DX), colon (e.g., Oncotype DX), and prostate (e.g., Prolaris, Oncotype DX) cancers are now available for use in the clinical setting.

REVIEW QUESTIONS

1. A 36-year-old woman is found to have acute myelogenous leukemia. Family history obtained on diagnosis reveals that the patient's mother died from a glioblastoma multiforme detected at the age of 40. The patient's older brother died from recurrent osteogenic sarcoma at the age of 39, and her maternal grandmother succumbed to metastatic breast cancer before the onset of menopause. Mutations in which one of the following genes is associated with this familial cancer syndrome?

A. *NF1*
B. *APC*
C. *TP53*
D. *MLH1*
E. *WTI*

Answer: C This family demonstrates the varied range of expression of the Li-Fraumeni syndrome, caused by mutations in the TP53 tumor suppressor. Although *NF1* mutations can be associated with breast cancer and leukemia, glioblastoma multiforme does not occur with this mutation. *MLH1* and *APC* mutations are associated with gastrointestinal malignancies for the most part. *WTI* mutations are specifically associated with familial Wilms tumor (See Table 181-1.)

2. Viral infections are not associated with which one of the following malignancies:

A. Cervical cancer
B. Merkel cell carcinoma
C. B-cell non-Hodgkin's lymphoma
D. Colorectal carcinoma
E. Hepatocellular carcinoma

Answer: D The major etiologic factor in the causation of cervical cancer is the human papillomavirus. Merkel cell carcinomas are associated with the Merkel cell polyomavirus. Epstein-Barr virus causes B-cell non-Hodgkin's lymphoma, and hepatocellular carcinomas are associated with hepatitis B and C viruses. There is no virus known to be associated with the development of colon cancer.

3. One mechanism related to the unlimited replicative potential of tumor cells is:

A. Low threshold for necrotic cell death
B. Increased apoptotic gene expression
C. Tumor cell heterogeneity
D. Overexpression of telomerase
E. Deregulation of cellular energetics

Answer: D High levels of tumor cell telomerase limit tumor cell senescence, promoting cellular longevity. Cells with a low threshold for necrosis or apoptosis have a diminished lifespan. Tumor cell heterogeneity is not directly related to the ability of tumor cells to replicate.

4. There is increasing evidence that specific genetic abnormalities in certain tumors are associated with alterations in tumor cell energy metabolism. Which of the following such associations is correct?

A. Mutations in the mitochondrial fumarate hydratase gene and hereditary renal cancer
B. Mutations in membrane-bound NADPH oxidase 1 and colon cancer
C. Mutations in mitochondrial complex I and breast cancer
D. Mutations in ribonucleotide reductase and CML

Answer: A Hereditary renal cancers have been associated with mutations in the fumarate hydratase gene that produce tumors that upregulate HIF-1α and are highly vascular, related in part to enhanced oxidative glycolysis.

MYELODYSPLASTIC SYNDROMES

DAVID P. STEENSMA AND RICHARD M. STONE

DEFINITION

The myelodysplastic syndromes (MDS) are a heterogeneous group of bone marrow failure syndromes collectively characterized by ineffective hematopoiesis resulting in peripheral blood cytopenias, most commonly anemia. MDS have a tendency to evolve over time, and there is a risk of progression to acute myeloid leukemia (AML), which is arbitrarily defined by the World Health Organization (WHO) as the presence of 20% or more immature myeloid "blast" cells in the blood or bone marrow.

Although some investigators feel that MDS should not be considered a form of cancer because some cases remain stable for many years, and a few patients have a pathophysiology dominated by autoimmune suppression of hematopoietic progenitor cells and resembling aplastic anemia, MDS are classified as myeloid neoplasms by the WHO and other organizations. Many of the somatic gene mutations that are recurrent in MDS are also present in AML and other myeloid neoplasms, and there are typically one or just a few mutant clones in the bone marrow contributing to most of the marrow cellularity.[1]

The minimal diagnostic criteria for MDS as defined by the WHO include the presence of a meaningful and persistent cytopenia (i.e., hemoglobin <11 g/dL, absolute neutrophil count <1500/mm^3, or platelet count <100,000/mm^3) together with at least one of the following features: (1) greater than 5% blasts in the bone marrow, (2) an abnormal marrow karyotype with an acquired chromosome anomaly that is consistent with the diagnosis of MDS, (3) other evidence of clonal hematopoiesis besides marrow karyotype (e.g., abnormal result using a fluorescence in situ hybridization [FISH] panel of probes directed at common MDS-associated chromosomal abnormalities), or (4) greater than 10% cells in any given hematopoietic linage that appear dysplastic (i.e., morphologically abnormal, described further below) in a patient in whom other causes of dysplastic cell morphology such as nutritional deficiency have been ruled out. Patients sometimes have persistent cytopenias and do not quite meet these diagnostic criteria, yet no other diagnosis is apparent after detailed investigation. These disorders are sometimes termed *idiopathic cytopenias of undetermined significance* (ICUS), and such patients should be followed over time because they have a risk of developing overt MDS.[2]

EPIDEMIOLOGY

The incidence and prevalence of MDS have been difficult to estimate accurately, in part because of varying definitions and imprecise terminology historically, and also because until recently, MDS cases were not captured by most global cancer registries. The U.S. National Cancer Institute's Survey, Epidemiology, and End Results (SEER) data indicate that 10,000 to 12,000 new cases are diagnosed in the United States each year. However, analysis of insurance claims data, including Medicare claims, suggests that the actual incidence of MDS is much higher—at least 40,000 new U.S. cases per year, several times higher than the incidence of AML.[3] In addition, many geriatric patients who have cytopenias of uncertain etiology and may have MDS are incompletely evaluated (e.g., they do not undergo bone marrow aspiration) and never receive an MDS diagnosis.

The primary risk factor for development of MDS is aging, with disease a consequence of cumulative acquisition of somatic mutations in marrow stem cells. The rate at which MDS is diagnosed is slightly increased in workers in certain industries such as the petroleum industry and agricultural sector, probably owing to exposure to genotoxic hydrocarbons, accelerating acquisition of such mutations. There is a slight male predominance overall, perhaps representing patterns of occupational exposure. In Asia and Eastern Europe, MDS is typically diagnosed at younger ages than in the West; in the United States, the median age at which MDS is diagnosed is 71 years, whereas in China it is closer to 50 years.

Individuals who have been exposed to ionizing radiation or certain types of cytotoxic chemotherapy (e.g., alkylating agents such as chlorambucil or mephalan, or topoisomerase II inhibitors such as etoposide or doxorubicin) have an increased risk of developing MDS subsequently. The peak incidence of MDS diagnosis after alkylating agent or radiation exposure is 5 to 10 years later, whereas after a topoisomerase inhibitor exposure, it is 1 to 3 years. The risk never goes away entirely; even 50 years after the Hiroshima and Nagasaki atomic bomb events in Japan, radiation-exposed individuals continued to be diagnosed with MDS at a higher rate than the unexposed population. Patients with a chemotherapy or radiation exposure history are said to have therapy-related MDS (t-MDS) or "secondary" MDS.

Although familial MDS is rare, germline gene mutations in several genes, including *RUNX1* and *GATA2*, predispose to MDS.[4] *RUNX1* mutations are associated with a prodrome of thrombocytopenia that can be mistaken for immune thrombocytopenic purpura, whereas *GATA2* mutations are associated with a history of mycobacterial infections and monocytopenia.

PATHOBIOLOGY

MDS are clonal disorders, meaning that one or several stem or progenitor cells in the marrow that bear somatic gene mutations expand and proliferate at the expense of healthy stem cells and come to dominate the bone marrow. These clones can then acquire additional mutations that give rise to subclones that contribute to progression of disease. The process of somatic mutation acquisition can be accelerated through exposure to radiation or DNA-damaging chemicals, as noted earlier.

Marrow cellularity is usually normal or increased in MDS, but excessive apoptosis (i.e., programmed cell death) of hematopoietic cells within the bone marrow accounts for the peripheral blood cytopenias. Excessive apoptosis within the marrow characterizes earlier MDS, but as the disease progresses toward AML and one clone begins to dominate, intramedullary apoptosis may decrease. In addition, hematopoietic differentiation, which is disordered but still can proceed in earlier stages of the disease, may become completely impaired late in the disease, such that most developing hematopoietic cells are arrested at the myeloblast stage. If 20% or more of the cells in the marrow or blood are blast cells, this is considered AML; MDS by definition is associated with less than 20% blast cells.

Large gains and losses of chromosomal material within diseased cells, including monosomies, trisomies, and large chromosomal deletions, are detectable by routine metaphase karyotyping present in one half of patients

with de novo MDS and more than 80% of patients with t-MDS.[5] Newer genetic techniques such as array-based comparative genomic hybridization may uncover cryptic chromosomal deletions in patients with MDS who have normal karyotype results.

More than 25 genes are now known to be recurrently mutated in MDS.[6,7] No one mutation dominates; MDS are associated with considerable genetic heterogeneity. These genes and the probable function of the proteins they encode are listed in Table 182-1. More than 90% of patients have at least one detectable clonal somatic mutation, and most patients with MDS have several such mutations detectable in their marrow cells. Mutations affecting epigenetic patterning (e.g., DNA methylation) and chromatin conformation (e.g., histone-DNA interactions) are common in MDS, and this may be why agents that affect DNA methylation, such as azacitidine and decitabine, are effective in some patients. In addition, mutations affecting pre-mRNA splicing are common, especially in patients with MDS subtype refractory anemia with ring sideroblasts, but the specific genes that are misspliced and give rise to an MDS phenotype are unclear.

A subset of patients with pathologic findings that resemble MDS will have autoimmune suppression of hematopoiesis, which may be driven by a clonal T-lymphocyte population.[8] Patients are more likely to have an immune component to their marrow failure if they are younger than 55 years and have a hypocellular marrow similar to that seen in aplastic anemia, a normal

TABLE 182-1 GENE MUTATIONS ASSOCIATED WITH MDS AND FUNCTIONAL CLASS OF THE ASSOCIATED PROTEIN

RECURRENTLY MUTATED GENES	MUTATION FREQUENCY IN MDS	ADDITIONAL NOTES
SPLICEOSOME COMPONENTS (ALTER PRE-mRNA SPLICING)		
SF3B1	20-25%	Strongly associated with presence of ring sideroblasts (60-80% of RARS cases), often co-occurs with *DNMT3A** mutations
*U2AF1**	5-10%	Often co-occurs with del(20q)
SRSF2	5-10%	More frequent in CMML (25-30%), often co-occurs with *RUNX1** or *ASXL1** mutations
ZRSR2	5-10%	
U2AF2, SFRA1, PRPF40B, SF1	<2% each	
EPIGENETIC PATTERN & CHROMATIN CONFORMATION MODIFIERS		
TET2	20%	More frequent in CMML (≈40%)
*DNMT3A**	10-15%	Associated with poor outcome after transplant
SETBP1	5-10%	More common in CMML; germline mutations cause Schinzel–Giedion syndrome
*ASXL1**	10-20%	More frequent in CMML (≈40%)
*EZH2**	6%	More frequent in CMML (≈12%)
KDM6A	<2%	Rare in MDS, more frequent in CMML
IDH1, IDH2	<2%	More frequent in AML than MDS
PHF6	<1%	
ATRX	Rare	Associated with acquired α-thalassemia (hemoglobin H inclusions in RBCs)
TRANSCRIPTION FACTORS		
*RUNX1**	10-15%	Germline mutations cause familial platelet disorder with propensity to AML (FPD-AML)
*ETV6**	<5%	Translocations common in AML; formerly known as *TEL*
MYBL2	<1%	
GATA2	Rare	Germline mutations cause familial MDS with monocytopenia
CEBPA	Rare	More frequently mutated in AML, germline mutations cause familial AML without preceding dysplasia
WT1	Rare	More frequently mutated in AML
GENOME STABILITY		
*TP53**	5-10%	Associated with very poor prognosis; associated with t-MDS and with complex karyotype
TYROSINE KINASE SIGNALING		As a group, these genes are more often mutated in myeloid malignancies with a proliferative component
NRAS, KRAS, BRAF*	5-10% collectively	*NRAS* mutations more common in CMML and AML; first mutations described in MDS (1987)
JAK2	<5%	More frequent in RARS with thrombocytosis (RARS-T) (50%)
CBL, CBLB	<5%	More frequently mutated in CMML than MDS
FLT3, MPL, KIT	<1%	*MPL* mutated in (5%) of RARS-T, *FLT3* and *KIT* mutations are rare in MDS and much more common in AML
NF1	<1%	Germline mutations cause neurofibromatosis type 1
PTPN11	<1%	Rare in MDS, more frequent in JMML (30%)
OTHERS		
NPM1	<2%	Much more frequently mutated in AML
GNAS	<1%	
BCOR, BCORL1	<1%	
UMODL1	<1%	
ZSWIM4	<1%	
Cohesins *(RAD21, STAG1, STAG2, SMC3, SMC1A)*	Rare	

*Those mutations that appear to be independently associated with poor outcomes in MDS are denoted by an asterisk. (Bejar R. Clinical and genetic predictors of prognosis in myelodysplastic syndromes. *Haematologica* 2014;99:956-964.) AML = acute myelogenous leukemia; CMMS = chronic myelomonocytic leukemia; JMML = juvenile myelomonocytic leukemia; RARS = refractory anemia with ring sideroblasts; t-MDS = therapy-related MDS. Data based on Bejar R, Levine R, Ebert BL. *J Clin Oncol.* 2011;29:504-515, and others.

chromosome pattern or trisomy 8 rather than a more complex karyotype, a paroxysmal nocturnal hemoglobinuria cell population (Chapter 160) detectable by flow cytometry, and HLA-DR15 tissue type. Such patients may respond to immunosuppressive therapy with anti–T-cell therapies.

Most patients with MDS come to medical attention because they have anemia (which is present in 95% cases and is often macrocytic); one half of patients also have neutropenia, thrombocytopenia, or both at the time of diagnosis. The peripheral blood and bone marrow exhibit characteristic "dysplastic" cell morphologic abnormalities. In the peripheral blood, these include hypogranular neutrophils, hypolobated neutrophils such as the two-lobed pseudo-Pelger-Hüet cell, platelet size and granularity abnormalities, poorly hemoglobinized red cells, and circulating early myeloid cells such as small numbers of myeloblasts. Maturation abnormalities in the bone marrow include megaloblastoid erythroid maturation, multi-nucleated erythroid cells, ring sideroblasts (i.e., erythroid precursors with abnormal peri-nuclear iron-containing mitochondria visible with Perls' Prussian blue reaction), nuclear karyorrhexis, myeloid lineage abnormalities such as left-shifted myelopoiesis and the presence of hypogranular white cells, and megakaryocytic abnormalities such as micromegakaryocytes, very large hypernucleated megakaryocytes, or hypolobated megakaryocytes (Fig. 182-1). A mild increase in reticulin fibrosis is common in MDS, but severe reticulin fibrosis or collagen fibrosis are rare. Extramedullary hematopoiesis is uncommon in MDS, and the presence of splenomegaly or hepatomegaly should prompt consideration of another cause.

CLINICAL MANIFESTATIONS

The natural history of MDS is highly variable. Approximately half of patients will die of complications of the cytopenias, particularly infection due to both neutropenia and to functional neutrophil defects (i.e., impaired bactericidal activity due to hypogranularity). Among lethal infections in MDS, pneumonia and bacteremia due to gastrointestinal or urinary infections are the most common. Bleeding is the second leading common cause of death. In addition, anemia may exacerbate cardiovascular or cerebrovascular disease. Approximately 25% of patients will progress to AML, which is usually a fatal complication. Finally, because MDS is often diagnosed in elderly patients or in those with a history of cancer, unrelated causes are the chief contributor to death in at least one third of patients.

The clinical course in MDS is dominated by complications of the cytopenia, including mucosal bleeding, recurrent infections, and exertional dyspnea and fatigue. Fatigue correlates poorly with the degree of anemia and may be due in part to cytokine release by the abnormal clonal cells. Paraneoplastic manifestations including neutrophilic dermatosis (Sweet syndrome, Chapter 440), inflammatory arthritis, and other rheumatologic syndromes occur in 10 to 15% of patients. Repeated transfusions of red cells can lead to transfusional hemosiderosis and organ dysfunction, including hepatic and cardiac abnormalities. The frequency with which actual clinical complications of iron overload occur, as well as the importance of chelation therapy in MDS, are controversial topics.

DIAGNOSIS

The diagnosis of MDS is usually suspected when the patient is discovered to have cytopenias, especially macrocytic anemia in an older person that is not due to B_{12} or folate deficiency, medication effect (e.g., methotrexate or azathioprine), or alcohol abuse. The blood count abnormality may be an incidental finding, but most patients with MDS are symptomatic with fatigue, dyspnea, and other cytopenia-associated symptoms.

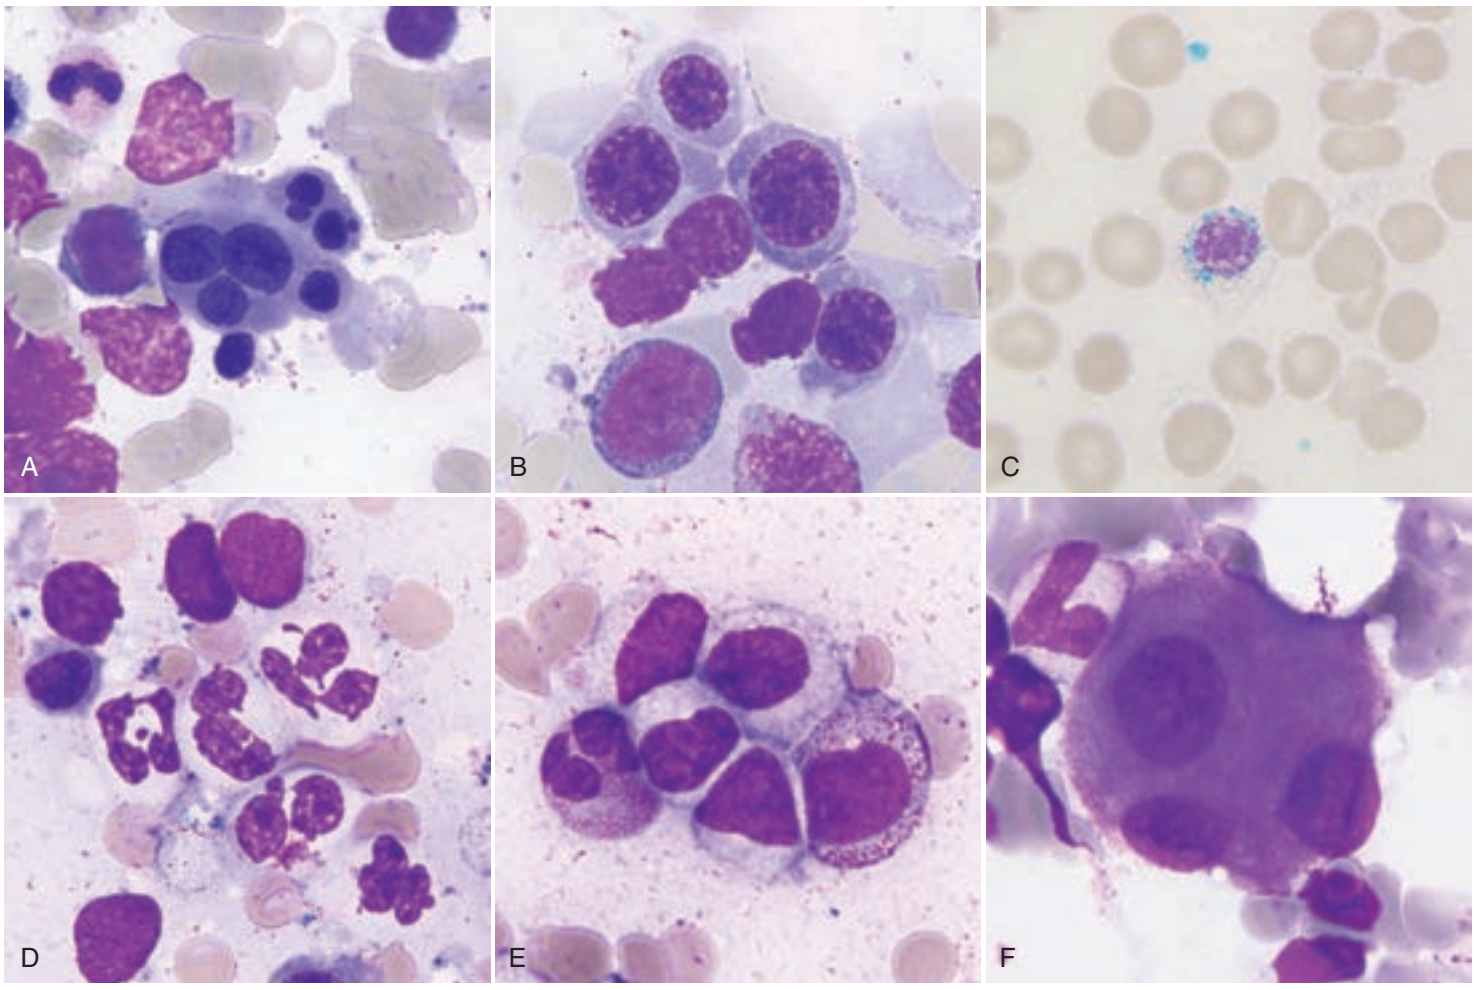

FIGURE 182-1. Dysplastic cell morphologic abnormalities commonly observed in the peripheral blood or marrow of patients with myelodysplastic syndrome (MDS). A, Multinucleated erythroid precursor. **B,** Megaloblastoid maturation of erythroid precursors with "open" nuclear chromatin. **C,** Ring sideroblast (pathologic erythroid precursor). **D,** Hypogranular neutrophils. **E,** Pseudo-Pelger-Huët anomaly (hypolobated neutrophil). **F,** Abnormal nuclear lobation in a megakaryocyte—a "Pawn Ball" cell with three separated nuclei/nuclear lobes. *A, B, D,* and *F* are Wright-Giemsa–stained marrow aspirate; *C* is Perls' Prussian blue reaction of marrow aspirate; *E* is Wright-Giemsa–stained peripheral blood. (Figures courtesy Elizabeth A. Morgan, MD, PhD, Brigham & Women's Hospital.)

A bone marrow aspirate is required to make the diagnosis, and bone marrow core (trephine) biopsy is also useful and can provide information about the marrow architecture and overall marrow cellularity.[9] Metaphase cytogenetics is essential, but FISH is only necessary if karyotyping fails because of an unsuccessful aspiration. FISH abnormalities are rarely detected in patients for whom at least 20 metaphases can be counted during karyotyping.

Not all that is dysplastic is MDS, and it is important to consider other potential causes for cytopenias and morphologic abnormalities. The differential diagnosis includes nonclonal disorders such as B_{12} or folate deficiency, copper deficiency, iron deficiency, HIV infection, medication exposure (especially cytotoxic chemotherapy agents), or an immune disorder such as T-cell large granular lymphocyte (T-LGL) leukemia. In patients with isolated sideroblastic anemia, it is important to rule out congenital sideroblastic anemias, including those due to germline mutations in *ALAS2*, which can present late in life.

In addition, MDS must be separated from aplastic anemia (Chapter 165), which can be oligoclonal but is not typically associated with Pelger-Hüet cells or other morphologic abnormalities, and the chromosome karyotype in aplastic anemia is usually normal. MDS can also be mistaken for AML or a myeloproliferative neoplasm (MPN) such as primary myelofibrosis. Cases in which MDS features, such as cytopenias, overlap with MPN features (Chapter 166), such as leukocytosis and splenomegaly, include chronic myelomonocytic leukemia (CMML). The WHO categorizes MDS/MPN overlap syndromes separately from MDS, and these cases have a unique mutational spectrum.

Several different MDS subtypes of varying risk of progression to leukemia are recognized by the WHO; these are listed in Table 182-2. If a patient has cytopenias but does not have characteristic MDS-associated morphologic abnormalities, yet has a typical MDS-associated marrow cytogenetic abnormality such as loss of chromosome 7 or deletion of the long arm of chromosome 5, the patient can be considered to have "unclassifiable MDS" (MDS-U) and does have a risk of progression.

TREATMENT

Given the heterogeneity of MDS and the wide spectrum of functional status and comorbidities present in the typically older population with MDS, treatment must be individualized. Currently, lack of a specific well-characterized molecular target in most patients with MDS precludes a true biologically based approach to therapy. Algorithms for treatment (Fig. 182-2) are based primarily on the patient's prognosis, as discussed further below.

General Approach to the Patient

When choosing a potential therapy for a patient with MDS, clinicians should consider the patient's age, comorbidity and functional status, disease biology (currently based on assessment of bone marrow and peripheral blood findings plus cytogenetic analysis), and pace of evolution of the disease. Some patients with MDS have mild cytopenias and minimal or no symptoms, and they can reasonably be observed without therapy. For higher-risk patients (e.g., International Prognosis Scoring System [IPSS] intermediate 2 or high risk), immediate therapy is usually indicated because patients are usually severely cytopenic and have a life expectancy of less than 2 years. For lower-risk patients (IPSS low and intermediate 1 risk) a more cautious approach is appropriate. The only curative modality for MDS is allogeneic stem cell transplantation, so this option should be considered in developing a therapeutic plan if the patient is young enough and lacks other major medical problems.

Supportive Care

Hematopoietic Growth Factors and Other Approaches to Cytopenias

Because most patients with MDS are anemic, erythropoiesis-stimulating agents (ESA) including epoetin and darbepoetin are often used, even though these are not specifically U.S. Food and Drug Administration (FDA) approved for treatment of MDS. The benefits of ESAs are generally modest and of limited duration, and no prospective data confirm that they prolong survival. Patients with lower baseline serum erythropoietin levels (<500 U/L, and especially <100 U/L) are more likely to respond to ESAs than patients with higher baseline serum erythropoietin levels. An inappropriately low erythropoietin

TABLE 182-2 WORLD HEALTH ORGANIZATION (WHO) SUBTYPES OF MYELODYSPLASTIC SYNDROME

MDS SUBTYPE	DYSPLASIA	BLAST COUNT	OTHER FINDINGS

Refractory cytopenia with unilineage dysplasia (RCUD)	• Present in only 1 lineage (>10% of cells in that lineage):
	  • Erythroid (subtype: refractory anemia)
	  • Myeloid (subtype: refractory neutropenia)
	  • Megakaryocytic (subtype: refractory thrombocytopenia)
		• Peripheral blood: <1%
		• Bone marrow: <5%
			• Cases with bilineage cytopenias may be included in this category, but marrow dysplasia must be limited to 1 lineage
			• Ring sideroblasts represent <15% of erythroid precursors

Refractory anemia with ring sideroblasts (RARS)	• Present in the erythroid lineage (>10% of erythroid precursors)	• Peripheral blood: none • Bone marrow: <5%	• Anemia (normocytic/macrocytic) • Ring sideroblasts comprise ≥ 15% of erythroid precursors
Refractory cytopenia with multilineage dysplasia (RCMD)	• Present in 2 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: <1% • Bone marrow: <5%	• One or more cytopenias • No Auer rods • May or may not have ≥ 15% ring sideroblasts
Refractory anemia with excess blasts-1 (RAEB-1)	• Present in 1 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: <5% • Bone marrow: 5-9%	• One or more cytopenias • No Auer rods • 2-4% blasts in the peripheral blood → RAEB-1
Refractory anemia with excess blasts-2 (RAEB-2)	• Present in 1 or more lineages (>10% of cells in each affected lineage)	• Peripheral blood: 5-19% • Bone marrow: 10-19%	• One or more cytopenias • Presence of Auer rods for any blast count <20% → RAEB-2
MDS with isolated deletion of chromosome 5q (5q– syndrome)	• Increased numbers of megakaryocytes, many small and with hypolobated/nonlobated nuclei • Dysplasia in other lineages less common	• Peripheral blood: no or rare blasts (<1%) • Bone marrow: <5%	• Anemia (often macrocytic) with or without other cytopenias/thrombocytosis • No Auer rods • Interstitial or terminal deletion of the long arm of chromosome 5
MDS, unclassifiable (MDS-U)	• Unequivocal, but present in <10% of cells of one or more lineages	• Peripheral blood: ≤1% • Bone marrow: <5%	• May progress to a specific MDS • Can also include cases otherwise classified as RCUD or RCMD but with 1% blasts in peripheral blood; RCUD but with pancytopenia • Cases with an MDS-associated chromosome abnormality (other than loss of Y chromosome or trisomy 8 or deletion of chromosome 20) but without dysplasia can be included in this category

Data based on Swerdlow SH, Campo E, Harris NL, et al, eds. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*. 4th ed. Lyon: IARC Press; 2008.

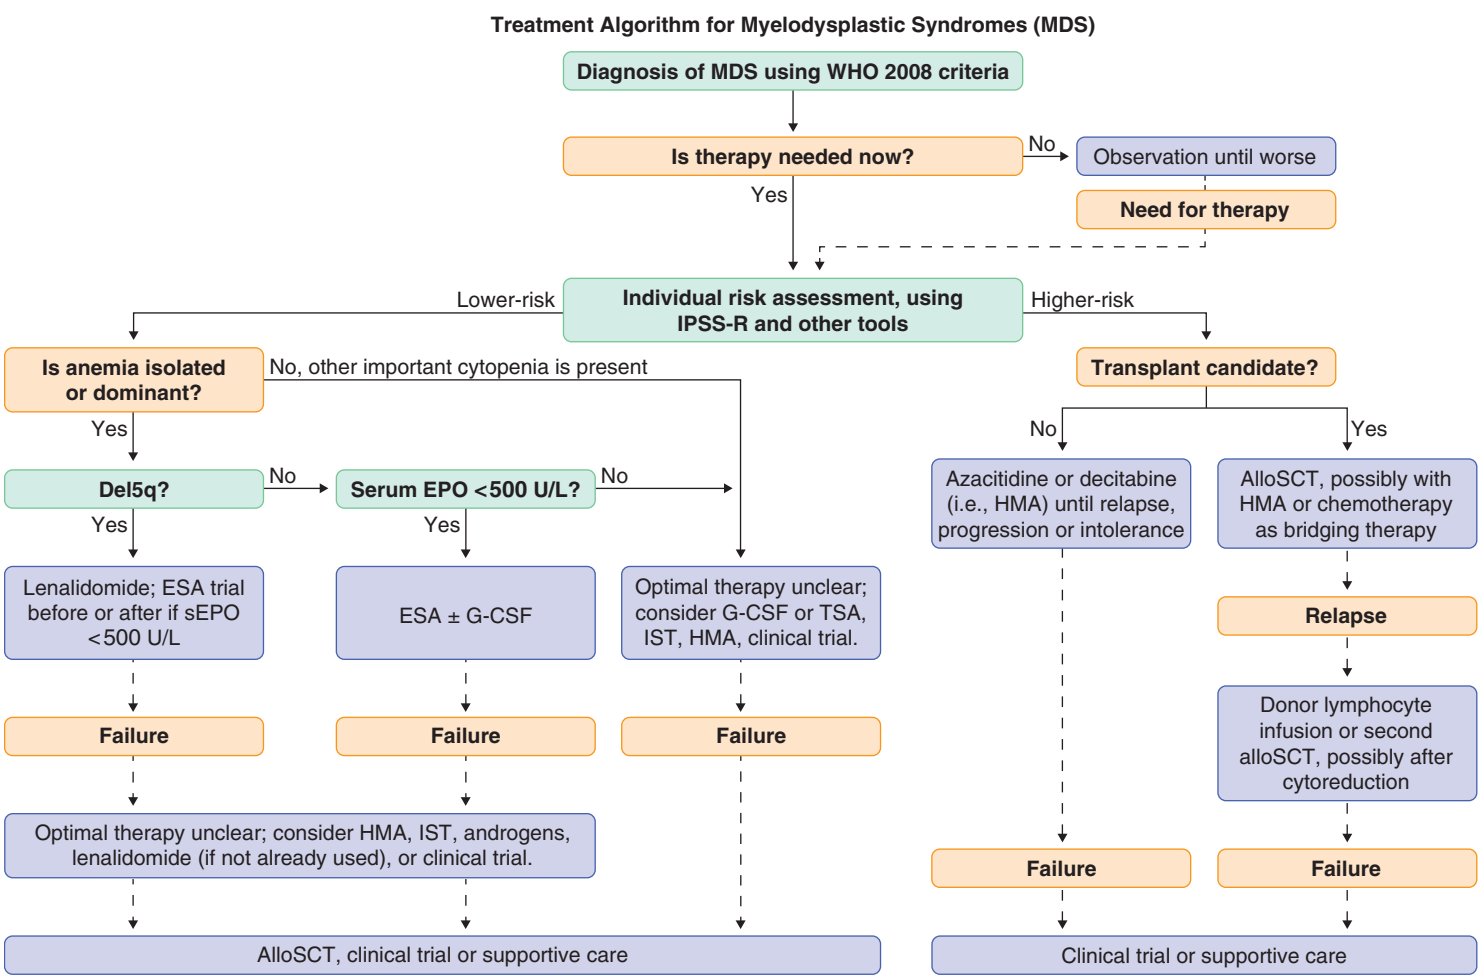

FIGURE 182-2. Suggested treatment algorithm for myelodysplastic syndrome (MDS). AlloSCT = allogeneic stem cell transplant; Del5q = deletion of long arm of chromosome 5 (5q–); EPO = erythropoietin; ESA = erythropoiesis-stimulating agent; G-CSF = granulocyte colony-stimulating factor; HMA = hypomethylating agent; IST = immunosuppressive therapy; sEPO = serum erythropoietin; TSA = thrombopoiesis-stimulating agent; WHO = World Health Organization.

response to a given degree of anemia is more likely in older patients because of the higher frequency of renal insufficiency. If no response is observed after 2 to 3 months of ESA therapy, the trial should be concluded. For patients with refractory anemia with ring sideroblasts (RARS), the addition of granulocyte colony-stimulating factor (G-CSF) to the ESA may potentiate the erythropoietic response.[10] A few patients will benefit from treatment with androgens, but the risk of prostate enlargement in men and other complications such as hepatotoxicity must be considered.

Although myeloid growth factors such as G-CSF can ameliorate the neutropenia often seen in MDS patients, such an approach (probably not leukemogenic, as was once feared) is not likely to reduce the risk of infections or provide other clinical benefit, probably because of the neutrophil dysfunction that may occur in addition to neutropenia. There is no clear role for prophylactic antibiotics.

The thrombopoiesis-stimulating agents romiplostim and eltrombopag have been approved to treat immune thrombocytopenic purpura. These agents have undergone limited study in MDS and are not FDA approved in MDS. They probably should not be used in higher-risk patients with excess blasts, because they could potentially promote leukemogenesis, but a therapeutic trial could be justified in a patient with lower-risk disease with severe thrombocytopenia or bleeding. Platelet transfusions (Chapters 172 and 177) should be used judiciously in MDS patients owing to the risk of alloimmunization, with prophylactic transfusion appropriate only in those with platelet counts less than 5000 to 10,000/mm^3. Patients with mucosal bleeding and refractory thrombocytopenia may benefit from treatment with antifibrinolytic agents such as aminocaproic acid.

Iron Chelation Therapy

The multiple red blood cell (RBC) transfusions needed by some patients with MDS may cause iron overload and tissue injury, but the frequency with which this complication occurs with clinical significance is unclear. Patients with higher serum ferritin levels fare less well than patients with lower values, both in the transplant and nontransplant settings. However, whether the ferritin is simply a marker of inflammation or more advanced disease, or whether the iron deposition in marrow, liver, heart, and pancreas directly results in this adverse outcome, remains uncertain. That uncertainty coupled with the rarity of reported deaths in MDS secondary to iron overload, as well as the toxicity of available chelators, makes the role of iron chelation therapy with agents such as deferasirox or deferoxamine in this disease quite controversial. Although it is reasonable to recommend a trial of iron chelation therapy in patients with lower-risk disease and high transfusional burdens (e.g., >20 to 40 RBC units transfused), there are no prospective data yet to suggest a clear-cut benefit in this setting. Retrospective data suggest that chelated patients live longer than nonchelated patients, but these studies are confounded by patient selection factors.

Disease-Modifying Therapy

Immunosuppressive Therapy

As described earlier, some patients with MDS display a pathophysiology that seems similar to aplastic anemia (Chapter 165), including T-lymphocyte–driven autoimmune attack against hematopoietic cells. Such patients may respond to anti–T-cell therapies, including antithymocyte globulin and calcineurin inhibitors such as cyclosporine or tacrolimus. However, although younger patients with normal karyotype, trisomy 8, paroxysmal nocturnal hemoglobinuria clones, or HLA-DR15 status seem to have a higher likelihood of benefitting, there are currently no good predictive strategies for selecting patients for immunosuppressive therapy.

Immunomodulatory Agents

Early reports showing improvements in anemia in some MDS patients during thalidomide therapy prompted a trial of the immunomodulatory lenalidomide in patients with lower-risk disease. An initial trial and a large phase II trial that followed clearly showed that patients with loss of chromosome 5q (5q–), either alone or in conjunction with other chromosomal abnormalities, had high response rates to lenalidomide, including a nearly 70% transfusion independence rate and better than 30% cytogenetic normalization rate, lasting a median of more than 2 years. Therefore, in the United States, lenalidomide has become the treatment of choice for such

5q– lower-risk MDS patients. Lenalidomide has also been used in higher-risk MDS and AML with 5q– chromosomal abnormalities, but it is less effective.[11] A large randomized trial of two doses of lenalidomide versus placebo shows that AML progression was not increased in lower-risk 5q– MDS with lenalidomide therapy and that responses to a 10-mg dose were more frequent than to a 5-mg dose. In patients with lower-risk MDS without a chromosome 5 abnormality, the response rate to lenalidomide is approximately 25%, which is about the same as one might expect with hypomethylating agents; responses last a median of 8 to 9 months. Important adverse effects of lenalidomide include cytopenias, diarrhea, and rash.

DNA Hypomethylating Agents

Low doses of the nucleoside analogue cytarabine (Ara-C) were used in the 1980s as cytoreductive and so-called differentiating therapy in patients with MDS, with limited effect. Use of low-dose Ara-C has largely been supplanted by azacitidine and decitabine, two azanucleoside analogues that irreversibly inhibit the enzyme DNA methyltransferase, thereby reducing the cytosine methylation "epigenetic" status of DNA and altering gene expression. Whether or not this putative epigenetic mechanism of action accounts for the response to these agents is unproven, but hypomethylating agents have become the mainstay of therapy for most patients with higher-risk MDS, as well as for patients with lower-risk MDS who are refractory to other therapies.

A randomized trial showed that the use of azacitidine at a dose of 75 mg/m^2 subcutaneously daily for 7 days every month (given until disease progression or toxicity), compared to observation, resulted in a delay in time to progression to AML and improved quality of life. Subsequently, an international multicenter trial randomized patients to receive either 7-day azacitidine or conventional care therapies (i.e., doctor's choice of either AML induction chemotherapy, low-dose Ara-C, or supportive care alone) and found a 9-month survival prolongation (from 15 to 24 months) in patients receiving azacitidine, compared with the control arm. These results made azacitidine the standard of care for patients with higher-risk MDS. Cytopenias and gastrointestinal upset are the most common adverse effects of this class of drugs.

Decitabine is also an active agent in patients with MDS. However, a randomized trial of decitabine compared to observation failed to show survival benefit, probably because of a suboptimal dose and schedule of decitabine.

The complete and partial response rates associated with these drugs are low, but at least half of the patients who receive a hypomethylating agent do experience an improvement in at least one cytopenia. Despite these relatively modest responses, a survival benefit is seen even in patients who do not have a complete response.[12] The major problem is that these agents are not curative, and once they fail, the patient's life expectancy is less than 6 months. There are numerous therapies in development that are being tested, but at present there is no standard of care for patients whose disease worsens while undergoing therapy with azacitidine or decitabine.

Stem Cell Transplantation

Because allogeneic stem cell transplantation (Chapter 178) is potentially curative, this modality should be considered in all patients with higher-risk MDS who are approximately 75 years old or younger and lack major comorbid conditions. Reduced-intensity conditioning stem cell transplantation is feasible in adults up to that age, whereas myelosuppressive stem cell transplants are generally reserved for those younger than approximately age 55. Studies considering both types of stem cell transplants suggest that patients with higher-risk disease should be referred immediately for stem cell transplantation if feasible.[13] The optimal conditioning regimen is unclear.

Relapses are common after stem cell transplantation. It is uncertain whether there is benefit from the administration of so-called bridging therapy with azacitidine or decitabine before a planned transplant in an effort to reduce the leukemic burden. Because most patients with MDS are older and uncommonly have a younger sibling who is a suitable stem cell donor, azacitidine or decitabine may be useful to stabilize a patient prior to transplant while an unrelated donor search is ongoing. Although the long-term outcome of patients undergoing stem cell transplant varies widely according to disease and host features,[14] approximately one third of patients with MDS can expect to be long-term disease-free survivors after a stem cell transplant at a cost of 20 to 30% in treatment-related mortality, a figure that may be dropping with time.

Summary

For higher-risk patients, if feasible, urgent transplantation should be the goal, either directly or after exposure to a hypomethylating agent to decrease marrow blasts. If transplant is not the goal, prolonged administration of hypomethylating agents is generally indicated. In lower-risk patients who have a chromosome 5 abnormality, the immunomodulatory agent lenalidomide is the treatment of choice. For other lower-risk patients, supportive care alone, hematopoietic growth factors, immunosuppressive therapy, immunomodulatory therapy, or hypomethylating agents can be considered, depending on the clinical situation.

PREVENTION

At present there is no clear way MDS can be prevented, with the exception of avoiding known precipitants (e.g., using lower doses of radiotherapy or avoiding radiation altogether, and avoiding exposure to alkylating agents or topoisomerase II inhibitors). In the future, it is likely that emerging clonal hematopoiesis following treatment for cancer or arising de novo may be recognized at an early stage. Initiation of immune-based therapies designed to break the lymphocyte tolerance of such abnormal clones may become useful.

PROGNOSIS

Because the natural history of MDS varies widely among patients, several prognostic tools have been derived to help clinicians distinguish patients with a high risk of progression to AML and death from cytopenias within a few months, from those patients whose disease is likely to be more indolent and stable for several years. Among these tools is the 1997 International Prognosis Scoring System (IPSS), which assessed patients' risk by scoring the number of cytopenias, the chromosome pattern (some anomalies are associated with a better prognosis than others), and the proportion of blast cells in the marrow. In 2012, a revised version of the IPSS (IPSS-R) was published; it included a broader range of cytogenetic abnormalities than the original IPSS and weighted abnormal cytogenetics more heavily.[15] The IPSS-R (Table 182-3) defines five different subgroups of MDS with varying risks of death and progression to AML.

Comorbid conditions also influence prognosis independently of the MDS. Other relevant factors that are not included in current prognostic models include serum ferritin and lactate dehydrogenase levels, aberrant expression of certain cell surface markers on myeloid cells detected by flow cytometry (e.g., CD5 or CD56 on myeloid cells), rarer cytogenetic abnormalities not included in the IPSS, and most importantly, the presence of certain molecular abnormalities.[16,17] Several molecular changes, including mutations in *EZH2*, *TP53*, *ASXL1*, *RUNX1*, and *ETV6* are associated with a poorer prognosis than would have been predicted by the IPSS; in patients with lower-risk disease, only *EZH2* retains independent prognostic value. Additionally, the presence of either a *TP53* or a *DNMT3A* mutation predicts for a worse outcome after stem cell transplant.

TABLE 182-3 2012 REVISED INTERNATIONAL PROGNOSTIC SCORING (IPSS-R) FOR MYELODYSPLASTIC SYNDROMES

RISK GROUP	INCLUDED KARYOTYPES	MEDIAN SURVIVAL, YEARS	25% OF PATIENTS TO AML, YEARS	PROPORTION OF PATIENTS IN THIS GROUP
Very good	del(11q), –Y	5.4	N/R	4%
Good	Normal, del(20q), del(5q) alone or with 1 other anomaly, del(12p)	4.8	9.4	72%
Intermediate	+8, del(7q), i(17q), +19, any other single or double abnormality not listed	2.7	2.5	13%
Poor	Abnormal 3q, –7, double abnormality include –7/del(7q), complex with 3 abnormalities	1.5	1.7	4%
Very poor	Complex, with >3 abnormalities	0.7	0.7	7%

REVIEW QUESTIONS

1. A 69-year-old man presents with complaints of dyspnea on exertion, intermittent palpitations, and excessive fatigue. His history is significant only for gastroesophageal reflux and hypertension, and his medications include omeprazole and metoprolol. There is no family history of cancer or hematologic disorders. Physical examination reveals generalized pallor and regular tachycardia (106 beats/minute.) A complete blood count is as follows:

White blood cell count: 6.1×10^9/L

51% neutrophils, 2% bands, 17% monocytes, 28% lymphocytes, 1% basophils, 1% eos

Hemoglobin 8.1 g/dL; mcv 92 fL

Platelets: 216×10^9/L

B_{12} and folate levels are within normal limits, and serum ferritin is 710 ng/mL. The bone marrow is 70% cellular and exhibits erythroid dysplasia with <5% myeloblasts. Prussian blue reaction demonstrates 55% ring sideroblasts, consistent with a diagnosis of myelodysplastic syndrome, subtype refractory anemia with ring sideroblasts. The karyotype is normal male (46,XY). Which of the following genes is most likely to be mutated in this patient's marrow and blood cells?

A. *BCR-ABL*
B. *SF3B1*
C. *GATA2*
D. *TP53*
E. *JAK2*

Answer: B This patient has refractory anemia with ring sideroblasts (RARS), according to the WHO classification of myelodysplastic syndromes (see Table 182-2). *SF3B1* mutations are strongly associated with RARS (occurring in 60-80% of cases; see Table 182-1). Mutations in the transcription factor *GATA2* are rare germline mutations in patients with familial MDS with monocytopenia; however, this patient has no family history of cancer or hematologic disorders. *TP53* mutation has a very poor prognosis and occurs in treatment-related MDS and is associated with a complex karyotype; however, this patient has not had such drug, toxic, or radiation exposures, and his karyotype is normal (46,XY). The *BCR-ABL* mutation is characteristic of Philadelphia chromosome–positive chronic myelogenous leukemia (CML); however, this patient does not have that clinical phenotype and does not have the Philadelphia chromosome on cytogenetics. *JAK2* mutations (specifically JAK2-V617F) are found in a large percentage of chronic myeloproliferative neoplasms, especially polycythemia vera, and can also be seen in RARS with thrombocytosis; however, the patient has a normal platelet count.

2. A 51-year-old elementary school teacher develops fatigue, dyspnea on exertion, and cold/tingling extremities. Exam reveals generalized pallor and mildly decreased proprioception and hyperreflexia. Past history is significant for hypertension, impaired glucose tolerance, and bariatric surgery 3 years ago for obesity. Her medications include metoprolol, aspirin, a multivitamin, and zinc and echinacea supplements.

The complete blood count is as follows: hemoglobin 10.2 g/dL, MCV 88 fL, white blood cell count 2.9×10^9/L, absolute neutrophil count 380/mm^3, and platelet count 218×10^9/L. Peripheral blood smear shows some hypochromic red cells and neutropenia but is otherwise unrevealing.

Serum B_{12}, red cell folate, serum ferritin, and homocysteine levels are within normal limits. A serum chemistry panel is unremarkable. The bone marrow is normocellular for age, with erythroid dysplasia, 40% ring sideroblasts, granulocytic dysplasia with vacuolization of neutrophil precursors, and no increase in myeloblasts. The karyotype is normal female. What is the most likely cause of her cytopenias?

A. Congenital sideroblastic anemia
B. Myelodysplastic syndrome, subtype refractory anemia with ring sideroblasts
C. Vitamin/mineral deficiency
D. Alcohol abuse
E. Myeloproliferative neoplasm

Answer: C The differential diagnosis in this patient from among the choices offered is quite challenging. Vitamin and mineral deficiencies like advanced folate or B_{12} deficiency can cause dysplastic changes in blood cell precursors in the bone marrow that might be difficult to distinguish morphologically from MDS. In particular, copper deficiency is being increasingly recognized today as a cause of sideroblastic anemia (which this patient has, with 40% ring sideroblasts in the marrow) in individuals who have had bariatric surgery (as in this case). Copper deficiency also causes neuropathy, which appears to be present here. Therefore, the picture is most consistent with copper deficiency secondary to bariatric surgery. MDS (refractory anemia with ringed sideroblasts [RARS]) has many of the features present in this case, including dysplastic changes in both myeloid and erythroid precursors in the marrow, but only drawing a blood copper level and giving a therapeutic trial of copper replacement would rule out the working diagnosis. Congenital sideroblastic anemia can present in adulthood, but it is much less likely here because these inherited anemias typically have changes only in the erythroid series. There is nothing to support the diagnosis of alcohol abuse or a myeloproliferative neoplasm in this case presentation. (See: Steensma DP. Dysplasia has a differential diagnosis: distinguishing genuine myelodysplastic syndromes [MDS] from mimics, imitators, copycats and impostors. *Curr Hematol Malig Rep.* 2012;7:310-320.)

3. A 58-year-old woman is found to be anemic during an evaluation for excessive fatigue. Her history is significant only for cholecystectomy and quiescent rheumatoid arthritis. Other than generalized pallor and borderline regular tachycardia, her exam is unrevealing. A complete blood count is as follows:

Hemoglobin 6.0 g/dL

Mean cell volume 102 fL

White blood count 4.8×10^9/L

Absolute neutrophil count 2.55×10^9/L

Platelet count 466×10^9/L

The reticulocyte count is 0.7%. Serum chemistries and serum B_{12} and red blood cell folate levels are normal. A peripheral blood smear is nondiagnostic. The serum erythropoietin level is measured at 702 U/L.

The patient is admitted to the hospital, where red cell transfusions are administered. There is no evidence of gastrointestinal bleeding. Bone marrow aspirate/biopsy shows a hypercellular marrow with erythroid dysplasia. Megakaryocytes are increased in number, and many are dysplastic with occasional small monolobated forms. The karyotype is 46,XX del(5)(q13q33) [18]/46,XX [2]. Which of the following is the most appropriate initial treatment for this patient?

A. Darbepoetin alfa
B. Lenalidomide
C. Azacitidine
D. Antithymocyte globulin plus cyclosporine
E. Referral for allogeneic stem cell transplantation

Answer: B This patient has the 5q− syndrome, which has a relatively favorable prognosis among the myelodysplastic syndromes. It was the first form of MDS found to be significantly responsive to lenalidomide therapy. Initial trials of lenalidomide in these patients demonstrated high response rates, including a nearly 70% transfusion independence rate and better than 30% cytogenetic normalization rate lasting a median of more than 2 years. (See section on "Immunomodulatory Agents" under "Disease-Modifying Therapy" in the Treatment box.) Therefore, lenalidomide should be first-line treatment for this patient.

4. A 79-year-old man with a history of congestive heart failure due to multivessel coronary artery disease (most recent echocardiogram showed a left ventricular ejection fraction of 30%), renal insufficiency due to hypertension, and two hospitalizations for exacerbations of chronic obstructive pulmonary disease within the last year has developed worse fatigue and dyspnea. His medications include furosemide, lisinopril, metoprolol, aspirin, inhaled salmeterol and fluticasone, and fluvastatin. A complete blood count is as follows:

Hemoglobin 8.8 g/dL

Mean cell volume 103 fL

White blood cell count 1.9×10^9/L

Absolute neutrophil count 0.48×10^9/L

Platelet count 77×10^9/L

Serum vitamin B_{12} and folate levels are within normal limits. The creatinine is 1.8 mg/dL, and blood urea nitrogen is 52; a chemistry group is otherwise unremarkable.

The bone marrow is hypercellular for age with multilineage dysplasia, increased reticulin fibrosis, and 12% blasts, and the marrow karyotype is complex with 4 different chromosome abnormalities and 2 separate clones. Which of the following is the most appropriate treatment for this patient?

A. Induction chemotherapy with daunorubicin and cytarabine
B. Lenalidomide
C. Epoetin alfa
D. Azacitidine
E. Allogeneic stem cell transplantation

Answer: D Azacitidine. This patient has higher-risk MDS, associated with both increased blasts and a high-risk, complex karyotype. He is too old and has too many comorbid conditions to be a viable candidate for allogeneic stem cell transplantation or intensive induction chemotherapy. Azacitidine, a DNA methyltransferase inhibitor, has been demonstrated in a randomized trial to improve survival compared to conventional care (i.e., supportive care or low-dose cytarabine). Patients who have thrombocytopenia and lack chromosome 5q deletion are less likely to respond to lenalidomide.

5. A 19-year-old man was recently found to have pancytopenia (hemoglobin 9.3 g/dL, absolute neutrophil count of 0.45×10^9/L, and platelet count of 23×10^9/L) during routine follow-up of a pediatric cancer. At age 15, he was treated for locally advanced osteosarcoma of the left tibia, with limb sparing surgery, radiotherapy, and adjuvant combination chemotherapy. He sees his pediatric oncologist annually, and at his last visit 9 months ago there was no evidence of recurrence of the sarcoma. Other than fatigue, he is asymptomatic.

His bone marrow aspirate and core biopsy show trilineage dysplasia and 6% myeloblasts, consistent with a diagnosis of MDS, subtype refractory anemia with excess blasts-1. The karyotype is complex and includes 2 marker chromosomes and monosomy 7 in 16 of 20 examined metaphases. He has 3 siblings, and one is fully HLA matched. Which of the following treatments is most appropriate for this patient?

A. Allogeneic stem cell transplantation
B. Lenalidomide
C. Azacitidine
D. Decitabine
E. Epoetin alfa and filgrastim

Answer: A Allogeneic stem cell transplantation. Unfortunately, this patient has developed a late complication of curative therapy for his sarcoma: secondary, therapy-related MDS (t-MDS). t-MDS has a poor prognosis and often progresses rapidly to AML. This patient would benefit from proceeding to allogeneic stem cell transplant as soon as possible, because this is the only potentially curative therapy for his MDS. Since he does not have >10% blasts, there is no clear role for pre-transplant cytoreductive therapy.

183

THE ACUTE LEUKEMIAS

FREDERICK R. APPELBAUM

DEFINITION

Normal hematopoiesis (Chapter 156) requires tightly regulated proliferation and differentiation of pluripotent hematopoietic stem cells that become mature peripheral blood cells. Acute leukemia is the result of a malignant event or events occurring in an early hematopoietic precursor. Instead of proliferating and differentiating normally, the affected cell gives rise to progeny that fail to differentiate but continue to proliferate in an uncontrolled fashion. As a result, immature myeloid cells in acute myeloid leukemia (AML) or lymphoid cells in acute lymphoblastic leukemia (ALL)—often called blasts—rapidly accumulate and progressively replace the bone marrow, diminishing the production of normal red cells, white cells, and platelets. This loss of normal marrow function in turn gives rise to the common clinical complications of leukemia: anemia, infection, and bleeding. With time, the leukemic blasts pour out into the blood stream and eventually occupy the lymph nodes, spleen, and other vital organs. If untreated, acute leukemia is rapidly fatal; most patients die within several months after diagnosis. With appropriate therapy, however, the natural history of acute leukemia can be markedly altered, and many patients can be cured.

EPIDEMIOLOGY

Incidence

There were 14,590 new cases of AML and 6075 new cases of acute ALL in the United States in 2013, leading to 10,320 deaths from AML and 1430 deaths from ALL. The incidence of acute leukemia has remained relatively stable over the past 3 decades. Although acute leukemia accounts for only about 2% of cancer deaths, the impact of leukemia is heightened because of the young age of some patients. For example, with a maximum incidence between ages 2 and 10 years, ALL is the most common cancer in children younger than 15 years and accounts for one third of all childhood cancer deaths. The incidence of AML gradually increases with age, without an early peak. The median age at diagnosis of AML is about 60 years.

Determinants

In most cases, acute leukemia develops for no known reason, but sometimes a possible cause can be identified.

Genetic Predisposition

The concordance rate is virtually 100% in identical twins if one twin develops leukemia during the first year of life. Single germline mutations in *RUNX1*, *CEBPA*, and *GATA2* cause rare syndromes leading to acute leukemia without other manifestations. The incidence of acute leukemia is markedly increased in syndromes involving defective DNA repair, such as Fanconi's anemia and Bloom's syndrome, and in bone marrow failure syndromes associated with ribosomal abnormalities (Chapter 165), including Diamond-Blackfan syndrome, Shwachman-Diamond syndrome, and dyskeratosis congenita. Germline mutations in P53 (Li-Fraumeni syndrome) and abnormalities in chromosome number, as in Down and Klinefelter's syndromes, are also associated with an increased incidence of acute leukemia.

Radiation

Ionizing radiation (Chapter 20) is leukemogenic. The incidence of ALL, AML, and chronic myeloid leukemia (CML) is increased in patients given therapeutic radiation and among survivors of the atomic bomb blasts at Hiroshima and Nagasaki. The magnitude of the risk depends on the dose of radiation, its distribution in time, and the age of the individual. Greater risk results from higher doses of radiation delivered over shorter periods to younger patients. In areas of high natural background radiation (often from radon), chromosomal aberrations are reportedly more frequent, but an increase in acute leukemia has not been consistently found. Concern has been raised about the possible leukemogenic effects of extremely low-frequency nonionizing electromagnetic fields emitted by electrical installations. If such an effect exists at all, its magnitude is small.

Oncogenic Viruses

The search for a viral cause of leukemia has been pursued intensely, but only two clear associations have been found. Human T-cell lymphotropic virus type I (HTLV-I), an enveloped, single-stranded RNA virus, is considered the causative agent of adult T-cell leukemia (Chapter 378). This distinct form of leukemia is found within geographic clusters in southwestern Japan, the Caribbean basin, and Africa. Because HTLV-I seropositivity was found with increasing frequency among heavily transfused patients and intravenous drug users, screening of blood products for antibodies to HTLV-I is now routine practice in blood banks in the United States. Epstein-Barr virus (Chapter 377), the DNA herpes family virus that causes infectious mononucleosis, is associated with the endemic African form of Burkitt's lymphoma/leukemia (Chapter 185).

Chemicals and Drugs

Heavy occupational exposure to benzene and benzene-containing compounds such as kerosene and carbon tetrachloride may lead to marrow damage, which can take the form of aplastic anemia, myelodysplasia, or AML. A link between leukemia and tobacco use has been reported.

With the increasing use of chemotherapy and radiotherapy to treat other malignancies, as much as 10% of AMLs and a smaller percentage of ALLs are likely the consequence of prior therapy.[1] Prior exposure to alkylating agents such as melphalan and the nitrosoureas is associated with an increased risk for secondary AML, which often manifests initially as a myelodysplastic syndrome (Chapter 182), frequently with abnormalities of chromosomes 5, 7, and 8 but with no distinct morphologic features. These secondary AMLs typically develop 4 to 6 years after exposure to alkylating agents, and their incidence may be increased with greater intensity and duration of drug exposure. Secondary AML associated with exposure to topoisomerase II inhibitors, including the epipodophyllotoxins (teniposide or etoposide) and doxorubicin, tends to have a shorter latency period (1 to 2 years), lacks a myelodysplastic phase, has a monocytic morphology, and involves abnormalities of the long arm of chromosome 11 (band q23) or chromosome 21 (band q22). Recently, concern has been raised about an increased risk for second cancers including myeloid malignancies in patients receiving lenalidomide as maintenance therapy in multiple myeloma. Because patients frequently receive combination chemotherapy, it is often difficult to identify a single causative agent.

PATHOBIOLOGY

Clonality and Cell of Origin

The acute leukemias are clonal disorders, and all leukemic cells in a given patient are descended from a common progenitor. The clonal nature of acute leukemia suggests that there are leukemic stem cells capable of both self-renewal and proliferation. Leukemic stem cells in AML are rare among the leukemic mass, with a frequency of 0.2 to 10 per 10^6, and are within the primitive $CD34^{2+}$ $CD38^{-}$ fraction. Less is known about the ALL stem cell.

Classification

The World Health Organization (WHO) classification of acute leukemias is based on clinical, morphologic, immunophenotypic, cytogenetic, and molecular features (Table 183-1).

TABLE 183-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE LEUKEMIAS

CLASSIFICATION SUBTYPES (2008)
Acute Myeloid Leukemia (AML) and Related Neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
Acute promyelocytic leukemia (APL) with t(15;17)(q22;q12); *PML-RARA*
AML with t(9;11)(p22;q23); *MLLT3-MLL*
AML with t(6;9)(p23;q34); *DEK-NUP214*
AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*
AML (megakaryoblastic) with t(1;22)(p13;q13); *RBM15-MKL1*
Provisional entity: AML with mutated *NPM1*
Provisional entity: AML with mutated *CEBPA*
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, not otherwise specified
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Acute erythroid leukemia
Pure erythroid leukemia
Erythroleukemia, erythroid/myeloid
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis
Myeloid leukemia associated with Down syndrome
Blastic plasmacytoid dendritic cell neoplasm
B-Lymphoblastic Leukemia (ALL)/Lymphoma
B-lymphoblastic leukemia/lymphoma, not otherwise specified
B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11.2); *BCR-ABL1* (Philadelphia chromosome–positive ALL)
B-lymphoblastic leukemia/lymphoma with t(v;11q23); *MLL* rearranged
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22); *TEL-AML1* (*ETV6-RUNX1*)
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31;q32); *IL3-IGH*
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*
T-Lymphoblastic Leukemia (ALL)/Lymphoma

ALL = acute lymphoblastic leukemia.

Morphology

Leukemic cells in AML are typically 12 to 20 nm in diameter, with discrete nuclear chromatin, multiple nucleoli, and cytoplasm that usually contains azurophilic granules (Fig. 183-1). Auer rods, which are slender, fusiform cytoplasmic inclusions that stain red with Wright-Giemsa stain, are virtually pathognomonic of AML (Fig. 183-2). The French-American-British (FAB) morphologic system divides AML into eight subtypes: M0, M1, M2, and M3 reflect increasing degrees of differentiation of myeloid leukemic cells; M4 and M5 leukemias have features of the monocytic lineage; M6 has features of the erythroid cell lineage; and M7 is acute megakaryocytic leukemia. The WHO system also recognizes acute basophilic leukemia and acute leukemia with predominant myelofibrosis.

The leukemic cells in ALL tend to be smaller than AML blasts and relatively devoid of granules (see Fig. 183-1). ALL can be divided by FAB criteria into L1, L2, and L3 subgroups. L1 blasts are uniform in size, with homogeneous nuclear chromatin, indistinct nucleoli, and scanty cytoplasm with few, if any, granules. L2 blasts are larger and more variable in size and may have nucleoli. L3 blasts are distinct, with prominent nucleoli and deeply basophilic cytoplasm with vacuoles.

Immunophenotyping

Immunophenotyping by multiparameter flow cytometry is used to determine lineage involvement of newly diagnosed acute leukemias and to detect aberrant immunophenotypes, allowing the measurement of minimal residual disease after therapy. Most cases of AML express antigens seen on normal immature myeloid cells. The most immature forms of AML express CD34,

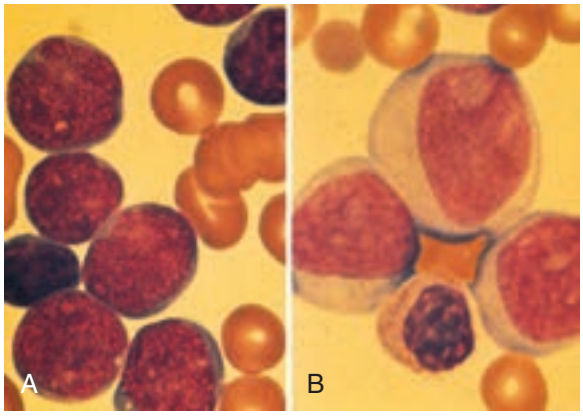

FIGURE 183-1. Acute leukemia. A, Acute lymphoblastic leukemia (ALL). **B,** Acute myeloid leukemia (AML). Lymphoblasts in ALL are smaller, with a higher ratio of nuclear to cytoplasmic material and less distinct nucleoli than in the myeloblasts in AML. The nucleoli in the myeloblasts are clear and "punched out."

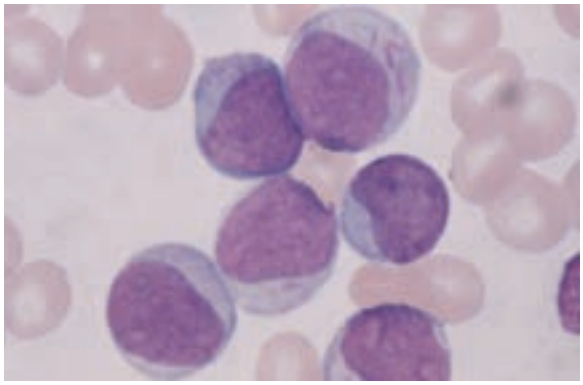

FIGURE 183-2. Acute myeloid leukemia. The myeloblasts in the smear show Auer rods as cytoplasmic inclusions.

CD117 and HLA-DR, whereas more differentiated forms express CD13 and CD33. CD14, CD15, and CD11b are expressed by AMLs with monocytic features, erythroid leukemias express CD36 and CD71, and megakaryocytic AMLs express CD41a and CD61. In 10 to 20% of patients, otherwise typical AML blasts also express antigens usually restricted to B- or T-cell lineage. Expression of a single lymphoid antigen by AML cells does not change either the natural history or the therapeutic response of these leukemias.

Approximately 75% of cases of ALL express B-lineage antigens and can be subdivided into four categories. The most immature group, pro-B ALL, expresses CD19 and/or CD 22 but not CD10 and represents about 10% of cases of ALL. Approximately 50 to 60% of cases of ALL express the early B-cell antigens CD19 and/or CD22 along with the common ALL antigen (CALLA, or CD10), a glycoprotein that is also found occasionally on normal early lymphocytes. CALLA-positive ALL is thought to represent an early pre-B-cell differentiation state. Approximately 10% of cases of ALL have intracytoplasmic immunoglobulin and are termed pre-B-cell ALL. Mature B-cell ALL is signified by the presence of surface immunoglobulin and accounts for less than 5% of cases of ALL. In general, the best therapeutic outcomes among B-cell ALL types are with early pre-B-cell (CALLA positive) ALL. The 25% of cases of ALL that express T-lineage antigens can be separated into three groups: (1) early T-precursor ALL expressing CD7 but not CD1a or CD3, (2) thymic T-ALL expressing CD1a but not surface CD3, and (3) mature T-ALL expressing surface CD3. The prognosis for thymic T-cell ALL is superior to that of the other forms of T-ALL. In about 25% of patients with ALL, the leukemic cells may also express a myeloid antigen, but with current therapies, this does not affect outcome.

Acute leukemias of ambiguous lineage are rare cases with no evidence of lineage differentiation (i.e., acute undifferentiated leukemia [AUL]) or those with blasts that express definitive markers of more than one lineage (i.e., mixed phenotype acute leukemia [MPAL]). MPAL can contain either distinct blast populations of different lineages (bilineal) or a single population expressing features of both lineages (biphenotypic). In general, the prognosis of patients with AUL or MPAL is poor when treated with standard chemotherapy.[2]

Cytogenetics and Molecular Biology

In most cases of acute leukemia, an abnormality in chromosome number or structure is found. These abnormalities are clonal, involving all the malignant cells in a given patient; they are acquired and are not found in the normal cells of the patient; and they are referred to as "nonrandom" because specific abnormalities are found in multiple cases and are associated with distinct morphologic or clinical subtypes of the disease. These abnormalities may be simply the gain or loss of whole chromosomes, but more often they include chromosomal translocations, deletions, or inversions. When patients with acute leukemia and a chromosomal abnormality receive treatment and enter into complete remission, the chromosomal abnormality disappears; when relapse occurs, the abnormality reappears. In many cases, these abnormalities have provided clues into the pathobiology of acute leukemia.

The most common cytogenetic abnormalities seen in AML can be categorized according to their underlying biology and prognostic significance.[3] The translocation t(8;21) and the inversion inv(16) result in abnormalities of a transcription factor made up of core binding factor-α (CBF-α) and CBF-β. The t(8;21) results in the fusion of CBF-α on chromosome 21 with the *MTG8* gene on chromosome 8, whereas inv(16) results in the fusion of CBF-β on the q arm of chromosome 16 with the *MYH11* gene on the p arm. Both of these "core binding factor" AMLs are characterized by a high complete response rate and relatively favorable long-term survival. An additional translocation with a favorable prognosis, t(15;17), involves two genes, *PML* and *RAR-α* (a gene encoding the α-retinoic acid receptor), and is invariably associated with acute promyelocytic leukemia (APL), the M3 subtype of AML. Translocations involving the *MLL* gene, located at chromosome band 11q23, are seen in 5-7% of AMLs. *MLL* is perhaps the most promiscuous oncogene partner in oncology, with more than 30 fusion partners identified. The prognosis of MLL-associated AML depends on the fusion partner, with t(9;11) and t(11;19) predicting an intermediate prognosis and all others considered unfavorable. Trisomy 8 is among the most common nonrandom cytogenetic abnormalities seen in AML; it accounts for 9% of cases and carries an intermediate prognosis. Trisomies of chromosome 21, chromosome 11, and other chromosomes are sometimes seen as well. Deletions of part or all of chromosome 5 or 7 each account for 6 to 8% of cases of AML. These abnormalities are seen with greater frequency in older patients and in patients with AML secondary to myelodysplasia or prior exposure to alkylating agents, and are associated with an unfavorable prognosis. The presence of multiple (more than three) cytogenetic abnormalities in individual cases of AML defines "complex cytogenetics" and also is associated with an unfavorable prognosis.

The identification of recurrent chromosomal abnormalities in acute leukemia, including translocations, inversions, and gene duplications, led to the identification and cloning of the involved genes. More recently, directed and genome-wide assays have provided a better understanding of the genomic landscape of AML.[4] AML cells appear to carry, on average, a total of approximately 13 mutations per cell, far less than found in epithelial cancers. Of these, on average 5 mutations are in genes recurrently mutated in AML (so called driver mutations), with the remainder being considered as passenger mutations. Among the recurrently mutated driver mutations, several are of significant prognostic importance and thus are part of the standard evaluation of AML. *CEBPA*, a gene encoding a leucine zipper transcription factor involved in myeloid differentiation, is mutated in 4 to 15% of cases of AML and is associated with a more favorable prognosis. *NPM1* encodes a nucleolar phosphoprotein with multiple functions. Mutations in *NPM1* are found in approximately 30% of AML cases and are also associated with a more favorable prognosis. *FLT3* is a receptor tyrosine kinase and is mutated in 30 to 35% of AML patients, one fourth of the time as a point mutation and three fourths of the time as an internal tandem duplication. Mutations in *FLT3* are associated with a poorer clinical outcome. Other driver mutations recurrently mutated in AML include *DNMT3A, IDH 1* and *2, NRAS* and *KRAS, RUNX1, TET2,* and *TP53*. Although assays of the mutational status of these genes has not yet become standard, increasing numbers of studies are suggesting their possible utility both for prognosis and for treatment selection.[5]

Whole-genome sequencing of paired samples of skin and bone marrow in individuals who transform from myelodysplastic syndromes to secondary

AML shows that the genetic evolution of secondary AML is a dynamic process shaped by multiple cycles of mutation acquisition and clonal selection. The preexisting myelodysplastic syndrome–founding clone persists with transformation to AML. With the acquisition of each new set of mutations, all the preexisting mutations are carried forward, resulting in daughter subclones that contain increasing numbers of mutation during evolution.[6]

The most common cytogenetic abnormality seen in adults with ALL is the Philadelphia (Ph) chromosome, or t(9;22).[7] This translocation results in fusion of the *BCR* gene on chromosome 22 to the *ABL* tyrosine kinase gene on chromosome 9. This results in the constitutive activation of *ABL*, but the precise mechanism by which this activity leads to leukemia is unclear. The *BCR-ABL* fusion is associated with both ALL and CML (Chapter 184), with a difference in the breakpoint of *BCR* distinguishing the two. A slightly smaller 190-kD fusion protein is usually found in ALL, whereas a larger 210-kD protein is characteristic of CML. The frequency of t(9;22) in ALL increases with age: it is found in approximately 5% of childhood cases and 25% of adults. Before the development of specific tyrosine kinase inhibitors, ALL with t(9;22) had a poor prognosis; newer regimens combining tyrosine kinase inhibitors with chemotherapy are providing improved outcomes. The most common translocation seen in childhood ALL is t(12;21), which involves the genes *TEL* and *AML1*. Like the AML-associated t(8;21) and inv(16), t(12;21) is thought to result in abnormal DNA transcription by interfering with the normal function of CBF. Although t(12;21) is difficult to diagnose by routine cytogenetics, by molecular studies it has been shown to account for 25% of childhood ALL and 4% of adult ALL and has a favorable prognosis. Partial deletions in 9p, seen in 5 to 7% of adults with ALL, are also associated with a favorable outcome. Other abnormalities sometimes seen in B-cell ALL include t(8;14) and t(8;22), which result in translocation of the *MYC* gene on chromosome 8 and immunoglobulin enhancer response genes on chromosomes 14 or 22; they are associated with a poor therapeutic outcome. T-cell ALLs are frequently associated with abnormalities of chromosome 7 or 14 at the sites of T-cell receptor enhancer genes on these chromosomes. The leukemia cells in about 20% of patients with ALL have a propensity to gain chromosomes, sometimes reaching an average of 50 to 60 chromosomes per cell. Patients with such hyperdiploid leukemias tend to respond well to chemotherapy.

As in AML, directed and genome-wide evaluation of cases of ALL have revealed recurrent mutations in addition to those already identified through cytogenetics.[8] Among the most common are mutations in *PAX5* and *IKZF1* seen in 30 and 25% of cases of B-cell ALL respectively, and mutations in *NOTCH1* seen in 35% of cases of T-cell ALL.

CLINICAL MANIFESTATIONS

The signs and symptoms of acute leukemia are usually rapid in onset, developing over a few weeks to a few months at most; they result from decreased normal marrow function and invasion of normal organs by leukemic blasts. Anemia is present at diagnosis in most patients and causes fatigue, pallor, headache, and, in predisposed patients, angina or heart failure. Thrombocytopenia is usually present, and approximately one third of patients have clinically evident bleeding at diagnosis, usually in the form of petechiae, ecchymoses, bleeding gums, epistaxis, or hemorrhage. Most patients with acute leukemia are significantly granulocytopenic at diagnosis. As a result, approximately one third of patients with AML and slightly fewer patients with ALL have significant or life-threatening infections when initially seen, most of which are bacterial in origin.

In addition to suppressing normal marrow function, leukemic cells can infiltrate normal organs. In general, ALL tends to infiltrate normal organs more often than AML does. Enlargement of lymph nodes, liver, and spleen is common at diagnosis. Bone pain, thought to result from leukemic infiltration of the periosteum or expansion of the medullary cavity, is a common complaint, particularly in children with ALL. Leukemic cells sometimes infiltrate the skin and result in a raised, nonpruritic rash, a condition termed *leukemia cutis*. Leukemic cells may infiltrate the leptomeninges and cause leukemic meningitis, typically manifested by headache and nausea. As the disease progresses, central nervous system (CNS) palsies and seizures may develop. Although less than 5% of patients with ALL have CNS involvement at diagnosis, the CNS is a frequent site of relapse; therefore, CNS prophylaxis is an essential component of ALL therapy. Because the incidence of CNS disease is low in AML, there is no proven benefit to CNS surveillance or prophylaxis. Testicular involvement is seen in ALL, and the testicles are a frequent site of relapse. In AML, collections of leukemic blast cells, often referred to as *chloromas* or *myeloblastomas*, can occur in virtually any soft tissue and appear as rubbery, fast-growing masses.

Certain clinical manifestations are unique to specific subtypes of leukemia. Patients with acute promyelocytic leukemia (APL) of the M3 type commonly have subclinical or clinically evident disseminated intravascular coagulation (DIC; Chapter 175) caused by tissue thromboplastins released by the leukemic cells. Acute monocytic or myelomonocytic leukemias are the forms of AML most likely to have extramedullary involvement. M6 leukemia often has a long prodromal phase. Patients with T-cell ALL frequently have mediastinal masses.

DIAGNOSIS

Abnormalities in peripheral blood counts are usually the initial laboratory evidence of acute leukemia. Anemia is present in most patients. Most are also at least mildly thrombocytopenic, and up to one fourth have severe thrombocytopenia (platelets <20,000/μL). Although most patients are granulocytopenic at diagnosis, the total peripheral white cell count is more variable; approximately 25% of patients have very high white cell counts (>50,000/μL), approximately 50% have white cell counts between 5000 and 50,000/μL, and about 25% have low white cell counts (<5000/μL). In most cases, blasts are present in the peripheral blood, although in some patients the percentage of blasts is quite low or absent.

The diagnosis of acute leukemia is typically established by marrow aspiration and biopsy, usually from the posterior iliac crest. Marrow aspirates and biopsy specimens are usually hypercellular and contain 20 to 100% blast cells, which largely replace the normal marrow (see Figs. 183-1 and 183-2). Occasionally, in addition to the blast cell infiltrate, other findings are present, such as marrow fibrosis (especially with M7 AML) or bone marrow necrosis. Marrow samples should also be evaluated by immunophenotyping and cytogenetics. If AML is suspected, samples should be evaluated for the presence of mutations in *FLT3*, *NPM1*, and *CEBPA*. A diagnostic lumbar puncture is generally recommended in suspected cases of ALL, but not in asymptomatic cases of AML.

The prothrombin and partial thromboplastin times are sometimes elevated. In APL, reduced fibrinogen and evidence of DIC are often seen. Other laboratory abnormalities frequently present are hyperuricemia, especially in ALL, and increased serum lactate dehydrogenase. In cases of high cell turnover and cell death (e.g., L3 ALL), evidence of *tumor lysis syndrome* may be noted at diagnosis, including hypocalcemia, hyperkalemia, hyperphosphatemia, hyperuricemia, and renal insufficiency. This syndrome, which is more commonly seen shortly after therapy is begun, can be rapidly fatal if untreated.

Differential Diagnosis

The diagnosis of acute leukemia is usually straightforward but can occasionally be difficult. Both leukemia and aplastic anemia (Chapter 165) can manifest with peripheral pancytopenia, but the finding of a hypoplastic marrow without blasts usually distinguishes aplastic anemia. An occasional patient has hypocellular marrow and a clonal cytogenetic abnormality, which establishes the diagnosis of myelodysplasia (Chapter 182) or hypocellular leukemia. A number of processes other than leukemia can lead to the appearance of immature cells in the peripheral blood. Although other small round cell neoplasms can infiltrate the marrow and mimic leukemia, immunologic markers are effective in differentiating the two. Leukemoid reactions to infections such as tuberculosis can result in the outpouring of large numbers of young myeloid cells, but the proportion of blasts in marrow or peripheral blood almost never reaches 20% in a *leukemoid reaction* (Chapter 167). Infectious mononucleosis (Chapter 377) and other viral illnesses can sometimes resemble ALL, particularly if large numbers of atypical lymphocytes are present in the peripheral blood and the disease is accompanied by immune thrombocytopenia or hemolytic anemia.

TREATMENT Rx

With the development of effective programs of combination chemotherapy and advances in hematopoietic cell transplantation, many patients with acute leukemia can be cured. These therapeutic measures are complex and are best carried out at centers with appropriate support services and experience in treating leukemia. Because leukemia is a rapidly progressive disease, specific antileukemic therapy should be started as soon after diagnosis as possible, usually within 72 hours. The goal of initial chemotherapy is to induce a complete remission (CR) with restoration of normal marrow function. In general, induction chemotherapy is intensive and is accompanied by significant

toxicities. Therefore, patients should be stabilized to the extent possible before specific antileukemic therapy is begun.

Preparing the Patient for Therapy

Severe bleeding usually results from thrombocytopenia, which can be reversed with platelet transfusions (Chapter 177). Once thrombocytopenic bleeding is stopped, continued prophylactic transfusions of platelets is warranted to maintain the platelet count higher than 10,000/μL. Occasionally, patients also have evidence of DIC, usually associated with the diagnosis of M3 AML. If M3 AML is suspected as the cause, all-*trans*-retinoic acid (ATRA) should be started without waiting for molecular confirmation of the diagnosis; the drug can be discontinued if the diagnosis is not M3 AML. If active bleeding is due to DIC (Chapter 175), low doses of heparin (50 U/kg) given intravenously every 6 hours can be of benefit. Platelets and fresh-frozen plasma (or cryoprecipitate) should be transfused to maintain the platelet count higher than 50,000/μL and the fibrinogen level greater than 100 mg/dL until the DIC abates. Whether heparin should be given prophylactically to patients with laboratory evidence of DIC but no active bleeding is an often debated but unsettled question.

Blood cultures should be obtained in patients with fever and granulocytopenia; while awaiting culture results, infection should be assumed and broad-spectrum antibiotics begun empirically (Chapters 167 and 281). It is preferable to bring an infection under control before starting initial chemotherapy if the patient has an adequate granulocyte count. However, patients often have infection but essentially no granulocytes; in this situation, delaying chemotherapy is unlikely to be beneficial.

Patients with very high blast counts may develop symptoms attributable to the effect of masses of these immature cells on blood flow (leukostasis). Although randomized trials are lacking, many experts suggest immediate leukapheresis and administration of hydroxyurea (3 g/m^2/day orally for 2 or 3 days) in an effort to rapidly lower counts in asymptomatic patients with AML presenting with while blood cell counts greater than 100,000/μL and for ALL patients presenting with counts greater than 300,000/μL.[9] The most often affected organs are the CNS and lungs. If CNS symptoms occur, immediate whole-brain irradiation (600 cGy in one dose) should be added. If pulmonary symptoms occur, high-dose corticosteroids are often used.

Before treatment, management in all patients should be aimed at preventing the tumor lysis syndrome. Patients should be hydrated and given allopurinol 100 to 200 mg orally or intravenously three times a day before chemotherapy is initiated. Allopurinol prevents the conversion of xanthine and hypoxanthine to uric acid, but does not affect already formed uric acid. Patients presenting with very high white cell counts may have uremia and anuria secondary to greatly increased serum uric acid levels and intratubular crystallization, even before starting therapy. These patients should be treated with rasburicase 0.20 mg/kg/day for up to 5 days intravenously, given over 30 minutes. Rasburicase promotes the catabolism of already formed uric acid to allantoin. Urinary alkalinization, a past standard, is no longer recommended because, although it increases uric acid solubility, it also increases the possibility of xanthine and calcium phosphate precipitation in the kidney.

The diagnosis of leukemia usually comes as a profound psychological shock to the patient and family. Therefore, in addition to stabilizing the patient hematologically and metabolically, it is worthwhile to have at least one formal conference in which the patient and family are advised about the meaning of the diagnosis of leukemia and the consequences of therapy before treatment is initiated.

Treatment of Acute Lymphoblastic Leukemia

After the patient's condition has been stabilized, antileukemic therapy should be started as soon as possible.[10] Treatment of newly diagnosed ALL can be divided into three phases: remission induction, postremission therapy, and CNS prophylaxis.

Remission Induction

The initial goal of treatment is to induce CR, defined as the reduction of leukemic blasts to undetectable levels and the restoration of normal marrow function. A number of different chemotherapeutic combinations can be used to induce remission; all include vincristine and prednisone, and most add L-asparaginase and daunorubicin, administered over a period of 3 to 4 weeks. With such regimens, CR is achieved in 90% of children and 80 to 90% of adults (Table 183-2). Because vincristine, prednisone, and L-asparaginase are relatively nontoxic to normal marrow precursors, the disease often enters CR after a relatively brief period of myelosuppression. Failure to achieve CR is usually due to either the leukemic cells' resistance to the drugs or progressive infection. These two complications occur with approximately equal frequency.

Postremission Chemotherapy

If no further therapy is given after induction of CR, relapse occurs in almost all cases, usually within several months. Chemotherapy after CR can be given in a variety of combinations, dosages, and schedules. The term *consolidation chemotherapy* refers to short courses of further chemotherapy given at doses similar to those used for initial induction (requiring rehospitalization). Usually, different drugs are selected for consolidation chemotherapy than were used to induce the initial remission. In the case of ALL, such drugs include high-dose methotrexate, cyclophosphamide, and cytarabine, among others. Most regimens include six to eight courses of intensive consolidation therapy. Maintenance involves the administration of low-dose chemotherapy on a daily or weekly outpatient basis for long periods. The most commonly used maintenance regimen in ALL combines daily 6-mercaptopurine and weekly or biweekly methotrexate. The optimal duration of maintenance chemotherapy is unknown, but it is usually given for 2 to 3 years. Maintenance is most beneficial for patients with pro- and pre-B-cell ALL, less so for T-cell ALL, and of no apparent benefit for patients with mature B-cell ALL.

TABLE 183-2 COMMON REGIMENS FOR COMMON FORMS OF ACUTE LEUKEMIA

I. MANAGEMENT OF NEWLY DIAGNOSED ACUTE MYELOID LEUKEMIA

A. Induction—daunorubicin 60-90 mg/m^2/day for 3 days (or idarubicin 10-12 mg/m^2/day for 3 days) and cytarabine 200 mg/m^2/day for 7 days
B. Postremission
   1. Favorable risk—cytarabine 3 g/m^2 over 3 hr q12h on days 1, 3, and 5 every month for 4 mo
   2. Intermediate risk—as for favorable risk; or, if HLA-matched related or unrelated donor exists, allogeneic hematopoietic cell transplantation
   3. Unfavorable risk—proceed to allogeneic transplantation if possible; if not, treat as for intermediate risk

II. MANAGEMENT OF NEWLY DIAGNOSED ACUTE PROMYELOCYTIC LEUKEMIA

A. Induction—ATRA 45 mg/m^2/day until complete remission plus daunomycin 45-60 mg/m^2/day for 3 days and cytarabine 200 mg/m^2/day for 7 days
B. Consolidation #1—arsenic trioxide 0.15 mg/kg/day 5 days/wk for 5 wk; repeat course after 2-wk rest
   Consolidation #2—ATRA 45 mg/m^2/day for 7 days and daunomycin 50 mg/m^2/day for 3 days; repeat course 1 mo later
C. Maintenance—ATRA 45 mg/m^2/day for 15 days every 3 mo plus 6-MP 100 mg/m^2/day and MTX 10 mg/m^2/wk for 2 yr

Or, if intermediate/good risk, consider:

   A. Induction: Arsenic trioxide 0.15 mg/kg/day plus ATRA 45 mg/m^2/day until complete remission
   B. Consolidation: Arsenic trioxide 0.15 mg/kg/day 5 days/wk, 4 wk on, 4 wk off for 4 cycles
      ATRA 45mg/m^2/day 2 wk on, 2 wk off for 7 cycles

III. MANAGEMENT OF NEWLY DIAGNOSED ADULT PH-NEGATIVE ACUTE LYMPHOID LEUKEMIA

A. Induction (and courses 3, 5, 7)—cyclophosphamide 300 mg/m^2 over 3 hr q12h for 6 doses on days 1, 2, 3; doxorubicin 50 mg/m^2 on day 4; vincristine 2 mg/day on days 4 and 11; and dexamethasone 40 mg/day on days 1-4 and days 11-14
B. Consolidation (courses 2, 4, 6, 8)—MTX 200 mg/m^2 over 2 hr, followed by 800 mg/m^2 over 22 hr on day 1; high-dose cytarabine 3 g/m^2 over 2 hr q12h for 4 doses on days 2 and 3
C. Four intrathecal treatments of MTX 12 mg alternating with cytarabine 100 mg are given during the first four courses of systemic therapy

ATRA = all-*trans*-retinoic acid; HLA = human leukocyte antigen; 6-MP = 6-mercaptopurine; MTX = methotrexate; Ph = Philadelphia chromosome [t(9;22)].

Central Nervous System Prophylaxis

Most chemotherapeutic agents that are given intravenously or orally do not penetrate the CNS well, and if no form of CNS prophylaxis is given, at least 35% of adults with ALL will develop CNS leukemia. With prophylaxis, relapse in the CNS as an isolated event occurs in less than 10% of patients. Systemic chemotherapy with high-dose methotrexate (e.g., 200 mg/m^2 intravenously over 2 hours, followed by 800 mg/m^2 over 22 hours) and cytarabine (e.g., 3 g/m^2 over 2 hours every 12 hours for four doses) can achieve therapeutic drug levels within the CNS. Alternatives are intrathecal methotrexate, intrathecal methotrexate combined with 2400 cGy radiation to the cranium, or 2400 cGy to the craniospinal axis.

Treatment of Burkitt-like ALL

Burkitt-like ALL (also called FAB L3 or mature B-cell ALL) is characterized by the presence of monoclonal surface immunoglobulin, cytogenetics showing t(8;14), and the constitutive expression of the *MYC* oncogene. Burkitt-like ALL, which accounts for 3 to 5% of adult cases of ALL, responds well to regimens that incorporate short, intensive courses of high-dose methotrexate (1.5 g/m^2 over 24 hours with leucovorin), cytarabine (3 g/m^2 over 2 hours every 12 hours for four doses), and cyclophosphamide (200 mg/m^2/day for 5 days); this regimen yields high rates of complete response and cures in about 50% of

patients. Recent results suggest that the addition of rituximab may further improve outcomes.

Treatment of Philadelphia Chromosome–Positive ALL

Approximately 5% of pediatric cases and 25% of adult cases of ALL have cytogenetics showing t(9;22), the Ph chromosome. Historically, such patients had CR rates slightly lower than those seen in Ph-negative ALL and markedly reduced remission durations, averaging less than a year; few if any such patients were cured with conventional chemotherapy. Therefore, the general recommendation has been that such patients receive an allogeneic transplant during the first remission, if possible. With this approach, approximately 50% of patients can be cured. More recently, the addition of the tyrosine kinase inhibitor imatinib mesylate to conventional chemotherapeutic regimens has increased complete response rates, equaling those seen in Ph-negative ALL, but the impact of the addition of imatinib mesylate on the duration of remission is not yet known. Dasatinib, a second-generation BCR-ABL tyrosine kinase inhibitor, has demonstrated efficacy in relapsed/refractory adult Ph-positive ALL. Therapy with dasatinib and prednisone alone without chemotherapy appears sufficient to allow the majority of older patients with Ph-positive ALL to achieve an initial hematologic remission.[11]

Prognosis of ALL after Initial Chemotherapy

A number of factors are predictive of outcome in ALL, the most important of which are younger age, a lower white cell count at diagnosis, and favorable cytogenetics. With currently available treatment regimens, 80 to 85% of children and 35 to 40% of adults who initially achieve CR maintain that state for more than 5 years, and these patients are probably cured of their disease.

Treatment of Relapsed ALL

Most relapses occur within 2 years after diagnosis, and most occur in the marrow. Occasionally, relapse is initially found in an extramedullary site such as the CNS or testes. Extramedullary relapse is usually followed shortly by systemic (marrow) relapse and should be considered part of a systemic recurrence. With the use of chemotherapeutic regimens similar to those used for initial induction, 50 to 70% of patients achieve at least a short-lived second remission. A small percentage of patients for whom the initial remission was longer than 2 years may be cured with salvage chemotherapy. If the CNS or testes is the initial site of the relapse, specific therapy to that site is also required, along with systemic retreatment. Because the prognosis of relapsed leukemia treated with chemotherapy is so poor, hematopoietic stem cell transplantation is usually recommended in this setting. Newer agents active in recurrent ALL include nelarabine for T-cell ALL and the anti-CD19 targeted agent blinatumomab and the anti-CD22 immunoconjugate inotuzumab in B-cell ALL. Complete responses have also recently been reported in early trials using chimeric antigen receptor T cells targeting CD19.[12]

Hematopoietic Stem Cell Transplantation

The use of high-dose chemoradiotherapy followed by hematopoietic stem cell transplantation (Chapter 178) from an HLA-identical sibling can cure 20 to 40% of patients with ALL who fail to achieve an initial remission or who have a relapse after an initial CR; it can cure 50 to 60% of patients who undergo transplantation during a first remission. Although there is still considerable debate, several recent studies have reported improved survival for adults with high-risk or standard-risk ALL who receive a hematopoietic stem cell transplant during a first remission rather than being treated with standard chemotherapy.■■ The major limitations of transplantation are graft-versus-host disease, interstitial pneumonia, and recurrence of disease. If an HLA-identical sibling is not available, transplantation from a matched unrelated donor or transplantation of cord blood from a partially matched unrelated donor can be conducted, with results that approach those seen with matched related donors.

Treatment of Acute Myeloid Leukemia

Remission Induction

Treatment with a combination of an anthracycline and cytarabine (100 to 200 mg/m^2/day for 7 days) leads to CR in 60 to 80% of patients with AML. Prospective randomized trials have demonstrated that for patients aged 65 years or less idarubicin (10 to 12 mg/m^2/day for 3 days) or a higher dose of daunorubicin (60 to 90 mg/m^2/day for 3 days) is superior to the conventional daunorubicin dose of 45 mg/m^2/day for 3 days.■■ Profound myelosuppression always follows when these agents are used at doses capable of achieving CR. Failure to achieve CR is usually due to either drug resistance or fatal complications of myelosuppression. In a randomized study of adults with AML, five doses of intravenous gemtuzumab ozogamicin (3 mg/m^2 on days 1, 4, and 7 during induction and day 1 of each of the two consolidation chemotherapy courses) doubled the probability of event-free survival at 2 years.■

Postremission Therapy

Intensive consolidation chemotherapy with repeated courses of daunorubicin and cytarabine at doses similar to those used for induction, high-dose cytarabine (1 to 3 g/m^2/day for 3 to 6 days), or other agents prolongs the average remission duration and improves the chances for long-term disease-free survival. The best results reported to date have generally been achieved with repeated cycles of high-dose cytarabine.[13] Unlike the situation with ALL, low-dose maintenance therapy is of limited benefit after intensive consolidation treatment. In AML, leukemic recurrence occurs less often in the CNS (approximately 10% of cases), most commonly in patients with the M4 or M5 variant. There is no evidence that CNS prophylaxis improves survival in AML.

Prognosis of AML after Initial Chemotherapy

Among patients in whom CR is achieved, 20 to 40% remain alive in continuous CR for more than 5 years, suggesting a probable cure. As with ALL, younger patients and those with a low white cell count at diagnosis have a more favorable outcome. The European LeukemiaNet recognizes four risk categories of AML based on cytogenetics and molecular testing.[14] The favorable group includes those with t(8;21) or inv(16) and those with normal cytogenetics but mutated *CEBPA* or mutated *NPM1* and wild-type *FLT3*. Intermediate I patients are those with normal cytogenetics but without mutations in *NPM1* and *CEBPA*, or with mutations in *FLT3*. Intermediate II includes those with t(9;11), t(11;19), or those with cytogenetics abnormalities not classified as favorable or unfavorable. Finally, the unfavorable group includes those with inv(3), t(6:9), –5 or del5, –7 or del7, and those with complex cytogenetics (Fig. 183-3). Patients with *DNMT3A* and *NPM1* mutations and those with *MLL* translocations appear to selectively benefit from higher dose induction.[15] Patients who have a preleukemic phase before their condition evolves into acute leukemia and those whose leukemia is secondary to prior exposure to chemotherapy have a poorer prognosis. Increased expression of the multidrug resistance gene 1 *(MDR1)* is also associated with a worse outcome.

Treatment of Recurrent AML

Patients whose AML recurs after initial chemotherapy can achieve a second remission in about 50% of cases after retreatment with daunorubicin-cytarabine or high-dose cytarabine. The likelihood of achieving a second

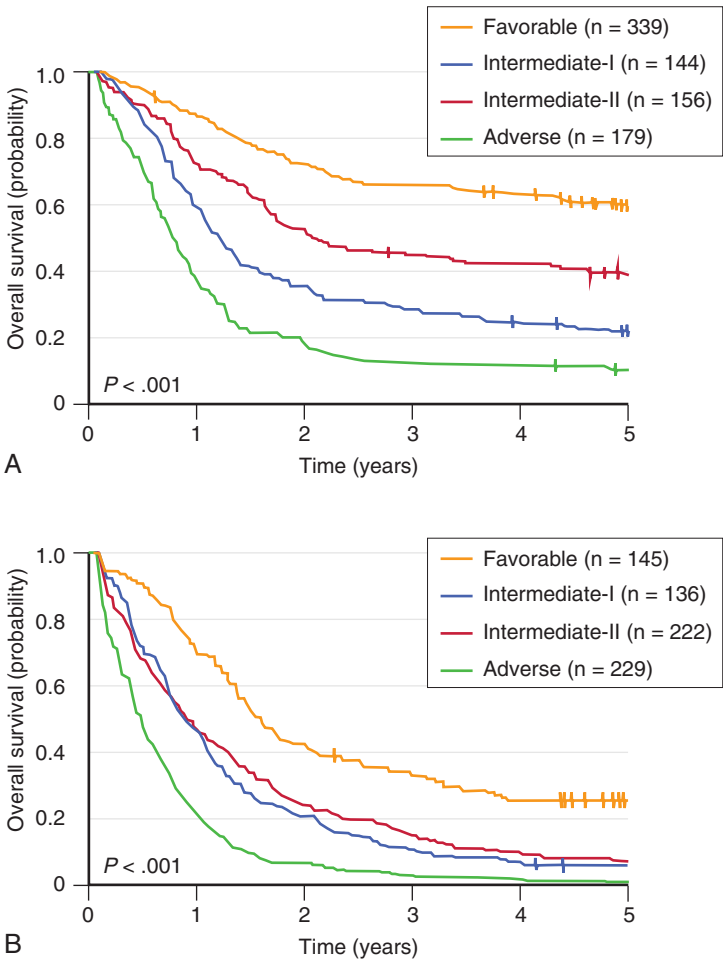

FIGURE 183-3. Overall survival in acute myeloid leukemia according to European LeukemiaNet risk groups. A, Overall survival in patients younger than 60 years. **B,** Overall survival in patients 60 years and older. (From Mrózek K, et al. Prognostic significance of the European LeukemiaNet standardized system for reporting cytogenetic and molecular alterations in adults with acute myeloid leukemia. *J Clin Oncol.* 2012;30:4515-4523).

remission is predicted by the duration of the first remission: 70% in patients whose first remission persisted beyond 2 years, compared with less than 15% in those whose first remission lasted less than 6 months. Older patients may benefit from gemtuzumab ozogamicin (9 mg/m^2 intravenously on days 1 and 15), a form of antibody-targeted chemotherapy. Second remissions tend to be short-lived, however, and few patients in whom relapse occurs after first-line chemotherapy are cured by salvage chemotherapy.

Treatment of Acute Promyelocytic Leukemia

CR can be induced in at least 90% of patients with APL by using ATRA (45 mg/m^2/day orally until CR is achieved) in combination with an anthracycline.[16] Patients treated with ATRA usually have their coagulation disorders corrected within several days. A unique toxicity of ATRA in the treatment of APL is the development of hyperleukocytosis accompanied by respiratory distress and pulmonary infiltrates. The syndrome responds to temporary discontinuation of ATRA and the addition of corticosteroids. By combining ATRA with anthracyclines for induction and consolidation and then using ATRA as maintenance therapy, approximately 70% of patients can be cured. Arsenic trioxide (0.15 mg/kg/day intravenously until CR is achieved) is effective in patients with recurrent APL and appears to improve overall survival if used as part of consolidation therapy for patients in their first CR. The combination of ATRA plus arsenic trioxide without any chemotherapy has recently been shown to be as effective as the standard ATRA-chemotherapy combination for patients with low- or-intermediate risk APL (i.e., those who present with white blood cell counts <10,000/μL).

Hematopoietic Stem Cell Transplantation

For patients with AML in whom an initial remission cannot be achieved or for those who relapse after chemotherapy, hematopoietic stem cell transplantation (Chapter 178) from an HLA-identical sibling offers the best chance for cure. Fifteen percent of patients with end-stage disease can be saved by this treatment. If the procedure is applied earlier, the outcome is better: approximately 30% of patients who undergo hematopoietic stem cell transplantation at first relapse or second remission are cured, and 50 to 60% of patients are cured if hematopoietic stem cell transplantation is performed during the first remission. A large number of studies have prospectively compared the outcome of allogeneic hematopoietic stem cell transplantation with that of chemotherapy in patients with AML in first remission. The trends in all these studies have been toward higher treatment-related mortality but improved disease-free and overall survival time with allogeneic transplantation. Meta-analyses conclude that survival is improved with allogeneic transplantation from a matched sibling in first remission when compared with continued chemotherapy. This improvement is clearest in patients with unfavorable or intermediate-risk disease and is not seen in those in the favorable-risk category. The major limitations of allogeneic hematopoietic stem cell transplantation are lack of a matched sibling donor, graft-versus-host disease, interstitial pneumonia, and disease recurrence. Because transplant-related toxicities increase with patient age, some centers limit hematopoietic stem cell transplantation to those 65 years of age or younger. However, recent studies of reduced-intensity or nonmyeloablative allogeneic transplantation have shown encouraging results in patients with AML in remission at ages up to 75 years. Allogeneic transplantation using matched unrelated donors results in survival essentially equivalent to that seen using matched siblings, although there is a higher incidence of complications.[17] Autologous hematopoietic stem cell transplantation offers an alternative for patients without matched siblings to serve as donors. In randomized trials, the use of autologous transplantation after consolidation chemotherapy significantly prolonged the duration of disease-free survival for patients with AML in first remission but did not alter overall survival.[18]

Treatment of AML in Older Patients

The benefits of intensive consolidation chemotherapy in younger patients do not translate to patients older than 65 years, in part because older patients are less able to tolerate therapy, but also because AML in older patients is more often associated with unfavorable cytogenetics (particularly abnormalities of chromosomes 5 and 7) and more often overexpresses P-glycoprotein, resulting in the multidrug resistance phenotype. Accordingly, long-term survival rates of only 10 to 15% are seen with chemotherapy in patients older than 65 years. Otherwise healthy older patients can usually tolerate intensive chemotherapy and should be offered this treatment. However, intensive chemotherapy can cause more harm than good in older patients with poor performance status. In prospective randomized trials, low-dose cytarabine prolonged survival in older patients unfit for intensive therapy. Other alternative therapies for this group of patients include the demethylating agents azacitidine or decitabine or entry onto clinical trials.[19]

MANAGEMENT OF COMPLICATIONS

Treatment of acute leukemia, especially AML, is accompanied by a number of complications, the two most serious and frequent being infection and bleeding. During the granulocytopenic period that follows induction and consolidation chemotherapy, the risk for bacterial infection is high. A Cochrane review examined results of antibiotic prophylaxis compared with placebo in afebrile neutropenic patients. Antibiotic prophylaxis significantly decreased infection-related deaths, with the best results seen with quinolones. Despite prophylaxis, many patients are febrile while neutropenic, and patients can still develop important infections. The most common bacterial species vary somewhat from medical center to medical center, but *Staphylococcus* (primarily *S. epidermidis*) and *Enterococcus* species are the most frequent gram-positive organisms, whereas *Pseudomonas aeruginosa* and enteric organisms such as *Escherichia coli* and *Klebsiella* species are the most common gram-negative organisms isolated.

Even if no cause for fever is found, bacterial infection should be assumed, and, in general, all patients with fever and neutropenia should receive broad-spectrum antibiotics (Chapters 167 and 281). Monotherapy with an intravenous antipseudomonal agent, such as a carbapenem (e.g., imipenem-cilastatin), a cephalosporin (e.g., cefepime), or an antipseudomonal penicillin (e.g., piperacillin-tazobactam), is recommended as empirical therapy. Vancomycin should not be part of standard coverage in most patients but may be used in those with suspected catheter infections or severe mucositis and in patients with hemodynamic instability or altered mental status. Combination therapy with other gram-negative agents (e.g., aminoglycosides) may be needed. Once begun, antibiotics should be continued until patients recover their granulocyte counts, even if they become afebrile first. If documented bacteremia persists despite appropriate antibiotics, the physician should consider removal of indwelling catheters.

Invasive fungal infections are also common following chemotherapy for acute leukemia and are associated with significant morbidity and mortality. A review of randomized trials found a significant reduction in death from fungal infection in patients given antifungal prophylaxis. Posaconazole is considered by many to be more effective than fluconazole or itraconazole. In addition to being granulocytopenic, patients undergoing induction chemotherapy for leukemia have deficient cellular and humoral immunity, at least temporarily, and therefore are subject to infections common in other immunodeficiency states, including *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) infection and a variety of viral infections. *P. jirovecii* infection can be prevented by the prophylactic use of trimethoprim-sulfamethoxazole. In cytomegalovirus (CMV) -seronegative patients, CMV-seronegative or leukocyte-reduced blood products should be used to prevent primary infection (Chapter 376). Herpes simplex (Chapter 374) can often complicate existing mucositis and can be prevented with prophylactic acyclovir. Acyclovir is also useful for the prevention and treatment of herpes zoster (Chapter 375).

Myeloid growth factors (granulocyte or granulocyte-macrophage colony-stimulating factor; Chapter 156), if given shortly after the completion of chemotherapy, shorten the period of severe myelosuppression by, on average, 4 days. In most studies, this accelerated recovery has resulted in fewer days with fever and less use of antibiotics, but it has not improved the complete response rate or altered survival.

The platelet count that signals a need for platelet transfusion has been the subject of debate. Traditionally, platelet transfusions from random donors were used to maintain platelet counts greater than 20,000/μL, but more recently it has been demonstrated that lowering this threshold to 10,000/μL is safe in patients with no active bleeding. In contrast, a no-prophylaxis strategy results in more days with bleeding and a shorter time to first bleeding episode and therefore is not recommended. In 30 to 50% of cases, patients eventually become alloimmunized and require the use of HLA-matched platelets (Chapter 177). Transfusion-induced graft-versus-host disease (Chapter 177), manifesting as a rash, low-grade fever, elevated values in liver function tests, and decreasing blood counts, can be prevented by irradiating all blood products before transfusion.

REVIEW QUESTIONS

1. A 66-year-old man presents with fatigue and is found to have pancytopenia with a hematocrit of 31%, a white blood cell count of 2300/μL with peripheral blasts, and a platelet count of 9000/μL. A bone marrow study shows 60% myeloblasts consistent with M1 acute myelogenous leukemia (AML). The patient had previously been in outstanding health. The choice is made to attempt induction therapy with daunorubicin and cytarabine. Which of the following statements is correct concerning prophylaxis against bleeding during induction?

A. No platelet prophylaxis is necessary. It is sufficient to wait until clinical evidence of bleeding (petechiae or ecchymoses) for transfusing platelets.
B. Prophylactic platelet transfusions from random donors should be given when platelet counts drop below 10,000/μL.
C. Prophylactic platelet transfusions from random donors should be given when platelet counts drop below 20,000/μL.
D. Prophylactic platelet transfusions from HLA-matched donors should be given when platelet counts drop below 10,000/μL.
E. Prophylactic platelet transfusions from HLA-matched donors should be given when platelet counts drops below 20,000/μL.

Answer: B See Stanworth SJ, Estcourt LJ, Powter G, et al. A no-prophylaxis platelet-transfusion strategy for hematologic cancers. *N Engl J Med*. 2013;368:1771-1780.

2. A 24-year-old woman presents with bleeding gums and easy bruising. She is found to have a hematocrit of 29%, a white blood cell count of 4800/μL with 5% peripheral promyelocytes, and a platelet count of 38,000/μL. A bone marrow study shows morphologic and molecular evidence of promyelocytic leukemia. She is begun on ATRA and daunorubicin. Infection prophylaxis includes a quinolone and Bactrim. Six days after starting therapy, the patient presents with fever and increasing shortness of breath that has developed over several days. Her white blood cell count has risen to 15,000/μL with 20% promyelocytes and metamyelocytes. A chest radiograph shows diffuse pulmonary infiltrates. What would be the most appropriate next step?

A. Add daunorubicin to therapy.
B. Add arsenic trioxide to therapy.
C. Perform a bronchoscopy.
D. Add posaconazole for antifungal coverage.
E. Temporarily discontinue the ATRA and add dexamethasone.

Answer: E See Sanz MA, Lo-Coco F. Modern approaches to treating acute promyelocytic leukemia [review]. *J Clin Oncol.* 2011;29:495-503.

3. An 84-year-old man presents with increasing angina and is found to have a hematocrit of 21%, a white blood cell count of 22,000/μL, and a platelet count of 78,000/μL. A bone marrow examination shows AML with complex cytogenetics including monosomy 7. The patient has a known past history of coronary artery disease, hypertension, and peripheral vascular disease. His ECOG performance status is 2. Which of the following would you recommend?

A. Supportive care only
B. Supportive care plus therapy with low-dose cytarabine
C. Imatinib
D. Conventional induction with cytarabine and daunorubicin
E. Conventional induction with cytarabine but with reduced-dose daunorubicin

Answer: B See Fenaux P, Mufti GJ, Hellstrom-Lindberg E, et al. Azacitidine prolongs overall survival compared with conventional care regimens in elderly patients with low bone marrow blast count acute myeloid leukemia. *J Clin Oncol.* 2010;28:562-569.

4. A 44-year-old woman presents with increasing bone pain and pallor and is found to have a hematocrit of 24%, a white blood cell count of 32,000/μL with circulating myeloblasts, and a platelet count of 45,000/μL. A bone marrow study shows AML with t(4;11). Three years earlier, she had been diagnosed with breast cancer and had been treated with surgery, radiation, and adjuvant chemotherapy including cyclophosphamide and doxorubicin. She is treated for her AML with daunorubicin and cytarabine and after one cycle achieves a complete remission. She does not have a matched sibling or a matched unrelated donor. What would you recommend for her further therapy?

A. Three cycles of consolidation therapy using high-dose cytarabine
B. Three cycles of consolidation therapy using high-dose cytarabine combined with gemtuzumab ozogamicin
C. Cord blood transplantation as soon as possible
D. Autologous stem cell transplantation as soon as possible
E. Three cycles of consolidation therapy followed by autologous transplantation

Answer: C See Lowenberg B, Pabst T, Vellenga E, et al. Cytarabine dose for acute myeloid leukemia. *N Engl J Med.* 2011;364:1027-1036.

5. A 74 year-old woman presents with increasing peripheral edema and is found to have a hematocrit of 26%, a white blood cell count of 38,000/μL with circulating lymphoblasts, and a platelet count of 110,000/μL. A bone marrow shows Ph+ acute lymphoblastic leukemia. She has a prior history of compensated congestive heart failure. What therapy would you recommend for her?

A. Supportive care only
B. Supportive care plus low-dose cytarabine
C. Dasatinib plus dexamethasone
D. Vincristine, prednisone, L-asparaginase, daunorubicin, and imatinib
E. Gemtuzumab ozogamicin

Answer: C See Bassan R, Hoelzer D. Modern therapy of acute lymphoblastic leukemia [review]. *J Clin Oncol.* 2011;29:532-543.

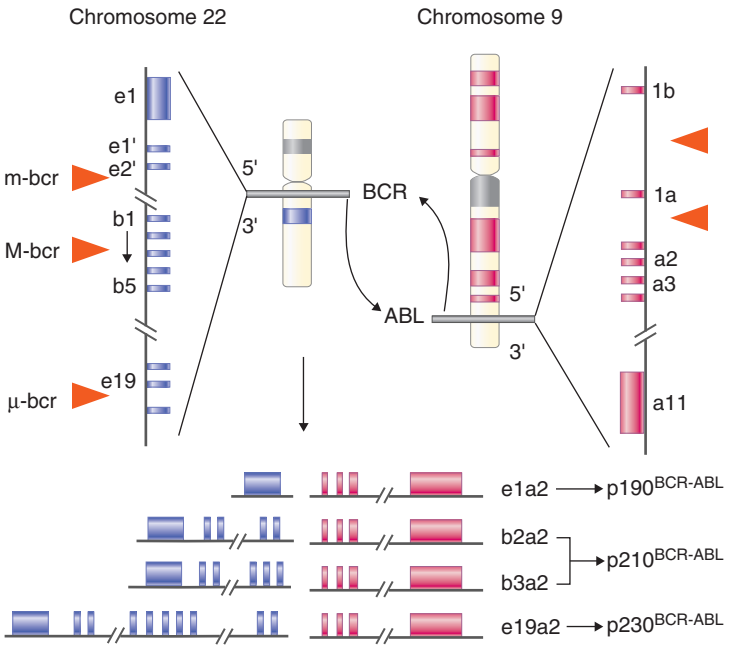

FIGURE 184-1. The Philadelphia chromosome. Originally described as a shortened long arm of chromosome 22, the Philadelphia chromosome (Ph) was later found to be the result of a balanced translocation of genetic material between the long arms of chromosomes 9 and 22: t(9;22)(q34;qll.2). This results in the juxtaposition of *ABL1* to *BCR,* producing a hybrid *BCR-ABL1* oncogene. Depending on the breakpoint on *BCR,* three oncoproteins may be produced: $p210^{BCR-ABLI}$, which is associated with 98% or more of the cases of Ph-positive chronic myelogenous leukemia (CML); $p190^{BCR-ABL1}$, which is associated with 60 to 80% of cases of Ph-positive acute lymphocytic leukemia (the other 20 to 40% of cases are $p210^{BCR-ABL1}$); and $p230^{BCR-ABL}$, which is associated with rare cases of Ph-positive CML.

THE CHRONIC LEUKEMIAS

SUSAN O'BRIEN AND ELIAS JABBOUR

CHRONIC MYELOGENOUS LEUKEMIA

DEFINITION

Chronic myelogenous leukemia (CML), also called chronic myeloid leukemia, is a clonal myeloproliferative neoplasm of the primitive hematopoietic stem cell that is characterized by overproduction of cells of the myeloid series, resulting in marked splenomegaly and leukocytosis. Basophilia and thrombocytosis are common. A characteristic cytogenetic abnormality, the Philadelphia (Ph) chromosome, which produces the fusion oncogene *BCR-ABL,* is present in the bone marrow cells in more than 90% of cases. Most patients (85 to 90%) present in the chronic phase. Eventually, if poorly controlled, CML evolves into the accelerated and blastic phases.

EPIDEMIOLOGY

CML constitutes one fifth of all cases of leukemia in the United States. It is diagnosed in 1 or 2 persons per 100,000 per year and has a slight male preponderance. This incidence of 4800 to 5000 cases annually has not changed significantly in the past few decades. The incidence of CML increases with age; the median age at diagnosis is 50 to 55 years. Ph-positive *BCR-ABL*-positive CML is uncommon in children and adolescents. No familial association of CML has been noted; for example, the risk is not increased in monozygotic twins or in relatives of patients with CML. Because of the availability of effective therapy, the annual mortality has been reduced from 15 to 20%, before 2000, to 1 to 2% currently.[1] Thus, the prevalence of CML is predicted to increase gradually, from 15,000 to 20,000 cases before 2000 up to 180,000 cases by 2030 in the United States.

Usually, no etiologic agent is incriminated in CML. Exposure to ionizing radiation (e.g., in survivors of the atomic bomb explosions in Japan in 1945, in those undergoing radiation treatment for ankylosing spondylitis or cervical cancer) increases the risk for CML; the peak incidence occurs 5 to 12 years after exposure and is dose related. No increase in the risk for CML has been demonstrated among individuals working in the nuclear industry. Radiologists working without adequate protection before 1940 were more likely to develop myeloid leukemia, but no such association has been found in recent studies. Benzene exposure increases the risk for acute myelogenous leukemia (AML) but not of CML. CML is not a frequent secondary leukemia after treatment of other cancers with radiation, alkylating agents, or both.

PATHOBIOLOGY

Molecular Pathogenesis

The Ph chromosome abnormality, present in more than 90% of patients with typical CML (Fig. 184-1), results from a balanced translocation of genetic material between the long arms of chromosomes 9 and 22: t(9;22)(q34;q11.2). The breakpoint at band q34 of chromosome 9 results in translocation of the cellular oncogene *ABL1* (previously *c-ABL)* to a region on chromosome 22 coding for the major breakpoint cluster region *(BCR). ABL1* is a homologue of *v-ABL,* the Abelson virus that causes leukemia in mice. This translocation allows juxtaposition of a 5′ portion of a *BCR* and 3′ position of *ABL;* the two genetic sequences produce a new hybrid oncogene *(BCR-ABL1),* which codes for a novel BCR-ABLl oncoprotein with a molecular weight of 210 kD ($p210^{BCR-ABLI}$). The $p210^{BCR-ABLI}$ oncoprotein results in uncontrolled kinase activity of BCR-ABLl, which triggers the excessive proliferation and reduced apoptosis of CML cells, thereby giving CML cells a growth advantage over normal cells and suppressing normal hematopoiesis. Although in most cases 100% of the metaphases on cytogenetic analysis show *BCR-ABL1,* normal stem cells emerge on long-term bone marrow culture and after treatment with interferon-α (IFN-α), imatinib, and other BCR-ABLl-selective tyrosine kinase inhibitors (TKIs).

The constitutive activation of BCR-ABLI results in autophosphorylation and activation of multiple downstream pathways that affect gene transcription, apoptosis, cytoskeletal organization, cytoadhesions, and degradation of inhibitory proteins. The signal transduction pathways implicated involve RAS, mitogen-activated-protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidyl inositol 3-kinase (PI3K), MYC, and others. Many of these interactions are mediated through tyrosine phosphorylation and require binding of the BCR-ABLI to adapter proteins such as GRB-2, CRK, CRK-like protein (CRKL), and SCR homology-containing proteins (SHC). Although imatinib and new-generation TKIs (nilotinib, dasatinib, bosutinib, ponatinib) have been extremely successful at targeting BCR-ABLI, understanding of the pathophysiology of the downstream events of BCR-ABLI is important for the future development of agents that may target these events.

In Ph-positive acute lymphocytic leukemia (ALL), the breakpoint in *BCR* is proximal, in the minor *BCR,* resulting in a smaller *BCR* gene apposing *ABL1*; the resulting fusion gene, messenger RNA, and BCR-ABLI oncoprotein ($p190^{BCR-ABLI}$) are smaller. A third rare, "micro" *BCR* breakpoint distal to the major *BCR* produces a $p230^{BCR-ABLI}$ hybrid oncoprotein, which is associated with a more indolent CML course.

What induces this molecular rearrangement is unknown. Molecular techniques that amplify detection of *BCR-ABL1* have demonstrated its presence in the marrow cells of 25 to 30% of healthy volunteers and 5% of infants, but not in cord blood. Because clinical CML develops in only 1 to 2 of 100,000

individuals (i.e., 1 to 2 per 25,000 to 30,000 individuals who express *BCR-ABL* in their bone marrow), immune regulatory processes or additional molecular events presumably contribute to the development of CML.

BCR-ABL1 is found only in hematopoietic cells and has its origin close to the pluripotent stem cell. The Ph chromosome occurs in erythroid, myeloid, monocytic, and megakaryocytic cells; less commonly in B lymphocytes; rarely in T lymphocytes; and not at all in marrow fibroblasts. The fusion *BCR-ABL1* gene and the p210 protein can be found in cases of morphologically typical CML in which no cytogenetic abnormality occurs or in which changes other than the typical t(9;22) (q34;q11.2) are identified. These patients have a survival rate and a response to therapy similar to those of patients with Ph-positive CML. Patients with atypical CML (usually older and more frequently exhibiting anemia, thrombocytopenia, monocytosis, and dysplasia) who are Ph negative and *BCR-ABL1* negative have a worse prognosis than those who are either Ph positive or Ph negative and *BCR-ABL1* positive; they more closely resemble patients with myelodysplastic syndrome (Chapter 182). Thus, three groups of patients with CML can be identified: (1) those who are positive for Ph and *BCR-ABL1;* (2) those who are Ph negative but *BCR-ABL1* positive; and (3) those who are negative for Ph and *BCR-ABL1*. *PDGFB* (previously *SIS),* which codes for platelet-derived growth factor (PDGF) and is the homologue of the simian sarcoma virus, is also translocated from chromosome 22 to chromosome 9 in CML, but it is distant from the breakpoint and is not expressed.

The pathophysiologic mechanisms underlying CML resistance to TKIs is a fascinating topic that has now been replicated with other targeted therapies in other hematologic and solid tumors. Several mechanisms of resistance to TKIs have been identified; the most common are mutations in the BCR-ABLl kinase domain. More than 100 different mutations have been reported and can involve any of the important domains in the BCR-ABLl structure, including the P-loop (the area where adenosine triphosphate [ATP] binds), the activation loop, and the catalytic domain, as well as the amino acids where imatinib makes contact with BCR-ABLl. The different mutations have considerable variability with respect to resistance to imatinib and other TKIs. Some mutations are overcome by higher concentrations of imatinib than required to inhibit the wild-type form; others are completely insensitive to imatinib. Mutational analysis is useful in patients with imatinib resistance to identify those with the T3151 mutation, who do not respond to imatinib or the second-generation TKIs (dasatinib, nilotinib, bosutinib) but do respond to ponatinib therapy. Knowledge of the sensitivity of the different mutations, as determined by the IC_{50} for particular agents, can help select the TKIs.

CLINICAL MANIFESTATIONS

About 40 to 50% of patients diagnosed with CML do not have symptoms, and the disease is found on routine physical examinations or blood tests. In these patients, the white blood cell (WBC) count may be relatively low at diagnosis. The degree of leukocytosis correlates with tumor burden, as defined by spleen size.

The symptoms of CML, when present, are due to anemia and splenomegaly; they include fatigue, weight loss, malaise, easy satiety, and left upper quadrant fullness or pain. Rarely, bleeding or thrombosis occurs. Other rare presentations include gouty arthritis (from elevated uric acid levels), priapism (usually with marked leukocytosis or thrombocytosis), retinal hemorrhages, and upper gastrointestinal ulceration and bleeding (from elevated histamine levels due to basophilia). Headaches, bone pain, arthralgias, pain from splenic infarction, and fever are uncommon in the chronic phase but more frequent as CML progresses. Symptoms of leukostasis, such as dyspnea, drowsiness, loss of coordination, or confusion, which are due to leukocyte sludging in the pulmonary or cerebral vessels, are uncommon in the chronic phase despite WBC counts exceeding 50×10^9 cells/μL, but these symptoms appear more frequently in the accelerated or blastic phases of the disease.

Splenomegaly, the most consistent physical sign in CML, occurs in 30 to 50% of cases. Hepatomegaly is less common (10 to 20%) and usually minor. Lymphadenopathy is uncommon, as is infiltration of skin or other tissues. If present, these findings suggest Ph-negative CML or the accelerated or blastic phase of CML.

DIAGNOSIS

The diagnosis of typical CML is not difficult. Patients with untreated CML usually have leukocytosis ranging from 10 to 500×10^9/μL. The predominant cells are neutrophils, with a left shift extending to blast cells. Basophils and eosinophils are commonly increased. Monocytes may be slightly increased in some cases that overlap with chronic myelomonocytic leukemia (CMML; see later discussion). Thrombocytosis is common, whereas thrombocytopenia is rare and, if present, suggests a worse prognosis. A hemoglobin level of less than 11 g/dL is present in one third of patients. Some patients demonstrate a cyclic oscillation of the WBC count. The presence of unexplained myeloid leukocytosis (Fig. 184-2) with splenomegaly should lead to a bone marrow examination and cytogenetic and molecular analysis.

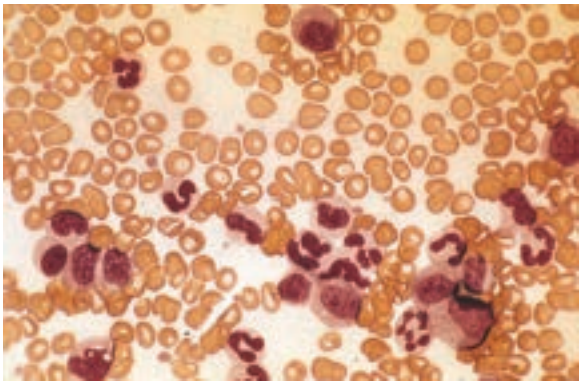

FIGURE 184-2. Chronic myelogenous leukemia, chronic phase. Peripheral smear shows leukocytosis, with representation by the entire spectrum of leukocyte differentiation, ranging from myeloblasts to mature neutrophils. (Courtesy Andrew Schafer, MD.)

Bone Marrow

The bone marrow is hypercellular, with marked myeloid hyperplasia and, at times, evidence of increased reticulin or collagen fibrosis. The myeloid-erythroid ratio is 15 : 1 to 20 : 1. About 15% of patients have 5% or more blast cells in the peripheral blood or bone marrow at diagnosis.

Cytogenetics

The presence of the t(9; 22) (q34; q11.2) abnormality establishes the diagnosis of CML. If the Ph chromosome is not found in a patient with suspected CML, molecular studies for the presence of the hybrid *BCR-ABL1* gene should be performed. About 25 to 30% of patients with a typical morphologic picture of CML who are Ph negative have the *BCR-ABL1* rearrangement. The Ph chromosome is usually present in 100% of metaphases, often as the sole abnormality. Between 10 and 15% of patients have additional chromosomal changes (loss of the Y chromosome, trisomy 8, an additional loss of material from 22q, or double Ph). Some patients have complex chromosomal changes involving chromosome 9 or chromosome 22 (Ph variants, three-way translocations).

Differential Diagnosis

CML must be differentiated from leukemoid reactions (Chapter 167), which usually produce WBC counts lower than 50×10^9/μL, and toxic granulocytic vacuolation, Döhle bodies in the granulocytes, absence of basophilia, and normal or increased leukocyte alkaline phosphatase (LAP) levels (which are typically low in CML). The clinical history and physical examination generally suggest the origin of the leukemoid reaction. Corticosteroids can rarely cause extreme neutrophilia with a left shift, but this abnormality is self-limited and of short duration.

CML may be more difficult to differentiate from other myeloproliferative or myelodysplastic syndromes (Chapters 166 and 182). Patients with myeloid metaplasia with or without myelofibrosis frequently have splenomegaly, neutrophilia, and thrombocytosis. Polycythemia vera with associated iron deficiency, which causes normal hemoglobin and hematocrit values, can manifest with leukocytosis and thrombocytosis. Such patients usually have a normal or increased LAP score, a WBC count less than 25×10^9/μL, and no Ph chromosome or *BCR-ABL1* rearrangement.

The greatest diagnostic difficulty lies with patients who have splenomegaly and leukocytosis but do not have the Ph chromosome. In some, the *BCR-ABL* hybrid gene can be demonstrated despite a normal or atypical cytogenetic pattern. Patients who are Ph negative and *BCR-ABLI* negative are considered to have Ph-negative CML or CMML (see later discussion). Isolated megakaryocytic hyperplasia can be seen in essential thrombocythemia (Chapter 166), with marked thrombocytosis and splenomegaly. Some patients who present with clinical characteristics of essential thrombocythemia (with marked thrombocytosis but without leukocytosis) have CML; cytogenetic

and molecular studies showing the Ph chromosome, the *BCR-ABLI* rearrangement, or both lead to the appropriate diagnosis and treatment.

Rarely, patients have myeloid hyperplasia, which involves almost exclusively the neutrophil, eosinophil, or basophil cell lineage. These patients are described as having chronic neutrophilic, eosinophilic, or basophilic leukemia and do not have evidence of the Ph chromosome or the *BCR-ABLI* gene but may have other molecular abnormalities. Most patients with *chronic neutrophilic leukemia*, characterized clinically by sustained, mature neutrophilic leukocytosis, hepatosplenomegaly, and bone marrow granulocytic hyperplasia, have oncogenic mutations in the gene for colony-stimulated factor 3 receptor (*CSF3R*).[2] Patients with *chronic eosinophilic leukemia* (or clonal hypereosinophilic syndrome) (Chapter 170) have mutations in the genes for platelet-derived growth factor receptor-aα (*PDGFRA*) or *PDGFRB* or *FGFR1*; the prototypical abnormality is the *FIP1L1-PDGFRA* gene fusion.[3] Peripheral blood or bone marrow can be tested for these genetic markers by reverse transcription–polymerase chain reaction (RT-PCR) or interphase/metaphase fluorescent in situ hybridization (FISH), as can the *BCR-ABL1* rearrangement for CML.

Clinical Course

Evolution to Accelerated and Blastic Phases

More than 90% of patients present with CML in the benign or chronic phase. If symptomatic at presentation, it becomes asymptomatic once the disease is controlled. Death rarely occurs during the chronic phase of CML. When poorly controlled, CML evolves into an accelerated phase, usually defined by the presence of 15% or more blasts, 30% or more blasts plus promyelocytes, 20% or more basophils, thrombocytopenia (platelets $<100 \times 10^9/\mu L$) unrelated to therapy, or cytogenetic clonal evolution. The accelerated phase can be also characterized by worsening anemia; increasing splenomegaly or hepatomegaly; infiltration of nodes, skin, bones, or other tissues; and fever, malaise, and weight loss. In the accelerated phase, bone marrow studies may show dysplastic changes, increased percentages of blasts and basophils, myelofibrosis, and chromosomal abnormalities in addition to the Ph chromosome (clonal evolution). About 5 to 10% of patients present in the accelerated phase.

Before the era of imatinib therapy, the risk for developing accelerated or blastic phase CML was 10% per year in the first 2 years after diagnosis and 15 to 20% per year thereafter, unless therapies such as IFN-α or allogeneic hematopoietic stem cell transplantation (AHSCT) were used. With imatinib, the annual incidence of progression of CML from the chronic to the accelerated or blastic phase has been 2% in the first 10 years of observation (Fig. 184-3). Before imatinib therapy, the median survival of accelerated phase CML was 18 months or less, but survival has now increased to 4 years or more. In de novo accelerated phase CML, the estimated 8-year survival rate with TKI therapy is 75%.

The blastic phase of CML is diagnosed when 30% or more blast cells are present in the bone marrow and/or peripheral blood or when extramedullary blastic disease is present. Most patients develop features of the accelerated phase before progressing to the blastic phase, but 20% of patients evolve quickly into a blastic phase without warning. Most patients in the accelerated or blastic phase have additional chromosomal abnormalities (clonal evolution) such as duplication of the Ph chromosome, trisomy of chromosome 8, or development of an isochromosome 17. The extramedullary blastic phase of CML can occur in the spleen, lymph nodes, skin, meninges (especially in the lymphoid blastic phase), bones, and other sites; extramedullary transformation is usually followed shortly by evidence of marrow involvement. Blastic phase CML is associated with a very poor median survival time of 5 months. About 25% of patients develop a lymphoid blastic phase. Ph-negative and *BCR-ABL1*-negative CML often appear to overlap clinically with CMML in their behavior, progress, and response to therapy and seem to resemble the myelodysplastic syndromes (Chapter 182) more than Ph-positive CML. A male preponderance and older age are noted; splenomegaly is common (60 to 70%).

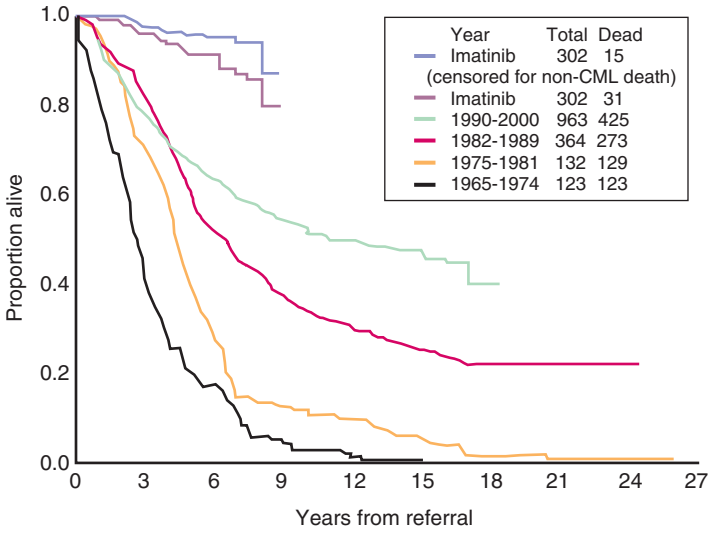

FIGURE 184-3. Survival of patients with Ph-positive chronic myelogenous leukemia (CML) in chronic phase CML. In single-institutional studies, industry-sponsored trials, and national reports where TKI therapy has full penetration, the estimated 8- to 10-year survival rates are high. The survival rates are lower where TKI treatment penetration is not optimal. **A,** From Bjorkholm M, Ohm L, Eloranta S, et al. Trends in chronic myeloid leukemia incidence and survival in the United States from 1975-2009. *Leuk Lymphoma.* 2013;54:1411-1417.

TREATMENT

Today, there are five TKIs that have been approved for the treatment of CML. Imatinib mesylate was approved in 2001 by the U.S. Food and Drug Administration (FDA) for CML salvage and in 2002 for CML firstline therapy. Nilotinib, a more potent selective BCR-ABL1 TKI, was approved in 2007 for CML salvage and in 2010 for first-line CML therapy. Dasatinib, a dual BCR-ABL TKI, was approved for CML salvage therapy in 2006 and for first-line therapy in 2010. In 2012, two additional TKIs were approved for CML salvage: bosutinib, a dual SRC-ABL1 inhibitor, and ponatinib, a pan BCR-ABL1 kinase inhibitor with selective potency against the resistant T315I mutation. In 2012, omacetaxine mepesuccinate, a semisynthetic cephalotaxine that inhibits protein synthesis, was also approved for the treatment of CML following failure of two or more TKIs.

First-line therapy for CML today includes imatinib, nilotinib, or dasatinib.[4,5] Patients who demonstrate CML resistance or intolerance to treatment may be offered salvage TKI therapy with any of the other available TKIs. The choice of second-line therapy with a TKI versus allogeneic hematopoietic stem cell transplantation (AHSCT) depends on several factors: (1) the patient's age and general condition; (2) the availability of acceptable donors (related or matched unrelated); (3) whether a patient has intolerance or CML resistance to first-line TKI therapy; (4) the emerging mutation in the resistant CML clone; (5) whether there is additional clonal evolution at the time of relapse; (6) the response to second-line therapy with the new TKI; (7) the estimated safety and success of the AHSCT; and (8) additional comorbid conditions of the patients (e.g., diabetes, pulmonary conditions, cardiac status, prior history of pancreatitis or pulmonary hypertension) (Chapter 178).

Patients who present with or develop accelerated or blastic phase should receive second-line TKIs to reduce the disease burden and should be offered AHSCT as soon as possible (the exception possibly being de novo CML accelerated phase which may respond durably to first-line TKI therapy, particularly with achievement of a complete cytogenetic response). Patients who develop intolerance to first-line TKI in chronic phase could be offered second-line TKIs as durable therapy, particularly if they achieve complete cytogenetic response. Patients who develop resistance to a first-line TKI in chronic phase are offered a second-line TKI based on their mutation analysis. A T3151 mutation in the CML clone requires therapy with ponatinib and (as of today) early consideration of AHSCT until the results of ponatinib therapy mature. Mutations involving V299L, T315A, or F317LN/I/C are sensitive to nilotinib therapy. Mutations involving Y253H, E255KN, or F359N/C/I are sensitive to dasatinib and bosutinib therapy. Patients who harbor clonal evolution in the CML cells (additional chromosomal abnormalities in the Ph positive cells) or mutations at the time of second-line therapy, or those who do not achieve a complete cytogenetic response by 1 year of second-line TKI therapy, should be considered early for AHSCT. However, if there is no clonal evolution or mutations at the time of second-line therapy, and if the patient achieves complete cytogenetic response with second-line TKI therapy, responses are durable, and TKIs can be continued until evidence of cytogenetic relapse before AHSCT is considered as third-line therapy. Older patients (e.g., 65 to 70 years or older) may forgo a curative option of AHSCT in favor of several years of good disease control. In such patients, TKI therapy with or without additional (older) agents (hydroxyurea, cytarabine, decitabine, 6-mercaptopurine) may sustain less than a complete cytogenetic response (partial, minor) or a complete hematologic response for many years with a good quality of life, and without the risk for mortality or morbidities associated with AHSCT, particularly if the donor is not

optimal (unrelated, mismatched). Treatment options and choice and timing of AHSCT in CML are detailed in Tables 184-1 and 184-2.

Recent trials with different TKIs have indicated that early and "deep" cytogenetic and molecular responses are predictive of improved progression-free and overall survival.[6]

Imatinib Mesylate

Since its discovery in 1999, imatinib mesylate has become standard therapy for CML. Imatinib is a 2-phenylaminopyrimidine derivative that binds to the canonical ATP lining the groove between the N and C lobes of the ABL1 kinase domain, thus blocking the phosphorylation of tyrosine residues on substrate protein. Blocking of ATP binding inactivates the ABLl kinase because it cannot transfer phosphate to its substrate. By inhibiting phosphorylation, imatinib prevents the activation of signal transduction pathways that induce the leukemic transformation processes that cause CML (Fig. 184-4). Imatinib inhibits several tyrosine kinases, including $p210^{BCR\text{-}ABLl}$, $p190^{BCR\text{-}ABLl}$, v-ABL, c-ABL, c-Kit, and PDGF receptor.

In a randomized trial of 1106 patients with newly diagnosed CML, imatinib 400 mg/day orally provided significantly higher rates of major cytogenetic response (87% vs. 35%) and complete cytogenetic response (76% vs. 14%), as well as lower rates of progression (8% vs. 26%) and transformation (3% vs. 9%) after 12 months of therapy, compared with the prior standard nontransplantation therapy (a combination of IFN-α and cytosine arabinoside).[7] The longer term follow-up results continue to demonstrate excellent outcomes with imatinib therapy (Table 184-3; see Fig. 184-3); with a median follow-up of 8 years, the complete cytogenetic response rate (occurring at least once during therapy) is 83%, the estimated 8-year event-free survival rate is 81%, and the transformation-free survival rate 92%. The estimated 8-year survival rate is 85% (93% if only CML-related deaths are included). The annual rate of transformation was 1.5 to 2.8% in the first 3 years and decreased to less than 1% in the subsequent 5 years among patients who continued on imatinib therapy. Therapy with high-dose imatinib or with combinations of imatinib and other agents (e.g., peg-IFN-α2) did not show convincingly improved results compared with standard imatinib 400 mg daily.

Imatinib has a 5% or lower rate of serious side effects, which include nausea, vomiting, diarrhea, skin rash, muscle cramps, bone pain, periorbital or leg edema, weight gain, and rarely, hepatic, renal, or cardiopulmonary dysfunction; most of these are manageable with dose reduction or treatment interruption. Drug-related myelosuppression occurs in 10 to 20% of patients with newly diagnosed CML and is manageable with brief treatment interruptions, dose modifications, or both, or with the administration of growth factors (erythropoietin for anemia, granulocyte colony-stimulating factor for neutropenia). Imatinib and other TKIs may prolong the cardiac QTc interval; medications that contribute to QTc prolongation should be avoided. Hypophosphatemia associated with altered bone metabolism can occur, and the serum phosphate level should be monitored. Chromosomal abnormalities may appear in the Ph-negative diploid cells in 5 to 10% of responding patients, probably owing

Omacetaxine	Salvage	10 (2)	—	85-90 (2)

to unmasking of a fragile stem cell prone to the development of CML or to chromosomal instability; such changes disappear spontaneously in 70% of cases and rarely evolve into a myelodysplastic syndrome or acute myeloid leukemia, probably as part of the natural course of CML.

Nilotinib

Nilotinib, a selective BCR-ABLI TKI 30 times more potent than imatinib, was initially approved for the treatment of CML after imatinib failure. In CML chronic phase after imatinib failure, nilotinib 400 mg orally twice daily was associated with complete cytogenetic response rates of 40 to 50%. The major molecular response rates, defined as BCR-ABL1 transcripts, 0.1% by International Scale [IS], are 30 to 40%, and the estimated 3-year survival rate is 80%. Subsequent studies compared nilotinib to imatinib in newly diagnosed patients with CML. In a three-arm randomized study,[6] patients received imatinib 400 mg daily, nilotinib 400 mg twice a day, or nilotinib 300 mg twice daily. With a minimum follow-up of 4 years, the two arms of nilotinib demonstrate better early results compared with imatinib. There was no difference in the estimated 4-year survival rates (94%, 97%, 93%, respectively). Nilotinib therapy was associated with lower rates of fluid retention, diarrhea, headaches, muscle cramps, nausea and vomiting, and neutropenia. However, it was associated with higher rates of headache, rash, pruritus, and hyperglycemia, and with a low but notable incidence of pancreatitis (<2%), ischemic heart disease (4 to 5% vs. 1% with imatinib), and peripheral arterial occlusive disease (1.4 to 1.8% vs. 0%).

Dasatinib

Dasatinib, a dual SRC-ABL1 inhibitor, is 300 times more potent than imatinib. In chronic phase CML after imatinib failure, dasatinib therapy was associated with complete cytogenetic response rates of 45 to 60%, major molecular response rate of 43%, and estimated 6-year survival rate of 71%. A first-line study comparing dasatinib to imatinib (DASISION trial)[6] randomized patients to receive either imatinib 400 mg daily or dasatinib 100 mg daily. With a minimum follow-up of 48 months, the incidence of complete cytogenetic response by 24 months was 86% with dasatinib and 82% with imatinib. The incidence of major molecular response was 74% vs. 60%. The rate of transformation to accelerated or blastic phase was 4.6% vs. 7%. The estimated 4-year progression-free survival rates were similar, 90%. The estimated 4-year survival rates were 93% and 92%, respectively. Dasatinib therapy was associated with lower rates of fluid retention, edema, myalgia, nausea, vomiting, and rashes. However, it was associated with higher rates of pleural effusions (about 10 to 15%) and cytopenias, particularly thrombocytopenia, as well as a low but notable incidence of pulmonary hypertension (<2 to 3%).

Bosutinib

Bosutinib, a dual SRC-ABLI inhibitor (similar to dasatinib), is 30 to 200 times more potent than imatinib. It has minimal inhibitory activity against c-Kit and PDGF receptor and therefore is expected to produce less myelosuppression and fewer pleural effusions. In studies of patients with chronic phase CML after imatinib failure treated with bosutinib 500 mg orally daily, the major cytogenetic response rate was 53%, the complete cytogenetic response rate was 41%, and the estimated 2-year survival rate was 92%.[6] Grade 3 to 4 toxicities included diarrhea (8%), rashes (9%), and thrombocytopenia (5 to 10%).

Ponatinib

Ponatinib is a pan-BCR-ABLI TKI with potent activity against native and mutated BCR ABLI kinases, including T3151. In a phase II study of patients with chronic, accelerated, or blastic (CML) or Ph-positive acute lymphocytic leukemia, all of whom were resistant or intolerant to several TKIs, ponatinib showed high activity. In these chronic phase CML patients, the complete cytogenetic response rate was 44%, and the major molecular response rate was 30%. In the subset of patients with T3151 mutation, the major cytogenetic response rate was 70%, the complete cytogenetic response rate 66%, and the major molecular response rate 50%.[7] Significant side effects included pancreatitis (5 to 10%), thrombocytopenia (30%), and skin rash (30%). Because of the cumulative incidence of serious thrombotic events since the approval of ponatinib, the FDA has restricted its use to patients resistant to other TKIs. Additional clinical trials assessing the safety profile and different dose schedules of ponatinib are being considered.

Omacetaxine

Omacetaxine mepesuccinate, a semisynthetic analogue of homoharringtonine, is a first-in-class cephalotaxine that acts as a protein synthesis inhibitor that induces apoptosis in leukemic cells by reducing levels of multiple oncoproteins, including BCR-ABL1. Data pooled from two phase II trials of subcutaneous omacetaxine, 1.25 mg/m^2 twice daily for 2 weeks every 4 weeks until response, then for 1 week every 4 weeks, in patients with chronic phase CML after failure of two TKIs, a major cytogenetic response was reported in 20% and complete cytogenetic response in 10%.[8] Grade 3 to 4 side effects included cytopenias in 37 to 67% of patients, which were reversible. This led to FDA approval of omacetaxine for patients whose disease has progressed despite treatment with two TKIs.

Allogeneic Hematopoietic Stem Cell Transplantation

AHSCT (Chapter 178), a potentially curative therapy in selected patients with CML, is most effective during the chronic phase, when it is associated with a 20-year survival rate of 40 to 50%. Transplant-related mortality rates range from 5 to 50%, depending on the patient's age, whether the donor is related or unrelated, the degree of matching, and other, less important factors such as positivity for cytomegalovirus, preparative and post-transplantation regimen, and institutional expertise. Disease-free survival rates with related allogeneic stem cell transplantation are 40 to 80% in chronic phase, 15 to 40% in accelerated phase, and 5 to 20% in blastic phase. In chronic phase CML, patients younger than 30 to 40 years have disease-free survival rates of 60 to 80%, compared with only 30 to 40% for patients older than 50 years. A major limitation of allogeneic stem cell transplantation is the availability of related donors. Human leukocyte antigen (HLA)-compatible unrelated donors can be found for 50% of patients; the median time from initiation of the donor search to transplantation is 3 to 6 months.

Nonmyeloablative preparative regimens have expanded the indications for AHSCT to older patients and have reduced transplant-related mortality and complications (Chapter 178). Early results show acceptable degrees of engraftment, less mortality and organ damage, more persistent residual disease, and similar degrees of graft-versus-host disease. Patients whose CML recurs after AHSCT may respond to imatinib or new-generation TKIs, donor lymphocyte infusions, IFN-α, or a second AHSCT.

AHSCT can produce an estimated cure rate of 40% at 20 years. However, it is associated with a 1-year mortality rate of 5 to 40% and with morbidities such as cataracts, infertility, second cancers (5 to 10%), immune-mediated complications, and chronic graft-versus-host disease. Delaying AHSCT beyond 1 to 3 years after diagnosis may be associated with worse results and with occasional sudden blastic transformation, which may not be salvageable. The outcome of AHSCT may be even better after exposure to TKIs.

Choice of First-Line Chronic Myelogenous Leukemia Therapy

Currently, all three TKIs (imatinib, nilotinib, and dasatinib) are acceptable first-line therapies for CML. The choice of TKI may depend on patient and physician preferences and patient prior history and comorbidities (e.g., diabetes, pancreatitis, cardiopulmonary conditions, and pulmonary hypertension). Current oncology practice trends appear to increasingly favor nilotinib and dasatinib over imatinib as initial therapy because of their better early results, particularly the lower early incidence of CML transformation. However, the costs of TKIs may shift treatment paradigms in some emerging nations to using a particular TKI over others, or even to consider first-line AHSCT (total one-time procedure cost of $30 to $100,000) in situations in which patients or the national health care system cannot afford the burden of the TKI. Imatinib may become available in generic formulations in 2015. The price of generic imatinib is unknown but may be lower than that of other agents ($2000 to $10,000 per year). The choice of first-line TKI therapy may then depend on the differential pricing of generic imatinib versus dasatinib and imatinib and on the maturing long-term data (5 to 8 years) for survival, transformation-free survival, and event-free survival with the three TKIs. With an estimated 8-year survival rate of 93% with imatinib (considering only CML-related deaths) and the high efficacy of new-generation TKIs as salvage therapies, the survival benefit with dasatinib or nilotinib may or may not be apparent compared with imatinib first-line therapy, careful monitoring for cytogenetic relapse, and rapid institution of second-line TKI therapies at that time.

Treatment of Chronic Phase Chronic Myelogenous Leukemia after Failure of Therapy with Imatinib or Other TKIs

In several studies, the achievement of a complete cytogenetic response (Ph-positive metaphases 0%; BCR-ABLI transcripts 1%) at 12 months or later on TKI therapy was associated with significant survival benefit compared with achievement of lesser degrees of response. Therefore, achievement of complete cytogenetic response is now the primary end point of TKI therapy. The achievement of complete molecular response (nonmeasurable BCR-ABLI transcripts) offers the possibility of treatment discontinuation in the clinical trial setting. Lack of achievement of major molecular response or of complete molecular response should not be interpreted as a need to change TKI therapy or to consider AHSCT. Response assessments at earlier times on first-line TKI therapy (3 to 6 months) have shown better outcomes, with achievement of a major cytogenetic response by 3 to 6 months on imatinib therapy (Ph-positive metaphases 35%, or BCR-ABLI transcripts 10%). Although this is interpreted to mean that a change to a second TKI therapy may be considered if such an outcome is not obtained, no studies have shown that changing therapy from imatinib to second TKI for this indication has improved patient outcome. When nilotinib or dasatinib is used for first-line therapy, achievement of complete cytogenetic response by 3 to 6 months of TKI therapy has been associated with improved outcomes.

Currently, imatinib failure (requiring a change of therapy) should be strictly defined as failure to achieve a major cytogenetic response after 6 months of

imatinib therapy and a complete cytogenetic response after 12 months or cytogenetic or hematologic relapse at any later time, on an optimal imatinib dose schedule (adjusting dose for significant side effects or for intolerance and checking for treatment compliance). With the use of second-generation TKIs in the first-line setting, failure of TKI therapy has been suggested to be lack of achievement of complete cytogenetic response or BCR-ABLI transcript levels of 1% by 3 to 6 months of therapy. Such patients (<10% of the denominator) have a worse event-free survival, although their survival at 3 to 5 years remains in the range of 90%, better or equivalent to what would be achievable with AHSCT. Thus, although the early surrogate response parameters at 3 to 6 months on first-line TKI therapy predict for differences in outcome, a change of therapy at that point in time has not been proved to improve longer term prognosis.

Patients with CML whose disease progresses on imatinib therapy may be treated with a newer generation TKI or with AHSCT, as discussed earlier. Patients with CML and failure on first-line dasatinib or nilotinib therapy may possibly be salvaged with ponatinib if the CML clones exhibit a T3151 mutation. If no such mutation is detected, they could be considered for other TKI therapies, AHSCT, treatment with omacetaxine, or combined-modality therapies including TKIs and older agents (hydroxyurea, cytarabine, decitabine). The choice of AHSCT as second-line versus later salvage therapy was discussed earlier.

Treatment of Accelerated and Blastic Phase Chronic Myelogenous Leukemia

Patients with accelerated or blastic phase CML may receive initial therapy with TKIs (newer generation TKIs like dasatinib or ponatinib are preferred over imatinib) to reduce the CML burden and may be considered for early AHSCT. Response rates with combinations of TKIs and chemotherapy are 40% in nonlymphoid blastic phase CML and 70 to 80% in lymphoid blastic phase CML. Median survival times are 6 to12 months and 12 to 24 months, respectively. The addition of TKIs to chemotherapy has improved the response rates and prolonged the median survival time in blastic phase CML.

At present, AHSCT is the only curative therapy for accelerated and blastic phase CML; overall cure rates are in the range of 15 to 40% and 5 to 20%, respectively. Patients with cytogenetic clonal evolution as the only accelerated phase criterion have a long-term event-free survival rate of about 60%. Otherwise, TKIs provide hematologic responses in 80% of patients and an estimated 4-year survival rate of 40 to 55% in accelerated phase CML, but only a 40% response rate and a median survival of 9 to 12 months in blastic phase CML. Patients in the accelerated or blastic phase should be encouraged to participate in investigational strategies to improve their prognosis. Patients with de novo CML accelerated phase have a better outcome with first-line TKI therapy than patients who evolve from chronic to accelerated phase. The estimated 6- to 8-year survival rates with TKI therapy in de novo accelerated phase CML are 60 to 80%. Such patients may continue on TKI therapy as their long-term treatment if they achieve a complete cytogenetic response on TKI therapy.

Special Therapeutic Considerations

Patients with severe leukocytosis and manifestations of leukostasis may benefit from initial leukapheresis. Severe thrombocytosis uncontrolled with anti-CML measures may respond to anagrelide, thiotepa, IFN-α, 6-mercaptopurine, 6-thioguanine, hydroxyurea, and platelet pheresis. CML during pregnancy may be controlled with pheresis in the first trimester and then with hydroxyurea until delivery. Use of IFN-α during pregnancy has been reported anecdotally to be safe. An analysis of 125 babies delivered to women with CML on imatinib therapy (who discontinued imatinib once the pregnancy was known) showed most babies to be healthy. However, the study demonstrated imatinib therapy to be associated with a syndrome of ocular, skeletal, and renal abnormalities in three babies delivered. Therefore, imatinib (and presumably other TKIs, although there is little experience with them) should be discontinued immediately once pregnancy is documented, but abortion is not recommended because fetal malformations are rare. Partners of men with CML on TKI therapy who become pregnant have delivered normal babies. Splenectomy can be useful as a palliative measure in patients with massive, painful splenomegaly, hypersplenism, or thrombocytopenia.

Monitoring Response to Therapy in Chronic Myelogenous Leukemia

With TKI therapy, complete cytogenetic response, major molecular response, and even complete molecular response have been achieved. These response rates improve with continued therapy and are higher with new-generation TKIs (dasatinib, nilotinib) compared with imatinib as first-line therapy (see Table 184-3). Techniques have been developed to measure these responses more accurately (rather than relying on only 20 metaphases by cytogenetic analysis), with less tedious and less painful procedures (peripheral blood rather than marrow studies), and at levels below the level of detection by routine cytogenetic evaluations. FISH studies with improved probes can measure 200 interphase cells using peripheral blood, and they have false-positive rates of less than 2 to 3%. Quantitative PCR tests usually measure the BCR-ABLI transcript levels (ratio of the abnormal message, BCR-ABLI, to a normal message, such as ABL1). BCR-ABLI transcript levels of 0.1% [IS], about a 3-log reduction of disease, have been associated with a very low risk for CML relapse on TKI therapy. This is referred to as a *major molecular response*. Undetectable BCR-ABL1 transcript levels, (usually <0.0032% [IS], or 4.5 log of reduction) are sometimes referred to as *complete molecular response*. The percentage of patients achieving complete molecular response is significantly higher with new-generation TKIs compared with imatinib.

In monitoring the response to TKI-based therapies, patients require a bone marrow analysis before treatment (to determine the percentages of blasts and basophils and clonal evolution) and FISH and quantitative PCR analyses. Quantitative PCR can be falsely negative at diagnosis in 5 to 8% of patients with unusual breakpoints and messages (e.g., b2a3 or b3a3) if proper procedures are not used. Thus, knowledge of the pretreatment BCR-ABL1 transcript levels avoids the false assumption of complete molecular response because of the false negativity. Bone marrow analysis may be useful at 6 and 12 months (to assess cytogenetic response and confirm complete cytogenetic response) and once every 1 to 3 years in patients with stable, durable complete cytogenetic responses (to look for chromosomal abnormalities in both Ph-positive and Phnegative cells). Monitoring in patients with confirmed durable complete cytogenetic responses can be continued with either FISH or quantitative PCR studies every 6 months (or more often, such as every 3 months, if there are concerns about significant and consistent increases in BCR-ABLI transcripts levels). Some CML experts have shifted from monitoring by marrow studies to monitoring by peripheral blood studies using molecular analysis, with or without FISH studies. Among patients achieving major molecular response, molecular analysis without FISH studies is sufficient.

Resistance to imatinib therapy (discussed earlier) requires a change of therapy to other TKIs, TKI combinations with chemotherapy, or consideration of AHSCT. It is important to emphasize that many patients with apparent CML resistance to a TKI therapy may be noncompliant with the treatment. This should be discussed clearly with patients when they exhibit signs of CML progression by either molecular or FISH studies. If they are noncompliant, they may continue on the same TKI treatment with emphasis on compliance and evaluated 3 to 6 months later, before CML resistance is declared.

Among patients in complete cytogenetic response on a particular TKI, failure to achieve a major molecular response does not, at present, indicate resistance to the particular TKI or a need to change therapy. Mutational studies are recommended in patients who develop cytogenetic or hematologic resistance or relapse on a particular TKI therapy, when considering changing therapy to another TKI. The detection rate of mutations in this situation is 30 to 50%. Mutational studies are not recommended in patients in complete cytogenetic response on a particular TKI because the detection rate of mutations are then very low (<3 to 5%).

FUTURE DIRECTIONS

In 2014, patients with CML have multiple treatment options, including several TKIs, omacetaxine (protein synthesis inhibition), and several older agents (hydroxurea, IFN-α, busulfan, 6-mercaptopurine, cytarabine, decitabine). Most patients with CML would be expected to live their normal functional life and to be functionally, although not molecularly, cured, as long as they continue therapy with TKI-based regimens, are compliant with the treatment, and are monitored closely for signs of resistance in order to change therapy in a timely manner and/or consider AHSCT before CML progression. Future directions will focus on the potential molecular cure of CML (i.e., achievement of a durable complete molecular response and its persistence after discontinuation of TKI therapy). This is not a trivial issue because, with effective TKI therapy and full treatment penetration worldwide (to 100% of all diagnosed patients and continuation of TKI therapy without interruptions), the prevalence of CML would increase annually and plateau in about 2030 to 2040 at a rate 35 times the incidence. This figure is estimated to be close to 160,000 patients with CML in the United States and about 3 million patients worldwide. This may represent a considerable burden on patients and the health care systems in relation to drug availability, compliance, potential development of long-term side effects, and costs. Therefore, it is critical to continue research into therapies that increase the rates of durable complete molecular responses. This may be achievable with the current more potent new-generation TKIs alone or in combination with other available (pegIFN-α, omacetaxine, decitabine) or investigational therapies (JAK2 inhibitors, hedgehog inhibitors, stem cell poisons, vaccines). Such strategies may improve the eradication of minimal residual disease, potentially obviating the need for indefinite therapy with TKIs. Further understanding of the pathophysiologic events downstream of BCR-ABLI may help in the development of new strategies to target them.

PROGNOSIS

Treatment of CML with imatinib and other TKIs has revolutionized the outcome of the disease. In patients with newly diagnosed CML, imatinib therapy is associated with an estimated 8- to 10-year survival rate of 85% (93% if non-CML deaths are censored). If this favorable trend continues with longer follow-up, the median survival time in CML may exceed 25 years. The annual mortality rate of CML with TKIs in the first decade of experience has been reduced from the historical rate of 10 to 20%, down to 2% (1% if only CML deaths are counted). Many well established poor prognostic factors in CML (e.g., older age, splenomegaly, presence of marrow fibrosis, deletion of 9q) have lost much of their prognostic importance since the advent of TKI therapy. With AHSCT, cures can be expected in 40 to 80% of patients with chronic phase CML, 15 to 40% of those with accelerated phase CML, and 5 to 20% of those with blastic phase CML.

CHRONIC MYELOMONOCYTIC LEUKEMIA AND ATYPICAL CHRONIC MYELOID LEUKEMIAS

DEFINITION AND EPIDEMIOLOGY

Although superficially resembling CML in its clinical and morphologic presentation, CMML should be considered a separate entity because of its particular clinical, therapeutic, and prognostic aspects. CMML is a hybrid entity manifesting as a proliferation of the myeloid monocytic series and dysplasia of the erythroid-megakaryocytic series. Patients with CMML are older (median age, 65 to 70 years) than most patients with CML.

PATHOBIOLOGY

The cytogenetic findings in patients with CMML are either normal or involve an additional chromosome 8 or findings other than the Ph chromosome. Patients with CMML have *RAS* mutations in 40 to 60% of cases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients often present with symptoms related to anemia and thrombocytopenia (fatigue, bleeding). Other typical features include splenomegaly, leukocytosis, and monocytosis. Organ infiltration (lymph nodes, skin, liver) is less common. Basophilia and thrombocytosis are not presenting features. High-frequency mutations in the granulocyte colony-stimulating factor 3 receptor gene (*CSF3R*) in *chronic neutrophilic leukemia* (CNL) and in some patients with *atypical chronic myeloid leukemia* (aCML) have been identified. In addition, recurrent mutations in *SETBP1* (Set binding protein) have been identified in 25% of aCML patients.

TREATMENT AND PROGNOSIS

Rx

AHSCT (Chapter 178), which is the only curative modality, should be considered first-line therapy in candidate patients. Other therapies include hydroxyurea to control leukocytosis, erythropoietin to improve anemia, azacitidine or decitabine (both approved by the FDA for the treatment of CMML), topotecan and cytarabine or other intensive anti-AML (Chapter 183) regimens for CMML transformation, splenectomy for symptomatic splenomegaly and/or hypersplenism, and investigational agents. Inhibition of Janus kinase 2 or SRC kinase signaling downstream of mutated CSF3R is being explored therapeutically.

Poor prognostic factors include the presence of anemia (hemoglobin <10 g/dL), thrombocytopenia, and more than 5% blasts. Median survival is 12 to 18 months.

HAIRY CELL LEUKEMIA

DEFINITION AND EPIDEMIOLOGY

Hairy cell leukemia (HCL) is an uncommon and indolent B-cell leukemia (1 to 2% of all leukemias). The median age at diagnosis is 50 years, and there is a 4 : 1 male preponderance.

PATHOBIOLOGY

The cell of origin of HCL is the B lymphocyte, as documented by the demonstration of heavy and light chain immunoglobulin gene rearrangements. In a series of 47 patients, all had a *BRAF V600E* activating mutation. Hairy cells express CD19, CD20, CD11C, CD103, FMC7, and CD22, but not CD21, CDS, CD10, or CD23. The cells demonstrate a κ or λ light chain phenotype. The cells also express CD25 (TAC), the low-affinity interleukin-2 (IL-2) receptor, and CD103, a unique hairy cell antigen. High levels of soluble IL-2 receptor (more than five times normal) are present in the sera of almost all patients with HCL, with extremely high levels noted in many cases. Immune dysfunction is wide ranging in HCL. Monocytopenia is universal; B and T lymphocytes are decreased in number; the CD4/CD8 (helper T/suppressor T) ratio is often inverted; and skin test reactivity to recall antigens is impaired, as is antibody-dependent cellular cytotoxicity. Humoral immunity is relatively preserved, with normal immunoglobulin levels. Marrow failure in HCL may be due in part to inhibitory factors (e.g., tumor necrosis factor) produced by the leukemic infiltrate; the pancytopenia is often more marked than would be anticipated from the degree of leukemic infiltration.

CLINICAL MANIFESTATIONS

Most patients present with pancytopenia and splenomegaly. Patients may also have fatigue, fever, weight loss, and infection secondary to granulocytopenia or monocytopenia. Leukocytosis is uncommon, and lymphadenopathy is rare. Anemia is present in up to 85% of patients, whereas leukopenia and thrombocytopenia are present in 60 to 75%. The cytopenias are caused by a combination of bone marrow failure due to leukemic infiltration and hypersplenism. Patients may experience repeated infections and, rarely, a systemic vasculitis resembling polyarteritis nodosa. Although bacterial infections occur, as would be expected with neutropenia, patients with HCL have a predilection to develop tuberculosis, atypical mycobacterial infections, and fungal infections, perhaps related to the severe monocytopenia that is characteristic of this disorder.

DIAGNOSIS

In conjunction with the clinical features, careful examination of the peripheral blood smear may demonstrate the occasional typical cells with cytoplasmic projections, giving rise to the name *hai1y cell leukemia* (Fig. 184-5). The hairy cells are 10 to 15 mm in diameter, with pale blue cytoplasm, a nucleus with a loose chromatin structure, and one or two indistinct nucleoli. Bone marrow aspiration is often inadequate owing to increased deposition of reticulum, collagen, and fibrin; bone marrow biopsy is usually necessary. Bone marrow involvement is interstitial or patchy, and the infiltrate is characterized by widely spaced nuclei due to the abundant cytoplasm, giving rise to the commonly described fried-egg appearance.

Hairy cells exhibit a strong acid phosphatase (isoenzyme 5) cytochemical reaction in 95% of cases, a reaction that is resistant to the inhibitory effect of tartaric acid (TRAP). Other lymphoproliferative diseases are rarely TRAP positive. Electron microscopy clearly demonstrates the microvillar projections. Often, ribosomal-lamellar complexes, which are characteristic but not diagnostic of HCL, can be identified. The peroxidase stain is negative, and lysozyme activity is absent in hairy cells, thereby differentiating these cells from monocytes.

Differential Diagnosis

The differential diagnosis must distinguish HCL from non-Hodgkin lymphoma (Chapter 185) or chronic lymphocytic leukemia (CLL) (see later), which can manifest with predominant splenomegaly and minimal lymphadenopathy. Some patients with a myelodysplastic syndrome (Chapter 182) or

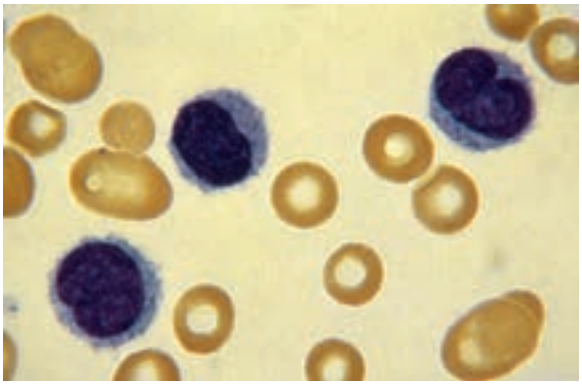

FIGURE 184-5. Hairy cell leukemia. Peripheral smear shows hairy cells with blue-gray cytoplasm; fine, hair-like projections (resembling ruffles); and oval or slightly indented nuclei with loose chromatin and indistinct nucleoli. (Courtesy Andrew Schafer, MD.)

a chronic myeloproliferative neoplasm (Chapter 166) have splenomegaly and pancytopenia with only a few atypical cells. Patients with other diseases, such as systemic lupus erythematosus (Chapter 266) and other autoimmune diseases, B-cell and T-cell prolymphocytic leukemias (see later), infiltrative splenomegaly (Chapter 168), or tuberculosis (Chapter 324), may have splenomegaly and cytopenia, but these diagnoses can usually be made by history, physical examination, and appropriate blood and bone marrow tests. Splenomegaly, cytopenia, and nonaspirable marrow in a middle-aged man should create a high index of suspicion for HCL. Splenectomy or lymph node biopsy is sometimes necessary to establish the diagnosis in difficult cases. Cases of HCL variant manifest with higher WBC counts, are TRAP negative, have prominent nucleoli, and are only occasionally positive for antibodies against CD25. HCL variant does not respond as well to the agents that are usually effective in the management of typical HCL.

TREATMENT

Rx

A small proportion (<5%) of patients with HCL do not require therapy. These patients have mild cytopenias, are not transfusion dependent, have no history of infections, and have a low level of marrow infiltration by hairy cells. 2-Chlorodeoxyadenosine (cladribine), an adenosine analogue that *is* resistant to deamination by adenosine deaminase, produces complete remission in more than 80% of HCL patients after a single course of 0.1 mg/kg/day for 7 days given by continuous intravenous infusion, and it is now the recommended first-line therapy.[9] It can also be given at 0.14 mg/kg/day for 5 days as a short daily intravenous infusion. Remissions are durable, and patients who relapse can often attain a second remission after retreatment with cladribine. The drug is well tolerated, with a low infection rate. Despite long-lasting suppression of $CD4^+$ lymphocyte counts, there does not appear to be an increase in late opportunistic infections or second malignancies. Partial response to purine analogs is regarded as a poor prognostic factor, and a second course of purine analog therapy is recommended if patients do not enter complete remission, with the addition of rituximab to be considered. Rituximab in combination with a purine analogue is often used in the treatment of relapsed disease.

Deoxycoformycin (pentostatin; 4 mg/m^2 weekly or every 2 weeks for up to 6 months), an adenosine deaminase inhibitor, produces complete remission in 70 to 80% of patients. The response to treatment is rapid. Toxicity includes nausea and vomiting, infection, renal and hepatic dysfunction, conjunctivitis, and photosensitivity, albeit mild in most cases.

Human leukocyte interferon (HuIFN), or recombinant interferon-α (r-IFN-α), rapidly improves granulocyte, platelet, and hemoglobin levels (within 1 to 3 months); reduces spleen size; and decreases marrow infiltration. Peripheral blood cell counts return to normal in 80% of cases, but complete remission is uncommon. In addition, when treatment is discontinued, relapse occurs within 1 to 2 years. Rituximab, the monoclonal antibody targeting CD20, also produces responses; eight weekly infusions appear to be more effective than four. Two immunotoxins can produce responses in refractory patients. LMB2 is composed of the Fc portion of the anti-TAC antibody linked to a *Pseudomonas* exotoxin. Moxetumomab also contains a *Pseudomonas* exotoxin linked to an antibody targeting CD22. The B-RAF inhibitor, vemurafenib, has successfully been used to treat a patient with HCL, and a clinical trial in relapsed HCL is underway.[10] Splenectomy is recommended mainly for patients with splenic infarcts or massive splenomegaly.

PROGNOSIS

More than 85 to 90% of patients treated with cladribine or pentostatin are expected to be alive at 10 years.

CHRONIC LYMPHOCYTIC LEUKEMIA

DEFINITION

CLL is a neoplasm characterized by the accumulation of monoclonal lymphocytes of B-cell origin. The cells accumulate in the bone marrow, lymph nodes, liver, spleen, and occasionally other organs. After decades of chemotherapy-based treatment of CLL, recent progress has turned attention to mechanism-driven therapy with targeting of the B-cell receptor signaling pathway.[11]

EPIDEMIOLOGY

CLL is the most common leukemia (one third of all cases) in the Western world and is twice as common as CML. The disease occurs rarely in those younger than 30 years; most patients with CLL are older than 60 years. CLL increases in incidence exponentially with time; by age 80 years, the incidence rate is 20 cases per 100,000 persons per year. The male-to-female ratio is approximately 2 : 1. The incidence of CLL among Asians in Japan and China is only 10% of that in the United States and other Western countries. Intermediate incidence rates are seen in persons of Hispanic origin.

The cause of CLL is unknown. Ionizing radiation and viruses have not been associated with CLL, although hepatitis C infection has recently been associated with splenic lymphoma with villous lymphocytes (another indolent B-cell disorder). Familial clustering in CLL is more common than in other leukemias; first-degree relatives of patients have a two- to four-fold higher risk and develop CLL at a younger age compared with the general population. Farmers have a higher incidence of CLL than do those in other occupations, raising the possibility of an etiologic role for herbicides or pesticides. Agent Orange, the defoliating agent used in Vietnam, has been associated with the development of CLL.

PATHOBIOLOGY

Leukemia cells in CLL are homogeneous and have the appearance of normal mature lymphocytes. However, clonality can be documented by the presence of immunoglobulin gene rearrangements and the restriction to either κ or λ light chains on the cell surface. The cells express low-intensity monoclonal surface immunoglobulin (Smig; usually immunoglobulin [Ig] M ± IgD) and the pan-B-cell antigens CD19, CD20, CD23, and CD24 in almost all cases, as well as CD21 (which includes the receptor for the Epstein-Barr virus and the C3d component of complement) in more than 75% of cases. Almost all cells exhibit Ia antigen and receptors for the Fc fragment of IgG and spontaneously form rosettes with mouse erythrocytes. In addition to B cell antigens, CLL cells express CDS (Leu 1, Tl, and TlOl), a pan-T-cell antigen. Other T-cell antigens are absent. CD25 (TAC, IL-2 receptor) antigen is positive in about 25% of cases. T cells are increased in number at diagnosis, and the CD4/CD8 ratio is often inverted, owing to a relatively greater increase in $CD8^+$ cells. The CD4/CD8 ratio declines as the disease progresses and after therapy. The T cells have a blunted response to T-cell mitogens and decreased delayed hypersensitivity reactions to recall antigens. However, these T-cell functions are impaired by factors produced by the CLL cells because purified T cells have a normal response to T-cell mitogens.

GENETICS

Genes mutated in CLL include *TP53* (15% of patients), *SF3B1* (15%), *ATM* (9%), *MYD88* (10%), and *NOTCH1* (4%). Standard cytogenetic analysis identifies abnormalities in 40 to 50% of cases of CLL, but CLL cells have low mitotic activity. By FISH, the likelihood of detecting abnormalities increases to 80%. A 13q deletion is the most common abnormality; other abnormalities include llq deletion (15 to 20%), trisomy 12 (15 to 20%), and 17p deletion (5 to 10%). The 17p deletion increases in frequency as the disease progresses, recurs after therapy, and is associated with a very poor prognosis. The llq deletion also is associated with a poorer prognosis, whereas the 13q deletion, if present as the sole abnormality, is associated with a favorable prognosis.

CLINICAL MANIFESTATIONS

Most patients with CLL do not have symptoms, and the disease is diagnosed when absolute lymphocytosis is noted in the peripheral blood (Fig. 184-6)

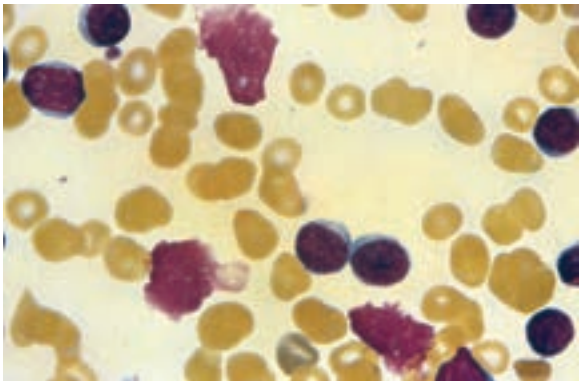

FIGURE 184-6. Chronic lymphocytic leukemia. Peripheral smear shows that the predominant leukocytes are "normal," mature-appearing lymphocytes, with occasional "smudge" cells. (Courtesy Andrew Schafer, MD.)

during evaluation for other illnesses or when the patient undergoes a routine physical examination. Symptoms such as fatigue, lethargy, loss of appetite, weight loss, and reduced exercise tolerance are nonspecific. Many patients have enlarged lymph nodes. B symptoms (fever, night sweats, weight loss) are rarely present initially, and their presence in later stages of the disease suggests transformation to large cell lymphoma (Richter transformation). The most common infections are sinopulmonary. As the disease progresses, the frequency of neutropenia, T-cell deficiency, and hypogammaglobulinemia increases, resulting in infections with gram-negative bacteria, fungi, and viruses such as herpes zoster and herpes simplex.

The major physical findings relate to infiltration of the reticuloendothelial system. Lymphadenopathy with discrete, soft, mobile lymph nodes is present in two thirds of patients at diagnosis. Later, as the lymph nodes enlarge, they can become matted. Enlargement of the liver or spleen is less common at diagnosis (approximately 10% and 40% of cases, respectively) but occurs more frequently with progression. Organ failure resulting from infiltration with CLL is uncommon. Infiltration of the central nervous system in CLL is rare, and central nervous system symptoms are more likely to be caused by opportunistic infections such as cryptococcosis or listeriosis.

DIAGNOSIS

CLL is characterized by absolute lymphocyte counts that typically range from 5000 to 600,000 $\times 10^9/\mu L$ in the peripheral blood. Even with markedly elevated WBC counts, hyperviscosity symptoms rarely occur, probably because of the small size and pliability of the cells. Anemia (hemoglobin <11 g/dL) is present in 15 to 20% of patients at diagnosis and thrombocytopenia (platelet count $<100 \times 10^9/\mu L$) in 10%. However, bone marrow replacement and hypersplenism, which are seen with progressive disease, increase the frequency of anemia and thrombocytopenia. The anemia is usually normochromic and normocytic, and the reticulocyte count is normal unless the patient has autoimmune hemolytic anemia (Chapter 160), which usually results from the development of a warm-reacting IgG antibody. The diagnosis of autoimmune hemolytic anemia, which occurs in 10% of cases, is confirmed by a positive direct Coombs (DAT) test (80 to 90% of cases), reticulocytosis, a low serum haptoglobulin concentration, and an elevated unconjugated serum bilirubin level. In such patients, reactive erythroid hyperplasia as a response to the hemolysis may be masked in the bone marrow by the marked lymphocytic infiltration. Cold agglutinin hemolysis occurs rarely in CLL. Autoimmune thrombocytopenia (immune thrombocytopenic purpura; Chapter 172) can be diagnosed in 10 to 15% of cases. The antibodies causing red cell and platelet destruction are not produced by the CLL cells, and the mechanisms for the associated autoimmune diseases are not known. Pure red cell aplasia (Chapter 165) is an additional, underappreciated cause of anemia in CLL.

The lymphocytes in CLL are indistinguishable on light or electron microscopy from normal small B lymphocytes (see Fig. 184-6). On bone marrow aspiration, the proportion of lymphocytes is greater than 30% and may be up to 100%. Four patterns of lymphocyte infiltration on bone marrow biopsy occur: nodular (15%), interstitial (30%), mixed nodular and interstitial (30%), and diffuse (35%). Most early-stage cases have one of the first three patterns; diffuse histology is common in advanced-stage disease and becomes more prominent as the disease evolves. A diffuse histologic pattern confers a poor prognosis regardless of the stage of disease.

Differential Diagnosis

There are many diseases that can cause lymphocytosis, including pertussis (Chapter 313), cytomegalovirus (Chapter 370), Epstein-Barr virus mononucleosis (Chapter 377), tuberculosis (Chapter 324), toxoplasmosis (Chapter 349), chronic inflammatory disorders, and autoimmune syndromes. These diseases are seldom confused with B-cell CLL, largely because the lymphocytosis in these conditions is usually less than $15 \times 10^9/\mu L$ and is not sustained. If doubt persists, immunophenotypic or molecular studies can distinguish the monoclonal lymphocytosis in CLL from the T-cell or polyclonal B-cell proliferation in the other disorders.

In individuals 62 to 80 years old, monoclonal CLL-phenotype B cells are found in about 5% of individuals with normal blood counts. In patients with greater than 4000 lymphocytes/mL, about 45% have CLL, about 40% have reactive lymphocytosis, and about 15% have monoclonal CLL-phenotype B cells that confer a 1.1% per year risk for developing CLL. The latter is a more recently recognized entity that has been termed *monoclonal B-cell lymphocytosis*. In patients ultimately diagnosed with CLL, B-cell clones were previously present in peripheral blood in 98% of patients, sometimes many years before diagnosis.

Other Chronic Lymphocytic Leukemias

The more difficult differential diagnosis is distinguishing CLL from other lymphoproliferative disorders such as prolymphocytic leukemia (PLL), splenic lymphoma with villous lymphocytes, HCL (see earlier section), the leukemic phase of mantle cell lymphoma, and Waldenström macroglobulinemia (Chapter 187). Although certain clinical features are more common in some of these disorders (e.g., marked splenomegaly with minimal or no lymphadenopathy in PLL, splenic lymphoma, and HCL vs. extensive lymphadenopathy with or without splenomegaly in CLL), none of these clinical features is specific. The differential diagnosis therefore depends largely on histopathologic and, more specifically, immunophenotypic features (Table 184-4).

Prolymphocytic Leukemia

PLL is an uncommon disease (incidence <5% that of CLL), and its characteristics of massive splenomegaly, minimal lymphadenopathy, and markedly elevated WBC count (often $>100 \times 10^9/\mu L$), with 10 to 90% of the cells being prolymphocytes, distinguish this disease from typical B-cell CLL. Prolymphocytes are larger cells that have a distinct nucleolus and express FMC-7. The male-to-female ratio is 4 : 1, and the median age at diagnosis is 70 years. Survival is shorter than in CLL (median, 3 years), and response to therapies usually applied in CLL is poor. A serum paraprotein, typically IgG or IgA, is present in one third of cases. The immunoglobulin on the surface of the cells is occasionally IgG or IgA, not IgM ± IgD, as in CLL. Several karyotypic abnormalities have been reported in PLL, including t (11; 14) (q13; q32). Deletions of llq3, 23, and 17p are more common in B-cell PLL than in CLL. Abnormalities in the *TP53* oncogene are found in 75% of cases of B-cell PLL. One fifth of PLL cases express a T-cell phenotype.

Small Lymphocytic Lymphoma

Small lymphocytic lymphoma (SLL) shares histopathologic and immunophenotypic features with CLL, differing only in the lack of lymphocytosis in

TABLE 184-4 DIFFERENTIAL DIAGNOSIS OF INDOLENT LYMPHOPROLIFERATIVE DISORDERS

DISEASE	LYMPHADENOPATHY (%)	SPLENOMEGALY(%)	CELL OF ORIGIN (BIT)	POSITIVE MARKERS			
				Smlg	*CD5*	*CD19, CD20 (%)*	*Other*
Chronic lymphocytic leukemia (CLL)	75	50	B (20 : 1)	Weak	>90%	90	Mouse red blood cell receptors
Prolymphocytic leukemia (PLL)	33	95	B (4 : 1)	Bright	T-cell PLL	75	FMC-7
Hairy cell leukemia	<10	80	B (T rare)	Bright	—	>90	CD25, CD11C, CD103
Lymphoma (leukemic phase)	90	90	B (T rare)	Bright	Some	>90	CD10
Splenic lymphoma with villous lymphocytes	10	80	B	Bright	20%	>90	FMC-7, CD22
Waldenström macroglobulinemia	33	33	All B	Weak	Some	Many	CD38, PCA-1
Large granular lymphocytosis	10	10	All T	Absent	-	-	CD2, CD3, CD8

CD2 = pan-T cell; CD3 = pan-mature T cell; CDS = pan-T cell, B-cell CLL; CD8 = T cell (suppressor cytotoxic); CD10 = early B cell; CD11C = hairy cell, activated T cell, NK cell; CD19 =early pan-B cell; CD20 = pan-B cell; CD25 = low-affinity interleukin-2 receptor; CD38 = activated B cell, thymocyte, plasma cell; FMC-7 = PLL, hairy cell leukemia; PCA-1 = plasma cell; Smlg = monoclonal surface immunoglobulin.

the peripheral blood. The bone marrow in SLL may or may not have more than 30% lymphocytes. LFA-1 adhesion protein is much more commonly expressed on SLL cells than on CLL cells. Other lymphomas, such as follicular and mantle cell lymphomas (Chapter 185), occasionally manifest a leukemic phase on initial presentation. Follicular lymphoma cells are often cleaved on light microscopy, have bright staining for Smlg, and are positive for FMC-7 and CD10. Lymph node biopsy should be performed to identify these cases with greater precision. The presence of lymphoma cells in the blood in follicular lymphoma is more common with advanced disease. Follicular lymphoma can usually be identified by the presence of the translocation t(14;18) and consequent *BCL2* rearrangement, both of which are rare in CLL. The WBC count in Waldenström macroglobulinemia (Chapter 187) is usually much lower than in CLL ($<10 \times 10^9/\mu L$), and many patients are leukopenic. The cells have a plasmacytoid appearance, CD38 and PCA-1 positivity, and more Smlg and cytoplasmic Ig. A serum monoclonal IgM peak is present in almost all cases of Waldenström macroglobulinemia but is uncommon in CLL.

T-Cell Leukemias

The predominant clinical manifestation of *Sézary syndrome* (a $CD4^+$ T-cell malignant disorder related to *mycosis fungoides*) is chronic exfoliative erythroderma with a low number of circulating monoclonal T cells. The clinical and laboratory differentiation from CLL is not difficult.

Other T-cell malignant disorders with peripheral blood involvement are *adult T-cell leukemia-lymphoma* and *large granular lymphocytosis*, also referred to as *large granular lymphoproliferative disorder*, T-cell lymphocytosis with neutropenia, or T-γ lymphocytosis syndrome. Adult T-cell leukemia-lymphoma is associated with a retrovirus (human T-lymphotropic virus I) and is common in Japan and the Caribbean. It frequently manifests with lytic bone lesions and hypercalcemia. In T-cell large granular lymphoproliferative disorders, the absolute lymphocyte count is usually low ($<5 \times 10^9/\mu L$). The disease is defined by clonal amplification of either $CD3^+$ cytotoxic T-lymphocytes or $CD3^-$ natural killer (NK) cells.[12] These patients often have splenomegaly, neutropenia, and rheumatoid arthritis–like symptoms. A subset, called NK-cell large granular lymphocytosis, has an NK-cell phenotype ($CD16^-$) and no molecular evidence of T-cell receptor rearrangement. The lymphocytes in large granular lymphoproliferative disorder have abundant cytoplasm with azurophilic granules. Most patients have a benign course, although repeated infections can occur.

Staging and Prognostic Factors

The natural history of CLL is heterogeneous, with survival times ranging from 2 to 20 years after diagnosis. Either of two validated clinical staging systems can be used. The Rai staging system (1975) defines five stages and is most frequently used in the United States, whereas the Binet system (1981) defines three stages and is most frequently used in Europe (Table 184-5). Patients with anemia and thrombocytopenia (Rai III and IV, Binet C) have the worst prognosis; patients with lymphocytosis alone (Rai 0, some Binet A patients) have an excellent prognosis. A group of patients with a lymphocyte count of less than $30 \times 10^9/\mu L$, hemoglobin greater than 13 g/dL, platelet count greater than $100 \times 10^9/\mu L$, fewer than three involved node areas, and lymphocyte doubling time greater than 12 months has been described as having "smoldering" CLL, with survival equal to that of an age- and sex-matched control population. Patients tend to progress through stages, with many patients developing more sites of involvement over time and eventually experience marrow failure; however, anemia and thrombocytopenia can develop abruptly, even without antibody-mediated destruction or markedly increased tumor burden.

Other adverse factors include a diffuse pattern of lymphocytic infiltration observed on bone marrow biopsy; molecular abnormalities, including deletion of llq or 17p; advanced age; male sex; elevated serum levels of thymidine kinase, β_2-microglobulin, and soluble CD23; rapid lymphocyte doubling time; an increased proportion of large or atypical lymphocytes in the peripheral blood; and lack of somatic mutation of the *VH* gene within the B-CLL cell or the presence of the ZAP-70 protein or CD38 on the CLL cell surface.

TREATMENT

The major therapeutic questions are when to treat and which therapeutic regimen to use. Recent progress has transformed the treatment of CLL, initially from chemotherapy to chemoimmunotherapy and now to mechanism-driven drugs that target the B-cell receptor signaling pathway.[13] Patients with CLL are usually older, and the prognosis of the disease is variable (with some early-stage cases being stable for 10 to 20 years). Treatment of early-stage CLL (Rai 0, Binet A) is delayed until the disease progresses. In randomized trials, early treatment with alkylating agents did not prolong survival and was associated with a heightened risk for developing second malignant tumors. Treatment of Rai stages III and IV (Binet stage C) is recommended at the time of diagnosis because of the morbidities associated with cytopenias and the poor survival time of these patients. Treatment of intermediate-stage disease (Rai I and II, Binet B) is recommended if symptomatic disease (fever, sweats, weight loss, severe fatigue) or massive lymphadenopathy, with or without hepatosplenomegaly, is present.

Medical Therapy

Chemotherapy

Fludarabine monophosphate (25 mg/m^2/day for 5 days every 4 weeks), an adenosine analogue, is approved by the FDA for treatment of relapsed CLL; it produces an overall response rate of 50 to 60%. The dose-limiting toxicity is myelosuppression. In a large randomized trial of initial therapy for CLL, fludarabine was compared with chlorambucil, the historical standard therapy; it resulted in higher overall and complete remission rates, longer duration of remission, and improved response rates on crossover. Ten-year follow-up showed a survival benefit in the fludarabine arm. Cladribine is used primarily in Europe, where it appears to have efficacy similar to fludarabine. Pentostatin has not been as widely studied in CLL as in HCL.

The combination of fludarabine and cyclophosphamide (FC) was a logical attempt to improve on the efficacy of fludarabine alone by combining it with the other most active agent in this disease, an alkylating agent. The FC combination has been compared with fludarabine alone in three randomized trials. All these trials consistently showed a higher complete response rate, higher overall response rate, and longer progression-free survival with the FC combination.

TABLE 184-5 RAI AND BINET STAGING SYSTEMS IN CHRONIC LYMPHOCYTIC LEUKEMIA

STAGE	LYMPHOCYTOSIS	LYMPHADENOPATHY	HEPATOMEGALY OR SPLENOMEGALY	HEMOGLOBIN (g/dL)	PLATELETS $\times 10^3$/mL
RAI STAGING SYSTEM					
0	+	–	–	≥11	≥100
I	+	+	–	≥11	≥100
II	+	±	+	≥11	≥100
III	+	±	±	<11	≥100
IV	+	±	±	Any	<100
BINET STAGING SYSTEM					
A	+	±	± (<3 lymphatic groups* positive)	≥10	≥100
B	+	±	± (≥3 lymphatic groups* positive)	≥10	≥100
C	+	±	±	<10†	<100†

*The three lymphatic groups are (1) cervical, axillary, and inguinal nodes; (2) liver; and (3) spleen. Each group is considered one group whether unilateral or bilateral.
†The criterion is hemoglobin <10 g/dL and/or platelets $<100 \times 10^3$/mL.

TABLE 184-6 DEFINITION OF REMISSION IN CHRONIC LYMPHOCYTIC LEUKEMIA: THE INTERNATIONAL WORKSHOP IN CHRONIC LYMPHOCYTIC LEUKEMIA–NATIONAL CANCER INSTITUTE WORKING GROUP CRITERIA

CRITERION	COMPLETE REMISSION	PARTIAL REMISSION
Physical examination		
Nodes	None ≥1.5 cm	≥50% decrease
Liver/spleen	Not palpable	≥50% decrease
Symptoms	None	N/A
Peripheral blood		
Neutrophils	≥1500 m/L	≥1500/mL or ≥50% increase from baseline
Platelets	>100,000/μL	>100,000/μL or ≥50% increase from baseline
Hemoglobin	>11 g/dL	11 g/dL or >50% increase from baseline
Lymphocytes	≤4000 /mL	>50% decrease
Bone marrow	<30%, no B-lymphoid nodules	50% reduction in infiltrate or B-lymphoid nodules

After therapy, many patients remain stable for months to years before progressive disease indicates the need for further treatment. The goal of treatment is to achieve complete response (Table 184-6).

Bendamustine is a potent alkylating agent that has some structural similarity to nucleoside analogues, but preclinical data suggest that it does not function as a nucleoside analogue. Bendamustine was recently approved by the FDA for the treatment of CLL based on a randomized trial comparing this agent to chlorambucil as initial therapy for patients with CLL. Complete and overall response rates were higher with bendamustine, and progression-free survival was longer. The main side effect is myelosuppression.

Monoclonal Antibodies Alone and with Chemotherapy

Rituximab, a monoclonal antibody targeting the CD20 antigen, is associated with response rates of about 50% when given at the standard dose (375 mg/m^2/week for 4 weeks) as initial therapy for CLL and significantly lower rates when used in the salvage setting; complete responses are rare in either situation. The major benefit of this antibody appears to be its use in combination with chemotherapy. Fludarabine combined with rituximab produces better responses than those seen historically with fludarabine alone. In addition, progression-free and overall survival rates are better than those seen in the historical cohort. A three-drug regimen of fludarabine, cyclophosphamide, and rituximab (FCR) appears to produce the best and most durable complete remission rates when used as first-line therapy. A randomized trial compared the activity of FC to that of FCR. The complete response rate and the overall response rate were significantly higher with FCR, and progression-free and overall survival rates were significantly longer than with chemotherapy alone. A trial of previously untreated CLL patients with coexisting conditions tested the efficacy of chlorambucil alone versus chlorambucil plus rituximab versus chlorambucil plus obinutuzumab, a glycoengineered anti-CD20 monoclonal antibody. Combining an anti-CD20 antibody with chemotherapy improved outcomes, and obinutuzumab was found to be superior to rituximab when each was combined with chlorambucil.

Alemtuzumab (Campath-IH; 30 mg intravenously three times a week for 4 to 12 weeks), a monoclonal antibody that binds to the CD52 antigen, was originally approved for the treatment of fludarabine-refractory CLL. One third of such patients can achieve remission. Recently, alemtuzumab was compared with chlorambucil as initial therapy for symptomatic patients with CLL. Alemtuzumab produced higher complete and overall response rates and longer progression-free survival. In the first-line treatment of high-risk CLL, the addition of subcutaneous alemtuzumab to oral FC chemotherapy (fludarabine plus cyclophosphamide) improved progression-free survival and overall survival (the latter only in patients younger than 75 years) compared with FC chemotherapy alone. Alemtuzumab was withdrawn from the market in the United States and Europe in 2012 but is available free of charge from the company by compassionate request.

Ofatumumab is a humanized monoclonal antibody that binds to CD20, but to a different epitope than rituximab. This drug was recently approved by the FDA for the treatment of fludarabine- and alemtuzumab-refractory CLL. In the pivotal trial, the drug was given intravenously for 8 weeks and then monthly for 4 months. The overall response rate in this highly refractory population was 58%; the median progression-free survival was 6 months, with a median overall survival of 13.7 months. As with other monoclonal antibodies, the predominant side effects are infusion reactions, which tend to be more common with the initial doses.

B-Cell Receptor Signaling Pathway Inhibitors

A new category of targeted agents, called B-cell receptor signaling pathway inhibitors, is providing significant increased efficacy in CLL. Several inhibitors are being tested, targeting different kinases in the B-cell receptor pathway. Recent data have demonstrated that B-cell receptor signaling inhibitors are very active, particularly for the treatment of relapsed CLL. Ibrutinib is a first-in-class, oral covalent inhibitor of Bruton tyrosine kinase, an essential enzyme in B-cell receptor signaling, homing, and adhesion. It has been granted accelerated approval by the FDA for use in CLL. A randomized trial compared the effect of ibrutinib with that of the anti-CD20 antibody ofatumumab, both used alone, in the treatment of patients with relapsed or refractory CLL or small lymphocytic lymphoma. Ibrutinib significantly improved both progression-free and overall survival, compared with ofatumumab. Idelalisib is an inhibitor of phosphatidylinositol 3-kinase δ (PI3Kδ). Signaling through the B-cell receptor is mediated in part by activation of PI3Kδ. The δ isoform of PI3K is highly expressed in lymphoid cells, and it is the most critical isoform involved in the malignant phenotype of CLL. In a randomized, phase 3 study, patients with relapsed CLL who had clinically significant coexisting medical conditions that made them less able to undergo standard chemotherapy were randomized to receive eight intravenous infusions of rituximab plus either idelalisib 150 mg orally twice daily or placebo. The combination of idelalisib and rituximab, compared with rituximab alone, significantly improved response rate, progression-free survival, and overall survival.

Chimeric Antigen Receptor–Directed T Cells

Chimeric antigen receptors (CARs) are fusion proteins that combine antigen moieties and costimulatory T-cell receptors to redirect T cells toward malignant cells. All CARs targeting CLL have thus far directed the T cells through recognition of CD19.[14] Complete remissions, including absence of residual disease by sensitive testing, has been produced in refractory patients. *Cytokine release syndrome*, which can be life-threatening, is the initial toxicity. (Cytokine release syndrome, a rare phenomenon, also occurs in graft-versus-host disease after transplantation, severe infections, hemophagocytic lymphohistiocytosis or macrophage activation syndrome, and monoclonal antibody therapy; cytokines trigger an acute systemic inflammatory response that leads to endothelial and organ damage, microvascular leakage, and heart failure.[15]) Late toxicity includes the need for immunoglobulin replacement due to simultaneous eradication of normal B cells. CARs targeting other antigens in CLL are being investigated.

Stem Cell Transplantation

Autologous stem cell transplantation has no proven benefit in terms of survival or longterm disease control in CLL. Data on allogeneic stem cell transplantation are limited to young patients with refractory disease, in whom a long-term control rate of 40 to 55% has been reported. Nonmyeloablative stem cell transplantation, which works mainly by its graft-versusleukemia effect, has been used in older patients with CLL with some success.

Radiation Therapy

In CLL, radiation therapy is used palliatively to shrink unsightly or painfully enlarged nodal masses or an enlarged spleen.

Autoimmune and Infectious Manifestations

Autoimmune hemolytic anemia and immune-mediated thrombocytopenia do not correlate closely with the activity of CLL. Prednisone (60 to 100 mg/day) is indicated as treatment for autoimmune hemolytic anemia (Chapter 160) and for some cases of immune-mediated thrombocytopenia (Chapter 172) in CLL. If there is no response in 3 to 4 weeks, the treatment has failed, and the dose should be tapered over 1 to 2 weeks. If a response is obtained, the dose is reduced by 25% each week over 4 weeks. Patients for whom corticosteroids fail often respond to low-dose oral cyclosporine 100 mg three times a day. Other therapeutic options include splenectomy, intravenous immunoglobulin, rituximab, and alemtuzumab. Intravenous immunoglobulin (400 mg/kg every 3 to 4 weeks) significantly decreases the incidence of infections in patients with recurrent infections and hypogammaglobulinemia. However, the cost of this therapy is substantial.

PROGNOSIS

Approximately one third of patients who present with early-stage CLL never require therapy and have the same survival as age-matched controls. Frequent characteristics of such patients include WBC less than 30×10^9/L, hemoglobin greater than 13 g/dL, nondiffuse pattern on bone marrow biopsy, and slow lymphocyte doubling time.

Factors associated with shorter time to treatment failure as well as either poorer response to at least chemotherapy-based regimes, or shorter remission durations, include an unmutated *IgVH* gene, presence of 17p or llq

deletions, presence of ZAP70 and CD38, and mutations in *TP53, SF3Bl, ATM,* and *NOTCH*. A poor response to therapy is an adverse factor in all phases of the disease. As CLL progresses, the development of a prolymphocytic transformation (10% of cases) or transformation to large cell lymphoma (Richter transformation) portends a median survival time of less than 6 months. Other factors that may suggest transformation are the development of B symptoms (fevers, night sweats, weight loss), a markedly elevated lactate dehydrogenase level, or fluorodeoxyglucose-avid disease on positron emission tomography. A high incidence of second malignant tumors (10 to 20% of patients) either precedes or follows the diagnosis of CLL; the roles of therapy versus impaired immune surveillance as causative factors are unclear. Skin cancer, including melanoma, as well as colorectal and lung cancers particularly are common. CLL tends to develop in older people; in indolent cases, death occurs from other intercurrent illnesses seen in this age group. Almost all patients younger than 60 years and those with progressive disease die as a result of CLL, primarily from infections. Gram-positive organisms usually cause nonfatal infections early in CLL, but most deaths due to infection are associated with gram-negative bacterial or fungal infections. Infection with other opportunistic organisms, such as *Mycobacterium tuberculosis,* herpes virus, and *Pseudomonas jiroveci*, may also be fatal.

REVIEW QUESTIONS

1. 35-year-old man was diagnosed with chronic phase chronic myelogenous leukemia (CML) following a regular check-up. He had no significant comorbidities or medical history and was initiated on imatinib 400 mg daily. At 12 months, he achieved a complete cytogenetic response with transcripts level of 0.6% (IS). At 18 and 24 months, his transcripts levels were 0.5% and 0.4% (IS), respectively. Which of the following would be the next step in treatment?

A. Continue imatinib.
B. Switch to nilotinib.
C. Switch to dasatinib.
D. Switch to ponatinib
E. Consider allogeneic stem cell transplantation

Answer: A "Resistance" to imatinib therapy requires a change of therapy to other tyrosine kinase inhibitors (TKIs), TKI combinations with chemotherapy, or consideration of allogeneic stem cell transplantation. Resistance can be defined as persistent 100% Ph positivity after 6 months of therapy, Ph positivity of more than 35% after 12 months of therapy, or cytogenetic or hematologic relapse. It is important to emphasize that many patients with CML resistance to a TKI therapy may be noncompliant with the treatment. This should be discussed clearly with patients when they exhibit signs of CML progression by either molecular or fluorescent in situ hybridization studies. If they are noncompliant, they may continue on the same TKI treatment with emphasis on compliance and evaluated 3 to 6 months later, before CML resistance is declared. Among patients in complete cytogenetic response on a particular TKI, failure to achieve a major molecular response in a patient with a complete cytogenetic response does not, at present, indicate imatinib resistance to the particular TKI or the need to change therapy. The rate of resistance to imatinib in chronic phase CML is less than 4% per year; for those who achieve a complete cytogenetic response, the rate of resistance beyond year 3 of imatinib therapy is 1% or less, suggesting the durable stability of a complete cytogenetic response on imatinib and the predictability of the CML course after such a response is obtained.

2. A 68-year-old woman was diagnosed with chronic phase CML after a regular check-up. She was initiated on dasatinib 100 mg daily. At 6 months, she achieved a major cytogenetic response with transcripts level of 9% (IS). At 12 months, she lost her cytogenetic response with transcripts levels of 30% (IS). A T315I mutation was identified. Which of the following would be the next step in treatment?

A. Increase dasatinib dose to 140 mg daily.
B. Switch to nilotinib.
C. Switch to bosutinib.
D. Switch to ponatinib.
E. Switch to omacetaxine.

Answer: D Patients who develop resistance to first-line TKI in chronic phase are offered second-line or third-line TKI based on their mutation analysis. A T315I mutation in the CML clone requires therapy with ponatinib and (as of today) early consideration of allogeneic stem cell transplantation until the results of ponatinib therapy mature. Mutations involving V299L, T315A, or F317LIV/1/C are sensitive to nilotinib therapy. Mutations involving Y253H, E255K/V, or F359/V/C/I are sensitive to dasatinib and bosutinib therapy. Omacetaxine is approved for patients who had failed two TKIs.

3. A 34-year-old woman was diagnosed with chronic phase CML and was initiated on imatinib 400 mg daily. She achieved a complete cytogenetic response by 12 months of therapy. Her last transcripts level was reported to be 0.5% (IS). She comes to see you for advice regarding her desire to become pregnant. Which of the following would be the next step in treatment?

A. Stay on imatinib and try to conceive.
B. Switch to dasatinib and try to conceive.
C. Switch to nilotinib and try to conceive.
D. Switch to ponatinib and try to conceive.
E. You should not conceive while you are taking any TKIs.

Answer: E CML during pregnancy may be controlled with pheresis in the first trimester and then with hydroxyurea until delivery. Use of interferon-α during pregnancy has been reported anecdotally to be safe. An analysis of 125 babies delivered to women with CML on imatinib therapy (who discontinued imatinib after the pregnancy was known) showed most babies to be healthy. However, the study showed imatinib therapy to be associated with syndrome of ocular, skeletal, and renal abnormalities in three babies delivered. Therefore, imatinib (and presumably other TKIs, although there is little experience with them) should be discontinued immediately when pregnancy is documented, but abortion is not recommended because fetal malformations are rare. Partners of men with CML on TKI therapy who become pregnant have delivered normal babies.

185 NON-HODGKIN LYMPHOMAS

PHILIP J. BIERMAN AND JAMES O. ARMITAGE

DEFINITION

Lymphomas are solid tumors of the immune system. Increasing knowledge of the biology of the immune system has led to a corresponding increase in the understanding of these malignancies. In addition to better systems of classification and clinical evaluation, this new knowledge has led to the development of new therapies. Beneficial treatment is available for essentially every patient with non-Hodgkin lymphoma. The overall survival of lymphoma patients has increased steadily over the past 30 years, and many patients can be cured.

EPIDEMIOLOGY

In the United States, approximately 70,000 new cases of non-Hodgkin lymphoma are diagnosed annually, and about 19,000 people are estimated to die each year of this disease. Non-Hodgkin lymphomas account for about 4% of new cancers in the United States and result in about 3% of cancer deaths. The U.S. lifetime risk for developing non-Hodgkin lymphoma is estimated to be 2.4% (1 in 42) for men and 1.90% (1 in 52) for women. In 2010 the U.S. age-adjusted incidence rate for non-Hodgkin lymphoma was about 26.82 per 100,000 for men and 17.39 per 100,000 for women.[1] The incidence rate increases dramatically with age and is higher in whites than in other ethnic groups.

Geographic differences in the incidence of non-Hodgkin lymphomas vary as much as five-fold. The highest rates are seen in the United States, Europe, and Australia, whereas lower rates are seen in Asia. Even more striking are geographic differences in the incidence of certain types of non-Hodgkin lymphoma, such as Burkitt lymphoma, follicular lymphoma, extranodal natural killer (NK)/T-cell nasal lymphoma, and adult T-cell leukemia/lymphoma (see later).

Between 1950 and the beginning of the 21st century, the incidence rate for non-Hodgkin lymphomas in the United States increased by about 3 to 4% yearly. Since then, the incidence rate for non-Hodgkin lymphoma has reached a plateau. Increases occurred among both men and women in all parts of the world. The increase in incidence was partially related to the aging population (Fig. 185-1) and to the acquired immunodeficiency syndrome (AIDS) epidemic (Chapter 393). Occupational and environmental exposures (e.g., agricultural chemicals) may also explain some of the increase. Finally, some of the increase may be explained by improvements in the ability of pathologists to diagnose lymphoma and by improvements in imaging techniques.

PATHOBIOLOGY

For most cases of non-Hodgkin lymphoma, the cause is unknown, although genetic, environmental, and infectious agents have been implicated (Table 185-1).[2-4]

Genetic Factors

Familial non-Hodgkin lymphoma clusters have been described, and there is a slightly higher risk for non-Hodgkin lymphoma among siblings and first-degree relatives of patients with lymphoma or other hematologic malignancies. There is increasing recognition that host genetics are involved in the development of lymphomas. The incidence of non-Hodgkin lymphoma has

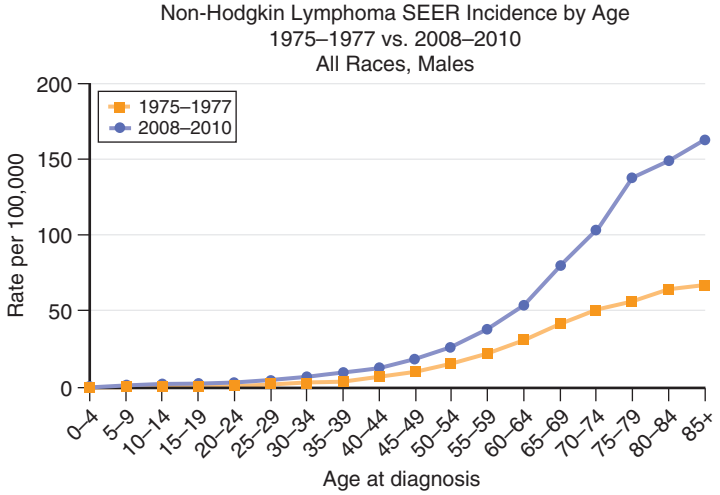

FIGURE 185-1. Non-Hodgkin lymphoma incidence by age in men, 1975-1977 versus 2008-2010. (From the Surveillance, Epidemiology, and End Results [SEER] Program of the National Cancer Institute, http://seer.cancer.gov/csr/1975_2010/.)

TABLE 185-1 FACTORS ASSOCIATED WITH THE DEVELOPMENT OF NON-HODGKIN LYMPHOMA

Inherited immune disorders
Severe combined immunodeficiency disease
Common variable immunodeficiency disease
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
X-linked lymphoproliferative disorder
Autoimmune lymphoproliferative syndrome
Acquired immune disorders
Solid organ transplantation
Acquired immunodeficiency syndrome (AIDS)
Methotrexate therapy for autoimmune disorders
Rheumatoid arthritis and systemic lupus erythematosus
Sjögren syndrome
Hashimoto thyroiditis
Infectious agents
Epstein-Barr virus
Human T-lymphotropic virus type 1
Human herpesvirus type 8
Hepatitis C virus
Helicobacter pylori
Borrelia burgdorferi
Chlamydia psittaci
Campylobacter jejuni
Occupational and environmental exposure
Herbicides
Organic solvents
Hair dyes
Ultraviolet light
Diet
Smoking
Drugs

been associated with polymorphisms in a variety of genes related to immunity, including chemokines, tumor necrosis factor, interleukin-10 (IL-10), and lymphotoxin-α. Polymorphisms in other genes related to the cell cycle and apoptosis have also been associated with an increased risk for developing lymphoma.

Immune System Abnormalities

Several inherited disorders increase the risk for developing non-Hodgkin lymphoma as much as 250-fold (see Table 185-1). In some of these conditions, the lymphoma may be related to Epstein-Barr virus (EBV; Chapter 377). For example, patients with X-linked lymphoproliferative disorder have mutations in the *SH2D1A* gene, which encodes proteins that regulate the host immune response against EBV-infected cells. Patients may develop fatal infectious mononucleosis or non-Hodgkin lymphoma after primary exposure to EBV. Acquired immunodeficiency states are also associated with an increased risk for non-Hodgkin lymphoma. For example, post-transplantation lymphoproliferative disorders occur in as many as 20% of solid organ transplant recipients, related to the proliferation of B lymphocytes that have been transformed during immunosuppressive therapy. The risk for non-Hodgkin lymphoma is also increased more than 100-fold in patients infected with the human immunodeficiency virus (HIV). Almost all central nervous system (CNS) lymphomas and approximately 50% of other lymphomas in patients with AIDS are related to EBV. Some studies have shown a two-fold increase in the incidence of non-Hodgkin lymphomas among patients with rheumatoid arthritis (Chapter 264), and the risk for marginal zone lymphomas is increased approximately 30- to 40-fold in patients with Sjögren syndrome (Chapter 268). Increases in the incidence of thyroid lymphoma are seen in patients with Hashimoto thyroiditis (Chapter 226). Enteropathy-type T-cell lymphomas are associated with celiac disease (Chapter 140). Patients with the autoimmune lymphoproliferative syndrome, associated with mutations in the *FAS* gene, also appear to be at higher risk for developing lymphoma.

Infectious Agents

EBV is associated with the majority of post-transplantation lymphoproliferative disorders and many AIDS-associated lymphomas. This viral genome is detectable in more than 95% of cases of endemic Burkitt lymphoma and in approximately 15 to 35% of cases of sporadic Burkitt lymphoma and AIDS-associated lymphomas. This virus is also associated with EBV-positive diffuse large B-cell lymphoma of elderly people, plasmablastic lymphoma, and extranodal NK/T-cell lymphoma.

The human T-lymphotropic virus type 1 (HTLV-1; Chapter 378) is detectable in virtually all cases of adult T-cell leukemia/lymphoma. The risk for lymphoma is approximately 3% in patients infected with HTLV-1. In endemic areas, up to 50% of all non-Hodgkin lymphomas may be related to HTLV-1.

Human herpesvirus-8 (HHV-8, Kaposi sarcoma–associated herpesvirus; Chapter 393), which is associated with expansion of the B-cell population, is also associated with primary effusion lymphoma (see later) in immunocompromised patients and with multicentric Castleman disease. Patients with primary effusion lymphoma are often coinfected with EBV.

Epidemiologic evidence has linked hepatitis C virus (Chapter 149) to lymphoplasmacytic lymphoma associated with type II cryoglobulinemia, nodal marginal zone lymphoma, and splenic marginal zone lymphoma. Chronic antigenic stimulation from this virus may lead to the emergence of malignant B-cell clones.

Helicobacter pylori is associated with gastric lymphoma (Chapter 192) of extranodal marginal zone/mucosa-associated lymphoid tissue (MALT). Colonized patients develop gastritis from chronic antigenic stimulation mediated by T cells, which respond to *H. pylori*–specific antigens and emergence of malignant B-cell clones. *Borrelia burgdorferi* (Chapter 321) has been associated with marginal zone B-cell lymphoma of the skin. Evidence also links *Chlamydia psittaci* (Chapter 318) with ocular adnexal lymphomas and *Campylobacter jejuni* with immunoproliferative small intestinal disease (Chapter 303).

Environmental and Occupational Exposure

Agricultural chemicals have been associated with an increased risk for developing non-Hodgkin lymphomas, and the strongest associations involve phenoxy herbicides such as 2,4-dichlorophenoxyacetic acid (2,4-D), which was also a component of Agent Orange (Chapter 19). An increased risk has also been associated with ionizing radiation (Chapter 20), organic solvents, hair dyes, and nitrates in drinking water, although contradictory results have been reported. Some studies have also linked non-Hodgkin lymphomas to high-fat diets and ultraviolet radiation (Chapter 180). The risk for non-Hodgkin lymphomas is increased approximately 20-fold after treatment for Hodgkin lymphoma (Chapter 186). Heavy smokers (Chapter 32) have an increased risk for developing follicular lymphoma. Low levels of vitamin D have been associated with increased risk for recurrent lymphoma, as well as poor outcome. Anti–tumor necrosis factor (anti-TNF) agents might be associated with an increased risk for developing lymphoma—particularly hepatosplenic T-cell lymphoma. There is also a reported association of breast implants with the development of anaplastic large cell lymphoma.

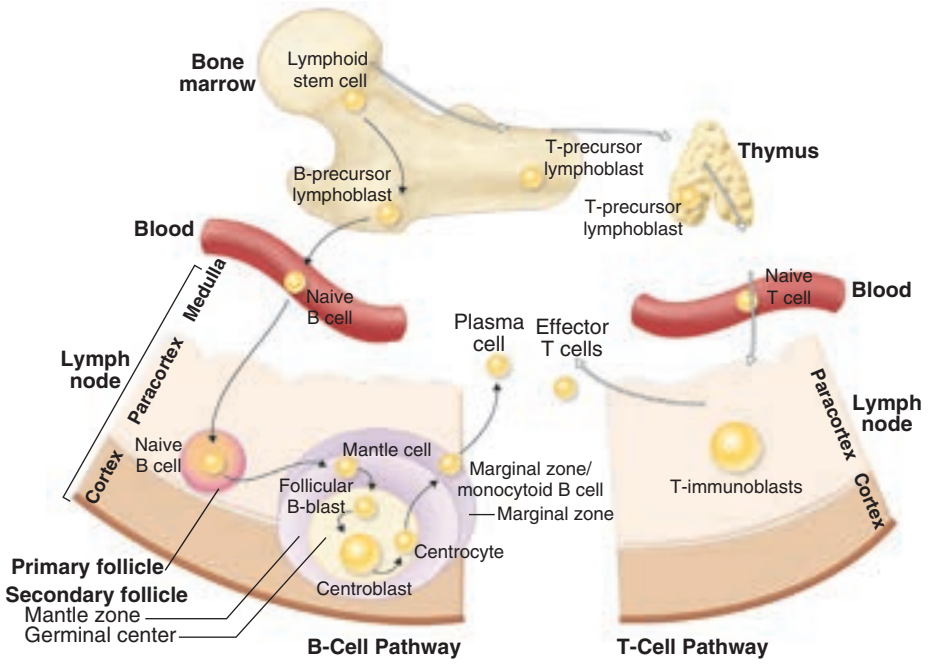
Pathology

Non-Hodgkin lymphomas are derived from cells of the immune system at varying stages of differentiation. In some cases, the cell of origin is directly linked to the morphology, immunophenotype, and clinical behavior of the lymphoma (Fig. 185-2 and Table 185-2).

The transformation of cells from the normal immune system into malignant lymphoma reflects the acquisition of specific genetic abnormalities. In many cases, cytogenetic studies can identify chromosomal translocations that underlie the development or progression of the lymphoma. In most cases of non-Hodgkin lymphoma, the activation of proto-oncogenes is the major abnormality, but occasionally chromosomal translocations can lead to fusion genes that code for chimeric proteins. In addition, some cases are associated with deletion of tumor suppressor genes. Specific genetic abnormalities are associated with some specific subtypes of non-Hodgkin lymphoma (Table 185-3). It is becoming clear that the tumor microenvironment from cells of the host immune system is important in tumor cell survival and response to therapy.[5,6]

Classification

Recognition of the Reed-Sternberg cell approximately 100 years ago made it possible to define Hodgkin lymphoma (Chapter 186) as a distinct entity, whereas other lymphomas were included under the heading "non-Hodgkin lymphomas." In the 1990s, a classification system incorporating morphologic, immunologic, genetic, and clinical information (the Revised



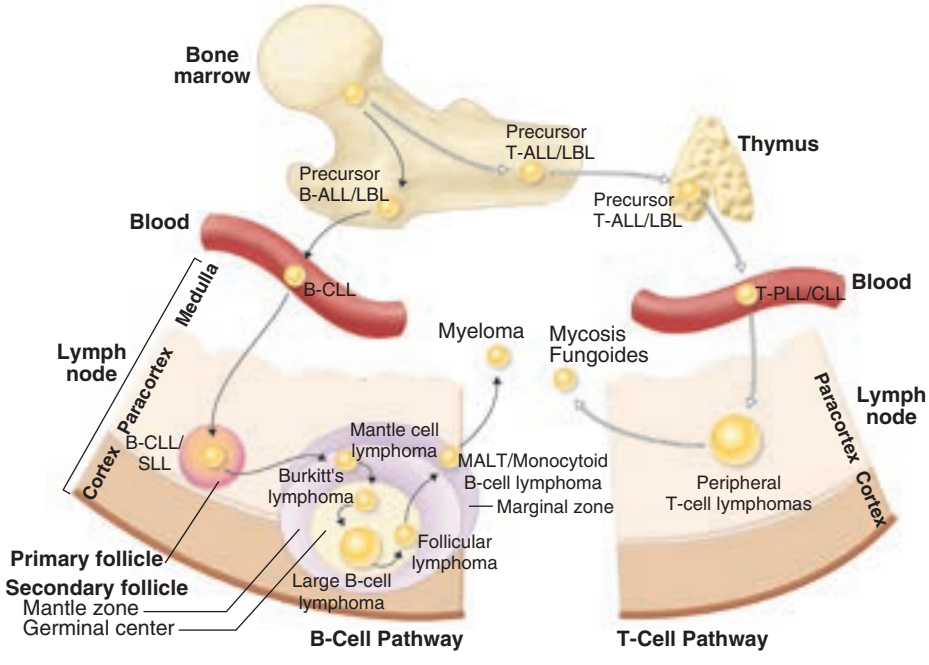


FIGURE 185-2. Postulated normal counterparts of currently recognized B- and T-cell malignancies. A, Schema of normal B- and T-cell differentiation. Bone marrow–derived lymphoid stem cells differentiate into committed B-cell precursors or into T-cell precursors that undergo further maturation in the thymus. These B- and T-cell precursors mature into naïve B or T cells that circulate to lymph nodes. After antigen exposure, normal B blasts proliferate and undergo further differentiation in the germinal center of the secondary follicle. The germinal center is surrounded by a mantle zone and a marginal zone. Antigen-specific B cells generated in the germinal center leave the follicle and reappear in the marginal zone. Thereafter, immunoglobulin-producing plasma cells accumulate in the lymph node medulla and subsequently exit to the periphery. Antigen-dependent T-cell proliferation occurs in the lymph node paracortex. After antigen exposure, mature T cells become immunoblasts and, subsequently, antigen-specific effector T cells that exit to the periphery. The postulated normal counterparts of many currently recognized T- and B-cell neoplasms are shown. **B,** T- and B-cell malignancies derived from the postulated normal counterparts shown in **A.** ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia; LBL = lymphoblastic lymphoma; MALT = mucosa-associated lymphoid tissue; PLL = prolymphocytic leukemia; SLL = small lymphocytic lymphoma.

European-American Lymphoma classification, or REAL) was developed to identify distinct clinicopathologic subgroups representing diseases that can be recognized by clinicians. This system was subsequently adopted as the World Health Organization (WHO) classification of lymphomas in 2008 (Table 185-4).[7]

The WHO classification divides lymphomas on the basis of B-cell or T/NK-cell origin and whether they are derived from primitive precursor cells or from more mature "peripheral" cells. Specific clinical and pathologic entities are recognized within each of these groupings. In the United States and Europe, 85 to 90% of non-Hodgkin lymphomas are B cell in origin.

The most frequent type is diffuse large B-cell lymphoma, which represents 31% of all non-Hodgkin lymphomas worldwide. The next most frequent type is follicular lymphoma, which represents 22% of cases. Follicular lymphoma is relatively more frequent in North America and Western Europe and less frequent in Asia. Less common types, each representing between 5 and 10% of all non-Hodgkin lymphomas, are extranodal marginal zone/MALT

TABLE 185-2 TYPICAL IMMUNOPHENOTYPES OF COMMON NON-HODGKIN LYMPHOMAS

LYMPHOMA	CD20	CD3	CD10	CD5	CD23	OTHER
Small lymphocytic	+	–	–	+	+	
Lymphoplasmacytic	+	–	–	–	–	Cytoplasmic Ig^+
Extranodal marginal zone MALT	+	–	–	–	–	
Nodal marginal zone	+	–	–	–	–	
Follicular	+	–	+	–		
Mantle cell	+		–	+	–	Cyclin $D1^+$
Diffuse large B cell	+	–				
Mediastinal large B cell	+	–				
Burkitt	+	–	+	–		TdT^-
Precursor T lymphoblastic	–	+/–				TdT^+, $CD1a^{+/-}$, $CD7^+$
Anaplastic large T cell	–	+/–				$CD30^+$, $CD15^-$, EMA^+, ALK^+
Peripheral T cell	–	+/–				Other pan-T variable

ALK = anaplastic lymphoma kinase; EMA = epithelial membrane antigen; MALT = mucosa-associated lymphoid tissue; TdT = terminal deoxynucleotidyl transferase.

TABLE 185-3 CHROMOSOMAL TRANSLOCATIONS CHARACTERISTIC OF NON-HODGKIN LYMPHOMA

LYMPHOMA SUBTYPE	TRANSLOCATION	GENES INVOLVED	FREQUENCY (%)
Diffuse large B cell	t(3q27) t(14;18)(q32;q21) t(18;14)(q24;q32)	*BCL6* *IgH, BCL2* *MYC (c-Myc), IgH*	35 15-20 <5
Burkitt	t(8;14)(q24;q32) t(8;22)(q24;q11) t(2;8)(p12;q24)	*MYC, IgH* *MYC, IgL* *IgK, MYC*	100% have one of these, most commonly t(8;14)
Follicular	t(14;18)(q32;q21)	*IgH, BCL2*	~90
Mantle cell	t(11;14)(q13;q32)	*BCL1, IgH*	>90
ALCL	t(2;5)(p23;q35)	*ALK, NPM*	>80 of ALK+ ALCLs
MALT	t(11;18)(q21;q21) t(14;18)(q21;q32) t(1;14)(p22;q32)	*API2, MALT1* *IgH, MALT1* *BCL10, IgH*	35 20 10

ALCL = anaplastic large cell lymphoma; ALK = anaplastic lymphoma kinase; MALT = mucosa-associated lymphoid tissue.

lymphomas, peripheral T-cell lymphomas, small lymphocytic lymphoma, and mantle cell lymphoma. Other types each represent less than 2% of non-Hodgkin lymphomas seen in the United States.

The non-Hodgkin lymphomas recognized in the WHO classification have clinically distinctive characteristics (Table 185-5), such that an experienced hematopathologist can accurately classify 85% or more of patients by WHO criteria when adequate material is available. Some diagnoses, such as follicular lymphoma, can be made with a high degree of accuracy without immunologic or genetic studies. The diagnosis of T-cell lymphomas cannot be made accurately without immunophenotyping. Cytogenetic studies and molecular genetic studies (fluorescent in situ hybridization, or FISH) can help resolve difficult differential diagnoses. For example, the presence of a t(8;14) translocation supports the diagnosis of Burkitt lymphoma, whereas a t(11;14) with cyclin D1 overexpression can confirm the diagnosis of mantle cell lymphoma (see Tables 185-2 and 185-3).

The use of DNA microarrays has allowed the identification of distinct subsets of patients with diffuse large B-cell lymphoma. Patients with histologically identical lymphomas can be divided into those with gene expression patterns resembling normal germinal center B cells (GCB), those whose tumors resemble activated post–germinal center B cells (ABC), or those with patterns resembling that seen in Hodgkin lymphoma. The last pattern is most frequently found in young women who present with large mediastinal masses. Use of immunohistochemistry to subdivide diffuse large B-cell lymphoma into GCB and ABC subtypes is widely used but does not correlate perfectly with DNA microarray results.

CLINICAL MANIFESTATIONS

The most common presentation of non-Hodgkin lymphoma is lymphadenopathy (Fig. 185-3; Chapter 168). In many cases, patients notice cervical, axillary, or inguinal adenopathy and seek a physician's advice. In general, lymph nodes containing lymphoma are firm, nontender, and not associated with a regional infection. In other patients, lymphadenopathy occurring in sites such as the mediastinum or retroperitoneum causes symptoms that bring the patient to the physician. Chest pain, cough, superior vena cava syndrome, abdominal pain, back pain, spinal cord compression, and symptoms of renal insufficiency associated with ureteral compression are characteristic.

Non-Hodgkin lymphomas are often associated with systemic symptoms that may lead to the diagnosis. The most obvious symptoms are fever, night sweats, and unexplained weight loss. Any of these symptoms without an obvious cause should lead a physician to consider the diagnosis of lymphoma. Other, less characteristic symptoms include fatigue, which is frequently present at the time of diagnosis if the patient is questioned carefully, and pruritus.

Non-Hodgkin lymphomas can involve essentially any organ in the body, and malfunction of that organ can cause symptoms that lead to the diagnosis. Examples include neurologic symptoms with primary brain lymphoma (Chapter 189), shortness of breath with MALT lymphomas in the lung, epigastric pain and vomiting with gastric MALT lymphomas or diffuse large B-cell lymphomas (Chapter 192), bowel obstruction with small bowel lymphomas (Chapter 193), testicular masses with diffuse large B-cell lymphoma (Chapter 200), and skin lesions with cutaneous lymphomas (Chapter 440). Many lymphomas involve the bone marrow and occasionally cause extensive myelophthisis (Chapter 165) and bone marrow failure. These patients may present with infections, bleeding, and anemia.

Non-Hodgkin lymphomas can also manifest with a variety of immunologic abnormalities. For example, autoimmune hemolytic anemia (Chapter 160) and immune thrombocytopenia (Chapter 172) can be the presenting manifestations of non-Hodgkin lymphoma, especially small lymphocytic

lymphoma/chronic lymphocytic leukemia as well as other subtypes, including diffuse large B-cell lymphoma. Peripheral neuropathies (Chapter 420), often associated with overproduction of a monoclonal protein, can be seen in a variety of subtypes but are most characteristic of lymphoplasmacytic lymphoma; sometimes they are also seen with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes; Chapter 187). Paraneoplastic neurologic complications of non-Hodgkin lymphoma include demyelinating polyneuropathy, Guillain-Barré syndrome, autonomic dysfunction, and peripheral neuropathy. Paraneoplastic syndromes (Chapter 179) associated with non-Hodgkin lymphoma can affect the skin (e.g., pemphigus), kidney (e.g., glomerulonephritis), and miscellaneous organ systems (e.g., vasculitis, dermatomyositis, cholestatic jaundice).

The differential diagnosis in patients with non-Hodgkin lymphoma is broad. Any cause of lymphadenopathy or splenomegaly can potentially be confused with non-Hodgkin lymphoma (Chapter 168). However, this confusion is resolved by an appropriate biopsy. It is extremely important to recognize that the diagnosis of non-Hodgkin lymphoma must be considered in patients with compatible clinical presentations and then confirmed by an adequate biopsy read by an experienced hematopathologist. The diagnosis should never be inferred, and patients should not be treated until the diagnosis is confirmed by biopsy. This is also true for patients who achieve a

complete remission with initial therapy; they should not be treated for presumed relapse on the basis of symptoms or abnormal images without a biopsy.

DIAGNOSIS

Each new patient with a non-Hodgkin lymphoma should be thoroughly evaluated in a systematic manner (Table 185-6). Because subtle pathologic distinctions may alter therapy, the most important issue in managing non-Hodgkin lymphoma is to establish an accurate diagnosis. Core needle biopsies can occasionally be used for a primary diagnosis if the specimen is handled properly. Fine-needle aspirates should not be used to diagnose lymphoma, and they preclude an accurate diagnosis of the specific subtype of non-Hodgkin lymphoma. In most cases, an excisional biopsy is necessary (and is always preferred) for the initial diagnosis. Another biopsy should be performed if sufficient material is not obtained. Review by an experienced hematopathologist is essential.

Staging and Prognostic Systems

After diagnosis, a meticulous staging evaluation is necessary to estimate prognosis and determine therapy. Staging requires a careful history and physical examination; complete blood count; renal and hepatic function tests; serum lactate dehydrogenase (LDH) level; computed tomography (CT) of the chest, abdomen, and pelvis; and bone marrow biopsy. Positron emission tomography (PET) can identify initial sites of involvement and, after treatment, can distinguish persisting lymphoma from residual fibrosis in masses seen on CT. The most common staging system is the Ann Arbor classification, which separates patients into four stages based on anatomic sites of disease (Table 185-7). In addition, each stage is subdivided into A (no defined general symptoms) and B (unexplained weight loss >10% of body weight in the previous 6 months, unexplained temperature >38° C, or night sweats) categories. Known sites of disease can be reexamined later to evaluate the response to therapy.

Although a wide variety of patient factors (e.g., age, symptoms, LDH level) and tumor factors (e.g., bulk, gene expression pattern, proliferation rate) can affect treatment outcomes, two prognostic systems can help in choosing therapy and determining an accurate prognosis. The International Prognostic Index (IPI; Table 185-8) is the most widely used method to predict treatment outcome and survival. The IPI is based on five adverse factors (age >60 years, performance status ≤2, elevated serum LDH level, two or more extranodal sites of disease, Ann Arbor stage III or IV), which are summed to give the score. This index was developed for patients with diffuse aggressive lymphoma (predominantly diffuse large B-cell lymphoma), but it can be used to predict treatment outcome with any subtype. For young patients, an abbreviated index that uses only reduced performance status, elevated serum LDH level, and high stage can be applied. Because patients with follicular lymphoma rarely have a reduced performance status or a large number of extranodal sites, an alternative index termed the *Follicular Lymphoma International Prognostic Index* (FLIPI) was developed. It substitutes more than four nodal areas of involvement and a hemoglobin less than 12 g/dL as staging criteria and does a somewhat better job of predicting treatment outcome in follicular lymphoma.

Other prognostic indices have been developed for mantle cell lymphoma and the peripheral T-cell lymphomas.

TREATMENT

Rx

Lymphomas may behave in an indolent or an aggressive manner. The behavior of many of these neoplasms is distinctive, but within each category, behavior is frequently influenced by disease site, tumor bulk, and performance status of the patient. Some lymphomas can be managed, at least initially, with observation, whereas other situations are medical emergencies, such as spinal cord compression (Chapter 189). It is important to consider three questions before starting therapy: (1) Does treatment have curative potential? (2) Can treatment prolong survival? (3) Will treatment alleviate symptoms?

SPECIFIC TYPES OF NON-HODGKIN LYMPHOMAS

Precursor T-Cell and B-Cell Lymphomas

These tumors are nodal or other solid tissue infiltrates of cells that are morphologically and immunophenotypically identical to the immature cells seen in B-cell or T-cell acute lymphoblastic leukemia (Chapter 183). Patients who have predominantly nodal disease with minimal or no involvement of the bone marrow are frequently classified as having *lymphoblastic lymphoma,* whereas those with more than 25% neoplastic cells in the marrow are classified as having *lymphoblastic leukemia.* These distinctions are arbitrary and reflect the stage of disease rather than different diagnoses. These neoplasms are more common in children than in adults.

B-cell precursor lymphomas frequently manifest as solid tumors with involvement of the skin and bones, whereas T-cell neoplasms typically

manifest as a mediastinal mass in a young male. Involvement of the CNS is common. Approximately 90% of patients who present with lymphoblastic lymphoma have a T-cell phenotype, whereas about 85% of patients who present with acute lymphoblastic leukemia have a B-cell phenotype. Adverse prognostic characteristics include CNS involvement, stage IV disease, and elevated LDH level.

TREATMENT Rx

Patients with either T-cell lymphoblastic lymphoma or precursor B-cell lymphoblastic lymphoma are typically treated with regimens modeled after those used for acute lymphoblastic leukemia (Chapter 183). These regimens frequently contain cytarabine and high-dose methotrexate, and they often include maintenance therapy. CNS prophylaxis with intrathecal chemotherapy, high-dose methotrexate, or cranial irradiation is often a component of these regimens.

Mature B-Cell Lymphomas

SMALL LYMPHOCYTIC LYMPHOMA AND CHRONIC LYMPHOCYTIC LEUKEMIA

Small lymphocytic lymphoma is defined as a lymph node or other tissue infiltrate that is morphologically and immunophenotypically identical to chronic lymphocytic leukemia (Chapter 184). Patients frequently are symptom free, and the diagnosis is often made when blood counts are performed for other reasons. Patients frequently have lymphadenopathy or splenomegaly. Fatigue is common. Hypogammaglobulinemia can occur and may lead to an increased susceptibility to infection.

A poor prognosis is associated with advanced stage and systemic symptoms, expression of high levels of CD38 and ZAP-70 on tumor cells, lack of rearranged immunoglobulin heavy chain genes, and genetic abnormalities such as del(17p) and del(11q). As many as 10% of patients exhibit transformation to diffuse large B-cell lymphoma (Richter syndrome), which is associated with a poor prognosis.

The median survival time is more than 10 years for patients without adverse characteristics, and these patients can often be managed initially with observation. Therapy is necessary for patients who have systemic symptoms, for those with rapidly progressive or symptomatic lymphadenopathy or splenomegaly, and for those who develop cytopenias.

TREATMENT Rx

Management must be individualized because therapy is unlikely to be curative, and patients are often elderly. A regimen consisting of fludarabine in combination with cyclophosphamide and rituximab (FCR) (Table 185-9) has a high complete remission rate and is frequently used in the United States for relatively young, fit patients. Fludarabine plus rituximab or the combination of chlorambucil and obinituzumab is used in elderly patients. Bendamustine plus rituximab (B-R) is an active combination. It is better tolerated but has a lower response rate than FCR. The immune modulator lenalidomide is also an active agent. The B-cell receptor pathway inhibitors ibrutinib and idelalisib are new highly active oral agents that may transform the management of this lymphoma.[8] Allogeneic hematopoietic stem cell transplantation may be curative, but few patients are candidates for this approach.

Patients may develop autoimmune thrombocytopenia (Chapter 172), autoimmune neutropenia (Chapter 167), and red blood cell aplasia (Chapter 165). These disorders may respond to treatment with corticosteroids, intravenous immune globulin, rituximab, or splenectomy, as used in patients without underlying lymphoma.

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMA)

MALT lymphomas are indolent tumors that originate in association with epithelial cells and are seen most commonly in the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, and lung. The majority of cases are stage I or II at diagnosis, although in some series as many as 30% disseminate to bone marrow or other sites. These lymphomas tend to remain localized for extended periods. Local treatment with surgery or radiation therapy cures a high proportion of localized neoplasms. Disseminated disease is treated similarly to follicular lymphoma (see later).

TABLE 185-9 COMBINATION CHEMOTHERAPY REGIMENS FOR NON-HODGKIN LYMPHOMA

REGIMEN	DOSE	DAYS OF ADMINISTRATION	FREQUENCY
R-CHOP			**EVERY 21 DAYS**
Cyclophosphamide	750 mg/m^2 IV	1	
Doxorubicin	50 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 mg PO	1-5	
Rituximab	375 mg/m^2 IV	1	
R-EPOCH§			**EVERY 21 DAYS**
Etoposide	50 mg/m^2/d IV¶	1-4	
Doxorubicin	10 mg/m^2/d IV¶	1-4	
Vincristine	0.4 mg/m^2/d IV¶	1-4	
Cyclophosphamide	750 mg/m^2 IV	5	
Prednisone	60 mg/m^2 bid PO	1-5	
Rituximab	375 mg/m^2 IV	1	
R-CVP			**EVERY 21 DAYS**
Cyclophosphamide	1000 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 mg PO	1-5	
Rituximab	375 mg/m^2 IV	1	
FCR			**EVERY 28 DAYS**
Fludarabine	25 mg/m^2 IV	1-3	
Cyclophosphamide	250 mg/m^2 IV	1-3	
Rituximab	375 mg/m^2	1	
B-R			**EVERY 28 DAYS**
Bendamustine	90 mg/m^2 IV	1-2	
Rituximab	375 mg/m^2 IV	1	

*Vincristine dose is often capped at 2 mg total.
§Doses are adjusted based on myelosuppression with previous cycle.
¶Continuous infusion.

Gastric MALT lymphomas are frequently associated with infection by *H. pylori*. About 75% of patients achieve remission after eradication of *H. pylori*, and more than 90% remain in remission for prolonged periods of time. Nonresponders are more likely to have submucosal invasion by endoscopic ultrasonography. Approximately 25% progress, of which about 25% develop diffuse large B-cell lymphoma. Response to antibiotic therapy is less likely if invasion is deeper, lymph node metastases are found, or the t(11;18) chromosomal translocation is present.

TREATMENT Rx

Patients may have tumors in more than one extranodal site, and these locations can sometimes be successfully treated with local therapy. Patients without symptoms can be monitored closely without therapy until symptoms progress. Patients with symptoms can be treated with rituximab, single-agent chemotherapy, or combinations. Gastric MALT lymphoma that does not respond to antibiotics can be treated with radiation, rituximab as a single agent (similar to its use in follicular lymphoma), or several traditional combination chemotherapy regimens (see Table 185-9).[9]

FOLLICULAR LYMPHOMA

Follicular lymphoma accounts for the majority of indolent or "low-grade" lymphomas in the United States. Follicular lymphoma is divided into three grades based on the proportion of large, transformed cells (centroblasts).

Patients with follicular lymphoma are frequently asymptomatic. The most common presenting complaint is painless lymphadenopathy. Some patients have cough or dyspnea related to pulmonary or mediastinal involvement or pleural effusions. Other patients have symptoms of abdominal pain or

fullness related to subdiaphragmatic or splenic disease. A minority of patients have systemic symptoms of fevers, night sweats, or weight loss.

The clinical behavior and treatment of follicular lymphoma grades 1 and 2 are the same and are discussed in this section. Some grade 3 follicular lymphomas have a more aggressive clinical course and are treated similarly to diffuse large B-cell lymphoma (see later). This distinction between grade 3a (indolent behavior) and 3b (aggressive behavior) is based on the presence or absence of sheets of centroblasts, although this separation may not be reproducible among pathologists. Because of this, we favor treating all patients with grade 3 follicular lymphoma like diffuse large B-cell lymphoma.

TREATMENT Rx

Localized Disease

Approximately 5 to 15% of patients have localized disease (stage I or minimal stage II disease) at diagnosis. These lymphomas are usually treated with involved-field radiation, and most series report 10-year disease-free survival rates of approximately 50% and overall survival rates of 60 to 70%.[10] Some retrospective series have reported improved outcomes when chemotherapy plus rituximab is combined with radiation.[11]

Advanced Disease

Most patients with follicular lymphoma have extensive disease at diagnosis. The median survival time of these patients has improved after the addition of rituximab and is now 10 to 20 years. Spontaneous regression has been described. As many as 30 to 50% of patients experience transformation to a more aggressive histology—usually diffuse large B-cell lymphoma. Transformation is frequently associated with new systemic symptoms and rapidly progressive lymphadenopathy, an aggressive clinical course, and a poor prognosis.

Asymptomatic patients, especially elderly patients and those with other medical illnesses, are frequently managed with a "watch and wait" approach. Prospective trials have demonstrated that this approach does not influence overall survival, and patients can sometimes be observed for long periods before treatment is required.

Most patients with follicular lymphoma eventually require treatment because of systemic symptoms, symptomatic or progressive lymphadenopathy, splenomegaly, effusions, or cytopenias. In elderly patients, those who are poor candidates for intensive chemotherapy regimens, and those who want to avoid the side effects of chemotherapy, single-agent rituximab (375 mg/m^2 intravenously, given weekly for 4 consecutive weeks) yields an objective response rate of well over 50%. The median duration of response is approximately 1 to 2 years for patients who receive no additional therapy, but the response can be extended with ongoing administration of rituximab once every 2 or 3 months or by repeating the initial four doses every 6 months. When rituximab is combined with standard chemotherapy regimens (see Table 185-9), the response rate, duration of response, and survival are increased compared with the chemotherapy regimen alone. Maintenance rituximab is widely used and extends the duration of remission.

Salvage Therapy

Most patients respond to initial chemotherapy. However, follicular lymphoma recurs in the majority of patients with advanced-stage disease. Patients who relapse usually respond to additional therapy, often with the same agents, although the duration of response becomes progressively shorter with repeated courses of therapy. Some patients respond to the radiolabeled antibodies tositumomab or ibritumomab. Radiation therapy may also be useful for patients with a localized site of symptomatic disease.

Prolonged remissions have been observed after autologous hematopoietic stem cell transplantation. Allogeneic hematopoietic stem cell transplantation may cure some patients with relapsed follicular lymphoma.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma is a B-cell neoplasm composed of small lymphoid cells that may resemble small lymphocytic lymphoma or follicular lymphoma. It is most common in elderly patients and is usually at an advanced stage at the time of diagnosis. Males are more frequently affected, and extranodal disease, especially involvement of the bone marrow, Waldeyer's ring, and the gastrointestinal tract, is common. Mantle cell lymphoma is the most common cause of multiple lymphomatous polyposis, and many oncologists recommend that the gastrointestinal tract be evaluated with endoscopy during the initial evaluation.

Some patients present with involvement of the peripheral blood as well as the bone marrow, a clinical picture that resembles chronic lymphocytic leukemia (Chapter 184). The lymphocytes in both disorders are CD5$^+$, but the t(11;14) and overexpression of cyclin D1 seen in mantle cell lymphoma usually allow an accurate diagnosis.

The median survival of mantle cell lymphoma has significantly improved with new therapies. Occasional patients may have an indolent course without initial therapy—particularly those with a leukemic presentation. Patients have a poor outcome when treated with the same regimens used for diffuse large B-cell lymphoma. Regimens similar to those used for Burkitt lymphoma and lymphoblastic lymphoma are effective. The combination of bendamustine plus rituximab and regimens that incorporate high-dose cytarabine are efficacious. Maintenance rituximab seems to prolong remission duration. Autologous hematopoietic stem cell transplantation for patients in their first remission is widely used.[12] Several new agents, including lenalidomide, bortezomib, and the Bruton tyrosine kinase inhibitor ibrutinib,[13] are very active and may become part of standard therapy. Allogeneic transplantation can be curative but is associated with considerable morbidity and mortality.

DIFFUSE LARGE B-CELL LYMPHOMA

These tumors are the most common type of non-Hodgkin lymphoma, but their morphology and genetic features are heterogeneous. Signs and symptoms are similar to those of other subtypes, although patients are more likely to have B symptoms or symptoms from the local tumor than are patients with follicular lymphoma.

The WHO classification of non-Hodgkin lymphomas has identified several variants and subtypes of diffuse large B-cell lymphoma (Table 185-10). Many of these are histologic or genetic subtypes or variants for which treatment is the same as the standard approach for diffuse large B-cell lymphoma. Other subtypes present unusual clinical syndromes or specific therapeutic problems.

TREATMENT Rx

Localized Disease

As many as 30% of patients with diffuse large B-cell lymphoma have stage I or minimal stage II disease. These patients are occasionally cured with radiation therapy alone, but initial treatment with chemotherapy is more effective. In the United States, most patients are treated with R-CHOP. Some patients can be treated with fewer courses of chemotherapy if radiotherapy is included. For patients with bulky disease, a complete course of chemotherapy is usually used. Some physicians advocate the use of PET scans to shorten the duration of therapy or eliminate the need for radiotherapy in complete responders.

TABLE 185-10 DIFFUSE LARGE B-CELL LYMPHOMA VARIANTS AND SUBTYPES

Diffuse large B-cell lymphoma, not otherwise specified (NOS)
Common morphologic variants
Centroblastic
Immunoblastic
Anaplastic

ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma arising in HHV-8-associated multicentric Castleman disease
Primary effusion lymphoma

ALK = anaplastic lymphoma kinase; CNS = central nervous system; DLBCL = diffuse large B-cell lymphoma; EBV = Epstein-Barr virus; HHV = human herpesvirus.

Advanced Disease

R-CHOP is the most widely used regimen for adults of all ages with advanced-stage diffuse large B-cell lymphoma. Among patients older than 60 years, 75% achieve a complete response, with a 10-year progression-free survival rate of 36.5% and a 10-year overall survival rate of 43.5%. In younger patients, the outcome is better.[] In younger patients, R-EPOCH and the intensive regimen R-ACVBP may yield superior results.[] Autologous transplantation in first remission may benefit very high-risk patients.[]

Salvage Therapy

A variety of chemotherapy regimens have been developed for patients who relapse after attaining a remission with initial chemotherapy. These regimens commonly contain agents such as cisplatin, cytarabine, etoposide, carboplatin, and ifosfamide. Response rates exceeding 50% can be observed with these combinations, although no more than 10% of patients achieve long-term disease-free survival. High-dose therapy followed by autologous hematopoietic stem cell transplantation has become accepted therapy for patients with relapsed diffuse large B-cell lymphoma. Approximately 20 to 50% of these patients attain long-term disease-free survival, depending on their response to conventional salvage chemotherapy.[] Several new drugs such as lenalidomide and ibrutinib seem to particularly benefit patients with ABC subtype.

Subtypes of Diffuse Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma originates in the thymus and is most common in young women. This subtype shares genetic features with classic Hodgkin lymphoma. This entity is distinguished by the presence of a mediastinal mass, which usually causes symptoms of cough, chest pain, or superior vena cava syndrome. A very large mass (>10 cm) or the existence of a malignant pleural effusion is associated with a worse prognosis. Mediastinal large B-cell lymphoma is treated with the same chemotherapy regimens used for diffuse large B-cell lymphoma, followed, in some cases, by consolidative radiation therapy.[14] The prognosis is similar to that of other diffuse large B-cell lymphomas. Relapses often occur in extranodal sites such as the CNS, lungs, gastrointestinal tract, liver, ovaries, and kidneys.

Intravascular large B-cell lymphoma is an aggressive lymphoma caused by cells that infiltrate the lumens of small blood vessels. Widespread extranodal involvement is common. Focal neurologic deficits and mental status changes are frequent. Cases are often diagnosed at autopsy, although durable responses to combination chemotherapy have been described.

Primary effusion lymphoma is associated with HHV-8 and is seen in HIV-infected and other immunosuppressed patients. Effusions occur in serous body cavities. Peripheral lymphadenopathy is not seen. Prognosis is poor despite chemotherapy.

Plasmablastic lymphoma is most often seen in patients with HIV infection and frequently presents with involvement of the head and neck. This tumor does not express CD20 and thus does not benefit from treatment with rituximab.

Primary cutaneous diffuse large B-cell lymphoma of the leg (leg type) is one of two presentations of B-cell lymphoma in the skin. This tumor occurs mostly in older patients and follows an aggressive course. This neoplasm must be distinguished from primary cutaneous follicle center lymphoma, which might also be diagnosed as a cutaneous diffuse large B-cell lymphoma but follows an indolent course and requires only local therapy.

Double-hit and gray-zone lymphomas are newly described entities. Double-hit lymphomas have rearrangements of *Myc* in combination with *Bcl-2* and/or *Bcl-6*. They have a poor outcome when treated with standard chemotherapy regimens. Gray-zone lymphomas include those with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma and those with features intermediate between mediastinal diffuse large B-cell lymphoma and classic Hodgkin lymphoma.[15]

BURKITT LYMPHOMA

Burkitt lymphoma is a highly aggressive B-cell lymphoma that is more common in children and immunosuppressed individuals than in healthy adults (see later). Widespread extranodal involvement is common. The endemic form of Burkitt lymphoma is seen most frequently in children who reside in equatorial Africa. Involvement of bones of the jaw is common in this form. The sporadic form of Burkitt lymphoma is seen most commonly in children in the United States. Males are more frequently affected. Both children and adults frequently have bulky abdominal disease, sometimes with involvement of the kidneys, ovaries, and breasts. Bone marrow involvement is seen in about one third of cases.

TREATMENT Rx

Tumors may progress extremely rapidly, so therapy should be started as soon as possible. Tumor lysis syndrome may occur because of the frequent presence of bulky disease, the high rate of tumor proliferation, and the extreme sensitivity of the tumor to chemotherapy. Patients are usually treated with specialized high-intensity regimens, including rituximab, of relatively short duration.[16] Treatment with the R-CHOP regimen used for diffuse large B-cell lymphoma has a poor outcome. CNS prophylaxis with intrathecal chemotherapy or high-dose methotrexate is required. Cure rates well in excess of 50% are typical with appropriate therapy. Excellent results have been described with R-EPOCH.

RARE TYPES OF B-CELL LYMPHOMA

Several rare types of lymphoma have distinct clinical features.

Lymphoplasmacytic lymphoma is an indolent lymphoma that frequently involves the bone marrow, peripheral blood, and spleen. Patients frequently have an immunoglobulin M (IgM) paraprotein (and therefore the disease could be called Waldenström macroglobulinemia) that may lead to symptoms of hyperviscosity, autoimmune phenomena, or neuropathies (Chapter 187). Plasmapheresis can reduce symptoms of hyperviscosity. Chemotherapy with alkylating agents, combination chemotherapy, or fludarabine all in combination with rituximab may be used.[] Newer agents such as bortezomib and ibrutinib are active.

Splenic marginal zone lymphoma is an indolent lymphoma that usually manifests with splenomegaly and lymphocytosis. A monoclonal gammopathy is frequently seen. Peripheral lymphadenopathy is unusual. Anemia and thrombocytopenia may respond to splenectomy. Chemotherapy with single agents or anthracycline-based combinations may be useful, and when the lymphoma is associated with hepatitis C, antiviral therapy may be effective. Responses to interferon have been described. This lymphoma appears to be particularly responsive to rituximab.

Nodal marginal zone B-cell lymphoma is an indolent disorder that is usually associated with generalized lymphadenopathy. The clinical course and prognosis are similar to those of follicular lymphoma, and it is usually treated in a similar manner.

Small intestinal immunoproliferative disease, a disorder seen most frequently in the Middle East, begins as a polyclonal process and can progress to a large B-cell lymphoma. The process is often associated with *C. jejuni* infection. Early in the disease, patients may respond to antibiotics, and frank lymphoma may respond to combination chemotherapy regimens.

Mature T-Cell Lymphomas (Peripheral T-Cell Lymphomas)

Peripheral (or mature) T-cell lymphomas are neoplasms of post-thymic T cells. These include relatively indolent disorders such as mycosis fungoides and $CD30^+$ cutaneous lymphoproliferative disorders, but most patients diagnosed with peripheral T-cell lymphoma have an aggressive neoplasm. Peripheral T-cell lymphomas represent only 10% of the non-Hodgkin lymphomas occurring in the United States. Unfortunately, the treatment for these lymphomas has not progressed as rapidly as the treatments for B-cell lymphomas.[17]

MYCOSIS FUNGOIDES

Mycosis fungoides (often referred to as *cutaneous T-cell lymphoma*) is an indolent malignancy that is most common in middle-aged and older adults.[18] The clinical course is usually a slow progression from isolated patches or plaques to thickened, more widespread plaques and then to multiple cutaneous tumors that may ulcerate (Chapter 440). A subset of patients presents with generalized erythroderma and circulating tumor cells, called *Sézary syndrome*. Lymph node and visceral involvement may occur late in the course of the disease.

TREATMENT Rx

Cutaneous radiation therapy may be curative for patients with limited patch or plaque disease. Patients with early-stage disease (<10% body surface area) are frequently treated with skin-directed therapy that may include ultraviolet radiation, topical steroids, or topical nitrogen mustard.

Patients with more advanced disease frequently benefit from total skin electron beam therapy or extracorporeal photopheresis. Medical treatments

include interferon-α, retinoids, monoclonal antibodies, histone deacetylase inhibitors (vorinostat, depsipeptide), the fusion toxin denileukin diftitox, and traditional cytotoxic chemotherapeutic agents. However, these treatments are usually only palliative. Results with autologous hematopoietic stem cell transplantation are usually poor, although allogeneic stem cell transplantation has yielded promising results in some cases.

ADULT T-CELL LYMPHOMA/LEUKEMIA

Adult T-cell lymphoma/leukemia, which is associated with HTLV-1 infection (Chapter 378), is most commonly seen in southern Japan and the Caribbean. Most infected patients are asymptomatic, and the lifetime risk for developing adult T-cell lymphoma/leukemia is approximately 3%.

Patients may have acute leukemia, aggressive lymphoma, or an indolent lymphoproliferative disease. Patients with aggressive disease present with generalized lymphadenopathy, hepatosplenomegaly, cutaneous infiltration, and hypercalcemia. Many patients have characteristic circulating tumor cells with a "flower" or "cloverleaf" nucleus.

TREATMENT Rx

Patients with indolent disease can sometimes be monitored without therapy. Aggressive disease is usually treated with combination chemotherapy, but there is no consensus on the best regimen. Historically, the 5-year survival rate has been less than 10%, although recent trials have reported better outcomes.

CD30⁺ CUTANEOUS LYMPHOPROLIFERATIVE DISORDERS

These disorders represent a spectrum of diseases that may have an identical histologic appearance and overlapping clinical manifestations. Treatment decisions are often based on the clinical behavior of the lesions. These lymphomas express CD30 but do not express the anaplastic lymphoma kinase (ALK) protein (see later).

Lymphomatoid papulosis is a "histologically malignant" clonal disorder consisting of erythematous or skin-colored papules that frequently undergo spontaneous ulceration and necrosis over a period of weeks. The prognosis is excellent, although patients may eventually develop lymphoma.

Primary cutaneous anaplastic large cell lymphoma occurs most commonly in older men and also undergoes frequent spontaneous regression. The 5-year survival rate is greater than 90%. Treatment usually consists of local measures (surgery or radiation), although chemotherapy may be required.

PRIMARY SYSTEMIC ANAPLASTIC LARGE CELL LYMPHOMA

Anaplastic large cell lymphoma (ALCL) is an aggressive, CD30⁺, T-cell non-Hodgkin lymphoma that is seen most frequently in young males. B-cell lymphomas with similar morphology can occur, but they have clinical features identical to other diffuse large B-cell lymphomas and are not considered part of this disease. A morphologically similar but biologically unrelated and clinically distinct neoplasm, primary cutaneous ALCL, occurs predominantly in older adults and represents part of the spectrum of cutaneous CD30⁺ lymphoproliferative disorders (see earlier). Primary systemic ALCL frequently has a t(2;5) chromosomal translocation that leads to overexpression of ALK, a protein not normally detectable in lymphoid cells.

Patients usually have lymphadenopathy, and involvement of the skin, bone, and gastrointestinal tract may be observed.

A newly described entity of anaplastic large cell lymphoma of the breast is associated with breast implants. When localized, these patients may be cured with surgery including removal of the implant.

TREATMENT Rx

Patients are usually treated with chemotherapy regimens such as CHOP with or without the addition of etoposide.[19] Patients whose tumors express ALK have an excellent outcome, and 5-year survival rates of 70 to 90% have been observed. ALK-negative ALCL is more common in older patients and is associated with an inferior response rate and shorter survival time. Autologous hematopoietic stem cell transplantation may be curative for patients who relapse. The anti-CD30 antibody-drug conjugate brentuximab vedotin is highly active for patients with relapsed disease and may be incorporated into primary therapy. Patients whose lymphomas express ALK usually respond to the ALK inhibitor crizotinib.

PERIPHERAL T-CELL LYMPHOMAS, UNSPECIFIED

The largest group of patients with peripheral T-cell lymphomas is defined in the WHO classification as having "peripheral T-cell lymphoma, unspecified." These patients' signs and symptoms are similar to those of patients with aggressive B-cell lymphomas, although systemic symptoms (fevers, night sweats, and weight loss) and extranodal involvement are frequent. The diagnosis of peripheral T-cell lymphoma requires immunophenotyping to demonstrate the T-cell origin.

TREATMENT Rx

Patients are generally treated with the same regimens used for diffuse large B-cell lymphomas (e.g., CHOP with or without etoposide), often in combination with upfront autologous hematopoietic stem cell transplantation, although the outcome is substantially worse.[20] Patients who relapse after complete remission can sometimes be cured with hematopoietic stem cell transplantation.

UNUSUAL SUBTYPES OF T-CELL LYMPHOMA

Angioimmunoblastic T-cell lymphoma is associated with generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobulinemia. Results of therapy are similar to those for peripheral T-cell lymphoma, unspecified.

Extranodal NK/T-cell lymphoma usually occurs in extranodal sites, especially the nose, palate, and nasopharynx. Involvement of the nose and face leads to the syndrome that was previously called lethal midline granuloma. This disorder is unusual in the United States, but it is frequent in Southeast Asia and Latin America. The prognosis is extremely poor, although patients with localized disease can sometimes be cured with aggressive combination radiation therapy and chemotherapy.

Hepatosplenic T-cell lymphoma is characterized by sinusoidal infiltration of the spleen, liver, and bone marrow, which leads to hepatosplenomegaly, systemic symptoms, and cytopenias. Lymphadenopathy is unusual. Patients are typically young males, and this disease can occur in allograft recipients and in the setting of immune dysfunction. The prognosis is poor, and remissions are rarely observed with chemotherapy.

Enteropathy-type T-cell lymphoma is usually seen in patients with gluten-sensitive enteropathy (Chapter 140). Patients typically present with abdominal pain and diarrhea and sometimes with bowel perforation. Treatment of celiac disease with a gluten-free diet may reduce the risk for lymphoma. The prognosis in these often undernourished patients is poor.

Subcutaneous panniculitis-like T-cell lymphoma manifests with multiple subcutaneous nodules and is often misdiagnosed as panniculitis. Patients with disseminated disease can have a syndrome consisting of fevers, weight loss, hepatosplenomegaly, pancytopenia, and phagocytosis of blood cells (hemophagocytic syndrome). Patients sometimes respond to combination chemotherapy regimens used for diffuse large B-cell lymphoma, interferon, and radiation therapy, but long-term disease-free survival is unusual.

SPECIAL CLINICAL SITUATIONS

The diagnosis and management of patients with the various types of non-Hodgkin lymphoma can be profoundly influenced by the site of origin of the lymphoma and by certain clinical characteristics of the patients. Examples of the latter include pregnant patients with lymphoma, elderly patients with lymphoma, and lymphoma in patients who are severely immunosuppressed.

Specific Primary Sites of Diffuse Large B-Cell Lymphoma

Approximately 30% of diffuse large B-cell lymphomas originate in extranodal sites. Presentation in certain extranodal sites is associated with unique clinical behaviors that may necessitate diagnostic studies or additional therapy beyond that used for patients with nodal presentations.

Patients with primary CNS lymphoma (Chapter 189) commonly have ocular involvement, and all patients with this diagnosis should have a slit lamp

examination. Surgical resection of primary CNS lymphoma is usually not performed, and the primary role of surgery is for diagnosis. Primary lymphomas of the CNS are very sensitive to corticosteroids, but the best results have been observed with chemotherapy regimens that use high-dose methotrexate alone or in combination with other agents such as cytarabine and temozolomide. By comparison, conventional chemotherapy regimens, such as CHOP, are of little benefit. Whole brain irradiation is also effective therapy, although the incidence of leukoencephalopathy is extremely high, especially in elderly patients. Radiation therapy is frequently reserved for relapse rather than being used as adjunctive treatment with primary chemotherapy.

Treatment of primary testicular lymphoma, the most common testicular cancer in men older than 60 years (Chapter 200), usually consists of orchiectomy followed by combination chemotherapy. Relapse in the contralateral testicle is common, and most oncologists recommend adjuvant radiation to the scrotum. CNS involvement is common, and prophylactic intrathecal chemotherapy is usually recommended. Late relapses occur frequently.

Diffuse large B-cell lymphoma of the stomach and gastrointestinal tract is treated differently from gastric MALT lymphoma, even if there is a history of prior MALT lymphoma. Patients can be cured with surgery and adjunctive radiation or chemotherapy, although surgery is rarely performed for gastric lymphomas because of the morbidity associated with gastric resection. Patients should be treated with chemotherapy regimens used for other diffuse large B-cell lymphomas. Radiation therapy is sometimes used after chemotherapy, although the role of combined-modality treatment is not defined.

Lymphoma in AIDS and Post-transplantation Lymphoproliferative Disorders

Non-Hodgkin lymphoma is an AIDS-defining illness in HIV-infected individuals (Chapter 393), and the risk for developing a non-Hodgkin lymphoma is increased more than 150-fold after the diagnosis of another AIDS-defining illness. Most cases are diffuse large B-cell lymphomas or Burkitt lymphomas. AIDS-associated lymphomas behave aggressively and frequently involve the CNS and other unusual sites, such as the gastrointestinal tract, anus, rectum, skin, and soft tissue (Chapter 393). Factors associated with poor survival include low CD4 counts, poor performance status, older age, and advanced stage. The incidence of AIDS-associated non-Hodgkin lymphoma has declined, and the prognosis has improved considerably. Patients are generally treated in the same manner as non-immunocompromised patients, and the prognoses are similar. Intrathecal prophylaxis is generally recommended because of a higher risk for CNS involvement.

The risk for developing a non-Hodgkin lymphoma is also markedly increased in patients who have received a solid organ transplant. The histologic appearance of these lymphomas is variable, but they frequently resemble aggressive lymphomas in non-immunocompromised patients. Similar disorders can be seen in patients who are treated with methotrexate and other drugs for autoimmune disorders and in recipients of allogeneic hematopoietic stem cell transplants, especially if the transplants are T-cell depleted. These post-transplantation lymphoproliferative disorders, which may develop within weeks after surgery, are more common in patients who receive aggressive immunosuppression after transplantation. Involvement of extranodal sites is common, and lymphoma frequently involves the transplanted organ. Post-transplantation lymphoproliferative disorders may respond to reduction or withdrawal of immunosuppression. Some investigators have advocated the use of acyclovir or ganciclovir because these lymphomas are usually related to EBV, but this practice is controversial. High response rates are also seen with rituximab. Other patients require treatment with combination chemotherapy regimens.

Non-Hodgkin Lymphoma in Elderly Patients

More than 50% of patients who develop non-Hodgkin lymphomas are older than 60 years, and the prognosis is generally worse for elderly patients. These poorer outcomes are related to increased toxicity of drug therapy, lower remission rates, increased rates of relapse, and higher death rates from cardiovascular disease and causes other than the lymphoma itself. Older patients are more likely to have other adverse prognostic characteristics (see Table 185-8), which also contribute to poorer outcomes. The practice of arbitrary dose reductions based solely on age should be discouraged if patients have a good performance status and no comorbid illnesses.

Non-Hodgkin Lymphoma and Pregnancy

Non-Hodgkin lymphoma in pregnancy involves major clinical and ethical issues, and a multidisciplinary approach is needed (Chapter 239). Although chest radiographs are generally considered safe, ultrasound examination is usually used instead of CT for staging in the abdomen and pelvis.

Treatment can occasionally be delayed until after delivery; however, most women have a tumor that is potentially curable, and treatment delays may decrease the chance for cure. Other patients have conditions such as superior vena cava syndrome that require immediate treatment. After the first trimester, full-dose standard therapy such as R-CHOP-R may be used. Several studies indicate high probabilities of cure without significantly increased adverse long-term physical or intellectual deficits for the child. Although it is reasonable to offer therapeutic abortion for women in the first trimester, chemotherapy may also be successful in this situation. Regimens using methotrexate or abdominal radiation must be avoided.

DISEASES SOMETIMES CONFUSED WITH LYMPHOMA

A variety of conditions are associated with lymphadenopathy that can be confused with lymphoma.[21] The most common atypical lymphoid proliferations that can be confused with lymphoma are florid reactions to immune stimulation. Follicular hyperplasia with diffuse proliferation of B cells and T cells can be seen in a variety of autoimmune diseases (e.g., Sjögren syndrome, systemic lupus erythematosus, rheumatoid arthritis) and infectious processes (e.g., EBV, cytomegalovirus, cat-scratch disease) (Chapter 168). If the definitive diagnosis of lymphoma cannot be made even after immunologic and molecular studies, the patient should be closely observed. The clinical course or subsequent biopsies can usually resolve the confusion.

Castleman disease, or angiofollicular lymph node hyperplasia, usually appears with a hyaline vascular pattern of lymphoid proliferation, but a subset of patients has hyperplastic lymphoid follicles and sheets of plasma cells. Patients with Castleman disease often present with a localized lymphoid mass, but some patients have a systemic illness with fevers, night sweats, weight loss, and fatigue. Frequently, the systemic symptoms of Castleman disease are related to excessive production of IL-6. Castleman disease in HIV-infected patients is frequently associated with HHV-8. Patients with disseminated and plasma cell–rich forms of Castleman disease may occasionally progress to lymphoma. Patients with localized Castleman disease can be treated with surgical removal or radiation therapy. Patients with systemic disease may respond to treatment with high-dose corticosteroids. Patients with overexpression of IL-6 frequently benefit from treatment with an anti-IL-6 antibody. If other treatments fail, patients sometimes benefit from combination chemotherapy regimens, autologous or allogeneic hematopoietic stem cell transplantation, or both.

Sinus histiocytosis with massive lymphadenopathy, also known as *Rosai-Dorfman disease,* manifests as bulky lymphadenopathy in children and young adults. Extranodal sites such as the skin, upper airways, gastrointestinal tract, and CNS can be involved. The disease is usually self-limited, but it has been associated with autoimmune hemolytic anemia.

Kikuchi's disease (histiocytic necrotizing lymphadenitis) is a disease of unknown origin that most commonly affects young women. Symptoms most commonly consist of painless cervical lymphadenopathy that is often accompanied by fever, flu-like symptoms, and rash. Treatment is symptomatic, and manifestations usually resolve within weeks or months.

IgG4-related disease is a systemic immune-mediated fibrosing inflammatory disease in which various organs are infiltrated by IgG4-positive plasma cells. Patients often have accompanying asymptomatic lymphadenopathy that usually responds to corticosteroids.

REVIEW QUESTIONS

1. A 66-year old man develops cough and chest pain. A chest radiograph shows a mediastinal mass. A biopsy of the mass shows diffuse large B-cell lymphoma. Additional studies reveal enlarged lymph nodes in the para-aortic and mesenteric regions. His bone marrow biopsy is negative. His performance status is otherwise normal, and his serum lactate dehydrogenase level is normal. How should this man be treated?

A. Observation (watch and wait)
B. CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone)
C. CHOP + rituximab
D. Radiation to the chest and abdomen
E. CHOP + rituximab followed by autologous stem cell transplantation

Answer: C This man has a stage III diffuse large B-cell lymphoma. His IPI score is II (low-intermediate risk). A watch and wait approach is reasonable for some patients with indolent lymphoma, but not for patients with diffuse large B-cell lymphoma. There is no role for radiation, alone, in this situation. Treatment with CHOP would yield a high response rate, although randomized trials show improved survival with the addition of the anti-CD20 antibody rituximab (Coiffier B, Thieblemont C, Van Den Neste E, et al. Long-term outcome of patients in the LNH-98.5 trial, the first randomized study comparing rituximab-CHOP to standard CHOP chemotherapy in DLBCL patients: a study by the Groupe d'Etudes des Lymphomes de l'Adulte. *Blood.* 2010;116:2040-2045). There is no evidence that upfront autologous stem cell transplantation is beneficial for patients in low-risk groups.

2. A 27-year old woman has an unexplained 20-lb weight loss, drenching night sweats, and bulky bilateral cervical lymphadenopathy. A chest radiograph shows bilateral cervical lymphadenopathy. Fine-needle aspirate (FNA) of a cervical lymph node reveals cells consistent with a B-cell non-Hodgkin lymphoma. What should you do next?

A. Performa FNA on another cervical lymph node.
B. Prescribe antibiotics for 10 days and reevaluate.
C. Start ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine).
D. Perform an excision biopsy of a cervical lymph node.
E. Start CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) + rituximab.

Answer: D This woman has an obvious systemic illness. Empirical antibiotic therapy would be inappropriate. All non-Hodgkin lymphomas are treatable, and many are curable. It is essential to have an accurate diagnosis before starting therapy so that appropriate therapy is administered. Core needle biopsies can occasionally be used for a primary diagnosis if the specimen is handled properly. Fine-needle aspirates should not be used to diagnose lymphoma, and they preclude an accurate diagnosis of the specific subtype of non-Hodgkin lymphoma. In most cases, an excisional biopsy is necessary (and is always preferred) for the initial diagnosis. Her diagnosis from FNA is inadequate. An excisional biopsy with review by an expert hematopathologist is necessary for appropriate treatment (Swerdlow SH. Lymphoma classification and the tools of our trade: an introduction to the 2012 USCAP Long Course. *Mod Pathol.* 2013;26:S1-S14). It would be inappropriate to start CHOP + rituximab before an accurate diagnosis is established. The ABVD regimen is used for Hodgkin lymphoma.

3. Patients with mantle cell lymphoma are most likely to have the following cytogenetic abnormality in their lymph node biopsy?

A. t(11;14)
B. t(11;18)
C. t(14;18)
D. t(8;14)
E. t(2;5)

Answer: A Non-Hodgkin lymphomas are often associated with cytogenetic abnormalities. These abnormalities often consist of translocations that result in overproduction of fusion proteins with result in cell proliferation or inhibit apoptosis (Nogai H, Dörken B, Lenz G. Pathogenesis of Non-Hodgkin lymphoma. *J Clin Oncol.* 2011;29:1803-1811). Certain subtypes of non-Hodgkin lymphoma are associated with specific cytogenetic abnormalities. The t(11;18) is associated with MALT lymphoma, the t(14;18) is associated with follicular lymphoma, the t(8;14) is associated with Burkitt's lymphoma, and the t(2;5) is associated with anaplastic large cell lymphoma. The t(11;14) is characteristic of mantle cell lymphoma. This translocation results in overproduction of cyclin D1 and resultant cell proliferation.

4. A 40-year old woman has a history of a mediastinal large B-cell lymphoma. She was treated several years ago with R-CHOP followed by radiation therapy involving the chest and neck. She comes to you with complaints of fatigue, trouble concentrating at work, and feeling cold. Her examination reveals no lymphadenopathy. Her chest radiograph is unchanged from 1 year ago. Laboratory tests are normal except for high cholesterol. What should you do?

A. Order a computed tomography (CT) scan of the chest, abdomen, and pelvis.
B. Check serum vitamin B_{12} and folic acid levels.
C. Perform a bone marrow aspirate and biopsy.
D. Check a thyroid-stimulating hormone (TSH) level.
E. Order a positron emission tomography (PET) scan.

Answer: D It is important to monitor patients for late effects of therapy. Although disease recurrence should always be considered, there is no evidence of this. It would be inappropriate to order additional imaging at this time. There is no evidence that she is B_{12} or folic acid deficient. Hypothyroidism is a frequent complication of radiation therapy and should always be considered. Her history increases her risk for cardiovascular disease, and strict control of modifiable risk-factor, such as cholesterol, is necessary (http://www.nccn.org/professionals/physician_gls/pdf/survivorship.pdf).

5. Which patient is least likely to have a lymphoma associated with the Epstein-Barr virus (EBV)?

A. A 42-year old man with a history of a liver transplantation
B. A 31-year old woman with chronic HIV infection
C. A 45-year old woman with an extranodal NK/T-cell lymphoma
D. A 68-year old woman with follicular lymphoma
E. A child from sub-Saharan Africa with Burkitt's lymphoma

Answer: D EBV, as well as other infectious agents, is associated with several types of non-Hodgkin lymphoma *Semin Diagn Pathol.* 2011;28:178-187). Follicular lymphoma is not usually associated with EBV. (De Falco G, Rogena EA, Leoncini L. Infectious agents and lymphoma.

186

HODGKIN LYMPHOMA

JOSEPH M. CONNORS

DEFINITION

Hodgkin lymphoma, formerly called Hodgkin disease, is one of the B-cell lymphomas. It consists of two major types: classic Hodgkin lymphoma, with a characteristic neoplastic cell, the Hodgkin-Reed-Sternberg cell; and the much less common (~5% of cases) nodular lymphocyte-predominant Hodgkin lymphoma, with a characteristic lymphocyte-predominant cell. Both types have a distinct natural history, and most important, an excellent response to treatment, with the large majority of patients being cured. Its management, which requires careful multidisciplinary cooperation, serves as a paradigm for the successful application of modern oncologic concepts. Highly effective multiagent chemotherapy is the cornerstone of treatment. Carefully selected patients may require the addition of radiation or, if the lymphoma recurs after primary treatment, high-dose chemoradiation therapy and autologous hematologic stem cell transplantation (HDC/HSCT). The major challenge to clinicians managing this neoplasm is to cure the disease while minimizing long-term toxicity.

EPIDEMIOLOGY

The incidence of Hodgkin lymphoma varies substantially around the world. The highest rates occur in the United States, Canada, Switzerland, and northern Europe. Intermediate rates are seen in southern and eastern Europe and low rates in eastern Asia. No clear explanation for this variation in incidence has been found. Postulated reasons include differences in the age at onset or genotype of any associated Epstein-Barr virus (EBV) infection; crowding during childhood as a result of lower socioeconomic status, predisposing to passage of an as yet undiscovered infectious vector; and intrinsic genetic differences in susceptibility.

Approximately 20,000 new cases are seen annually in North America and Europe. The age-adjusted incidence of Hodgkin lymphoma declined modestly over the 20 years before 1990 at a rate of approximately 0.9% per year but has leveled off since then and is now approximately 2.7 per 100,000. Age-adjusted annual mortality is 0.5 per 100,000. Hodgkin lymphoma occurs slightly more often in men and is seen more frequently in whites than African Americans and much less frequently in Asian populations. Much of the difference in incidence between whites and blacks in North America can be attributed to the higher incidence seen in higher socioeconomic classes. The cumulative lifetime risk for development of Hodgkin lymphoma is approximately 1 in 250 to 1 in 300 in North America.

The incidence of Hodgkin lymphoma is bimodal in distribution, rising from very low in childhood to an early peak in young adulthood (25 to 30 years) and a later peak in late adulthood (>50 years). In the Western world, only about 5% of cases occur in persons younger than 15 years and 5% in individuals older than 70 years. In contrast, the age distribution in the Indian subcontinent is strongly shifted into childhood.

PATHOBIOLOGY

The cause of Hodgkin lymphoma remains unclear. Hodgkin lymphoma is not associated with exposure to radiation, chemicals, biocidal agents, working in health care–related professions, or previous tonsillectomy. The leading suspect remains EBV, based on much suggestive evidence but no definitive proof.[1]

Epstein-Barr Virus

EBV is a large B-lymphocyte tropic herpesvirus (Chapter 377). Approximately 90% of the general population acquires infection with EBV by early adulthood. In the developing world, this infection usually occurs in childhood, but in developed countries, infection is often delayed into the teens, when it is associated with the syndrome of infectious mononucleosis in up to 30% of new cases. A history of infectious mononucleosis increases the likelihood for subsequent Hodgkin lymphoma three-fold. Antibodies to the viral capsid antigen reach higher levels in patients with Hodgkin lymphoma than in controls, and these higher levels appear several years before the neoplasm. In situ hybridization studies have demonstrated that the Hodgkin-Reed-Sternberg cells in approximately 50% of cases of Hodgkin lymphoma contain EBV-encoded small RNA (EBER), and in these cases, virtually all the Hodgkin-Reed-Sternberg cells are positive for the virus. The EBV genome is amplified 50-fold or more in Hodgkin-Reed-Sternberg cells and is monoclonal in an individual patient's Hodgkin-Reed-Sternberg cells. In some populations, virtually all cases of Hodgkin lymphoma occur in EBV-positive individuals, but up to 50% of patients in developed countries do not have EBV in their Hodgkin-Reed-Sternberg cells. Thus, although EBV may play an important role in the development of Hodgkin lymphoma, that role is neither straightforward nor universal.

Genetic Factors

Circumstantial evidence for a genetic contribution to the etiology of Hodgkin lymphoma comes from studies showing that Hodgkin lymphoma is almost 100-fold more likely to develop in the monozygotic twin of an affected individual than in a dizygotic twin. First-degree relatives of individuals with the disease have up to a five-fold increased risk for development of the lymphoma. Perhaps genetically predisposed individuals react differently to EBV, thereby increasing the chance that a lymphoid neoplasm will develop.

Polymerase chain reaction–based genotypic analysis has demonstrated the clonal derivation of Hodgkin-Reed-Sternberg cells, including identical *p53* mutations from multiple Hodgkin-Reed-Sternberg cells extracted from a single biopsy specimen, thereby unequivocally establishing clonality. The presence of clonal immunoglobulin gene rearrangements from multiple cells in the same biopsy specimen also confirms a B-cell origin. Only a few rare cases with a T-cell genotype have been reported, but these are exceptional. The presence of clonal somatic mutations provides proof of the germinal center origin of the neoplastic cells. Finally, identification of cells with identical immunoglobulin gene rearrangements both at diagnosis and at relapse verify that the B-cell clonality of the disease is preserved over time.

Despite their B-cell origin, the neoplastic cells of Hodgkin lymphoma are incapable of making intact antibodies, perhaps because they lack the ability to make the transcription factors necessary to activate the immunoglobulin promoter. B cells that are incapable of manufacturing antibody should undergo apoptosis, but the Hodgkin-Reed-Sternberg cells avoid

self-destruction. The observation that the antiapoptotic nuclear transcription factor NFκB is constitutively activated in these cells may provide an explanation.

Classic cytogenetics has been unrevealing in Hodgkin lymphoma. Aneuploidy and hyperploidy consistent with the multinucleated nature of Hodgkin-Reed-Sternberg cells are frequent, but no consistent translocations have been detected. A germline *NPAT* mutation and multiple possible sites on chromosome 6 at 6p21.3[2,3] have been associated with an increased risk for Hodgkin lymphoma.

CLINICAL MANIFESTATIONS

Hodgkin lymphoma is usually manifested as lymphadenopathy (Chapter 168), typically in the cervical, axillary, or mediastinal areas, and only about 10% of patients present with nodal disease below the diaphragm. Although peripherally located nodes seldom reach large size, very large mediastinal masses or, less often, retroperitoneal masses can develop with only modest symptoms. Lymph node involvement in Hodgkin lymphoma is usually painless, but an occasional patient notes discomfort in involved nodal sites immediately after drinking alcohol.

Approximately 25% of patients with Hodgkin lymphoma have constitutional symptoms. The classic B symptoms, significant weight loss (>10% of baseline), night sweats, and persistent fever, usually signal widespread or locally extensive disease and imply a need for systemic treatment. Generalized pruritus, occasionally severe, can antedate the diagnosis of Hodgkin lymphoma by up to several years. Some patients have symptoms suggestive of a growing mass lesion, such as cough or stridor as a result of tracheobronchial compression from mediastinal disease or bone pain secondary to metastatic involvement. Because Hodgkin lymphoma can involve the bone marrow extensively, an occasional patient presents with symptomatic anemia or incidentally noted pancytopenia. Paraneoplastic neurologic or endocrine syndromes have been reported with Hodgkin lymphoma but are rare.

DIAGNOSIS

The diagnosis of classic Hodgkin lymphoma is based on recognition of Hodgkin-Reed-Sternberg cells (Fig. 186-1) or Hodgkin cells (or both) in an appropriate cellular background in tissue sections from a lymph node or extralymphatic organ, such as bone marrow, lung, or bone. Fine-needle aspiration biopsy is not adequate for the diagnosis of Hodgkin lymphoma. Open biopsy and standard histochemical staining are required to establish the diagnosis unequivocally and to determine the histologic subtype. Immunohistochemical studies can prove helpful in difficult cases or to distinguish special subtypes such as the lymphocyte-rich classic and nodular lymphocyte-predominant types. In classic Hodgkin lymphoma, scattered large Hodgkin-Reed-Sternberg cells either are multinucleated or have large polyploid nuclei. Variations include mononuclear cells that are similar to the usual polylobated or multinuclear cells but have only one large nucleus with a prominent nucleolus, as well as lacunar cells, which are Hodgkin-Reed-Sternberg variants with abundant cytoplasm that has retracted as an artifact of formalin fixation. The infrequent Hodgkin-Reed-Sternberg cells are usually present in a background mixture of polyclonal lymphocytes, eosinophils, neutrophils, plasma cells, fibroblasts, and histiocytes. A high number of associated macrophages have been demonstrated to be a strong predictor of treatment resistance. Occasionally, granulomas form with a prominent histiocytic component.

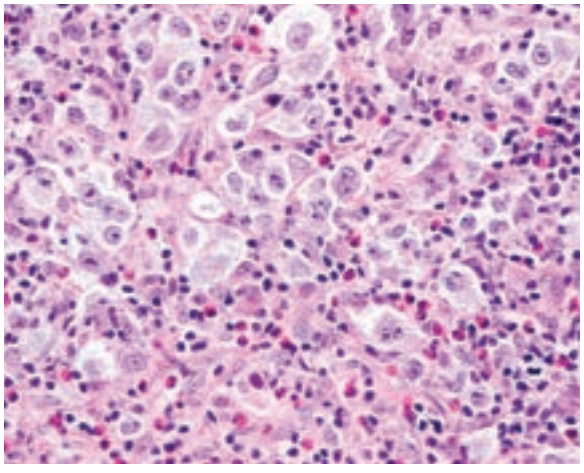

FIGURE 186-1. Nodular sclerosing Hodgkin lymphoma. This figure shows a typical case of classic nodular sclerosing Hodgkin lymphoma with many lacunar cells, occasional diagnostic Hodgkin-Reed-Sternberg cells, and the characteristic background of lymphocytes and eosinophils. (Photomicrograph courtesy of Randy D. Gascoyne, MD, British Columbia Cancer Agency.)

Hodgkin lymphoma can typically be classified into well-described subtypes (Table 186-1). Reproducibility of the distinctions among these subtypes has been confirmed in the current widely accepted World Health Organization classification of lymphoid neoplasms. With addition of the new category of lymphocyte-rich classic Hodgkin lymphoma, this newest classification scheme permits confident identification of nodular lymphocyte-predominant Hodgkin lymphoma as a separate entity. The most common subtype is nodular sclerosing, which has characteristic coarse bands of sclerosis surrounding nodules composed of typical Hodgkin-Reed-Sternberg cells in the usual background mixture of reactive and inflammatory cells.

The immunophenotype of the neoplastic cells in Hodgkin lymphoma can help identify the specific subtype. Typically, the Hodgkin-Reed-Sternberg cells stain positively for CD30 (80 to 100% of cases), CD15 (75 to 85% of cases), and B-cell-specific activating protein (BSAP), which is the product of the *PAX5* gene (>90% of cases). However, often only a minority of the malignant cells stain positively for the CD15 and BSAP markers. CD20, a generally reliable marker of B-cell lineage, is positive in about 40% of cases of classic Hodgkin lymphoma, but usually only in a minority of cells, and the staining can be weak. In contrast, nodular lymphocyte-predominant Hodgkin lymphoma almost always stains strongly positive for CD20 and for the specialized B-cell markers CD79a and CD45, but it is negative for CD30 and CD15. Anaplastic large cell lymphoma (Chapter 185) is positive for CD30 but reliably negative for CD15, CD20, and CD79a.

Differential Diagnosis

Depending on the site of occurrence and associated symptoms, the differential diagnosis of Hodgkin lymphoma includes non-Hodgkin lymphoma (Chapter 185), germ cell tumors (Chapter 200), thymoma (Chapter 422), sarcoidosis (Chapter 95), and tuberculosis (Chapter 324). However, the specific diagnosis is readily determined by obtaining an adequate biopsy specimen for review by an experienced hematopathologist. Proceeding to such a biopsy early in the assessment of patients with lymphadenopathy (Chapter 168), especially of the mediastinum, often saves time and spares the patient needless testing and delay in diagnosis.

With computed tomography (CT) and appropriate biopsy procedures to investigate enlarged central thoracic or intra-abdominal lymph nodes, the diagnosis of Hodgkin lymphoma seldom presents difficulty. The immunophenotype helps distinguish Hodgkin lymphoma from other diseases. For example, T-cell-rich B-cell lymphoma (Chapter 185) is distinguished from classic Hodgkin lymphoma by being CD30 and CD15 negative but positive for CD20 and CD45. However, T-cell-rich B-cell lymphoma (Chapter 185) can be very difficult to distinguish from nodular lymphocyte-predominant Hodgkin lymphoma because both are negative for CD30 and CD15 but positive for CD45. This distinction is best made by focusing on the histologic pattern of the neoplastic cells. In fact, the combination of appropriate immunohistopathologic evaluation by an expert hematopathologist and clinical assessment has virtually eliminated difficulties with the differential diagnosis. Problems mostly arise when inadequate or improperly processed material is all that is available for diagnosis.

TABLE 186-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HODGKIN LYMPHOMA SUBTYPES

SUBTYPE NAME	FREQUENCY (%)*
Classic Hodgkin lymphoma	
Nodular sclerosis	70
Lymphocyte rich	3
Mixed cellularity	10
Lymphocyte depleted	1
Nodular lymphocyte-predominant Hodgkin lymphoma	7
Hodgkin lymphoma, not otherwise classifiable	9

*Frequency based on all new cases ($N = 1043$) seen in British Columbia since January 1998 when the category of lymphocyte-rich classic Hodgkin lymphoma became well established.

Staging

Physical Examination

Given its tendency to spread in an orderly fashion, usually from initially involved lymph nodes, the stage of Hodgkin lymphoma can be established by using readily available imaging and laboratory tests (Fig. 186-2 and Table 186-2). The evaluation should start with a careful history to search for the presence of localizing signs, such as bone pain, or the constitutional symptoms of fever, weight loss, or night sweats. The history may also reveal comorbid conditions that may affect the safe delivery of planned treatment. The physical examination may identify lymphadenopathy or organomegaly.

Laboratory Testing

Laboratory testing should include blood cell counts and the erythrocyte sedimentation rate, assessment of liver and renal function, serum albumin level, serum protein electrophoresis, and serologic testing for hepatitis B. Also, the patient should be tested for hepatitis C if liver enzyme abnormalities are detected and human immunodeficiency virus (HIV) antibody if the history indicates an increased risk or if the sites of extranodal disease are unusual. Bone marrow aspiration and biopsy are only useful for the minority of patients with constitutional (B) symptoms or those with lower than normal peripheral blood counts at diagnosis and may be rendered entirely unnecessary by fluorodeoxyglucose positron emission tomography if current studies are validated.[4]

TABLE 186-2 TESTS REQUIRED FOR STAGING OF HODGKIN LYMPHOMA

Complete history to search for B symptoms (fever, weight loss, night sweats) or other symptomatic problems suggesting more advanced disease	
Physical examination for lymphadenopathy or organomegaly	
Complete blood count	
Serum creatinine, alkaline phosphatase, lactate dehydrogenase, bilirubin, and protein electrophoresis (including serum albumin level)	
Chest radiograph, posteroanterior and lateral views	
Computed tomography scan of the neck, thorax, abdomen, and pelvis	
Fluorodeoxyglucose positron emission tomography with computed tomography (PET/CT)	
Certain tests are required only for specific manifestations	
MANIFESTATION/CONDITION	**TEST**
B symptoms or WBC count <4.0 × 10^9/L, Hgb <120 g/L (women) or 130 g/L (men), or platelets <125 × 10^9/L	Bone marrow biopsy and aspiration
Stage IA or IIA disease with upper cervical lymph node involvement (suprahyoid)	ENT examination

ENT = ear, nose, and throat; Hgb = hemoglobin; WBC = white blood cell.

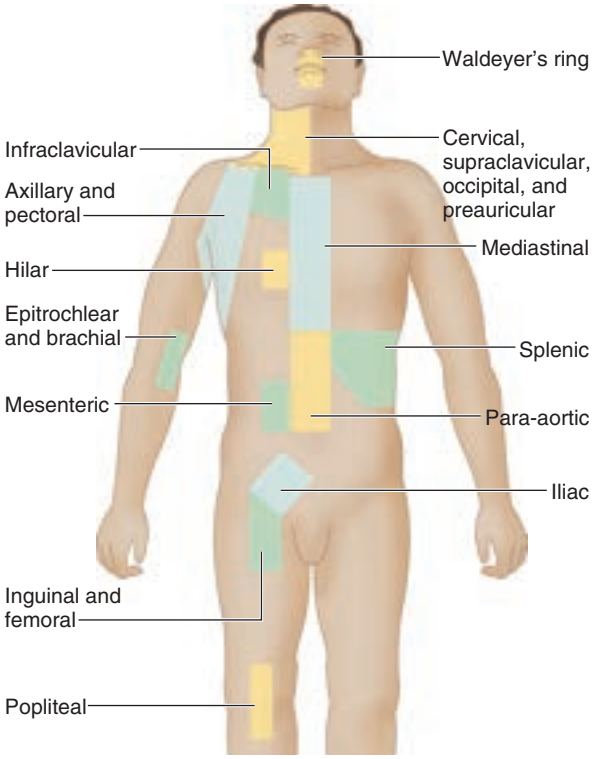

FIGURE 186-2. Anatomic definition of lymph node regions for staging of Hodgkin disease. (From Kaplan HS, Rosenberg SA. The treatment of Hodgkin disease. *Med Clin North Am*. 1966;50:1591-1610.)

Imaging

Imaging techniques to evaluate Hodgkin lymphoma continue to evolve (Fig. 186-3). All patients should undergo contrast-enhanced CT scanning of the neck, thorax, abdomen, and pelvis with slices at intervals of 1 cm or less. Magnetic resonance imaging is occasionally useful when the extent of bone or soft tissue involvement must be determined precisely or for a patient with an absolute contraindication to the use of intravenous contrast agents.

Positron Emission Tomography

Fluorodeoxyglucose positron emission tomography (PET) is more sensitive and specific than CT or gallium scanning both for staging and for assessment of residual masses after treatment and is now considered mandatory for staging of Hodgkin lymphoma.[5] It may also be useful for the assessment of residual masses during or after planned treatment, allowing better selection of patients who should receive altered or additional therapy, especially radiotherapy.

Staging System

The Ann Arbor staging system with the Cotswold modification (Table 186-3) categorizes patients into four stages. The first three indicate the expanding extent of lymph node disease (see Fig. 186-2): stage I, a single nodal area; stage II, two or more nodal areas but still on one side of the diaphragm; and stage III, nodal disease on both sides of the diaphragm. The spleen and the lymphoid tissue of Waldeyer's ring each count as nodal sites in this system. Stage IV is reserved for extranodal disease, which for all practical purposes is disease in the bone marrow, lung, bone, or liver. Hodgkin lymphoma at any other extranodal site should prompt questioning of the diagnosis or a search for HIV infection.

Bulky disease is defined as the presence of any tumor mass with the largest diameter greater than 10 cm or a mediastinal mass with a transverse diameter exceeding one third of the largest transverse transthoracic diameter. With CT scanning, use of the mediastinal mass ratio is obsolete, and the term *bulky* is best assigned to tumors exceeding 10 cm in largest single diameter.

The E lesion designation identifies patients whose limited extranodal extension of Hodgkin lymphoma could be included in a reasonable involved field of irradiation. As part of staging, patients are further subdivided into those with or without fever, night sweats, or weight loss (B symptoms).

TREATMENT

Over the past 70 years, Hodgkin lymphoma has been transformed from a nearly uniformly fatal illness to one that is usually cured. This remarkable success has provided a paradigm on which much of modern oncologic treatment is based. The principles underlying combined-modality treatment and multiagent chemotherapy, the mainstays of today's successful treatment of many malignancies, were first demonstrated to be effective with Hodgkin lymphoma. The essential involvement of a multidisciplinary team, including pathologists, experts in diagnostic imaging, medical and radiation oncologists, nurses, and support staff, has served as a model for all cancer. The necessity to balance greater efficacy of initial treatment, which often requires an increase in intensity and therefore toxicity, against troublesome and occasionally fatal late complications has encouraged a long-term perspective and careful monitoring for late treatment-related side effects.

From a practical therapeutic viewpoint, patients with stage III or IV disease or bulky disease are defined as having advanced disease, whereas patients without these characteristics have limited-stage disease. In Europe, patients with limited disease are further subdivided into those with favorable and unfavorable outcomes. Cure rates exceed 90 to 95% for patients with nonbulky stage IA or IIA (limited) disease. However, for patients with advanced-stage disease, independent predictors of progression include gender, age, stage, hemoglobin level, white blood cell count, lymphocyte count, and serum albumin level (Table 186-4). Based on results obtained in the 1980s, the 80% of patients with fewer than four factors had a progression-free survival of 70%,

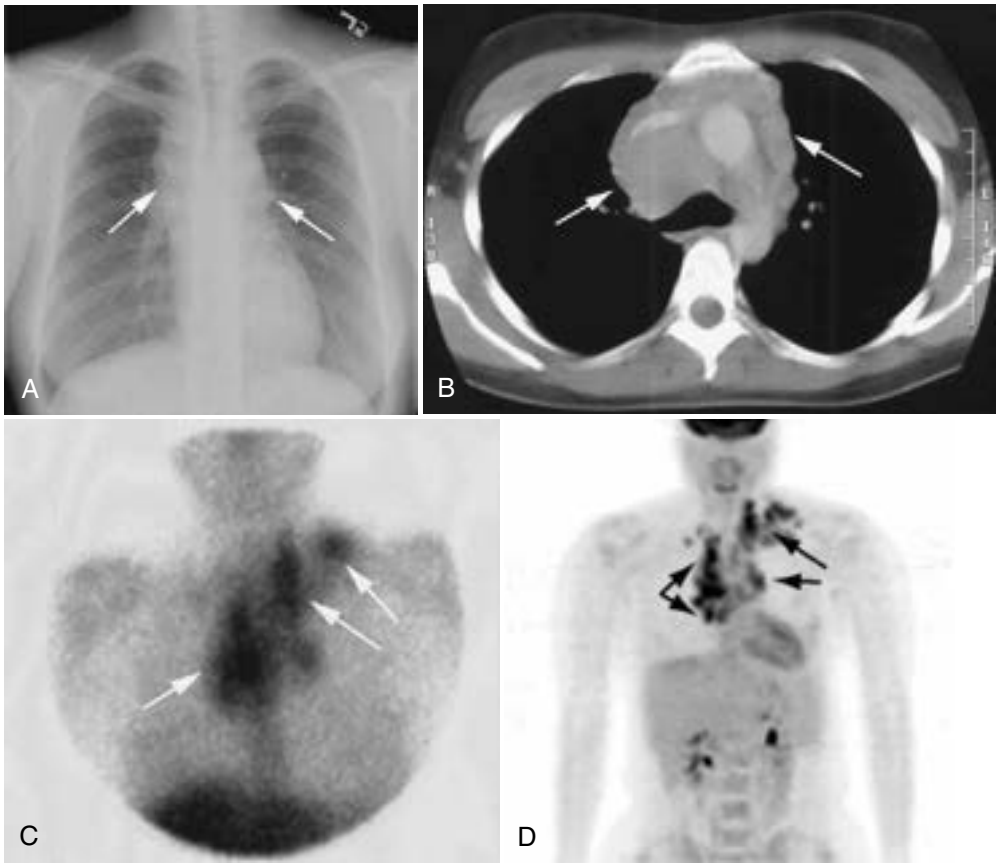

FIGURE 186-3. Imaging of Hodgkin lymphoma. Bulky Hodgkin disease as seen on chest radiograph (**A**), computed tomography (CT) of the chest (**B**), gallium scan (**C**), and positron emission tomography (PET) (**D**). The *arrows* indicate sites of disease. Note that the PET and CT scans provide more detailed information than the chest radiograph and gallium scan.

TABLE 186-3 MODIFIED ANN ARBOR STAGING SYSTEM FOR HODGKIN LYMPHOMA

STAGE	INVOLVEMENT
I	Single lymph node region (I) or one extralymphatic site (I_E)
II	Two or more lymph node regions, same side of the diaphragm (II), or local extralymphatic extension plus one or more lymph node regions, same side of the diaphragm (II_E)
III	Lymph node regions on both sides of the diaphragm (III); may be accompanied by local extralymphatic extension (III_E)
IV	Diffuse involvement of one or more extralymphatic organs or sites
A	No "B" symptoms
B	Presence of at least one of the following: Unexplained weight loss >10% of baseline during 6 mo before staging Recurrent unexplained fever >38° C Recurrent night sweats

TABLE 186-4 RATES OF PROGRESSION IN 5 YEARS IN PATIENTS WITH ADVANCED-STAGE HODGKIN LYMPHOMA

NO. OF FACTORS*	FREQUENCY (%)	PERCENTAGE WITH PROGRESSION-FREE SURVIVAL AT 5 YEARS
0-3	81	70
4-7	19	47

*Male sex, age older than 45 years, stage IV, hemoglobin level less than 10.5 g/dL, white blood cell count greater than 15,000/mL, lymphocyte count less than 600/mL or less than 8% of the white cell count, or serum albumin less than 4 g/dL.

TABLE 186-5 TREATMENT PLAN FOR HODGKIN LYMPHOMA BASED ON STAGE

STAGE	TREATMENT
IA or IIA, no bulky disease*	ABVD† × 4 if CR after 2 cycles, or ABVD × 2 + IRRT
IB, IIB, or any stage III or IV or bulky disease, any stage	ABVD† until 2 cycles past CR (minimum 6, maximum 8) or escalated BEACOPP†

*Bulky refers to disease with the largest diameter of any single mass equal to or greater than 10 cm.
†See text for drugs in each regimen. Optimal dosing must be individualized.
CR = complete response.

but for the 20% who had four or more factors, the progression-free survival rate fell to less than 50%. However, with better attention to dose delivery, more current results indicate a spread of only 80% to 60% between these two groups.[6] A straightforward plan of treatment for the 90% of patients in whom Hodgkin lymphoma is diagnosed between the ages of 16 and 70 years can be based on clinical stage, the presence of B symptoms, and bulk of the largest tumor mass (Table 186-5).

Treatment of Limited-Stage Hodgkin Lymphoma

More than 95% of the one third of patients with Hodgkin lymphoma initially found to have limited-stage disease can be cured regardless of the site of occurrence, the presence of disease above or below the diaphragm, or the histologic subtype. The challenge is to achieve this goal with the least toxicity and cost.

Two cycles of ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) chemotherapy followed by involved-field irradiation cures nearly 95% of patients with limited-stage disease, nearly completely eliminates the risk for infertility, premature menopause, and leukemia, and minimizes cardiopulmonary toxicity.[7] However, chemotherapy alone has been shown to be

a viable alternative for patients with a good initial response to treatment and further reduces the risks of exposure to radiation.[7] More intensified approaches have been tested for early-stage but unfavorable Hodgkin lymphoma with adverse prognostic factors such as bulky mediastinal mass, extranodal extension, elevated erythrocyte sedimentation rate (ESR), or three or more lymph node areas involved. In such patients, two cycles of BEACOPP (bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone), followed by two cycles of ABVD before involved-field radiotherapy, significantly improves tumor control compared with only four cycles of ABVD before involved-field radiotherapy, but long-term results do not differ.[8] The chemotherapy in the combined-modality treatment of limited-stage Hodgkin lymphoma eradicates subclinical disease and allows smaller fields of irradiation to be used. However, a substantial proportion of the excess, long-term mortality in patients with limited-stage Hodgkin lymphoma is due to cardiovascular disease and second neoplasms that are closely related to the use of irradiation.[9] In a randomized trial that compared four to six cycles of ABVD chemotherapy alone versus irradiation, either alone or augmented with two cycles of ABVD chemotherapy, the strategy of chemotherapy alone proved equivalent to irradiation-based treatment in terms of event-free and overall survival, although the irradiation-based approach did produce a modest improvement in progression-free survival. At 12 years, however, ABVD therapy alone without subtotal nodal radiation therapy is associated with a better overall survival (94% vs. 87%) owing to a lower rate of death from other causes. These data suggest that patients with limited-stage Hodgkin lymphoma can be successfully treated with four to six cycles of ABVD alone; for the minority whose lymphoma does not completely regress after two cycles, probably best assessed by PET scanning, the addition of radiation may be optimal.

Treatment of Advanced-Stage Hodgkin Lymphoma

In advanced-stage Hodgkin lymphoma (stages IIIA, IIIB, IVA, and IVB), ABVD has become the most widely used regimen. The addition of radiation therapy significantly improves progression-free survival at 10 years in patients with advanced-stage Hodgkin lymphoma, but it does not improve overall survival. The adverse long-term effects of radiation therapy and its lack of improvement in overall survival appear to outweigh any benefits for the usual patient with advanced-stage disease. A negative PET scan at the end of chemotherapy distinguishes between residual fibrosis and persistent lymphoma and identifies the three fourths of patients with a residual mass who do not require radiation therapy.[7]

Recently devised regimens for patients with advanced Hodgkin lymphoma are the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone) and escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide vincristine, procarbazine, and prednisone) (see Table 186-5). As originally described, both include post-chemotherapy irradiation to sites of initial or residual tumor bulk (≥5 cm), but radiation does not appear to be routinely necessary after BEACOPP. Although initial results appeared quite promising, the Stanford V regimen is no more effective than standard ABVD.[7] Assessing the role of escalated BEACOPP for advanced-stage Hodgkin lymphoma requires consideration of potential secondary treatments for those not cured by primary therapy. About 50% of patients who are not cured by primary chemotherapy can be effectively treated with HDC/HSCT (Chapter 178). Thus, although escalated BEACOPP offers better initial disease control, randomized trials have failed to demonstrate its superiority over ABVD for overall survival.[7,8]

Management of Refractory or Relapsed Hodgkin Lymphoma

HDC/HSCT has become the established treatment for most patients whose Hodgkin lymphoma persists or recurs despite primary chemotherapy. However, the treatment-related mortality, high levels of toxicity, and cost associated with HDC/HSCT demand that it be reserved for patients in whom it clearly increases the chance of cure over alternative treatments;[10] such patients include those whose disease progresses during or within 3 months of initial multiagent chemotherapy (refractory Hodgkin lymphoma) and those who relapse more than 3 months after multiagent chemotherapy (relapsed Hodgkin lymphoma). For relapsed lymphoma, controversy remains, however, for two special subgroups: patients who relapse solely in originally involved but unirradiated lymph nodes and without B symptoms or extranodal disease, who may obtain up to a 40 to 50% cure rate with wide-field irradiation, and patients who relapse without B symptoms more than 1 year after completion of primary chemotherapy, who may achieve up to a 30 to 40% cure rate with additional chemotherapy with or without irradiation. However, even these two subgroups may achieve up to an 80% 10-year disease-free survival rate after HDC/HSCT. Thus, data suggest that standard treatment for patients with progressive Hodgkin lymphoma after primary chemotherapy for advanced-stage disease should be HDC/HSCT regardless of the characteristics of the relapse.

Management of Complications

Follow-up and Late Complications of Treatment

Most adult patients with Hodgkin lymphoma are cured and experience minimal long-term toxicity from their treatment. However, the risk for certain predictable and rare and less predictable late effects warrants careful but not intrusive follow-up and selective intervention (Table 186-6). At the conclusion of treatment, a thorough reassessment of the initial sites of lymphoma should be completed to provide post-treatment baseline measurements. Patients should be seen by a specialist knowledgeable in the management of lymphoma, preferably about every 3 months for 2 years, then every 6 months for 3 years, then annually. Patients should be strongly encouraged to refrain from smoking, to perform careful breast and skin examinations on a regular basis, and to undergo regular immunizations for influenza annually, pneumococcus at diagnosis and 5 years after treatment, and diphtheria and tetanus every 10 years (Chapter 18). Patients who have received radiation to the head or neck area should follow a vigorous program of dental prophylaxis in anticipation of the deleterious effect of reduced saliva production and should have their thyroid-stimulating hormone (TSH) level checked annually in recognition of the 50% risk for eventual hypothyroidism.

Other potential long-term sequelae of Hodgkin lymphoma treatment[11] include second malignancies. Radiation therapy–related solid tumors, most commonly nonmelanoma skin cancers, lung, breast, and colorectal malignancies, have a median latency period of more than 14 years after treatment. Chemotherapy-related myelodysplasia and acute myelogenous leukemia are more likely to be caused by alkylating agents that are included in regimens like MOPP and BEACOPP compared with ABVD and have shorter latency periods (median of 3 years) after treatment.[11] Long-term (usually >10 years after treatment) cardiovascular complications are coronary artery disease (related to mediastinal irradiation) and cardiomyopathy (caused by the cardiotoxicity of cumulative doses of anthracycline chemotherapy). Chemotherapy, particularly alkylating agents in MOPP and BEACOPP but not ABVD regimens, can cause permanent infertility. Long-term survivors of childhood Hodgkin lymphoma (median age at diagnosis of 15 years) are at increased risk for neurocognitive impairment.[12]

TABLE 186-6 MONITORING AFTER SUCCESSFUL PRIMARY TREATMENT OF HODGKIN LYMPHOMA

RISK/PROBLEM	INCIDENCE/RESPONSE
Relapse	Ten to 30% of patients experience relapse. Careful attention should be directed to lymph node sites, especially if previously involved with disease and not treated with radiation. New persistent focal symptoms such as bone pain should be investigated with appropriate laboratory and imaging studies.
Dental caries	Neck or oropharyngeal irradiation may cause decreased salivation. Patients should have regular dental care and should make their dentist aware of the previous irradiation.
Hypothyroidism	After external beam thyroid irradiation at doses sufficient to cure Hodgkin lymphoma, at least 50% of patients eventually become hypothyroid. All patients who have been exposed to neck irradiation should have an annual TSH level determined. Patients whose TSH level becomes elevated should be treated with lifelong thyroxine replacement in doses sufficient to suppress TSH levels to low normal (Chapter 226).
Infertility	ABVD is not known to cause permanent gonadal toxicity, although temporary oligospermia or irregular menses may persist for 1 to 2 years after treatment. Direct or scatter radiation to gonadal tissue may cause infertility, amenorrhea, or premature menopause, but this adverse event seldom occurs with the current fields used for the treatment of Hodgkin lymphoma. In general, women who continue menstruating are fertile, but men require semen analysis to provide a specific answer.
Secondary neoplasms	Although uncommon, certain secondary neoplasms occur with increased frequency in patients who have been treated for Hodgkin lymphoma: acute myelogenous leukemia; thyroid, breast, lung, cervical, and upper gastrointestinal carcinoma; and melanoma. It is appropriate to "be vigilant" for these neoplasms for the remainder of the patient's life because they may have a lengthy induction period.

ABVD = doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine; TSH = thyroid-stimulating hormone.

Special Problems in the Management of Hodgkin Lymphoma

Hodgkin Lymphoma during Pregnancy

Between 0.5 and 1.0% of cases of Hodgkin lymphoma occur coincident with pregnancy (Chapter 239). When the lymphoma is discovered during pregnancy, it is almost always possible to keep it under control and allow the pregnancy to go to full term.

Standard staging tests (see Table 186-2) should be completed, except that imaging requiring radiation must be minimized. For example, abdominal ultrasonography can identify bulky retroperitoneal disease, and a single posteroanterior radiograph of the chest, with proper shielding, can identify bulky mediastinal disease.

Patients can often continue the pregnancy to term without any treatment of the lymphoma.[13] If symptomatic or progressive disease develops, systemic chemotherapy can be given in the second and third trimester with very low risk for injuring the fetus. An attractive alternative to multiagent chemotherapy is intermittent single-agent vinblastine, given in the lowest dose that can control symptoms until delivery, followed by a full course of six to eight cycles of multiagent chemotherapy after delivery.

Hodgkin Lymphoma and Acquired Immunodeficiency Syndrome

In patients with HIV infection, the incidence of Hodgkin lymphoma is increased as much as 5- to 10-fold, and the lymphoma manifests differently and pursues a more aggressive natural history (Chapter 393). Hodgkin lymphoma in HIV-positive individuals is almost always associated with EBV within Hodgkin-Reed-Sternberg cells. The histology is much more likely to be mixed cellularity or lymphocyte depleted. The disease most commonly develops in extranodal sites, especially the bone marrow. More than 80% of patients have advanced-stage disease, and most patients have B symptoms.

Patients are prone to opportunistic infections, and the interaction of chemotherapeutic agents with other medications may compromise the patient's ability to tolerate treatment. The best approach is a combination of highly active antiretroviral agents (Chapter 389), vigorous supportive care with antiherpetic and antifungal agents and neutrophil-stimulating growth factors, and standard multiagent chemotherapy. With appropriate supportive care, regimens such as ABVD can be delivered. However, more severe than normal toxicity must be anticipated, and although cure rates for the lymphoma are comparable to those seen in HIV-negative individuals, median overall survival is much shorter than that seen in the non-HIV-infected patients, typically 3 to 4 years.[14]

Hodgkin Lymphoma in the Elderly Population

Elderly patients with Hodgkin lymphoma have a worse outcome. For example, the 5-year overall survival rate falls from 80% in patients younger than 65 years to less than 50% in patients older than 65 years. Explanations include more advanced stage at diagnosis, comorbid diseases, delay in diagnosis, incomplete staging, inadequate adherence to treatment protocols, and failure to maintain full dose intensity.

Of note is that elderly patients achieve outcomes equivalent to those of younger patients when they receive similar doses of chemotherapy. The best approach for elderly patients is to attempt to treat them in a manner similar to younger patients, with vigorous supportive care and the addition of neutrophil growth factors if necessary to enable safe delivery of full doses. For patients with preexisting pulmonary or cardiac disease, it might be necessary to reduce or eliminate bleomycin or doxorubicin, respectively.

FUTURE DIRECTIONS

The ability to profile multigene expression patterns and identify genetic polymorphisms associated with specific malignancies may provide better insight into the molecular genesis of Hodgkin and other lymphomas.[15] Therapeutic agents more specifically targeted at the malignant Hodgkin-Reed-Sternberg cells, such as those coupling an antibody to the CD30 antigen with a cellular toxin, have proved remarkably effective and hold substantial promise to improve treatment outcome.

REVIEW QUESTIONS

1. A 23-year-old man has noticed bilateral lower neck firm masses eventually reaching about 3 cm in greatest diameter over the past 3 months, which have not resolved after 2 more weeks of observation during which he took a 7-day course of oral antibiotics. A fine-needle aspiration biopsy reveals predominantly small lymphocytes and granulocytes, small numbers of eosinophils, and occasional monoclonal large multinucleated cells that are positive for CD30 and variably positive for CD20 and are judged consistent with Hodgkin-Reed-Sternberg cells and a diagnosis of probable Hodgkin lymphoma. What is the most appropriate next step in this patient's evaluation?

A. Computed tomography (CT) of the neck, chest, abdomen and pelvis
B. Whole body positron emission tomography/computed tomography (PET/CT)
C. Bone marrow biopsy
D. Whole lymph node excisional biopsy of an abnormal neck lymph node
E. A 14-day course of ciprofloxacin

Answer: D This patient probably has Hodgkin lymphoma; however, a firm diagnosis cannot be made based on needle aspiration biopsy. Other conditions that could be present and cannot be distinguished from Hodgkin lymphoma using only a needle aspiration biopsy include anaplastic large cell lymphoma, primary mediastinal B-cell lymphoma, T-cell-rich B-cell lymphoma, or unusual atypical lymphoid hyperplasia. Accurate diagnosis of Hodgkin lymphoma requires at least an incisional biopsy of involved nodal tissue, preferable an entire enlarged lymph node. Initiating extensive evaluation or further delay in assessment without a firm diagnosis is inappropriate.

2. A 26-year-old schoolteacher seeks a second opinion from you. She has been found to have neck and mediastinal nodular sclerosing Hodgkin lymphoma based on an excisional biopsy of a left supraclavicular fossa lymph node, PET/CT scanning showing definitely enlarged lymph nodes in the lower neck bilaterally, the mediastinum and closely contiguous left hilar lymph nodes with standardized uptake values (SUVs) ranging from 4.2 to 18.9, but no disease outside the neck and thorax. The largest nodal mass is 4.5 cm in diameter. Peripheral blood cell counts, serum creatinine, and screening liver function tests including alkaline phosphatase are all normal except for a mildly elevated neutrophil count. She has received a recommendation that she be treated with six cycles of ABVD chemotherapy (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) followed by involved-field radiation if residual disease remains abnormal on PET/CT scanning. What is your recommendation?

A. Omit the chemotherapy and proceed with irradiation to the neck, axillae. and mediastinum using the mantle technique.
B. Shorten the ABVD chemotherapy to two cycles and follow that with mantle radiation.
C. Shorten the ABVD chemotherapy to two cycles and follow that with involved-field radiation.
D. Perform a PET/CT scan after two cycles of ABVD chemotherapy and stop treatment if it is negative.
E. Agree with the previous specialist's recommendation.

Answer: C Treatment with two cycles of ABVD followed by involved-field radiation has been shown be equivalent to more chemotherapy plus involved-field radiation. Answer B is incorrect because it is not necessary to use a larger radiation field, and the larger field would be expected to increase the risk for serious late complications. Answer D is incorrect because it has not been proved that radiation can be omitted based on a negative PET/CT scan after only two cycles of chemotherapy. The previous consultant recommended more chemotherapy than is necessary for limited-stage Hodgkin lymphoma.

3. An 18-year-old college student is referred to you to investigate new palpable inguinal lymphadenopathy. He has been experiencing drenching night sweats on at least 4 nights each week for the past month and has lost 7 kg of weight on a baseline weight of 84 kg. You document palpable abnormal lymph nodes in the left neck, left axilla, and bilateral inguinal/femoral areas. An excisional biopsy of a left supraclavicular fossa lymph node demonstrates nodular sclerosing Hodgkin lymphoma, and PET/CT scanning shows definite enlarged lymph nodes in the lower neck bilaterally, mediastinum, retroperitoneum, common iliac, and inguinal/femoral areas and there are multiple nodules within the spleen, with SUVs ranging from 3.2 to 28.9. The largest nodal mass is in the mediastinum and measures 15.5 cm in diameter. Peripheral blood cell counts show hemoglobin 9.2 g/L, white blood cell count 13.5×10^9/L, normal differential except for increased neutrophils, and normal serum creatinine. Alkaline phosphatase and lactate dehydrogenase are both twice the upper limit of normal. Bone marrow biopsy demonstrates involvement with Hodgkin lymphoma. What is your recommendation?

A. Initiate ABVD chemotherapy with the plan to continue through six cycles if the lymphoma shows continuous response through that time.
B. Give escalated BEACOPP chemotherapy (bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone) for eight cycles followed involved-field radiation.
C. Give four cycles of ABVD followed by high-dose chemotherapy and autologous peripheral blood stem cell transplantation.
D. Give two cycles of ABVD followed by six cycles of escalated BEACOPP chemotherapy if the PET/CT scan remains abnormal after the ABVD.
E. Give involved-field radiation followed by six cycles of ABVD.

Answer: A ABVD has emerged as the best chemotherapy overall because of its balance of high efficacy and moderate toxicity. Although escalated BEACOPP produces a higher initial response rate, overall survival is not improved compared with ABVD. Neither regimen must be followed by radiation if the chemotherapy induces a complete response as measured by PET/CT scanning. Planned escalation to high-dose chemotherapy and autologous peripheral blood stem cell transplantation has not been shown to improve overall survival for Hodgkin lymphoma. Altering treatment based on interim PET/CT scanning, although an attractive concept, has not been shown to improve ultimate disease control for Hodgkin lymphoma. It is never appropriate to initiate treatment of Hodgkin lymphoma with radiation because that will compromise safe delivery of necessary chemotherapy without improving outcome.

4. Two years ago, you treated a 47-year-old housewife with six cycles of ABVD for stage IIIA mixed-cellularity Hodgkin lymphoma, and the patient has been off treatment and well for 18 months. She now returns with new palpable bilateral neck lymph nodes, and a biopsy confirms recurrent Hodgkin lymphoma. Complete reassessment confirms recurrent disease in the neck and retroperitoneum. What is your recommendation?

A. Initiate MOPP/ABVD chemotherapy (mechlorethamine, vincristine, procarbazine, and prednisone alternating with ABVD) with the plan to continue through six cycles if the lymphoma shows continuous response through that time.
B. Give escalated BEACOPP chemotherapy (bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone) for six cycles.
C. Give mantle followed by inverted-Y extended-field radiation.
D. Give two cycles of ABVD followed by high-dose chemotherapy and autologous peripheral blood stem cell transplantation.
E. Give two cycles of cisplatin- or carboplatin-based multiagent chemotherapy followed by high-dose chemotherapy and autologous peripheral blood stem cell transplantation.

Answer: E Choices A, B and D are incorrect because repeating ABVD chemotherapy by itself or with addition of other agents is inappropriate since this patient's lymphoma has already demonstrated resistance to ABVD by relapsing. Although wide-field radiation may be able to cure some patients with lymph node–only Hodgkin lymphoma relapsing after ABVD, it is much less likely to do so than high-dose chemotherapy and autologous peripheral blood stem cell transplantation and is likely to contribute substantially to potentially lethal toxicity if treatment is necessary for another relapse. Two to three cycles of cisplatin- or carboplatin-based multiagent chemotherapy followed by high-dose chemotherapy and autologous peripheral blood stem cell transplantation is the treatment of choice for Hodgkin lymphoma that has relapsed after primary treatment with ABVD for advanced-stage disease.

5. Which of the following statements about Hodgkin lymphoma occurring in an individual known to harbor HIV infection is *true*?

A. Coincident HIV infection can be ignored when found in a patient with Hodgkin lymphoma.
B. HIV-associated Hodgkin lymphoma is incurable and thus best approached with palliative intent.
C. Stage IV is uncommon in patients with HIV-associated Hodgkin lymphoma.
D. Patients with HIV-associated Hodgkin lymphoma should be treated with standard ABVD.
E. Patients with HIV-related Hodgkin lymphoma are at high risk for central nervous system (CNS) involvement with the lymphoma.

Answer: D Although patients with HIV-associated Hodgkin lymphoma can and should be treated curatively with standard chemotherapy, such as ABVD (B is *false*; D is *true*), these patients require substantial special supportive care with antiviral, antifungal, and anti-*Pneumocystis* antibiotics, coincident treatment with highly active antiretroviral therapy (HAART) and often neutrophil growth factors (A is *false*). HIV-associated Hodgkin lymphoma causes stage IV disease much more often than non-HIV-associated disease (C is *false*). Although HIV-associated non-Hodgkin lymphoma is linked to a markedly increased risk for CNS involvement, the same has not been noted with Hodgkin lymphoma.

PLASMA CELL DISORDERS

S. VINCENT RAJKUMAR

Plasma cell disorders are neoplastic or potentially neoplastic diseases associated with the clonal proliferation of immunoglobulin-secreting plasma cells (Table 187-1). They are characterized by the secretion of electrophoretically and immunologically homogeneous (monoclonal) proteins that represent intact or incomplete immunoglobulin molecules. Monoclonal proteins are commonly referred to as M proteins, myeloma proteins, or paraproteins.

Syndromes associated with plasma cell disorders and monoclonal proteins include premalignant disorders (monoclonal gammopathy of undetermined significance, smoldering multiple myeloma), malignant neoplasms (multiple myeloma, Waldenström macroglobulinemia), and disorders primarily related to the unique properties of the secreted monoclonal protein (cryoglobulinemia, immunoglobulin light chain [AL] amyloidosis, light chain deposition disease) (see Table 187-1).[1]

Serum Immunoglobulins

Intact immunoglobulins consist of two heavy (H) polypeptide chains of the same class and subclass and two light (L) polypeptide chains of the same type (Chapter 45). The heavy polypeptide chains are designated by Greek letters: γ in immunoglobulin G (IgG), α in immunoglobulin A (IgA), μ in immunoglobulin M (IgM), δ in immunoglobulin D (IgD), and ε in immunoglobulin E (IgE). The light chain types are kappa (κ) and lambda (λ). Both heavy chains and light chains have constant and variable regions with respect to the amino acid sequence. The class specificity of each immunoglobulin is defined by a series of antigenic determinants on the constant regions of the heavy chains (γ, α, μ, δ, and ε) and the two major classes of light chains (κ and λ). The amino acid sequence in the variable regions of the immunoglobulin molecule corresponds to the active antigen-combining site of the antibody.

In the majority of clonal plasma cell disorders, *intact* immunoglobulin molecules are secreted as monoclonal (M) proteins. In addition, there can also be abnormal secretion of excess monoclonal *free* light chains that are released without being bound to immunoglobulin heavy chains. In some patients, heavy chain expression is completely lost, and only monoclonal free light chains (commonly referred to as Bence Jones proteins) are secreted. Even less frequently, only heavy chains are secreted, resulting in heavy chain diseases (HCDs). Rare patients with multiple myeloma secrete no identifiable immunoglobulin (nonsecretory myeloma).

Washington, DC: ASM Press; 1997:156, with permission of the American Society for Microbiology.)

Identification of Monoclonal Proteins

Protein electrophoresis of the serum and urine detects M protein as a narrow peak (like a church spire) on the densitometer tracing or as a dense, discrete band on agarose gel (Fig. 187-1). Electrophoresis also permits quantitation of M proteins. Monoclonal light chains (Bence Jones proteinemia) are rarely seen on serum electrophoresis but are easily detected on urine electrophoresis. Urine electrophoresis requires a 24-hour urine collection.

Immunofixation of the serum and urine is performed when a peak or band is first seen on protein electrophoresis to identify the heavy and light chain types of the M protein. Immunofixation is also a more sensitive test than protein electrophoresis, and it should always be performed in conjunction with electrophoresis when multiple myeloma or related disorders are first suspected to detect small, unmeasurable M proteins that may be missed on electrophoresis. This is particularly important in oligosecretory myeloma, primary amyloidosis, and solitary plasmacytoma and after successful treatment of multiple myeloma or macroglobulinemia. In these instances, a small M protein can be concealed in the normal β or γ areas of the electrophoresis gel and may be overlooked.

Monoclonal proteins must be distinguished from an excess of polyclonal immunoglobulins (one or more heavy chain types and both κ and λ light chains, usually limited to the γ region), which produce a broad-based peak or broad band (Fig. 187-2). This finding is associated with chronic infectious or inflammatory states, including chronic liver disease.

Detection of Serum Free Light Chains

The serum free light chain assay measures the level of free κ and λ immunoglobulin light chains (i.e., light chains that are not bound to intact immunoglobulin). An abnormal κ/λ free light chain ratio (normal range, 0.26 to 1.65) indicates an excess of one light chain type versus the other and is interpreted as representing a monoclonal elevation of the corresponding light chain type. The serum free light chain assay is more sensitive than electrophoresis or immunofixation in detecting free monoclonal light chains and is useful in the diagnostic evaluation of plasma cell disorders and in risk stratification.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

DEFINITION

Monoclonal gammopathy of undetermined significance (MGUS; formerly called benign monoclonal gammopathy) is a premalignant clonal plasma cell disorder characterized by the presence of a serum M protein in persons who lack evidence of multiple myeloma, macroglobulinemia, amyloidosis, or other related diseases. MGUS is defined by a serum M protein concentration lower than 3 g/dL; less than 10% clonal plasma cells in the bone marrow; and absence of lytic bone lesions, anemia, hypercalcemia, and renal insufficiency that can be attributed to a plasma cell disorder. The main clinical significance of MGUS is its lifelong risk of transformation to myeloma or related malignant disease at a fixed but unrelenting rate of 1% per year.

EPIDEMIOLOGY

More than 50% of patients in whom a serum M protein is detected have MGUS (Fig. 187-3). The prevalence of MGUS in the general population increases with age, from approximately 1% in persons 50 to 60 years old to more than 5% in those older than 70 years.[2] The age-adjusted prevalence is higher in men than in women and is twice as high in blacks compared with whites. There is an increased prevalence of MGUS as well as of multiple myeloma among blood relatives of individuals with monoclonal gammopathies.

PATHOBIOLOGY

MGUS represents a limited, nonmalignant expansion of monoclonal plasma cells. The etiology of MGUS is unknown, but age, male gender, family history, immunosuppression, and exposure to certain pesticides are known risk factors. It is hypothesized that infection, inflammation, or other antigenic stimuli, acting in concert with the development of cytogenetic abnormalities in the plasma cells, are the initiating pathogenetic events in most patients. Approximately 40% of MGUS is associated with plasma cell translocations involving the immunoglobulin heavy chain (IgH) locus on chromosome 14q32 (IgH-translocated MGUS), 40% with trisomies involving odd-numbered chromosomes (hyperdiploid MGUS), 15% with both trisomies and IgH translocations, and the remaining with other cytogenetic abnormalities. The primary IgH translocations seen in MGUS commonly involve one of five recurrent partner chromosome loci: 11q13 (*CCND1* [cyclin D1 gene]), 4p16.3 (*FGFR3* and *MMSET*), 6p21 (*CCND3* [cyclin D3 gene]), 16q23 (c-*maf*), and 20q11 (*mafB*).

CLINICAL MANIFESTATIONS

MGUS is asymptomatic and is usually diagnosed incidentally on laboratory testing. Patients with MGUS progress to multiple myeloma or related malignant disease at a rate of approximately 1% per year. The interval from the time of recognition of the M protein to the diagnosis of serious disease ranges from 1 to 32 years (median, 10.6 years), and the relative risk versus a control population is 25.0 for progression to multiple myeloma, 8.4 for primary amyloidosis, 46.0 for Waldenström macroglobulinemia, 2.4 for the development of other forms of non-Hodgkin lymphoma, and 8.5 for plasmacytoma.

DIAGNOSIS

MGUS is differentiated from multiple myeloma and smoldering multiple myeloma by the size of the M protein; the bone marrow plasma cell

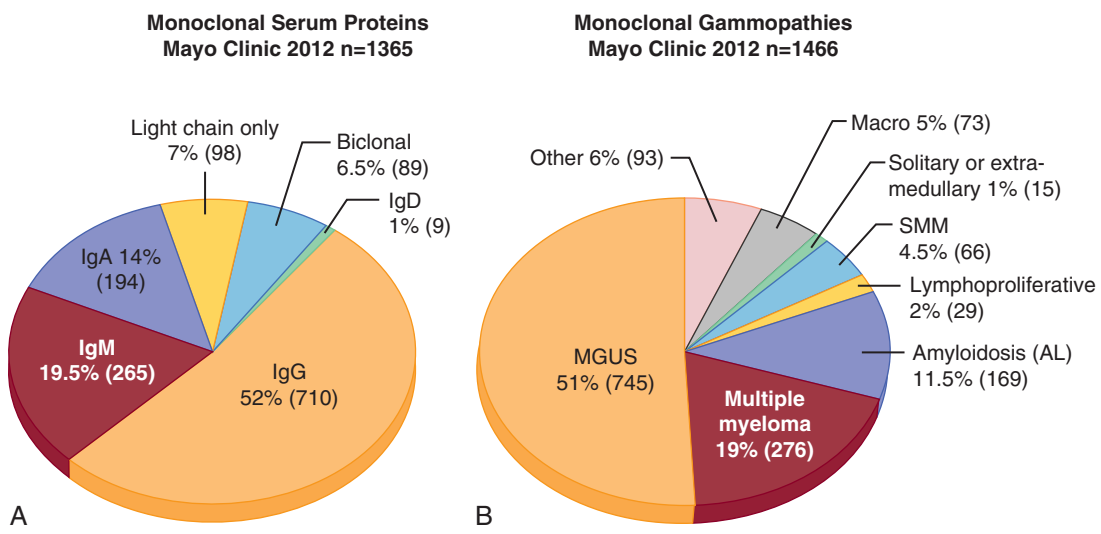

FIGURE 187-3. Monoclonal gammopathy. A, Distribution of serum monoclonal proteins in patients seen at the Mayo Clinic. **B,** Diagnoses in cases of monoclonal gammopathy seen at the Mayo Clinic. Ig = immunoglobulin; Macro = Waldenström macroglobulinemia; MGUS = monoclonal gammopathy of undetermined significance; SMM = smoldering multiple myeloma.

percentage; and the presence or absence of anemia, renal failure, hypercalcemia, or lytic bone lesions (Table 187-2). Because anemia and renal insufficiency are relatively common in the elderly population with MGUS, the causes of these conditions should be carefully investigated with adequate laboratory studies. For example, in a patient with anemia, tests to exclude iron, vitamin B_{12}, or folate deficiency must be performed. In certain instances, such as unexplained renal failure, a renal biopsy may be needed. Only patients with strong evidence of end-organ damage thought to be directly related to a plasma cell disorder can be considered to have myeloma or a related malignant disease.

Although a reduction in the levels of the immunoglobulin classes other than M protein (i.e., the normal polyclonal or background immunoglobulins) is more frequently seen in multiple myeloma or Waldenström macroglobulinemia, such reductions also occur in almost 40% of patients with MGUS.

Association of MGUS with Other Diseases

MGUS is associated with numerous diseases. However, because 3% of the general population older than 50 years has MGUS, it is often difficult to determine whether these reported associations are causal or coincidental. Some associations have been verified on the basis of epidemiologic studies; these include peripheral neuropathy (Chapter 420), proliferative glomerulonephritis, deep venous thrombosis (Chapter 81), osteoporosis (Chapter 243), and lymphoproliferative disorders (Chapter 185). A secondary form of MGUS also occurs with immunosuppression after organ transplantation (Chapter 49) and autologous or allogeneic stem cell transplantation (Chapter 178). M proteins also occur in the sera of some patients with chronic lymphocytic leukemia (Chapter 184) but have no recognizable effect on the clinical course.

Approximately 5% of patients with sensorimotor peripheral neuropathy of unknown cause (Chapter 420) have an associated monoclonal gammopathy (monoclonal gammopathy–associated neuropathy). In half of such patients, the M protein binds to myelin-associated glycoprotein. These patients have a slowly progressive sensory neuropathy more than motor neuropathy, beginning in the distal ends of the extremities and extending proximally. The clinical and electrodiagnostic manifestations of MGUS neuropathy resemble those of a chronic inflammatory demyelinating polyneuropathy. A causal relationship is usually assumed in younger patients and those without other conditions known to cause neuropathy in whom the neuropathy is severe and progressive. Therapeutic approaches include plasmapheresis and, occasionally, chemotherapy (similar to myeloma for IgG or IgA monoclonal proteins, and rituximab or rituximab-based regimens for IgM monoclonal proteins; see the later section on the treatment of multiple myeloma).

Monoclonal gammopathy is also thought to be the underlying cause of approximately 50% of idiopathic proliferative glomerulonephritis, including membranoproliferative glomerulonephritis and C3 glomerulopathy (Chapter 121). Certain skin disorders are also known to be associated with MGUS. Lichen myxedematosus (papular mucinosis, scleromyxedema) is associated with an IgG γ protein. Pyoderma gangrenosum (Chapter 440) and necrobiotic xanthogranuloma are other associated skin disorders.

PREVENTION AND TREATMENT

Rx

No treatment is necessary for MGUS. Low-risk patients (Table 187-3) can be evaluated when symptoms suggestive of myeloma or related disorders occur. In all other patients with MGUS, the M protein level in serum and urine should be measured serially, together with periodic reevaluation of clinical and other laboratory findings, to determine whether multiple myeloma or another related disorder is present. In general, electrophoresis, complete blood count, and creatinine and calcium levels should be repeated at 6 months and, if stable, yearly thereafter.

PROGNOSIS

Differentiating a patient with MGUS in whom the disorder will remain stable for life from one in whom multiple myeloma, macroglobulinemia, or a related disorder will eventually develop is difficult when the M protein is first recognized. The size and type of the M protein at diagnosis of MGUS and an abnormal serum free light chain ratio are prognostic factors for progression (see Table 187-3). A study of 728 Swedish cases of MGUS observed for up to 30 years showed a cumulative risk of 15.4% for development of lymphoid disorder and a cumulative risk of 10.6% for progression to multiple myeloma (approximately 0.5% annual risk). Three factors were significantly associated with progression: (1) abnormal free light chain ratio (<0.26 or >1.65); (2) M-protein level of 1.5 g/dL and higher; and (3) reduction of one or two noninvolved immunoglobulin isotype levels (immunoparesis).[3] The first two of these confirm the factors considered by the Mayo Clinic group (see Table 187-3).

BICLONAL GAMMOPATHIES

Biclonal gammopathies occur in at least 5% of patients with clonal plasma cell disorders. A biclonal gammopathy of undetermined significance (analogous to MGUS) accounts for about two thirds of such patients. The remainder have multiple myeloma, macroglobulinemia, or other lymphoproliferative diseases. Rarely, triclonal gammopathies may occur.

LIGHT CHAIN MGUS AND IDIOPATHIC BENCE JONES PROTEINURIA

The diagnosis of typical MGUS requires expression of an intact heavy chain type. In some patients, a premalignant clonal plasma cell disorder characterized by the presence of monoclonal immunoglobulin light chains without expression of heavy chains can occur (light chain MGUS).[4] By definition, these patients should not have evidence of end-organ damage attributable to the light chain, and the clonal bone marrow plasma cell percentage should be

TABLE 187-2 CRITERIA FOR THE DIAGNOSIS OF PLASMA CELL DISORDERS

DISORDER	DISEASE DEFINITION
Monoclonal gammopathy of undetermined significance (MGUS)	All 3 criteria must be met: 1. Serum monoclonal protein (IgG, IgA, or IgM) <3 g/dL 2. Clonal bone marrow plasma cells <10% 3. Absence of end-organ damage, such as hypercalcemia, renal insufficiency, anemia, and bone lesions, that can be attributed to the plasma cell proliferative disorder (or, in the case of IgM MGUS, no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder)
Light chain MGUS	All 6 criteria must be met: 1. Abnormal FLC ratio (<0.26 or >1.65) 2. Increased level of the appropriate involved light chain (increased κ FLC in patients with ratio >1.65 and increased λ FLC in patients with ratio <0.26) 3. No immunoglobulin heavy chain expression on immunofixation 4. Absence of end-organ damage that can be attributed to the plasma cell proliferative disorder 5. Clonal bone marrow plasma cells <10% 6. Urinary monoclonal protein <500 mg/24h
Smoldering multiple myeloma (also referred to as asymptomatic multiple myeloma)	Both criteria must be met: 1. Serum monoclonal protein (IgG or IgA) ≥3 g/dL (or urinary monoclonal protein ≥500 mg/24 hours) and/or clonal bone marrow plasma cells 10-60% 2. Absence of myeloma defining events or amyloidosis

Multiple myeloma	Both criteria must be met:
	1. Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma
	2. Any one or more of the following myeloma defining events:
	• Evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
	  • Hypercalcemia: serum calcium >1 mg/dL (>0.25 mmol/L) higher than the upper limit of normal or >11 mg/dL (>2.75 mmol/L)
	  • Renal insufficiency: creatinine clearance <40 mL per minute or serum creatinine >2 mg/dL (>177 μmol/L)
	  • Anemia: hemoglobin value of >2 g/dL below the lower limit of normal, or a hemoglobin value <10 g/dL
	  • Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or PET-CT
	• Any one or more of the following biomarkers of malignancy:
	  • Clonal bone marrow plasma cell percentage ≥60%
	  • Involved: uninvolved serum free light chain ratio ≥100 (involved free light chain level must be ≥100 mg/L)
	  • >1 focal lesions on MRI studies (at least 1mm in size)

Waldenström macroglobulinemia	Both criteria must be met: 1. IgM monoclonal gammopathy (regardless of the size of the M protein) 2. >10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (surface IgM^{+}, $CD5^{+/-}$, $CD10^{-}$, $CD19^{+}$, $CD20^{+}$, $CD23^{-}$) that satisfactorily excludes other lymphoproliferative disorders, including chronic lymphocytic leukemia and mantle cell lymphoma
Smoldering Waldenström macroglobulinemia (also referred to as indolent or asymptomatic Waldenström macroglobulinemia)	Both criteria must be met: 1. Serum IgM monoclonal protein ≥3 g/dL and/or bone marrow lymphoplasmacytic infiltration ≥10% 2. No evidence of end-organ damage, such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly, that can be attributed to a lymphoplasma cell proliferative disorder
Solitary plasmacytoma	All 4 criteria must be met: 1. Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells 2. Normal bone marrow with no evidence of clonal plasma cells 3. Normal skeletal survey and either MRI of spine and pelvis or PET computed tomography (except for the primary solitary lesion) 4. Absence of end-organ damage, such as hypercalcemia, renal insufficiency, anemia, or bone lesions, that can be attributed to a plasma cell proliferative disorder
POEMS syndrome	All 4 criteria must be met: 1. Presence of a monoclonal plasma cell disorder (almost always λ type) 2. Peripheral neuropathy 3. Any one of the following 3 major features: sclerotic bone lesions, Castleman disease, elevated levels of vascular endothelial growth factor 4. Any one of the following 7 minor features: organomegaly, edema, endocrinopathy (excluding diabetes mellitus or hypothyroidism), typical skin changes, papilledema, thrombocytosis, polycythemia The features should have a temporal relationship to one another, with no other attributable cause

CT = computed tomography; FLC = free light chain; MRI = magnetic resonance imaging; PET = positron emission tomography.

less than 10%. No therapy is indicated unless progression to malignancy occurs.

MULTIPLE MYELOMA

DEFINITION

Multiple myeloma is a malignant neoplasm of plasma cells characterized by bone marrow infiltration and extensive skeletal destruction resulting in anemia, bone pain, and fractures. Multiple myeloma (commonly referred to as myeloma) is defined by the presence of 10% or more clonal plasma cells on bone marrow examination or biopsy-proven plasmacytoma; and evidence of one or more myeloma defining events (see Table 187-2).[5] Patients with multiple myeloma must be differentiated from those with MGUS and smoldering multiple myeloma.

EPIDEMIOLOGY

Multiple myeloma accounts for 1% of all malignant disease and slightly more than 10% of hematologic malignant neoplasms in the United States. The annual incidence of multiple myeloma is 4 per 100,000. Its incidence in blacks is almost twice that in whites. Multiple myeloma is slightly more common in men than in women. The median age of patients at the time of diagnosis is about 65 years; only 2% of patients are younger than 40 years.

PATHOBIOLOGY

The cause of multiple myeloma is unclear. Exposure to radiation, benzene, and other organic solvents, herbicides, and insecticides may play a role. Multiple myeloma has been reported in familial clusters of two or more first-degree relatives and in identical twins.

Almost all cases of myeloma evolve from a premalignant MGUS phase, although the MGUS is clinically recognized before the diagnosis of myeloma in only a small minority of patients. The progression of MGUS to myeloma suggests a simple, random, two-hit genetic model of malignant transformation in which the risk of progression is fixed (approximately 1% per year) regardless of the duration of MGUS. Unfortunately, the precise mechanisms of progression are unknown, although several potentially pathogenetic abnormalities have been described in the clonal plasma cells. These include *RAS* and *p53* mutations, p16 methylation, *MYC* abnormalities, and secondary translocations. Changes in the bone marrow microenvironment may also play a role in the pathogenesis, including induction of angiogenesis and abnormal paracrine loops involving cytokines such as interleukin (IL)–6, which serves as a major growth factor for plasma cells.

The lytic bone lesions, osteopenia, hypercalcemia, and pathologic fractures in patients with myeloma are a result of abnormal osteoclast activity induced by the neoplastic plasma cells as well as inhibition of osteoblast differentiation. Osteoclasts are activated by stimulation of the transmembrane receptor RANK (receptor activator of nuclear factor κB), which belongs to the tumor necrosis factor receptor superfamily. The ligand for this receptor (RANKL) also has a decoy receptor, osteoprotegerin (OPG). In myeloma, there is an increase in RANKL expression by osteoblasts (and possibly plasma cells), accompanied by a reduction in the level of OPG. The resultant increase in the RANKL/OPG ratio causes osteoclast activation and increased bone resorption and turnover (Chapter 242). Other factors that may play a role in osteoclast activation include increased levels of macrophage inflammatory protein 1α, stromal cell–derived factor α, IL-3, IL-1β, and IL-6. In addition to these changes that promote osteoclast activation, there is simultaneous suppression of osteoblasts mediated by increased levels of IL-3, IL-7, and dickkopf 1 (DKK1). This combination leads to the pure osteolytic bone disease that is the hallmark of multiple myeloma.

Cytogenetic Abnormalities

As discussed earlier (see pathobiology of MGUS), primary translocations involving the IgH loci (chromosome 14q32) are seen in up to 40% of patients with multiple myeloma (IgH-translocated or nonhyperdiploid myeloma). Approximately 40% of patients do not have IgH translocations but have evidence of trisomies (hyperdiploid myeloma), 15% have both IgH translocations and trisomies, and 5% have other abnormalities. Although primary IgH translocations and trisomies originate at the MGUS stage, response to therapy and prognosis of myeloma are affected by the specific underlying abnormality (Table 187-4). Besides these cytogenetic abnormalities, other secondary cytogenetic abnormalities occur as late events during the course of symptomatic myeloma; these include activating mutations of N- and K-*RAS*, inactivating mutations of *p53*, and dysregulation of c-*MYC*. Complete or partial deletions of chromosome 13 are well described in myeloma and have prognostic value, but they also occur at the MGUS stage.

TABLE 187-4 STAGING AND PROGNOSTIC FACTORS IN MULTIPLE MYELOMA

STAGE/RISK FACTOR	MEDIAN SURVIVAL
INTERNATIONAL STAGING SYSTEM	
Stage I (serum β_2-microglobulin <3.5 mg/L and serum albumin ≥3.5 g/dL)	62 months
Stage II (neither stage I nor stage III)	44 months
Stage III (serum β_2-microglobulin ≥5.5 mg/L)	29 months
RISK STRATIFICATION*	
High-risk myeloma (any one of the following in the absence of trisomies): Translocations t(14;16), t(14;20) Deletion 17p	24-36 months
Intermediate-risk myeloma Translocation t4;14	Similar to standard-risk myeloma with bortezomib-based induction, transplantation, and maintenance
Standard-risk myeloma Translocations t(11;14), t(6;14) Trisomies	84-120 months
OTHER ADVERSE PROGNOSTIC FACTORS	
Elevated lactate dehydrogenase level	
Poor performance status	
Increased circulating plasma cells	
Plasmablastic morphology	
Increased plasma cell labeling index ≥1%	

*Typically detected in clonal plasma cells by fluorescence in situ hybridization of plasma cells.

TABLE 187-5 MAJOR CLINICAL MANIFESTATIONS OF MULTIPLE MYELOMA

CLINICAL FINDINGS	APPROXIMATE PERCENTAGE OF PATIENTS WITH ABNORMALITY AT DIAGNOSIS
Skeletal involvement: pain, reduced height, lytic bone lesions, pathologic fractures	80
Anemia (hemoglobin ≤12 g/dL): caused mainly by decreased erythropoiesis; produces weakness and fatigue	75
Renal insufficiency (serum creatinine ≥2 mg/dL): caused mainly by "myeloma kidney" from light chains or hypercalcemia, rarely from amyloidosis	20
Hypercalcemia (≥11 mg/dL)	15
Light chain amyloidosis	10
Evidence of monoclonal protein by immunofixation and serum free light chain assay	97
Evidence of clonal plasma cells ≥10% in bone marrow	96

CLINICAL MANIFESTATIONS

History

Bone pain, particularly in the back or chest and less often in the extremities, is present at the time of diagnosis in more than two thirds of patients (Table 187-5). The patient's height may be reduced by several inches because of vertebral collapse. Weakness and fatigue are common and are often associated with anemia. Fever is rare and, when present, is generally from an infection; in some patients, the infection itself is the initial feature. Other symptoms may result from renal insufficiency, hypercalcemia, nephrotic syndrome, radiculopathy, or amyloidosis (Chapter 188).

Physical Examination

Pallor is the most frequent physical finding. The liver is palpable in about 5% of patients and the spleen in 1%. Tenderness may be noted at sites of bone involvement. Radiculopathy may be caused by spinal compression fractures. On occasion, extramedullary plasmacytomas are palpable.

DIAGNOSIS

Laboratory Findings

A normocytic, normochromic anemia (Chapter 158) is present initially in approximately 75% of patients, but it eventually occurs in nearly every patient with multiple myeloma. Serum protein electrophoresis shows an M protein in 80% of patients. With serum immunofixation, an M protein can be detected in 93% of patients. When these serum studies are combined with urine electrophoresis plus immunofixation, an M protein can be detected in 97% of patients with myeloma. The serum free light chain assay is more convenient and can be used in place of urine studies in the diagnostic evaluation. The type of M protein is IgG in 52%, IgA in 21%, light chain only (Bence Jones proteinemia) in 16%, IgD in 2%, and biclonal gammopathy in 2%; the light chain type is κ in 65% of cases and λ in 35%. In 3% of patients, no secreted M protein can be identified; these patients are considered to have nonsecretory myeloma.

In the bone marrow, clonal plasma cells account for more than 10% of all nucleated cells in 96% of patients (Fig. 187-4). In 4% of patients, bone marrow examination shows less than 10% plasma cells, even though the patient otherwise meets the criteria for myeloma; because bone marrow involvement in myeloma may be focal rather than diffuse, repeated bone marrow examinations or biopsy of a discrete bone or extramedullary lesion may be required. In most cases, the plasma cells in myeloma are cytoplasmic Ig^+, $CD38^+$, $CD45^-$, $CD138^+$, $CD56^+$, and $CD19^+$; only a minority express CD10 and HLA-DR, and 20% express CD20. The clonality of the plasma cells is established by the κ/λ ratio, which is abnormal in myeloma (either >4 : 1, indicating a clonal κ population, or <1 : 2, indicating a clonal λ population). This is helpful for differentiation of monoclonal plasma cell proliferation in multiple myeloma from reactive plasmacytosis related to connective tissue disease, metastatic carcinoma, liver disease, and infection.

Radiologic Findings

Conventional radiographs reveal abnormalities consisting of punched-out lytic lesions (Fig. 187-5), osteoporosis, or fractures in nearly 80% of patients. The vertebrae, skull, thoracic cage, pelvis, and proximal ends of the humerus and femur are the most frequent sites of involvement. Technetium Tc99m bone scanning is inferior to conventional radiography and should not be used. Positron emission tomography (Fig. 187-6) and magnetic resonance imaging are increasingly used to evaluate patients in whom there is doubt about the magnitude of the disease burden, in those who have skeletal pain but no abnormality on radiographs, and for monitoring of the response to therapy.

Organ Involvement

Renal

At diagnosis, the serum creatinine value is increased initially in almost half of patients and is more than 2 mg/dL in 20%.

The two major causes of renal insufficiency are light chain cast nephropathy (*myeloma kidney*) and hypercalcemia. Light chain cast nephropathy is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. The casts are composed mainly of precipitated monoclonal light chains. The extent of cast formation correlates directly with the amount of free urinary light chain and with the severity of renal insufficiency. Dehydration may precipitate acute renal failure.

Hypercalcemia (Chapter 245), which is present in 15 to 20% of patients initially, is a major and treatable cause of renal insufficiency. It results from destruction of bone. Hyperuricemia may contribute to renal failure. Besides light chain cast nephropathy and hypercalcemia, there are other mechanisms by which renal dysfunction can occur in myeloma. For example, light chain amyloidosis (Chapter 188) occurs in nearly 10% of patients and may produce nephrotic syndrome, renal insufficiency, or both. Acquired Fanconi syndrome (Chapter 122), characterized by proximal tubular dysfunction, results in glycosuria, phosphaturia, and aminoaciduria. Deposition of monoclonal light chains in the renal glomerulus (light chain deposition disease) may also produce renal insufficiency and nephrotic syndrome.

Neurologic

Radiculopathy (Chapter 400), the single most frequent neurologic complication, usually occurs in the thoracic or lumbosacral area and results from compression of the nerve by the vertebral lesion or by the collapsed bone itself. Compression of the spinal cord occurs in up to 10% of patients. Peripheral neuropathy (Chapter 420) is uncommon in multiple myeloma and, when present, is generally caused by amyloidosis. Rarely, myeloma cells diffusely infiltrate the meninges. Intracranial plasmacytomas almost always represent extensions of myelomatous lesions of the skull.

FIGURE 187-5. Skull radiograph of a patient with multiple myeloma showing multiple lytic lesions.

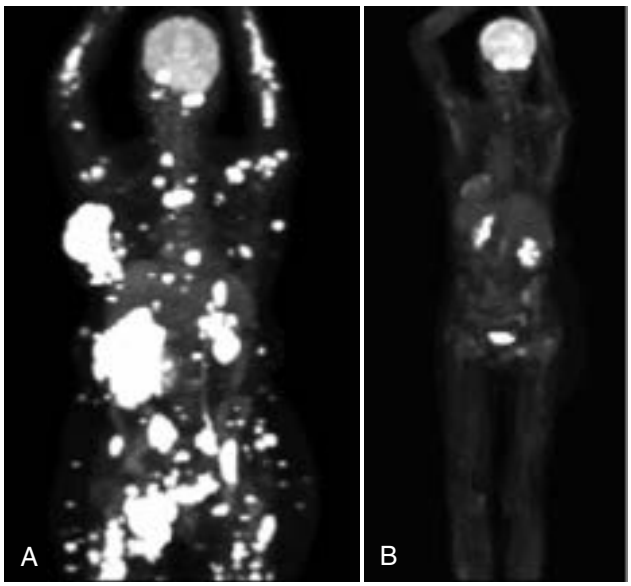

FIGURE 187-6. Positron emission tomography in multiple myeloma. A, Extensive bone and extramedullary disease. **B,** Significant improvement after systemic chemotherapy for myeloma.

Other Systemic Involvement

Hepatomegaly from plasma cell infiltration is uncommon. Plasmacytomas of the ribs are common and arise either as expanding bone lesions or as soft tissue masses. The incidence of infections is increased in patients with multiple myeloma. Historically, *Streptococcus pneumoniae* and *Staphylococcus aureus* have been the most frequent pathogens, but gram-negative organisms now account for more than half of all infections. The propensity for infection results from impairment of the antibody response, deficiency of normal immunoglobulins, and neutropenia. Bleeding from coating of the platelets by M protein may occur. Myeloma patients have an increased risk of deep venous thrombosis, particularly in relation to its therapy (see later).

PREVENTION AND TREATMENT

Rx

Patients with MGUS or smoldering multiple myeloma should not be treated until evidence of multiple myeloma develops. The approach to treatment of multiple myeloma is illustrated in Figure 187-7.

Initial Therapy for Patients Who Are Candidates for Autologous Stem Cell Transplantation

In the approximately 50% of patients with newly diagnosed multiple myeloma who are considered candidates for autologous stem cell transplantation on the basis of good performance status, no or limited comorbid conditions, and younger physiologic age (<65 to 70 years), autologous peripheral blood stem cell transplantation (Chapter 178) with high-dose chemotherapy improves overall survival in comparison to conventional chemotherapy.[■] Currently, it is not possible to eradicate myeloma cells completely with conditioning regimens, and reinfused autologous stem cells are usually contaminated by myeloma cells or their precursors. As a result, autologous transplantation is not curative, but it prolongs event-free and overall survival.

Initial therapy for stem cell transplant candidates typically consists of a non–melphalan-containing induction regimen for approximately 4 months followed by the stem cell collection. Most modern induction regimens have not been compared against each other in randomized trials, and the choice of regimen is dependent on availability and costs.[6] Common induction regimens include lenalidomide plus low-dose dexamethasone (Rd); bortezomib, thalidomide, plus dexamethasone (VTD); bortezomib, lenalidomide, plus dexamethasone (VRD); and bortezomib, cyclophosphamide, plus dexamethasone (VCD) (Table 187-6). VTD is associated with superior response rates and progression-free survival compared with thalidomide-dexamethasone (TD).[■] In a randomized trial, lenalidomide plus low-dose dexamethasone (40 mg once a week) was associated with superior overall survival compared with lenalidomide and high-dose dexamethasone (40 mg on days 1 to 4, 9 to 12, and 17 to 20). As a result, high-dose pulse dexamethasone is no longer recommended in the context of initial therapy.[■] Toxicities of lenalidomide include deep venous thrombosis, and all patients must be treated with prophylactic aspirin or an anticoagulant.

After induction therapy, peripheral blood stem cells adequate for one or two stem cell transplants are collected with the use of granulocyte colony-stimulating factor, with or without plerixafor or cyclophosphamide to aid in mobilization. Autologous stem cell transplantation (Chapter 178) is performed with melphalan 200 mg/m^2 as the conditioning regimen, followed by infusion of the peripheral blood stem cells. Patients who do not achieve a complete or very good partial response with the first autologous transplant can be considered for a second autologous transplant.[■]

An alternative approach in patients with newly diagnosed disease is to cryopreserve stem cells for future use after initial therapy. Patients then continue initial therapy, such as lenalidomide plus low-dose dexamethasone, until progression or achievement of a plateau phase, with stem cell transplantation reserved for the first relapse. Data from randomized trials comparing early versus delayed transplantation indicate no significant difference in survival between the two strategies. The choice is based on the patient's preferences and other clinical conditions, but early transplantation is often preferred

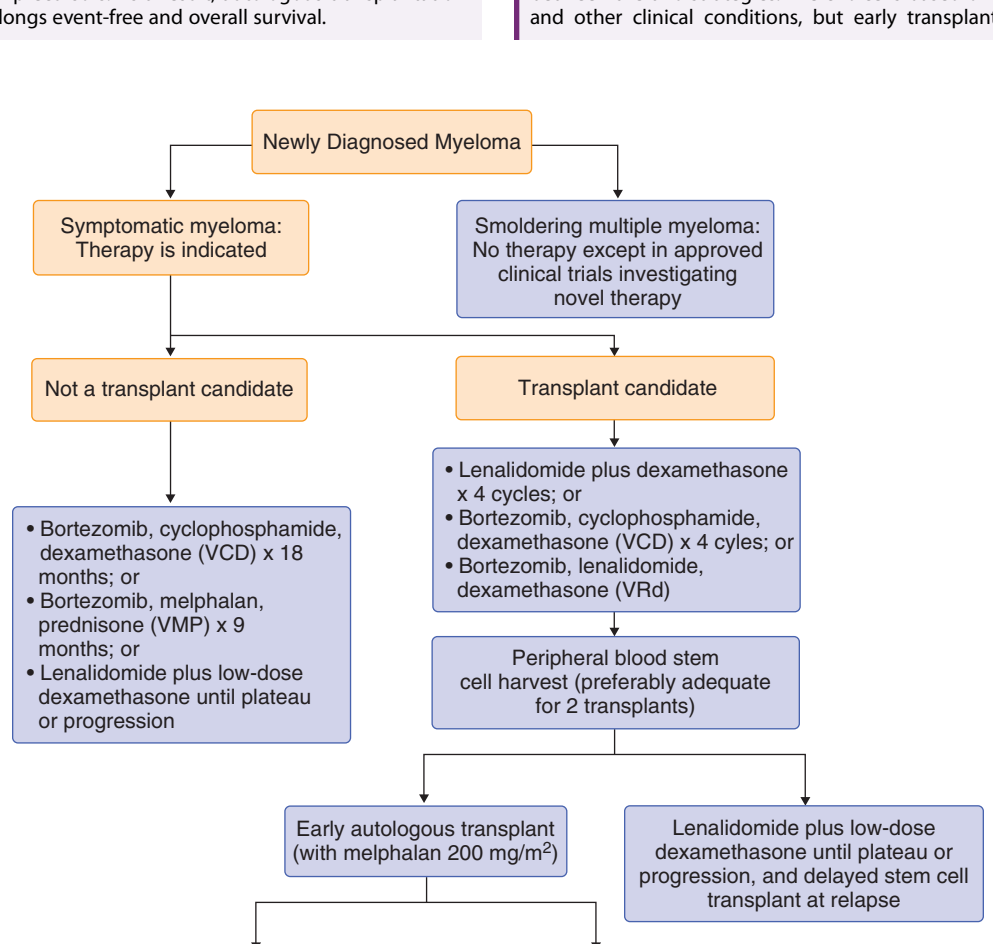

FIGURE 187-7. Therapeutic approach to newly diagnosed multiple myeloma.

TABLE 187-6 TREATMENT REGIMENS IN NEWLY DIAGNOSED MULTIPLE MYELOMA

REGIMEN	SUGGESTED STARTING DOSES*	OVERALL RESPONSE RATE (%)
REGIMENS FOR TRANSPLANT-ELIGIBLE AND TRANSPLANT-INELIGIBLE PATIENTS		
Lenalidomide-dexamethasone (Rd)	Lenalidomide, 25 mg orally, on days 1-21 every 28 days Dexamethasone, 40 mg orally, on days 1, 8, 15, 22 every 28 days Repeated every 4 weeks	70
Bortezomib-thalidomide-dexamethasone* (VTD)	Bortezomib, 1.3 mg/m^2 IV, on days 1, 8, 15, 22 Thalidomide, 100-200 mg orally, on days 1-21 Dexamethasone, 20 mg on day of/after bortezomib (or 40 mg on days 1, 8, 15, 22) Repeated every 4 weeks	95
Bortezomib-cyclophosphamide-dexamethasone* (VCD)	Cyclophosphamide, 300 mg/m^2 orally, on days 1, 8, 15 and 22 Bortezomib, 1.3 mg/m^2 IV, on days 1, 8, 15, 22 Dexamethasone, 40 mg orally, on days 1, 8, 15, 22 Repeated every 4 weeks	90
Bortezomib-lenalidomide-dexamethasone* (VRD)	Bortezomib, 1.3 mg/m^2 IV, on days 1, 8, 15 Lenalidomide, 25 mg orally, on days 1-14 Dexamethasone, 20 mg on day of and day after bortezomib (or 40 mg on days 1, 8, 15, 22) Repeated every 3 weeks	100
REGIMENS FOR TRANSPLANT-INELIGIBLE PATIENTS		
Melphalan-prednisone-thalidomide (MPT)	Melphalan, 0.25 mg/kg orally, on days 1-4 (use 0.20 mg/kg/day orally on days 1-4 in patients older than 75 years) Prednisone, 2 mg/kg orally, on days 1-4 Thalidomide, 100-200 mg orally, on days 1-28 (use 100-mg dose in patients >75 years) Repeated every 6 weeks	70
Bortezomib-melphalan-prednisone* (VMP)	Bortezomib, 1.3 mg/m^2 IV, on days 1, 8, 15, 22 Melphalan, 9 mg/m^2 orally, on days 1-4 Prednisone, 60 mg/m^2 orally, on days 1-4 Repeated every 35 days	70

*Doses of dexamethasone and bortezomib reduced from initial trial reports to once-weekly schedules.
Reproduced from Rajkumar SV. Treatment of multiple myeloma. *Nat Rev Clin Oncol.* 2011;8:479-491.

because its mortality is low (<1%), and it avoids the inconvenience, cost, and potential side effects of prolonged chemotherapy.

After stem cell transplantation, a short course of bortezomib administered as consolidation has been shown to improve response rates and progression-free survival. Similarly, studies suggest that long-term outcome may be improved by the administration of prolonged maintenance therapy after autologous stem cell transplantation. In randomized trials, lenalidomide maintenance (10 mg/day for the first 3 months, increased to 15 mg if tolerated) significantly prolongs progression-free survival but has the potential for more toxicity and second cancers. There are emerging data that bortezomib maintenance administered every 2 weeks may also provide a similar benefit. At present, the routine use of consolidation and maintenance in all patients after transplantation remains controversial because of lack of clear overall survival benefit and concerns about toxicity, cost, and impact on quality of life. Consolidation and maintenance should be considered, however, in intermediate- and high-risk myeloma (bortezomib maintenance preferred) and in patients not achieving a very good partial response or better with transplantation (lenalidomide maintenance preferred) (see Table 187-4 for definitions of intermediate- and high-risk myeloma).

Role of Allogeneic Bone Marrow Transplantation

Most patients with multiple myeloma cannot undergo allogeneic bone marrow transplantation because of their age, lack of an HLA-matched sibling donor, or inadequate renal, pulmonary, or cardiac function (Chapter 178). There are no clear data showing the benefit of either conventional myeloablative allogeneic transplantation or nonmyeloablative (mini) allogeneic transplantation compared with autologous stem cell transplantation, and results of randomized trials are conflicting. The treatment-related mortality is approximately 20%. Allogeneic transplantation for myeloma is best performed in the context of clinical trials or as second-line salvage therapy in selected high-risk patients who are willing to accept the high treatment-related mortality rate associated with the procedure.

Initial Therapy for Patients Who Are Not Candidates for Transplantation

Approximately 50% of newly diagnosed patients are not considered candidates for stem cell transplantation because of advanced age, poor performance status, or associated comorbidities. For decades, the oral administration of melphalan and prednisone was the standard of care. Randomized trials have shown that the addition of thalidomide or bortezomib to the standard regimen of melphalan plus prednisone improves event-free and overall survival compared with melphalan plus prednisone alone in patients with newly diagnosed myeloma who are not candidates for transplantation. On the basis of these data, melphalan and prednisone plus either thalidomide (MPT) or bortezomib (VMP) are two treatments for this population of patients. More recently, non–melphalan-containing regimens such as Rd, VRD, and VCD used in patients who are candidates for stem cell transplantation are being increasingly preferred over melphalan-based regimens in this group of patients as well. In a large randomized trial, Rd administered until progression was associated with superior progression-free and overall survival compared with MPT. By contrast, the addition of lenalidomide to melphalan and prednisone does not improve overall survival and is not recommended.

Regimens such as VCD, VRD, MPT, and VMP are typically given for approximately 12-18 months. Rd can be given until progression or for approximately 18 months, based on tolerability.

Treatment of Relapsed Refractory Myeloma

Almost all patients with multiple myeloma eventually relapse. Single-agent dexamethasone, alkylating agents, thalidomide, lenalidomide, and bortezomib, administered alone or in combination, are options for the treatment of relapsed refractory myeloma. Methylprednisolone, 2 g three times a week intravenously for a minimum of 4 weeks, then reduced to once or twice a week if there is a response, is helpful for patients with pancytopenia and may be associated with fewer side effects than with dexamethasone.

Thalidomide (50 to 200 mg/day orally) produces an objective response, with a median duration of about 1 year, in about a third of patients with refractory myeloma. Side effects are sedation, constipation, peripheral neuropathy, rash, bradycardia, and thrombotic events. The addition of dexamethasone to thalidomide increases the response rate to approximately 50%, and combinations of thalidomide, dexamethasone, and alkylating agents produce response rates exceeding 70% in patients with relapsed refractory disease.

Lenalidomide, an analogue of thalidomide, is better tolerated and produces objective benefits in approximately 40% of patients with relapsed refractory myeloma as a single agent; in combination with dexamethasone, 60% of patients benefit. Lenalidomide plus dexamethasone significantly prolongs time to progression and overall survival compared with dexamethasone alone. The starting dose of lenalidomide is 25 mg orally on days 1 to 21, every 28 days. Lenalidomide has significantly fewer nonhematologic toxicities than thalidomide does; myelosuppression is the most common adverse event.

Bortezomib, an inhibitor of the ubiquitin-proteasome pathway, acts through multiple mechanisms to arrest tumor growth, tumor spread, and angiogenesis. It produces objective responses in about a third of patients with refractory myeloma and is superior to single-agent dexamethasone. Bortezomib is usually combined with dexamethasone and other active agents (e.g., lenalidomide, thalidomide, or cyclophosphamide) to increase response rates. The usual dose is 1.3 mg/m^2 administered subcutaneously on days 1, 8, 15, and 22

every 28 days. The once-weekly subcutaneous dosing is associated with significantly lower neuropathy than the twice-weekly intravenous schedule. The most common adverse events are gastrointestinal side effects, fatigue, and neuropathy.

Options for the treatment of patients with myeloma refractory to lenalidomide and bortezomib include pomalidomide (an analogue of lenalidomide) and carfilzomib (a novel keto-epoxide tetrapeptide proteasome inhibitor).[7,8] Pomalidomide and carfilzomib have a response rate of approximately 25% in this population of patients and can be combined with other active agents to improve response rates. In a randomized trial, the addition of carfilzomib to lenalidomide and dexamethasone significantly improved progression-free survival.

Patients with relapsed refractory myeloma should also be considered for clinical trials. Promising investigational agents with single-agent activity include MLN 9708 (an oral proteasome inhibitor), marizomib (proteasome inhibitor), ARRY-520 (kinesin spindle protein inhibitor), monoclonal antibodies to CD38, and cyclin-dependent kinase inhibitors. Additional agents with potential activity in combination with standard anti-myeloma agents include panobinostat (histone deacetylase inhibitor) and elotuzumab (an anti–CS-1 antibody).

Role of Radiation Therapy

Palliative radiation in a dose of 20 to 30 Gy should be limited to patients who have multiple myeloma with disabling pain and a well-defined focal process that has not responded to chemotherapy and to patients with spinal cord compression from a plasmacytoma. Analgesics in combination with chemotherapy can usually control the pain (Chapter 30).

Management of Complications

Hypercalcemia

Hypercalcemia, present in 15 to 20% of patients at diagnosis, should be suspected in those with anorexia, nausea, vomiting, polyuria, polydipsia, constipation, weakness, confusion, or stupor. If hypercalcemia is untreated, renal insufficiency may develop. Hydration, preferably with isotonic saline plus prednisone (25 mg four times/day), usually relieves the hypercalcemia. Bisphosphonates, such as zoledronic acid or pamidronate, are recommended and will correct hypercalcemia in almost all patients (Chapter 243).

Renal Insufficiency

The most common cause of acute renal failure is light chain cast nephropathy in patients who have excess excretion of monoclonal protein in urine (myeloma kidney). Aggressive treatment of acute renal failure due to light chain cast nephropathy is critical for long-term overall survival. If the patient is not oliguric, intravenous fluids and furosemide are needed to maintain a high urine flow rate (100 mL/hour). If the underlying cause is thought to be light chain cast nephropathy on the basis of clinical findings (e.g., serum free light chains >150 mg/dL) or renal biopsy, plasmapheresis is recommended daily for 5 days to reduce the levels of circulating light chains. Hemodialysis is necessary for symptomatic azotemia. The mainstay of therapy is aggressive treatment of myeloma with a regimen such as bortezomib, thalidomide, and dexamethasone (VTD) or bortezomib, cyclophosphamide, and dexamethasone (VCD). Allopurinol is necessary if hyperuricemia is present.

Infection

Prompt, appropriate therapy for bacterial infections is necessary. Prophylactic antibiotics, such as trimethoprim-sulfamethoxazole, should be considered in patients taking high-dose corticosteroids. Acyclovir should be given as prophylaxis against herpes zoster in patients receiving bortezomib. Intravenously administered gamma globulin is reserved for patients with hypogammaglobulinemia and recurrent severe infections. Pneumococcal and influenza immunizations (Chapter 18) should be given to all patients.

Skeletal Lesions

Patients should be encouraged to be as active as possible but to avoid trauma. Pamidronate (90 mg infused intravenously during a 4-hour period every 4 weeks) or zoledronic acid (4 mg intravenously during at least 15 minutes every 4 weeks) reduces the incidence of bone pain, pathologic fractures, and spinal cord compression; such prophylaxis is now routinely recommended for all patients with myeloma bone disease and may improve overall survival. After 1 to 2 years, the dosing can be reduced to once every 3 months in patients who are stable to minimize the risk of osteonecrosis of the jaw, which is a complication of long-term bisphosphonate therapy.

Spinal cord compression from an extramedullary plasmacytoma (Chapter 400) should be suspected in patients who have severe back pain, weakness or paresthesias of the lower extremities, or bladder or bowel dysfunction. Initial treatment is with dexamethasone-based therapy or radiation therapy. If the neurologic deficit increases, surgical decompression is necessary.

Miscellaneous Complications

Symptomatic hyperviscosity (see later) is less common than in Waldenström macroglobulinemia. Anemia that persists despite adequate treatment of underlying myeloma often responds to erythropoietin.

PROGNOSIS

Multiple myeloma is considered incurable at present, but survival has improved significantly in recent years. The median survival is approximately 5 years, but it varies widely according to clinical stage and risk stratification factors (see Table 187-4).[9] In some patients, an acute or aggressive terminal phase is characterized by rapid tumor growth, pancytopenia, soft tissue subcutaneous masses, decreased M protein levels, and fever; survival in this subset is generally only a few months.

FUTURE DIRECTIONS

Future efforts must be directed toward identifying new active agents and developing effective combinations of active drugs. Studies are under way to improve the conditioning regimen used in autologous stem cell transplantation and to better integrate novel therapies with stem cell transplantation.

VARIANT FORMS OF MULTIPLE MYELOMA

Smoldering Multiple Myeloma

Smoldering (asymptomatic) multiple myeloma is defined by the presence of an M protein level higher than 3 g/dL in serum or 10 to 60% clonal plasma cells in bone marrow in the absence of myeloma defining events and amyloidosis.[10] Patients with smoldering multiple myeloma are biologically similar to those with MGUS but carry a much higher risk for progression to myeloma or related malignant disease: 10% per year for the first 5 years, 5% per year for the next 5 years, and 1 to 2% per year thereafter. As a result, patients must be observed more closely (every 3 to 4 months), but they should not be treated unless progression to symptomatic multiple myeloma occurs. A small randomized trial found improved survival with the use of Rd as preventive therapy in patients with high-risk smoldering multiple myeloma, but additional data are needed before this approach can be recommended as routine practice. However, patients with ultrahigh-risk features (such as serum free light chain ratio ≥100 or presence of one or more focal lesions on magnetic resonance imaging) are candidates for therapy similar to that for symptomatic myeloma because they are at imminent risk of progression.

Plasma Cell Leukemia

Patients with plasma cell leukemia have more than 20% plasma cells in the peripheral blood and an absolute plasma cell count of 2000/μL or higher.[11] Plasma cell leukemia is classified as primary when it is diagnosed in the leukemic phase (60%) or as secondary when there is leukemic transformation of a previously recognized multiple myeloma (40%). Patients with primary plasma cell leukemia are younger and have a greater incidence of hepatosplenomegaly and lymphadenopathy, higher platelet count, fewer bone lesions, smaller serum M protein component, and longer survival (median, 6.8 vs. 1.3 months) than do patients with secondary plasma cell leukemia. Treatment of plasma cell leukemia is unsatisfactory. An aggressive initial treatment regimen such as bortezomib, dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, and etoposide (VDT-PACE) for two cycles, followed by autologous stem cell transplantation and subsequent maintenance therapy with a bortezomib-based regimen, is a reasonable strategy if the patient's clinical condition permits such an approach. Secondary plasma cell leukemia rarely responds in a durable manner to chemotherapy because the patients have already received chemotherapy and are resistant.

Nonsecretory Myeloma

Patients with nonsecretory myeloma have no M protein in either serum or urine and account for only 3% of cases of myeloma. For the diagnosis to be made, the clonal nature of bone marrow plasma cells should be established by immunoperoxidase, immunofluorescence, or flow cytometric methods. Treatment and survival are similar to those of patients with typical myeloma. The serum free light chain assay is abnormal in more than 60% of patients and can be used to monitor the response to therapy.

Osteosclerotic Myeloma (POEMS Syndrome)

This syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS) (see Table 187-2). The major clinical features are a chronic inflammatory-demyelinating polyneuropathy with predominantly motor disability and sclerotic skeletal lesions. The bone marrow usually contains less than 5% plasma cells, and hypercalcemia and renal insufficiency rarely occur. Almost all patients have a λ-type

M protein. The diagnosis is confirmed by identification of monoclonal plasma cells obtained at biopsy of an osteosclerotic lesion.

If the lesions are in a limited area, radiation therapy substantially improves the neuropathy in more than 50% of patients. If the patient has widespread osteosclerotic lesions, treatment is with autologous stem cell transplantation or other systemic therapy similar to that used for myeloma.

Solitary Plasmacytoma (Solitary Myeloma) of Bone

The diagnosis of solitary bone plasmacytoma is based on histologic evidence of a solitary tumor consisting of monoclonal plasma cells identical to those in multiple myeloma. In addition, complete skeletal radiographs and magnetic resonance imaging of the spine and pelvis must show no other lesions of myeloma, and the bone marrow aspirate must contain no evidence of clonal plasma cells. An M protein may be present in serum or urine at diagnosis, but persistence of the M protein after radiation therapy is associated with an increased risk for progression to multiple myeloma. Treatment consists of radiation in the range of 40 to 50 Gy. Almost 50% of patients who have a solitary plasmacytoma are alive at 10 years, and disease-free survival rates at 10 years range from 15 to 25%. Progression to myeloma, when it occurs, usually takes place within 3 years, but patients must be monitored indefinitely. There is no convincing evidence that adjuvant chemotherapy decreases the rate of conversion to multiple myeloma.

Extramedullary Plasmacytoma

Extramedullary plasmacytomas outside the bone marrow are most commonly found in the upper respiratory tract (80% of cases), especially in the nasal cavity and sinuses, nasopharynx, and larynx. Extramedullary plasmacytomas may also occur in the gastrointestinal tract, central nervous system, urinary bladder, thyroid, breast, testes, parotid gland, or lymph nodes. Extramedullary plasmacytomas may be solitary, or they may occur in the context of existing myeloma. The diagnosis of solitary extramedullary plasmacytoma is based on detection of a plasma cell tumor in an extramedullary site, absence of clonal plasma cells on bone marrow examination, and absence of other bone or extramedullary lesions on radiographic studies. Treatment of solitary extramedullary plasmacytoma consists of either complete surgical resection or tumoricidal irradiation. The plasmacytoma may recur locally, metastasize to regional nodes, or, rarely, develop into multiple myeloma.

WALDENSTRÖM MACROGLOBULINEMIA (PRIMARY MACROGLOBULINEMIA)

DEFINITION

Waldenström macroglobulinemia is the result of the uncontrolled proliferation of lymphocytes and plasma cells in which an IgM M protein is produced.[12] The cause is unknown; familial clusters have been reported. The median age of patients at the time of diagnosis is about 65 years, and approximately 60% are male. The diagnostic criteria are IgM monoclonal gammopathy (regardless of the size of the M protein), 10% or greater bone marrow infiltration (usually intertrabecular) by clonal lymphocytes that exhibit plasmacytoid or plasma cell differentiation, and a typical immunophenotype (e.g., surface IgM^+, $CD5^{+/-}$, $CD10^-$, $CD19^+$, $CD20^+$, $CD23^-$) that would satisfactorily exclude other lymphoproliferative disorders, including chronic lymphocytic leukemia (Chapter 184) and mantle cell lymphoma (Chapter 185). A recurrent mutation of the *MYD88* gene (MYD88 L265P) has recently been shown to be present in most patients with Waldenström macroglobulinemia and is thought to be relatively specific for this disease.[13]

CLINICAL MANIFESTATIONS

Weakness, fatigue, and bleeding (especially oozing from the oronasal area) are common initial symptoms. Blurred or impaired vision, dyspnea, weight loss, neurologic symptoms, recurrent infections, and heart failure may occur. In contrast to multiple myeloma, lytic bone lesions, renal insufficiency, and amyloidosis are rare. Physical findings include pallor, hepatosplenomegaly, and lymphadenopathy. Retinal hemorrhages, exudates, and venous congestion with vascular segmentation ("sausage" formation) may occur. Sensorimotor peripheral neuropathy is common. Pulmonary involvement is manifested by diffuse pulmonary infiltrates and isolated masses.

Laboratory Evaluation

Almost all patients have moderate to severe normocytic, normochromic anemia. The serum electrophoretic pattern is characterized by a tall, narrow peak or dense band that is of the IgM type on immunofixation. Quantitative IgM levels are high. A monoclonal light chain is detected in the urine of 80% of patients, but the amount of urinary protein is generally modest.

The bone marrow aspirate is often hypocellular, but the biopsy specimen is hypercellular and extensively infiltrated with lymphoid cells and plasma cells. The number of mast cells is frequently increased. Rouleau formation is prominent (Chapter 157), and the sedimentation rate is markedly increased. About 10% of cases may have an associated type I cryoglobulinemia (see later).

DIAGNOSIS

Diagnosis requires the combination of typical symptoms and physical findings, the presence of an IgM M protein, and 10% or greater lymphoplasmacytic infiltration of the bone marrow. The lymphoplasmacytic cells express CD19, CD20, and CD22, whereas expression of CD5 and CD10 occurs in a minority. Asymptomatic patients with 10% or greater lymphoplasmacytic infiltration of the bone marrow are considered to have smoldering Waldenström macroglobulinemia. Multiple myeloma, chronic lymphocytic leukemia, and MGUS of the IgM type must be excluded.

Patients meeting the diagnostic criteria for Waldenström macroglobulinemia but who have less than 3 g/dL IgM protein at diagnosis have sometimes been classified as having lymphoplasmacytic lymphoma with an IgM M protein (Chapter 185). However, except for hyperviscosity, the clinical picture, therapy, and prognosis for these patients do not differ from those of patients with an IgM level of 3 g/dL or higher; thus, these patients are also considered to have Waldenström macroglobulinemia by the current definition.

PREVENTION AND TREATMENT

Rx

Patients should not be treated unless they have anemia, constitutional symptoms (such as weakness, fatigue, night sweats, or weight loss), hyperviscosity, or significant hepatosplenomegaly or lymphadenopathy. Rituximab, a chimeric anti-CD20 monoclonal antibody (Chapter 36), produces a response in at least 50% of untreated patients. The most common regimen used as front-line therapy is the combination of rituximab with cyclophosphamide and dexamethasone (RCD).[14] This combination is highly active and also preserves the ability to mobilize stem cells for transplantation, if necessary. Alternatives include bendamustine plus rituximab (BR); rituximab, bortezomib plus dexamethasone; and cladribine with or without rituximab.[15]

In general, for minimally symptomatic patients, rituximab as a single agent is an excellent choice for initial therapy. For patients with more advanced symptoms, including severe anemia or hyperviscosity, combination approaches such as RCD or BR are preferred.

For relapse, the agents used as initial therapy can be given alone or in combination. Autologous stem cell transplantation can be considered for eligible patients with relapsed disease.

Spuriously low hemoglobin and hematocrit levels may occur because of the increased plasma volume from the large amount of intravascular M protein. Consequently, transfusions should not be given solely on the basis of the hemoglobin or hematocrit value. Symptomatic hyperviscosity should be treated by plasmapheresis. The median survival of patients with macroglobulinemia is 5 years.

HYPERVISCOSITY SYNDROME

Hyperviscosity syndrome occurs in patients with Waldenström macroglobulinemia who have high levels of serum IgM M protein (>5 g/dL) and occasionally in those with myeloma, especially of the IgA type. Hyperviscosity is disproportionately more common relative to the same serum concentration of IgM and IgA M proteins compared with IgG M proteins because of the inherent tendency of IgM and IgA molecules to polymerize. Typically, IgM forms pentamers, whereas IgA forms dimers or sometimes trimers, resulting in high-molecular-weight complexes. Chronic nasal bleeding and oozing from the gums are the most frequent symptoms of hyperviscosity, but postsurgical or gastrointestinal bleeding may also occur. Retinal hemorrhages are common, and venous congestion with sausage-like segmentation and papilledema may be seen (Fig. 187-8). The patient occasionally complains of blurring or loss of vision. Dizziness, headache, vertigo, nystagmus, decreased hearing, ataxia, paresthesias, diplopia, somnolence, and coma may occur. Hyperviscosity can precipitate or exacerbate heart failure. Most patients have symptoms when the relative viscosity is greater than 4 cP, but the relationship between serum viscosity and clinical manifestations is not precise. There have

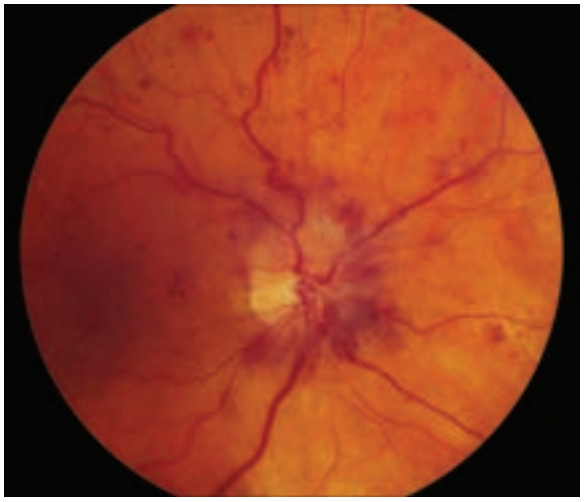

FIGURE 187-8. Hyperviscosity syndrome. Right eye retinal image in a patient with Waldenström macroglobulinemia and hyperviscosity syndrome showing sausaging (focal venular dilations), intraretinal hemorrhages, microaneurysms, and peripapillary cotton-wool spots and disc swelling (papilledema).

FIGURE 187-9. Skin infarction in cryoglobulinemia. The skin has a reticulated pattern as a result of leakage of red blood cells from damaged skin capillaries. Necrosis and ulceration have occurred in peripheral sites because of vessel blockage. This patient eventually required plastic surgery. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)

been no randomized trials on management of hyperviscosity syndrome. Patients with symptomatic hyperviscosity should be treated with plasmapheresis and with chemotherapy to treat the underlying malignant disease. Plasma exchange of 3 to 4 L with albumin should be performed daily until the patient is asymptomatic. Plasma exchange is rapidly effective (two or three exchanges) in the case of IgM M proteins, which are primarily distributed in the intravascular space; with IgG M proteins, in contrast, multiple attempts may be needed because a significant amount of IgG can exist in the extravascular space.

HEAVY CHAIN DISEASES

The HCDs are characterized by the presence of an M protein consisting of a portion of the immunoglobulin heavy chain in serum, urine, or both. These heavy chains are devoid of light chains and represent a lymphoplasma cell proliferative process. There are three major types: γ-HCD, α-HCD, and μ-HCD.

γ-HCD

Patients with γ-HCD often initially have a lymphoma-like illness, but the clinical findings are diverse and range from an aggressive lymphoproliferative process (Chapter 185) to an asymptomatic state. Hepatosplenomegaly and lymphadenopathy occur in about 60% of patients. Anemia is found in approximately 80% initially and in nearly all eventually. The electrophoretic pattern often shows a broad-based band more suggestive of a polyclonal increase than an M protein. The diagnosis depends on the identification of an isolated monoclonal γ heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression.

Treatment is indicated only for symptomatic patients and consists of chemotherapy with melphalan plus prednisone or regimens used to treat non-Hodgkin lymphoma (Chapter 185), such as cyclophosphamide, vincristine, and prednisone. The prognosis of γ-HCD is variable and ranges from a rapidly progressive downhill course of a few weeks' duration to the asymptomatic presence of a stable monoclonal heavy chain in serum or urine.

α-HCD

α-HCD is the most common form of HCD and occurs in patients from the Mediterranean region or the Middle East, generally in the second or third decade of life. About 60% are men. The gastrointestinal tract is most commonly involved, and severe malabsorption with diarrhea, steatorrhea, and weight loss is noted (Chapter 140). Plasma cell infiltration of the jejunal mucosa is the most frequent pathologic feature. Immunoproliferative small intestinal disease is restricted to patients with small intestinal lesions who have the pathologic features of α-HCD but do not synthesize α heavy chains.

The serum protein electrophoretic pattern is normal in half the cases; in the remainder, an unimpressive broad band may appear in the α_2 or β region. The diagnosis depends on identification of an isolated monoclonal α heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression. The amount of α heavy chain in urine is small.

In the absence of therapy, α-HCD is typically progressive and fatal. The usual treatment consists of antibiotics, such as tetracyclines, and the eradication of any concurrent parasitic infection. Patients who do not respond adequately to antibiotics are given chemotherapy similar to that used to treat non-Hodgkin lymphoma, for example, the cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP) regimen (Chapter 185).

μ-HCD

This disease is characterized by the demonstration of an isolated monoclonal μ chain fragment on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression.

The serum protein electrophoretic pattern is usually normal, except for hypogammaglobulinemia. Bence Jones proteinuria has been found in two thirds of cases. Lymphocytes, plasma cells, and lymphoplasmacytoid cells are increased in the bone marrow. Vacuolization of the plasma cells is common and should suggest the possibility of HCD. The course of μ-HCD is variable, and survival ranges from a few months to many years. Treatment is with corticosteroids and alkylating agents.

CRYOGLOBULINEMIA

Cryoglobulins are plasma proteins that precipitate when cooled and dissolve when heated. They are designated idiopathic or essential when they are not associated with any recognizable disease. Cryoglobulins are classified into three types: type I (monoclonal), type II (mixed monoclonal plus polyclonal), and type III (polyclonal).

Type I Cryoglobulinemia

Type I (monoclonal) cryoglobulinemia is most commonly of the IgM or IgG class, but IgA and Bence Jones cryoglobulins have been reported. Most patients, even with large amounts of type I cryoglobulin, are completely asymptomatic from this source. Others with monoclonal cryoglobulins in the range of 1 to 2 g/dL may have evidence of vasculitis with pain, purpura, Raynaud phenomenon, cyanosis, and even ulceration and sloughing of skin and subcutaneous tissue (Fig. 187-9) on exposure to cold because their cryoglobulins precipitate at relatively high temperatures. Type I cryoglobulins are associated with macroglobulinemia, multiple myeloma, or MGUS. Therapy for patients with symptomatic type I cryoglobulinemia and significant symptoms is similar to that for Waldenström macroglobulinemia for the IgM type and multiple myeloma for the non-IgM type.

Type II Cryoglobulinemia

Type II (mixed) cryoglobulinemia typically consists of an immune complex of IgM M protein and polyclonal IgG, although monoclonal IgG or monoclonal IgA may also be seen with polyclonal IgM. Serum protein electrophoresis generally shows a normal pattern or a diffuse, polyclonal hypergammaglobulinemic pattern. The quantity of mixed cryoglobulin is

usually less than 0.2 g/dL. Despite the monoclonal component, most patients do not have a clonal plasma cell disorder; rather, they have serologic evidence of infection with hepatitis C virus (Chapter 149). At present, hepatitis C is thought to be the cause of most cases of type II cryoglobulinemia.

Most clinical manifestations are related to the development of vasculitis and include palpable purpura, livedo reticularis, polyarthralgias, and neuropathy. Involvement of the joints is symmetrical, but joint deformities rarely develop. Raynaud phenomenon, necrosis of the skin, and neurologic involvement may be present. In almost 80% of renal biopsy specimens, glomerular damage can be identified. Nephrotic syndrome may result, but severe renal insufficiency is uncommon.

Early administration of corticosteroids is the most frequent therapy. Treatment should also target underlying hepatitis C infection with interferon alfa-2 or ribavirin (Chapter 149). Agents to treat the monoclonal component, such as cyclophosphamide, chlorambucil, azathioprine, or rituximab, are used if there is no response. Plasmapheresis (with a warmed circuit) is helpful in the acute management of symptoms by removal of circulating immune complexes.

Type III Cryoglobulinemia

Type III (polyclonal) cryoglobulinemia does not have a monoclonal component and is not associated with a clonal plasma cell proliferative disorder. Type III cryoglobulins are found in many patients with chronic infections or inflammatory diseases and are usually of no clinical significance unless they are associated with hepatitis C infection.

REVIEW QUESTIONS

1. A 63-year-old man is found to have a serum monoclonal protein level of 1.6 g/dL during work-up of joint pains. The monoclonal protein is IgG κ on immunofixation. He has no anemia, hypercalcemia, renal failure, or bone lesions. Bone marrow biopsy shows 8% plasma cells. The most likely diagnosis is

A. Multiple myeloma
B. Smoldering multiple myeloma
C. Monoclonal gammopathy of undetermined significance (MGUS)
D. Idiopathic Bence Jones proteinuria
E. Waldenström's macroglobulinemia

Answer: C This patient has a small monoclonal protein, without evidence of end-organ damage. This could be either MGUS or smoldering myeloma. The bone marrow plasma cell percentage is less than 10%, and the serum monoclonal protein level is less than 3 g/dL. Thus the diagnosis is MGUS. In contrast to MGUS, smoldering multiple myeloma requires either 10-60% plasma cells on bone marrow or 3 g/dL or more M spike on serum protein electrophoresis. The diagnosis of myeloma requires presence of one or more myeloma defining events. (See Table 187-2.)

2. Which of the following are risk factors for progression in monoclonal gammopathy of undetermined significance?

A. Size of the M protein
B. Type of the M protein
C. Abnormal free light chain ratio
D. A and C
E. A, B, and C

Answer: E The best predictors of progression of MGUS are the size of the M protein, the type of the M protein, and an abnormal baseline free light chain ratio. Patients with a serum M protein of less than 1.5 g/dL, IgG type, and normal free light chain ratio have a 5% probability of progression during 20 years. In contrast, if all three factors were abnormal, the risk of progression during that time is in excess of 50%. Another predictor of progression has recently been reported: reduction of one or two noninvolved immunoglobulin isotype levels (immunoparesis). (See section on prognosis under MGUS.)

3. Autologous stem cell transplantation is commonly used in the treatment of multiple myeloma in eligible patients. Which of the following statements is true about this procedure for the treatment of myeloma?

A. It is less commonly used more recently as therapy for myeloma compared with nonmyeloablative allogeneic transplantation.
B. It is not curative but prolongs overall and event-free survival.
C. Patients typically receive four to six cycles of melphalan, prednisone, and bortezomib (VMP) before transplantation.
D. Patients typically receive four to six cycles of thalidomide, melphalan, and prednisone (MPT) before transplantation.
E. The typical conditioning regimen is total body irradiation plus high-dose melphalan.

Answer: B Autologous stem cell transplantation for myeloma is not curative. Transplantation prolongs overall and event-free survival by about 12 to 18 months. It is much more commonly used than nonmyeloablative allogeneic transplantation, which should still be considered investigational for this disease. Melphalan should be avoided before induction because it may affect stem cells and prevent adequate mobilization; therefore, VMP and MPT are not good options before transplantation. The typical conditioning regimen is melphalan 200 mg/m^2.

4. Which of the following agents is associated with a high risk of peripheral neuropathy?

A. Bortezomib
B. Lenalidomide
C. Pomalidomide
D. Carfilzomib
E. Melphalan

Answer: A Of the agents listed, bortezomib is the drug associated with the highest risk of neuropathy. The major adverse effects with lenalidomide and pomalidomide include thrombosis, rash, low blood counts, and fatigue. Carfilzomib is a new proteasome inhibitor that unlike bortezomib appears to have less risk of neuropathy. Melphalan is an alkylating agent that is associated with low blood counts and risk of myelodysplastic syndrome. The rate of bortezomib neuropathy and its severity can be limited by use of a once-weekly dosing schedule and the subcutaneous route of administration. (See section on treatment of relapsed refractory myeloma under prevention and treatment of multiple myeloma.)

5. Which of the following is *not* true of Waldenström macroglobulinemia?

A. The type of monoclonal protein in Waldenström macroglobulinemia tends to form a pentamer.
B. Most patients have a mutation of the *MYD88* gene (MYD88 L265P).
C. Hyperviscosity is an important feature of the disease.
D. Osteosclerotic bone lesions are seen in 25% of patients.
E. Rituximab, cyclophosphamide, dexamethasone (RCD) is a commonly used treatment regimen.

Answer: D Osteosclerotic bone lesions are a feature of the POEMS syndrome, not of Waldenström's macroglobulinemia. Unlike with myeloma, in which osteolytic bone disease is present in most patients, patients with Waldenström's macroglobulinemia do not have bone disease. The type of monoclonal protein is IgM; this molecule tends to pentamerize, and the high molecular weight leads to hyperviscosity. Rituximab, cyclophosphamide, dexamethasone (RCD) is a commonly used treatment regimen for initial therapy. (See section on Waldenström macroglobulinemia.)

188

AMYLOIDOSIS

MORIE A. GERTZ

DEFINITION

Immunoglobulin light chain amyloidosis is characterized by a clonal population of bone marrow plasma cells that produces a monoclonal light chain of the κ or λ type, as either an intact molecule or a fragment. The light chain protein, instead of conforming to the α-helical configuration of most proteins, misfolds and forms a β-pleated sheet.[1] This insoluble protein is deposited in tissues and interferes with organ function. The β-pleated sheet configuration is responsible for the tinctorial properties; when the protein is stained with Congo red and viewed under polarized light, apple-green birefringence is demonstrated and is required for the diagnosis. Systemic light chain amyloidosis (AL) must be distinguished from the much less common amyloidosis associated with chronic infection and inflammatory arthropathies (secondary amyloidosis or AA) or with inherited amyloid cardiomyopathies and neuropathies (familial amyloidosis or AF).

CLINICAL MANIFESTATIONS

Amyloidosis is particularly difficult to diagnose and is a challenge for internists. The presenting symptoms can be diverse and are mimicked by far more common disorders (Table 188-1). The signs include tongue enlargement with dental indentations (Fig. 188-1) and "pinch" or periorbital purpura (Fig. 188-2), a result of vascular fragility. The signs are specific but lack sensitivity in that they are present in no more than 20% of patients. No single imaging procedure or laboratory study is diagnostic for the disease. The clinician must therefore be aware of the possibility of amyloidosis, or it may be overlooked. The kidney is commonly involved in amyloidosis (50% of cases). The diagnosis should be suspected in any patient who presents with nondiabetic nephrotic-range proteinuria (Chapter 121).[2] One third of patients with amyloidosis have nephrotic syndrome that is manifested with dramatic increases in the blood cholesterol level (median, 270 mg/dL), and urinalysis for proteinuria should be done in patients with a sudden increase in the serum cholesterol level. A patient with nondiabetic proteinuria may receive an empirical course of corticosteroids for possible minimal-change glomerulopathy. This treatment delays the diagnosis of amyloidosis and allows other organs to become involved.[3] Ten percent of renal biopsy specimens from patients with nondiabetic nephrotic syndrome are subsequently shown to be involved by amyloidosis. The incidence of bleeding after percutaneous renal biopsy is not increased in patients with AL.

The heart is involved in approximately 50% of patients with amyloidosis, and the presentation is subtle because fatigue is often the only manifestation.[4] Because amyloid heart disease (Chapter 60) is a disorder of diastolic failure, the typical findings of cardiomyopathy (enlarged cardiac silhouette on chest radiography, depressed ejection fraction by echocardiography, and pulmonary vascular redistribution) are absent. The effect of amyloidosis on the heart is poor filling during diastole. Patients have low end-diastolic volume and, as a consequence, poor stroke volume, despite a completely

TABLE 188-1 SYMPTOMS, SIGNS, AND SYNDROME OF AMYLOIDOSIS

SYMPTOMS AND SIGNS
Common symptoms: fatigue, edema, dyspnea, anorexia, paresthesias
Rare symptoms: claudication, joint pain and stiffness, sicca syndrome
Common signs: periorbital purpura, glossomegaly, hepatomegaly
Rare signs: waxy infiltration of eyelids, shoulder pad sign
SYNDROMES
Nondiabetic nephrotic syndrome
Nonischemic cardiomyopathy with an echocardiogram showing "hypertrophy"
Hepatomegaly or increased alkaline phosphatase with no imaging abnormality
Peripheral neuropathy with monoclonal gammopathy of undetermined significance or chronic inflammatory demyelinating polyneuropathy with autonomic features
Atypical myeloma with monoclonal light chains and modest marrow plasmacytosis

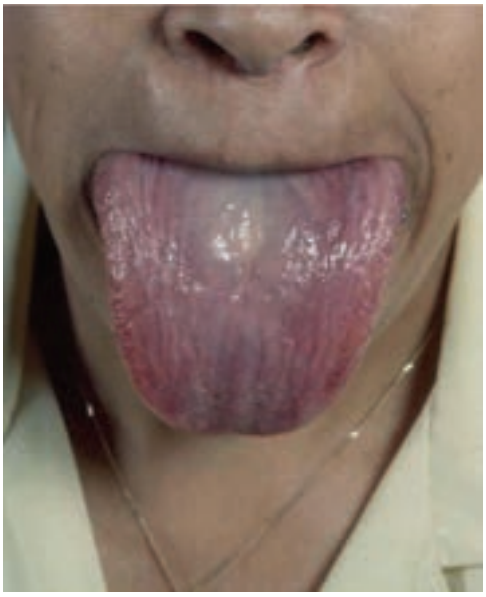

FIGURE 188-1. Macroglossia (or glossomegaly) in a patient with amyloidosis. (From Esplin BL, Gertz MA. Current trends in diagnosis and management of cardiac amyloidosis. *Curr Probl Cardiol.* 2013;38:53-96.)

FIGURE 188-2. Periorbital purpura in amyloidosis. (From Kitchens CS. Purpura and other hematovascular disorders. In: Kitchens CS, Konkle BA, Kessler CM, eds. *Consultative Hemostasis and Thrombosis.* 3rd ed. Philadelphia: Elsevier; 2012.)

normal ejection fraction. Electrocardiography frequently shows a pseudoinfarct pattern, which can be interpreted as demonstrating silent ischemic infarction; this finding leads to coronary angiography, which is invariably negative (unless there is coincidental coronary artery disease). Echocardiography, which shows thickening of the heart walls due to amyloid infiltration, is frequently interpreted as showing left ventricular hypertrophy, and the cause of heart failure can be ascribed to silent hypertension or, alternatively, hypertrophic cardiomyopathy. Restrictive cardiomyopathy has been confused with pericardial disease, and patients have undergone unnecessary pericardiectomy, without clinical benefit. The classic granular sparkling appearance on the echocardiogram is not a useful diagnostic finding. Patients with amyloidosis rarely have symptoms of ischemic heart disease. Enhancement on magnetic resonance imaging with gadolinium is delayed in 69% of patients with cardiac amyloidosis. Myocardial enhancement is associated with increased ventricular mass and impaired left ventricular systolic function.

The liver is involved in 13% of patients. The typical presentation is hepatomegaly and an increased serum alkaline phosphatase value. Increased transaminase values and hyperbilirubinemia are late signs. Imaging is not helpful, and liver uptake is homogeneous. Many patients undergo evaluation for metastatic malignant disease. Liver biopsy is not associated with an increased rate of bleeding and is not contraindicated in the presence of hepatic amyloidosis. Rarely, patients present with spontaneous splenic rupture. Acquired deficiency of coagulation factor X (Chapter 174) is specific to AL and can be associated with clinically severe hemorrhage. Levels of coagulation factor X improve with effective therapy because the cause of low levels of circulating factor X is binding of factor X to the amyloid fibrils.

The peripheral neuropathy (Chapter 420) associated with amyloidosis begins in the lower extremities, is symmetrical, and is generally sensory or mixed sensorimotor. When a monoclonal protein is recognized, frequent diagnoses are chronic inflammatory demyelinating polyneuropathy and neuropathy associated with monoclonal gammopathy of undetermined significance because amyloidosis has not been considered in the differential diagnosis. Associated autonomic neuropathy occurs in approximately 4% of patients and can be characterized by orthostatic hypotension, which may be misattributed to cardiac failure. Autonomic dysmotility of the bowel is a common associated finding (Chapter 136). It can be upper intestinal, leading to pseudo-obstruction and recurrent emesis, or lower intestinal, characterized by alternating obstipation and fecal incontinence. Diarrhea caused by autonomic failure has been misdiagnosed as collagenous colitis when eosinophilic deposits are found in the bowel mucosa on hematoxylin-eosin staining in the absence of Congo red staining. Carpal tunnel syndrome (Chapter 420) occurs in approximately 13% of patients; it is not clinically distinguishable from the syndrome associated with repetitive stress injury but frequently fails to improve after surgical release. Rarely, interstitial lung disease, pseudoclaudication, periarticular deposits, and unexplained weight loss are presenting symptoms.

Systemic amyloidosis can be confused with early multiple myeloma (Chapter 187). Patients who present with vague symptoms of fatigue and edema are found to have a monoclonal protein in the urine, and a bone marrow biopsy specimen shows a clonal plasmacytosis with a median of 5% plasma cells in the bone marrow; however, a quarter of patients have more than 10% plasma cells in the bone marrow, a finding that qualifies as a diagnosis of multiple myeloma. These patients are often considered to have atypical multiple myeloma when the underlying amyloid syndrome is undetected. In these patients, a misdiagnosis of myeloma kidney or demyelinating neuropathy is made when an adequate diagnostic evaluation to exclude amyloidosis has not been performed.

DIAGNOSIS

Screening for Amyloidosis

In a patient with nondiabetic proteinuria, cardiomyopathy without ischemic risk factors, unexplained hepatomegaly, peripheral or autonomic neuropathy, or carpal tunnel syndrome, amyloidosis is not the most likely cause. The disorder occurs in only 8 per million persons per year, and routine biopsy is not appropriate whenever consistent symptoms are found. The classic physical finding of periorbital purpura occurs in only 10% of patients, is often limited to petechial eruptions over the eyelids, and is easily overlooked. Enlargement of the tongue occurs in 10 to 15% of patients; therefore, although it is specific, it is not sensitive for the diagnosis. Amyloidosis in patients with enlarged tongues may be unrecognized, or these patients may be evaluated for acromegaly or undergo unnecessary tongue biopsies because of the suspicion of squamous cell cancer. If biopsy is not an appropriate screening technique, what algorithm should be used to recognize AL?

By definition, amyloidosis is a plasma cell dyscrasia (Chapter 187); therefore, virtually all patients have a detectable immunoglobulin abnormality by immunofixation of the serum or urine, or they have abnormal results on a serum immunoglobulin free light chain assay. When a patient presents with a compatible clinical syndrome, these diagnostic studies should be completed before invasive diagnostic studies are performed (Fig. 188-3). Simple electrophoresis without immunofixation is inadequate because the monoclonal proteins are quantitatively very small in most patients and will not cause a detectable peak on serum protein electrophoresis. When these three diagnostic studies are used in combination, the sensitivity is 100%. If a monoclonal protein is detected, further investigations for amyloid should proceed, as described later. If a monoclonal protein is not found, three possibilities exist: (1) the patient does not have amyloidosis; (2) if the patient is known to have amyloidosis, it may be localized rather than systemic; or (3) if the patient is known to have systemic amyloidosis, it may be the senile systemic or familial type rather than the light chain type (see later section on other forms of amyloidosis).

Confirming the Diagnosis of Amyloidosis

In view of the grave prognosis associated with AL, the diagnosis must be confirmed by biopsy (with Congo red staining) in all cases.[5] Although it is reasonable to biopsy the kidney when proteinuria is the presenting symptom,

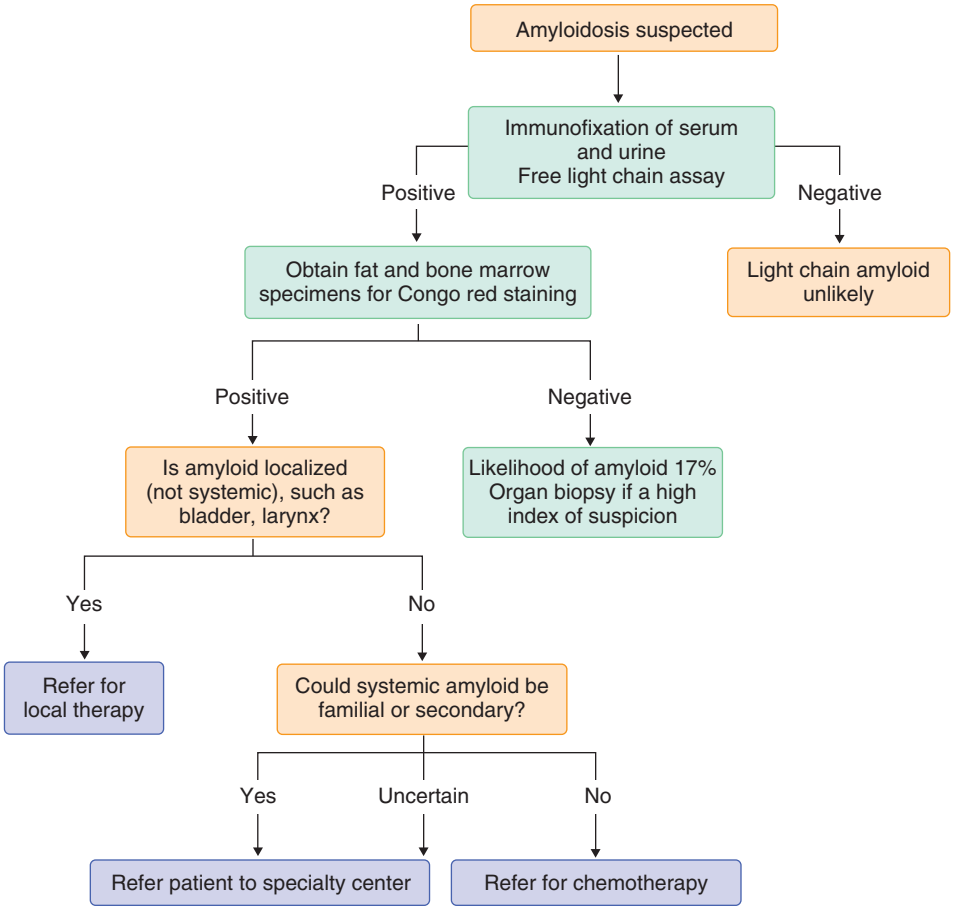

FIGURE 188-3. **Algorithm for the cost-effective pursuit of a diagnosis of systemic light chain amyloidosis.**

the heart when cardiomyopathy is recognized, the liver when there is hepatomegaly and increased alkaline phosphatase, or the nerve when there is a sensorimotor functional loss, these invasive and occasionally risky procedures are not required. Subcutaneous fat aspiration is an outpatient procedure that has a 24-hour turnaround time and recognizes amyloid deposits in 70% of patients. Bone marrow is a second convenient biopsy site, and this test is often required to exclude the possibility of associated multiple myeloma. Bone marrow biopsy is positive in 50% of patients. When both subcutaneous fat aspiration and bone marrow biopsy are done, amyloid is detected in 83% of patients. The remaining patients should have biopsy of the appropriate organ.

Once amyloid deposits are detected in tissues, further diagnostic evaluation is required. The presence of a monoclonal protein in the serum or urine and the presence of congophilic deposits in tissue do not verify that amyloidosis is light chain in origin. Further diagnostic studies are essential to classify the type of amyloid before therapy is initiated. Immunohistochemical studies on the tissue may be useful, but misfolding of the amyloid light chain often prevents epitopes from being recognized by commercial antisera; thus, false-negative results are common. Mass spectrometric analysis of the amyloid deposit can be done on paraffin-embedded tissue and validates the type of amyloid by direct amino acid sequencing, leaving no question about the origin of the amyloid protein as an immunoglobulin light chain. The incidence of monoclonal gammopathies in the elderly ranges from 3 to 5%. Therefore, that fraction of patients with senile systemic, localized, and familial amyloidosis (see section on other forms of amyloidosis) could be expected to have an associated monoclonal gammopathy, which would be misleading. Mass spectrometric analysis is feasible on subcutaneous fat tissue.

TREATMENT

Amyloidosis was previously thought to be untreatable and invariably fatal. With current therapy, response rates of about 70% regularly occur, and the median duration of survival is reportedly upward of 5 years.[6] Agents to reverse the misfolding of the protein and render it soluble would be ideal, but they are not available. The source of the immunoglobulin light chain is the clonal plasma cell population in the bone marrow. All known therapies are directed at destruction of the plasma cell clone.

The two treatment choices are generally traditional-dose chemotherapy and high-dose chemotherapy with autologous stem cell transplantation. Most patients are not candidates for high-dose therapy because of age, advanced cardiac dysfunction, or renal insufficiency. High-dose melphalan is a feasible approach in selected patients with cardiac AL and is associated with a high rate of hematologic and organ responses that lead to prolonged survival. Current therapies include combinations of melphalan, cyclophosphamide, dexamethasone, bortezomib, and lenalidomide. Treatment with a combination of bortezomib (1.5 mg/m^2 weekly or 1.3 mg/m^2 on days 1, 4, 8, and 11 every 28 days), cyclophosphamide (300 mg/m^2 orally weekly), and dexamethasone (40 mg weekly) has produced rapid and complete hematologic responses in the majority of patients with AL with few side effects.[7] Effective therapy has been associated with resolution of nephrotic syndrome, cardiac failure, and hepatomegaly. Imaging has shown amyloid deposits to regress after the suppression of light chain synthesis.

A systematic review and meta-analysis indicated that autologous hematopoietic stem cell transplantation does not appear to be superior to conventional chemotherapy in improving overall survival in patients with AL amyloidosis, although the quality of evidence was deemed low.

Assessing the Effect of Therapy

The serum immunoglobulin free light chain assay has been cited as a useful screening test for patients with a compatible clinical syndrome. This assay is also used to measure the therapeutic effect of intervention because the light chain level is quantifiable and reproducible. On the basis of current hematologic response criteria, successful therapy is characterized by a 50% reduction in the abnormal free light chain level.[8,9] Because the tissue toxicity associated with amyloid is related to the deposition of small amounts of light chain, it is unclear whether a successful outcome requires complete eradication of the light chain product. Studies have shown that patients achieving complete normalization of the free light chain have a better outcome, but it is uncertain whether patients who do not achieve this level of response should be subjected to more intensive treatment in an effort to remove this pathogenic amyloid serum precursor.

PROGNOSIS

The outcome of patients with AL depends on the extent of cardiac involvement (Chapter 60). With the advent of routine hemodialysis for this population, death due to renal failure is uncommon. The greater the involvement of the heart, the shorter a patient's survival. Echocardiography provides useful information about the ejection fraction, the thickness of the ventricular septum and left ventricular free wall, and the strain percentage (the rate at which wall shortening occurs). Doppler echocardiography allows quantitative measurements of diastolic function and reflects the slowing of blood flow into the ventricular chamber as the noncompliant left ventricle fills. This "stiffness," measured by the deceleration time, provides useful information and correlates well with survival.

Cardiac biomarkers are extremely sensitive measures of myocardial function, are reproducible, and can be used not only for prognosis but also to follow cardiac response after effective therapy. The serum troponin value is a powerful predictor of survival in patients with amyloidosis, and the N-terminal pro–brain natriuretic peptide value predicts survival after a diagnosis of amyloidosis. A staging system has been developed with these two cardiac biomarkers and the difference between involved and uninvolved free light chain levels to accurately predict survival.

OTHER FORMS OF AMYLOIDOSIS

Localized amyloidosis can be confused with systemic amyloidosis, but it has a much better prognosis. Localized AL amyloidosis represents a true plasma cell neoplasm and not a pseudotumor.[10] However, patients with localized amyloidosis generally do not require systemic therapy; management can be supportive or localized to the deposition. The location of the amyloid deposits can be a clue to the localized nature. Typical sites for localized amyloid deposition include the ureter, bladder, urethra, and prostate. Therapy entails cystoscopic resection or intravesical instillation of dimethyl sulfoxide. Most forms of cutaneous amyloidosis are localized, although nodular cutaneous amyloidosis has occurred in systemic AL. Tracheobronchial and laryngeal amyloidosis and nodular pulmonary amyloidosis are localized, are not associated with a plasma cell dyscrasia, and generally require only local therapy. Nodular pulmonary amyloidosis is often diagnosed after thoracotomy for a presumed malignant pulmonary nodule. Most cases of laryngeal amyloidosis are found when the patient presents to an otorhinolaryngologist with hoarseness and amyloid deposits are found on endoscopic biopsy. Patients with localized amyloidosis do not have a demonstrable monoclonal protein in the serum or urine and have a normal free light chain ratio. The localized amyloidosis found in Alzheimer disease is chemically unrelated to AL, and AL patients have no increased risk of dementia.

Senile systemic amyloidosis results from the deposition of a normal serum protein, transthyretin (TTR), in the myocardium. It has a much better prognosis than cardiac AL and generally necessitates endomyocardial biopsy for diagnosis; most patients are older than 70 years. When a monoclonal protein is present, it is incidental, and confirmation of type generally requires analysis of the amyloid-laden tissues. Therapy is supportive. The clinical presentation of senile systemic amyloidosis is not distinguishable from that of cardiac AL.

AF is uncommon in the United States and represents only 3% of cases of systemic amyloidosis. Patients present with the full clinical spectrum associated with amyloidosis, including cardiomyopathy, peripheral neuropathy, and proteinuria. Patients do not have a monoclonal protein because the deposited precursor is a mutant form of TTR, fibrinogen, lysozyme, or apolipoprotein A. Diflunisal (250 mg twice dail) can slow the rate of progression of the AF associated polyneuropathy.■ Selected patients with AF with polyneuropathy have benefited from liver transplantation because this disease is characterized by systemic accumulation of polymerized TTR in the peripheral nerves and systemic organs and liver transplantation stops the major production of amyloidogenic TTR.[11] In one hospital, the estimated probability of 10-year survival in patients with familial amyloid polyneuropathy was 100% after liver transplantation compared with 56% for the nontransplantation group, with the survival curves diverging at 6 years.[12]

One important form of AF in the United States is associated with an allele of the normal serum protein TTR in which isoleucine is substituted for valine at position 122 (TTR Val-122-Ile). The prevalence of this mutation in blacks in the United States is as high as 3.9%. Heterozygous inheritance of this mutant TTR is associated with late-onset cardiomyopathy in this population. Wall thickening is found on echocardiography. Heart failure is often mild at onset. The prognosis is far better than that of cardiac AL, and its recognition has important implications for genetic counseling.

SECONDARY AMYLOIDOSIS

Systemic AA is the rarest form in Western countries.[13] Previously, it was a consequence of uncontrolled sustained inflammation, usually infectious, and causes included tuberculosis and osteomyelitis. Cystic fibrosis, bronchiectasis, decubitus ulcers, and skin abscesses related to subcutaneous injection of illicit drugs are modern-day infectious causes. Today it occurs primarily in patients with difficult-to-control inflammatory syndromes, including Crohn's disease, juvenile arthritis, and ankylosing spondylitis. Organ damage results from the extracellular deposition of proteolytic fragments of the acute phase reactant serum amyloid A (SAA) as amyloid fibrils. However, because only a minority of patients with chronic inflammatory disorders actually develop this complication, disease-modifying factors must be also operative. The best characterized of these is the *SAA1* genotype. There has been a recent decline in numbers of patients presenting with AA amyloidosis due to rheumatic diseases, at least in part due to the use of disease-modifying antirheumatic therapy.[14]

The large majority of these patients present with proteinuria, nephrotic syndrome, or renal dysfunction. Diarrhea related to intestinal involvement (22%) and thyromegaly (9%) also occur.

Suppression of the inflammatory process results in regression of tissue amyloid deposits. Early diagnosis and rapid control of the underlying inflammatory disease are critical to prevent irreversible organ damage and to improve survival of patients with AA amyloidosis. Therefore, monitoring of patients with chronic, active inflammatory disease by serial testing of SAA, C-reactive protein, microalbuminemia, proteinuria, and other indicators of amyloid development, as well as possibly determination of the *SAA1* genotype, can guide approach to management. Anti– tumor necrosis factor-α agents have markedly reduced the incidence of AA from inflammatory arthritis. There are familial forms of AA associated with familial periodic fever syndromes, the most common being familial Mediterranean fever (Chapter 261) due to mutations in the tumor necrosis factor receptor. Interleukin-1 inhibitors (anakinra) have been used successfully in these inherited periodic fever syndromes.

REVIEW QUESTIONS

1. A 61-year-old man presents to an otorhinolaryngologist with hoarseness. During laryngoscopy, a mass is found on the left vocal cord. A biopsy specimen shows dense deposits of amyloid. The patient is referred to you for subsequent evaluation. What is the most likely next step?

A. Cardiac biopsy to assess suitability for high-dose chemotherapy and stem cell transplantation
B. Initiation of bortezomib-based chemotherapy
C. Bone marrow biopsy to determine whether this represents coexistent multiple myeloma
D. Referral back to the otorhinolaryngologist for therapy
E. Bronchoscopy to assess status of mainstem bronchi

Answer: D Laryngeal and vocal cord amyloid is always localized (not associated with systemic amyloid). Therefore, the treatment is local and usually involves endoscopic laser therapy of the amyloid deposits. Recurrence is common, and the patient is likely to require ongoing monitoring. Pulmonary function testing would be reasonable to detect flow obstruction. Computed tomography imaging would not add value to the evaluation.

2. A 76-year-old black man is referred to you by a cardiologist after an endomyocardial biopsy specimen showed amyloid deposits. The patient was seen for dyspnea on exertion that evolved during 24 months. The echocardiogram was clinically suggestive of infiltrative cardiomyopathy. The patient has congestive heart failure. Serum and urine immunofixation assays were negative, and a free light chain assay showed a normal ratio. What should be your next step in the evaluation?

A. Classify the amyloid by mass spectrometry.
B. Chemotherapy is urgent in the presence of progressive congestive heart failure.
C. If a bone marrow assay is negative for amyloid deposits, the patient is eligible for cardiac transplantation.
D. Computed tomography imaging of the chest, abdomen, and pelvis should be performed to screen for occult amyloid deposits.

Answer: A The absence of serum and urine light chains and a normal light chain ratio make light chain amyloidosis highly unlikely. This patient is more likely to have non–immunoglobulin-related amyloidosis. Three percent of black men have a mutation in transthyretin, which causes late-onset familial amyloid cardiomyopathy. At 76 years of age, senile cardiac (systemic) amyloidosis is a definite possibility. There is a 1% possibility that this is light chain amyloidosis. The evaluation cannot move forward until the type of amyloid is identified. Mass spectrometry is the method most likely to provide this information (see reference 2).

3. Your patient with renal amyloidosis read that cerebral amyloid angiopathy is found in most patients with Alzheimer disease. The patient is concerned that dementia will soon follow. What is your next step?

A. Referral to a neurologist for neurocognitive studies
B. Magnetic resonance imaging to look for cerebral amyloid angiopathy
C. Aspirin therapy to prevent subcortical infarcts
D. Tell the patient not to worry

Answer: D The amyloid in Alzheimer disease is composed of amyloid-β protein, which is chemically unrelated to immunoglobulin light chains. There is no increased risk of Alzheimer disease in the patient.

4. A 58-year-old man is referred to you with endomyocardial biopsy–proven amyloidosis. The λ monoclonal protein in the serum is 0.6 mg/dL. The κ/λ free light chain ratio is 0.01. You perform a bone marrow biopsy that shows 7% plasma cells. The serum troponin level is 0.08 ng/mL. The N-terminal pro–brain natriuretic peptide value is 7800 pg/mL. What is your recommendation?

A. Referral to a transplant center for high-dose therapy
B. Referral for cardiac transplantation
C. Initiation of conventional chemotherapy
D. Initiation of digoxin to prevent atrial fibrillation
E. Referral for consultation in palliative care

Answer: C This patient's cardiac biomarkers suggest a degree of cardiac dysfunction that is associated with an excessive risk of death during a transplant procedure. This patient cannot be considered for cardiac transplantation until the underlying hematologic disorder is under control. Even patients with advanced cardiac failure can have improvement of cardiac function with appropriate systemic chemotherapy. Digoxin is contraindicated in cardiac amyloidosis.

5. Which is (are) the most important test(s) for assessing prognosis in a patient with light chain amyloidosis?

A. Troponin
B. Free light chains
C. N-terminal pro–brain natriuretic peptide
D. β_2-Microglobulin
E. Fluorescence in situ hybridization (genetic test)
F. A through C
G. B and D
H. A and C
I. A through D
J. A through E

Answer: F The cardiac biomarkers (troponin and N-terminal pro–brain natriuretic peptide) determine the prognosis in this disease and are the most important tests to perform. Testing for free light chains would complete the evaluation of prognosis as a measure of tumor mass. β_2-Microglobulin and albumin are not important markers for light chain amyloidosis, although they are important in multiple myeloma. The role of genetics is presently undefined in amyloidosis, and very few patients carry the adverse t(4;14) and −17p chromosomal abnormalities seen in myeloma.

TUMORS OF THE CENTRAL NERVOUS SYSTEM

LISA M. DEANGELIS

INTRACRANIAL TUMORS

General Approach to Brain Tumors

EPIDEMIOLOGY

About 23,000 new primary brain tumors and nervous system cancers are diagnosed annually in the United States, making central nervous system (CNS) tumors more than twice as common as Hodgkin disease and approximately one third as common as melanoma. There is no definitive evidence that any of them are linked to cell phone use. In contrast, intracranial metastases are five times more common than primary brain tumors. More than 120 types of primary brain tumors arise from the different cells that make up the CNS (Table 189-1). In addition to classifying tumors by their cell of origin, in clinical practice it is often useful to classify a tumor by its intracranial site as well, such as pineal region tumors or pituitary and suprasellar tumors.

TABLE 189-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF BRAIN TUMORS

TUMORS OF NEUROEPITHELIAL TISSUE
Astrocytic tumors
Astrocytoma

PATHOBIOLOGY

In contrast to tumors arising elsewhere in the body, there is little distinction between benign and malignant tumors when they occur in the brain. The growth of brain tumors is restricted to the CNS; they rarely if ever metastasize to other organs. In the CNS, a malignant tumor is characterized by aggressive pathologic features, including local tissue invasion, neovascularity, regional necrosis, and cytologic atypia. These features confer a growth advantage to malignant cells and lead to rapid expansion and, frequently, to early regrowth after treatment. Tumors lacking these aggressive histologic features are preferably classified as low grade rather than benign. Many low-grade tumors continue to grow within the CNS, causing progressive neurologic disability, and some may acquire a more malignant phenotype over time. The low-grade tumors that transform into high-grade neoplasms are primarily the intra-axial tumors that cannot be cured by resection because of their diffuse infiltration of brain. Almost all truly benign CNS tumors are extra-axial tumors, such as meningiomas and acoustic neuromas that can be cured with complete surgical resection.

CLINICAL MANIFESTATIONS

A patient with a brain tumor can present with one or both of two types of symptoms and signs. *Generalized symptoms,* which typically reflect the increased intracranial pressure (ICP) that often accompanies cerebral tumors include headache, lethargy, personality change, nausea, and vomiting. *Localizing symptoms,* which reflect the specific location of the tumor include hemiparesis, hemisensory deficits, aphasia, visual field impairment, and seizures (Table 189-2).

Most patients have symptoms that progress during a week to a few months. A sudden intensification of symptoms may precipitate the patient's initial visit to the physician; however, a careful history usually reveals symptoms that predated the acute deterioration and slowly worsened over time. Two exceptions are the new appearance of a seizure in a previously asymptomatic individual (Chapter 403) and sudden hemorrhage into a tumor.

Symptoms of brain tumors can be produced by tumor invading brain parenchyma, tumor and edema compressing brain tissue, cerebrospinal fluid (CSF) obstruction caused directly by the tumor or by a shift of brain tissue, and herniation. Invasion and compression typically produce focal symptoms, many of which can be relieved if the compression is reduced. Obstruction of CSF flow and herniation are frequently a consequence of elevated ICP and typically produce generalized symptoms of headache, nausea, and vomiting, but they can also cause false localizing signs, such as an abducens nerve palsy as a result of diffuse increased ICP.

Headache (Chapter 398) is a presenting symptom of approximately 35% of brain tumors. It is more common in younger than in older patients and more common in patients who have rapidly growing tumors than in those whose tumors have evolved slowly (Fig. 189-1). Mental and cognitive abnormalities may be a reflection of local tumor (e.g., aphasia, alexia, agnosia) or of general impairment (e.g., lethargy, confusion, word finding difficulty, apathy). Seizures affect approximately one-third of patients with brain tumors, and they are especially common as the presenting and only symptom of a low-grade tumor. The seizures, which are focal because they originate at the site of the tumor, may remain restricted (e.g., focal motor seizures), or they may generalize secondarily, producing loss of consciousness, sometimes so quickly that the focal signature is missed by the patient or even an observant witness.

DIAGNOSIS

Imaging

Magnetic resonance imaging (MRI) is far superior to computed tomography (CT) and should be used in all cases of suspected intracranial tumor. MRI should be performed both without and with intravenous administration of gadolinium. A well performed MRI scan identifies any intracranial tumor, and a normal finding on MRI effectively excludes a neoplasm. The MRI of some extra-axial tumors (e.g., acoustic neuromas, meningiomas) is so characteristic that histologic confirmation is not required. A non–contrast-enhancing infiltrative lesion that is visible primarily on T2-weighted or fluid-attenuated inversion recovery images is most consistent with a low-grade glioma (Fig. 189-2), whereas a contrast-enhancing lesion with an area of central necrosis and surrounding edema is most likely to be a glioblastoma or possibly a brain metastasis. Although these diagnoses must be confirmed histologically, the preoperative diagnostic possibilities affect the surgical approach to the lesion.

Perfusion MRI after rapid infusion of gadolinium can measure the relative cerebral blood volume and neovascularity associated with a tumor; high perfusion is associated with higher grade of malignancy. This technique can help estimate the tumor grade preoperatively and guide the planning of treatment.

Magnetic resonance spectroscopy noninvasively assesses tissue composition. High-grade primary brain tumors are associated with a decrease in *N*-acetylaspartate and an increase in choline. More malignant tumors are

The images are typical of this tumor, which is being detected with increasing frequency by magnetic resonance imaging in seizure patients. Many are invisible on computed tomography scans.

associated with a greater choline/*N*-acetylaspartate ratio and frequently contain areas with elevation of lactate and lipid.

Surgical resection is a major objective in the treatment of almost every kind of brain tumor, but resection must be balanced against possible damage to adjacent normal brain. The development of functional MRI (fMRI), which measures cerebral blood flow when areas of cortex are activated, has greatly enhanced the ability to localize critical neurologic functions and their relationship to the tumor preoperatively. When the fMRI is fused with the anatomic MRI, essential functions can be identified in relationship to the patient's tumor, and a safer and more complete resection may be planned.

On positron emission tomography (PET), high-grade tumors are usually hypermetabolic, whereas low-grade tumors are hypometabolic. New technologies using ^{11}C-methionine PET may differentiate low- from high-grade gliomas much more efficiently than deoxyglucose PET.

CT, without and with intravenous administration of contrast material, should be used only for patients who cannot undergo MRI. A CT scan, even with the administration of contrast material, may miss low-grade tumors and tumors in the posterior fossa.

Angiography no longer has a role in the diagnosis of intracranial tumors. However, angiographic embolization is occasionally useful preoperatively to reduce the vascularity of some meningiomas, thereby making a complete resection safer and more feasible.

Other Tests

Electroencephalography is rarely needed in the diagnosis or management of brain tumors. An electroencephalogram can occasionally be useful in a patient who has prolonged or unexplained stupor and in whom nonconvulsive status epilepticus is a consideration. Intraoperative monitoring is also used frequently to help guide resection of epileptogenic cortex adjacent to or within brain tumor tissue.

CSF analysis has little role in the diagnosis of most intracranial neoplasms. In primary CNS lymphoma (Chapter 185), the diagnosis may be established on CSF cytologic examination in about 15% of patients. The sensitivity of CSF cytology in the diagnosis of CNS lymphoma increases when it is combined with flow cytometry and is further enhanced by immunophenotypic and molecular genetic analyses of the CSF.[1] Rarely, a lumbar puncture is

required to exclude inflammatory conditions or other processes that may be confused with a primary brain tumor. Lumbar puncture must be avoided in patients with cerebellar tumors because the release of pressure through the spinal needle may result in herniation of the cerebellar tonsils through the foramen magnum.

Differential Diagnosis

Patients who present with symptoms of raised ICP or the new onset of central neurologic symptoms, such as hemiparesis or seizure, should be evaluated rapidly. Prompt neuroimaging discloses a mass, and the radiographic features narrow the differential diagnosis (Table 189-3). Extra-axial tumors, such as a meningioma or acoustic neuroma, can be confused with a dural metastasis. Low-grade intra-axial tumors, which are nonenhancing on MRI, have been confused with infections such as herpes encephalitis when they involve the temporal lobe. Contrast-enhancing intra-axial tumors can be confused with a stroke, brain abscess, or focal plaque of demyelination. Subacute infarction can show brisk contrast enhancement, usually in a gyral pattern, unlike brain tumors in which enhancement is primarily in the white matter; however, the two are occasionally indistinguishable radiographically. Brain abscesses typically have a thinner enhancing wall than a malignant tumor and have restricted diffusion. Despite careful evaluation, patients thought to have a malignant glioma occasionally are found at surgery to have a brain abscess. A single large plaque of demyelination can also be confused radiographically with a brain tumor, and sometimes the diagnosis can be established only by biopsy.

When MRI suggests a primary brain tumor, there is no need for an extensive systemic search for a possible source of metastasis. Brain metastases are more common than primary brain tumors, but most occur in patients with known cancer, typically with active systemic disease. If an obvious systemic cancer is not revealed by a thorough physical examination, chest radiograph, routine blood tests, and urinalysis, the patient should proceed to craniotomy. Even if a brain metastasis is found at surgery, resection of a single brain metastasis is the appropriate treatment, and the pathologic examination of the lesion guides the subsequent search for the primary tumor.

TREATMENT

The treatment for all brain tumors can be divided into two main categories: symptomatic and definitive (Table 189-4). Symptomatic treatment addresses the associated problems, such as cerebral edema, seizures, and thromboembolic disease, which can contribute substantially to clinical symptoms. Definitive treatment addresses the tumor itself.

Symptomatic Treatment

Symptomatic management includes the use of corticosteroids, anticonvulsants, and prophylaxis for deep venous thrombosis (Chapter 38). Corticosteroids decrease the vasogenic edema that surrounds primary and metastatic brain tumors. Blood vessels associated with tumor formation are leaky and do not share the normal morphologic and physiologic features that form the blood-brain barrier; corticosteroids effectively reconstitute the blood-brain barrier by decreasing the abnormal permeability of these neovessels. Clinical improvement may begin within minutes, and frequently patients are dramatically improved within 24 to 48 hours.

Dexamethasone is the most commonly used glucocorticoid because it has the least mineralocorticoid activity. The usual starting dose is 12 to 16 mg/day, but this can be adjusted to find the lowest possible dose that alleviates neurologic symptoms. After definitive treatment is instituted, many patients can be tapered off their corticosteroid completely. Chronic high-dose corticosteroid therapy is associated with substantial side effects (Chapter 35) and should be avoided if possible. Patients who will be taking glucocorticoids for 6 weeks or longer should receive prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*; Chapter 341).

Anticonvulsants are administered to any patient who has had a seizure, but prophylactic anticonvulsants should not be prescribed for patients who have never had a seizure, except in the immediate perioperative period.[A1] A taper should begin 2 to 3 weeks after craniotomy.

Venous thromboembolism, which occurs in about 25% of patients with brain tumors, can occur early in the illness or at any time during treatment. All patients undergoing neurosurgery should have pneumatic compression boots in the postoperative period to reduce the incidence of venous thromboembolism. Prophylactic anticoagulants have also been used successfully in the immediate postoperative period without increasing postoperative hemorrhage. Appropriately regulated anticoagulation (Chapter 38) is the optimal therapy for deep venous thrombosis and is not associated with an increased risk of intracerebral hemorrhage in patients with intracranial tumors. Inferior vena cava filters can be used for patients who have deep vein thrombi or pulmonary emboli and who cannot be fully anticoagulated.

Definitive Treatment

Surgery

Complete excision is the goal for a primary brain tumor. Surgical excision can often be accomplished for primary extra-axial tumors, such as meningiomas and acoustic neuromas, unless their intracranial location makes resection impossible. Tumors of the skull base are particularly difficult to remove, and partial resection for decompression is often performed to preserve neurologic function. The safe boundaries for resecting cortical lesions while preserving function can often be elucidated by preoperative fMRI and intraoperative cortical mapping. However, lesions involving critical structures, such as the brainstem or thalamus, cannot be excised safely.

Lesions that cannot be resected are still amenable to biopsy for diagnostic purposes. Stereotactic biopsy can reach lesions in almost any area of the brain with minimal morbidity. The risks of stereotactic biopsy include inadequate tissue sample to make a diagnosis; a tissue sample that does not accurately reflect the most malignant grade of the tumor; and a procedure-related complication, such as hemorrhage. Hemorrhage that causes neurologic impairment occurs in only 2% of stereotactic biopsies, typically in patients with glioblastoma.

Complete excision can cure an extra-axial primary brain tumor and is associated with prolonged survival and better neurologic outcome even in patients with primary intra-axial tumors. Gross total excision, as measured by postoperative neuroimaging, is associated with prolonged survival in patients with malignant gliomas and probably in those with low-grade gliomas as well. However, most low-grade gliomas are not amenable to gross total excision, and usually only partial excision is feasible. Macroscopic tumor can frequently be removed completely in patients with high-grade gliomas, but there is always remaining microscopic disease that infiltrates surrounding brain.

Some tumors, such as brainstem gliomas, are in such critical locations that biopsy is not attempted. Their characteristic radiographic appearance permits diagnosis and initiation of medical treatment.

Radiation Therapy

A course of external beam radiation therapy is delivered in small daily fractions to a total cumulative dose usually between 45 and 60 Gy. Dividing the treatment into small daily fractions permits sublethal repair in normal tissues and markedly reduces neurologic toxicity associated with cerebral irradiation. External beam irradiation, which is the most effective nonsurgical treatment of brain tumors, doubles median survival time of patients with malignant primary brain tumors or metastatic lesions. It can also be useful for recurrent meningiomas and acoustic neuromas. However, it only rarely cures any of these lesions, and most patients develop recurrent disease despite maximal radiation therapy.

Stereotactic radiosurgery has been developed to deliver high fractions of focused radiation therapy that spare normal surrounding tissue. The technique is limited to tumors that are 3 cm in diameter or smaller and is less useful for malignant gliomas because of their infiltrative nature.

The neurologic complications of radiation therapy, which are usually observed in patients months to years after completion of treatment, include radionecrosis, dementia, and leukoencephalopathy. The incidence is reported as less than 5%, and most patients die of their brain tumor before the delayed consequences of treatment can be observed. However, in long-term survivors (e.g., patients with low-grade glioma or children with medulloblastoma), the late consequences of radiation therapy are important. Dementia accompanying radiation-induced leukoencephalopathy can progress and result in severe neurologic impairment. Radionecrosis can mimic recurrent tumor with a large contrast-enhancing lesion on MRI. Corticosteroids can reduce the edema and sometimes are sufficient to treat small areas of radionecrosis. However, if the lesion is sufficiently large, resection may be required to decompress the mass and reduce the steroid requirements.

Chemotherapy

Chemotherapy for brain tumors has usually been disappointing because of the intrinsic resistance of these tumors to most conventional agents. Carboplatin and cisplatin are active agents against medulloblastoma, even when the tumor is disseminated in the CSF. Temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks) is active in all gliomas, and high-dose methotrexate (3 to 8 g/m^2 for 3 to 12 months) is effective for primary CNS lymphoma. For patients with glioblastoma, polymers impregnated with carmustine (BCNU) and placed in a resection cavity offer modest benefit compared with no chemotherapy, but they are associated with local tissue injury and edema.

Specific Types of Brain Tumors

PRIMARY EXTRA-AXIAL TUMORS

The most common primary extra-axial tumors are meningiomas, pituitary adenomas, and acoustic neuromas. These tumors arise within the intracranial cavity but are not tumors of brain tissue. Almost all are benign; because the brain is rarely invaded, complete excision often enables cure with full recovery of neurologic function. These tumors produce neurologic symptoms and signs by compressing the underlying brain; however, edema of the underlying brain is infrequent, so glucocorticoids have a limited role.

Meningiomas

EPIDEMIOLOGY

Meningiomas are usually benign. Between 5 and 10% of meningiomas are atypical or malignant variants with a more aggressive course.[2] Meningiomas are more common in women, may be multiple in about 10% of patients with sporadic meningioma, and are occasionally part of a familial syndrome. They occur with increased frequency in patients with neurofibromatosis type 2. *NF2* inactivation is seen in approximately 50% of sporadic tumors, and mutations in *AKT1*, *SMO*, and *TRAF7* have also been identified.

DIAGNOSIS

Meningiomas grow slowly and produce symptoms that are insidious in onset and typically slowly progressive. Tumors can reach a considerable size, but they grow so slowly that the brain accommodates to the progressive compression. Meningiomas typically occur in specific locations: over the convexity, along the falx and parasagittal area, in the olfactory groove, at the base of the skull near the sphenoid bone, in the cavernous sinus (Fig. 189-3), in the cerebellopontine angle, and in the foramen magnum. Cortical and parasagittal tumors typically are manifested with seizures or progressive hemiparesis. Tumors in the anterior cranial fossa can cause slowly progressive changes in personality and cognition. Meningiomas at the base of the skull are manifested with cranial neuropathies and gait difficulties when there is brainstem compression. Frequently, tumors are completely asymptomatic and are identified on neuroimaging done for another purpose, such as head trauma.

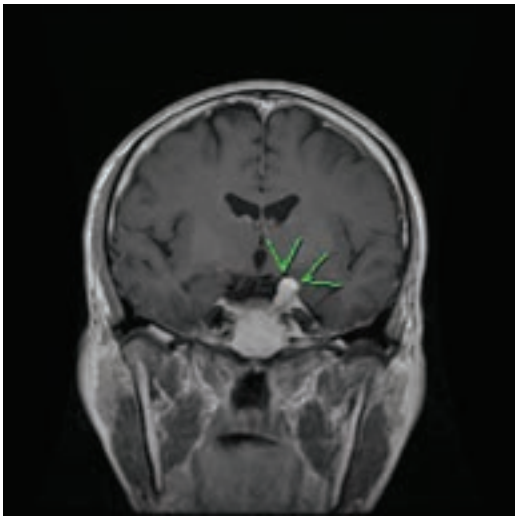

FIGURE 189-3. Skull base meningioma. A post-gadolinium coronal magnetic resonance image demonstrating a small left meningioma arising from the clinoid.

On MRI, meningiomas have a characteristic appearance consisting of a diffusely enhancing, dural-based lesion that is associated with a thin enhancing dural tail extending from the tumor. The radiographic features are often so characteristic that surgery is performed for therapeutic purposes only. The radiographic differential diagnosis includes the less common hemangiopericytoma and dural metastasis. Most meningiomas are not accompanied by significant edema, but marked edema is seen with high-grade malignant lesions or the secretory variant.

If small meningiomas are discovered in the absence of clinical symptoms or the symptoms are minor, lesions may be monitored with serial images because growth can be so slow.

TREATMENT

If treatment is indicated, complete resection is often curative, but even completely resected benign tumors may recur (as many as 20% in some series), so radiologic follow-up is essential.[3] Tumors at the base of the skull often cannot be resected completely and tend to recur despite successive attempts at surgical resection. Stereotactic radiosurgery may be an alternative to surgery if the lesion is small or there is progressive or residual tumor. External beam radiation therapy may slow progression of recurrent lesions and is essential for the treatment of malignant meningiomas. No effective chemotherapy has yet been identified.[4]

Acoustic Neuromas

Acoustic neuromas (Chapter 428), better called vestibular schwannomas, are benign tumors that arise from the eighth cranial nerve. Acoustic neuromas are twice as common in women as in men; the peak age is between 40 and 60 years. Sporadic vestibular schwannomas are unilateral; bilateral acoustic neuromas are pathognomonic of neurofibromatosis type 2 (Chapter 417).

Acoustic neuromas usually arise from the vestibular portion of the nerve and typically are manifested with unilateral hearing loss, sometimes preceded or accompanied by tinnitus and a sensation of dizziness or unsteadiness but not true vertigo. The slow, progressive enlargement of the tumor produces ipsilateral facial numbness or weakness by compressing the fifth or seventh cranial nerve, respectively. Tumors originate within the internal auditory meatus but grow out of the acoustic canal and into the cerebellopontine angle, where they can compress the brainstem and cause ataxia and ipsilateral cerebellar signs. Cranial MRI with gadolinium delineates even small acoustic neuromas with ease (Fig. 189-4).

Treatment is often surgical; stereotactic radiosurgery may be an alternative for lesions smaller than 3 cm. It is preferable to treat the tumors when they are small to preserve facial nerve function and hearing.

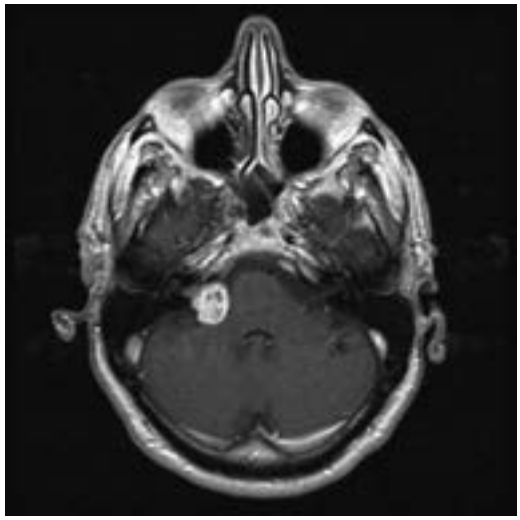

FIGURE 189-4. Acoustic neuroma. A post-gadolinium magnetic resonance image demonstrating a large right acoustic neuroma. The origin can be seen in the acoustic canal, but the tumor has grown into the cerebellopontine angle, where it is compressing the brainstem.

Pituitary Adenomas

Pituitary adenomas (Chapter 224) can be classified according to their size as microadenomas (<1 cm in diameter) or macroadenomas; by the presence or absence of endocrine function; and by the endocrinologic or neurologic syndromes caused by tumor compression. Microadenomas typically manifest with endocrine symptoms as described in Chapter 224. As pituitary tumors enlarge and become macroadenomas, they compress the surrounding neural structures, including the optic chiasm and optic nerves, typically causing bitemporal hemianopia and occasionally causing unilateral visual loss. Macroadenomas are frequently nonsecreting but destroy pituitary tissue, causing panhypopituitarism. Rarely, pituitary tumors manifest with the abrupt onset of headache, ophthalmoplegia, unilateral blindness, and even a depressed level of alertness or coma—a syndrome of *pituitary apoplexy* caused by hemorrhage or infarction.

Cranial MRI, particularly with coronal images and gadolinium administration, can completely outline the pituitary tumor and surrounding neural structures. All microadenomas and some macroadenomas can be treated with transsphenoidal pituitary surgery, which is associated with minimal morbidity. On occasion, residual or recurrent tumor necessitates radiation therapy. Some hormone-secreting tumors, particularly prolactinomas or growth hormone–secreting tumors, can be treated medically with cabergoline or somatostatin analogues such as octreotide, respectively (Chapter 224). These medications not only correct the hormonal excess but also shrink the tumor; they must be taken for life.

Other tumors in the pituitary and suprasellar region include craniopharyngiomas, suprasellar epidermoid cysts, Rathke cleft cysts, germinomas (discussed later), and lymphocytic hypophysitis, which is a benign inflammatory condition that usually is manifested with diabetes insipidus (Chapter 225). MRI frequently differentiates these conditions, which are usually suprasellar and erode into the pituitary fossa only secondarily. Some of these lesions also have characteristic radiographic features. These lesions are benign. Except for hypophysitis, which resolves completely with corticosteroid treatment (e.g., methylprednisolone 120 mg daily for 2 weeks and then tapered for 1 additional week), complete surgical excision is the curative therapy.

Other Extra-Axial Tumors

Pineal region tumors all have a characteristic clinical presentation that includes Parinaud syndrome, which consists of paresis of upward gaze, poor pupillary reaction to light with brisk reaction on accommodation, impairment of convergence, and convergence-retraction nystagmus. Some of these lesions may also cause hydrocephalus and symptoms of increased ICP. Pineal region tumors include pineal parenchymal tumors, such as pineocytomas and the more aggressive pineoblastomas, and germ cell tumors, including germinomas and nongerminomatous germ cell tumors. Germinomas can be completely cured with focal radiation therapy, whereas nongerminomatous germ cell tumors are more aggressive and frequently relapse despite chemotherapy plus cranial irradiation.

Chordomas are rare tumors of residual notochordal tissue. They usually occur at the base of the skull, are locally invasive, and are characterized by multiple recurrences despite surgery and radiation therapy. Chordomas are characterized by overexpression of the transcription factor brachyury. They also have activation of several receptor tyrosine kinases with overactivation of the downstream pathways, specifically the PI3K/AKT mTOR pathway. Inhibitors of the epidermal growth factor receptor and platelet-derived growth factor β have each been reported to produce responses and clinical benefit in patients with recurrent disease.[5] PI3K/AKT/mTOR inhibitors are under investigation.

Lipomas are benign tumors that can occur in midline structures, particularly near the corpus callosum. They can be cured by complete removal.

Arachnoid cysts are not tumors but can manifest with headache, seizures, or focal neurologic symptoms if they become large enough to compress underlying brain tissue. Many are completely asymptomatic and are found incidentally on neuroimaging. Only symptomatic cysts require removal.

PRIMARY INTRA-AXIAL TUMORS

Most primary intra-axial brain tumors are gliomas, including the astrocytomas, oligodendrogliomas, and ependymomas. Less common are medulloblastomas, other rare neuroectodermal tumors, and primary CNS lymphomas. All of these tumors have a tendency to invade brain tissue, and none can be completely excised surgically.

Glioma

DEFINITION

Astrocytomas, which are the most common glioma, are classified into one of four World Health Organization categories: grade I, the pilocytic astrocytoma; grade II, the fibrillary astrocytoma; grade III, the anaplastic astrocytoma; and grade IV, the glioblastoma. Pilocytic astrocytomas (grade I) are extremely low-grade focal tumors that are more common in children and may be associated with neurofibromatosis type 1; they are often cured by complete surgical excision. Fibrillary astrocytomas, anaplastic astrocytomas, and glioblastomas are diffuse tumors that infiltrate widely into brain; even grade II tumors progress over time, and most acquire the histologic features and growth patterns of grade III and IV tumors.

EPIDEMIOLOGY

Gliomas occur at any age, but the peak age is 20 to 30 years for an astrocytoma, 40 years for anaplastic astrocytoma, and 55 to 60 years for glioblastoma. Age is the single most important prognostic factor; younger patients live substantially longer than older patients. Histology is also critical; patients with glioblastoma do significantly worse than patients with lower-grade lesions. Performance status, duration of symptoms, and whether a complete resection has been achieved are also strong predictors of improved outcome and prolonged survival. For all grades of glioma, men are more frequently affected than women, and whites are significantly more frequently affected than blacks. Gliomas are typically single lesions, but multifocal disease is seen in approximately 5% of patients with high-grade tumors. A variant of gliomas, called gliomatosis cerebri, causes widespread infiltration of the entire brain; most patients have relatively low-grade pathologic findings on biopsy, but focal regions of high-grade transformation can exist.

PATHOBIOLOGY

At least 95% of gliomas are sporadic, and only 5% occur in patients with a family history of brain tumor. Furthermore, patients with a familial history of glioma usually do not fall into a well-recognized hereditary syndrome. However, neurofibromatosis 1 (von Recklinghausen disease; Chapter 417) is associated with an increased incidence of gliomas, particularly in the optic pathway, hypothalamus, and brainstem. Gliomas also occur with increased frequency in Turcot and Lynch syndrome, in which colorectal neoplasms are seen in association with a variety of CNS tumors. Somatic mutations of the isocitrate dehydrogenase 1 and 2 genes (*IDH1* and *IDH2*) have been identified in most low-grade gliomas and secondary glioblastomas; these patients have a better outcome than do those with wild-type *IDH* genes.[6] Molecular profiling has identified four subclasses of glioblastoma: (1) classical, defined by overactivation of the epidermal growth factor receptor pathway; (2) proneural, defined by *IDH* mutation and alterations of *PDGFRA* and expression of neural markers; (3) mesenchymal, defined by *NF1* loss and expression of mesenchymal markers; and (4) neural, characterized by expression of neuronal markers. These categories

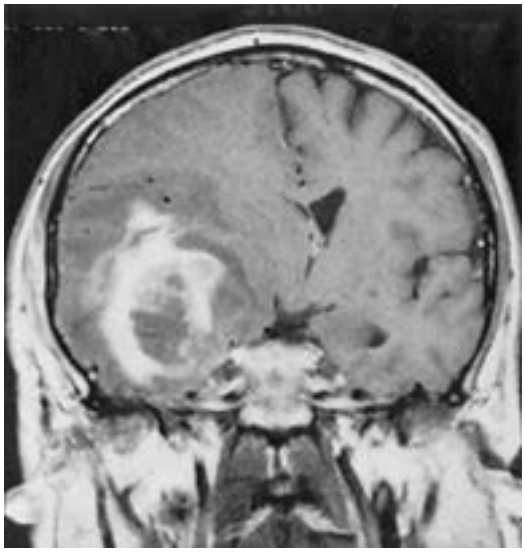

FIGURE 189-5. Temporal lobe glioblastoma. This T1-weighted gadolinium-enhanced magnetic resonance image shows a typical ring configuration of contrast material with central necrosis and marked mass effect.

define distinctly different pathways to histologically identical glioblastomas. The prognostic and therapeutic implications of these distinctions are under investigation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with gliomas often present with seizures, headache, and lateralizing signs such as hemiparesis, aphasia, or a visual field deficit.[7] On MRI, low-grade gliomas typically appear as diffuse, nonenhancing lesions with a propensity to occur in the frontal lobe and insular cortex. High-grade gliomas, which typically enhance with contrast material, occur in the cortical white matter and are accompanied by significant surrounding edema. Glioblastomas frequently have regions of central necrosis (Fig. 189-5), and hemorrhage can occur in 5 to 8% of patients.

TREATMENT

Rx

For all gliomas, treatment frequently involves surgery, radiation therapy, and chemotherapy. The surgical goal of complete removal of all visible disease is often impossible. A prospective, randomized trial provided evidence for the use of intraoperative MRI guidance in optimizing the extent of resection of gliomas.[A2] The adequacy of resection is best assessed on a postoperative MRI study, without and with gadolinium, performed within 72 to 96 hours after surgery. Glioma resections with intraoperative stimulation mapping are associated with fewer severe neurologic deficits and more extensive resection. Surgical removal usually improves neurologic function and reduces dependency on corticosteroids.

Anaplastic Astrocytoma and Glioblastoma

All anaplastic astrocytomas and glioblastomas should be treated with postoperative radiation therapy to a dose of approximately 60 Gy. In a randomized trial of patients with glioblastoma, the alkylating agent temozolomide (75 mg/m^2 daily), administered concurrently with radiation therapy and followed by adjuvant temozolomide (150 to 200 mg/m^2 for 5 consecutive days every 4 weeks for six cycles), significantly improved survival (median, 14.6 months) compared with radiation therapy alone (median, 12.1 months; $P < .001$), and the 2-year survival rate more than doubled to 26.5%.[A3] Patients whose tumors contained a methylated promoter of the O^6-methylguanine-DNA methyltransferase (*MGMT*) DNA repair gene benefited most from the addition of temozolomide. On the basis of these data, combined treatment is the current standard of care for patients with glioblastoma. Chemotherapy is generally well tolerated and associated with minimal toxicity. Elderly patients often do poorly, but a randomized trial showed that radiation therapy (compared with supportive care only) results in a modest improvement in survival, without reducing quality of life or cognition, in elderly patients with glioblastoma.[A4] In the Nordic randomized phase III trial, standard radiation therapy was associated with poor outcomes in elderly patients with glioblastoma, especially those older than 70 years. Both temozolomide and hypofractionated radiation therapy should be considered as standard treatment options in elderly individuals with glioblastoma.[A5] The addition of bevacizumab (an anti-vascular endothelial growth factor molecule, initially at 10 mg/kg intravanously every 2 weeks) may further improve progression-free survival.[A6][A7] Recurrences can be treated with re-resection, additional chemotherapy or, occasionally, stereotactic radiosurgery or a combination of these. Despite aggressive treatment, disease recurs in almost all patients, and the median survival time is 15 months for glioblastoma. Patients with anaplastic gliomas (including anaplastic oligodendrogliomas) had an identical median survival of about 7 years whether the initial treatment was radiation therapy alone or chemotherapy alone.[A8] However, some young patients with anaplastic astrocytoma can survive much longer before the tumor recurs.

Optic and Brainstem Glioma

Optic gliomas, which can involve the optic nerve or optic chiasm, are usually associated with neurofibromatosis type 1. These gliomas are typically pilocytic tumors that can have an indolent course including rare spontaneous regression. They are often not amenable to surgical resection, and they can have a stuttering clinical course, with periods of visual loss punctuated by prolonged periods of visual stability. When necessary, radiation therapy or even chemotherapy may be useful, but often no treatment is required. Brainstem gliomas usually involve the pons, less often the medulla or midbrain. Brainstem gliomas are most commonly seen in children in the first decade of life but can be found even in elderly people; they can have a low-grade or high-grade histology, but outcome is primarily determined by the location of the tumor. In general, most brainstem gliomas have a dismal outcome with survival of 1 year or less, but relatively benign variants occasionally occur.

Low-Grade Astrocytoma

Low-grade astrocytomas have a variable course. In patients who present with isolated seizures that can be controlled easily with antiepileptics, treatment with radiation therapy or chemotherapy immediately after surgery may prolong progression-free but not overall survival, and such patients can be monitored until there is clinical or radiographic evidence of tumor progression. However, resection should be performed at diagnosis, if feasible.[8] Patients with progressive neurologic symptoms or cognitive impairment require immediate treatment after diagnosis, and focal radiation therapy to a total of about 54 Gy is the optimal choice. For low-grade gliomas, progression-free and overall survival appear to be better when chemotherapy is added to radiation therapy. An astrocytoma can progress as a low-grade tumor or transform to a higher-grade malignant neoplasm, a change that typically is associated with the appearance of contrast enhancement on MRI. Resection or a biopsy may be necessary in these patients, followed by radiation therapy if they have not received it previously; chemotherapy with temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks for anywhere from 6 to 24 cycles) is also used. Patients with an astrocytoma have a median survival of about 5 years, but the range is wide.

Oligodendroglioma

Oligodendrogliomas occur as low-grade tumors and, less commonly, as anaplastic lesions. Treatment of these tumors differs from that of their astrocytic counterparts because oligodendrogliomas are uniquely chemosensitive due to their characteristic loss of chromosomes 1p and 19q. As with the low-grade astrocytomas, treatment should be withheld in patients with low-grade oligodendrogliomas who have no symptoms other than well-controlled seizures. Patients with progressive neurologic symptoms or radiographic progression require treatment, and initial therapy is often chemotherapy, usually with single-agent temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks for 6 to 24 cycles) or the combination of procarbazine, lomustine, and vincristine (PCV). Radiation therapy is withheld until chemotherapy fails.

By comparison, all anaplastic oligodendrogliomas require immediate treatment. The standard approach includes focal radiation therapy. Adjuvant chemotherapy significantly prolongs disease-free and overall survival in patients with codeleted tumors but not in those with intact 1p and 19q chromosomes.[A9] However, there is a growing movement toward treatment of high-grade tumors with chemotherapy alone initially[9]; this can be considered only in neurologically healthy patients. Tumor progression should be treated with re-resection, radiation therapy if it has not been previously administered, and additional chemotherapy. Patients with low-grade oligodendrogliomas have a median survival time in excess of 15 years. Median survival is about 14 years

for patients with a 1p/19q codeleted anaplastic oligodendroglioma compared with the median survival of about 3 years for patients with an intact 1p/19q.

Medulloblastoma

Medulloblastomas usually occur in the vermis of the cerebellum and principally affect children and young adults. Boys outnumber girls by about 2 : 1, and peak onset is 7 years of age; medulloblastoma in adulthood is rare and usually affects the cerebellar hemisphere.

Transcription profiles have identified four distinct subclasses that include: (1) the Wnt subtype driven by a stabilizing mutation in *CTNNB1* (β-catenin), which has an excellent prognosis; (2) the SHH subtype with mutations in *PTCH1*, *SMO*, *GLI2*, or *SUFU*, which has an intermediate prognosis; (3) group 3, which has an increased expression of *MYC* and has the worst prognosis; and (4) group 4, which is characterized by isochromosome 17q and marked male predominance. Medulloblastomas have a characteristic clinical presentation, with ataxia (due to cerebellar and brainstem involvement) and headache, nausea, and vomiting (due to increased ICP from obstructive hydrocephalus). Aggressive surgery with complete excision is strongly associated with improved outcome. Surgery is always followed by neuraxis radiation therapy. Chemotherapy with vincristine, etoposide, carboplatin, and cyclophosphamide significantly improves 5-year event-free survival from 60 to 74% but has not significantly prolonged overall survival, which is about 70 to 80% at 5 years when all patients are considered together. However, clinical high-risk patients do worse and standard-risk patients do better. It is unknown if molecular subclasses should supersede clinical stratification or dictate treatment selection. This vigorous therapy often results in delayed complications in survivors, including intellectual deficits, growth impairment, and endocrinologic dysfunction.[10] Late relapses as well as secondary neoplasms compromise long-term outcome.

Ganglioglioma

Gangliogliomas, as the name implies, possess both a glial component and a neoplastic neural component (ganglion cell). Some low-grade gangliogliomas are indolent and do not require additional treatment after surgical extirpation. Patients with anaplastic tumors may fare better than patients with malignant gliomas, but recurrence is the rule despite surgery and radiation therapy.

Primary Central Nervous System Lymphoma

Primary CNS lymphomas are associated with immunodeficiency states, particularly acquired immunodeficiency syndrome and organ transplantation, and are seen with increased frequency among the apparently immunocompetent population, in whom the median age at diagnosis is about 60 years. These tumors are usually diffuse large B-cell non-Hodgkin's lymphomas identical to systemic diffuse large B-cell lymphoma (Chapter 185). The tumor can involve the CSF, eye, and brain, where it is multifocal in about 40% of patients at presentation (Fig. 189-6). In contrast to all other brain tumors, surgical resection may not be associated with improved survival and can cause significant neurologic morbidity; therefore, biopsy is usually the preferred surgical approach. Chemotherapy is the primary treatment, and high-dose methotrexate (3 to 8 g/m^2 on alternate weeks for 3 to 12 months) is the most important chemotherapeutic agent. In most patients, radiation therapy is avoided because the necessary whole brain irradiation causes significant cognitive impairment when it is combined with chemotherapy and does not prolong survival.[A10] Corticosteroids (e.g., dexamethasone 8 to 16 mg/day), which are frequently used as part of the chemotherapeutic regimen, not only help manage the associated cerebral edema but also can cause tumor regression. With the use of multiagent chemotherapy, with or without cranial irradiation, median survival times is 3 to 5 years.

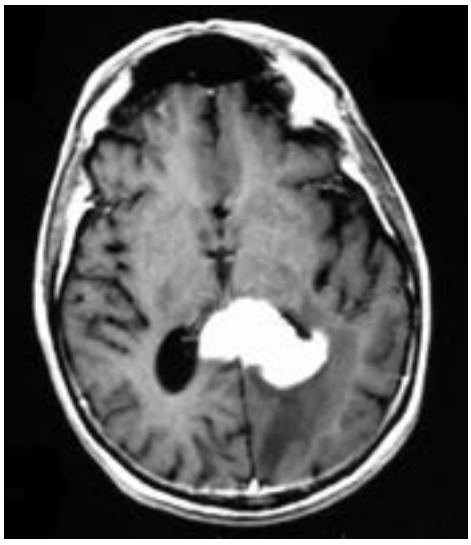

FIGURE 189-6. Primary CNS lymphoma. A post-gadolinium magnetic resonance image demonstrating a diffusely enhancing splenial lesion. The periventricular location and absence of central necrosis are characteristic of primary CNS lymphoma.

Other Intra-Axial Tumors

Rare, intra-axial cerebral tumors include the *ependymoma*, which is optimally treated with surgical excision followed by radiation therapy. *Choroid plexus papillomas* and *carcinomas* may be manifested with hydrocephalus or lateralizing signs. Resection may be sufficient for the benign papilloma, but carcinomas rapidly recur even when postoperative radiation therapy is also used. *Colloid cysts* of the third ventricle are benign tumors that can cause obstructive hydrocephalus; they may be treated with a third ventriculostomy or with resection by use of an intraventricular endoscope. *Hemangioblastomas* occur primarily in the cerebellum but can also occur in the spinal cord and the hemispheres. About 15% of patients with a hemangioblastoma have the autosomal dominant disorder von Hippel–Lindau disease (Chapter 417), which is characterized by hemangioblastomas in the CNS and retina, renal cell carcinoma, pheochromocytoma, endolymphatic sac tumors, and cysts in a variety of visceral organs. Hemangioblastomas are treated by surgical excision and require radiation therapy only for recurrence. Complete removal usually results in cure.

METASTATIC TUMOR

Brain Metastasis

DEFINITION AND EPIDEMIOLOGY

Every systemic cancer is capable of metastasizing to the brain. Melanoma (Chapter 203) has the greatest propensity to spread to the CNS, but the most common causes of CNS metastases are cancers of the breast (Chapter 198) and lung (Chapter 191), followed by cancers of the colon (Chapter 193) and kidney (Chapter 197). CNS metastases are being seen with greater frequency as patients with systemic cancers have prolonged survival with better treatments. In most patients with brain metastases, CNS disease develops late in the course of their illness, but a brain metastasis may be the initial presentation of a systemic cancer. In most of these patients, lung cancer is the primary site; in some, however, a primary site is never identified (Chapter 204).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with brain metastases present with progressive neurologic symptoms and signs that typically include headache, seizures, and lateralizing signs. Metastases are best diagnosed by cranial MRI with gadolinium (Fig. 189-7). All lesions can be clearly seen by MRI, which is better than CT for visualizing the posterior fossa. Metastases, which are usually well-circumscribed lesions at the gray matter–white matter junction, are often associated with extensive edema. Hemorrhage into a metastasis occurs most frequently with metastases from melanoma, renal cancer, or thyroid cancer; however, because brain metastases from lung cancer are so common, they are the type most commonly associated with hemorrhage. Sometimes, hemorrhage into a brain metastasis is best visualized by noncontrast head CT.

TREATMENT

Rx

Because brain metastases do not widely infiltrate into brain tissue and tend to have a pseudocapsule around them, they can be completely excised surgically. In randomized controlled studies, complete removal of a single brain metastasis substantially prolonged life and maintained neurologic function for a longer period. Postoperative whole brain radiation therapy significantly improves control of CNS disease after resection of a single brain metastasis, but it does not prolong survival because patients die of progressive systemic tumor. Consequently, the use of postoperative whole brain radiation therapy is frequently decided on an individual basis. If multiple lesions can be completely resected, these patients do as well as those with a single lesion that has been removed.

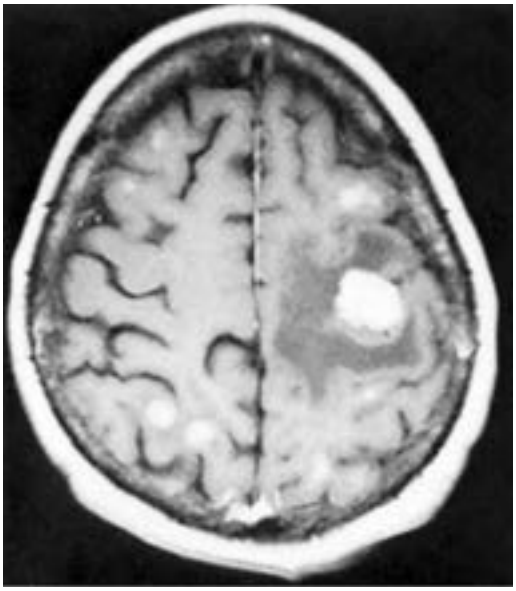

FIGURE 189-7. Brain metastasis. Multiple metastases from breast carcinoma are seen on this T1-weighted gadolinium-enhanced magnetic resonance image. The multiple smaller tumors were not visible on computed tomography, even after a contrast agent was given.

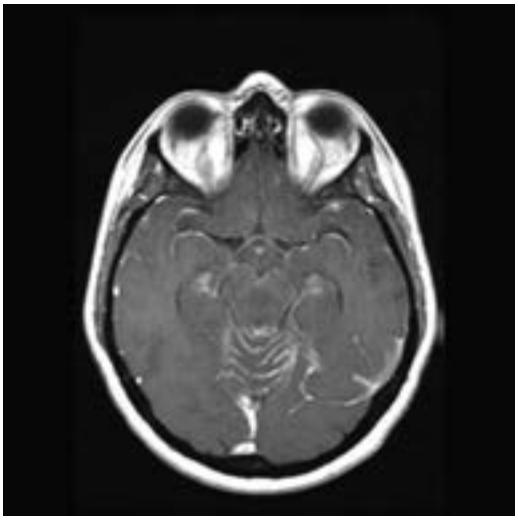

FIGURE 189-8. Leptomeningeal metastases. A post-gadolinium cranial magnetic resonance image demonstrating enhancement of all sulci of the cerebellar vermis representing tumor cells in the subarachnoid space of this patient with breast cancer.

Most patients with multiple brain metastases are best treated with a course of whole brain radiation therapy, most commonly 3 Gy in 10 fractions for a total of 30 Gy.[11] Some patients with single brain metastasis are also treated with whole brain irradiation if they are in poor general condition, have uncontrolled systemic disease, or are not good candidates for surgical treatment.

Stereotactic radiosurgery, with either a gamma knife that delivers gamma radiation from multiple cobalt sources or a linear accelerator that delivers x-rays to a highly focused area involving the tumor, has been effective for the treatment of one or a few brain metastases.[12] Most patients tolerate radiosurgery without difficulty, but the procedure is occasionally complicated by seizures or acute swelling that causes more neurologic dysfunction. Approximately 20 to 30% of patients develop radionecrosis, which may be indistinguishable clinically and on MRI from recurrent tumor. One advantage of stereotactic radiosurgery is that most of the normal brain is not exposed to the radiation.

Chemotherapy is used to treat brain metastases from only a few chemosensitive primary cancers, such as choriocarcinoma, small cell lung cancer, and, to a lesser extent, breast cancer. Because few patients have a significant response to chemotherapy, it is usually used as a last resort, although it has increasingly been employed in asymptomatic patients in whom brain metastases are identified at diagnosis on a screening MRI examination and who require chemotherapy for their systemic disease. The planned chemotherapy is often administered and the brain metastases will frequently respond in a fashion comparable to other systemic sites of disease. The choice of agents is based on the primary cancer type and the patient's prior drug exposures. Some targeted therapies have also been effective against brain metastases, such as in *BRAF* mutant melanoma, in which responses are seen after vemfurafenib.[13]

Leptomeningeal Metastasis

The brain is the most common intracranial site of metastases, but systemic cancer can spread to the dura and the leptomeninges as well. Dural metastases most commonly arise from breast (Chapter 198) or prostate (Chapter 201) cancer, frequently from a metastasis in the overlying calvaria. Metastasis to the leptomeninges often is manifested as multifocal neurologic symptoms and signs. These metastases involve the cranial nerves to cause diplopia or bulbar palsy (Fig. 189-8); the cervical and lumbar roots to cause limb pain or weakness; and the intracranial space to cause headache, nausea, vomiting, and elevated ICP. The diagnosis is established by the presence of tumor cells in the CSF, by cytologic examination or novel techniques to identify isolated cancer cells,[14] or by neuroimaging that definitively outlines tumor in the subarachnoid space (Fig. 189-9). Treatment frequently involves radiation therapy to symptomatic sites; intrathecal chemotherapy, usually through an intraventricular cannula (Ommaya reservoir); or systemic chemotherapy with agents or doses that penetrate into the CSF.

FIGURE 189-9. Leptomeningeal metastases. Gadolinium-enhanced magnetic resonance imaging of the lumbosacral spine in a patient with leptomeningeal metastases from melanoma. Multiple enhancing nodules are seen on the cauda equina, and the conus medullaris and lower spinal cord are encased by tumor.

SPINAL TUMORS

Tumors involving the spine can be classified according to the anatomic area they involve: extradural, intradural extramedullary, and intramedullary tumors (Table 189-5). Extradural tumors typically arise from the bone elements of the spine and cause neurologic symptoms and signs by spinal cord compression. Intradural but extramedullary tumors arise from the pachymeninges or nerve roots (meningiomas or schwannomas) and can cause either radicular symptoms or spinal cord compression. Intramedullary spinal cord tumors are rare; they arise from the spinal cord parenchyma and have a biology similar to that of brain tumors.

Extradural Tumors

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Most extradural tumors originate from a metastasis to the bone elements of the spine, typically the vertebral body and occasionally the vertebral lamina or spinous process. Less common are primary tumors of the spine, including chordoma, osteogenic sarcoma, plasmacytoma, and chondrosarcoma. Expansile growth of the bone tumor impinges on the spinal canal and, if untreated, compresses the spinal cord or the nerve roots as they exit the intervertebral foramina. Whereas most of these lesions arise from bone

metastases, extradural tumors can also arise from paravertebral metastases that can grow through the intervertebral foramina and into the epidural space without affecting surrounding bone structures; very rarely, a direct metastasis to the epidural space is also seen. The most common primary cancers that cause extradural metastases are prostate cancer (Chapter 201), breast cancer (Chapter 198), and lung cancer (Chapter 191) as well as the lymphomas (Chapter 185). Hematologic malignant neoplasms may also be associated with paravertebral disease that grows through the intervertebral foramina.

Whether the mass is a primary bone tumor or a metastasis from a distant source, 98% of patients present with pain that is usually localized to the site of the tumor. Because there are more thoracic than cervical or lumbar vertebrae, the tumor and pain are likely to be in the middle or high back, a less common site for benign pain (Chapter 400). Motor impairment and sensory symptoms are present in about 50% of patients, whereas sphincter disturbances are found in only about 25% of patients. Back pain often precedes the development of any other neurologic symptom or sign, frequently by weeks and occasionally by months.

DIAGNOSIS

Severe back pain in a patient with cancer should be evaluated by MRI which does not require intravenous administration of contrast material. Plain films of the spine, bone scans, or even CT scans may show bone disease, but epidural tumor can be seen only on MRI (Fig. 189-10). Furthermore, MRI is the only technique that can reveal paravertebral or direct epidural metastasis. Patients who cannot have an MRI study should be imaged by CT with sagittal reconstruction images.

Differential Diagnosis

The differential diagnosis of extradural tumors includes epidural abscess (Chapter 413), acute or subacute epidural hematomas (Chapter 400), herniated intervertebral discs (Chapter 400), spondylosis (Chapter 400), epidural lipomatosis, and, rarely, extramedullary hematopoiesis. On occasion, a percutaneous needle biopsy or decompressive laminectomy is required to make a definitive diagnosis.

TREATMENT

Rx

Epidural metastases require immediate treatment because patients can develop acute and unpredictable neurologic deterioration resulting in paraplegia. Patients should be started on high-dose corticosteroids (usually >20 mg IV dexamethasone), which rapidly relieve pain and may contribute to neurologic recovery. Surgery followed by postoperative radiation therapy is superior to radiation therapy alone in preserving the ability to walk and may prolong survival in a wide population of patients with metastatic spinal cord compression, but its advantage may be lost in patients 65 years of age and older.[A11] It is much easier to preserve neurologic function than to reverse impairment, so clinically silent areas of extradural tumor that are detected on MRI should be treated before neurologic compromise develops. Patients with epidural metastasis can have a good neurologic outcome if they are treated before the onset of severe neurologic compromise, but their overall survival is usually short because of the presence of widespread metastatic disease. Patients whose primary tumor arises in the spine, such as an osteogenic sarcoma (Chapter 202), should undergo definitive surgery; the need for postoperative radiation therapy is based on the tumor's histology.

Intradural Extramedullary Tumors

Meningiomas

Most intradural extramedullary tumors are benign. Meningiomas are benign, slow-growing tumors that occur primarily in middle-aged women and are predominantly located in the thoracic region. Back pain is a common symptom, but about 25% of patients have no pain and present with slowly progressive neurologic dysfunction, typically a gait disorder that has been progressing, frequently for years. Spinal MRI with gadolinium clearly delineates the lesion. Surgical resection is curative, and a complete resection can usually be accomplished easily.

Nerve Sheath Tumors

Nerve sheath tumors include schwannomas and neurofibromas. Both typically arise from the dorsal root, and the first symptom is often radicular pain that precedes symptoms of spinal cord compression by months or even years. Some patients with spinal neurofibroma or schwannoma have neurofibromatosis type 1 (Chapter 417), but most do not. The diagnosis is clearly established by gadolinium-enhanced MRI of the spine. The treatment is surgical, and complete removal results in cure.

Metastases

Metastasis to the spinal leptomeninges can be manifested as an intradural extramedullary lesion. A single large tumor nodule can cause focal symptoms and signs referable to that spinal level, but in most patients, multiple levels of the neuraxis are involved, causing multifocal neurologic symptoms and signs. Cervical and lumbosacral radicular pain as well as sensory and motor loss is seen in more than half of patients. The diagnosis is established by gadolinium-enhanced MRI showing multifocal nodules or sometimes a layer of cells coating the spinal cord or nerve roots (see Fig. 189-9). If imaging is negative, the diagnosis can be established by demonstrating tumor cells in the CSF. Treatment is complicated and frequently requires radiation therapy to symptomatic sites of disease, intrathecal chemotherapy best administered through an intraventricular cannula (Ommaya device), and occasionally systemic chemotherapy. Radiation therapy can ameliorate neurologic symptoms, particularly pain, but the disease often has a relentless progressive course, resulting in death in 3 to 6 months despite aggressive therapy. Because of the diffuse nature of the disease, surgery is not an option.

Intramedullary Tumors

Intramedullary spinal cord tumors are similar to neoplasms that arise in brain parenchyma. The most common spinal cord tumors are ependymomas and

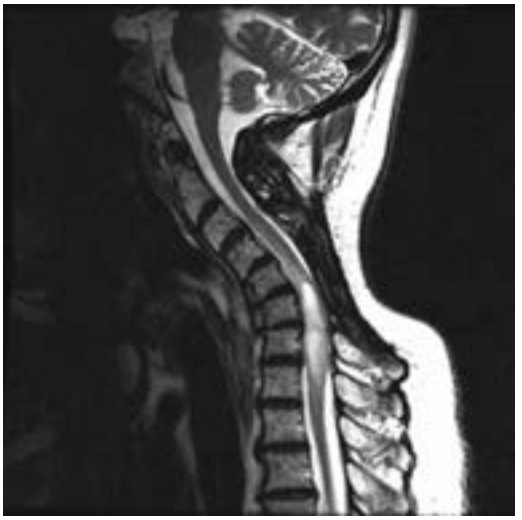

FIGURE 189-11. Spinal cord astrocytoma. T2-weighted sagittal magnetic resonance image demonstrating a lower cervical intramedullary low-grade astrocytoma; no enhancement was evident.

astrocytomas; hemangioblastomas (particularly in association with von Hippel–Lindau disease; Chapter 417), lipomas, and, rarely, intramedullary metastases are also seen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

All intramedullary tumors have a similar clinical presentation, and pain is a common initial symptom. Signs of spinal cord dysfunction subsequently ensue and reflect the location of the lesion. In addition, some intramedullary tumors are accompanied by a syrinx (Chapter 417), which can contribute to symptoms. The classic signs of intramedullary spinal cord lesions, such as dissociated sensory loss, sacral sparing, and early sphincter problems, are not sufficiently reliable to distinguish intramedullary from extramedullary lesions on the basis of clinical findings. The diagnosis is established by gadolinium-enhanced and T2-weighted MRI (Fig. 189-11).

TREATMENT

Rx

Surgery is the first therapeutic intervention, both to obtain a definitive diagnosis and to resect the lesion. Complete resection of spinal cord tumors is possible, particularly in the case of ependymomas and hemangioblastomas. However, spinal cord tumors are rare, and only neurosurgeons experienced in removal of this type of lesion should perform the procedure. High-grade gliomas and residual ependymomas should be treated with postoperative radiation therapy.[15] Low-grade astrocytomas of the spinal cord can be treated with radiation therapy when the patient develops symptomatic neurologic impairment, but presymptomatic treatment does not prevent the development of impairment nor necessarily delay it. Intramedullary metastases do not require surgery because the diagnosis is usually straightforward; radiation therapy provides limited benefit because these patients typically have other CNS metastases.

REVIEW QUESTIONS

1. A 78-year-old woman is brought to the hospital by her family, who are complaining that she has lost interest in her usual activities and appears depressed during the past 4 to 6 months. She was started on an antidepressant by her internist 3 months ago without any response. They have also noticed that her walking has deteriorated in the past month, and in the last week she has developed incontinence. On examination, you find she is indifferent and has a flat affect and bilateral frontal release signs. She shuffles when she walks and her balance is poor. You order magnetic resonance imaging (MRI), which shows a large bifrontal diffusely enhancing tumor compressing the frontal lobes without much underlying edema; a dural tail is evident. The tumor type is likely to be

A. Glioblastoma
B. Meningioma
C. Metastasis
D. Primary CNS lymphoma
E. Anaplastic oligodendroglioma

Answer: B Meningiomas can grow to a huge size without causing problems because they grow so slowly and the underlying brain accommodates the compression. Subacute onset of social withdrawal in an older patient should always be suggestive of an underlying neurologic process, particularly when other findings, such as a gait disorder and incontinence, are apparent; all these symptoms can be caused by compression of both frontal lobes. Resection can completely remove this tumor and restore the patient to normal function, and she is unlikely to experience recurrence. (Rocha H, Cerejo A, Garrett MC, Massano J. Reversible parkinsonism due to a large intracranial tumour. *BMJ Case Rep*. 2012; pii: bcr2012007823.)

2. A 56-year-old man with lung cancer comes to the emergency department complaining of progressively severe upper back pain that can occasionally radiate around his chest. The pain increases with cough or Valsalva maneuver. He has no sensory or motor symptoms. His examination reveals no neurologic deficits. The next step in evaluating his pain is

A. Spine radiograph
B. Chest radiograph
C. Bone scan
D. Treat with pain medications and observe
E. Spine MRI

Answer: E This patient has a high likelihood of having metastases to the spinal column. The pain is located in the upper back, which is atypical for the common musculoskeletal causes of back pain, and the pain radiating around his chest suggests compression of the thoracic nerve roots; exacerbation of the pain with cough or Valsalva maneuver indicates compression on the thecal sac. Imaging is essential, so observation is not an option, and plain radiographs or bone scan cannot visualize tumor extending into the epidural space. A complete spine MRI study was obtained and demonstrated marked epidural tumor with spinal cord compression at T6. Because it was a single site of disease and the patient had few comorbidities, he had a complete resection followed by focal radiation therapy and did well.

3. A 72-year-old man has a history of prior myocardial infarction, congestive heart failure, atrial fibrillation with anticoagulation, and metastatic renal cell cancer. He was at home when he had the sudden onset of left hand twitching that progressed to involve his whole arm and the left side of his face. It stopped after 45 seconds, and he had mild weakness of his left arm and hand, which resolved completely during 12 hours. He went to the local emergency department, where MRI revealed a single enhancing mass 1×0.8 cm in the right frontal lobe with surrounding edema, consistent with a metastasis. What is the best therapeutic approach in this man with poor renal function and severe cardiac disease?

A. Supportive care only
B. Surgical resection
C. Whole brain radiation therapy
D. Stereotactic radiosurgery
E. A change in chemotherapy

Answer: D This is a single brain metastasis in a patient with a primary tumor type that is relatively radioresistant. Furthermore, he is older and likely to experience greater neurologic toxicity if his whole brain is irradiated, so whole brain radiation therapy is a poor option. Resection could be considered, but his medical condition is too poor for surgery. Chemotherapy is unlikely to be effective for a brain metastasis from renal cancer. Stereotactic radiosurgery is an excellent option. The tumor is small and therefore a good candidate for this approach. Relatively radioresistant primaries respond better to the single high-dose fraction of stereotactic radiosurgery; it is also easy to administer, and with a good response the patient is more likely to discontinue steroids and avoid their attendant toxicities. Supportive care could be a reasonable option, but given that his brain metastasis has never been treated and stereotactic radiosurgery has a high probability of being efficacious with minimal toxicity, it is the best option.

4. A 67-year-old right-handed woman comes to your office complaining of several episodes during the past 2 months of the abrupt onset of an inability to speak. She knows what she wants to say but is unable to get the words out. These episodes can last for about 1 minute and then resolve and she is normal. In addition, in the past 2 to 3 weeks, she has noticed progressive word finding difficulty and occasional word substitutions and very mild headache during the past few days. MRI reveals a contrast-enhancing mass in the left temporal lobe. She has a surgical resection, and the pathologic examination reveals a glioblastoma. The next steps in her treatment are

A. Radiation therapy with concurrent and adjuvant temozolomide
B. Radiation therapy alone
C. Temozolomide alone
D. No further treatment after resection
E. Radiation therapy, temozolomide, and bevacizumab

Answer: A Despite a complete resection, a glioblastoma requires additional therapy after surgery because there are always infiltrative cells left behind even when postoperative MRI shows that all the enhancing disease was removed. A large phase III trial has established that the standard of care for a newly diagnosed glioblastoma includes focal radiation therapy with concurrent and adjuvant temozolomide. This is clearly superior to either modality alone. Two recent studies demonstrated that the addition of bevacizumab to radiation therapy and temozolomide failed to improve survival, so it is not included in the initial regimen.

190 HEAD AND NECK CANCER

MARSHALL R. POSNER

DEFINITION

The principal cancers of the head and neck include squamous cell cancers arising from the mucosal surfaces of the upper aerodigestive tract and a diverse group of salivary gland neoplasms. Unique cancers of the region include Epstein-Barr virus (EBV)–associated nasopharyngeal carcinoma, human papillomavirus (HPV)–associated oropharynx cancer (HPVOPC), thyroid malignant neoplasms (Chapter 226), esthesioneuroblastoma, and sinonasal undifferentiated carcinoma. A variety of other cancers arise from structures and tissues in the head and neck, including the more common skin cancers (Chapter 203), lymphomas (Chapters 185 and 186), and sarcomas (Chapter 202).

EPIDEMIOLOGY

Squamous cell carcinomas account for 95% of all malignant neoplasms of the head and neck, whereas salivary gland cancers represent nearly all of the remaining 5%. They represent 4% of all malignant neoplasms in the United States. Squamous cell cancers of the head and neck can be divided into two distinct groups based on pathogenesis, biology, and prognosis. Environmentally related cancers, caused principally by tobacco and alcohol, have been declining in incidence; however, they remain common. There has been an increasing incidence of HPV-related oropharynx cancer.[1] HPVOPC now represents about 75% of oropharynx cancers seen in the United States and Europe.[2] HPVOPC affects a younger population (50 to 60 years) than environmental cancers do (55 to 65 years). HPVOPC patients are also generally healthier and are not prone to comorbid illnesses and second cancers seen in environmentally related squamous cancers.

The mucosal surfaces of the head and neck are divided into six anatomic regions: the oral cavity, oropharynx, hypopharynx, larynx, nasopharynx, and paranasal sinuses. The site of anatomic origin for a squamous cell carcinoma of the head and neck has important albeit imperfectly defined implications for diagnosis, pathogenesis, spread, prognosis, and treatment. This is because of intrinsic differences in the biology of the mucosal cells and subsequent cancers at the sites of origin, carcinogenic viral tropisms, and differences in lymphatic drainage patterns and proximity to other structures in this compact region.

Oral Cavity

The oral cavity includes the floor of the mouth, anterior or oral aspect of the tongue, lips, buccal surfaces, hard palate, retromolar trigone, and gums. This region is easily appreciable by physical examination, and thus tumors in this area can frequently be detected early in their course. Tumors of the oral cavity, which are strongly related to the use of smokeless tobacco and other

oral tobacco products (Chapter 32) and, in southern Asia, to betel nut and pan chewing, appear on the mid oral tongue and buccal and gingival surfaces in the sites where these products are held in contact with the mucosa for long periods. Anterior tongue cancers are more common in smokers. Lip cancers are particularly prevalent in transplant recipients and can be caused by DNA damage from solar ultraviolet light.

Oropharynx

The oropharynx consists of the tongue from the circumvallate papillae posteriorly to the epiglottis, the tonsils, the associated pharyngeal walls, and the soft palate. The oropharynx has become the most common location for head and neck tumors in the United States and is a common site of origin in Europe. This is due to a high rate of HPVOPC, which continues to increase in incidence.[3] HPVOPC is caused almost exclusively by HPV-16, a high-risk HPV type associated with cervical, anal, and vulvar cancers. Other high-risk HPV types account for 10 to 15% of new diagnoses. High-risk HPV types are transmitted in body fluids and infect squamous mucosal surfaces of the anogenital tract and the oropharynx. Whereas smoking does not increase the risk of HPVOPC, 50% of smokers with oropharynx cancer have HPV as a cause. Compared with environmental cancers, HPVOPC often presents with lower primary T stage (T1 and T2) and higher nodal stage (N2 and N3), and it is frequently a cause of cancer of unknown primary origin (Chapter 204) because of small and difficult-to-identify primary tumors.[4]

Hypopharynx

The hypopharynx comprises the piriform sinuses, the lateral and posterior pharyngeal walls, and the posterior surfaces of the larynx. These structures surround the larynx posteriorly and laterally. Tumors in this region can be difficult to detect because of the recesses and spaces surrounding the larynx. As a result, primary hypopharyngeal tumors may be asymptomatic and, like oropharyngeal tumors, may initially be recognized in an advanced state or diagnosed as an unknown primary (Chapter 204). These tumors are associated with tobacco (Chapter 32) and alcohol (Chapter 33) use.

Larynx

The larynx includes the vocal cords, the subglottis, and the supraglottic larynx as well as the thyroid, cricoid, and arytenoid cartilages. Tumors arising in the true vocal cords are frequently symptomatic early and rarely spread beyond the confines of the larynx, whereas subglottic and supraglottic cancers can be relatively asymptomatic and have a much higher and earlier risk of spread to the lymphatics and regional sites. Laryngeal cancers are strongly associated with smoking (Chapter 32).

Nasopharynx

The nasopharynx includes the mucosal surfaces and structures of the cavity behind the nasal passages. Nasopharyngeal cancers are common in the Pacific Rim, northern Africa, and the Middle East. In some areas of China and Southeast Asia, nasopharyngeal cancers occur with a frequency that rivals that of lung cancer. In North America, there are about 2000 cases each year, but numbers are increasing as high-risk ethnic populations settle in North America. Nasopharyngeal cancers are frequently associated with the presence of latent infection of the epithelial tumor cells by EBV, the etiologic agent of infectious mononucleosis (Chapter 377). Nasopharyngeal cancers are also associated with both environmental and genetic factors in susceptible populations that have migrated to North America and remain at high risk for this disease. Unlike other squamous cell carcinomas of the head and neck, nasopharyngeal cancers can occur at an early age, with a distinct peak in adolescence and young adulthood. Nasopharyngeal cancers are categorized into three histologic subtypes by the World Health Organization (WHO): the undifferentiated (WHO III) and nonkeratinizing forms (WHO II) are latently infected with EBV in 95% of cases and represent the majority of cases in North America and worldwide; the well-differentiated (WHO I) form is rarer and represents about 5% worldwide but about 15 to 25% of all nasopharyngeal cancers in North America, and it is usually associated with traditional risk factors such as smoking. Nasopharyngeal cancers have a high risk of early regional lymph node involvement, a prolonged natural history, and a very high risk of spread to distant sites.

Paranasal Sinuses

The paranasal sinuses comprise the maxillary, ethmoid, sphenoid, and frontal sinuses as well as the nasal cavity. These are relatively rare locations for tumors of the head and neck in North America, but there is an unexplained higher rate of malignant sinus disease among the Japanese. Squamous maxillary sinus cancers are more common in smokers. Up to 50% of cancers of the sinuses may be of salivary gland origin. Adenocarcinomas have often been related to exposure to dust from woodworking, tanning, or leather working (Chapter 19). On occasion, neuroendocrine tumors and the rare sinonasal undifferentiated carcinoma are found. Sinus cancers are frequently diagnosed late in their course at the time of symptomatic invasion of surrounding structures, including the orbit, nasal cavity, base of the skull, and cranial nerves.

Salivary Glands

Salivary glands occur in all the regions described as well as in the trachea and esophagus. Tumors can develop in all of the major and minor salivary glands with an incidence that is roughly proportional to the quantity of glandular tissue. The most common single site is the parotid. Although tumors can develop at any age, including childhood, the peak incidence is between 55 and 65 years of age. Salivary gland cancers have diverse histologic findings and manifest different behavior on the basis of their histologic classification. A substantial fraction of parotid salivary tumors can be benign. Risk factors for salivary gland cancers are poorly understood, but previous radiation therapy in adjacent areas increases the risk (Chapter 20).

PATHOBIOLOGY

Tobacco products and alcohol are major etiologic and risk factors for squamous cell carcinoma of the head and neck. Both show a clear dose response. Any irritating smoked product increases the risk for local cancer, but nicotine in tobacco as well as in other tobacco leaf components directly affects the oral mucosa and increases the risk for squamous cancer (Chapter 32). Alcohol is also a carcinogen, and alcohol consumption (Chapter 33) as well as its direct application in mouthwashes is associated with an increased risk. Moreover, alcohol affects local and systemic detoxification enzymes and may increase the carcinogenic potential of other environmental carcinogens. Other environmental risk factors include radiation exposure and solar radiation; welding, metal refining, diesel and wood stove exhaust, and asbestos exposure; chronic irritants; vitamin A deficiency; and immunosuppression.

Carcinogenic viruses are responsible for the increasing incidence of head and neck cancer in the United States and Europe. Pathogenic HPV subtypes, most frequently HPV-16, independently account for approximately 75% of oropharyngeal cancer cases. HPV is transmitted by epithelial contact and body fluids. There is increased risk of HPVOPC associated with increasing numbers of individual sexual partners, although the majority of HPVOPC patients do not have sexual activity above the average. HPV DNA can be found in the tumor cells, and the oncogenic viral proteins E6 and E7 are frequently expressed and are responsible and necessary for the growth and survival of the cancer cells by affecting critical signaling pathways. Men have a three-fold greater incidence of HPVOPC than women do, although the cause for this imbalance in incidence is not known. Of great importance, HPVOPC patients have a three-fold better prognosis than that of patients with environmentally related cancers. This is due to three factors: fewer comorbid illnesses in patients with HPVOPC; few second cancers caused by tobacco and alcohol; and increased sensitivity of HPVOPC tumors to treatments. The majority of nasopharyngeal cancer is caused by another more complex virus that infects keratinocytes, EBV (Chapter 377). The classic nasopharyngeal cancer, which is also called *lymphoepithelioma*, is associated with a brisk lymphoid infiltrate that can be confused with a lymphoma. Careful examination reveals the malignant epithelial cells, with EBV detectable in the tumor cells. EBV is also rarely associated with epithelial tumors of the oropharynx, tonsil, and salivary gland.

Several inherited diseases and genetic abnormalities are associated with the development of head and neck cancer.[5,6] Fanconi anemia (Chapter 165), a rare disorder of a family of related gene products, has been linked to the development of tongue cancer, as has Cowden syndrome (Chapter 181), which is associated with mutation of the *PTEN* gene. *NOTCH1* may function as a tumor suppressor gene rather than as an oncogene in head and neck squamous cell carcinoma. Finally, common inherited allelic variants of the alcohol dehydrogenase and P-450 genes may be associated with increased susceptibility to alcohol and other environmental carcinogens.

The development of environmentally related squamous cell carcinoma of the head and neck is a multistep process in which early genetic changes evolve into frank malignancy. In environmentally related cancers, an abnormal premalignant clone of mucosal cells may be localized to a single site within the head and neck, or clones may occur independently in many sites. The

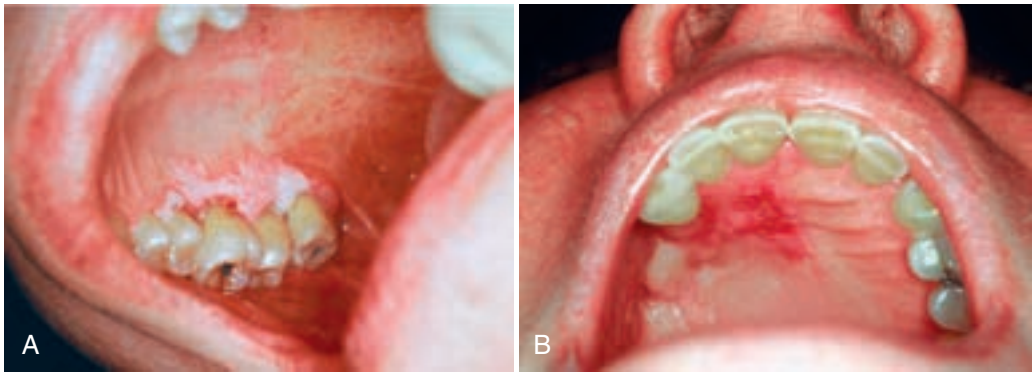

FIGURE 190-1. High-risk early mouth lesions. A, Oral leukoplakia. **B,** Oral erythroplakia.

pathogenesis of HPVOPC is less well understood. Second cancers are rare with HPVOPC in the short term, and long-term risk is unknown. In contrast, about 20% of patients with environmentally caused cancers will develop a second primary cancer, most commonly in the head and neck, lung, and esophagus; 5% of patients are initially seen with a synchronous second primary. In environmentally related cancers, the cell cycle is dysregulated by the early loss of p16, an inhibitor of cyclin D1, or by upregulation of cyclin D1; p53 is disabled through a number of mechanisms preventing programmed cell death; mitogenic signaling is enhanced by upregulation of epidermal growth factor (EGF) receptor function; cyclooxygenase 2 is overexpressed, thereby inhibiting apoptosis and promoting angiogenesis; and chromosomal instability with aneuploidy develops. Many of these early molecular and functional changes occur without obvious alteration in the physical appearance of the oral mucosa, although leukoplakia can occur. In HPVOPC, the RB and p53 pathways are inactivated by the HPV oncogenic proteins E6 and E7. As a result, the p16 protein is upregulated as a biomarker of HPV tumor origin. As a consequence of RB and p53 inactivation, these patients have dysregulation of cell growth and DNA damage control/programmed cell death, respectively. The differences between the genetic and molecular determinants of cancer in HPVOPC and environmentally related cancers can be differentially targeted for therapy.

In environmentally related cancers, high-risk early lesions can occasionally be identified as leukoplakia and erythroplakia. Leukoplakia (Fig. 190-1A) is diagnosed clinically as a white patch of mucosal tissue in the oral mucosa or larynx. It can unpredictably progress to cancer during a period of several years in approximately 30% of patients. Erythroplakia (Fig. 190-1B), a red hyperkeratotic change in the mucosa, is a more advanced premalignant lesion with an approximately 60% rate of progression to oral cancer. Surgical resection of leukoplakia or erythroplakia has no effect on the subsequent development of invasive cancer. There is no proven chemopreventive therapy for persons with oral premalignant lesions. Because continued smoking or alcohol consumption increases the risk for recurrence and second primaries dramatically, patients with prior environmentally related cancers should stop alcohol and tobacco use.

CLINICAL MANIFESTATIONS

The symptoms and clinical manifestations of tumors in the head and neck can vary broadly and are related to the structures at the site of the primary tumor as well as regional lymph node drainage. Small tumors of the oral cavity and larynx can be easily appreciated because of physical self-discovery or early compromise of the function of a critical structure. As a result of the propensity for squamous cell carcinoma of the head and neck to remain a local and regional disease, it is unusual for this cancer to be associated with abnormalities outside the head and neck. Salivary gland malignant neoplasms are less constrained and frequently spread distantly; however, because the primary tumors are also frequently accessible to direct physical examination and early discovery, it is still uncommon to identify these tumors as a result of metastatic spread outside the region.

Clinical manifestations of *tumors in the oral cavity* include a painless lump, a painful mass or ulcer, or simple thickening of the mucosa. Small lesions in the lateral aspect of the tongue and the floor of the mouth can cause pain referred to the mandible, gums, and ear because of the shared sensory nerves supplying these areas. Antibiotics can relieve symptoms and even reduce the size of a tumor or lymph nodes when superficial infection and inflammation are contributing to the pain; however, recurrent or continued pain in an adult should trigger early suspicion about more ominous disease. Speech may be affected late if the tumor causes restricted tongue motion or cranial nerve XII dysfunction. Gingival tumors can loosen teeth and invade the mandible along tooth sockets.

In true vocal cord cancer, hoarseness and other forms of voice change are common and expected early symptoms, but they may be later manifestations of *supraglottic and subglottic laryngeal tumors*, which become relatively large without affecting the voice. Tumors of the piriform sinus can affect the voice when they become large and impair the recurrent laryngeal nerve or are associated with deep local invasion; pain in the ear or pain on swallowing referred to the ear is also a common and important feature of these tumors. Adults with ear pain or persistent hoarseness should be referred to an otolaryngologist for evaluation. Because this posterior area is difficult to assess directly, primary tumors are frequently missed in routine office examinations. *Tumors of the supraglottic region, subglottic cancers, and cancers of the piriform sinus* can also be manifested as acute, emergency airway obstruction. Frequently, patients have a history of wheezing and mild upper airway distress in the period leading up to the emergency situation. On occasion, such findings are confused with adult-onset asthma.

A middle ear infection or effusion in an adult should also prompt an ear, nose, and throat evaluation. Nasopharyngeal cancer may be manifested as an ear infection in young adults. Hemoptysis or epistaxis may be the only clue to a nasopharyngeal cancer or a *paranasal sinus tumor*. Cranial nerve findings from deep invasion of the base of the skull are late events and include lateral gaze abnormalities, diplopia, facial pain, or facial nerve paralysis. *Sinus tumors* can also be associated with these later findings, although nasal stuffiness occurs frequently and can be confused with sinusitis. New and persistent symptoms of sinusitis or facial pain should raise suspicion of sinus cancer and prompt an evaluation.

Tumors in the tonsil or base of the tongue can cause local pain and referred ear pain; however, they are frequently asymptomatic and can attain a large size before becoming evident as a result of changes in speech ("hot potato voice"), a sense of globus, trismus, or restriction of tongue movement. Manifestation as a painless lump in the neck is increasingly common with the increased incidence of HPVOPC. Tumors of the tonsil or base of the tongue may also lose their mucosal component, not be seen or felt on direct inspection, and occur as a solid or cystic neck mass. Isolated neck masses can wax and wane with antibiotics. A mass, especially a cystic mass, in the neck in an adult is cancer and specifically HPVOPC until proved otherwise and should prompt an ear, nose, and throat evaluation and positron emission tomography (PET)/computed tomography (CT) imaging, fine-needle aspiration, and examination under anesthesia before excisional biopsy.

The staging of squamous cell carcinoma of the head and neck is based on the TNM (tumor, node, metastasis) staging system, and prognosis is related primarily to the N and T stages. The risk of the cancer's spreading to lymph nodes is directly related to the location of the primary and secondarily to the size of the primary. Tumors of the oropharynx have a high risk for nodal metastases, followed in risk by the supraglottic larynx and piriform sinus (hypopharynx), oral portion of the tongue, soft palate, oral cavity and floor of the mouth, and larynx. Nasopharyngeal cancer is often associated with extensive nodal spread, whereas paranasal sinus cancers rarely spread to the lymph nodes. The location of lymph node spread is determined in part by site. Nasopharyngeal cancer spreads to the posterior cervical lymph nodes as

well as to the high cervical nodes. Oropharynx, larynx, and piriform sinus tumors spread to the high cervical nodes. Nodal metastases from these locations can be bilateral. Oral cavity tumors spread to the submental nodes and submandibular nodes. Spread tends to be orderly from the submandibular nodes to the midcervical nodes. Oral cavity cancers can have as high as a 20% risk of clinically unappreciated contralateral spread.

DIAGNOSIS

The relative accessibility of the head and neck to direct inspection makes physical examination critical for diagnosis and staging. Patients with localized symptoms or a sign such as an ulcer or a small mass should have a thorough head and neck office examination performed by their primary physician and by a specialist, including inspection of the visible structures and palpation of the base of the tongue and tonsil areas as well as the neck. Specialized office examination with fiberoptics should be included in the preliminary assessment. Regardless of whether cancer is suspected, excisional biopsies should be discouraged because margins are frequently violated and inadequate, thereby leading to larger re-excisions. A simple punch biopsy is sufficient for diagnosis, particularly in the oral portion of the tongue where tumors can spread readily through lymphatics.

When cancer is highly suspected and before definitive surgical intervention, PET/CT of the body and a high-resolution CT scan from the base of the skull to the clavicles, preferably with the spiral technique, are indicated. Magnetic resonance imaging (MRI) provides added information in evaluating soft tissue involvement, especially in the base of the tongue and the parapharyngeal spaces and for sinus tumors. MRI can distinguish between soft tissue masses and retained secretions, whereas PET/CT and high-resolution CT are more helpful in assessing nodal spread in the neck, and CT is effective in identifying extracapsular nodal extension and bone invasion, which are important prognostic and clinical findings. PET scanning provides an important adjunct to CT scanning and can identify occult disease. PET is particularly helpful when the patient has an "unknown primary tumor," before biopsy, to guide the evaluation and to reduce the risk of inadequate diagnostic and premature therapeutic procedures (Fig. 190-2).

When a biopsy indicates cancer or cancer is highly suspected, an examination under anesthesia with endoscopy can be performed to stage the primary tumor before definitive therapy is undertaken. This procedure, which may be part of definitive therapy, provides information about the extent of disease, the appropriateness of the planned definitive procedure, and the presence of second primaries. It is an absolute requirement before definitive therapy can be completed. Endoscopy and palpation under anesthesia can identify unexpected local spread or a synchronous second primary (found synchronously in about 5% of patients with environmentally related cancers), which can substantially alter the treatment plan.

Approach to the Patient with an Unknown Primary Site

Patients frequently seek care from their primary physician because of an enlarged lymph node, a cystic mass, or a collection of lymph nodes in the upper part of the neck (Fig. 190-3). Such masses in an adult should be considered cancer until proved otherwise. Masses in the supraclavicular areas usually derive from primary tumors below the clavicles, and masses in the midneck and cervical regions are almost always from the head and neck. Identification of a primary site is critical to focus therapy, to reduce morbidity, and to determine prognosis.

The most common primary sites for painless lumps are the oropharynx (base of the tongue and tonsil) and piriform sinus. Oropharynx cancers are frequently due to HPV, and a positive HPV or EBV-encoded RNA (EBER) finding in the biopsy specimen or fine-needle aspirate is presumptive evidence of oropharynx or nasopharynx origin, respectively. Salivary gland cancers, lymphomas, melanomas, and skin cancers can also occur in this manner. Bilateral nodal disease or nodal disease with systemic symptoms may suggest lymphoma. By comparison, pain, warmth, and erythema may suggest an infectious etiology. Intraparotid nodes most likely represent metastases from skin malignant neoplasms. Physical examination should include a careful investigation for primary skin cancers. CT, PET, and MRI should be part of the initial evaluation. Fine-needle aspiration with HPV and EBER

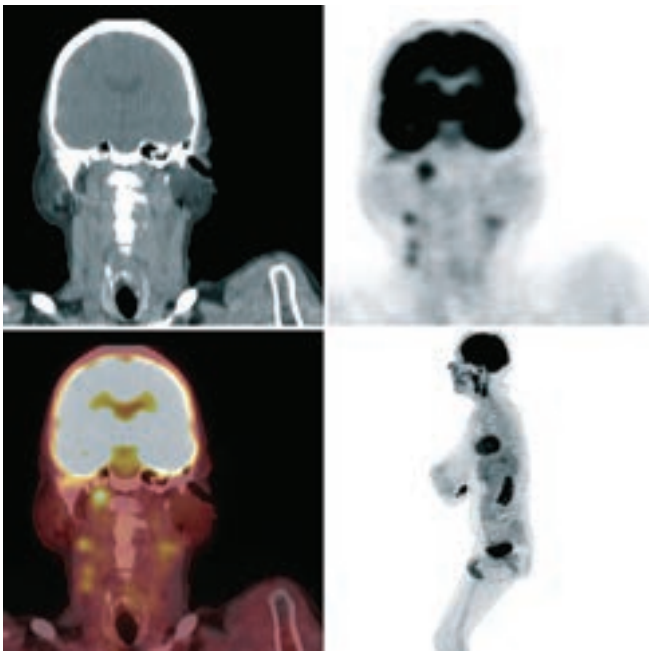

FIGURE 190-2. Positron emission tomography and computed tomography fused images. A primary human papillomavirus–positive base of tongue cancer and neck adenopathy are shown.

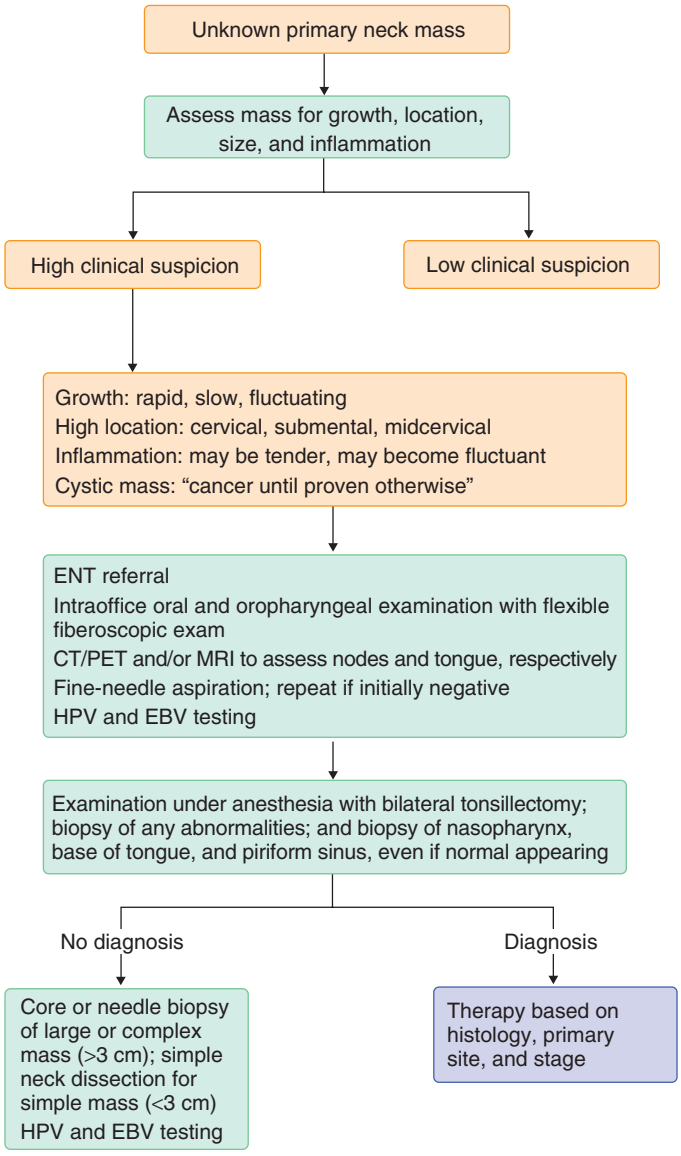

FIGURE 190-3. Evaluation of an unknown primary neck mass. CT = computed tomography; EBV = Epstein-Barr virus; ENT = ear, nose, and throat; HPV = human papillomavirus; MRI = magnetic resonance imaging; PET = positron emission tomography.

testing for squamous tumors should be performed. CT-guided biopsy may be indicated if the mass is difficult to approach. If squamous cells are identified, the tumor is most likely a squamous cell carcinoma of the head and neck. Next, endoscopy under anesthesia should be performed with bilateral tonsillectomy and directed biopsies of any abnormalities, areas of firmness, and the base of the tongue, nasopharynx, and ipsilateral piriform sinus, even if they appear normal. Core or excisional (single node <3 cm) biopsy of the lymph node should be performed if the pathologic findings are equivocal and a primary site is not confirmed. Neck dissection can be accomplished if a primary site is not identified and the patient has an N1 or small N2a/b manifestation. Some unknown primaries with squamous histology are never identified. Currently, HPV and EBV are the only molecular markers known to distinguish head and neck cancer from skin or salivary gland squamous cancer. EBV positivity indicates a nasopharyngeal cancer, and HPV an oropharyngeal primary. Although p16 immunohistochemistry is often used as a surrogate for HPV testing, it is not adequate for a final therapeutic decision to be made and may be positive in up to 20% of non-HPV cancers.

In contrast to squamous cell carcinoma of the head and neck, salivary gland cancers are heterogeneous in their natural history and treatment. The three most common histologic types are adenoid cystic carcinoma, mucoepidermoid cancer, and adenocarcinoma. Other histologic types include the aggressive salivary ductal cancer and squamous cell cancers, whereas less aggressive histologic varieties include adenocarcinoma ex pleomorphic adenoma and acinic cell carcinoma. Because adenoid cystic carcinoma travels along nerves and can spread hematogenously, careful assessment of the cranial nerves and the chest by CT is indicated before major surgery is undertaken. Patients should also be evaluated for bone and liver metastases. PET scan may not be positive in acinic cell carcinoma because of slow proliferation and metabolism in the malignant cells. Formal lymph node dissection is not indicated. Ethmoid and sphenoid sinus adenoid cystic carcinomas are locally and regionally aggressive and require specialized surgery and radiation therapy techniques for local and regional control. The behavior of mucoepidermoid carcinoma is determined by histology. Low- and intermediate-grade lesions rarely metastasize. Isolated high-grade tumors spread to local lymph nodes and by hematogenous routes and carry a high risk for the development of lung metastases. Local therapy should be directed at local and regional control with lymph node dissection. Radiation therapy is indicated for close microscopic margins or lymph node involvement. Adenocarcinoma, salivary ductal cancers, and squamous cell carcinoma are poor prognosis lesions with aggressive local and distant behavior. These tumors should be evaluated in the same fashion as aggressive mucoepidermoid carcinomas. Salivary ductal carcinomas may be positive for overexpression of EGFR2 or androgen receptor and should be tested for these markers to guide therapy with targeted agents. Acinic cell carcinoma and carcinoma ex pleomorphic adenoma are relatively rare. They have a propensity for local and regional recurrence if they are not removed in toto. Metastases are rare in acinic cell carcinoma and tend to be slow growing.

Other Tumors of the Head and Neck

Lymphomas in the head and neck frequently are manifested either as nodal disease in the neck or as tumor involving the lymphoid tissues of Waldeyer's ring (Chapters 185 and 186). A primary head and neck cancer may later develop in patients with lymphoma as a consequence of past exposure to tobacco, radiation therapy, or immunosuppression. The tonsil is a preferred site for mantle cell and undifferentiated lymphomas. Mucosa-associated lymphoid tissue lymphomas can affect the salivary glands.

In the context of an isolated neck mass, a systematic evaluation (see Fig. 190-3) should be undertaken, even in young adults without a smoking history. The sinonasal T-cell and natural killer cell lymphomas, also known as *lethal midline granulomas*, represent a unique family of lymphomas of the head and neck. These lymphomas are associated with EBV infection (Chapter 377). Solitary, extramedullary plasmacytoma can also occur in the nasopharynx or paranasal sinuses (Chapter 187).

Sarcomas that arise in the head and neck include osteogenic sarcomas (Chapter 202) and nerve sheath tumors. Paragangliomas, which are rare malignant tumors of the chief cells of nerve paraganglia, can be extensive, multicentric, and vascular. Rhabdomyosarcomas, which have a predilection for the orbit and sinuses, occur in younger persons; the prognosis tends to be better for tumors of the head and neck than for other locations. Olfactory neuroblastomas or esthesioneuroblastomas invade the nasal cavity and base of the skull.

Many skin tumors, including melanoma and squamous cell cancer, can be accompanied by adenopathy of the neck or parotid area (Chapter 203). An unusual skin appendage tumor, Merkel cell cancer, can be confused with other neuroendocrine epithelial tumors. Merkel cell tumors are associated with HIV infection and may, in up to 50% of cases, be caused by Merkel cell polyomavirus.

PREVENTION AND TREATMENT

Rx

Selection of a treatment program for an individual patient is based on three factors: (1) the primary site and stage of the tumor; (2) the patient's comorbid conditions, including performance status and preferences; (3) and the biology of the tumor (Table 190-1). Early-stage lesions, T1N0 and T2N0, are defined by their size, and their prognosis is site specific. For example, early *larynx cancer* involving the true vocal cords has an excellent prognosis and can be treated by local excision. Voice-preserving larynx conservation surgery is effective for selected patients. Radiation therapy is equally effective for early cancer. When there is a risk of lymph node spread, radiation therapy must be given postoperatively, and the primary value of surgery is significantly diminished. Intensity-modulated radiation therapy allows radiation to be delivered in a more conformal manner to the tumor and areas at risk while sparing critical structures such as the spinal cord and noncritical but important structures such as the salivary glands and swallowing structures. Intensity-modulated radiation therapy is now a standard of care for almost all patients with head and neck cancer.[7]

Oral tongue, piriform sinus, and environmentally related oropharynx tumors have a poor prognosis and are difficult to stage accurately because of submucosal spread or lymphatic involvement. Stage I and stage II cancers are cured with local and regional surgery or radiation therapy in 70 to 90% of cases. Surgery may be preferred for oral cavity and anterior lesions. In surgically treated patients, those with a positive margin, two or more positive lymph nodes, or extracapsular spread have a significantly poorer survival rate (<30%) at 5 years. Perineural invasion and lymphovascular invasion may also be associated with a poor prognosis. Postoperative cisplatin-based chemoradiotherapy improves local and regional control as well as has a trend to increased survival, and it should be given to patients with a poor prognosis if their condition permits. At present, aside from HPV status and p16 immunohistochemistry, no molecular or immunohistochemical finding definitively adds to the information gleaned from pathology, staging, and performance status.[8]

TABLE 190-1 GENERAL APPROACH TO SQUAMOUS CELL HEAD AND NECK CANCER

STAGE	TNM	DISEASE-SPECIFIC SURVIVAL	TREATMENT APPROACH	SPECIAL CONDITIONS
I	T1N0	85-95%	Surgery or radiation therapy	Consider organ function and long-term toxicity
II	T2N0	75-90%	Surgery, radiation therapy, or chemoradiotherapy	Consider organ function Combined modality treatment for high-volume tumor Postoperative chemoradiotherapy for poor prognostic findings on pathologic staging
III	T3N0 T1-3N1	50-75%	Combined modality treatment	Primary chemoradiotherapy or TPF induction therapy or sequential therapy for organ function Postoperative chemoradiotherapy More aggressive approach (sequential therapy) for high-volume disease or hypopharynx tumors
IV	T1-3N2-3 T4N0-3 Any M1	20-60%	Combined modality treatment	Combined modality therapy Limited surgery Postoperative chemoradiotherapy Palliative therapy for M1 (curative therapy for isolated lung metastases)

When organ preservation and function are issues for stage III or stage IV cancers or when radiation therapy is required regardless of surgical outcome, primary chemoradiotherapy or sequential therapy should be considered. The curative treatment of intermediate (stage III, T1-3N1, T3N0) and locally advanced (stage IV, T1-3N2-3, T4) disease remains controversial. Long-term (3 years) survival rates in patients with stage III disease are generally between 50 and 75%, whereas only 15 to 50% of stage IV patients survive for 3 years. Intermediate-stage tumors are usually resectable, but organ preservation may be an important consideration. In many of these cases, a combined modality approach that includes chemotherapy and radiation therapy is the standard of care.

Patients with anterior lesions may do better with initial surgical treatment. The oral cavity is easy to access and is relatively forgiving for surgery and reconstruction; postoperative radiation therapy or chemoradiotherapy can be moderated in the absence of poor prognostic features. For intermediate and advanced tumors of the oral cavity, newer microvascular surgical techniques can substantially improve functional outcome and may help increase local-regional control. Radiation therapy or chemoradiotherapy remains a necessary adjunct to prevent recurrence. In contrast, tumors of oropharyngeal base of tongue or hypopharynx are almost always more extensive than is clinically appreciated, and functional outcome can be compromised by surgery followed by chemoradiotherapy. These may be more suited to a nonsurgical regional and systemic approach. In addition, patients with rapidly growing tumors are more suitable for a combined modality approach. Patients with extensive N2 or N3 nodal disease (stage IV) should be considered relatively unresectable because of a poor prognosis from regional recurrence and distant metastases. Certain locations, such as the nasopharynx and posterior pharynx, should also be considered for definitive radiation therapy, sequential therapy, or chemoradiotherapy.

Surgical therapy has changed radically in the last 5 years. Microvascular reconstructive techniques have improved outcomes in the oral cavity and have substantially reduced functional morbidity and permitted previously morbid resections to be accomplished with good functional outcomes. Transoral laser microdissection and transoral robotic surgery have created the opportunity to operate on previously "inoperable" tumors of the oropharynx and hypopharynx. Surgery with these technologies is performed without bystander tissue damage, which often leads to complications and required prolonged hospitalizations. These technologies are being integrated into combined modality approaches.

Radiation therapy has been proved by randomized trials to yield better local control and disease-free survival if it is given in twice-daily fractionated treatments rather than as daily therapy. However, the absolute benefit of hyperfractionated radiation therapy at 5 years is only 3 to 4%, and a twice-daily schedule is not advantageous with chemotherapy or better than chemotherapy and standard once-daily approaches. Studies strongly support the notion that altered fractionation radiation therapy with chemotherapy is substantially less efficacious or more toxic than standard fraction chemotherapy and that chemoradiotherapy with standard fractionation is more efficacious than altered fractionation alone. Proton beam radiation therapy has become available for tumors of the base of skull or those close to the eyes or the optic chiasm and is suitable in that context.

Induction chemotherapy is the delivery of chemotherapy before definitive local-regional treatment. Sequential therapy adds chemoradiotherapy (see later) to induction chemotherapy. Induction chemotherapy with docetaxel (75 mg/m^2), cisplatin (75 to 100 mg/m^2 by intravenous bolus), plus 5-fluorouracil (750 to 1000 mg/m^2/day for 4 to 5 days by intravenous infusion), repeated every 3 or 4 weeks (TPF), is an effective, standard regimen. For patients with advanced oropharynx, larynx, and hypopharynx tumors, sequential chemotherapy with chemoradiotherapy using concomitant carboplatin and once-daily radiation therapy improves survival and preserves function compared with radiation, surgery, or cisplatin and 5-fluorouracil chemotherapy (PF).

Chemoradiotherapy integrates chemotherapy and radiation therapy together and has led to significant improvements in overall survival in patients with advanced disease compared with radiation therapy alone. For example, patients with unresectable disease who received cisplatin (100 mg/m^2 by intravenous bolus) every 3 weeks during radiation therapy have significantly better survival than do those treated with radiation therapy alone. In a trial of patients with oropharyngeal carcinoma, those treated with carboplatin and 5-fluorouracil plus simultaneous radiation therapy had significantly better survival than did those treated by radiation therapy alone. Cetuximab plus radiation therapy has also proved effective in improving survival in patients with locally advanced head and neck cancer compared with radiation therapy alone in a single trial. Compelling data for an improvement of cetuximab or equivalence with cisplatin-based chemoradiotherapy in either toxicity or survival has not been produced. Conventional chemoradiotherapy results in more favorable outcomes than chemotherapy with accelerated radiation therapy or very accelerated radiation therapy alone in patients with locally advanced head and neck carcinoma.

Patients with locally advanced or unresectable disease (or both) should receive chemotherapy and radiation therapy as part of a combined modality approach. Surgery may be integrated into this approach. Organ preservation should be offered to patients who can tolerate the treatment and participate in the post-treatment rehabilitation.

Treatment of *tumors of the paranasal sinuses* is a special case. They rarely metastasize, and treatment should focus on surgical resection with postoperative radiation therapy or chemoradiotherapy for resectable stage III and stage IV disease and on chemoradiotherapy for local and regional control of unresectable disease. Proton beam irradiation may be more suited for tumors in and around the base of the skull, optic chiasm, orbits, and brain.

Follow-up

Patients need lifelong follow-up. Surveillance examinations for second primaries and recurrences should be performed monthly to bimonthly in the first year and then less frequently over time. PET/CT scan can provide evidence of local-regional persistence approximately 12 to 16 weeks after completion of radiation therapy and can be used to guide early salvage surgery and neck management. Biannual PET/CT scan as postoperative surveillance can identify early metastases or recurrence and increase the rate and success of salvage surgery. Treatment failure after 5 years is uncommon, but second primaries and distant metastases may continue to be identified in environmentally related cancers and HPVOPC, respectively. It is important to counsel these patients to avoid tobacco products.

During radiation therapy and immediately after radiation therapy, patients benefit from pain medications, local anesthetics, mucolytics, and saline mouthwash. Patients must avoid alcohol-containing preparations or irritants. Long-acting agents such as fentanyl or time-release narcotics should be added when needed (Chapter 30). A percutaneous endoscopic gastrostomy feeding tube is often effective for maintaining weight, improving healing, and managing nutrition during radiation therapy. Because depression is a major problem, psychiatric support and antidepressants may be very helpful. Salivary function improves during more than 4 years after radiation therapy, but most improvement occurs in the first 2 years. Pilocarpine and cevimeline (Evoxac) are effective stimulants of salivary flow in about 20% of patients.

Long-term sequelae of radiation therapy include dependence on a feeding tube in patients treated with aggressive chemoradiotherapy or radiation therapy alone. Attention should be paid to preservation of swallowing function by means of training in speech and swallowing as well as by dilation in selected patients. Hypothyroidism occurs in up to 50% of patients and as early as 3 months after treatment. Patients should be monitored by determining serum thyroid-stimulating hormone levels at regular intervals and then treated as appropriate (Chapter 226). Dental failure is a common problem. Patients must be counseled to see their dentists regularly for cleanings and to obtain fluoride therapy daily for dental preservation. Patients are at substantial lifelong risk for complications from dental manipulations after radiation therapy. Bone necrosis is painful, can be confused with recurrent tumor, and requires vigorous antibiotic therapy, débridement, and possibly hyperbaric oxygen to promote healing. Late vascular compromise of the carotid artery should lead to routine carotid ultrasound beginning about 10 years after radiation therapy.

Patients with recurrent disease, a second primary, or metastatic disease must be evaluated for potential curability. Symptomatically, persistent pain may be the most important indicator of a recurrence, and repeated biopsy should be considered when a suspicious lesion is observed. If patients have a recurrence or second primary, curative treatment options are defined by their current stage, their previous therapy, and the interval from their original therapy. Patients who have previously been treated with surgery but not radiation therapy can undergo surgery and chemoradiotherapy as part of a curative treatment plan. Patients with a surgically treatable recurrence in an irradiated field should undergo surgery as appropriate. Surgical salvage may cure as many as 30% of patients with recurrent oral cavity, larynx, or hypopharyngeal tumors. The surgery must encompass the entire recurrence. A repeated course of radiation therapy or chemoradiotherapy is also acceptable in selected patients.

Patients who are incurable can be managed effectively with palliative therapy to improve quality of life and survival (e.g., tracheostomy for airway control, laryngectomy for pain and aspiration, percutaneous endoscopic gastrostomy tube for feeding). These maneuvers can improve comfort and care in appropriate patients.

Palliative chemotherapy can provide meaningful benefit to some patients. Response rates with single agents are generally poor, and combination therapy offers higher response rates (30 to 50%). The combination of a platinum (cisplatin or carboplatin) plus 5-fluorouracil with an anti-EGF receptor antibody, cetuximab, significantly improves survival, response rate, and progression-free survival compared with the same chemotherapy without cetuximab.

Salivary Gland Tumors

In contrast to squamous cell carcinoma of the head and neck, salivary gland cancers are heterogeneous in their natural history and treatment; however, the mainstays of therapy for these tumors are surgery and radiation therapy. Early symptoms of local-regional recurrence include cranial nerve dysfunction

and progressive pain. A PET scan may be useful in distinguishing recurrence from the neuropathy that may result from radiation therapy.

There are no highly active agents or combinations for treatment of metastatic salivary gland tumors with the exception of anti-Her2 therapy for Her2-positive tumors. Local therapy can include surgical removal of isolated metastases, radio frequency ablation, and radiation therapy. Response rates are generally in the range of 20 to 35%, but prolonged responses are occasionally seen.

Future Directions

Antibodies that target newly identified molecular targets are being evaluated and may improve local and regional control as well as survival when they are delivered in combination with other therapies. Therapeutic vaccines may improve outcomes in EBV nasopharyngeal carcinoma and HPVOPC, and preventive vaccines in adolescents may prevent later malignant disease. New immune checkpoint blockade inhibitors appear to be showing promise in viral and environmentally caused head and neck cancers.

PROGNOSIS

The prognosis for patients with squamous cell carcinoma of the head and neck (see Table 190-1) is directly related to the presence of HPV, stage, and performance status. The risk for recurrence declines dramatically at 3 years after definitive treatment, and survival and possible cure can be defined after 5 years. HPV status[9] and then N (nodal) stage are the most important prognostic indicators of potential recurrence, with T (tumor) stage and smoking history being next.[10] Stage I patients (T1N0) have a 90% likelihood of tumor control, whereas stage II patients (T2N0) have greater than 70 to 85% tumor control. Tumor control in stage III patients (T1-2N1, T3N0-1) is site dependent, is HPV status and smoking history dependent, and varies from 35 to 95%. Patients with stage IVa and IVb environmentally related cancers (T1-3, N2-3, or T4NX) have a 20 to 50% tumor-specific 5-year survival rate compared with 60 to 90% 5-year survival for HPVOPC. Poor prognostic signs in advanced-stage (IVb) patients are related to N3 nodal disease, extracapsular extension, and invasion of basic structures (carotid artery encasement, base of the skull, pterygoid muscles). Patients with M1 disease are categorized as stage IVc. Patients with single lung metastases, whether as a second primary or as an isolated recurrence, can be cured. Cures with metastatic disease caused by HPVOPC may be seen after aggressive management. Patients with recurrent disease and no curative options have a median survival of 6 to 9 months.

Distant metastases occur in about 15 to 20% of patients, but this rate is increasing as better local and regional control prolongs survival in patients with locally advanced disease. Oropharyngeal, tonsil, and piriform sinus tumors have the highest risk for distant metastases. A single synchronous lung metastasis in a patient at initial evaluation or at follow-up can be cured in about 20% of cases.

Salivary gland cancers vary in behavior, depending on their histology. Adenocarcinoma, salivary ductal cancer, salivary squamous cell cancer, and high-grade mucoepidermoid cancer not only spread to lymph nodes but also spread rapidly hematogenously. The presence of lymph node metastases signals a high risk for distant metastases. Adenoid cystic carcinoma infrequently involves lymph nodes but spreads along nerves. Regional recurrences along cranial nerves are frequent and associated with "skip" lesions. Adenoid cystic carcinoma is also associated with the late development of lung metastases, but these patients can have a prolonged lifespan lasting more than 20 years. Low-grade mucoepidermoid cancer and acinic cell carcinoma have little risk of distant spread and are more notable for local recurrence if they are not completely removed.

REVIEW QUESTIONS

1. The most important prognostic biomarker in squamous cell cancer of the head and neck is

A. Cytomegalovirus
B. Human papillomavirus
C. Herpes simplex virus
D. Merkel cell tumor virus
E. All of the above

Answer: B Human papillomavirus (HPV) is the single most important prognostic biomarker in squamous cell cancer of the head and neck. Patients with HPV cancers have a three-fold better survival than that of patients with cancers caused by environmental factors. Patients with HPV-related cancers also have fewer comorbid illnesses and less risk of second primaries.

2. The patient and the physician should discuss the possibility of organ-preserving therapy for patients with hypopharynx and larynx cancers. Some of the accepted strategies for organ preservation are

A. Chemoradiotherapy
B. Partial laryngectomy
C. Sequential therapy
D. Radiation therapy
E. All of the above

Answer: E All three treatments are reasonable larynx-preserving treatments, depending on stage, comorbidities, and lymph node involvement. For early-stage tumors in which radiation therapy may be avoided, partial surgery is indicated. For more advanced cancers, radiation therapy only or a combination of chemotherapy and radiation therapy is indicated. Laryngectomy is a reasonable therapy when the patient cannot tolerate treatment, is noncompliant, or already has a nonfunctional larynx.

3. Postoperative adjuvant cisplatin-based chemoradiotherapy is absolutely indicated for

A. Lymphovascular invasion
B. A positive margin
C. Perineural invasion
D. Extracapsular lymph node extension
E. Both B and D

Answer: E After surgery, pathologic findings of a positive margin and extracapsular lymph node extension are absolute indications for postoperative cisplatin-based adjuvant chemoradiotherapy if the patient can tolerate therapy. Lymphovascular invasion and perineural invasion are less robust criteria and can justify adjuvant chemoradiotherapy. Postoperative chemoradiotherapy is associated with a significant improvement in locoregional control and a trend to improved survival at 10 years.

4. What therapeutic biomarker is associated with prognosis in salivary ductal carcinoma?

A. EGFR1 expression
B. Her2 expression
C. Androgen receptor
D. *PTEN* deletion
E. Both B and C

Answer: E Salivary ductal carcinomas can express either Her2 or androgen receptor (AR). Her2-positive salivary ductal carcinoma will respond to Her2-specific therapies and combinations with long survival, and similarly there are data to support use of AR antagonists in AR-positive salivary ductal carcinoma. No other biomarkers have been identified in salivary gland tumors.

5. An adult presenting with a persistent cervical neck mass should be presumed to have

A. A throat infection
B. A cancer until proven otherwise
C. A branchial cleft cyst
D. Mononucleosis
E. Both B and C

Answer: B A neck mass, cystic or otherwise, presenting in an adult should be presumed to be cancer until proven otherwise. Even a normal finding on fine-needle aspiration is insufficient to rule out malignant disease. Patients should be worked up extensively before neck dissection.

191 LUNG CANCER AND OTHER PULMONARY NEOPLASMS

FADLO R. KHURI

BRONCHOGENIC LUNG CANCER

DEFINITION

Lung cancer, or bronchogenic carcinoma, is a proliferative malignant neoplasm arising from the primary respiratory epithelium. Lung cancer is generally divided into two major histologic groups: *non–small cell lung cancer* (NSCLC), which accounts for approximately 85% of all lung cancers, and *small cell lung cancer* (SCLC). There are several other less common pulmonary neoplasms including carcinoid tumors, primary soft tissue sarcomas of the lung, pulmonary blastomas, and lymphoma.

EPIDEMIOLOGY

Lung cancer is by far the leading cause of cancer-related mortality globally, with an estimated 1.3 million new cases diagnosed worldwide each year, accounting for nearly 12% of all cancers and an estimated 1.1 million deaths each year. Among men, lung cancer is the most common malignant neoplasm (incidence rate of 35.5 per 100,000), whereas in women, lung cancer incidence (12.1 per 100,000) is next only to breast, cervix, and colon cancers. The incidence and mortality related to lung cancer in men have declined during the last two decades in Western countries but continue to increase in the developing world; in women, lung cancer deaths are increasing in most regions of the world. The most dramatic increases in lung cancer incidence and death globally are in China, which has experienced a 465% increase in lung cancer–related deaths during the past 30 years.

Risk Factors

Cigarette smoking is the most common risk factor for lung cancer, with roughly 85% of lung cancer patients having a tobacco-smoking history and approximately 50% being former smokers (defined as free from smoking for at least 12 months before diagnosis). The risk for development of lung cancer correlates with the number of cigarettes smoked per day and the cumulative duration of smoking time. Patients with a smoking history of at least 20 to 30 pack-years (defined as 1 pack per day of cigarettes for 20 to 30 years) are at substantially increased risk for development of lung cancer. Since the release of the first U.S. Surgeon General's Report on the Hazards of Smoking in 1964, the prevalence of cigarette smoking has declined considerably in the United States but continues to increase at an alarming rate in developing and third world countries. As a result, the number of cases of lung cancer diagnosed annually is likely to rise during the next few decades, and it is estimated that the majority of lung cancer cases will occur outside the United States and Europe by the year 2030. Smoking cessation is associated with a gradual reduction in risk for development of lung cancer, although it does not reach that of a never-smoker. Second-hand exposure to smoke is another risk factor that contributes to nearly 1% of all cases of lung cancer.

Because only about 11% of heavy smokers develop lung cancer, genetic susceptibility to lung cancer also appears to play a role. Patients with a family history of early lung cancer (before 60 years of age) have a two-fold higher risk for development of the disease. Women appear to be at a higher risk for development of lung cancer at the same smoking exposure level as that of men, but the reasons behind this remain unclear. In recent years, an increasing number of never-smokers have been diagnosed with lung cancer.

TABLE 191-1 HISTOLOGIC MARKERS IN NON–SMALL CELL LUNG CANCER

	PERCENTAGE IHC-POSITIVE CASES AMONG HISTOLOGIC CARCINOMA SUBTYPES			POSITIVE AND NEGATIVE PREDICTIVE VALUE OF ANTIBODY PANEL	
	Adenocarcinoma (n = 215)	*Squamous Cell Carcinoma (n = 123)*	*Large Cell Carcinoma (n = 22)*	*Adenocarcinoma*	*Squamous Cell Carcinoma*
p63	7.0	99.2	52		88.9, 99.5
Cytokeratin 5/6	9.8	99.2	68		84.9, 99.5
TTF-1	83.5	3.4	23	97.7, 76.9	
Cytokeratin 7	97.2	23.5	77	88.4, 93.6	
Mucin	43.4	13.4	0		

Modified from Sterlacci W, Savic S, Schmid T, et al. Tissue-sparing application of the newly proposed IASLC/ATS/ERS classification of adenocarcinoma of the lung shows practical diagnostic and prognostic impact. *Am J Clin Pathol.* 2012;137:946-956.
IHC = immunohistochemically; TTF-1 = thyroid transcription factor-1.

The etiology behind this is unclear at this time. These individuals are more likely to harbor certain genetic alterations in the tumor, such as mutations in the gene encoding epidermal growth factor receptor (EGFR) and rearrangement in the gene encoding anaplastic lymphoma kinase (ALK). Occupational exposure to asbestos leads to an estimated four-fold higher risk of lung cancer, with cigarette smoking having an additive effect on risk. There is a latency of several decades between asbestos exposure and the development of lung cancer, and risk is related to the duration of exposure as well as to the quantity and the type of asbestos fiber. The Environmental Protection Agency and the World Health Organization consider all forms of asbestos to be carcinogenic; accordingly, the use of asbestos is banned in nearly 50 countries.

Radon exposure has also been implicated in the development of 5 to 8% of lung cancer cases.[1] Household exposure to radon, which results from the radioactive decay of uranium, is high in certain geographic regions. The Environmental Protection Agency recommends that the household radon level be less than 4 picocuries/liter of air, and simple remedial methods are available to reduce radon exposures above this threshold. Exposure to ionizing radiation in the form of therapeutic radiation or frequent diagnostic radiographic tests is also associated with a higher risk for development of lung cancer, as to a lesser degree are exposures to metals such as arsenic, nickel, and chromium as well as to silica and general air pollution, including biomass fuels such as coal and wood smoke. A study estimated that human immunodeficiency virus is associated with an increased risk for development of lung cancer with a hazard ratio of 3.6.

PATHOBIOLOGY

Pathology

Lung cancer is broadly subdivided into NSCLC and SCLC on the basis of the distinct biologic behavior and response to chemotherapy of these two subsets. NSCLC comprises *adenocarcinoma*, *squamous cell carcinoma*, and *large cell carcinoma* subtypes. In the past several years, distinct differences between the various histologic subtypes that comprise NSCLC have been recognized, with an increasing emphasis placed on the identification of histologic subtype from diagnostic specimens.

Adenocarcinoma is now the most common histologic subtype of lung cancer; never-smokers who develop lung cancer most frequently have adenocarcinoma. It has gradually increased in incidence, surpassing squamous cell cancer during the past two decades, and now represents nearly 50% of all newly diagnosed cases of lung cancer in the United States. Adenocarcinoma has a higher predilection for distant metastasis compared with squamous cell histology. In 2011, a new classification system for lung adenocarcinoma was developed dividing adenocarcinomas into preinvasive, minimally invasive, and invasive types.[2] *Atypical adenomatous hyperplasia* refers to a localized proliferative lesion consisting of atypical type II pneumocytes or Clara cells and measuring less than 5 mm. *Adenocarcinoma in situ* refers to lesions smaller than 3 cm that lack any invasive characteristics. This entity was previously referred to as bronchioloalveolar carcinoma or noninvasive adenocarcinoma. Lesions 3 cm or smaller with a predominantly lepidic pattern and with invasion of less than 5 mm in greatest dimension are referred to as *minimally invasive adenocarcinoma*. Adenocarcinoma in situ and minimally invasive adenocarcinoma have a more than 95% 5-year survival rate when they are treated with surgical resection, making the establishment of a precise pathologic diagnosis of great significance. Invasive adenocarcinoma represents nearly 90% of all cases of adenocarcinoma. Based on the predominant characteristic features, it is categorized as lepidic, acinar, papillary, micropapillary, or solid predominant with mucin production.

Squamous cell lung cancer is decreasing in incidence in the United States, most likely because of the changing smoking habits of the population. Squamous tumors of the lung are generally centrally located and are almost always seen in patients with a significant smoking history. Squamous dysplasia and squamous cell carcinoma in situ are preinvasive lesions that can develop into invasive cancers.

In addition to morphologic features, immunohistochemical studies are important in establishing NSCLC histologic subtype. Adenocarcinoma specimens usually stain positive for cytokeratin 7 and thyroid transcription factor-1 (TTF-1) and are negative for cytokeratin 20. The majority of squamous cell tumors stain positive for p40 and p63, members of the p53 family of proteins, whereas adenocarcinomas occasionally stain positive for p63. On the basis of these findings, a panel of markers including TTF-1, p63, and p40 is frequently evaluated in diagnostic specimens of patients with lung cancer to accurately identify the histologic subtype (Table 191-1). Large cell carcinoma represents 3 to 4% of NSCLC and is characterized by a high mitotic rate, necrosis, and morphologic features of NSCLC. Large cell tumors stain positively for neuroendocrine markers such as chromogranin A and synaptophysin. Because this histologic subtype is often difficult to accurately diagnose owing to an abundance of necrotic tissue and a poor degree of differentiation, diagnosis requires an adequate tissue specimen. Large cell carcinoma is often associated with an aggressive clinical course and poor survival rates, even when it is found in the setting of early-stage disease. Large cell carcinoma is strongly associated with a history of prior smoking.

SCLC is diagnosed in approximately 13% of lung cancer cases in the United States, and its incidence has gradually declined during the past three decades. SCLC is strongly associated with smoking and is rare in never-smokers. Pathologic diagnosis can be challenging because of an abundance of necrotic tissue but is established by characteristic features, such as a high degree of mitosis and necrosis. Diagnostic work-up of SCLC includes immunostaining for TTF-1, chromogranin, synaptophysin, and CD56. Approximately 15% of SCLC specimens have mixed morphology with components of NSCLC.

Molecular Pathology

In recent years, a number of molecular abnormalities have been identified in lung cancer. Many of these represent novel targets for therapy, strengthening the rationale for obtaining adequate tumor tissue to conduct molecular studies as an essential component of the diagnostic work-up for lung cancer. With modern genomic techniques, a greater understanding of the molecular features that account for the long-recognized clinical heterogeneity of lung cancer is leading to individualized treatment approaches.[3]

Oncogenes

In lung adenocarcinoma, nearly two thirds of patients harbor an oncogenic mutation that can potentially be targeted with specific agents (Fig. 191-1A).[4] The most common are mutations involving *KRAS*, *EGFR*, *BRAF*, *HER2*, and *PIK3CA* and gene rearrangements involving *ALK*, *RET*, and *ROS1*. *KRAS* mutations are present in approximately 25% of lung adenocarcinoma patients and are usually associated with cigarette smoking. The most common sites of mutation in *KRAS* include codons 12, 13, and 61, resulting in amino acid substitutions, which cause impaired GTPase activity and constitutive

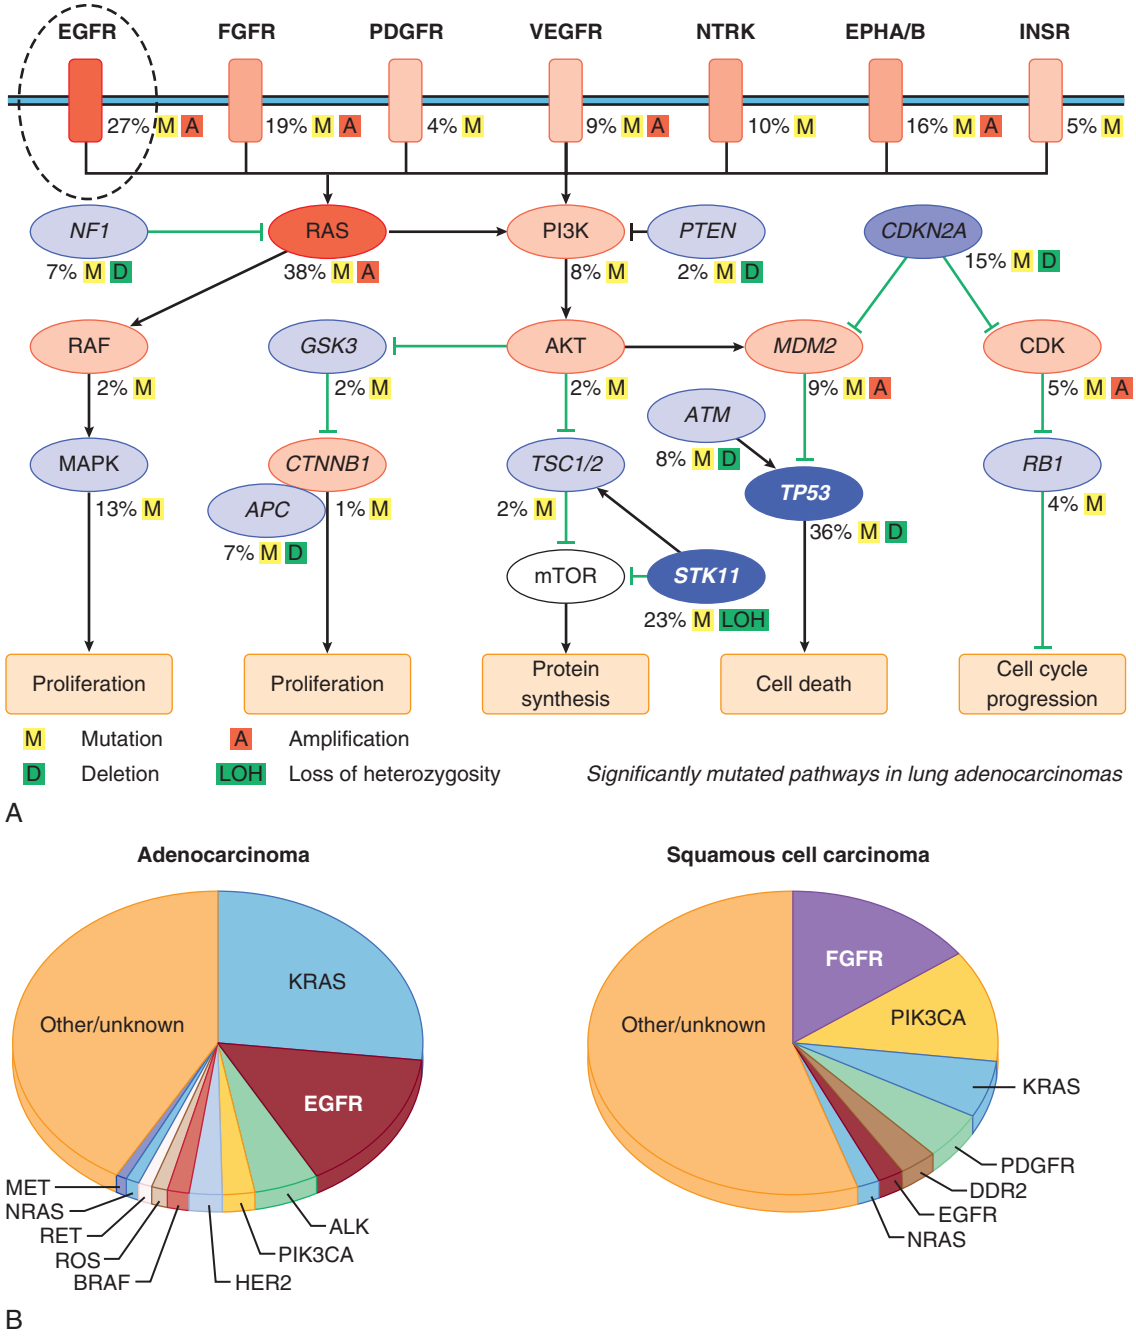

FIGURE 191-1. Altered signaling networks in lung cancer. A, Significantly mutated pathways in lung adenocarcinoma. (Modified from Ding L, Getz G, Wheeler DA, et al. Somatic mutations affect key pathways in lung adenocarcinoma. *Nature*. 2008;455:1069-1075.) **B,** Genetic profiles by histologic subtype. (From the Lung Cancer Mutation Consortium and modified from Sequist LV, Heist RS, Shaw AT, et al. Implementing multiplexed genotyping of non-small-cell lung cancers into routine clinical practice. *Ann Oncol*. 2011;22:2616-2624; Bergethon K, Shaw AT, Ou SH, et al. ROS1 rearrangements define a unique molecular class of lung cancers. *J Clin Oncol*. 2012;30:863-870; Weiss J, Sos ML, Seidel D, et al. Frequent and focal FGFR1 amplification associates with therapeutically tractable FGFR1 dependency in squamous cell lung cancer. *Sci Transl Med*. 2010;2:62ra93; Hammerman PS, Sos ML, Ramos AH, et al. Mutations in the DDR2 kinase gene identify a novel therapeutic target in squamous cell lung cancer. *Cancer Discov*. 2011;1:78-89.)

activation of RAS signaling. The prognostic value of *KRAS* mutation in patients with lung cancer is controversial.

Mutations in *EGFR* are observed in nearly 15% of white and almost 40% of Asian lung adenocarcinoma patients. Deletion mutations in exon 19 and a point mutation in exon 21 are located in the tyrosine kinase–binding domain of the receptor and result in constitutive activation of the signaling pathway, leading to proliferation, evasion of apoptosis, and enhanced angiogenesis. Patients with *EGFR*-activating mutations can derive robust and durable clinical benefit from treatment with EGFR tyrosine kinase inhibitors (TKIs). However, most of the benefit is limited in duration, and within 12 to 24 months, nearly 60% of these patients will develop a secondary mutation in exon 20 that confers resistance to EGFR TKI therapy. This mutation can also be found de novo in certain patients with lung adenocarcinoma along with an exon 19 or 21 mutation before exposure to EGFR TKI therapy. Another common mechanism of acquired resistance to EGFR TKI therapy is amplification of the growth factor receptor c-Met. In approximately 5% of patients with lung adenocarcinoma, gene rearrangement involving *ALK* is observed. Clinical features associated with the *ALK* gene rearrangement include never-smokers, adenocarcinoma histology, signet ring features on histopathologic evaluation, and younger age. The fusion gene results from inversion or translocation of portions of the *echinoderm microtubule-associated protein-like 4 (EML4)* with the *ALK* gene and leads to activation of downstream signals that can be inhibited by specific ALK kinase inhibitors. Crizotinib, an ALK inhibitor, induces objective tumor response in nearly two thirds of patients. *ALK* gene rearrangement is detected by fluorescent in situ hybridization, often in addition to immunohistochemistry. Other fusion abnormalities involving the *RET* and *ROS1* genes are each observed in 1% of lung adenocarcinoma specimens. It is noteworthy that *EGFR* and *KRAS* mutations

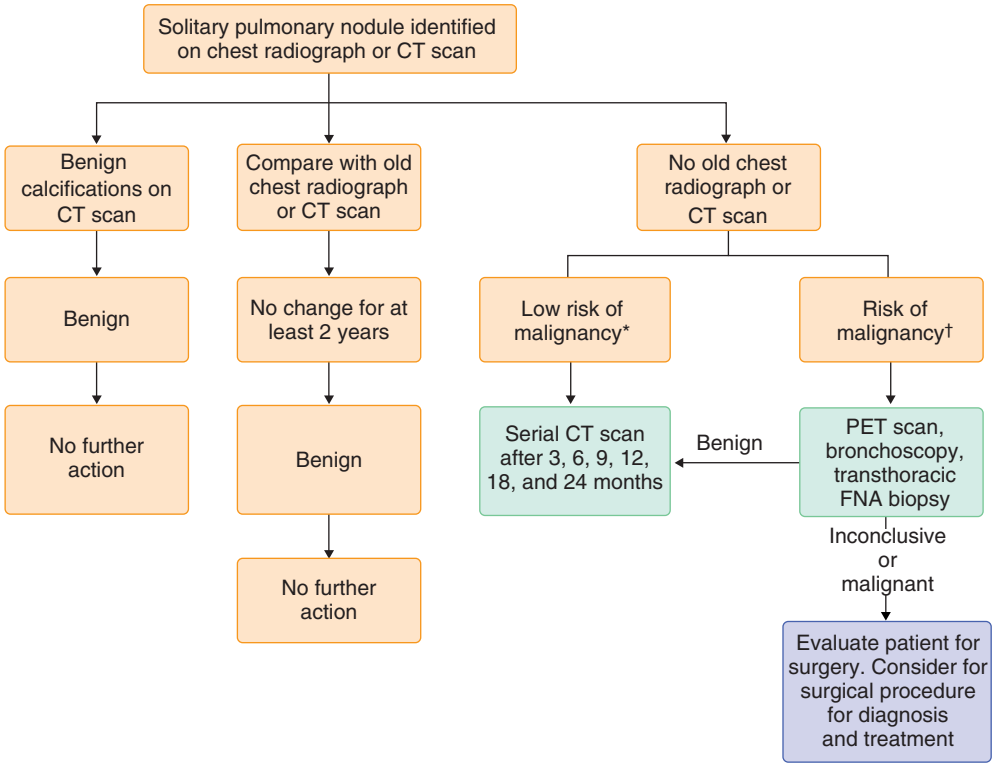

FIGURE 191-2. Evaluation of a patient with a solitary pulmonary nodule. *Patient with a minimal or absent history of smoking and other known risk factors for the development of lung cancer and a nodule 8 mm or smaller. †Patient with a history of smoking and other risk factors for the development of lung cancer and a nodule 8 mm or larger. CT = computed tomography; FNA = fine-needle aspiration; PET = positron emission tomography.

and *ALK* gene rearrangements are usually mutually exclusive. Squamous cell carcinoma has an entirely different spectrum of molecular abnormalities (Fig. 191-1B). Recent studies from the Cancer Genome Atlas (TCGA) project indicate common mutations in *p53*, *PTEN*, *PIK3CA*, *KEAP1*, *DDR2*, and *RB1*. Amplification of the gene for *fibroblast growth factor receptor* (FGFR) is also noted in 10 to 20% of squamous cell lung cancers. Many of these abnormalities provide potential opportunities for targeted therapies. The availability of highly sophisticated genomic sequencing has permitted the elucidation of hitherto unidentified molecular abnormalities, uncovering new therapeutic targets for lung cancer. Increasingly, the performance of "multiplex" testing for a number of molecular markers simultaneously, using limited amounts of tumor tissue, is changing the therapeutic paradigm for NSCLC. Guidelines from the International Association for the Study of Lung Cancer recommend routine testing for *EGFR* mutation and *ALK* translocation for all newly diagnosed patients with lung adenocarcinoma.[5] For patients with tumors of squamous cell histology, routine molecular testing is not yet recommended, although randomized clinical trials using this approach are in progress. In the absence of Food and Drug Administration–approved, molecularly directed therapies for squamous cancers, the use of standard chemotherapies is recommended for this disease at present.

Tumor Suppressor Genes

The function of multiple tumor suppressor genes is frequently lost in lung cancer, including *p53*, *Rb*, *LKB1*, and a number of genes found on the short arm of chromosome 3 (*3p*). *p53* mutation or loss correlates with cigarette smoking and has been detected in some preneoplastic lesions of the lung. Mutations of *p53* are common in both NSCLC (~50%) and SCLC (~80%). Mutations in *LKB1* are also common in NSCLC. The *STK11/LKB1* gene, which encodes a *serine/threonine kinase*, regulates cell polarity and functions as a tumor suppressor. One of the earliest genetic abnormalities in lung cancer occurs during the deletion of genetic material on chromosome 3p (p14-p23). The deletion occurs in approximately 50% of NSCLC and 90% of SCLC patients. The *FHIT* (fragile histidine triad) gene (3p14.2), which is abnormal in many lung cancers, may function as a tumor suppressor gene by limiting tumor growth and enhancing apoptosis. The Rb protein is not expressed in 90% of SCLC because of mutation or deletion. In NSCLC, Rb is normally expressed, but when Rb is phosphorylated, uncontrolled cell division can occur.

Epigenetics

Epigenetics refers to a change in gene expression that is heritable but does not involve a change in DNA sequence. Epigenetic modifications involving changes in DNA methylation are common in lung cancer and include hypomethylation, dysregulation of DNA methyltransferase I, and hypermethylation. Genes that are methylated in NSCLC include *p16*, *RARB*, *RASSFIA*, *MGMT* (methylguanine-methyltransferase), and death-associated protein kinase (DAP-kinase). Hypermethylation in lung cancer can often silence tumor suppressor genes, thereby promoting dysregulated cell growth. Silencing of tumor suppressor genes in histologically normal lymph nodes in patients with resectable NSCLC is associated with higher likelihood of disease relapse.

CLINICAL MANIFESTATIONS

Lung cancers grow from a single abnormal cell or small group of abnormal cells to develop into large macroscopic masses that may be several centimeters in diameter. Most lung cancers originate from the bronchial epithelium and are termed carcinomas. Primary noncarcinoma lung cancers are less common and include carcinoid, pulmonary blastomas (more common in younger patients), and sarcomas. Early lung cancers often are manifested as pulmonary nodules, defined as "a rounded opacity, well or poorly defined, measuring up to 3 cm in diameter" (see Fig. 191-2 for evaluation of a patient with a solitary pulmonary nodule). Abnormal lung tissues range in histologic grade from mildly atypical cells to aggressive cancers. Lesions such as atypical adenomatous hyperplasia are considered preinvasive lesions, with a continuum of cellular atypia through adenocarcinoma (Fig. 191-3).

Currently, only 15% of patients with lung cancer are asymptomatic when they are initially diagnosed. Diagnosis in these patients is often made incidentally on a chest radiograph obtained for other reasons (e.g., a preoperative study). The work-up for suspected lung cancers is dependent on the probability that the lesion in question is malignant or the stage of disease at presentation (see Fig. 191-2). Pulmonary nodules often are due to current or prior infection, although they may be the manifestation of early cancer. Results from the National Lung Screening Trial (NLST) showed that of all nodules detected, more than 95% were false positives and were noncancerous. However, most patients have symptoms and signs that are (1) caused by the pulmonary lesion itself—these include local tumor growth, invasion, and

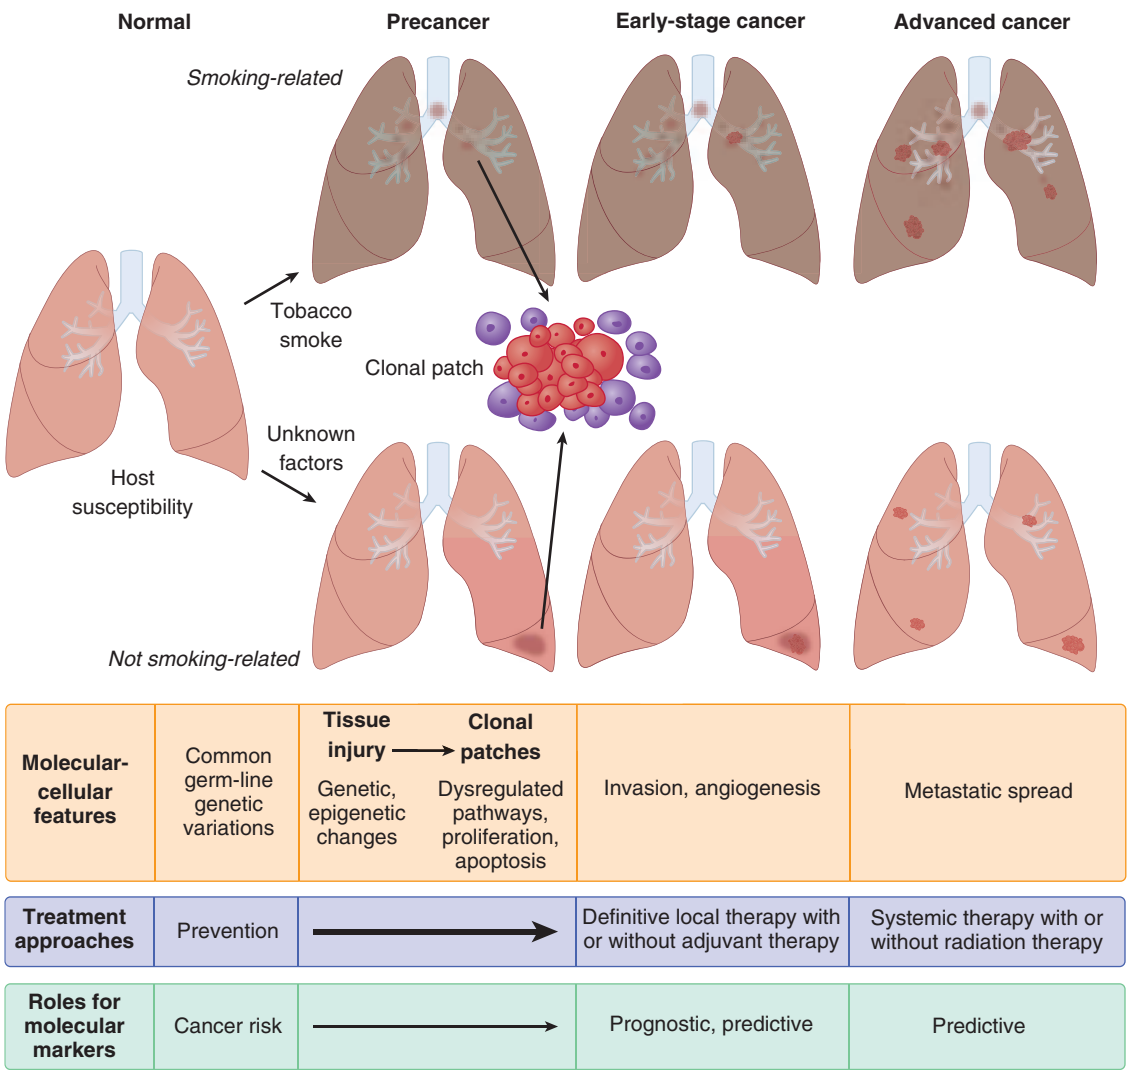

FIGURE 191-3. Carcinogenesis of lung cancer. (From Herbst RS, Heymach JV, Lippmann SM. Lung cancer. *N Engl J Med* 2008;359:1367-1380.)

obstruction; (2) intrathoracic-regional tumor spread to lymph nodes and adjacent structures; (3) extrathoracic-distant spread of disease; or (4) paraneoplastic syndromes. Common presenting symptoms of lung cancer include cough, dyspnea, pain, hemoptysis, and weight loss; anorexia occurs in about 30% of patients, fatigue in one third of patients, and anemia and fever in 10 to 20% of patients. More than 80% of patients initially have three or more symptoms or signs as a result of the lung cancer. Because the majority of patients with lung cancer have other tobacco-related cardiopulmonary diseases, such as emphysema/chronic obstructive pulmonary disease, ischemic heart disease, and others, these overlapping symptoms often result in a delay in diagnosis of the underlying malignant disease. Symptoms could also result from local invasion or metastasis of the tumor, such as headache, bone pain, airway obstruction, cough, and hemoptysis. Paraneoplastic syndromes associated with lung cancer include the syndrome of inappropriate antidiuretic hormone (Chapter 116), hypercalcemia (Chapter 245), pulmonary hypertrophic osteoarthropathy (Chapter 275 and Fig. 275-1), Eaton-Lambert myasthenic syndrome (Chapter 422), and Cushing's syndrome (Chapters 179 and 227). Hypercalcemia is common in squamous cell histology, whereas the syndrome of inappropriate antidiuretic hormone, Eaton-Lambert myasthenic syndrome, and Cushing's syndrome are most commonly associated with SCLC.

DIAGNOSIS

With the advent of computed tomography (CT) screening, it is anticipated that a greater subset of patients with lung cancer will be diagnosed before the onset of symptoms.[6] In patients with clinical or radiographic findings suggestive of lung cancer, CT scans of the chest and abdomen are indicated to determine the location of the primary tumor, involvement of mediastinal lymph nodes (Fig. 191-4), and spread to other anatomic sites.

Diagnostic Procedures

Accurate diagnostic characterization of lung cancers is essential because the presence or absence of mediastinal nodal metastases is crucial in determining prognosis, assessing resectability, and selecting the appropriate treatment strategy for primary lung cancer. Enlarged lymph nodes identified by CT or positron emission tomography (PET) require histologic confirmation. It is debatable whether all patients require invasive mediastinal staging before surgical resection or other local treatment modality, such as stereotactic body radiation therapy (SBRT). Only 5 to 15% of patients with peripheral T1 tumors with a negative mediastinum by CT or PET have mediastinal nodal metastases.

Invasive Diagnostic Procedures

Important advances in surgical diagnosis have been established and refined in the last few years. Transbronchial needle aspiration (TBNA) allows staging of the mediastinum during diagnostic bronchoscopy. Sensitivity of TBNA is dependent on lymph node size, location, and needle size, being best suited for large, clinically positive lymph nodes. On-site cytopathologic analysis increases the likelihood of obtaining a malignant diagnosis. Linear array ultrasound technology combined with TBNA allows endobronchial ultrasound (EBUS) fine-needle aspiration (FNA) of mediastinal and hilar lymph node stations. EBUS-FNA is superior in performance to TBNA, with overall sensitivity approaching 90%. Among the diseases that are also associated with enlarged and metabolically active mediastinal lymph nodes are sarcoidosis, tuberculosis, and multiple infectious causes, generally of a fungal, atypical, or viral nature (histoplasmosis, tuberculosis, and coccidioidomycosis among the differential diagnoses), making it mandatory to obtain nodal tissue.

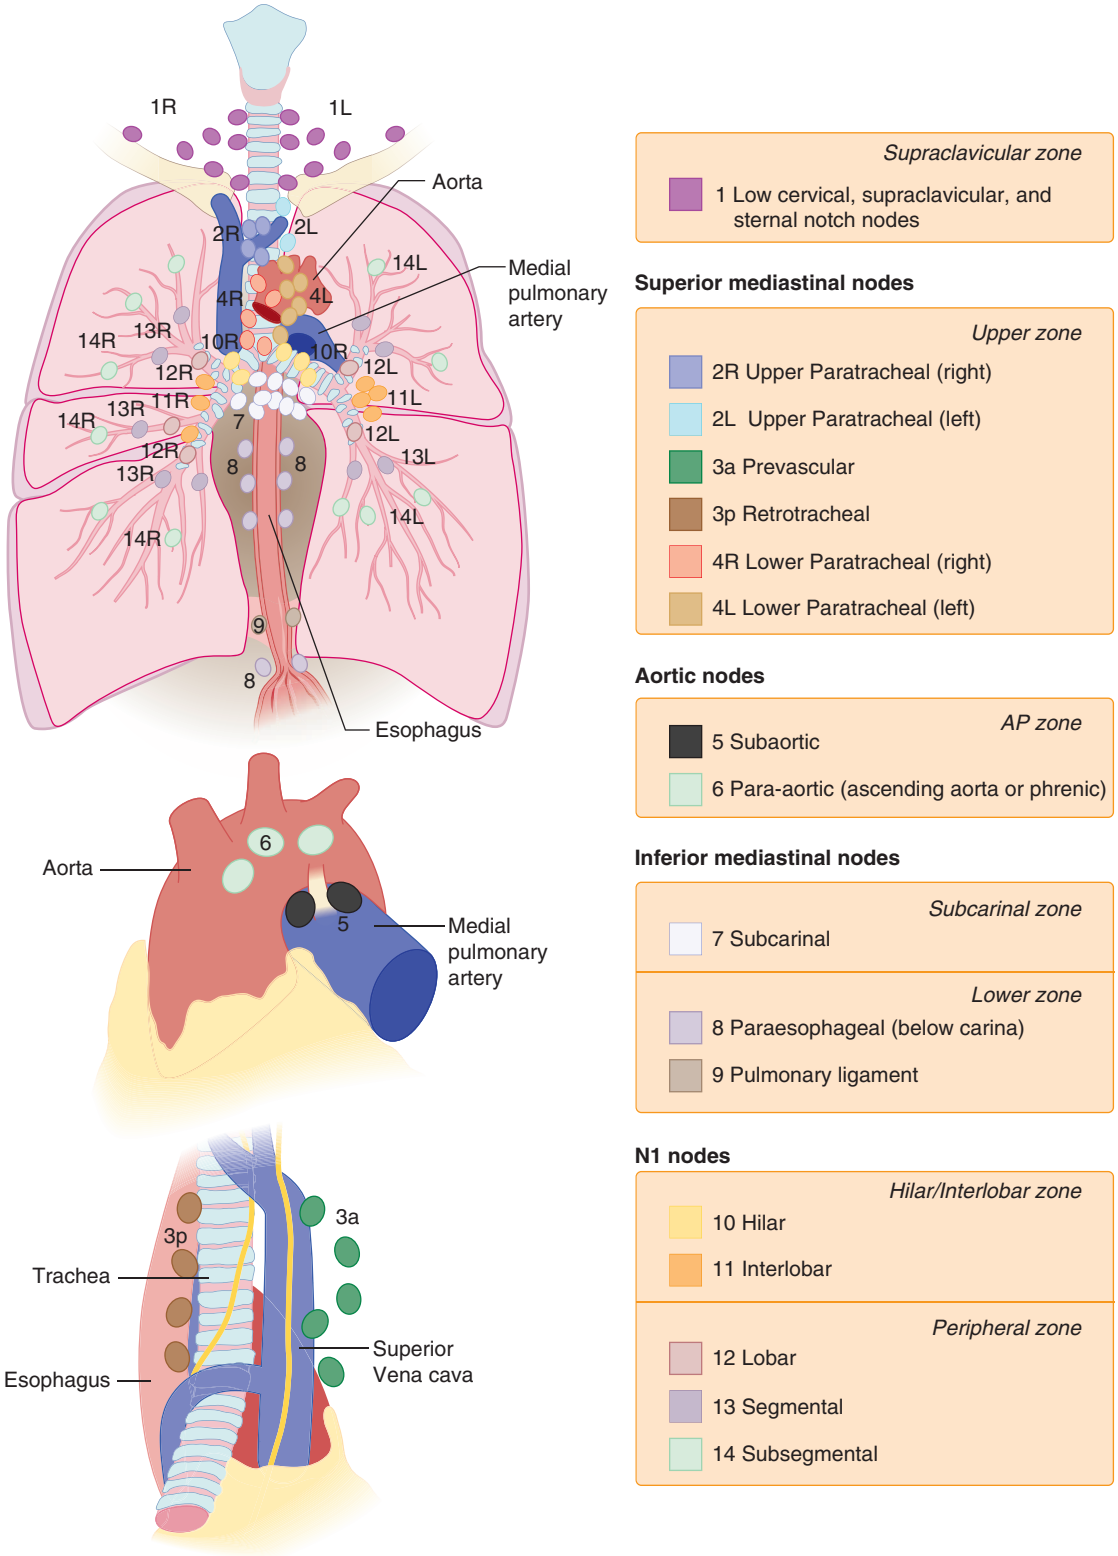

FIGURE 191-4. The International Association for the Study of Lung Cancer (IASLC) lymph node map. Included is the proposed grouping of lymph node stations into "zones" for the purposes of prognostic analyses. (From Rusch VW, Asamura H, Watanabe H. The IASCL lung cancer staging project. A proposal for a new international lymph node map in the forthcoming seventh edition of the TNM classification for lung cancer. *J Thorac Oncol.* 2009;4:568-577.)

Esophageal endoscopic ultrasonography (EUS), or EUS-FNA, allows sampling of inferior pulmonary ligament, periesophageal, and subcarinal lymph node stations (9, 8, and 7). Stations 2 and 4 are difficult to sample. The combination of EBUS-FNA and EUS-FNA can exceed 90% yield in obtaining a tissue diagnosis of lung cancer when it is present.

Mediastinoscopy involves surgical assessment of mediastinal lymph nodes for determination of tumor involvement. Cervical mediastinoscopy is the standard and allows sampling or removal of lymph node stations 2, 4, 7, and often 10. The complication rate is 2%, with few life-threatening complications. With video mediastinoscopy, sensitivity and specificity exceed 97%.

An anterior mediastinotomy (Chamberlain procedure) provides access to stations 5 and 6 (aortic and aortopulmonary window), generally not accessible with cervical mediastinoscopy. This is performed through an incision in the left second or third intercostal space or through excision of the second costal cartilage.

A biopsy is necessary to establish diagnosis and, in recent years, to conduct molecular studies that can further guide therapy. The most accessible site with the least invasive method is the preferred approach to obtaining diagnostic tissue. Whereas an FNA procedure is often adequate to establish diagnosis and can be accomplished by a transthoracic approach or by

bronchoscopy, the yield is often inadequate to conduct molecular studies. Therefore, a core needle biopsy to obtain sufficient tissue is recommended for patients with suspected lung cancer. For patients presenting with pleural or pericardial effusions, transthoracic aspiration of fluid is sufficient for diagnosis and staging. Cell blocks prepared from the fluid can be used to conduct molecular studies, although the success rate depends on the number of viable cancer cells in the specimen. The diagnostic yield of pleural fluid in patients with malignant effusion is approximately 50 to 70%. In instances in which repeated aspiration of pleural fluid is nondiagnostic, a video-assisted thoracoscopy procedure might be necessary to establish diagnosis. For patients with localized lung tumors that are suggestive of cancer, it is reasonable to proceed with surgical resection without a diagnostic biopsy if all other potential causes are excluded.

With the recent use of molecularly targeted therapies, understanding of the mechanisms of resistance is an important determinant of subsequent therapies. Therefore, it is recommended to obtain additional tumor biopsy specimens at various time points during the course of treatment.

Diagnostic Imaging

In conjunction with standard thoracic imaging procedures, additional sites of disease may require evaluation based on presenting complaints. The most common sites of lung cancer metastasis include contralateral lung, liver, adrenal gland, bones, and brain. Imaging of the brain is recommended to evaluate for metastasis in patients with suggestive symptoms and signs or those with lung adenocarcinoma larger than 3 cm and evidence of mediastinal nodal involvement. Magnetic resonance imaging (MRI) and CT scan with contrast enhancement are both acceptable modalities to evaluate for brain metastasis, although MRI is preferred for its superior sensitivity. Radionuclide study of the bones is indicated in patients with bone pain or an unexplained elevation in serum alkaline phosphatase level.

PET using [^{18}F]fluorodeoxyglucose (FDG) is included as part of staging in patients with localized lung cancer; however, the use of FDG-PET scan to assess response to anticancer therapy and in surveillance after curative therapy is controversial at this time and is not recommended. MRI scan of the chest may be useful in determination of invasion of surrounding structures, such as the brachial plexus, in patients with tumors involving the superior sulcus of the lung, but its use in staging is generally restricted to preoperative settings.

Solitary Pulmonary Nodule

The management of pulmonary nodules differs by whether they are solid (soft tissue attenuation) or subsolid (less than soft tissue attenuation without obscuring of the underlying lung architecture on CT). For larger nodules, CT characteristics suggestive of malignancy include irregular margins, spiculation, invasion of adjacent structures, lymphadenopathy, and distant metastases. Asymptomatic single pulmonary nodules less than 3 cm in diameter, the "solitary nodule," with normal surrounding lung architecture are found incidentally in up to 0.2% of chest radiographs; 10 to 70% are malignant. The potential for these lesions to be malignant increases with the patient's age, nodule size (< 4 mm vs. > 8 mm), growth rate, definite history of smoking, and size changes compared with prior imaging studies. PET scans may be helpful in defining abnormal mediastinal nodes in these patients. A pulmonary nodule that has not changed in size for more than 2 years is probably benign. For lesions larger than 8 mm, serial high-resolution CT scans are appropriate. Suspicious nodules should undergo definitive biopsy (see Fig. 191-2).

Staging

Stage is the most important determinant of prognosis in patients with lung cancer. The seventh edition of the *American Joint Committee on Cancer (AJCC) Cancer Staging Manual* is currently in use (Table 191-2). This staging system uses new T and M descriptors to determine lung cancer stage based on the TNM (tumor, node, and metastasis) profile of the patient. Individual T descriptors are defined on the basis of tumor size of less than 2, 2 to 3, 3 to 5, 5 to 7, and more than 7 cm. In the previous system, tumors were categorized on the basis of size of less than or more than 3 cm. Currently, satellite nodules in the same lobe as the primary tumor are categorized as T3 and nodules in another lobe of the ipsilateral lung as T4. Malignant pleural or pericardial effusion constitutes M1 disease. Presence of metastases within the thorax constitutes M1a and extrathoracic disease is classified as M1b because patients with M1a disease have a slightly better prognosis than those with M1b. Nodal descriptors were not changed from the previous system.

The TNM staging system is also now recommended for SCLC, given its ability to ascertain prognosis in a more accurate manner. SCLC was previously classified as limited or extensive stage on the basis of the ability to administer radiation therapy to the tumor with a single port. Treatment guidelines for localized SCLC have not been affected.

TABLE 191-2 TREATMENT BY AMERICAN JOINT COMMITTEE ON CANCER (AJCC) STAGE

	T	N	M	MEDICALLY FIT	MEDICALLY UNFIT
Stage IA	1	0	0	Surgery	SBRT
Stage IB	2	0	0	Surgery plus adjuvant chemotherapy if T ≥4 cm	SBRT plus chemotherapy at progression
Stage IIA/B	1-2	1	0	Surgery plus adjuvant concurrent chemoradiation	Thoracic radiation plus chemotherapy
Stage IIIA	X-3	2	0		Concurrent or sequential chemoradiation
	4	X	0		
Stage IIIB	X-4	3	0	Concurrent chemoradiation	
Stage IVA	X	X	1a	Chemotherapy (if *EGFR* mutation, treat with EGFR TKI)	
Stage IVB	X	X	1b	Chemotherapy (if *EGFR* mutation, treat with EGFR TKI); radiation for palliation	

T = tumor; N = node; M = metastasis; SBRT = stereotactic body radiation therapy; EGFR = epidermal growth factor receptor; TKI = tyrosine kinase inhibitor. (From AJCC Cancer Staging Manual. 7th ed. New York: Springer-Verlag; 2018)

TREATMENT

Non–Small Cell Lung Cancer

Surgery

Surgical management plays the major role in the treatment of patients with stage I, stage II, and selected stage III NSCLC. However, nearly 40% of patients with early-stage lung cancer are not candidates for surgery because of limiting comorbid conditions. The commonly used parameters for inoperability include pulmonary functions with baseline forced expiratory volume in the first second of expiration (FEV_1) of less than 40%, predicted postoperative FEV_1 of less than 30%, and severely limited diffusion capacity. Such patients are referred to as medically inoperable despite the presence of localized disease and may be candidates for SBRT, as discussed later.

The first step in managing localized lung cancer is to stage the mediastinal lymph nodes. For peripheral tumors that are not associated with mediastinal adenopathy and do not have FDG uptake in the nodes, many surgeons advocate proceeding with surgical resection and sampling mediastinal nodes intraoperatively. However, for patients with nodes that are positive on PET scan, sampling is strongly recommended before surgery. The false-positive rate for PET scan in the mediastinum for patients with localized lung cancer is approximately 20%. The likelihood of nodal involvement in patients with negative PET scan is approximately 5 to 15%.

Lobectomy is the standard surgical procedure for patients with localized lung cancer who are medically fit.[7] If anatomic resection cannot be achieved with lobectomy, bilobectomy or pneumonectomy might be necessary. Sleeve resection refers to removal of the tumor along with the bronchus and anastomosis of the remaining ends of the bronchial tree. Surgical resection can be achieved by performing an open thoracotomy or by video-assisted thoracic surgery (VATS). VATS is gaining wider use because of lower morbidity, faster recovery from surgery, and better ability to administer postoperative systemic therapy. The ability to achieve an R0 resection is critical, and surgery should not be attempted if this is not deemed feasible during preoperative work-up. For patients with positive surgical margins, re-resection should be attempted whenever it is feasible. If not, postoperative radiation therapy should be administered. Robotic resection of lung cancers, including robotic lobectomy and pneumonectomy, has increased in use but is not as widely employed as VATS approaches.

Sublobar resections are not recommended because of the higher risk of local recurrence. An exception to this rule is for patients with peripheral tumors smaller than 2 cm, for which studies have demonstrated excellent outcomes. An ongoing study is comparing sublobar resection to standard lobectomy and will likely provide definitive answers to this important question.

A randomized comparison of mediastinal lymph node dissection to nodal sampling demonstrated comparable outcomes for patients with NSCLC. Another study compared sublobar resection followed by placement of ^{125}I brachytherapy to the tumor bed with surgery alone in patients who are not candidates for standard lobectomy. There was no difference in overall survival between the two groups, and therefore the brachytherapy approach is not recommended. Tumors involving the superior sulcus are managed with preoperative chemoradiotherapy to enhance tumor resection and to gain local and distant tumor control. The decision to perform surgery for these anatomically challenging tumors depends on the extent of local invasion, involvement of the brachial plexus, and mediastinal lymph node involvement.

The role of surgery in the management of stage III NSCLC with mediastinal nodal involvement continues to be controversial. Surgery alone is associated with a poor outcome. In a randomized study, patients with N2-positive disease who underwent chemoradiotherapy followed by surgery did not have improved survival compared with chemoradiotherapy alone and had an unacceptably high rate (almost 30%) of postoperative mortality. Therefore, trimodality therapy is not recommended for patients who require pneumonectomy. For patients with multistation N2 disease or bulky nodal disease, surgical resection is not recommended. Clearance of mediastinal nodes after induction therapy might be the most important predictor of benefit from surgical resection, which calls for restaging of the mediastinum after induction therapy if surgery is contemplated.

The role of surgery in patients with oligometastatic disease can be considered under certain situations. Surgical resection of both the primary and a solitary brain metastasis has resulted in 5-year survival rates of approximately 20%. There are also limited data with oligometastatic disease to the adrenal glands, but similar approaches with solitary metastasis at other distant sites are not recommended. This approach cannot be recommended for patients with mediastinal nodal involvement.

Radiation Therapy

Radiation therapy is an important part of multimodality therapy for NSCLC. It plays a major role in curative therapy for stage III disease and palliation of stage IV disease and has been successfully tested for patients with medically unresectable stage I disease. Significant improvements in the delivery of radiation therapy in the past two decades allow use of smaller radiation field size, reducing exposure of normal tissue to radiation and facilitating more effective treatment of tumor. Respiratory gating techniques allow the delivery of radiation therapy to the tumor regardless of the phase of respiration. SBRT involves the delivery of high-dose radiation to a limited tumor volume after stereotactic localization.

Stage I and Stage II NSCLC

SBRT[8] has emerged as an effective treatment option for patients with T1 and T2 tumors who are node negative but are medically inoperable because of comorbid illness. In one study, delivery of SBRT over three to five fractions resulted in nearly 90% local control rate, prompting studies of SBRT in medically fit patients and in combination with systemic therapy for early-stage NSCLC. SBRT has shown considerable efficacy for peripheral tumors; studies are ongoing to examine its use in centrally located tumors.

Radiation therapy is indicated for patients with positive surgical margins after surgery for early-stage NSCLC but not for those with negative surgical margins. A meta-analysis reported a detrimental effect for patients treated with postoperative radiation therapy, especially for those with N0 and N1 disease. Patients with involved mediastinal nodes (or N2 disease) demonstrated favorable survival with radiation therapy. This has also been observed in an analysis of the U.S. Surveillance, Epidemiology and End Results (SEER) database. A prospective study is under way in Europe to compare postoperative radiation therapy with observation in patients with surgically resected N2 disease.

Stage III NSCLC

Whereas surgery is appropriate for patients with T3N1 disease, administration of radiation therapy results in improved outcomes for patients with involvement of the mediastinal lymph nodes. A subset of N2-positive patients might benefit from multimodality therapy involving neoadjuvant chemoradiation followed by surgical resection, including stage IIIA patients with single-station or microscopic lymph node involvement and disease amenable to resection with lobectomy or bilobectomy. Preoperative radiation consists of 45 Gy once daily, and a dose of 60 Gy has been piloted with acceptable safety results.

For patients with stage III disease that is not appropriate for surgical resection, thoracic radiation therapy to a dose of 60 to 66 Gy in once-daily fractions with concurrent (rather than sequential) chemotherapy is the recommended treatment. This category includes patients with bulky mediastinal disease, involvement of contralateral or supraclavicular nodes (N3), and direct invasion of major structures such as the vertebrae, trachea, major blood vessel, or esophagus by the primary tumor (T4). A 5-year survival rate of 20 to 25% has been reported with combined chemoradiotherapy in this setting. The main adverse events include esophagitis and pneumonitis, the latter depending on the extent of normal lung tissue and the dose of radiation received by normal lung tissue. Radiation-related pneumonitis can occur immediately after radiation therapy or after 6 to 9 months.

Several efforts to improve on standard chemoradiotherapy have been undertaken in the past two decades. Hyperfractionated radiation therapy with administration of two or three fractions per day has demonstrated favorable results over once-daily fractionation, particularly in squamous cell carcinoma. However, logistical constraints have limited the adoption of this approach. Single-arm studies showed the use of higher doses of up to 74 Gy in once-daily fractions to be a promising approach. However, randomized studies have failed to show benefit to dose escalation to 70 Gy or higher in this population of patients. Therefore, 60 to 66 Gy remains the standard radiation dose for stage III NSCLC.

Stage IV NSCLC

In patients with advanced-stage NSCLC, radiation therapy can be effective for palliation of spinal cord compression, brain metastasis, airway obstruction, hemoptysis, and pain.

Spinal cord compression is an emergency situation, and neurosurgical evaluation should be initiated to assess whether surgery is advised, which can be the case when there is a large tumor burden and rapidly deteriorating motor and sensory function. Surgical decompression is used when neurologic compromise is early and the patient has well-controlled systemic disease and it is followed by radiation therapy. Spinal cord compression is usually managed with external beam radiation therapy to 30 Gy and corticosteroids. For brain metastases, resection of oligometastatic disease has been associated with better outcomes. Whole brain radiation therapy of 30 to 37.5 Gy given in 10 to 15 fractions can be administered when multiple metastases are present. Stereotactic radiosurgery can be used instead of whole brain radiation therapy for patients with low-volume brain metastasis limited to one to three lesions and brain lesions that progress after whole brain radiation therapy. Pain control in sites of bone metastasis or chest wall involvement can be achieved by a short course of radiation therapy. Palliative radiation therapy is also administered to 30 to 45 Gy during 2 to 3 weeks before the initiation of systemic therapy in patients with systemic disease who present with hemoptysis or postobstructive pneumonia.

Systemic Therapy

Systemic therapy refers to the use of cytotoxic or molecularly targeted agent therapy or both. Although it was initially developed for patients with advanced-stage lung cancer, the high propensity for metastasis of lung cancer cells has extended the use of systemic therapy to patients with earlier stages of the disease. A number of effective and well-tolerated cytotoxic agents have been developed during the past three decades that are used for the routine care of patients with lung cancer. In addition, many targeted agents are under clinical investigation; six are currently approved for use in NSCLC (Table 191-3): the EGFR TKIs erlotinib, gefitinib, and afatinib; the vascular endothelial growth factor (VEGF) monoclonal antibody bevacizumab; and crizotinib, an inhibitor of MET, ALK, and ROS1 tyrosine kinases.

Systemic Therapy in Early-Stage NSCLC

Even in the setting of optimal surgery, patients with early-stage NSCLC remain at high risk for disease recurrence or metastases due to the presence of micrometastasis, which can increasingly be quantified by the evaluation of circulating tumor cells or circulating tumor DNA. A consistent benefit of 5 to 15% in 5-year survival rate observed across multiple trials has resulted in the adoption of four cycles of adjuvant cisplatin-based two-drug combination regimens as the standard of care for stage II and stage IIIA NSCLC. In stage IA disease, however, the potential benefits of chemotherapy are largely outweighed by the risks, and there is an overall detrimental effect. For patients with stage IB disease, post hoc analyses have revealed that improvement in survival with adjuvant therapy was restricted to patients with tumors larger than 4 cm, but this observation has yet to be validated in prospective trials.

Whereas cisplatin-vinorelbine has been the most commonly used combination in clinical trials of adjuvant therapy, the use of newer, better tolerated agents effective in the treatment of advanced NSCLC, such as taxanes, gemcitabine, and pemetrexed, is increasing. It is hoped that the future use of adjuvant chemotherapy may be tailored to patients at high risk for recurrence, based on genomic or proteomic markers, with circulating tumor cells or circulating tumor DNA among the most promising tools at present.[9]

Locally Advanced NSCLC

For patients with stage III disease that is not amenable to surgical resection, concomitant administration of chemotherapy with radiation therapy has

TABLE 191-3 TARGETED AGENTS IN LUNG CANCER THERAPY

MOLECULAR TARGET	FDA-APPROVED AGENTS	INVESTIGATIONAL AGENT
EGFR	Erlotinib Gefitinib Afatinib	Dacomitinib Cetuximab

FDA = Food and Drug Administration.

consistently demonstrated efficacy superior to that of sequential therapy. Both cisplatin- and carboplatin-based regimens are associated with meaningful survival results but have not been compared in this setting. The combination of cisplatin and etoposide allows administration of full systemic dose of chemotherapy with radiation therapy. The carboplatin and paclitaxel regimen involves administration of lower "radiosensitizing" doses of the two agents with radiation therapy followed by consolidation therapy with two cycles at regular doses. This approach has a favorable tolerability profile compared with cisplatin-based regimens. The use of induction or consolidation chemotherapy in other settings has not resulted in improved survival. With modern combined chemoradiotherapy, cure rates of nearly 20 to 25% are achieved in locally advanced NSCLC, with esophagitis and pneumonitis being the main toxicities.

Several systemic targeted agents, including cetuximab (a monoclonal antibody against EGFR), bevacizumab (a monoclonal antibody against VEGF), and ALK inhibitors, are under evaluation for the treatment of stage III disease. Ongoing studies continue to evaluate the role of EGFR TKIs in patients with activating *EGFR* mutations and locally advanced disease.

Advanced-Stage NSCLC

In patients with advanced-stage NSCLC, randomized trials have shown platinum-based systemic therapy to improve overall survival and quality of life compared with supportive care alone. Cisplatin treatment is associated with nausea, emesis, nephrotoxicity, and neurotoxicity, although the availability of highly effective antiemetic agents has greatly improved its tolerability. Carboplatin is a better tolerated alternative to cisplatin and is associated with ease of outpatient administration. The dose-limiting toxicity of carboplatin is thrombocytopenia. Two-drug combination regimens have proved superior to monotherapy with cisplatin alone or a nonplatinum compound, leading to the adoption of combination chemotherapy as the recommended treatment of advanced NSCLC.

A meta-analysis of randomized trials compared the efficacy of cisplatin to carboplatin in advanced-stage NSCLC and demonstrated comparable survival but a numerically higher incidence of treatment-related deaths with cisplatin-based regimens. Although cisplatin-based regimens have a narrow efficacy advantage, carboplatin-based regimens have found wider adoption because of their favorable therapeutic index.

A number of partner agents for platinum have demonstrated similar efficacy in advanced NSCLC in randomized trials, including etoposide, vinblastine, vindesine, vinorelbine, taxanes, gemcitabine, irinotecan, and pemetrexed. On the basis of several randomized studies, the choice of chemotherapy agent for frontline treatment is made on consideration of toxicity, preference of the patient, schedule, and cost. Recent trials involving superior supportive care have shown median survival for combinations of cisplatin with docetaxel, gemcitabine, or pemetrexed in the 10- to 11-month range. Combinations of three cytotoxic agents are not recommended because of a higher toxicity burden and lack of meaningful incremental benefit.

In randomized studies of patients with an activating *EGFR* mutation, treatment with gefitinib or erlotinib has been associated with improvements in progression-free survival and quality of life over platinum-based chemotherapy. This did not translate into a survival benefit because the majority of patients treated with chemotherapy were subsequently crossed over to receive an EGFR inhibitor on disease progression. The importance of molecular testing before initiation of EGFR inhibitor therapy in first-line treatment is highlighted by the inferior outcomes in wild-type patients treated with targeted therapy.[■] Afatinib, an irreversible EGFR TKI, has recently demonstrated superiority over chemotherapy in patients with an activating *EGFR* mutation, leading to its approval in this setting.

Initial studies of the VEGF antibody bevacizumab for first-line therapy for advanced NSCLC were promising, although squamous histology was associated with a higher incidence of life-threatening hemoptysis. Further studies limited to patients with nonsquamous histology demonstrated a significant improvement in overall survival and progression-free survival with the addition of bevacizumab to carboplatin and paclitaxel chemotherapy, leading to the Food and Drug Administration approval of bevacizumab in this setting. Notable adverse events included bleeding, hypertension, proteinuria, and neutropenia.

The MET, ALK, and ROS1 TKI crizotinib demonstrated a response rate of nearly 60% and a clinical benefit rate of 90% in patients with ALK-positive advanced-stage NSCLC, with a median progression-free survival of 10 months.[■] Accordingly, crizotinib is approved in this setting in the United States and Europe. The second-generation ALK inhibitor ceritinib also is useful and approved for the treatment of patients with ALK-positive metastatic NSCLC with disease progression or intolerance to crizotinib.[■]

Role of Histology in Choice of Chemotherapy

Until recently, chemotherapy regimens were considered to be suitable for all histologic subtypes of NSCLC. This notion was dispelled in a randomized phase III study demonstrating superior survival for patients with nonsquamous advanced-stage NSCLC treated with cisplatin-pemetrexed and superior survival for patients with squamous histology receiving cisplatin-gemcitabine. Nanoparticle albumin-bound paclitaxel (nab-paclitaxel) is associated with a favorable response rate in patients with advanced NSCLC, which is restricted to patients with squamous histology. The biologic basis for the histologically specific therapeutic activity of these drugs is not presently known; however, the variable efficacy of pemetrexed and nab-paclitaxel based on histology should be considered when chemotherapy is selected for first-line treatment of advanced NSCLC.

Maintenance Therapy

In the first-line treatment of advanced-stage NSCLC, continuation of combination, multi–cytotoxic drug treatment beyond four to six cycles is associated with cumulative toxicities but no tangible benefit. Recently, single-agent maintenance therapy has proved to be useful in patients who have a demonstrated clinical benefit from four cycles of platinum-based combination chemotherapy. Current therapeutic strategies employ either a "switch maintenance" approach, which uses an alternative cytotoxic or targeted agent that has not been previously administered, or "continuation maintenance," which involves continuing the nonplatinum agent beyond four cycles.

Pemetrexed is the only cytotoxic agent that provides a survival advantage as maintenance therapy in advanced NSCLC. It has demonstrated similar benefit in both continuation and switch maintenance strategies in randomized trials for patients with advanced nonsquamous histology and has thus been approved for maintenance therapy in the United States and Europe. The EGFR TKI erlotinib also extends survival when it is used as maintenance therapy in patients who have experienced stable disease with a platinum-based combination for four cycles, with greater benefit in patients with an activating *EGFR* mutation. The use of bevacizumab maintenance has been adopted for patients who receive it as part of their initial treatment regimen because all pivotal randomized trials performed with bevacizumab used it as maintenance therapy after six cycles of combination treatment.

Docetaxel, pemetrexed, and erlotinib are also efficacious when they are used as salvage therapy for patients with advanced NSCLC who experience disease progression during or after platinum-based chemotherapy. Therefore, the relative merits of using the last two agents as maintenance therapy versus use after disease progression has become controversial. Careful discussion with patients with nonsquamous lung cancers who have responded to frontline chemotherapy regarding the value of maintenance therapy versus close observation is recommended.

Salvage Therapy

Virtually all patients with advanced NSCLC will eventually experience disease progression regardless of the extent of benefit from first-line chemotherapy. Salvage therapy for these patients provides a modest but real improvement in survival. Docetaxel, at a dose of 75 mg/m^2 every 3 weeks, was the first agent proven in this setting to improve survival compared with best supportive care or first-generation cytotoxic agents. Pemetrexed has efficacy as salvage therapy similar to that of docetaxel and a more favorable toxicity profile, but its use is restricted to patients with nonsquamous histology. Targeted therapy with erlotinib has also been demonstrated to enhance survival and progression-free survival in the salvage setting. Overall, the presently available salvage therapy options are associated with response rates of less than 10%, with a median progression-free survival of 3 months and overall survival of 8 months.

Crizotinib significantly improves progression-free survival and response rate compared with chemotherapy in the salvage setting for patients whose tumors exhibit an *ALK* rearrangement. The use of bevacizumab as salvage therapy for NSCLC is currently being examined in ongoing clinical trials. Combinations of cytotoxic or targeted agents for salvage therapy have not resulted in improved survival, and these are therefore not recommended.

Investigational Targeted Agents

The use of targeted therapies has gained considerable momentum in recent years, and many investigational targeted agents are in preclinical and clinical development. The irreversible EGFR inhibitor dacomitinib demonstrated a favorable efficacy profile compared with erlotinib in a randomized phase II study in an unselected population of patients and is presently being evaluated in phase III trials. Several new agents and combinations are under study for managing resistance to EGFR TKIs. Cetuximab, a monoclonal antibody against EGFR, produces a modest improvement in overall survival when it is combined with cisplatin and vinorelbine for first-line treatment of advanced NSCLC. The identification of predictive biomarkers to select patients is necessary for the use of this combination in routine care.

LDK378, a potent ALK inhibitor, produced a response rate of 60% in patients who developed disease progression during crizotinib therapy. Other novel ALK inhibitors are also under development for management of crizotinib resistance or as primary therapy. Heat shock protein 90 (HSP90) plays a critical chaperone function for ALK, and HSP90 inhibitors have recently been found to possess single-agent activity in this subgroup of patients.

Besides the VEGF monoclonal antibody bevacizumab, other strategies to inhibit angiogenesis, including small-molecule VEGF TKIs and vascular disrupting agents, have not been successful to date in advanced NSCLC. Efforts

to identify biomarkers to predict benefit with bevacizumab and other antiangiogenic agents have also been unsuccessful and have consequently restricted optimal use of these agents.

Advances in genomic technology have made it possible to prospectively identify novel mutations that play a critical role in the growth of lung cancers. In adenocarcinoma, a fusion gene involving *ROS1*, observed in 1% of patients, also confers sensitivity to treatment with crizotinib. Another fusion involving the *RET* gene has been identified in 0.5 to 1% of patients. Patients with mutations in *BRAF* appear to respond to therapy with dabrafenib, a BRAF inhibitor. Recent DNA sequencing data from the Cancer Genome Atlas project in a cohort of patients with squamous cell lung carcinoma, together with the efforts of the Lung Cancer Mutation Consortium, have demonstrated several novel, potentially targetable mutations in this disease. Routine testing of tumor specimens of patients for molecular targets is increasingly seen as a strategy to personalize treatment options for lung cancer.

Management of Special Populations of Patients

Elderly patients represent a growing subset of lung cancer patients. In the United States, the median age at diagnosis of lung cancer is 70 years. Aging is associated with declines in physiologic and vital organ function that affect a patient's tolerance for systemic therapy, making current physical function and prospective quality of life considerations important factors in the choice of systemic treatment. Single-agent chemotherapy has a demonstrated survival benefit compared with supportive care in elderly patients; and for those with good performance status, platinum-based combinations are superior to single-agent therapy. The appropriate use of targeted agents may have clinical benefit in the elderly. The addition of bevacizumab to chemotherapy for nonsquamous cancers in older patients is, however, associated with a narrow therapeutic index and is recommended only with great caution.

A substantial percentage of NSCLC patients present with reduced performance status, which limits their ability to tolerate combination chemotherapy. The median survival for advanced NSCLC patients with a performance status of 2 or worse (Eastern Cooperative Oncology Group scale) is dismal at less than 4 months; however, studies conducted exclusively in patients with a poor performance status indicate that chemotherapy may be beneficial for highly selected patients. It is important to consider the underlying cause of poor performance status in making treatment plans for this population of patients. For those with limiting comorbid conditions, a less aggressive approach with single-agent chemotherapy might be more appropriate. For those with a targetable mutation, appropriate targeted therapy can be administered regardless of the performance status in view of the greater potential for benefit.

Small Cell Lung Cancer

SCLC is characterized by enhanced initial sensitivity to systemic chemotherapy, although disease recurrence is common regardless of the extent of initial response. Approximately two thirds of patients present with extensive-stage SCLC, defined as the presence of metastatic disease outside the chest or large-volume thoracic disease that cannot be treated with radiation therapy. The median survival of untreated extensive-stage SCLC is less than 2 months, and the overall goal of treatment is palliation. The use of platinum-based chemotherapy results in response rates of 50 to 70% and median survival of 9 to 11 months. The regimen of four to six cycles of cisplatin and etoposide is considered the standard approach for the treatment of SCLC, extending to six cycles in responding patients, with no proven role for maintenance therapy. Carboplatin is considered an acceptable alternative in the treatment of extensive-stage disease. Despite the extent of initial response, disease recurrence develops in a median of 4 to 6 months. Disease that progresses during or within 90 days of administration of cisplatin-based chemotherapy is referred to as refractory relapse. Recurrence outside this time window represents a "sensitive" subgroup that might benefit from salvage treatment. Other approaches, such as high-dose chemotherapy, alternating chemotherapy regimens, dose-dense therapy, and three-drug combination regimens, have been unsuccessful in improving survival. In the Japanese population but not in Western patients, the regimen of cisplatin and irinotecan has demonstrated superior results over cisplatin and etoposide.

Salvage therapy has yielded only modest results in sensitive relapsed SCLC. Topotecan is the only agent to demonstrate clinical benefit in relapsed SCLC, with a response rate of 20% and a favorable symptom improvement profile but no improvement in overall survival in randomized studies. Several novel agents, including molecularly targeted agents against known targets, are presently being studied in efforts to improve the outcomes for patients with SCLC.

For patients with limited-stage SCLC, radiation therapy is used in combination with chemotherapy and can achieve cure for approximately 20 to 30% of patients. Earlier initiation of radiation therapy appears superior to a delayed approach and has been adopted as the standard in fit patients. A randomized study demonstrated superior survival of twice-daily radiation therapy fractions compared with the same dose given once daily along with concomitant chemotherapy, and this is being further evaluated in an ongoing trial.

Prophylactic cranial irradiation is associated with a modest improvement in 5-year survival for patients with limited-stage SCLC who achieve complete remission after combined modality therapy. This is due to the high risk of brain recurrence observed in patients with SCLC. Similarly, studies have demonstrated that prophylactic cranial irradiation results in modest improvement in overall survival and reduced risk of brain recurrence in patients with extensive-stage disease who achieve a favorable response to combination chemotherapy.

The role of surgery is limited to the less than 5% of SCLC patients presenting with peripheral lung lesions without mediastinal nodal involvement. In 10 to 15% of patients with SCLC, a mixed histology with NSCLC features is observed. These patients may demonstrate local progression after combined modality therapy resulting from the NSCLC component. Therefore, these individuals could be considered for surgical resection in selected situations.

Treatment advances in SCLC have, unfortunately, lagged behind those for NSCLC during the past two decades; consequently, survival outcomes for SCLC have not changed considerably. Concerted efforts to develop appropriate preclinical models to test new agents, genomic subcategorization of SCLC, and discovery of new systemic anticancer agents are necessary to improve outcomes for this aggressive disease.

SURVIVORSHIP AND SURVEILLANCE

As outcomes for lung cancer have improved in recent years, with a concomitant increase in the number of survivors after surgery or chemoradiotherapy, an important part of lung cancer care has become defining the optimal surveillance, follow-up for second primary disease, and management of long-term consequences of chemoradiotherapy. The importance of smoking cessation cannot be overemphasized, given the high risk of enhanced complications of chemotherapy and the higher incidence of second primary tumors in lung cancer survivors. Patients should be provided with appropriate opportunities to receive counseling and behavioral therapy and other treatment modalities to assist their efforts to discontinue smoking (Chapter 32).

At present, there is no standard approach to optimal radiographic and clinical follow-up in patients who undergo surgical resection or chemoradiotherapy. CT scans are commonly used for follow-up of these patients. However, the relative merits of CT scan versus chest radiography, the frequency of evaluation, and the role of FDG-PET scans are unclear and will be answered only by prospective clinical trials. For patients with advanced-stage disease, CT scans are used to assess response to therapy every two or three cycles of treatment. In view of the proven role for salvage therapy, patients who are in follow-up after combination chemotherapy should be closely observed for development of new symptoms or clinical deterioration in addition to periodic radiographic studies.

Respiratory therapy should be offered and strongly recommended to patients with dyspnea after surgery or chemoradiotherapy. Because a high proportion of these patients also have smoking-related pulmonary diseases, referral to a pulmonologist should be considered in symptomatic patients. Overall, a team approach that includes supportive care personnel, oncologic psychiatrists, nutritionists, oncologists, and appropriate additional specialists should be used to ensure the return of lung cancer survivors to normalcy to the fullest extent possible.

SUPPORTIVE CARE

Patients with lung cancer have a cure rate of only 16%, even in the most advanced Western health systems, because the majority of patients present with locally advanced or metastatic disease. Early discussion and institution of palliative and supportive care are therefore critical for the patient to ensure maximal quality of life. Studies indicate that early integration of supportive care helps maintain and improve quality of life, with one randomized trial finding that the addition of early palliative care to chemotherapy for patients with advanced disease can produce a meaningful impact on overall survival,[■] a surprising but reaffirming finding.

EARLY DETECTION AND PREVENTION

Decades of research into the screening of high-risk individuals for earlier detection of lung cancer have recently met with success.[10] The NLST randomized more than 50,000 subjects between 55 and 74 years of age with a history of cigarette smoking of at least 30 pack-years to screening with low-dose CT scan or chest radiographs at baseline and 1 and 2 years after enrollment. The rate of adherence to scans was more than 90% in both arms. Positive results were observed in nearly 25% and 7% of subjects with CT screening and chest radiograph, respectively. Among patients with a positive CT scan, 96.4% were deemed false positive after additional evaluation. Adverse events were uncommon. Screening with annual low-dose CT scans in high-risk

individuals was associated with a reduction of 20% in lung cancer mortality and 6.7% in all-cause mortality. Nearly 80% of patients diagnosed with lung cancer with low-dose CT had stage I, II, or IIIA disease amenable to curative therapy. Subsequent analysis of the NLST data showed that screening with low-dose CT prevented the greatest number of deaths from lung cancer among participants who were at highest risk and prevented very few deaths among those at lowest risk. These results have led to the adoption of low-dose CT for early detection of lung cancer by major health organizations including the U.S. Preventive Services Task Force.[11,12] For lung nodules detected on low-dose CT screening, it has been shown that predictive tools based on patient and nodule characteristics can be used to accurately estimate the probability that they are malignant.[13]

Primary prevention of lung cancer focuses on ways to prevent individuals from smoking and promotion of smoking cessation, which remain the most effective means to prevent lung cancer. Smoking cessation efforts are often sporadic; but most studies indicate that patients who successfully quit smoking benefit from pharmacologic, psychological, and physician support.

Trials of supplemental β-carotene and vitamin E, stimulated by epidemiologic evidence of lower serum levels of these antioxidants in patients with lung cancer, not only have been unsuccessful but actually produced a higher risk of lung cancer in smokers. High concentrations of selenium in the blood are associated with a lower risk of lung cancer, but a phase III trial in patients with resected stage I lung cancer failed to show any benefit for selenium supplementation. These and other trials have indicated that lung cancer patients who continue to smoke have the highest incidence of recurrence and second primary tumor development.

OTHER PULMONARY NEOPLASMS

Malignant Mesothelioma

Malignant pleural mesotheliomas[14] are generally related to asbestos exposure, with a peak risk for development of the disease 30 to 35 years after the initial exposure. Additional possible risk factors include radiation and SV40 virus. Mesothelioma is generally diagnosed in the fifth to seventh decade of life (median age, 60 years), with a male-to-female preponderance of 5 : 1. Common symptoms include dyspnea (60%) and chest wall pain or discomfort (60%). Chest radiographs usually reveal the presence of a unilateral pleural effusion. Tumor progression and symptoms are generally the result of local progression, with symptomatic distant metastases a late occurrence. Cytologic evaluation of pleural fluid to establish diagnosis is difficult and often inaccurate. The diagnosis is generally made by a biopsy procedure under CT guidance or thoracoscopically, including VATS if necessary. Several staging systems have been proposed, but none has achieved complete acceptance. Treatment, depending on the extent of disease, includes surgery (thoracoscopy with sclerosis, pleurectomy, extrapleural pneumonectomy), radiation therapy, and, often, chemotherapy. These three modalities individually have not significantly improved survival rates, and chemotherapy or radiation therapy does not provide long-term palliation or relief of symptoms. Combination chemotherapy with pemetrexed and cisplatin is associated with symptomatic relief in patients with advanced, unresectable malignant mesothelioma and with a significant response rate in advanced disease. It is occasionally used as preoperative or induction chemotherapy before extrapleural pneumonectomy followed by radiation therapy. Multimodality and molecularly targeted agents are being evaluated. Mesothelioma unfortunately remains a nearly universally fatal illness, with a median survival of less than 12 months from the time of diagnosis.

Neuroendocrine and Other Lung Tumors

Neuroendocrine lung tumors are classified into four types: carcinoid tumors, atypical carcinoids, SCLC, and large cell neuroendocrine carcinomas. *Carcinoid tumors* (Chapter 232) are low-grade neuroendocrine tumors with a 10-year survival rate greater than 90%. Atypical carcinoid tumors are intermediate-grade tumors, significantly more aggressive than carcinoid, with 10-year survival of below 20%. *Large cell neuroendocrine carcinoma* is an aggressive neuroendocrine tumor that does not meet the criteria for carcinoid, atypical carcinoid, or SCLC. Considerable activity for everolimus and other inhibitors of the mammalian target of rapamycin (mTOR) has been demonstrated in low-grade carcinoid tumors.

Carcinoid tumors of the lung account for 1 to 2% of all lung neoplasms. These neuroendocrine tumors trace their origin to the Kulchitsky cell present in bronchial epithelium. Typical and atypical carcinoids differ in the number of mitoses (<2 per 10 high-power fields vs. 2 to 10 per 10 high-power fields, respectively), nuclear pleomorphism (absent vs. present), and regional lymph node metastases (5 to 15% vs. 20 to 28%). Distant metastases at initial evaluation are rare (<20%). Patients with typical carcinoid tumors usually live for many years, whereas patients with atypical carcinoid tumors have a 5-year mortality rate of 61 to 88%. Carcinoid tumors are not associated with cigarette smoking, are twice as common in women as in men, usually occur in patients younger than 40 years, and arise in the perihilar area of the lung. Treatment of bronchial carcinoid tumors is based on the stage of the disease. Mediastinal staging is usually followed by surgical resection. With mediastinal lymph node involvement, radiation therapy is recommended for typical carcinoid tumors if surgery cannot be performed. For atypical carcinoid or metastatic disease, chemotherapy (etoposide plus cisplatin every 3 weeks for four cycles) plus radiation therapy is commonly used, but there is no evidence for the benefit of one therapy over another.

Salivary gland carcinomas include mucoepidermoid carcinoma and adenoid cystic carcinoma, which represent approximately 0.2% of lung cancers. These slow-growing neoplasms arise from the bronchial glands and are usually treated with surgery.

Primary sarcomas of the lung are very rare and include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, epithelioid hemangioendothelioma, angiosarcoma, and liposarcoma (Chapter 202). The primary treatment is surgery, but depending on the size and grade of the tumor and whether the margins are clear, radiation therapy or chemotherapy may also be given. Primary lymphomas of the lung are also very rare, accounting for approximately 0.3% of all primary lung cancers. The most common type is a low-grade small lymphocytic lymphoma, for which surgery and chemotherapy are the usual treatments (Chapter 185).

REVIEW QUESTIONS

1. Which of the following individuals should not consider computed tomography (CT) screening for lung cancer because of an absence of increased risk?

A. Individuals who are older than 55 years and have at least 35 pack-years of smoking cigarettes
B. A woman with a heavy smoking history (more than 50 pack-years) and evidence for emphysema/chronic obstructive pulmonary disease
C. A former smoker who is 70 years old with a 60 pack-year history but who quit smoking 5 years ago
D. A patient with a prior history of laryngeal cancer treated by chemotherapy and radiation therapy, with a 40 pack-year history, who is down to one or two cigarettes per day
E. A 35-year-old man whose father died of lung cancer after a long smoking history

Answer: E There is no evidence that nonsmoking individuals who have family histories of lung cancer, particularly lung cancer that is attributable to smoking, will benefit by being screened with CT scans. The best evidence to date for the utility of CT screening is for individuals older than 55 years with at least a 30 to 35 pack-year smoking history. These individuals are more likely to have a nodule detected by CT scan than by chest radiography, as shown by the NLST study. Thus, individuals A, B, C, and D, all of whom are older than 55 years and have at least a 30 to 35 pack-year smoking history, are at increased risk for lung cancer, and all could potentially benefit from screening with CT scan.

2. Which of the following is most consistent with a tissue diagnosis of a lung adenocarcinoma?

A. TTF-1 positive, CK7 positive, EGFR driver mutation, and CK20 negative and p63 negative
B. TTF-1 negative, p63 positive, p40 positive, FGFR amplification, and EGFR wild type
C. Synaptophysin and chromogranin positive, p53 mutation and Rb mutation
D. Tumor positive for vimentin and melanin, negative for TTF-1 and for all cytokeratins
E. CD20 positive, negative for TTF-1 and for all cytokeratins

Answer: A Patients with lung adenocarcinoma are likely to have a TTF-1–positive tumor, with CK7 expressed. CK20 is more commonly expressed in colorectal cancers than in lung tumors. The fact that p63 is negative in this case makes this less likely to be a squamous cell carcinoma. The clearest indicator here is that the patient has an EGFR driver mutation. Mutations in exons 19 or 21 of EGFR are pathognomonic for lung adenocarcinoma, particularly in never-smokers. The other three cases are all less likely to be adenocarcinomas. Case B is p63 positive, which makes it more likely to be squamous cell cancer, and all the other features, including being p40 positive and FGFR amplification, are more frequently seen in squamous cell cancers. EGFR is mutated almost exclusively in lung adenocarcinomas as opposed to squamous cell carcinomas, although the fact that this case B is wild type does not make it less likely to be an adenocarcinoma. Case C is more likely to be a small cell carcinoma, as synaptophysin and chromogranin are positive for neuroendocrine tumors, and the combination of the p53 and Rb mutations makes this likely to be a small cell lung cancer. In case D, the tumor is positive for vimentin and melanin and negative for TTF-1 and all cytokeratins; this is not an epithelial tumor and is likely to be a melanoma or poorly differentiated sarcoma. The tumor in E that is CD20 positive is likely to be a lymphoma, and this is again negative for cytokeratins that are expressed on epithelial tumors as well as for TTF-1, which would make this highly unlikely to be an epithelial tumor in general and a lung cancer in particular.

3. A 63-year-old woman with a heavy smoking history presents with a diagnosis of a squamous cell lung cancer, staged radiographically as T3N2M0. She has been referred to a thoracic surgeon who is planning to perform a mediastinoscopy. If the mediastinoscopy confirms the presence of tumor cells in her mediastinal lymph nodes, the best recommendation for the multidisciplinary clinic is

A. Surgical resection of her tumor by a pneumonectomy and clearing of her mediastinum followed by radiation therapy to any positive margins
B. Induction or preoperative chemotherapy followed by radiation therapy followed by surgery
C. Concurrent chemotherapy and radiation therapy
D. Induction chemotherapy followed by radiation therapy
E. Palliative chemotherapy followed by hospice referral

Answer: C This is the presentation of a patient with stage 3A non–small cell lung cancer. A patient such as this with a good performance status would best be treated with concurrent chemotherapy and radiation therapy, which would give a 15 to 20% chance of 5-year survival. Surgical resection of the tumor by pneumonectomy and clearing of the mediastinum followed by radiation therapy is a highly morbid procedure and a particularly poor choice, given that the mediastinal lymph nodes are involved. This patient is at least as likely to fail at distant sites as in the mediastinum, and chemotherapy is as essential as radiation therapy to this patient. Option B is suboptimal in that randomized trials have shown that concurrent chemotherapy and radiation therapy is superior to induction or preoperative chemotherapy followed by radiation therapy. Following chemotherapy and radiation therapy with surgery is controversial, with evidence that patients receiving this trimodality therapy with all but the most limited mediastinal lymph nodes are more likely to do poorly. Option D is again inferior to option C as randomized trials have shown over time. Answer E is the most inappropriate of all. This is a patient with a 15 to 20% chance for a cure, and it is inappropriate to treat her with palliative chemotherapy followed by hospice referral, as long as the patient's performance status is good and the patient is willing to be treated fully in an attempt at cure.

4. A 70-year-old man with lung adenocarcinoma, diagnosed as stage IVB (T2N2M1) with metastases to the lymph nodes, bilateral adrenal glands, and liver, presents with an excellent performance status, an Eastern Cooperative Oncology Group (ECOG) status 1. He has never received prior chemotherapy for his lung cancer. He has no evidence of a driver mutation on genomic analysis of his tumor. Which of the above is *not* an acceptable approach to his management?

A. Combination chemotherapy with carboplatin, paclitaxel, and bevacizumab
B. Combination therapy with carboplatin and pemetrexed
C. Combination chemotherapy with supportive care initiated at the time of the first visit
D. Single-agent paclitaxel plus erlotinib, the EGFR tyrosine kinase inhibitor
E. A second opinion followed by participation in a frontline clinical trial combining chemotherapy and immunotherapy

Answer: D This question describes a patient with good performance status who does not have a driver mutation that would increase the likelihood of benefiting from frontline targeted therapy. As such, there are many reasonable options, all of them starting with platinum-based chemotherapy. ECOG-5597 showed that the combination of carboplatin, paclitaxel, and bevacizumab was associated with a median survival of more than 12 months, and studies with combination therapy with cisplatin or carboplatin and pemetrexed indicate similar survivals. Option C may be the best option of all, as recent data indicate that combination chemotherapy with early initiation of supportive care appears to be associated with a survival advantage. Finally, option E is also an excellent one with evidence that patients who do not have curable disease should strongly consider participating in a frontline clinical trial, in this case, combining immunotherapy and chemotherapy. In fact, the only inappropriate option is D, which is the correct answer to this question. Patients with lung cancer benefit from combination chemotherapy, and there is little evidence that combining paclitaxel with a small-molecule EGFR inhibitor such as erlotinib provides equivalent benefit to combination chemotherapy alone. Therefore, in the absence of a driver *EGFR* mutation, all options are acceptable, making D the only wrong choice.

5. A 50-year-old never-smoking woman presents with a headache followed by a seizure. Her emergent work-up reveals a solitary brain lesion, which is resected and reveals lung adenocarcinoma containing an EGFR driver mutation in exon 19. After consideration of radiation therapy to the brain, the optimal treatment approach would be

A. Combination chemotherapy with carboplatin, paclitaxel, and bevacizumab
B. Combination therapy with carboplatin and pemetrexed
C. Combination chemotherapy with supportive care initiated at the time of the first visit
D. Initiation of erlotinib, the EGFR tyrosine kinase inhibitor
E. A second opinion followed by participation in a frontline clinical trial combining chemotherapy and immunotherapy

Answer: D This question describes a woman who has an *EGFR* mutation–driven lung cancer. She presents with a solitary brain lesion and is treated. The patient may well benefit from radiation therapy, either sterotactic radiation to the residual lesion or whole brain irradiation, but it is clear that the optimal therapy for her, based on the randomized trial published by Mok along with an abundance of other data, is to initiate her treatment with erlotinib or gefitinib, first-generation tyrosine kinase inhibitors, which, in this population of patients, are far more active than chemotherapy combinations. Therefore, option D, given the documented *EGFR* mutation, is superior to options A, B, and C. Finally, whereas E is reasonable from the perspective that all patients with lung cancer should strongly consider a second opinion, this patient is far more likely to benefit from erlotinib or other EGFR tyrosine kinase inhibitors than from chemotherapy and immunotherapy.

NEOPLASMS OF THE ESOPHAGUS AND STOMACH

ANIL K. RUSTGI

NEOPLASMS OF THE ESOPHAGUS

DEFINITION

The esophagus is a hollow tubular organ with primary physiologic functions related to contraction to permit propulsion of solid and liquid food contents into the stomach. The mucosa is a stratified squamous epithelium that covers the submucosa and muscle; the latter is skeletal muscle in the proximal esophagus and smooth muscle in the mid-distal esophagus. Cancers of the esophagus may be classified broadly into epithelial versus nonepithelial.

There are benign epithelial tumors referred to as squamous cell papillomas. Malignant epithelial tumors are classified into two main subtypes: esophageal squamous cell carcinoma and esophageal adenocarcinoma. Other, less common, esophageal epithelium-derived cancers include verrucous squamous cell carcinoma, adenosquamous carcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Benign nonepithelial tumors include leiomyoma, granular cell tumors, fibrovascular polyp, hemangioma, lymphangioma, lipoma, and fibroma. Malignant nonepithelial tumors include leiomyosarcoma and other sarcomas, metastatic carcinoma (originating from breast, lung), and lymphoma.

Esophageal Squamous Cell Carcinoma

EPIDEMIOLOGY

Esophageal squamous cell carcinoma is the more common type of esophageal cancer worldwide and represents a leading cause of cancer-related mortality in men. Esophageal squamous cell carcinoma may have rates of up to 100 per 100,000 population in what is often termed the *Central Asian belt*, including regions around the Caspian Sea, Iran, India, and China; other areas of high incidence include some Mediterranean countries and South Africa. In the United States, esophageal squamous cell carcinoma is more common among African American males than white males, with risks of 15.1 per 100,000 compared with 2.9 per 100,000, respectively. Overall, although the U.S. incidence of esophageal squamous cell carcinoma is low in males or females younger than 50 years, it does increase with advancing age.

Risk Factors

Cancers in general are viewed in the context of hereditary or inherited forms versus sporadic or seemingly random diseases that are related to age, environmental exposures, and genetic alterations (Table 192-1). That being said, the hereditary basis for esophageal squamous cell carcinoma is exceedingly rare, consisting of a desquamating condition termed *tylosis palmaris et plantaris*. As implied, the desquamation most dramatically affects the hands and feet, but this extends to the esophagus as well. Another uncommon condition, Plummer-Vinson syndrome or Paterson-Brown Kelly syndrome, entails glossitis, cervical esophageal webs, and iron deficiency anemia. In both conditions, it is likely that chronic inflammation triggers the cascade of events that culminate in esophageal dysplasia and esophageal squamous cell carcinoma.

The preponderance of esophageal squamous cell carcinoma cases are attributable to cigarette smoking or alcohol, but especially so in combination, because there appear to be synergistic deleterious effects of various chemical carcinogens in both, including *N*-nitroso compounds, polycyclic aromatic hydrocarbons, and aromatic amines. The relative risk for esophageal squamous cell carcinoma is 6.2 in those who smoke more than 25 cigarettes on a daily basis. Cessation of cigarette smoking is helpful in attenuating risk after 10 years of abstinence. Cigarette smokers who partake in beer and whiskey have a 10- to 25-fold enhanced risk of developing esophageal squamous cell carcinoma. Indeed, it is the type of alcohol and the manner of distillation that are most critical. In endemic areas of the world, deficiencies of vitamins A, B_{12}, C, and E, folic acid, and certain minerals (zinc, selenium, molybdenum) are important risk factors. All these vitamins and minerals exert direct or indirect antioxidant effects, and their deficiencies impair epithelial and tissue homeostasis and regeneration.

Other risk factors for esophageal squamous cell carcinoma[1] include achalasia (Chapters 136 and 138), a disorder that involves agangliosis of Auerbach's plexus, resulting in dysphagia, chest pain, and weight loss, among other symptoms. The emergence of esophageal squamous cell carcinoma may be observed 10 to 20 years after the identification of achalasia in patients. Because head and neck squamous cell carcinoma (HNSCC) (Chapter 190) shares many of the environmental and lifestyle risk factors with esophageal squamous cell carcinoma, particularly alcohol and tobacco smoking, HNSCC and esophageal squamous cell carcinoma may occur synchronously or metachronously. In different parts of the world, esophageal squamous cell carcinoma is also associated with chronic esophageal stricture due to lye ingestion, consumption of maté (a hot herb-based beverage), celiac sprue, human papillomavirus (HPV) infection (especially genotypes HPV-16, HPV-18, and HPV-33), and radiation injury.

TABLE 192-1 RISK FACTORS FOR ESOPHAGEAL CANCER

Esophageal squamous cell cancer
Tylosis palmaris et plantaris
Achalasia
Plummer-Vinson syndrome
Cigarette smoking
Alcohol
Chronic lye ingestion
Human papillomavirus infection
Radiation injury
Celiac sprue
Esophageal adenocarcinoma
Gastroesophageal acid reflux
Bile reflux
Obesity
Barrett esophagus

PATHOBIOLOGY

Esophageal squamous cell carcinoma involves the transition from normal squamous epithelium to squamous dysplasia to cancer. Esophageal squamous cell carcinoma initiation, progression, and metastasis are associated with a number of genetic alterations. Among these genetic alterations are overexpression of epidermal growth factor receptor *(EGFR)* and cyclin D1 oncogenes, and inactivation of *TP53*, *p16INK4A*, *E-cadherin*, and p120-catenin *(p120ctn)* tumor suppressor genes. The frequency of these changes varies greatly based upon various studies, but the oncogenic alterations generally appear early in dysplasia and early esophageal squamous cell carcinoma, whereas the inactivation of tumor suppressor genes appear as later events in established primary and metastatic esophageal squamous cell carcinoma. From a genomic viewpoint, the SOX-2 transcription factor, important in the pluripotent capacity of somatic cells, has been shown to be an important gene involved in esophageal squamous cell carcinoma pathogenesis and transformation by virtue of SOX-2 amplification. The ability to model esophageal squamous cell carcinoma in vitro and in vivo has witnessed great strides in recent years through the advent and characterization of three-dimensional organotypic culture models, xenograft transplantation mouse models, and genetically engineered mouse models. For example, conditional knockout of the *p120ctn* tumor suppressor gene in the esophagus of mice results in invasive esophageal squamous cell carcinoma.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Although esophageal squamous dysplasia is typically not associated with symptoms, esophageal squamous cell carcinoma, which has a predilection for the proximal to midesophagus, may be associated with dysphagia, odynophagia, atypical or typical chest pain, gastrointestinal bleeding, nausea, vomiting, weight loss, and malnutrition. Esophageal squamous cell carcinoma may metastasize to local lymph nodes, lung, liver, and bone. Symptoms attributable to metastatic esophageal squamous cell carcinoma may involve bone-related pain, dyspnea, and evidence of jaundice and liver failure, depending upon the extent of metastatic disease.

Physical Examination

The patient should be evaluated for changes in hair, skin integrity, and nail beds as a reflection of malnutrition. Weight loss may result in general cachexia and muscle wasting. There may be lymphadenopathy in the anterior cervical and superclavicular regions. Hepatomegaly and complications of liver disease may be present with metastatic disease to the liver.

Laboratory Studies

There may be progressive iron deficiency anemia due to chronic indolent upper gastrointestinal bleeding. Additional abnormalities may be reflected in metabolic disturbances, such as metabolic alkalosis due to vomiting and hypernatremia due to dehydration. Liver enzyme abnormalities, both hepatocellular and cholestatic, may reflect metastasis to the liver. There are no specific markers for esophageal squamous cell carcinoma, but an elevated carcinoembryonic antigen (CEA) level may be used to aid in monitoring disease recurrence after therapy.

DIAGNOSIS

Barium swallow radiography is useful for the diagnosis of esophageal squamous cell carcinoma, with depiction of a filling defect due to the mucosal lesion or impaired transit of barium due to luminal growth (Chapter 138). However, definitive diagnosis involves direct visualization with upper endoscopy (Chapter 134); once the mass is visualized, biopsies are necessary for confirmation by histopathology and immunohistochemistry for

TABLE 192-2 TNM STAGING SYSTEM FOR CANCER OF THE ESOPHAGUS (AMERICAN JOINT COMMITTEE ON CANCER CRITERIA)

PRIMARY TUMOR (T)*	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia†
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.
*(1) At least maximal dimension of the tumor must be recorded, and (2) multiple tumors require the T(m) suffix. †High-grade dysplasia includes all noninvasive neoplastic epithelia that was formerly called carcinoma in situ.	
LYMPH NODE (N)*	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1-2 regional lymph nodes
N2	Metastasis in 3-6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
*Number must be recorded for total number of regional nodes sampled and total number of reported nodes with metastasis.	
DISTANT METASTASIS (M)	
MX	Metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

cytokeratins associated with proliferation and differentiation. Esophageal squamous cell carcinoma may involve local lymph nodes, which are best detected by endoscopic ultrasound (EUS); as needed, samples can then be analyzed by cytopathology following fine-needle aspiration (FNA). In high-volume centers in the United States, the cytopathologist will be in the procedure room with the gastroenterologist to provide an initial evaluation of the specimens obtained through FNA. Evaluation of metastatic disease involves chest and abdominal computed tomography (CT) scans. Bone scan might be useful in patients who are symptomatic with bone-related pain. Positron emission tomography (PET) has become increasingly used in some settings. In totality, these diagnostic modalities also allow for staging of esophageal squamous cell carcinoma (Table 192-2), which is important in guiding therapeutic options.[2]

TREATMENT

Surgical Therapy

Surgery is the cornerstone of therapy for curative intent. Technical advances have led to improvements in both operative mortality and postoperative morbidity. The different surgical techniques include transthoracic, transhiatal, and radical en bloc resections. Depending upon the location of the esophageal squamous cell carcinoma, either total esophagectomy or subtotal esophagectomy is pursued. For the latter, jejunal or colonic interposition can be done. Although there is currently a lack of high-quality studies comparing minimally invasive esophagectomy (MIE) to conventional approaches, MIE can achieve equivalent or better perioperative mortality, morbidity, and oncologic outcomes compared to open surgery in selected patients.[3]

Medical Therapy

Depending upon the stage of disease, there is some variation in whether to proceed with preoperative (neoadjuvant) chemoradiation therapy (preferred for early stage) or postoperative (adjuvant) chemoradiation therapy.

A study in which patients were randomized to receive surgery alone or surgery plus postoperative chemotherapy with 5-fluorouracil and leucovorin and concurrent radiation therapy revealed that the median survival was 36 months for patients in the adjuvant arm compared with 26 months for those in the surgery-only arm. The 3-year overall survival rates were 50% (surgery plus adjuvant therapy) compared with 40% (surgery alone), respectively.

PROGNOSIS

The 5-year survival for treated esophageal squamous cell carcinoma is dependent upon stage and types of therapies used. For stages T1 and T2 without lymph node involvement, surgery alone may be curative in more than 60% of cases. The occurrence of major postoperative complications, which occur in about one third of patients, exerts a long-lasting negative effect on health-related quality of life in patients who survive for 5 years after esophagectomy for cancer. Dyspnea, fatigue, eating restriction, sleep difficulty, and gastroesophageal reflux progressively worsen more during follow-up in those who suffer such major postoperative complications compared with those without major surgical complications. For patients with metastatic disease, therapy is palliative, involving endoscopically placed expandable prosthetic stents to open the nearly obstructed lumen for passage of food contents, percutaneous endoscopic gastrotomy tubes for delivery of nutrition to the stomach distal to the mass lesion, total parenteral nutrition, pain control, and systemic chemotherapy.

Esophageal Adenocarcinoma

EPIDEMIOLOGY

Esophageal adenocarcinoma affects whites more than African Americans and males much more than females (3 : 1 to 5.5 : 1); it increases in incidence after the age of 40 years. The age-adjusted incidence annually is 1.3 per 100,000. In this chapter, esophageal adenocarcinoma is discussed as a separate entity from gastroesophageal (GE) adenocarcinomas (so-called GE junctional cancer) and gastric cardia adenocarcinomas, although there has been an increasing tendency to think of these in aggregate. The incidence of esophageal adenocarcinoma is increasing dramatically in developed countries, especially in the United States (by 4 to 10% annually) and Western/Northern Europe.

Etiology

Obesity (central) is an important risk factor for esophageal adenocarcinoma. This may be related to either mechanical factors that foster greater gastroesophageal reflux disease (GERD) or the release of proinflammatory cytokines and chemokines that track to the esophagus, or both. The major recognized precursor of esophageal adenocarcinoma is Barrett esophagus. Barrett esophagus is the replacement of the normal stratified squamous epithelium by an incomplete small intestinal epithelium (metaplasia) in the distal esophagus, projecting from the GE junction in a distal-proximal gradient. In turn, it has been demonstrated that Barrett esophagus is fostered by GERD but also by an admixture of bile acids in the acid refluxate. Patients with scleroderma (Chapter 267) may be at increased risk for Barrett esophagus. A small subset of Barrett esophagus patients may progress to esophageal adenocarcinoma through intermediate stages of low-grade and high-grade dysplasia. In Barrett esophagus, one case of esophageal adenocarcinoma is estimated to arise in 55 to 441 patient-years, which corresponds to an approximately 125-fold increased risk for esophageal adenocarcinoma compared with that in the general population.

PATHOBIOLOGY

Barrett esophagus involves transdifferentiation from normal esophageal epithelium to an epithelium of the small intestine with columnar enterocytes and secretory goblet cells, but without Paneth cells and enteroendocrine cells—hence the designation of incomplete intestinal metaplasia. By itself, the metaplasia of Barrett esophagus cannot become esophageal adenocarcinoma. However, if and when Barrett esophagus transitions to low-grade and high-grade dysplasia, there is the aforementioned risk for esophageal adenocarcinoma. Barrett esophagus is associated with abnormal DNA ploidy based on flow cytometry analysis, and certain genetic alterations in epidermal growth factor receptor signaling, *TP53*, and *p16INK4A*. Microsatellite instability may be noted as well. Whole genome approaches are revealing gains and losses of chromosomal regions that might lead to identification of known and previously unknown genes critical in the pathogenesis of esophageal

adenocarcinoma.[4] Recent advances in genetically engineered mouse models have allowed the phenocopying of Barrett esophagus and esophageal adenocarcinoma through the direct targeting of interleukin (IL)-1β to the esophagus; and in another approach, through the global knockout of p63 (an important marker of stem cells and progenitor cells), Barrett esophagus is evident in the postnatal period.

CLINICAL MANIFESTATIONS

Symptoms and Signs

It is estimated that 5 to 15% of GERD patients may develop Barrett esophagus, but such population-based studies are difficult to pursue because vast millions of people are affected with GERD, and most GERD patients do not undergo upper endoscopy. Patients with Barrett esophagus may or may not have symptoms related to GERD. Chronic GERD with Barrett esophagus may be associated with distal esophageal strictures. With esophageal adenocarcinoma, patients may suffer from dysphagia, odynophagia, upper gastrointestinal bleeding, chest pain, nausea, vomiting, early satiety, weight loss, and malnutrition.

Physical Examination

Examination of the patient may reveal signs consistent with malnutrition and weight loss. Lymph adenopathy should be explored. There may be hepatomegaly. Paraneoplastic syndromes are unusual with esophageal adenocarcinoma (as well as with esophageal squamous cell carcinoma). Nevertheless, it is important to ensure that esophageal adenocarcinoma is not mistaken for a benign entity such as a primary esophageal motility disorder.

Laboratory Studies

Patients with esophageal adenocarcinoma may have iron deficiency anemia, metabolic derangements, and abnormal liver enzyme tests owing to metastatic disease. CEA may be elevated as a tumor serologic marker.

DIAGNOSIS

Barium swallow radiography may lead one to the suspicion of Barrett esophagus and can diagnose luminal mass lesions consistent with esophageal adenocarcinoma in the distal esophagus. However, the mainstay of diagnosis is upper endoscopy. At that time, a characteristic salmon-colored mucosa is visualized at the GE junction, with frondlike projections in a proximal direction. If the extent of Barrett esophagus is 3 cm or less, it is termed *short-segment Barrett esophagus*; if it is more than 3 cm, it is referred to as *long-segment Barrett esophagus*. This distinction is important in that the risk for esophageal adenocarcinoma in long-segment Barrett esophagus is greater than in short-segment Barrett esophagus. Noting that the normal esophageal mucosa is more pinkish-white in hue, one can visually distinguish the two different types of epithelia, with the caveat that the gastric cardia mucosa at the GE junction should not be mistaken for Barrett esophagus. Endoscopic mucosal biopsies from the Barrett esophagus region (with control biopsies from the normal esophagus and gastric cardia) are required for histopathologic diagnosis. Features of dysplasia are best appreciated in the absence of reflux-related esophagitis that can lead to nuclear architectural distortion; hence, suppression of acid production with proton pump inhibitor therapy for 6 to 8 weeks is needed, with a view to repeat biopsies.

If the patient has Barrett esophagus metaplasia, upper endoscopy should be repeated every 3 years. However, low-grade dysplasia (with confirmation by an expert pathologist) requires surveillance endoscopy every 6 to 12 months. High-grade dysplasia, if properly evaluated by the pathologist, may require reconfirmation, but then leads to either medical (radio frequency ablation [RFA], endoscopic mucosal resection) or surgical intervention because of the possibility of missed contiguous esophageal adenocarcinoma. EUS may be helpful in discriminating between high-grade dysplasia and esophageal intramucosal adenocarcinoma.

TREATMENT

Rx

The principles are very similar to those applied to esophageal squamous cell carcinoma in terms of surgery. Preoperative chemoradiotherapy (carboplatin titrated to achieve an area under the curve of 2 mg/mL/min and paclitaxel 50 mg/m^2 for 5 weeks) and concurrent radiotherapy (at 41.4 Gy in 23 fractions, 5 days per week) significantly improves median survival from 24 months to 49 months among patients with potentially curable esophageal or esophagogastric-junction cancer.[■] Overall prognosis for esophageal adenocarcinoma is not too dissimilar from that noted in esophageal squamous cell carcinoma. Major improvements in the treatment options for Barrett esophagus, the main precursor of esophageal adenocarcinoma, have witnessed dramatic growth (Chapter 138). RFA reduces progression of Barrett esophagus with low-grade dysplasia or possibly high-grade dysplasia to cancer.[■] Endoscopic mucosal resection (EMR) is used for Barrett esophagus–related high-grade dysplasia or Barrett esophagus associated with intramucosal esophageal adenocarcinoma. For advanced, unresectable tumors, self-expanding stents, often with localized brachytherapy, can provide palliation.[5]

NEOPLASMS OF THE STOMACH

DEFINITION

Gastric neoplasms are predominantly malignant, and nearly 90 to 95% of these tumors are adenocarcinomas. Less frequently observed malignant diseases include lymphomas, especially non-Hodgkin's lymphoma, and sarcomas such as leiomyosarcoma. Benign gastric neoplasms include leiomyomas, carcinoid tumors, and lipomas.

Adenocarcinoma of the Stomach

EPIDEMIOLOGY

The great geographic variation in the incidence of gastric cancer worldwide indicates that environmental factors influence the pathogenesis of gastric carcinogenesis. Further support for this notion comes from observations that groups emigrating from high-risk to low-risk areas, such as Japanese individuals moving to Hawaii and Brazil, acquire the low risk of the area into which they emigrate, presumably because of adoption of the endogenous lifestyle and exposure to different environmental factors.

Gastric adenocarcinoma was the most frequently observed malignant disease in the world until the mid-1980s, and it remains extremely common among men in certain regions such as tropical South America, some parts of the Caribbean, and Eastern Europe. Regardless of gender, it remains one of the most common malignancies in Japan and China.

Whereas gastric cancer was the most common cancer in the United States in the 1930s, its annual incidence has steadily decreased. The annual incidence is now fewer than 10,000 new cases per year. However, although the incidence of gastric adenocarcinoma localized to the distal stomach has declined, the incidence of proximal gastric and GE junctional adenocarcinomas has been steadily increasing in the United States, a finding that perhaps reflects differences in pathogenic factors. Typically, gastric cancer occurs between the ages of 50 and 70 years and is uncommon before age 30. The rates are higher in men than in women by 2 : 1. Five-year survival is less than 20%.

Risk Factors

Risk factors for the development of gastric adenocarcinoma[6] can be divided into environmental and genetic factors as well as precursor conditions (Table 192-3). For example, *Helicobacter pylori* infection is significantly more common in patients with gastric cancer than in matched control groups. Epidemiologic studies of high-risk populations have also suggested that genotoxic agents such as *N*-nitroso compounds may play a role in gastric tumorigenesis. *N*-nitroso compounds can be formed in the human stomach by nitrosation of ingested nitrates, which are common constituents of the diet. High nitrate concentrations in soil and drinking water have been observed in areas with high death rates from gastric cancer. Atrophic gastritis (Chapter 139), with or without intestinal metaplasia, is observed in association with gastric cancer, especially in endemic areas. Pernicious anemia (Chapter 139) is associated with a several-fold increase in gastric cancer. Atrophic gastritis and gastric cancer have certain environmental risk factors in common. It is likely that atrophic gastritis and intestinal metaplasia represent intermediary steps to gastric cancer. The achlorhydria associated with gastritis related to *H. pylori* infection, pernicious anemia, or other causes favors the growth of bacteria capable of converting nitrates to nitrites. The nitrosamine *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine causes a high rate of induction of adenocarcinoma in the glandular stomach of rats. At the same time, most patients with atrophic gastritis do not develop gastric cancer, a finding suggesting that neither atrophic gastritis nor achlorhydria alone is responsible.

Benign gastric ulcers do not appear to predispose patients to gastric cancer. However, patients who have a gastric remnant after subtotal gastrectomy for benign disorders have an increased relative risk for gastric cancer of 1.5 to 3.0 by 15 to 20 years after surgery.

TABLE 192-3 CONDITIONS PREDISPOSING TO OR ASSOCIATED WITH GASTRIC CANCER

ENVIRONMENTAL
Helicobacter pylori infection
Dietary: excess of salt (salted pickled foods), nitrates/nitrites, carbohydrates; deficiency of fresh fruit, vegetables, vitamins A and C, refrigeration
Low socioeconomic status
Cigarette smoking
GENETIC
Familial gastric cancer (rare)
Associated with hereditary nonpolyposis colorectal cancer
Blood group A
PREDISPOSING CONDITIONS
Chronic gastritis, especially atrophic gastritis with or without intestinal metaplasia
Pernicious anemia
Intestinal metaplasia
Gastric adenomatous polyps (>2 cm)
Postgastrectomy stumps
Gastric epithelial dysplasia
Ménétrier's disease (hypertrophic gastropathy)
Chronic peptic ulcer

PATHOBIOLOGY

Gastric adenocarcinomas can be divided into two types based on the Lauren classification: intestinal and diffuse. The intestinal type is typically in the distal stomach with ulcerations, is often preceded by premalignant lesions, and is declining in incidence in the United States. By contrast, the diffuse type involves widespread thickening of the stomach, especially in the cardia, and it often affects younger patients; this form may present as linitis plastica, a nondistensible stomach with the absence of folds and a narrowed lumen caused by infiltration of the stomach wall with tumor. Diffuse-type gastric cancers harbor mucin-producing cells. Other conditions may result in linitis plastica, such as lymphoma (Chapter 185), tuberculosis (Chapter 324), syphilis (Chapter 319), and amyloidosis (Chapter 188). The prognosis is generally worse in the diffuse type.

Key histopathologic features of gastric cancer include its degree of differentiation, invasion through the gastric wall, lymph node involvement, and the presence or absence of signet ring cells within the tumor itself. Other pathologic manifestations include a polypoid mass, which may be difficult to distinguish from a benign polyp. Early gastric cancer, a condition that is common in Japan and has a relatively favorable prognosis, consists of superficial lesions with or without lymph node involvement. Here, the Borrmann classification scheme is helpful: I, polypoid; II, fungating ulcer with sharp raised margins; III, ulcer with poorly defined infiltrative margins; and IV, infiltrative, mostly intramural lesion, not well demarcated.

The leading hypothesis explaining the way in which *H. pylori* predisposes to gastric cancer risk is the induction of an inflammatory response, in which IL-1β may be pivotal. Chronic *H. pylori* infection also leads to chronic atrophic gastritis with resulting achlorhydria, which in turn favors bacterial growth that can convert nitrates (dietary components) to nitrites. These nitrites, in combination with genetic factors, promote abnormal cellular proliferation, genetic mutations, and eventually cancer. In a mouse model of gastric cancer, *H. pylori* infection may play a role in the recruitment of bone marrow–derived stem cells that facilitate gastric carcinogenesis. Animal models can now recapitulate the cardinal features of gastric adenocarcinoma, either through the use of carcinogens or through genetic approaches.

Genetics

It is clear that genetic factors play a role in gastric cancer. For example, blood group A is associated with a higher incidence rate of gastric cancer, even in nonendemic areas. A three-fold increase in gastric cancer has been reported among first-degree relatives of patients with the disease. Furthermore, germline or inherited mutations in the genes for E-cadherin and α-catenin, albeit rare, have been described in diffuse hereditary gastric cancer, which is seen in young patients. In addition, in Lynch syndrome (Chapter 193), patients have associated extracolonic cancers, including gastric cancer. Patients with familial adenomatous polyposis (FAP) have an increased risk of distal (antral) gastric adenocarcinoma.

It now appears that several genetic mechanisms are important in gastric cancer: oncogene activation, tumor suppressor gene inactivation, and DNA microsatellite instability. For example, loss of heterozygosity of the *APC* (adenomatous polyposis coli) gene has been observed in gastric cancers. The p53 tumor suppressor gene product regulates the cell cycle at the G_1-S phase transition and probably also functions in DNA repair and apoptosis (programmed cell death). The *p53* gene is mutated not only in gastric cancer but also in gastric precancerous lesions, a finding suggesting that mutation of the *p53* gene is an early event in gastric carcinogenesis. Microsatellite DNA alterations or instability in dinucleotide repeats occur frequently in sporadic gastric carcinoma. Mutations in genes may accumulate as a result of DNA microsatellite instability.

CLINICAL MANIFESTATIONS

Symptoms and Signs

In its early stages, gastric cancer may often be asymptomatic or may produce only nonspecific symptoms that make early diagnosis difficult. Later symptoms include bloating, dysphagia, epigastric pain, or early satiety. Early satiety or vomiting may suggest partial gastric outlet obstruction, although gastric dysmotility may contribute to the vomiting in patients with nonobstructive cases. Epigastric pain reminiscent of that associated with peptic ulcer (Chapter 139) occurs in about one fourth of patients, but in most patients with gastric cancer, the pain is not relieved by food or antacids. Pain that radiates to the back may indicate that the tumor has penetrated the pancreas. When dysphagia is associated with gastric cancer, this symptom suggests a more proximal gastric tumor at the GE junction or in the fundus.

Signs of gastric cancer include bleeding, which can result in iron deficiency anemia that produces the symptoms of weakness, fatigue, and malaise, as well as (rarely) more serious cardiovascular and cerebrovascular consequences. Perforation related to gastric cancer is unusual. Gastric cancer metastatic to the liver can lead to right upper quadrant pain, jaundice, and fever. Lung metastases can cause cough, hiccups, and hemoptysis. Peritoneal carcinomatosis can lead to malignant ascites unresponsive to diuretics. Gastric cancer can also metastasize to bone.

Physical Examination

In the earliest stages of gastric cancer, the physical examination may be unremarkable. At later stages, patients become cachectic, and an epigastric mass may be palpated. If the tumor has metastasized to the liver, hepatomegaly with jaundice and ascites may be present. Portal or splenic vein invasion and thrombosis can cause splenomegaly. Lymph node involvement in the left supraclavicular area is termed *Virchow's node*, and periumbilical nodal involvement is called *Sister Mary Joseph's node*. The fecal occult blood test may be positive. Metastasis to the ovary is termed *Krukenberg's tumor*.

Paraneoplastic syndromes may precede or occur concurrently with gastric cancer. Examples include the following: Trousseau syndrome (Chapter 176), which is recurrent migratory superficial thrombophlebitis indicating a possible hypercoagulable state; acanthosis nigricans, which arises as raised and hyperpigmented skin lesions of flexor areas, neck, axilla, groin, and mucosal membranes; neuromyopathy with involvement of the sensory and motor pathways; and central nervous system syndromes with altered mental status and ataxia.

Laboratory Studies

Laboratory studies may reveal iron deficiency anemia. Microangiopathic hemolytic anemia has been reported. Abnormalities in liver tests generally indicate metastatic disease. Hypoalbuminemia is a marker of malnutrition. Protein-losing enteropathy is rare but can be seen in Ménétrier's disease, another predisposing condition. Serologic test results, such as those for CEA and CA72.4, may be abnormal. Although these tests are not recommended for initial diagnosis, they may be useful for monitoring disease after surgical resection.

DIAGNOSIS

The diagnostic accuracy of upper endoscopy with biopsy and cytologic examination approaches 95 to 99% for both types of gastric cancer.[7] Cancer may arise as a small mucosal ulceration, a polyp, or a mass (Fig. 192-1). In some patients, gastric ulceration may first be noted in an upper gastrointestinal barium contrast study. A benign gastric ulcer is associated with a smooth, regular base, whereas a malignant ulcer is associated with a surrounding mass, irregular folds, and an irregular base. Although these and other radiographic characteristics historically helped to predict benign versus malignant disease, upper gastrointestinal endoscopy with biopsy and cytologic examination is mandatory whenever a gastric ulcer is found in the radiologic study, even if the ulcer has benign characteristics.

Endoscopic ultrasonography (EUS) is very helpful in both diagnosis and staging of gastric cancer (Table 192-4). The extent of tumor, including gastric wall invasion and local lymph node involvement, can be assessed by EUS (Fig. 192-2), which provides information complementary to that obtained from CT scans. EUS can help guide aspiration biopsies of lymph nodes to determine their malignant features if any. CT of the chest, abdomen, and pelvis should be performed to document lymphadenopathy and extragastric organ (especially lung and liver) involvement. In some centers, staging of gastric cancer entails bone scans because of the proclivity of gastric cancer to metastasize to bone.

TREATMENT

Rx

Surgical Therapy

The only chance for cure of gastric cancer remains surgical resection, which is possible in 25 to 30% of cases. If the tumor is confined to the distal stomach, subtotal gastrectomy is performed, with resection of lymph nodes in the porta hepatis and the pancreatic head. By contrast, tumors of the proximal stomach merit total gastrectomy to obtain an adequate margin and to remove lymph nodes; distal pancreatectomy and splenectomy are usually also performed as part of this procedure, which carries with it higher mortality and morbidity rates. The addition of para-aorta nodal dissection does not improve survival. Even if a curative procedure is not possible because of metastasis, limited gastric resection may be necessary for patients with excessive bleeding or obstruction. If cancer recurs in the gastric remnant, limited resection may again be necessary for palliation. Most recurrences in both types of gastric cancer are in the local or regional area of the original tumor.

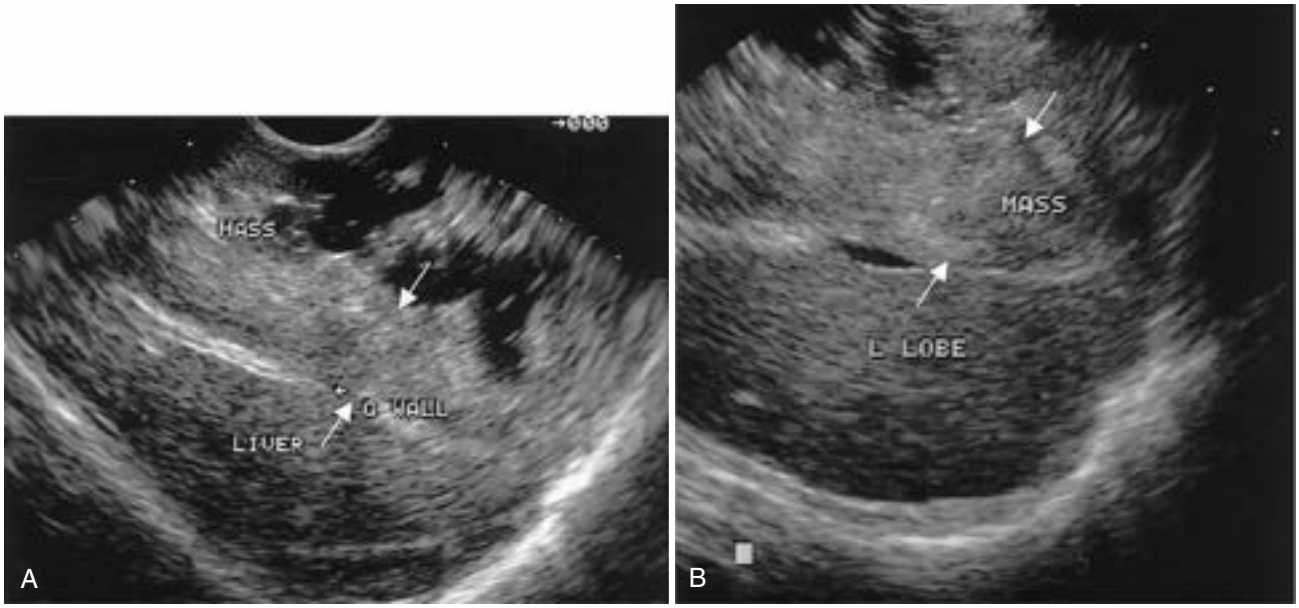

FIGURE 192-2. Gastric mass. Endoscopic ultrasonography depicting a large gastric mass that is compressing the liver and gallbladder wall (A) and, on a different view, the left lobe of the liver (B).

Medical Therapy

Gastric cancer is one of the few gastrointestinal cancers that is somewhat responsive to chemotherapy.[8] In patients with gastric cancer who undergo gastrectomy and extended lymph node dissection with curative intent, S-1 (an oral fluoropyrimidine, 80 mg daily for 4 weeks followed by 2 weeks off, repeated in 6-week cycles for 1 year starting within 6 weeks after surgery) significantly improves 3-year survival from 70 to 80%. Chemotherapy with the combination of epirubicin, cisplatin, and fluorouracil, given both preoperatively and postoperatively, significantly improves 5-year survival from 23 to 36% in patients with resectable GE cancer. Similarly, the combination of chemotherapy (fluorouracil and leucovorin) with radiation therapy has been shown to improve median survival from 27 to 36 months compared with surgery alone in patients with adenocarcinoma of the stomach or GE junction. With a more than 10-year median follow-up, overall survival and relapse-free survival demonstrate continued strong benefit from postoperative radiochemotherapy.

Single-agent chemotherapy treatment, which provides partial response rates of 20 to 30%, is reserved for patients with a poor performance status. Combination regimens that can yield partial response rates of 35 to 50% include the following: ECF, which is most popular in Europe (epirubicin, 50 mg/m^2 on day 1; cisplatin, 60 mg/m^2 on day 1; 5-fluorouracil, 200 mg/m^2/day as a continuous infusion through a central venous access device [CVAD] given throughout treatment, repeated every 21 days for a maximum of 8 cycles); CF (5-fluorouracil infusion, 1000 mg/m^2/day for 4 days; cisplatin, 75 to 100 mg/m^2 on day 1, every 4 weeks); or TCF (docetaxel [Taxotere], 75 mg/m^2 on day 1; cisplatin, 75 mg/m^2 on day 1; and 5-fluorouracil, 750 mg/m^2/day for 5 days, every 3 weeks), or capecitabine plus cisplatin. A randomized trial of triple chemotherapy for advanced esophagogastric cancer showed that oral capecitabine is at least as effective as infused fluorouracil, and that oxaliplatin (which does not require hydration) is at least as effective as cisplatin (which does require hydration) with respect to overall survival. Bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor A (VEGF-A), administered at a dose of 7.5 mg/kg by intravenous infusion every 3 weeks, was found to increase progression-free survival and overall response rate when it was given along with capecitabine-cisplatin chemotherapy as first-line treatment of advanced gastric cancer. Ramucirumab (a VEGF receptor antagonist) given as 8 mg/kg intravenously every two weeks can improve median survival from 3.8 to 5.2 months in advanced gastric cancer. Trastuzumab (8 mg/kg intravenously once, then 6 mg/kg every 3 weeks) can increase survival of HER2-positive advanced gastric or GE junction cancer from 11.1 months to 13.8 months. Radiation therapy alone is ineffective and is generally employed only for palliative purposes in the setting of bleeding, obstruction, or pain. Gene therapy and immune-based therapy are currently only investigational in animal models.

General Methods

Implicit in the management of the patient with gastric cancer is meticulous attention to nutrition (jejunal enteral feedings or total parenteral nutrition), correction of metabolic abnormalities that arise from vomiting or diarrhea, and treatment of infection from aspiration or spontaneous bacterial peritonitis. *H. pylori* eradication treatment reduces the risk for metachronous gastric carcinoma by about two thirds. To maintain lumen patency, endoscopic laser treatment or prosthesis placement can be used in a palliative fashion.

PROGNOSIS

Approximately one third of patients who undergo a curative resection are alive after 5 years. In aggregate, the overall 5-year survival rate in patients with gastric cancer is less than 10%. Prognostic factors include anatomic location and nodal status. Distal gastric cancers without lymph node involvement have a better prognosis than proximal gastric cancers with or without lymph node involvement. Other prognostic factors include depth of penetration and tumor cell DNA aneuploidy. Linitis plastica and infiltrating lesions have a much worse prognosis than polypoid disease or exophytic masses. In the subset of mostly Japanese patients with early gastric cancer that is confined to the mucosa and submucosa, surgical resection may be curative and definitely improves the 5-year survival rate to more than 50%. In fact, when early gastric cancer is confined to the mucosa, endoscopic mucosal resection may be an alternative.

Lymphoma of the Stomach

EPIDEMIOLOGY

Gastric lymphoma represents about 5% of all malignant gastric tumors and is increasing in incidence. Most gastric lymphomas are non-Hodgkin's lymphomas (Chapter 185), and the stomach is the most common extranodal site for non-Hodgkin's lymphomas. Patients with gastric lymphoma are generally younger than those with gastric adenocarcinoma, but the male predominance remains.

CLINICAL MANIFESTATIONS

Patients commonly present with symptoms and signs similar to those of gastric adenocarcinoma. Lymphoma in the stomach can be a primary tumor, or it can be secondary to disseminated lymphoma.

B-cell lymphomas (Chapter 185) of the stomach are most commonly large cell with a high-grade type. Low-grade variants are noted in the setting of chronic gastritis and are termed *mucosa-associated lymphoid tissue* (MALT) lymphomas. MALT lesions are strongly associated with *H. pylori* infection.

DIAGNOSIS

Radiographically, gastric lymphomas usually arise as ulcers or exophytic masses; diffusely infiltrating lymphoma is more suggestive of secondary lymphoma. Thus, upper gastrointestinal barium studies usually show multiple nodules and ulcers for a primary gastric lymphoma and typically have the appearance of linitis plastica (see earlier) with secondary lymphoma. As with gastric adenocarcinoma, however, upper endoscopy with biopsy and cytologic examination are required for diagnosis and have an accuracy of nearly 90%. Apart from conventional histopathologic analysis, immunoperoxidase staining for lymphocyte markers is helpful in diagnosis. As with gastric adenocarcinoma, proper staging of gastric lymphoma involves EUS, chest and abdominal/pelvic CT scans, and bone marrow biopsy as needed.

TREATMENT

Rx

Treatment of gastric diffuse large B-cell lymphoma is best pursued with combination chemotherapy with or without radiation therapy (Chapter 185). For MALT lesions, eradication of *H. pylori* infection with antibiotics should be attempted[9] (Chapter 139), but patients with refractory lesions that are confined to the stomach can sometimes be cured with chemoradiotherapy (Chapter 185).

Other Malignant Tumors of the Stomach

Leiomyosarcoma, which constitutes approximately 1% of all gastric cancers, usually occurs as an intramural mass with central ulceration. Symptoms may include bleeding accompanied by a palpable mass. Leiomyosarcomas are often relatively indolent; surgical resection yields a 5-year survival rate of about 50%. Metastasis can occur to lymph nodes and the liver. Other gastric sarcomas include liposarcomas, fibrosarcomas, myosarcomas, and neurogenic sarcomas.

Most gastrointestinal stromal tumors (GISTs)[10] have been associated with activating mutations in the C-*kit* gene; a subset of such tumors is associated with mutations in the platelet-derived growth factor receptor *(PDGFR)* gene. C-*kit* mutations are also found in chronic and acute myelogenous leukemia (Chapters 183 and 184), and approximately 50% of GISTs respond to imatinib mesylate, which should be continued for at least 3 years. If imatinib is not successful, sunitinib increases survival. If both fail, regorafenib, a multikinase inhibitor, can be tried.[11] Carcinoid tumors (Chapter 232) may begin in the stomach and are curable by removal if they have not yet spread to the liver.

Primary tumors can also spread to the stomach. In addition to lymphomas, other tumors found in the stomach include primary lung (Chapter 191) and breast (Chapter 198) cancers as well as malignant melanoma (Chapter 203).

Leiomyomas and Benign Tumors

Leiomyomas, which are smooth muscle tumors of benign origin, occur with equal frequency in men and women and are typically located in the middle and distal stomach. Leiomyomas can grow into the lumen, with secondary ulceration and consequent bleeding. Alternatively, they can expand to the serosa with extrinsic compression. Endoscopy may reveal a mass that has overlying mucosa or mucosa replaced by ulceration. On upper gastrointestinal series, leiomyomas are usually smooth with an intramural filling defect, with or without central ulceration. However, benign leiomyomas can be difficult to distinguish from their malignant counterparts radiographically or endoscopically; tissue diagnosis is imperative. Symptomatic leiomyomas should be removed, but those without associated symptoms do not require therapy.

Other benign gastric tumors include lipoma, neurofibroma, lymphangioma, ganglioneuroma, and hamartoma, the last associated with Peutz-Jeghers syndrome (Chapter 193) or juvenile polyposis (when restricted to the stomach).

Adenomas

Gastric adenomas and hyperplastic polyps are unusual but may be found in middle-aged and elderly patients. Polyps may be sessile or pedunculated. Although isolated gastric adenomatous polyps are generally asymptomatic, some patients may have dyspepsia, nausea, or bleeding. Gastric adenomas and hyperplastic polyps are smooth and regular on upper gastrointestinal series, but the diagnosis must be confirmed by upper endoscopy with biopsy. Pedunculated polyps that are larger than 2 cm or that have associated symptoms should be removed by endoscopic snare cautery polypectomy, whereas large sessile gastric adenomatous polyps may merit segmental surgical resection. If polyps progress to an intermediary stage of severe dysplasia or culminate in cancer, treatment is the same as for gastric adenocarcinoma.

REVIEW QUESTIONS

1. What is a leading risk factor for the development of Barrett's esophagus and esophageal adenocarcinoma?

A. Obesity
B. Nutritional deficiencies
C. Childhood gastroesophageal reflux disease
D. High-fiber diet

Answer: A Obesity, specifically central adiposity, has been associated with increased risk of Barrett's esophagus and esophageal adenocarcinoma in separate studies. Mechanistically, there is secretion of cytokines and chemokines from adipocytes that likely produce pro-inflammatory states in the esophagus in both conditions.

2. What is a key risk factor for the development of gastric adenocarcinoma?

A. Obesity
B. *Helicobacter pylori* infection
C. History of pancreatic cancer
D. Blood group O

Answer: B *Helicobacter pylori*, a common organism worldwide that affects nearly 2 billion individuals, causes gastric atrophy with achlorhydria and subsequent intestinal metaplasia in the gastric epithelium. This can evolve to dysplasia (low grade and high grade) and adenocarcinoma, so-called intestinal type. Note that only a subset of chronically *H. pylori*–infected patients progress to gastric adenocarcinoma, suggesting other cofactors are important.

3. Therapy of esophageal or gastric cancer may involve all the following modalities *except*:

A. Surgery
B. Chemoradiation therapy
C. Palliative chemotherapy
D. Bone marrow transplantation

Answer: D Bone marrow transplantation is not an option. The modalities in A, B, and C are all used and dictated by the stage of esophageal or gastric cancer.

4. What hereditary condition predisposes to gastric adenocarcinoma?

A. Germline *E-cadherin* mutation
B. Germline *TP53* mutation
C. Germline *p16INK4a* mutation
D. Germline *p120* catenin mutation

Answer: A Germline E-cadherin mutation predisposes to early-age onset of diffuse hereditary gastric adenocarcinoma and may also be associated with lobular-type breast cancer.

5. What is a likely treatment option for Barrett's esophagus with high-grade dysplasia and no surrounding esophageal adenocarcinoma?

A. Neoadjuvant chemoradiation therapy
B. Laser therapy
C. Endoscopic mucosal resection (EMR)
D. Endoscopic prosthetic stent

Answer: C Endoscopic mucosal resection (EMR) is a viable option for high-grade dysplasia, as well as intramucosal esophageal adenocarcinoma. Radiofrequency ablation via endoscopy is used for low-grade dysplasia Barrett's esophagus and may be used for high-grade dysplasia Barrett's esophagus under certain circumstances.

193 NEOPLASMS OF THE SMALL AND LARGE INTESTINE

CHARLES D. BLANKE AND DOUGLAS O. FAIGEL

NEOPLASMS OF THE SMALL INTESTINE

EPIDEMIOLOGY

The small intestine accounts for the majority of the length (≈75%) and absorptive surface (≈90%) of the gastrointestinal (GI) tract. Nonetheless, it is a rare site for the development of neoplastic disease, because only 1 to 2% of primary GI tumors originate in the duodenum, jejunum, or ileum. In fact, half of all small bowel neoplasms represent metastatic disease from other sites, particularly elsewhere in the GI tract. Although small bowel malignancies constitute less than 0.5% of all cancers, the incidence of small bowel tumors (especially carcinoids) has increased dramatically over the last several decades, which may possibly be a reflection of better diagnostic techniques. Overall, the mean age at diagnosis of a small bowel tumor is about 67 years (younger for those with sarcomas and lymphomas); neoplasms are more common in males, and they occur more frequently in African Americans than whites.

PATHOBIOLOGY

Adenocarcinomas, arising from mucosal glands, were formerly the most frequent primary small bowel tumor. They now constitute 25 to 33% of small bowel neoplasms, including benign growths, and 40% of all malignant tumors. Adenocarcinomas most commonly arise in the duodenum (65% of all small intestinal adenocarcinomas), even though the duodenum represents only a tiny fraction of the length of the small bowel. They occur less commonly in the jejunum and least commonly in the ileum. The majority are well or moderately differentiated.

Small bowel carcinoids, which derive from enterochromaffin cells in the crypts of Lieberkühn, are now the most common small bowel tumors, accounting for up to 44% of malignancies. They tend to be quite well differentiated. In contrast to glandular tumors, small intestinal carcinoids tend to arise in the distal ileum, and up to 30% are multifocal. Other small bowel neuroendocrine tumors are occasionally seen, including biochemically active neoplasms such as gastrinomas and somatostatinomas. Very rarely, high-grade true small-cell carcinomas occur.

Malignant connective tissue tumors account for 10 to 17% of small bowel neoplasms. Gastrointestinal stromal tumors (GISTs), which derive from the interstitial cells of Cajal or a common precursor, account for approximately 85% of these neoplasms (Fig. 193-1). GISTs, like adenocarcinomas, disproportionately arise in the duodenum, and the small bowel itself is the second most common primary site for these mesenchymal neoplasms (33% derive from small bowel). Morphologically, GISTs often resemble leiomyosarcomas (Fig. 193-2), but they can be differentiated by the expression of the Kit protein (CD117). Other small bowel sarcomas, such as true leiomyosarcomas, are seen more rarely (Chapter 202).

Primary GI lymphomas are the most common extranodal lymphomatous variation, and the small intestine is the second most common GI site for such tumors (Chapter 185). Lymphomas account for approximately 8% of small bowel neoplasms. The ileum, rich in submucosal lymphoid follicles, is the most common small bowel site. Tumors may be low or higher grade and can arise from precursor B or T lymphocytes. The overwhelming majority are non-Hodgkin tumors (Fig. 193-3). Lymphomas involving the small bowel may also be a manifestation of true systemic disease.

Malignant melanoma (Chapter 203) can develop as a primary mucosal small bowel tumor, probably arising from schwannian neuroblasts associated with GI innervation. In addition, the small bowel is the most common GI site for melanoma metastases.

Finally, a variety of common benign tumors may originate in the small bowel, including adenomas, leiomyomas, and lipomas. Desmoids (most often seen in patients with familial adenomatous polyposis [FAP]), hamartomas, and hemangiomas are relatively rare. Benign growths are more common in the distal small intestine.

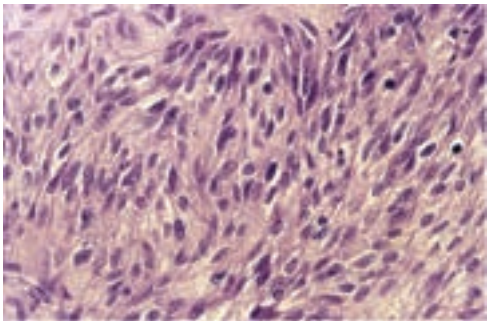

FIGURE 193-2. Histopathology of gastrointestinal stromal tumor.

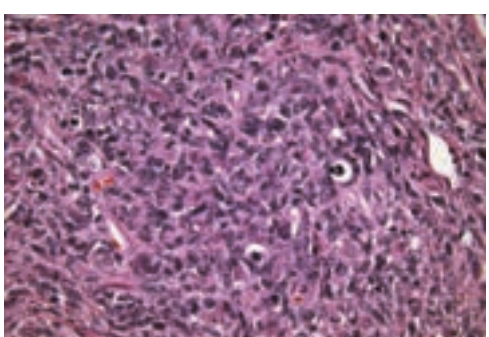

FIGURE 193-3. Histopathology of small bowel non-Hodgkin lymphoma. (Courtesy Dr. M.K. Washington.)

The small intestine can be involved with advanced cancers from other sites through direct invasion, extension of peritoneal metastases, or hematogenous spread. As noted, the small bowel is the most common GI site for melanoma metastases; involvement is also fairly common with ovarian, breast, lung, and other GI neoplasms.

Predisposing Conditions

Inflammatory bowel disease (Chapter 141) and some environmental factors (e.g., salt-cured foods, alcohol) predispose to small bowel adenocarcinomas. Data regarding tobacco exposure and obesity are conflicting. Additionally, many of the polyposis syndromes are associated with small bowel neoplasms. Most notably, FAP (see later) is associated with adenomas and carcinomas of the duodenum and jejunum, but especially in the ampullary and periampullary region. At least 90% of FAP patients develop duodenal adenomas, and up to 10% develop cancer. The risk of cancer is related to the number of polyps, their size and histologic type, and the presence of high-grade dysplasia. Patients with FAP should undergo regular screening for duodenal neoplasia with both forward- and side-viewing endoscopes beginning around the time of colectomy and repeated at 1- to 5-year intervals, depending on the presence and degree of duodenal polyposis. Patients with *MUTYH*-associated polyposis likewise develop duodenal neoplasia and should undergo screening. Patients with hereditary nonpolyposis colon cancer (HNPCC) are also at increased risk for small intestine adenocarcinoma, which may be the first manifestation of their disease. HNPCC-associated small bowel cancer may present at a young age (median, 39 years) and occurs with decreasing frequency from the duodenum to the ileum, with about 50% of occurrences in the duodenum. Screening may be considered beginning at age 30. Patients with sprue are at increased risk for small bowel lymphomas, and they have an almost 35-fold increased risk for developing adenocarcinomas.

CLINICAL MANIFESTATIONS

The most common presenting symptom of small bowel tumors is abdominal pain, especially for those that are true cancers. Weight loss, nausea, GI bleeding, and symptoms related to perforation are less common. Approximately 25% of patients have GI obstruction, and duodenal periampullary tumors can lead to obstructive jaundice. Most malignancies are symptomatic, whereas benign tumors may be asymptomatic in up to half of patients. Carcinoid tumors in the small bowel are often asymptomatic, although in the setting of advanced disease, they may secrete bioactive amines, leading to flushing, diarrhea, wheezing, and eventually symptoms of right heart failure (related to valvular fibrosis) (Chapter 232). This occurs more commonly with tumors originating in the jejunum and ileum. Benign tumors tend to be found incidentally, although intraluminal growth may eventually cause symptoms of obstruction, and some may grow large enough to ulcerate and bleed.

DIAGNOSIS

The physical examination in patients with small bowel tumors is often unremarkable, although a palpable mass and, in more advanced cases, ascites may be present. As discussed earlier, patients with periampullary neoplasms may be jaundiced and/or icteric. Obstructive signs such as hyperperistalsis may be present, and patients with lymphoma may also have splenomegaly or other signs of systemic involvement, such as lymphadenopathy. Laboratory findings may include iron deficiency anemia or increased hepatic enzymes (the latter is especially common in those with liver metastases or biliary obstruction). Serum levels of the carcinoembryonic antigen (CEA) tumor marker may be elevated in small bowel adenocarcinoma, especially in advanced cases, but it is neither sensitive nor specific enough for routine diagnostic use. Patients with neuroendocrine tumors may demonstrate elevated levels of serotonin, chromogranin A, tumor-specific bioactive amines (e.g., gastrin), or urinary 5-hydroxyindoleacetic acid. Variants of intestinal lymphomas may show heavy chain immunoglobulin A fragments in serum and urine.

Proper imaging is crucial for both diagnosis and staging of small bowel neoplasms, but no one method is clearly the best. Standard radiographic techniques of value include upper GI with small bowel follow-through (helpful in demonstrating both masses and potential mucosal defects), angiography (which may show a site of bleeding or tumor blush with specific neoplasms), and computed tomography (CT) or magnetic resonance imaging (MRI) enteroclysis (double-contrast studies are both sensitive and specific for small bowel masses). Transabdominal ultrasound and standard CT may indicate a primary mass as well as metastases; MRI appears to be superior to CT in detecting and characterizing liver metastases.

Primary neuroendocrine tumors and their metastases are often apparent on indium-111 octreotide scanning. A wide variety of histologies may have uptake on positron emission tomography (PET) scanning. PET does not yet have a well-defined role in the diagnosis of most small bowel malignancies, although PET scans are useful in those with GISTs, to monitor response to systemic therapy (see later). Plain films rarely are specific enough to lead to a diagnosis, but they may demonstrate intestinal obstruction.

Capsule endoscopy uses a wireless endoscopic device that allows minimally invasive imaging of the small intestine. The system consists of the capsule camera—a swallowable, self-contained, battery-operated device that transmits two images per second—a receiver worn on the patient's belt, and a computerized work station for downloading and viewing the images. The primary indications for capsule endoscopy are the evaluation of obscure GI bleeding and Crohn disease. Tumors are found in about 2 to 3% of patients undergoing capsule endoscopy for obscure GI bleeding, and they may be more common in younger patients. Tumors detected include lymphoma, adenocarcinoma, metastatic disease, carcinoid tumor, and GIST. Capsule endoscopy has also been used to assess the small intestines of patients with FAP and Peutz-Jeghers syndrome (PJS), although its clinical utility for routine screening of these patients has not been established.

Deep enteroscopy describes a group of related techniques to facilitate deep intubation of the small bowel with long endoscopes. The small bowel may be examined antegrade (through the mouth) or retrograde (through the colon), allowing the majority of the small bowel to be examined. Although more invasive than capsule endoscopy, deep enteroscopy has a similar diagnostic yield but allows for tissue sampling (biopsy) and therapy including polypectomy and control of bleeding.

Surveillance

Patients with FAP, *MUTYH* polyposis, PJS, and probably HNPCC require regular surveillance of the small intestine, with specific recommendations as noted earlier. Patients with sporadic small intestine adenomas and possibly carcinoid tumors should undergo colonoscopy because they are at increased risk for colonic neoplasia. No specific guidelines exist for following patients with resected small bowel adenocarcinomas.

Staging

The staging systems for small bowel tumors vary by histology. Adenocarcinomas and, more recently, neuroendocrine cancers and GISTs are staged using different classifications within the American Joint Committee on Cancer's TNM malignant tumors system. Intestinal non-Hodgkin lymphomas, whether primary or part of a systemic process, are staged in accordance with a modified Ann Arbor system originally used in Hodgkin disease (Chapter 185).

TREATMENT

Rx

In general, surgical excision is the treatment of choice for most localized small bowel tumors. The extent of excision necessary depends on the tumor's location and histology. Adenocarcinomas involving the first and second portions of the duodenum require pancreaticoduodenectomy, whereas those in the more distal small intestine may be treated with segmental or wide local resection, including regional lymph nodes. Low-grade neuroendocrine tumors

should be managed with en bloc resection, again including regional nodes. GISTs, which very rarely spread to regional nodes, may be treated with excision without lymphadenectomy (except in cases with gross involvement of nodes). Primary surgery for lymphomas may be offered for low-stage malignancies and may also be required for complications of disease (e.g., intussusception). Local management of benign small bowel tumors varies from observation (incidentally discovered lipomas) to endoscopic polypectomy (small adenomas) to pancreaticoduodenectomy (periampullary villous adenomas) (Video 193-2).

The need for and types of adjuvant therapy vary as well. Fully resected benign tumors require no additional therapy. Adenocarcinomas are often treated according to the principles developed for colorectal cancer, with some experts advocating fluoropyrimidine-based systemic chemotherapy, at least for patients with nodal involvement. Older retrospective studies demonstrated no benefit from adjuvant systemic therapy, but its use has still increased almost three-fold over the last two decades. Chemoradiotherapy has occasionally been recommended for those with more locally advanced duodenal adenocarcinomas. So far, no randomized trials have proven either strategy offers any advantage. Fully excised well- to moderately differentiated neuroendocrine cancers do not require adjuvant therapy. Postoperative imatinib mesylate treatment clearly postpones the recurrence of high-risk GISTs (Grade A)■; a survival benefit has been demonstrated for those with gastric and nongastric primaries. Questions remain regarding dose and ideal duration of therapy. There is no defined role for the postoperative treatment of other mesenchymal tumors. Lymphomas treated with excision alone have high rates of recurrence, and systemic chemotherapy is advocated for high-grade variants; some experts also recommend chemotherapy for low-grade subtypes.

Patients with advanced small bowel adenocarcinomas are often treated with systemic chemotherapy regimens known to be effective against cancers of similar histology originating in the colon. However, the data supporting any specific regimen are scant and are not derived from randomized trials. Approximately 90% of patients with incurable GISTs have durable disease control when treated with the tyrosine kinase inhibitor imatinib mesylate, and the median survival for patients with metastatic disease has recently improved from approximately 18 months to 5 years.

Patients with small bowel lymphomas may be treated with chemotherapy that is effective in similar tumors originating outside the GI tract.

PROGNOSIS

Patients with small bowel adenocarcinomas generally do worse than those with similarly staged colonic glandular tumors. Also, patients with duodenal primaries may have poorer outcomes than those with more distal small bowel cancers. In general, 5-year survival rates range from 4% for those with metastases to 80% for those with very early disease confined to the small bowel wall. Five-year survival in patients with small bowel carcinoids exceeds 50%. In the pre-imatinib era, patients with surgically resected small bowel GISTs had recurrence rates ranging to 90% or higher, depending on the tumor's size, precise location, and mitotic rates; those with more distal tumors had a worse prognosis than those with duodenal primaries. Patients with recurrences almost invariably died within 2 years because salvage surgery and systemic chemotherapy were ineffective. True life expectancy in the era of postoperative imatinib use is unknown, but the median survival of patients with advanced GISTs likely exceeds 5 years. Small intestinal lymphomas have 5-year survival rates surpassing 60%, although this is highly variable and depends on the histologic subtype.

NEOPLASMS OF THE LARGE INTESTINE

Colorectal cancer (CRC) is the third most common cancer in the United States. Disease that has spread beyond regional lymph nodes is, for the most part, incurable, and CRC in general remains the second leading cause of neoplastic death. The lifetime risk of developing CRC for the average individual is about 1 in 18 to 20.

EPIDEMIOLOGY

Almost three quarters of large bowel cancers arise proximally (i.e., are of colonic origin). Although CRC is primarily a disease of the elderly (median age ≈ 73 years), about 10% of cases occur in those aged 50 or younger. CRC incidence and mortality have decreased overall recently, although the incidence has been increasing in the young. Incidence rates for right-sided cancers have also been decreasing, possibly but not solely owing to effective distal large bowel screening with flexible sigmoidoscopy. CRC is slightly more common in men than in women and in African Americans than in whites. Men develop CRC an average of 5 to 10 years earlier than women; similarly, large bowel cancers seem to arise an average of 5 to 10 years earlier in African Americans than in whites. Significant geographic variation in incidence occurs, probably based more on environmental factors than on genetic ones, as suggested by migration studies.

PATHOBIOLOGY

Between 96 and 98% of CRCs are adenocarcinomas. Rarely seen histologies include neuroendocrine cancers, epidermoid carcinomas, lymphomas, and sarcomas (including GISTs). Composites, particularly adenocarcinomas with neuroendocrine differentiation, are frequently encountered.

Adenocarcinomas derive from colonic columnar glandular epithelium in the colorectal mucosal lining. They are equally common in males and females and are most frequently reported in the sigmoid colon. Adenocarcinomas most commonly present at a localized or regional (nodal) stage. About two thirds are of moderate grade. The majority are nonmucinous, although the mucinous phenotype constitutes up to one fifth of all CRCs. Another variant is the true signet ring carcinoma, identified by large quantities of single tumor cells with nuclear displacement by intracytoplasmic mucin. Data are controversial as to whether mucinous tumors have a worse prognosis, whereas signet ring histology is clearly associated with advanced disease and/or worse outcome.

Neuroendocrine cancers can have a variety of histologies ranging from bland, well-differentiated carcinoids to high-grade small-cell carcinomas. True carcinoids are the second most common histologic colorectal subtype. They are more common in nonwhites and make up the vast majority of non-adenocarcinoma epithelial cancers. Distal bowel carcinoids are hormonally inactive. Noncarcinoid neuroendocrine cancers tend to be high grade and commonly present with hepatic and other distant metastases.

Epidermoid carcinomas are rare overall but still account for up to one fourth of CRCs. Most are squamous cell subtypes. They are more common in women and Hispanic patients. Epidermoid carcinomas are located in the rectum more than 90% of the time, and they are usually moderately or poorly differentiated. Interestingly, they commonly present as localized cancers, regardless of their degree of differentiation.

Medullary carcinomas, which are more often right-sided and seen in older female patients, tend to have a lower incidence of lymph node involvement. The majority exhibit microsatellite instability, and they tend to have a relatively better prognosis.

Primary colorectal lymphomas are fairly rare, constituting 10 to 20% of all GI lymphomas but less than 1% of CRCs. They are much more common in males and in the elderly. The cecum is the most common site of origin. Tumors are usually of B-cell origin.

Sarcomas of the large bowel have no gender or racial predilections. More than 50% have been classified as leiomyosarcomas, and they are most commonly found in the rectum. Sarcomas are usually diagnosed at a localized stage, regardless of grade, although about 40% are actually poorly differentiated. Kaposi sarcomas and GISTs are other sarcoma histologies found in the large bowel; many of the distal tumors called "leiomyosarcomas" in older registries were likely true GISTs.

Predisposing Conditions

Predisposing conditions for colonic neoplasia include age (discussed previously), gender, race, inflammatory bowel disease, family history,[1] and defined inherited syndromes. Defined genetic cancer syndromes, however, account for only a small percentage of CRCs (see later). Patients with first-degree relatives who also have colon neoplasia (adenomas or carcinomas) are commonly seen. Individuals with a first-degree relative with CRC face a 2- to 3-fold increased risk for malignancy, and this risk rises to 5- or 6-fold if two first-degree relatives are affected. Patients whose relatives have adenomas face a 1.8-fold increased risk for CRC, and this rises to 2.6 if the relative is younger than 60 years.

Patients with ulcerative colitis and Crohn disease (Chapter 141) are at increased risk for CRC in proportion to the amount of bowel involved and the duration of illness.[2] For example, adenocarcinoma of the colon is 10 to 20 times more common in persons with ulcerative colitis than in the general population. Between 2 and 4% of all patients with long-term ulcerative colitis develop this malignancy, and the cumulative incidence over a 25-year period is approximately 12%. Overall, the incidence of colorectal adenocarcinoma is 60% higher in persons with inflammatory bowel disease than in the general population and has been stable over time. Patients with both ulcerative colitis and primary sclerosing cholangitis seem to be at even greater risk. For those with Crohn colitis, patients with extensive disease involving more than one third of the colon are at increased risk (six- to eight-fold), similar to those

VIDEO 193-2. **Laparoscopic-assisted double balloon enteroscopy with polypectomy of a jejunal adenoma, followed by surgical oversew of the polypectomy site.**

TABLE 193-1 GENERAL FEATURES OF INHERITED COLORECTAL CANCER SYNDROMES

SYNDROME	POLYP HISTOLOGY	POLYP DISTRIBUTION	AGE OF ONSET	RISK OF COLON CANCER	GENETIC LESION	CLINICAL MANIFESTATIONS	ASSOCIATED LESIONS
Familial adenomatous polyposis	Adenoma	Large intestine, duodenum	16 yr (range, 8-34 yr)	100%	5q (*APC* gene)	Rectal bleeding, abdominal pain, bowel obstruction	Desmoids, CHRPE
Peutz-Jeghers syndrome	Hamartoma	Large and small intestine	First decade	Slightly above average	19p *(STK11)*	Possible rectal bleeding, abdominal pain, intussusception	Orocutaneous melanin pigment spots, other tumors
MUTYH-associated polyposis	Adenoma	Large intestine, duodenum	45-50 yr (range, 13-60 yr)	75% (range, 50-100%)	1p (*MUTYH* gene)	Rectal bleeding, abdominal pain, bowel obstruction	CHRPE, osteomas
Juvenile polyposis	Hamartoma (rarely adenoma)	Large and small intestine	First decade	≈9%	*PTEN*, *SMAD4*, *BMPR1*	Possible rectal bleeding, abdominal pain, intussusception	Pulmonary AVMs
Hereditary nonpolyposis colon cancer	Adenoma	Large intestine	40 yr (range, 18-65 yr)	30%	Mismatch repair genes*	Rectal bleeding, abdominal pain, bowel obstruction	Other tumors (e.g., ovary, uterus, pancreas, stomach)

*Including *hMSH2*, *hMSH3*, *hMSH6*, *hMLH1*, *hPMS1*, and *hPMS2*.
AVM = arteriovenous malformation; CHRPE = congenital hypertrophy of the retinal pigment epithelium.

with ulcerative colitis. Isolated proctitis is not a risk factor. Patients with ulcerative colitis or extensive Crohn disease should undergo screening colonoscopy every 1 to 2 years beginning 8 to 10 years after disease onset. At colonoscopy, a dye spray may be used to identify suspicious areas, and multiple biopsies (at least 32 for pan-colitis) are obtained with targeting of suspicious lesions. The purpose of this is to identify the presence of dysplasia. The presence of high-grade dysplasia, any dysplasia in a mass or lesion that cannot be excised endoscopically, or multifocal low-grade dysplasia should prompt colectomy.

Patients who have had ureterocolostomy and those with acromegaly are also at increased risk. Case-control studies suggest that obesity, low physical activity, smoking, excessive alcohol, high-fat diet, and lack of dietary fiber increase the CRC risk. Patients with *Streptococcus bovis* bacteremia or endocarditis have increased rates of CRC and should undergo colonoscopy.

Polyposis Syndromes

Several defined dominant and recessive genetic conditions have been identified that convey an increased risk of CRC (Table 193-1). These include FAP, HNPCC, *MUTYH*-associated polyposis, PJS, juvenile polyposis, *PTEN* hamartoma syndrome, and Cronkhite-Canada syndrome.

FAMILIAL ADENOMATOUS POLYPOSIS

FAP is an autosomal dominant condition characterized by the development of hundreds to thousands of adenomatous polyps and CRC by age 40 (Fig. 193-4). Estimates of disease prevalence are 1 in 8000 to 15,000 births.

PATHOBIOLOGY

FAP is inherited as an autosomal dominant disease with incomplete penetrance. It has been mapped to the adenomatous polyposis coli *(APC)* gene located on the long arm of chromosome 5 (5q21). *APC* is a tumor suppressor gene that is a critical regulator of intestinal epithelial cell growth. Inherited mutations generally result in a truncated gene product. Patients with the familial syndrome inherit one mutant copy of *APC;* when a loss-of-function mutation develops in the other *APC* allele, mucosal epithelial cell growth is no longer controlled normally, and polyps develop. Variable phenotypes can be partly attributed to differences in the location of the *APC* mutation, with attenuated FAP being seen in mutations at the 5′ and 3′ ends of the gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Adenomas begin to appear early in the second decade of life, and GI symptoms begin to appear in the third or fourth decade. Polyps are distributed relatively evenly throughout the colon, although a slight predominance has been noted in the distal colon. Almost all patients with FAP develop frank colorectal carcinoma by age 40 years if the condition is left untreated. Gastric polyps (mostly nonadenomatous) occur in 30 to 100% of patients, and duodenal adenomas are found in 45 to 90%. Periampullary duodenal cancer develops in approximately 10% of cases. Small bowel lesions that are distal to the duodenum rarely progress to malignancy. In attenuated FAP, fewer than 100 colonic adenomas develop, there is a right colon predominance, and cancer develops approximately 10 years later. Genetic testing may identify the mutation in up to 85% of affected individuals and is useful for family screening.

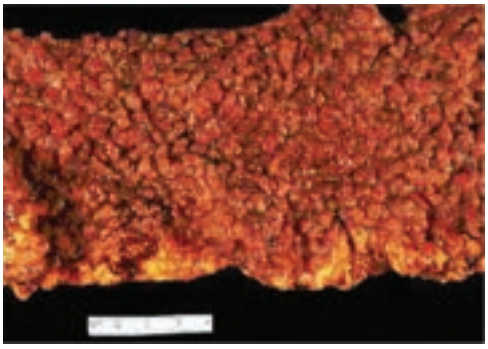

FIGURE 193-4. Resected colon lined with hundreds of adenomatous polyps in a patient with familial adenomatous polyposis.

TREATMENT Rx

The primary treatment option in FAP patients is total proctocolectomy with conventional ileostomy or ileoanal (pouch) anastomosis. Individuals with *APC* mutations and those with no identified mutation but clinical FAP in their families should be screened with annual sigmoidoscopy beginning at age 10 to 12 years. In families with known *APC* mutations, individuals who test negative do not require heightened surveillance but should undergo routine risk screening. FAP patients should be screened for duodenal polyposis with upper endoscopy beginning at age 20, with subsequent surveillance depending on polyp burden and histology. Cyclooxygenase-2 inhibition with sulindac or celecoxib may be considered in patients with small bowel adenomas or adenomas in the remnant rectum. Eicosapentaenoic acid supplementation has also been shown to decrease polyps in the remnant rectum.

GARDNER SYNDROME

Gardner syndrome is a phenotypic subtype of FAP that is also caused by mutations in the *APC* gene. It is distinguished by the presence of extraintestinal manifestations, including osteomas (particularly mandibular), soft tissue tumors (including lipomas, sebaceous cysts, and fibrosarcomas), supernumerary teeth, desmoid tumors, mesenteric fibromatosis, and congenital hypertrophy of the retinal pigment epithelium. The phenotypic differences between Gardner syndrome and FAP appear to result from variations in the location of the *APC* mutation, the presence of modifying genes, and environmental factors. Adenomatous polyps in Gardner syndrome have the

same malignant potential as those found in FAP, and CRC screening and treatment recommendations are the same.

TURCOT SYNDROME

A hallmark of Turcot syndrome is the combination of colorectal polyposis and malignant diseases of the central nervous system. Mutations in the *APC* gene account for two thirds of cases, and the remaining one third result from mutations in the DNA mismatch repair genes that are also mutated in HNPCC. Central nervous system manifestations include medulloblastomas, glioblastomas, and ependymomas.

HEREDITARY NONPOLYPOSIS COLON CANCER

HNPCC, also known as Lynch syndrome, is the most common hereditary CRC syndrome and accounts for approximately 2% of all cases of CRC. It is an autosomal dominant trait and is highly penetrant. Clinically, HNPCC has been defined by the presence of all three of the following: (1) three or more relatives with histologically verified HNPCC-associated cancer (CRC or cancer of the endometrium, small bowel, ureter, or renal pelvis), one of whom is a first-degree relative of the other two, in the absence of FAP; (2) CRC involving at least two generations; and (3) one or more family members with cancer diagnosed before age 50.

PATHOBIOLOGY

HNPCC is caused by loss-of-function germline mutations in a set of genes involved in the repair of DNA base pair mismatches that occur during DNA replication (also known as the mutation mismatch repair system).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The median age for diagnosis of HNPCC is the mid-40s. Although several adenomas may be present, the diffuse polyposis characteristic of FAP is not found. Colonic neoplasia has a right-sided predominance (proximal to the splenic flexure). Although the cancers tend to be poorly differentiated, they generally have a better prognosis than similar sporadic CRCs. Synchronous and metachronous CRC is common. Patients with HNPCC are also at high risk for other malignant diseases, especially endometrial carcinoma, as well as cancers of the ovary, stomach, small bowel, hepatobiliary tract, ureter, and pancreas.[3] The Muir-Torre syndrome variant is associated with cutaneous lesions and visceral malignancies. Screening for HNPCC may begin with testing of the tumor for microsatellite instability, performing immunohistochemical staining for products of mismatch repair genes (including *hMSH2*, *hMSH6*, *hMLH1*, and *hPMS2*). A positive screen does not definitely indicate HNPCC, because up to 15% of sporadic tumors may have these features; this should be followed with germline testing.

TREATMENT Rx

Persons potentially affected with HNPCC should undergo a colonoscopy every 2 years beginning at age 21 and annually beginning at age 40. Patients with CRC or large adenomas should undergo subtotal colectomy. Women in HNPCC-affected families should have pelvic examinations every 1 to 3 years beginning at age 18; annual pelvic examinations, transvaginal ultrasonography, and endometrial biopsy have been recommended beginning at age 25. Prophylactic total abdominal hysterectomy with bilateral salpingo-oophorectomy may also be considered at the time of colectomy. Chemoprophylaxis with aspirin 600 mg daily may be considered; one randomized controlled trial did show benefit.

MUTYH-ASSOCIATED POLYPOSIS

MUTYH-associated polyposis is a recently described autosomal recessive syndrome caused by mutations in the *MUTYH* gene (also called *MYH* [mutY homologue]). It is characterized by colonic polyposis and a high rate of CRC. Approximately 0.4% to 0.7% of CRC patients are homozygous for *MUTYH* mutations.

PATHOBIOLOGY

MUTYH-associated polyposis is caused by a biallelic inherited defect in the *MUTYH* gene located on chromosome 1p. Inherited as an autosomal recessive trait, this leads to defects in base excision repair and acquired mutations of the *APC* gene and other genes, such as *KRAS*. This results in adenoma formation and the subsequent development of adenocarcinoma.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Phenotypically, affected patients are similar to those with attenuated FAP. Patients have five to hundreds of adenomas. Multiple hyperplastic polyps and serrated adenomas may also be seen. The onset is later than in classic FAP, with cancers more likely to be right sided and to occur at age 45 to 50. Associated extracolonic features include gastroduodenal polyps, duodenal carcinoma, breast and ovarian cancer in female carriers, bladder cancer, skin cancer, congenital hypertrophy of the retinal pigment epithelium, and osteoma. Monoallelic carriers do not appear to have an increased cancer risk.

The diagnosis is suggested by the presence of colonic polyposis in the absence of FAP, or when there appears to be recessive inheritance. In these cases, genetic testing for *MUTYH* gene mutations should be considered. Whether heterozygote carriers are at increased risk has not been established, but screening similar to that for individuals with first-degree relatives with CRC may be advisable (i.e., colonoscopy at age 40 and then every 5 years).

TREATMENT Rx

Patients with numerous polyps should undergo colectomy. Patients with mild disease and a relatively small number of polyps may be considered for colonoscopy with polypectomy and regular surveillance. Colonoscopy should be performed beginning at age 18 to 20 and repeated every 1 to 2 years. Regular endoscopic surveillance for duodenal polyps should also be performed beginning at age 25 to 30.

PEUTZ-JEGHERS SYNDROME

PJS is an intestinal hamartomatous polyposis of the upper and lower GI tract that is associated with characteristic mucocutaneous pigmentation. The average age at diagnosis is in the mid-20s. PHS predisposes to both intestinal and extraintestinal malignancies.

PATHOBIOLOGY

PJS is a rare autosomal dominant syndrome with high penetrance. The prevalence is between 1 in 8300 and 1 in 29,000. The gene responsible for the syndrome is the serine-threonine kinase *(STK11)* gene located on chromosome 19p; a mutation in *STK11* is found in approximately 60% of patients with this syndrome. The hamartomatous polyps in PJS are located predominantly in the small intestine (64 to 96%), stomach (24 to 49%), and colon (60%). Histologically, these polyps are benign; they are unique in that a layer of muscle that extends into the submucosa or muscularis propria may surround the glandular tissue. Adenomatous and hyperplastic polyps may also be found.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptoms are small bowel intussusception, obstruction, and GI bleeding that may require surgery and may be recurrent. PJS is associated with an increased risk of cancer, with an estimated 47% of patients developing a malignancy by age 65. The most common cancers are those of the small intestine, stomach, colon, pancreas, testes, breast, ovary, cervix, and uterus. More than 95% of patients have a characteristic pattern of melanin spots on the lips, buccal mucosa, and skin (Fig. 193-5). Because genetic testing is not widely available, first-degree relatives should be screened beginning at birth with an annual history, physical examination, and evaluation for melanotic spots, precocious puberty, and testicular tumors.

TREATMENT Rx

Standard medical care for patients with PJS involves an annual physical examination that includes evaluation of the breasts, abdomen, pelvis, and testes, as well as a complete blood cell count. Surveillance for cancer includes small bowel radiography every 2 years, esophagogastroduodenoscopy and colonoscopy every 2 years, and endoscopic ultrasound of the pancreas every 1 to 2 years. For women, annual Pap smear, transvaginal ultrasound, CA125, and mammography are recommended. Polyps larger than 1 cm should be removed endoscopically. Laparotomy and resection are recommended for recurrent or persistent small intestinal intussusception, obstruction, or intestinal bleeding.

FIGURE 193-5. Mucosal pigmentation in a patient with Peutz-Jeghers syndrome.

JUVENILE POLYPOSIS

Familial juvenile (non-neoplastic, hamartomatous) polyposis is a rare (<1 in 100,000 births) syndrome characterized by 10 or more non-neoplastic hamartomatous polyps throughout the GI tract, or any number of polyps in a patient with a family history of juvenile polyposis. The syndrome is inherited in an autosomal dominant manner with high penetrance and is caused by mutations in the *SMAD4*, *PTEN*, or *BMPR1A* gene. The hamartomas are histologically distinct from the polyps seen in PJS. Patients generally present with rectal bleeding, anemia, abdominal pain, or intestinal obstruction in childhood or early adolescence. Extraintestinal symptoms include pulmonary arteriovenous malformations in some probands. The risk of malignancy in juvenile polyposis is reportedly as high as 20% and occurs in adulthood (median age, 37 years). Affected individuals should undergo regular colonoscopic surveillance. Patients with numerous, large, or high-grade dysplastic polyps may be considered for subtotal colectomy. Family members should be screened with colonoscopy every 3 to 5 years beginning at age 12 to 15 until age 40.

PTEN HAMARTOMA SYNDROME

PTEN hamartoma syndrome is a rare autosomal dominant syndrome consisting of multiple hamartomatous polyps of the skin and mucous membranes, including GI polyps, facial tricholemmomas, oral papillomas, and keratoses of the hands and feet. It was previously referred to as Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome. The causative genetic lesion has been mapped to the *PTEN* tumor suppressor gene. The rate of associated malignancy is high, particularly in the thyroid, breast, and reproductive organs. The polyps in *PTEN* hamartoma syndrome are benign. The incidence of CRC is approximately 10 times higher than in the general population.

CRONKHITE-CANADA SYNDROME

Cronkhite-Canada syndrome is a rare, sporadic, acquired condition characterized by multiple hamartomatous polyps throughout the GI tract, along with alopecia, dermal pigmentation, and atrophy of the nail beds. Symptoms include diarrhea, protein-losing enteropathy, GI bleeding, intussusception, and rectal prolapse. It carries a poor prognosis, with 5-year mortality rates as high as 55%. Patients are at risk for gastric and CRC, and endoscopic surveillance has been recommended.

MISCELLANEOUS GENETIC SYNDROMES

Recently, several new syndromes have been identified that predispose to CRC. In the serrated polyposis syndrome, affected individuals have multiple (≥5), large (at least 2 ≥ 10 mm), serrated adenomas, affected family members, and an increased CRC risk. Patients with defects in the epithelial cell adhesion molecule *(EPCAM)* gene have the phenotypic features of Lynch syndrome without mutations of the mismatch repair genes. Germline defects in the *POLE* and *POLD1* genes leads to DNA proofreading errors, polyposis, and/or CRC. The hereditary mixed polyposis syndrome is an autosomal dominant condition causing polyps of multiple and mixed morphologies and CRC; the causative genetic defect (a duplication spanning the 3′ end of the *SCG5* gene and a region upstream of the *GREM1* locus) has recently been discovered.

Polyps of the Colon

A polyp is defined as a grossly visible mass of epithelial cells that protrudes from the mucosal surface into the lumen of the intestine. A polyp may be sessile, flat, or pedunculated when it is attached by a stalk. Polyps are classified as either non-neoplastic or neoplastic (adenomatous). Polyps may rarely cause symptoms such as bleeding, prolapse, or obstruction. Neoplastic polyps have the potential to become malignant.

NON-NEOPLASTIC POLYPS

Non-neoplastic polyps account for approximately half of all mucosal polyps detected in the large bowel of average-risk individuals older than age 50 years. These polyps, which are also termed *nonadenomatous polyps*, can be subcategorized into hyperplastic, inflammatory, lymphoid, and juvenile polyps. Most non-neoplastic polyps are hyperplastic polyps that arise as a result of abnormal maturation of the mucosal epithelial cells; these polyps are usually small in diameter and are found predominantly in the distal sigmoid colon and rectum. Hyperplastic polyps are not malignant and are not thought to be associated with any measurable increase in malignant potential. Patients with inflammatory bowel disease may develop inflammatory pseudopolyps, which may require biopsy or removal to distinguish them from neoplastic polyps. Lymphoid polyps are regions of the mucosa that contain exaggerated intramucosal lymphoid tissue. Juvenile polyps usually develop in the rectum of children younger than 5 years and are termed *hamartomatous* because they are focal malformations that resemble tumors but are caused by abnormal development of the lamina propria; these polyps require no therapy unless they cause symptoms (e.g., obstruction, severe bleeding) or are part of a genetic syndrome.

ADENOMATOUS POLYPS

DEFINITION

Adenomatous polyps (or adenomas) are neoplastic polyps with malignant potential. They are benign glandular tumors that exhibit either low- or high-grade dysplasia under microscopy. Their anatomic distribution parallels that of colorectal adenocarcinoma. Adenomatous polyps manifest in a range of sizes and may be sessile, flat, or pedunculated in morphology. They are believed to be the precursor lesion to colorectal adenocarcinoma, a process that occurs along the adenoma-carcinoma sequence. Evidence supporting the adenoma-carcinoma sequence comes from several sources. Patients with genetic conditions that predispose to adenoma formation (e.g., FAP) develop cancer at high rates. Animal studies in which adenomas are induced by either carcinogens or genetic manipulation show carcinoma formation. Correlative evidence includes the observations that the epidemiology is similar for adenomas and carcinomas, that both lesions are more common in the same anatomic locations, and that adenomatous tissue can often be found in small adenocarcinomas. Intervention studies have shown that the removal of adenomatous polyps leads to a significant decrease in the risk for CRC.

EPIDEMIOLOGY

Adenomatous polyps are relatively common, particularly in elderly populations. Among healthy screening populations older than 50 years, adenomas are found in more than 15% of women and 25% of men. The prevalence of adenomas tends to be high in regions of the world where CRC is common. The importance of genetic risk factors is clear in the hereditary polyposis syndromes, and sporadic adenomas have a familial component; for example, individuals with a positive first-degree family history have a four-fold greater risk of developing adenomatous polyps. African Americans in the United States have an increased risk for developing adenomas and carcinomas relative to whites; the risk in Asian and Hispanic individuals is similar to that in whites.

PATHOBIOLOGY

The layer of epithelial cells lining the surface of the normal large bowel undergoes continuous self-renewal, with a turnover period of 3 to 8 days. Undifferentiated stem cells located at the base of invaginated crypts give rise to cells that migrate toward the lumen as they differentiate further into specialized enterocytes; these cells are subsequently removed by apoptosis, by extrusion, or by phagocytes underlying the epithelial layer. The development of adenomatous polyps is associated with a sequence-specific accumulation

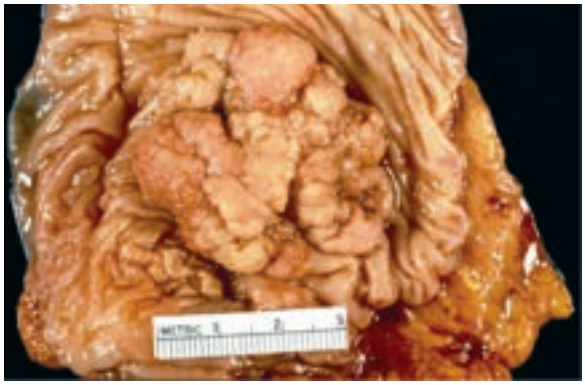

FIGURE 193-6. Villous adenoma. Large and sessile villous adenomas of the large bowel with finger-like projections into the gut lumen. (Courtesy Dr. M.K. Washington.)

of genetic lesions that cause an imbalance between epithelial cell proliferation and cell death. As a result, cells accumulate at the luminal surface, where they remain undifferentiated and continue to undergo cell division, eventually leading to the abnormal development of a mass of adenomatous tissue.

Adenomas are classified into three main histologic subtypes: tubular adenomas, villous adenomas (Fig. 193-6), and tubulovillous adenomas. Tubular adenomas account for 70 to 85% of all adenomas removed at colonoscopy. They are often small and pedunculated, and they consist of dysplastic tubular glands that divide and branch out from the mucosal surface; they rarely contain concomitant high-grade dysplasia or carcinoma. In contrast, villous adenomas (<5% of all adenomas) are generally large and sessile and are composed of strands of dysplastic epithelium that project, finger-like, into the lumen of the gut; they have a much higher prevalence of high-grade dysplasia or carcinoma. Tubulovillous adenomas (10 to 25% of all adenomas) have a mixture of tubular and villous architecture. Advanced adenomas are defined as those that measure 1 cm or greater or have any villous histology or high-grade dysplasia. Patients with advanced adenomas or multiple adenomas (three or more) are at much greater risk for synchronous (developing simultaneously) or metachronous (developing after a time interval) CRC.

CLINICAL MANIFESTATIONS

Patients with adenomatous polyps generally remain asymptomatic, but they may present with an asymptomatic positive stool occult blood test or with evident hematochezia. The lifetime incidence of additional adenomas in a patient with one known adenoma is 30 to 50%. Fewer than 5% of all adenomas eventually develop into carcinomas. Two critical factors that determine the likelihood of an adenoma developing into an invasive lesion are the size of the polyp and the grade of dysplasia. For polyps less than 1 cm, the risk for carcinoma is 1 to 3%; polyps between 1 and 2 cm have a 10% risk of becoming cancerous; and more than 40% of polyps greater than 2 cm progress to an invasive lesion. All adenomatous polyps contain some degree of dysplasia, but they can be further categorized as low- or high-grade to indicate the degree of dysplasia and the corresponding risk for invasive carcinoma. High-grade dysplasia is associated with a 27% rate of eventual transformation into carcinoma.

DIAGNOSIS

Adenomatous polyps in the colon and rectum can be diagnosed by endoscopy, barium radiography, or CT scanning (CT colography or virtual colonoscopy). Colonoscopy is the preferred method for diagnosing adenomas because of its high accuracy and the ability to immediately biopsy and resect most polyps. Barium enema, as assessed in the National Polyp Study, missed 52% of polyps measuring 1 cm or more. CT colography has good sensitivity for detecting large (>1 cm) polyps (>85%) and for detecting cancers (96%), but it is less sensitive and specific for smaller polyps. CT colography requires bowel preparation, exposes the patient to ionizing radiation, and cannot remove polyps. Colonoscopy may miss 6 to 12% of large (≥1 cm) polyps and 5% of cancers. Of note is that nonpolypoid (flat and depressed) colorectal neoplasms are found in about 9% of asymptomatic and symptomatic adults on colonoscopy and are more likely to contain a carcinoma than are polypoid lesions; these lesions may not be visible on barium radiography or CT.

Flexible sigmoidoscopy, which is often used to screen asymptomatic persons at average risk for colorectal adenocarcinoma, detects 50 to 60% of all polyps and cancers. Generally, patients who have polyps detected by barium radiography, CT colography, or flexible sigmoidoscopy should undergo colonoscopy to remove the lesion and search for additional polyps. In one study in which patients with polyps discovered by flexible sigmoidoscopy underwent subsequent colonoscopy, there was an 80% reduction in the incidence of CRC.

TABLE 193-2 COLONOSCOPY SURVEILLANCE INTERVALS

MOST ADVANCED FINDING	INTERVAL
No polyps or small (<10 mm) hyperplastic polyps	10 yr
1-2 adenomas, <1 cm	5-10 yr
3-10 adenomas or adenoma with villous features, ≥1 cm, or with high-grade dysplasia	3 yr
>10 adenomas	<3 yr
Sessile adenoma ≥ 2 cm, piecemeal excision	2-6 mo
Serrated lesions:	
<10 mm, no dysplasia	5 yr
≥10 mm or dysplasia	3 yr

SERRATED POLYPS

Sessile serrated adenomas/polyps (SSA/P) are a recently recognized neoplastic lesion with malignant potential. In the past, these have been confused with large, benign, hyperplastic polyps. SSA/P are characterized microscopically as having a disorganized and distorted crypt growth pattern. SSA/P are sessile or flat, may be difficult to distinguish on endoscopy and have a right colon predominance. The risk of progression to cancer is at least as high as for conventional adenomas. Pathogenesis is via hypermethylation of CpG islands ("CIMP-high") and *MLH1*, and have *BRAF* mutations, leading to polyps and tumors with microsatellite instability. Traditional serrated adenomas are a rare subtype that are histologically distinct from SSA/P and have a high prevalence of high-grade dysplasia and carcinoma in situ.

TREATMENT

Rx

The goal of treatment for neoplastic polyps is to remove or destroy the lesion during endoscopy. This recommendation is based on overwhelming evidence that endoscopic polypectomy reduces the subsequent incidence and mortality of CRC. Pedunculated adenomas are generally removed by snare polypectomy (Video 193-1), with subsequent submission of the tissue for pathologic analysis. Piecemeal snare resection may be required to remove sessile polyps. Surgical resection of a polyp is indicated when endoscopic resection of an advanced adenoma is not possible. The biopsied polyp must be evaluated histologically to determine the presence or absence of carcinoma; if a malignant lesion is found, its histologic grade, vascular and lymphatic involvement, and proximity to the margin of resection should be determined. Unfavorable histopathologic factors that should prompt surgical resection include poorly differentiated histology, vascular invasion, lymphatic invasion, and incomplete endoscopic resection. Malignant pedunculated polyps with cancer confined to the submucosa, with no evidence of unfavorable histologic features, can be definitively treated with endoscopic resection, without the need for surgical resection. Whether similar malignant sessile polyps can be managed nonoperatively is controversial. In these cases, the risk of surgery versus the risk of recurrence or lymphatic metastases needs to be balanced.

PROGNOSIS

Patients who have undergone resection of an adenomatous or sessile serrated polyp are at increased risk for the subsequent development of adenoma and colorectal adenocarcinoma. This risk is influenced by the size, histology, and number of adenomas, and the surveillance intervals differ (Table 193-2). Low-risk patients—those with only 1 or 2 small tubular adenomas—should undergo colonoscopy in 5 to 10 years. Patients with multiple (>2) adenomas, large (≥1 cm) adenomas, or adenomas with villous or high-grade histology should undergo colonoscopy in 3 years. Patients with numerous (>10) adenomas should undergo colonoscopy within 3 years. Patients who have had polypectomy of a large (≥2 cm) adenoma or an adenoma that had to be

removed in pieces (piecemeal resection) should undergo colonoscopy within 6 months to evaluate the completeness of the resection. Patients with sessile serrated polyps smaller than 10 mm without dysplasia should undergo surveillance colonoscopy at 5 years. Patients with sessile serrated polyps 10 mm or larger, high-grade dysplasia, or a traditional serrated adenoma should undergo colonoscopy at 3 years (Video 193-3).

Adenocarcinoma of the Colon and Rectum

PATHOBIOLOGY

Colorectal cancer is caused by the accumulation of multiple genetic lesions over time. Except for hypermutated tumors, colon and rectal primaries have similar patterns of alterations. Both the tissue architecture and the cellular genotype change as the disease progresses (Fig. 193-7).[4] Three distinct molecular pathways have been recognized: chromosomal instability, microsatellite instability, and CpG island methylator phenotype (CIMP). These pathways are not mutually exclusive, and tumors may exhibit features of more than one.

The chromosomal instability pathway is the most common, accounting for up to 70% of sporadic CRC. The most common gene mutations are in the *APC* gene (a tumor suppressor gene) and *KRAS* (a proto-oncogene involved in the transduction of mitogenic signals across cell membranes). Germline mutations in *APC* are the cause of FAP. Chromosomal instability leads to aneuploidy (imbalance in chromosome number), genomic amplifications, and loss of heterozygosity where cells have only one allele of a gene owing to the loss of individual chromosomes during mitosis. Additional important affected genes include the mutated in colon cancer *(MCC)* gene (a tumor suppressor gene), *p53* (a regulator of the cell cycle), *VEGF*, *MYC*, *MET*, *LYN*, *PTEN*, and others. Many of the genetic changes affect the Wnt signaling pathway, which appears to be important for initiation and progression of CRC.

The microsatellite instability (MSI) pathway is caused by defects in DNA mismatch repair. Microsatellites are short, repeating nucleotide sequences that are prone to errors owing to their repetitive nature. MSI-high tumors have genetic defects in the mismatch repair genes, especially *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Germline mutations in these genes are the cause of HNPCC (Lynch syndrome). Hypermethylation silencing of *MLH1* also results in MSI-high cancers. MSI-high tumors are more common in the right colon, in women, and have a lymphocytic infiltration and poor differentiation. They are associated with improved survival, despite being less responsive to some chemotherapeutic agents such as 5-fluorouracil.

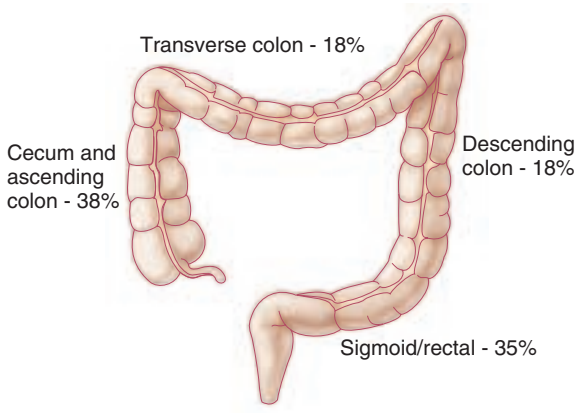

FIGURE 193-8. Sites of development of large bowel adenocarcinoma.

In the CIMP pathway, hypermethylation of DNA promoter regions leads to gene silencing, and silencing of tumor suppressor genes leads to carcinogenesis. In colorectal carcinogenesis, these include *APC*, *MCC*, *MLH1*, *MGMT*, and others. CIMP-high tumors are often poorly differentiated with mucinous or signet ring morphology, are MSI-high, and have *BRAF* mutations. The sessile serrated adenoma is likely the precursor lesion.

CLINICAL MANIFESTATIONS

The majority of patients with CRC present with symptoms; these may be emergent. Common symptoms related to primary disease include rectal bleeding with or without manifestations of anemia, abdominal pain, and change in bowel function. Patients with systemic disease may exhibit anorexia, weight loss, and symptoms related to hepatic dysfunction, such as jaundice, icterus, and ascites (the last may also be seen with peritoneal metastases). Symptoms vary depending on the primary site (Fig. 193-8). Proximal lesions are more likely to present with bleeding and associated symptoms; more distal disease has a higher risk of obstruction and perforation. Rectal cancers can also manifest with tenesmus and changes in stool caliber. They involve sacral nerve plexi, causing significant neuropathic pain. Patients with PJS or

Gardner syndrome may exhibit extraintestinal manifestations. Patients with *Streptococcus bovis* bacteremia or endocarditis are at increased risk of harboring CRC and should undergo colonoscopy.

TABLE 193-3 OPTIONS FOR COLORECTAL NEOPLASIA SCREENING*

TEST	INTERVAL
TESTS THAT DETECT ADENOMATOUS POLYPS OR CANCER	
Colonoscopy	Every 10 yr
Flexible sigmoidoscopy†	Every 5 yr
CT colography†	Every 5 yr
Double-contrast barium enema†	Every 5 yr
TESTS THAT DETECT PRIMARILY CANCER†	
Fecal occult blood tests	
High-sensitivity guaiac-based fecal occult blood test	Annually
Fecal immunochemical test	Annually
Stool DNA	Interval uncertain

*Beginning at age 50 for average-risk individuals.
†Positive test should prompt full colonoscopy.
CT = computed tomography.

DIAGNOSIS

The history, physical examination, and judicious use of both laboratory and radiologic tests are important in diagnosing CRC. The history should include the possibility of prior CRC or adenomatous polyps, inflammatory bowel disease, and family history of colonic neoplasia. On physical examination, extraintestinal lesions characteristic of PJS or Gardner syndrome may be noticed. Metastatic disease may be suggested by enlargement of left supraclavicular lymph nodes (Virchow's nodes) or the liver, or by the presence of an umbilical mass (Sister Mary Joseph's node) or ascites. The digital rectal examination may reveal a distal rectal cancer or spread of the tumor to the rectal shelf or pelvis (Blumer's shelf). The stool shows evidence of frank or occult blood in 40 to 80% of advanced cases. Iron deficiency anemia or an elevation in liver enzymes may aid in the diagnosis. The CEA level may be elevated, but it cannot be relied on for diagnosis, owing to inadequate sensitivity.

Methods for diagnosing CRC are similar to those used to detect adenomatous polyps. Colonoscopy is the procedure of choice for all patients who have occult blood in their stools, unexplained iron deficiency anemia, or signs and symptoms suggestive of CRC (Fig. 193-9). Colonoscopy is more accurate than barium radiographic studies for the detection of colorectal neoplasms of all sizes and has the advantage of enabling the clinician to detect synchronous cancers and to obtain tissue for histologic analysis.

Additionally, accurate *local* staging of rectal cancers is paramount. Endoscopic ultrasound combines high-frequency ultrasonography with videoendoscopy. It is superior to CT and allows an accurate determination of the degree of invasion and detection and sampling of enlarged lymph nodes. Endoscopic ultrasound is also highly sensitive for the detection of rectal cancer recurrence after local resection or low anterior resection. MRI using either endorectal or phased array coils can also provide accurate local staging of rectal cancer. Local staging of nonrectal large bowel cancer is generally not performed preoperatively, because this information is not used to guide therapy.

Many expert consensus guidelines now recommend CT scans of the abdomen and pelvis for CRC patients because advanced liver metastases would preclude resection of an asymptomatic primary. Chest imaging with plain films or CT is recommended as well. PET scans have specific uses in defined cases of CRC, such as precluding additional systemic disease before resection of a solitary metastatic site. They may also be used to further describe abnormalities seen on CT. However, there is no role for PET in the routine work-up. Plain abdominal films are mostly useful in diagnosing obstruction.

Screening

The purpose of screening is to reduce CRC-related mortality by removing the precursor adenomas and detecting prevalent cancers at earlier, more curable stages.[5] The long latency between adenoma development and subsequent cancer, on the order of 10 to 20 years, makes CRC a preventable disease through colonoscopy with polypectomy. It is an age-associated disease, and most patients should begin screening at age 50.[6] There is a range of options for average-risk individuals (Table 193-3). These can be divided into two categories: stool tests, which include tests for occult blood and abnormal DNA, and structural tests, which include colonoscopy, flexible sigmoidoscopy, CT colography, and double-contrast barium enema. Stool tests are best suited for detecting prevalent cancers (and some advanced adenomas), whereas structural tests detect both cancers and adenomas. In a randomized trial of asymptomatic adults 50 to 69 years of age, one-time colonoscopy and fecal immunochemical testing were equally good at finding prevalent colon cancer, but more adenomas were identified by colonoscopy.[6] These tests may be used alone or in combination. Current multisociety guidelines recognize the multiple screening options but encourage the use of structural tests that have the ability to both detect and prevent CRC. For example, the American College of Physicians recommends that clinicians screen for CRC in average-risk adults starting at age 50, and in high-risk adults starting at age 40 (or 10 years younger than the age at which the youngest affected relative was diagnosed with CRC), using a stool-based test, flexible sigmoidoscopy, or optical colonoscopy in patients who are at average risk, but optical colonoscopy in patients who are at high risk. Clinicians should stop screening for CRC in adults older than 75 years or in adults with a life expectancy of less than 10 years.

Tests for fecal occult blood detect hemoglobin in the stool from bleeding tumors. These tests are either guaiac based or immunochemical based. The guaiac tests detect blood in stool through the pseudoperoxidase activity of heme or hemoglobin. The immunochemical tests react with human globin and are therefore more specific. Guaiac testing consists of collecting two samples from three consecutive stools. To improve test accuracy, individuals undergoing guaiac testing are instructed to avoid aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), vitamin C, red meat, poultry, fish, and some vegetables. Three large prospective randomized trials demonstrated that guaiac-based testing decreased CRC mortality by 15 to 33%, and this benefit appears to persist for 30 years.[7] One large U.S. study also showed a 20% decrease in CRC incidence, attributed to the relatively higher rates of colonoscopy in the study group. Guaiac-based tests have sensitivities for cancer from 35 to 80%. Immunochemical-based tests do not rely on a peroxidase reaction and therefore may have fewer false positives and false negatives. They are done essentially the same way as the traditional guaiac, but they do not require the dietary restrictions of guaiac-based tests and only one stool specimen is collected. The immunochemical tests have better adherence, find 2.5 times as many cancers and advanced adenomas as guaiac-based tests, and are now the preferred fecal occult blood test for screening. Fecal occult blood tests are repeated annually, and any positive test should prompt colonoscopy.

Stool DNA tests rely on the observation that both adenomas and carcinomas contain altered DNA, and this DNA is shed in the stool. Tests contain a multiple marker panel designed to detect exfoliated DNA markers. Collection kits are designed to facilitate stool collection (at least 30 g) and mailing. First-generation stool DNA tests had better sensitivity for CRC (52%) than a guaiac-based test (unrehydrated Hemoccult II; 13% sensitivity) but poor sensitivity for advanced adenomas (15%). Next-generation stool DNA testing with an updated marker panel can identify about 90% of patients with CRC and about 40% of patients with advanced adenomas, with an 87% specificity.[8] Stool DNA testing is more expensive than fecal occult blood testing, and the optimal screening interval has not been defined.

Flexible sigmoidoscopy is capable of examining the distal 60 cm of the colon, or roughly the splenic flexure to the rectum. It can be done with minimal bowel preparation, does not require sedation, and can be performed

by primary care providers, nurses, or physician's assistants. Flexible sigmoidoscopy can detect distal cancers or polyps as well as colonoscopy can.[9] The detection of an adenoma should prompt referral for full colonoscopy, owing to the high prevalence of synchronous neoplasia in the unexamined proximal colon. In one randomized trial, a single flexible sigmoidoscopy performed once between ages 55 to 64 years reduced CRC incidence by 23% and mortality by 31%.[■] In another randomized trial, screening with flexible sigmoidoscopy led to a significant 29% decrease in CRC incidence in both the distal and proximal colon, and a significant 50% decrease in mortality from cancers of the distal colon only.[■] In a third trial, CRC incidence was reduced by 20% and death by 12%.[■] Sigmoidoscopy should be repeated every 5 years and may be combined with yearly fecal occult blood testing.

Colonoscopy allows complete examination of the colon as well as adenoma removal, and thus cancer prevention. In the United States, it is generally done under sedation after an oral bowel preparation, and by physicians with specific training in colonoscopy and polypectomy. Large cohort studies have found an up to 1% cancer rate, 5 to 10% advanced adenoma rate (size > 10 mm, villous histology, or high-grade dysplasia), and at least 20% with 1 or more adenomas.[10] Major complication rates are less than 0.5%, with more than half due to polypectomy. There are no direct randomized studies assessing the efficacy of colonoscopy for screening, although there is a large amount of indirect evidence. Colonoscopy is generally used as the gold standard in assessing other screening methods. In a large randomized Minnesota study of fecal occult blood testing, a decrease in cancer incidence was observed that could be explained only by the use of colonoscopy and polypectomy at a higher rate in the screened population. Randomized and case-control studies of sigmoidoscopy demonstrate a CRC mortality benefit that should also apply to colonoscopy. The National Polyp Study, which followed patients after polypectomy, found that the incidence of CRC was reduced 76 to 90% compared to three reference populations. In another study of patients who had adenomas detected and removed by colonoscopy, the risk of death from CRC at 16 years was only 50% of what was expected in the general population,[11] with most of the reduced incidence found among patients who had low-risk adenomas removed.[12] The efficacy of colonoscopy is influenced by the quality of the exam, with the most important quality markers being the cecal intubation rate (indicating a complete exam) and the adenoma or polyp removal rate. Studies have demonstrated superior CRC prevention when the colonoscopy is performed by a physician with a high adenoma or polyp removal rate.[13] Physician experience and specialty are also important, with gastroenterologists preventing more CRC than other specialties.[14] If the initial screening colonoscopy is normal, further screening can be deferred for 10 years.[15]

Double-contrast barium enema evaluates the entire colon by coating the mucosal surface with high-density barium and insufflating with air via a rectal tube. Multiple radiographs are obtained while varying the patient's position under fluoroscopy. It requires a colon preparation and exposes the patient to a small amount of ionizing radiation. There are no studies of double-contrast barium enema as a screening test. It is 85 to 97% sensitive for colon cancer, but its sensitivity for detecting large adenomas is only 48 to 73%. It should be repeated every 5 years. The finding of a polyp larger than 5 mm should prompt colonoscopy.

CT colography (also known as virtual colonoscopy) uses multidetector CT technology to obtain two- and three-dimensional images of the entire colon. It requires an adequate colon preparation and gaseous distention of the bowel using a rectal tube. Tagging of residual stool with barium or iodinated contrast material is frequently used. CT scanning is performed with the patient in the supine and prone positions. No studies have been done to evaluate the efficacy of CT colography in decreasing CRC incidence or mortality. CT colography has been compared with standard colonoscopy for the detection of neoplasia in screening populations. The sensitivity of CT colography for large (≥10 mm) polyps is 85 to 92%, with a specificity of 83 to 86%. For polyps 5 mm or larger, CT colography is about 65% sensitive and 89% specific. Sensitivity for CRC (96%) is similar to that of colonoscopy. Laxative-free CT colography is accurate in detecting adenomas 10 mm or larger but less so for smaller lesions.[16] Although the optimal interval for testing has not been established, it is recommended that CT colography screening begin at age 50; if negative, it should be repeated at 5-year intervals. If a polyp larger than 5 mm is found, colonoscopy should be performed.

Staging

Accurate staging of CRC is of the utmost importance in determining both prognosis and the most relevant and effective therapy. The versions of the TNM classification system for large bowel cancers used by the American Joint Committee on Cancer and the International Union Against Cancer are identical (Table 193-4). Differing from many solid tumors (although not those of other GI origin, except for anal cancer), CRCs are not staged according to size. Stage I cancers penetrate into but not through the bowel wall (T1–2N0M0), whereas stage II cancers penetrate through the wall and can involve nearby organs without spreading to regional lymph nodes. About 40% of patients present with stage I or II disease in the United States. Stage III cancers involve regional lymph nodes and constitute about 40% of presenting cases. Stage IV colorectal tumors (distant metastasis or metastases) commonly involve liver, lung, distant nodes, and peritoneum, with about 20% of patients presenting with this stage. Rectal primaries, because of early access to the systemic circulation, may involve the lungs without liver metastases; this pattern of spread is distinctly unusual in proximal large bowel cancers.

TABLE 193-4 STAGING FOR COLORECTAL ADENOCARCINOMAS

STAGE	TUMOR	NODE	METASTASIS
0	Tis	N0	M0
I	T1, T2	N0	M0
IIA	T3	N0	M0
IIB	T4a	N0	M0
IIC	T4b	N0	M0
IIIA	T1, T2 T1	N1 N2a	M0 M0
IIIB	T3, T4a T2, T3 T1, T2	N1 N2a N2b	M0 M0 M0
IIIC	T4a T3, T4a T4b	N2a N2b N1, N2	M0 M0 M0
IVA	Any T	Any N	M1a
IVB	Any T	Any N	M1b

Tis = in situ; T1 = submucosa; T2 = muscularis propria; T3 = subserosa, pericolorectal tissues; T4a = visceral peritoneum; T4b = other structures.
N1a = 1 regional node; N1b = 2-3 regional nodes; N1c = satellite(s) without regional nodes; N2a = 4-6 regional nodes; N2b = ≥7 regional nodes.
M1a = 1 organ; M1b = >1 organ, peritoneum.

TREATMENT

Chemoprevention

NSAIDs, including aspirin, are believed to reduce adenoma formation and inhibit colon cancer development by inhibiting cyclooxygenase and subsequent prostaglandin generation (Chapter 37). Prostaglandins (e.g., E_2) promote cell proliferation and tumor growth. The NSAIDs sulindac and celecoxib cause regression of existing adenomas and inhibit the formation of new adenomas in patients with FAP. Epidemiologic studies have shown decreased CRC rates in regular users of NSAIDs. Randomized trials of aspirin have shown 20 to 40% reductions in adenoma recurrence. A secondary analysis combining data from four European vascular event prevention trials reported up to a 70% reduction in the incidence of CRC when at least 75 mg of aspirin daily was continued for 5 or more years.[17] However, the 4 individual studies and two large American trials (Women's Health Trial, Physicians Health Study) did not find an aspirin benefit. Calcium supplementation (1200 mg/day) was shown to decrease the rate of metachronous adenomas by 20%. However, the large Women's Health Trial (36,000 participants) found that calcium (1000 mg) plus vitamin D (400 IU) had no effect in reducing CRC incidence. Currently, the routine use of aspirin and calcium for CRC prevention is not recommended, but it may be considered on an individual basis.

Dietary Prevention

Epidemiologic studies have reported correlations between CRC and obesity, smoking, inactivity, excessive alcohol use, and diets high in fat and low in fruits, vegetables, and fiber. These observations suggest that lifestyle modifications may decrease CRC risk. Unfortunately, three randomized intervention trials of modest dietary changes (10% less fat, 25 to 75% more fiber, 50% more fruits and vegetables) found no significant reductions in adenomas or CRC over 3 to 8 years of follow-up. Fish consumption is inversely associated with CRC

incidence, and eicosapentaenoic acid supplementation decreases polyp burden in FAP.

Surgery

Resection is the primary treatment modality for patients with regionally confined CRC. Highly selected patients with metastatic disease may also undergo surgery with curative intent. The goal of curative surgery for colonic adenocarcinoma is margin-negative elimination of the tumor, plus en bloc removal of the primary feeding arterial vessel and corresponding lymphatics for that segment of bowel. A minimum of 12 lymph nodes should be retrieved for microscopic examination to assure staging accuracy. Synchronous colon cancers may be removed individually or with subtotal colectomy, and tumors adherent to adjacent structures should be resected en bloc. Prophylactic oophorectomy is no longer recommended, but women with one ovary grossly involved with cancer should undergo bilateral oophorectomy because of the relatively high risk of involvement of the other side. Laparoscopic resection is currently thought to be as effective as open resection and requires a modestly shorter recovery time. Very preliminary data suggest elderly patients undergoing a laparoscopic procedure have a lower chance of being discharged to a nursing home (as opposed to their own residences) than those treated with standard resection.

In general, surgical considerations for rectal primaries are similar. Total mesorectal excision (en bloc removal of the lymphovascular and fatty envelope surrounding the rectum) is recommended for distal cancers, whereas tumor-specific mesorectal excision (en bloc removal of the mesorectum 5 cm distal to the tumor) should suffice for upper rectal tumors. Local transanal excision is acceptable for selected low rectal cancers thought to have minimal risk of nodal involvement. Selection criteria include the following: T1 disease, size less than 3 cm, low grade (well differentiated), location within 8 cm of the anal verge, no lymphovascular invasion, and less than one third circumferential. The wide spectrum of symptoms that occur in most patients after resection and reconstruction of the rectum, ranging from increased bowel frequency to fecal incontinence or evacuatory dysfunction, has been termed *anterior resection syndrome*.

Resection of the primary formerly was recommended for patients presenting with synchronous CRC and unresectable metastases, regardless of whether the primary caused symptoms. This practice pattern obviously had the potential to delay systemic treatment in patients who were markedly more likely to die from their metastases before suffering significant complications from the intact large bowel tumor. Recent data suggest that stage IV patients with an asymptomatic primary tumor can safely begin systemic therapy without undergoing surgery, with only a small chance of developing serious complications requiring urgent operative interaction. Patients with rectal primaries may be at slightly higher risk for developing complications than those with tumors originating in the proximal large bowel.

Obstructing tumors that can be fully removed should be resected, with bowel anastomosis usually being acceptable in this setting. Proximal diversion alone, especially in the setting of very locally advanced unresectable cancer, may be necessary; if the primary tumor responds to the point where it can later be removed, resection followed by ostomy closure is reasonable. Endoscopic stenting may be useful to relieve acute obstruction. Perforated bowel is usually resected, with the choice of anastomosis, with or without diversion, depending on a number of factors, including degree of fecal contamination and general health of the patient.

Radiation Therapy

Radiation therapy may be used as curative or palliative treatment of large bowel cancers. In general, it is employed much more commonly in treating rectal versus colonic primaries. Single-institution trials have shown that irradiation improves local control following resection of high-risk proximal large bowel (colonic) cancers, but these findings were not confirmed in a randomized intergroup trial that closed early owing to slow accrual. Current recommendations for adjuvant radiation to the tumor bed following colon cancer resection include positive margins and localized perforation. Some authorities also advocate its use in colon cancers at particularly high risk of local recurrence (T4, T3N1-2 tumors in the ascending or descending colon), but that recommendation is not universally accepted. Irradiation may still play a role in treating colon cancer metastases to bone, brain, liver, and lung, as well as in cases of bleeding, obstruction, and locally advanced unresectable disease.

A major use for radiation in the definitive treatment of large bowel adenocarcinoma involves perioperative therapy for resectable rectal cancer. It is also commonly employed with chemotherapy for unresectable locally advanced invasive tumors, which occasionally may downsize and be surgically removed after therapy. As with colon primaries, irradiation may be used to palliate bleeding, obstruction, or selected metastases from rectal cancers.

Systemic and Combination Therapies

The backbone of CRC treatment in both the adjuvant and metastatic settings is a fluorinated pyrimidine. The most commonly used drug is 5-fluorouracil (5-FU), although oral prodrugs are increasingly being used. 5-FU targets the enzyme thymidylate synthase, inhibiting DNA synthesis and/or repair. It also may be incorporated into RNA, interfering with further processing. Although not particularly effective as a single agent (see later), 5-FU's efficacy can be enhanced by changing its means of administration (prolonging infusion) and by administering it with a variety of biochemical modulators, most commonly leucovorin. Other chemotherapeutic agents commonly used in treating advanced CRC include irinotecan, a topoisomerase I inhibitor, and oxaliplatin, a later-generation platin that forms bulky DNA adducts that inhibit replication. Recent effective biologics[18] include agents targeting vascular endothelial growth factor (bevacizumab) or circulating VEGF (aflibercept), the epidermal growth factor receptor (cetuximab, panitumumab), or a combination of the VEGF and various tyrosine kinase receptors (regorafenib).

Patients with resected stage I colon cancers have a high cure rate, and this cannot easily be improved on with systemic therapy. Stage II patients have a higher chance of relapse (event-free survival ≈ 76% at 3 years), and systemic therapy with 5-FU and leucovorin improved that figure by about 3% for an unselected group of node-negative patients. Patients harboring highly microsatellite-unstable tumors have a better prognosis in general but may actually have worse outcomes with 5-FU treatment, although that is controversial. Treatment of stage II patients remains controversial in general: some experts suggest that the proportional benefit of systemic therapy is as great as it is in stage III disease, while others point out the low absolute magnitude of benefit and do not advocate its use. Risk stratification using molecular markers has been attempted but has not been demonstrated to have predictive capabilities, with the exception of microsatellite instability and its described resistance to fluoropyrimidines. Some clinical categories of stage II disease are believed to be at particularly high risk for recurrence (e.g., obstruction). These patients usually receive postoperative chemotherapy, often with regimens commonly prescribed for patients with stage III cancer. Radiation has been tested in patients thought to be at higher-than-average risk of local relapse (T4 tumors), but its use is not standard. Other drugs useful in metastatic disease and resected node-positive patients (specifically oxaliplatin) are not routinely recommended nor used in those with stage II cancers.

Five-year disease-free survival for patients with stage III colon cancer ranges from 45 to 85%, depending on substage. Barring significant comorbidities or other confounding factors, all patients with node-positive disease receive adjuvant systemic therapy. Combinations of 5-FU and oxaliplatin (usually FOLFOX [fluorouracil, leucovorin, oxaliplatin]) clearly improve long-term survival rates[19] and represent standard care. Regimens containing irinotecan and biologics (bevacizumab, cetuximab) are highly effective in the treatment of advanced disease (see later), but oddly they do not clearly benefit patients when they are given in the postoperative setting. Patients who are not candidates for combination chemotherapy may be offered capecitabine, an oral prodrug activated to 5-FU in sequential enzymatic steps. Capecitabine has also been combined effectively and relatively safely with oxaliplatin for adjuvant use. An important outstanding question regarding adjuvant chemotherapy is whether a shorter duration (3 months vs. the standard 6) might be equally effective, as suggested in one small randomized trial.

Rectal Adenocarcinoma

Therapeutic considerations are slightly different for patients with primary rectal adenocarcinomas, owing to the difficulty of achieving negative circumferential (radial) margins. Specifically, the risk of local recurrence is much more significant. Adjuvant chemotherapy for rectal cancer is still controversial.[20] In general, rectal cancer patients undergoing standard resection for stage I tumors do not receive additional treatment. However, higher-risk patients (T2 disease, T1 with poorly differentiated histology, perineural or lymphovascular invasion, or close margins) treated with local excision should receive postoperative pelvic irradiation with or without 5-FU chemotherapy, or they should return to the operating room for total mesorectal excision. Irradiation is standard for those with stage II and III rectal adenocarcinomas to decrease local relapse rates, increase the chance of sphincter preservation (when used in selected preoperative settings for low-lying cancers), and possibly improve survival. The major considerations are timing (pre- or postoperative use), course (short or long), and whether to combine it with fluoropyrimidine-based chemotherapy. Short-course (5-day) preoperative irradiation without chemotherapy may be considered and used if tumor downsizing is not necessary. When short-course radiation is used, patients still require postoperative systemic therapy with either a fluoropyrimidine alone (stage II) or a fluoropyrimidine-oxaliplatin combination regimen (node-positive disease). Long-course irradiation (≈5.5 weeks) is particularly important when tumor response is necessary to make surgery easier or more feasible. It is usually combined with continuous-infusion 5-FU or capecitabine, and it can be given pre- or postoperatively (if the patient did not receive preoperative short-course radiation). Including oxaliplatin preoperatively does not improve results and is not recommended independent of a clinical trial, owing to its higher toxicity profile. Oxaliplatin may be used postoperatively if the pathology specimen demonstrates nodal involvement. With long-course irradiation, preoperative (compared with postoperative) treatment is less toxic and may offer improved local control.[21] However, it requires accurate preoperative staging (to avoid treating patients who might have stage I disease). Highly

selected rectal cancer patients thought to be at low risk of local recurrence (T3N0 or T1-2N1) may receive total mesorectal excision plus best systemic therapy without irradiation, usually postoperatively.

Metastatic Colorectal Cancer

Metastatic disease is treated identically, regardless of the site of origin (colon vs. rectum). Patients with incurable metastatic CRC have a median survival of approximately 6 months with best supportive care alone; however, incremental gains made through the adoption of new systemic therapies have extended that time to nearly 2 years or more. For example, treatment with single-agent fluoropyrimidines leads to median survival in the 10- to 13-month range; adding one more effective chemotherapy drug (either irinotecan or oxaliplatin) affords survival of about 15 to 20 months, and adding both drugs to 5-FU has been reported to extend life to 23 months. Interestingly, long-term results seem to be similar regardless of which drug (oxaliplatin or irinotecan) is added to 5-FU first (although the toxicity pattern varies, depending on which drug is given), or even regardless of whether 5-FU is used first and combination chemotherapy is used subsequently, as long as patients are eventually exposed to all active agents.

Additional improvements have arisen through the development of drugs that are more convenient and/or less toxic than standard agents, although they may not be more effective. Capecitabine, an oral prodrug activated to 5-FU in three sequential enzymatic steps, can be substituted for that agent alone and in combination with oxaliplatin (although patients still need intravenous access for the latter drug).

Recent breakthroughs have mostly been related to use of biologic agents (Chapter 36). Drugs used successfully to date include several monoclonal antibodies and one oral tyrosine kinase inhibitor. Bevacizumab is a humanized monoclonal antibody directed against vascular endothelial growth factor, an important mediator of angiogenesis. Bevacizumab has little single-agent activity against CRC, but it improves the interval without progression when added to irinotecan- or oxaliplatin-containing chemotherapy. Bevacizumab with FOLFOX or FOLFIRI (fluorouracil, leucovorin, irinotecan) now represents first-line treatment for patients with advanced large bowel cancer in the United States,[A1] and many oncologists continue its use along with second-line fluoropyrimidine-based chemotherapy. Aflibercept, or VEGF trap, is a fusion protein with VEGF-binding portions from VEGFR and the Fc portion of IgG1. It prevents VEGF-A and B from binding to receptors. A second-line trial after oxaliplatin failure showed aflibercept with irinotecan- and fluoropyrimidine-based chemotherapy (FOLFIRI), improves survival over chemotherapy with placebo. It is unknown whether it is better to continue bevacizumab versus switching to aflibercept in the setting of second-line therapy.

The epidermal growth factor receptor (EGFR) is another important target in advanced CRC. Cetuximab and panitumumab are monoclonal antibodies (chimeric and human, respectively) directed against the EGFR. They have single-agent activity against CRCs, and both may be combined with irinotecan-based chemotherapy to improve progression-free survival. Panitumumab also improves progression-free survival front-line when combined with oxaliplatin-containing chemotherapy. Although both agents appear effective in front-line or later use, efficacy is restricted to patients whose tumors harbor wild-type *KRAS*.

Regorafenib is an oral inhibitor of angiogenic (VEGFR-1, -2, -3, and TIE-2), stromal (PDGFR-B, FGFR), and oncogenic (KIT, RET, BRAF) tyrosine kinases. It has activity in advanced CRC, improving progression-free and overall survival after failure of standard therapies.[A8]

Locally Directed Treatment of Metastatic Disease

Complete resection of hepatic or pulmonary metastases may result in long-term survival and is the standard of care for selected patients with CRC. The majority of data exist for hepatic metastasectomy. Actuarial 5-year survival rates have been in the 25 to 60% range. However, relapse after 5 years still occurs, suggesting that this percentage does not reflect the number actually *cured* with surgery. That figure, calculated from 10-year survival rates, is probably between 17 and 25%, which still compares quite favorably with the survival rate for patients with CRC metastatic to the liver who do not undergo surgery. The role of preoperative systemic therapy in potentially resectable patients remains controversial; if used, a fluoropyrimidine with either oxaliplatin or irinotecan +/– panitumumab (for wild-type *KRAS*) or irinotecan-based chemotherapy +/– cetuximab (for wild-type *KRAS*), or triple chemotherapy with a fluoropyrimidine, oxaliplatin, and irinotecan may be employed. In those undergoing metastasectomy, many experts advocate 6 months of postoperative fluoropyrimidine-based chemotherapy, often with oxaliplatin. Importantly, bevacizumab can impair wound healing, and most experts avoid its use in the immediate perioperative period.

Small liver metastases that are not resectable because of anatomic location or in a frail patient unable to undergo hepatic resection may be treated with radio frequency ablation, which uses alternating electric current to generate heat, destroying malignant cells through protein coagulation. Although it has never been directly compared with resection in a randomized trial, radio frequency ablation appears to offer inferior local control of disease. Some advocate the placement of a hepatic artery pump to infuse fluoropyrimidine-based chemotherapy to treat unresectable liver-predominant metastases. Other techniques useful in noncolorectal liver-based tumors (e.g., hepatocellular carcinoma), such as chemoembolization, have no proven role for large bowel liver metastases.

Surveillance

Surveillance should be undertaken in patients fit enough to undergo metastasectomy or systemic therapy for recurrent CRC. The American Society of Clinical Oncology recommends annual CT of the chest and abdomen for 3 years following resection of high-risk primary tumors, with pelvic CT added in cases of rectal origin. Colonoscopy should also be done at 3 years and then every 5 years, with flexible proctosigmoidoscopy offered to rectal cancer patients who have not received irradiation. Physical examinations should be performed every 3 to 6 months for 3 years, then biannually for at least 2 more years. CEA levels should be checked every 3 months for at least 3 years, although the benefits for improving outcome are uncertain.[A9]

PROGNOSIS

The prognosis for patients with CRC depends primarily on stage. Five-year survival for patients with proximal (colonic) adenocarcinomas ranges from a low of 6 to 8% for those with metastatic disease to approximately 95% for those with stage I resected tumors. Corresponding rates for rectal cancers are similar to slightly inferior overall, ranging from 4 to 72%. Besides TNM stage, additional factors that are prognostic for poorer outcomes in patients undergoing potentially curative resection include signet ring histologic subtype (see preceding discussion under Pathobiology), lymphovascular and perineural invasion, absence of host lymphoid response, presence of clinical obstruction preoperatively, high preoperative serum levels of the CEA tumor marker, positive margins, high tumor grade, and microsatellite-stable disease. Differing from many solid tumors originating outside the GI tract, CRCs do not have different prognoses based on size.

Genetic factors are important as well, even in the metastatic setting. Patients with tumors harboring *BRAF* mutations appear to have a worse outcome. *KRAS* mutations were formerly thought to be prognostic but now appear to be only predictive for lack of benefit from certain types of systemic therapy.

Colorectal cancer remains a significant problem despite the fact that most cases can be prevented. Large gains have been made in terms of overall survival, but the vast majority of patients with advanced disease still succumb to their malignancy. Minimal tailoring can currently be offered to patients (e.g., selecting a chemotherapeutic agent based on toxicity or not using an anti-EGFR antibody in those with *KRAS*-mutated tumors); the dream of truly individualized therapy remains elusive but is under active study.

REVIEW QUESTIONS

1. A 55-year-old average-risk patient undergoes a screening colonoscopy. There is no family history of polyps or colorectal cancer, and the patient is asymptomatic. A single 6-mm tubular adenoma was found in a well-prepared and otherwise normal colonoscopy. The next colonoscopy should be performed at:

A. 1 year
B. 2 years
C. 3 years
D. 5-10 years
E. Never. Surveillance is not indicated.

Answer: D For average-risk patients with otherwise normal colonoscopies, the finding of a single nonadvanced tubular adenoma (<10 mm, no villous histology or high-grade dysplasia) requires a next colonoscopy to be performed at 5-10 years. (See section on "Prognosis" under "Adenomatous Polyps.")

2. A patient with colorectal cancer (CRC) is found to have microsatellite instability on testing of the resected tumor. There is a strong family history of CRC, including a parent and a sibling. Germline mutation analysis is performed and finds a mutation in one of the mismatch repair genes *(MLH1)*. This patient most likely has:

A. Hereditary nonpolyposis colorectal cancer (Lynch syndrome)
B. Familial adenomatous polyposis
C. *MUTYH*-associated polyposis
D. CpG island methylation (CIMP)
E. *BRAF* mutation

Answer: A Mutations in the mismatch repair genes (*hMSH2*, *hMSH3*, *hMSH6*, *hMLH1*, *hPMS1*, and *hPMS2*) result in errors in DNA replication. These errors can be detected as microsatellite instability in the resected tumor. Errors in these genes result in hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome. (See section on "Hereditary Nonpolyposis Colon Cancer.")

3. The most important factor in deciding whether to offer adjuvant chemotherapy following potentially curative resection of colon cancer is:

A. Tumor size
B. Tumor grade
C. Patient age
D. Patient gender
E. Tumor stage

Answer: E Although multiple factors are prognostic and/or predictive, stage is the most important determinant in the decision regarding adjuvant systemic therapy. (See section on "Systemic and Combination Therapies" under "Treatment" of "Adenocarcinoma of the Colon and Rectum.")

4. Reasonable agents to offer a patient with resected stage III colon cancer include:

A. 5-Fluorouracil
B. Oxaliplatin
C. Irinotecan
D. A and B
E. A, B, and C

Answer: D All the listed agents have activity in metastatic disease, but irinotecan has not been proven to offer any benefit in the adjuvant setting. (See section on "Systemic and Combination Therapies" under "Treatment" of "Adenocarcinoma of the Colon and Rectum.")

5. A major difference between colonic and rectal adenocarcinoma is:

A. Treatment of metastatic disease
B. Underlying genetic makeup
C. Frequency of use of irradiation
D. Frequency of complications of an intact primary in the setting of treated metastatic disease
E. C and D

Answer: E Colonic and rectal cancers are for the most part biologically similar, including sensitivity to systemic agents. Because of anatomic concerns, treatment of higher-risk rectal cancer almost always involves irradiation, whereas that modality is seldom used in treating colon cancer. Similarly, rectal cancers have a slightly higher chance of bleeding or obstructing if not undergoing primary treatment.

194

PANCREATIC CANCER

DANIEL LAHERU

DEFINITION

Pancreatic cancer usually refers to ductal adenocarcinomas of the pancreas, because more than 90% of pancreatic tumors arise from the ductal epithelium. Other major tumors of the pancreas include endocrine malignancies (Chapter 195), carcinoid tumors (Chapter 232), lymphomas (Chapter 185), and a variety of rare sarcomas.

EPIDEMIOLOGY

Pancreatic ductal adenocarcinoma (PDAC) has one of the highest incidence-to-mortality ratios of any disease. Although it represents the tenth leading cause of cancer in the United States, it is the fourth leading cause of cancer-related deaths,[1] because the vast majority of patients will die from their disease. Annually, approximately 40,000 individuals will die in the United States from PDAC or its complications. The incidence of pancreatic cancer is slowly increasing based on the changing demographics of the U.S. population. The risk of developing PDAC increases with age, with a mean age at onset of 71 years; the risk in men and women is equivalent. The average lifetime risk for developing PDAC is about 1 in 78 for both men and women. Globally, 70% of all pancreatic cancer cases occur in people living in advanced economies, with over 270,000 deaths per year worldwide. Some PDACs occur in association with other cancers or diseases, but most do not occur in association with a defined syndrome. The overwhelming majority of PDAC cases are sporadic—that is, occurring without a history of the disease in first-degree relatives. Smoking tobacco, as well as passive exposure to tobacco smoke in the environment, contributes significantly to the development of PDAC. Occupational hazards that have been associated with an enhanced risk of developing PDAC include exposure to chlorinated hydrocarbon solvents and heavy metals.

Approximately 10% of PDACs occur in families with a history of PDAC; in these patients, the risk of developing PDAC is increased seven-fold compared with the general population. Premalignant cystic lesions of the pancreas also occur in pancreatic cancer families. In addition to the recent discovery of the *PALB2* gene in 3% of these families, mutations in *ATM* or *BRCA2*, critical partners in the DNA damage repair pathway, as well as *p16*, have also been discovered.

Chronic pancreatic inflammation from alcohol misuse or genetic anomalies significantly enhances the risk of being diagnosed with PDAC. Although the association between chronic pancreatitis and the development of PDAC has been well known for decades, only recently have studies clarified how pro-inflammatory cytokines contribute to the progression from premalignant lesion to advanced tumor. In addition to chronic pancreatitis, the role of diabetes mellitus and obesity in the development of PDAC has been emphasized. Long-standing type 1 and type 2 diabetes mellitus may represent increased risk of PDAC, but the cause-and-effect relationship between pancreatic cancer and diabetes is complex. Recently, epidemiologic studies have focused on the development of PDAC in patients with type 3c diabetes (diabetes related to pancreatic disease, or pancreatogenic diabetes), a major subset of diabetes characterized by a severe deficiency of all glucoregulatory hormones (Chapter 229). Patients with type 3c diabetes appear to have the highest associated risk of developing PDAC, especially in the setting of coexisting chronic pancreatitis. Type 3c diabetes is also a consequence of PDAC in approximately 30% of patients. The increase in obesity in the U.S. population and the concomitant increase in associated diabetes mellitus are strongly associated with an enhanced lifetime risk of developing PDAC.

PATHOBIOLOGY

Understanding the molecular characteristics of cancers of the exocrine pancreas is critical for the development of targeted therapies. Pancreatic cancer is caused by inherited (germline) and acquired (somatic) mutations in cancer-causing genes. Several oncogenes and tumor suppressor genes have been demonstrated to be involved in the development of pancreatic cancer, both by contributing to the growth of the tumor itself as well as to the surrounding microenvironment. Oncogenes, typically inactive in normal cells, cause uncontrolled cell proliferation by inhibiting apoptosis and activating the cell cycle when mutations render them constitutively active. The *KRAS* oncogene, located on chromosome 12, is the most frequently mutated oncogene in pancreatic cancer in (>90% of tumors). It encodes a membrane-bound protein that has GTP-ase activity and is involved in signal transduction.[2] When activated by mutation, typically a point mutation in codon 12, the functions of *KRAS* are independent of growth factor control, leading to chronic activation of its downstream signaling partners, *PI3K*, *MAPK*, and *RAF*, causing inhibition of apoptosis and activation of the cell cycle, migration, angiogenesis, cytoskeletal remodeling, and unchecked proliferation. Tumor suppressor genes, when functioning normally, act in the opposite manner by enhancing apoptosis and inhibiting cell proliferation. The tumor suppressor *CDKN2A/TP16*, a cell cycle control gene, is commonly inactivated in pancreatic cancer, with 80 to 95% loss of activity leading to increased cell cycle progression. *TP53* is activated by DNA damage to stop cell cycle progression and repair damaged DNA or initiate apoptosis. Mutations in this tumor suppressor gene are commonly found in 50 to 75% of pancreatic tumors. Inactivation of *SMAD4* (DPC4), involved in regulating cell cycle progression through the transforming growth factor (TGF)-β pathway, is observed in over 50% of pancreatic cancers and is associated with worse prognosis and the development of metastases. Inactivation of *RB1* (in < 10% of pancreatic cancers) and *STK11* (responsible for Peutz-Jeghers syndrome) is also observed.

There are several major signaling pathways involved in pancreatic tumorigenesis. Hedgehog (Hh) signaling, critical in embryogenesis, regulates the cell cycle and apoptosis, aids in the formation of tumor stroma, and is often upregulated and abnormal in pancreatic cancers. The NOTCH pathway, also important in normal embryogenesis to prevent terminal differentiation of cells until appropriate, can be abnormally activated in pancreatic cancer, allowing cells to remain in an undifferentiated state that contributes to tumor growth. When the Wnt pathway is activated, β-catenin is stabilized and migrates into the nucleus, where it activates its target genes. The epidermal growth factor receptor (EGFR), TGF-β, and JAK/STAT pathways have also been found to be abnormal in pancreatic cancer cells, leading to the promotion of cell growth, proliferation, differentiation, and cell survival. Epigenetic modification, the process by which gene expression is altered by mechanisms other than changes in actual DNA sequence, also has a role in pancreatic cancer tumorigenesis. Telomere shortening and overexpression of microRNAs lead to chromosomal instability and dysregulation of gene expression, respectively, and are also observed.

In addition to cancer cells themselves, the tumor microenvironment is composed of stromal cells, inflammatory cells, and endothelial cells that all play a particularly important role in pancreatic cancer growth. Cancer cells secrete growth factors, including insulin-like growth factor (IGF)-1, fibroblast growth factor (FGF), TGF-β, vascular endothelial growth factor (VEGF), and platelet-derived growth factor (PDGF), that stimulate pancreatic stellate cells (also called myofibroblasts) to secrete excess amounts of extracellular matrix. The matrix and its stromal cells, in turn, secrete cytokines and growth factors that promote cancer cell growth, invasion, and dissemination and protect pancreatic cancer cells from apoptosis, as well as generating a desmoplastic reaction that interferes with the delivery of chemotherapy to the tumor site.[3] The local presence of TGF-β also leads to decreased helper T-cell activity, which suppresses the body's immune reaction against pancreatic cancer cells.

Precursor Lesions

A major advance in understanding the development of pancreatic cancer has been the appreciation that the majority of pancreatic adenocarcinomas progress sequentially from histologically normal ductal epithelium to low-grade pancreatic intraepithelial neoplasia (PanIN), to high-grade PanIN, to invasive carcinoma. This process is associated with the accumulation of specific gene alterations (Fig. 194-1).

CLINICAL MANIFESTATIONS

Symptoms of early PDAC are often subtle and include nonspecific gastrointestinal complaints (nausea, vague abdominal pain), fatigue, and weight loss of undetermined etiology.[4] Epigastric pain and obstructive jaundice often prompt the initial diagnostic work-up of the biliary tree, but are frequently late symptoms that are associated with advanced local or regionally disseminated disease. Because approximately 75% of pancreatic carcinomas are located in the head of the pancreas, it is not unexpected that clinical presenta-

tions are often related to compression or invasion of the biliary tree or pancreatic ducts. Deep or superficial venous thrombosis (Trousseau syndrome) is not infrequent, either early or late in the presentation of PDAC (Chapter 176). Observation of a palpably distended gallbladder (from obstruction of the distal common bile duct), or Courvoisier's sign, is uncommon.

The laboratory abnormalities that accompany PDAC at presentation include anemia and elevations of serum bilirubin, alkaline phosphatase, and aminotransferases. A majority of patients eventually develop signs of obstructive jaundice as well as hyperglycemia, reflective of associated diabetes mellitus. Unfortunately, pre-neoplastic cystic lesions of the pancreas often remain asymptomatic until discovered following acute symptoms (due to ductal obstruction) that precipitate an abdominal computed tomography (CT) scan. Early PanIN lesions are asymptomatic.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of PDAC includes conditions that can present as a solid pancreatic mass, including acute (or an exacerbation of chronic) pancreatitis, ampullary or distal cholangiocarcinomas with associated biliary obstruction and jaundice, and non-neoplastic cystic pancreatic neoplasms.

Cystic neoplasms of the pancreas are frequent, detectable in 2% of abdominal magnetic resonance imaging (MRI) examinations. Whereas serous cystadenomas are benign abnormalities that do not connect to pancreatic ducts and warrant surgery only if symptomatic, mucinous cystadenomas (MCN) are precursors of PDAC that often occur in the tail of the pancreas, more frequently in women in their 40s; they are overtly malignant in 15% of patients and require surgical resection. Intraductal papillary mucinous neoplasms (IPMN) of the pancreas occur in the head of the organ, are often polycystic, and contain malignant elements in 40% of patients; all patients with this lesion require surgery.

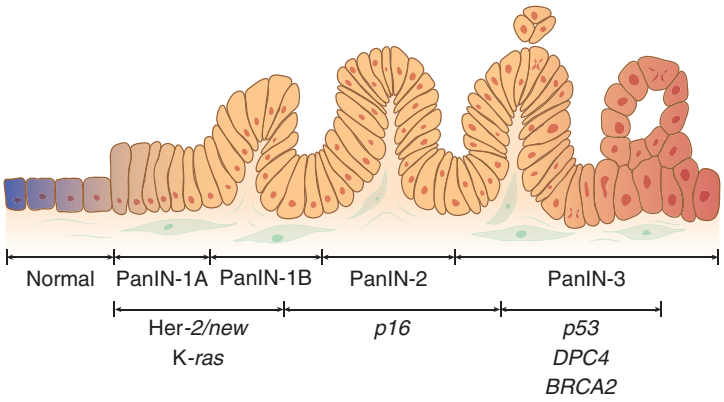

FIGURE 194-1. Genetic progression model of pancreatic adenocarcinoma. Molecular changes in the development of pancreatic ductal adenocarcinoma begin with early changes that include telomere shortening and development of mutations in *KRAS*; these are followed by loss of p16 function and expression of cyclin D1. Late changes include expression of p53 and loss of SMAD4/DPC4. PanIN = pancreatic intraepithelial neoplasia.

Imaging

CT scan with dynamic contrast and thin cuts through the pancreas is the imaging procedure of choice when PDAC is suspected. CT scans can provide information regarding the presence of metastatic disease, vascular invasion, and potential for resection. Endoscopic ultrasound (EUS) may provide additional information useful for preoperative assessment, including fine-needle aspiration biopsy under endoscopic guidance. It is important to point out that the typical desmoplastic reaction that can encase PDACs increases the possibility of false-negative biopsy findings. Patients with locally advanced or metastatic disease should have their diagnosis confirmed pathologically by fine-needle biopsy of the primary site or of a metastasis.

Biomarkers and Screening

A recent preliminary study identified two diagnostic panels based on microRNA expression in whole blood, with the potential to distinguish patients with pancreatic cancer from healthy controls.[5] However, so far, no serum- or tumor-based biomarkers or biomarker panels have been established that are both sensitive and specific enough for accurate early detection in clinical practice. CA19.9 is the most commonly used tumor biomarker for monitoring therapeutic progress in PDAC, but the lack of specificity of the assay is a concern, and CA19.9 therefore cannot be used for early detection. EUS is useful for the evaluation of cystic lesions and permits sampling of cystic fluid for genetic markers associated with the development of PDAC in cancer-prone families, as well as for cytologic studies.

TREATMENT

Resectable Pancreatic Cancer

Surgery offers the only chance to cure pancreatic cancer. Tumors are considered resectable if a clear fat plane is present around the celiac and superior mesenteric arteries, and if the mesenteric and portal veins are patent. Unfortunately, tumor will recur in the majority of patients who undergo resection. Adjuvant therapy is indicated to decrease the risk and delay the timing of locoregional and metastatic recurrence. It is typically started 1 to 2 months after surgery to allow the patient to recover from the complications associated with the underlying cancer as well as from surgery itself. Although no regimen has been proven substantially more effective than others, 6 months of adjuvant therapy with 5-fluorouracil (5-FU) or gemcitabine-based chemotherapy is an appropriate standard (Table 194-1). A meta-analysis has shown that chemotherapy with 5-FU or gemcitabine is the optimum adjuvant treatment for pancreatic adenocarcinoma and reduces mortality after surgery by about a third. Chemoradiation plus chemotherapy is less effective in prolonging survival and is more toxic than chemotherapy.

TABLE 194-1 SELECTED ADJUVANT STUDIES

STUDY	TREATMENT	1-YEAR SURVIVAL (%)	2-YEAR SURVIVAL (%)	5-YEAR SURVIVAL (%)	DISEASE-FREE SURVIVAL (MO)	MEDIAN SURVIVAL (MO)
ESPAC-1 (2004) N = 289	2 × 2 design: Observation v. Chemorad v. Chemo v. Chemorad plus chemo			 11 v. 7 v. 29 v. 13	 Chemorad, 10.7 v. no chemorad, 15.2 Chemo, 15.3 v. no chemo, 9.4	 16.9 v. 13.9 v. 21.6 v. 19.9

5-FU = 5-fluorocil; FOLFIRINOX = combination chemotherapy with oxaliplatin, irinotecan, fluorouracil, and leucovorin; gem = gemcitabine; NR = rot reported.

Neoadjuvant (presurgical) therapy remains an option in the treatment of pancreatic cancer. It has the potential to downstage patients of borderline resectability who achieve a partial response with therapy, allowing them to undergo surgery with a higher likelihood of complete resection. In fact, 15 to 40% of patients who initially present with borderline or unresectable tumors may eventually be deemed appropriate to undergo surgery. In addition, neoadjuvant therapy spares some patients the risks and stress of a complex surgical procedure, because rapidly developing metastatic disease may be detected by routine restaging following the completion of neoadjuvant treatment. Unfortunately, chemotherapy-resistant cancer can be demonstrated in 15 to 35% of patients initially considered for surgery in this setting. The use of neoadjuvant treatment also guarantees that almost all patients will receive some form of chemotherapy and/or chemoradiation because they do not have any postoperative complications from which to recover. Studies show that 73 to 100% of patients are able to complete the majority of their neoadjuvant regimens. The chemoradiation component of neoadjuvant therapy also decreases local recurrence rates in patients who undergo surgery.

However, surgery is required for cure, and neoadjuvant therapy does delay potentially curable surgery. Although the same percentage of patients ultimately undergo surgery, there are no randomized trials favoring neoadjuvant over adjuvant treatment. Therefore, at this time neoadjuvant therapy is usually reserved for borderline resectable patients, whereas resectable patients are taken to surgery immediately, with adjuvant therapy administered following recovery. Patients treated with either adjuvant or neoadjuvant therapy have similar survival rates when resection can be completed successfully. Decisions regarding initial treatment should, if possible, be made in a multidisciplinary manner to achieve the most timely and coordinated therapy.

Metastatic Disease

For many years, 5-FU was the standard of care to treat advanced PDAC. In 1997, a phase III trial demonstrated a survival benefit for gemcitabine over bolus 5-FU, with a median survival of 5.65 months compared to 4.41 months, and 1-year survival of 18% versus 2%, favoring treatment with gemcitabine. Gemcitabine also had a superior clinical benefit response, described as improvement in pain, performance status, or weight in 24% of patients versus 5% in the 5-FU group; it is therefore appropriate treatment for patients with moderate performance status.

Gemcitabine has also been combined with targeted therapies; however, addition of the EGFR inhibitor erlotinib has been the only molecularly targeted agent shown to improve overall survival, albeit modestly. Newer combination regimens, both with improved efficacy based on phase III clinical trials for metastatic PDAC patients, include FOLFIRINOX (oxaliplatin, irinotecan, fluorouracil, and leucovorin) and the nab-paclitaxel and gemcitabine doublet (Table 194-2).

PROGNOSIS AND SUPPORTIVE CARE

The overall 5-year survival for all patients with pancreatic cancer is less than 5%. This is in part because there is no appropriate screening test for the general population, and presenting symptoms are vague. Once patients are diagnosed, only 15 to 20% present with resectable, and thus potentially curable, disease. In these patients, the somatostatin analogue pasireotide (900 mg subcutaneously twice daily for 7 days beginning in the morning of surgery) can reduce the risk of fistula leak with abscess by 50%. However, even in patients with early-stage disease, median survival is 20 to 24 months, with a 5-year survival of only 15 to 20% because the majority will eventually recur despite surgery and adjuvant or neoadjuvant therapy. Patients with locally advanced (≈25 to 30% at presentation) and metastatic disease (≈50 to 60% at presentation) have median survivals of 8 to 14 months and 4 to 6 months, respectively. Because many patients suffer from biliary obstruction, diarrhea, pain, and malnutrition, palliative care can provide great benefit. Surgery can also play an important palliative role; patients found to be unresectable may be improved symptomatically by a biliary or gastric bypass procedure, depending on the site of obstruction. Placement of both biliary and duodenal stents in the absence of a surgical approach may also improve pruritus, pain, or other complications of biliary tract obstruction. Palliative care for patients with PDAC necessitates scrupulous attention to pain management that often requires a multidisciplinary approach, as well as maintenance of hydration and adequate nutritional status.

REVIEW QUESTIONS

1. Which of the following is *not* a known risk factor for pancreatic cancer:

A. Chronic proton pump inhibitor therapy
B. Positive family history
C. Cigarette smoking
D. Obesity
E. Chronic pancreatitis

Answer: A Gastrectomy, much more commonly performed in the past for refractory peptic ulcer disease, was considered to be a risk factor for pancreatic cancer; however, there is no evidence that medical therapy for it (e.g., with proton pump inhibitors) poses a risk. Approximately 10% of pancreatic cancer cases occur in families with a positive history. Cigarette smoking, even second-hand, has been clearly linked to pancreatic cancer risk. Obesity is associated with increased risk for a variety of cancers, including pancreatic. The long-known risk of pancreatic cancer with chronic pancreatic inflammation is now being elucidated at the molecular level as a function of the action of pro-inflammatory cytokines on progression from pre-malignant lesions to advanced tumor. (See section on "Epidemiology.")

2. Which of the following is *not* known to be a clinical manifestation of pancreatic cancer:

A. Diabetes mellitus
B. Courvoisier's sign
C. Superficial thrombophlebitis
D. Splenic infarction
E. Obstructive jaundice

Answer: D The symptoms of early pancreatic cancer are often subtle, and there may be no abnormal findings on physical exam. Although extensive pancreatic cancer could potentially cause portal vein or splenic vein thrombosis, compromise of the spleen's arterial supply to cause splenic infarction is not characteristic. Hyperglycemia and even frank clinical type 2 diabetes mellitus may be a harbinger of occult pancreatic cancer, and its onset may antedate the cancer diagnosis by months. Courvoisier's sign, a palpably distended gallbladder, is a striking physical finding resulting from distal common bile duct obstruction due to pancreatic cancer, although it is very rare. Obstructive jaundice that is often painless is, however, not an uncommon presenting manifestation because 75% of pancreatic cancers are located in the head of the pancreas. Superficial thrombophlebitis, particularly when it is migratory in nature (called Trousseau syndrome) is frequently a sign of occult cancer, with pancreatic cancer being among the most common.

3. Which of the following approaches provides the best results in increasing survival after surgery for pancreatic cancer:

A. Radiation therapy
B. Combined chemoradiation therapy and chemotherapy
C. Gemcitabine or 5-fluorouracil
D. Biologic agents
E. Unfortunately, no current therapy increases survival after surgery.

Answer: C A recently published meta-analysis of several clinical trials has shown that chemotherapy with 5-fluoruracil or gemcitabine is the currently optimum adjuvant treatment for pancreatic adenocarcinoma and reduces mortality after surgery by about a third. Adjuvant radiation therapy alone or combined chemoradiation and chemotherapy are less effective in prolonging survival and are more toxic than chemotherapy with 5-FU or gemcitabine. Biologic agents are not known to be effective at this time.

PANCREATIC NEUROENDOCRINE TUMORS

ROBERT T. JENSEN

DEFINITION

Pancreatic neuroendocrine tumors (pNETs) are also called islet cell tumors, but because the cell of origin of most of these tumors is unknown, the general term *pNET* is preferred. This term is also a misnomer, however, because pNETs can occur outside the pancreas. Eleven pNETs are well established (Table 195-1).[1] Other functional pNET syndromes have been rarely reported: pNETs secreting renin causing hypertension, pNETs secreting erythropoietin

TABLE 195-1 PANCREATIC NEUROENDOCRINE TUMORS

NAME OF TUMOR	NAME OF SYNDROME	MAIN SIGNS OR SYMPTOMS	LOCATION	MALIGNANCY (%)	HORMONE CAUSING SYNDROME
I. FUNCTIONAL pNET					
Gastrinoma	Zollinger-Ellison syndrome	Abdominal pain, diarrhea, esophageal symptoms	Pancreas—30% Duodenum—60% Other—10%	60-90	Gastrin
Insulinoma	Insulinoma	Hypoglycemic symptoms	Pancreas—100%	5-15	Insulin
Glucagonoma	Glucagonoma	Dermatitis, diabetes/glucose intolerance, weight loss	Pancreas—100%	60	Glucagon
VIPoma	Verner-Morrison, pancreatic cholera, WDHA	Severe watery diarrhea, hypokalemia	Pancreas—90% Other—10% (neural, adrenal, periganglionic tissue)	80	Vasoactive intestinal peptide (VIP)
Somatostatinoma	Somatostatinoma	Diabetes mellitus, cholelithiasis, diarrhea	Pancreas—56% Duodenum/jejunum—44%	60	Somatostatin
GRFoma	GRFoma	Acromegaly	Pancreas—30% Lung—54% Jejunum—7% Other—13% (adrenal, foregut, retroperitoneum)	30	Growth hormone–releasing factor (GRF)
ACTHoma	ACTHoma	Cushing's syndrome	Pancreas—4-16% of all ectopic Cushing's cases	>95	Adrenocorticotropic hormone (ACTH)
pNET causing carcinoid syndrome	pNET causing carcinoid syndrome	Diarrhea, flushing	Pancreas—<1% of all carcinoids	60-90	Serotonin, tachykinins
pNET causing hypercalcemia	pNET causing hypercalcemia	Signs/symptoms of hypercalcemia	Pancreas (rare cause of hypercalcemia)	>85	PTHrP, other unknown
CCKoma	CCKoma	Diarrhea, peptic ulcer, gallbladder disease,	Pancreas (1 case)	100	Cholecystokinin
II. NONFUNCTIONAL pNET					
Nonfunctioning PPoma	Nonfunctional PPoma	Weight loss, abdominal mass, hepatomegaly	Pancreas—100%	60-90	None: pancreatic polypeptide, chromogranin released, but no known symptoms due to hypersecretion

pNET = pancreatic endocrine tumor; PP = pancreatic polypeptide; PTHrP = parathormone-related peptide; WDHA = watery diarrhea, hypokalemia, and achlorhydria.

causing polycythemia, pNETs secreting luteinizing hormone that causes virilization, pNETs secreting insulin-like growth factor (IGF)-II or glucagon-like peptide (GLP)-1 causing hypoglycemia, and pNETs secreting enteroglucagon causing small intestinal hypertrophy1. In addition, pNETs synthesizing neurotensin, calcitonin, and ghrelin have been reported, but no distinct syndromes related to them have been generally accepted).

pNETs frequently are classified as functional or nonfunctional (see Table 195-1), depending on whether a clinical syndrome resulting from the autonomously released hormone is present).[2,3] Nonfunctional pNETs frequently release hormones and peptides (pancreatic polypeptide, neurotensin, α- and β-subunits of human chorionic gonadotropin, neuron-specific enolase, chromogranin A and breakdown products) that cause no distinct clinical syndromes.

EPIDEMIOLOGY

pNETs are uncommon, having a prevalence of less than 10 cases per 1 million population. Insulinomas, gastrinomas, and nonfunctional pNETs are the most common, with an incidence of 1 to 3 new cases per 1 million population.[4]

PATHOBIOLOGY

All pNETs share certain features. pNETs are classified as APUDomas (amine precursor uptake and decarboxylation), which share cytochemical features with carcinoid tumors, melanomas, and other endocrine tumors (pheochromocytomas, medullary thyroid cancer).[5] Except for insulinomas, these tumors are frequently malignant. All pNETs appear similar histologically, with few mitotic figures. Ultrastructurally, they have dense granules containing peptides, amines, and products of neuroendocrine differentiation (neuron-specific enolase, chromogranins, synaptophysin). The presence of chromogranin immunoreactivity in the tumor is now widely used to identify these tumors as endocrine tumors.

Molecular studies show that pNETs have a different pathogenesis than common gastrointestinal adenocarcinomas because they infrequently demonstrate mutations in common tumor suppressor genes (e.g., retinoblastoma gene, *p53*) or common oncogenes (*ras*, *c-Jun*, *c-Fos*).[6] Recent studies show important alterations are found in the *MEN1* gene, gene alterations affecting p53 and retinoblastoma activity, mutations in the DAXX-ATRX complex (important for transcription/chromatin remodeling), and the mTOR pathway.[7] Alterations in $p16^{INK4a}$, the *MEN1* gene, and the expression of growth factors, as well as chromosomal losses (1q, 3p, 3q, 6p, X) and gains (17p, 17q, 20q), have been associated with a worse prognosis in numerous studies.[8] A number of other factors have prognostic significance, the most important of which is the presence of liver metastases. Recently, classification systems including a TNM classification and a grading system (World Health Organization, ENETS [European Neuroendocrine Tumor Society], AJCC/UICC [American Joint Committee on Cancer/Union for International Cancer Control]) have been proposed for pNETs based on tumor size, presence of metastases, invasiveness, and proliferative indices; these classification systems have been recently shown to have prognostic value in a number of studies. Furthermore, they are important in choosing the proper treatment approach.[9]

Four autosomal dominant inherited disorders are associated with an increased occurrence of pNETs: multiple endocrine neoplasia type 1 (MEN 1; 80 to 100% develop pNETs), von Hippel-Lindau disease (VHL; 10 to 17% have pNETs), von Recklinghausen disease (neurofibromatosis [NF]-1; 12% develop duodenal somatostatinomas), and tuberous sclerosis (<1% develop pNETs).[10]

FUNCTIONAL PANCREATIC NEUROENDOCRINE TUMOR SYNDROMES

Zollinger-Ellison Syndrome (Gastrinomas)

DEFINITION AND EPIDEMIOLOGY

Zollinger-Ellison syndrome (ZES) is a clinical syndrome caused by a gastrin-releasing endocrine tumor usually located in the pancreas or duodenum and characterized by clinical symptoms and signs resulting from gastric acid hypersecretion (peptic ulcer disease, diarrhea, esophageal reflux disease).

ZES is diagnosed most frequently between the ages of 35 and 65 years and is slightly more common in men (60%).[11]

PATHOBIOLOGY

In recent surgical series, gastrinomas occur two to five times more frequently in the duodenum than in the pancreas. Duodenal gastrinomas are generally small (<1 cm), whereas pancreatic gastrinomas are generally larger. Occasionally ZES results from a gastrinoma in the splenic hilum, mesentery, stomach, or only in a lymph node or an ovary. Extrapancreatic gastrinomas producing ZES have been reported in the heart and as a result of small-cell lung cancer. As with other pNETs, malignancy can be reliably determined only by demonstrating the presence of metastatic disease, and no light microscopic or ultrastructural finding can clearly establish malignant behavior.

Gastrin stimulates parietal cells to secrete acid and also has a growth effect on cells of the gastric mucosa. Chronic hypergastrinemia thus leads to increased gastric mucosal thickness, prominent gastric folds, and increased numbers of parietal cells and gastric enterochromaffin-like cells. Patients with gastrinomas have increased basal and maximal acid outputs. *Helicobacter pylori* appears not to be important in the pathogenesis of the ulcer disease in ZES, in contrast to that of routine peptic ulcers (Chapter 139). Diarrhea is common because the large-volume gastric acid output leads to structural damage to the small intestine (inflammation, blunted villi, edema), interference with fat transport, inactivation of pancreatic lipase, and precipitation of bile acids. These same mechanisms, if prolonged, can lead to steatorrhea. If acid hypersecretion is controlled, the diarrhea will stop.

Twenty to 25% of ZES patients have MEN 1(MEN1/ZES) (Chapter 231). These patients have hyperplasia or tumors of multiple endocrine glands (parathyroid hyperplasia [>90%], pituitary tumors [60%], and pNETs [80 to 100%]). In 80 to 95% the gastrinomas are in the duodenum, frequently small (<0.5 cm), almost always multiple, and in 40 to 60% associated with lymph node metastases.

CLINICAL MANIFESTATIONS

Abdominal pain resulting from a peptic ulcer is the most common symptom (>80%). Most ulcers occur in the duodenum (>85%), but they occasionally occur in the postbulbar area, jejunum, or stomach, or in multiple locations. Initially, the pain is usually similar to that of patients with typical peptic ulcers (Chapter 139). With time, the symptoms become persistent and, in general, respond poorly to treatments aimed at eliminating *H. pylori* and to conventional doses of histamine-2 receptor antagonists, as well as to the now rarely used surgical treatments for ulcer disease. By comparison, conventional doses of proton pump inhibitors (PPIs) (e.g., omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole) can mask the symptoms of most patients with ZES and can also cause hypergastrinemia as seen in ZES. The widespread use of PPIs has delayed the diagnosis of ZES.[12]

Heartburn is also common (20%). Diarrhea (60 to 70%) occurs frequently and may be the first symptom (10 to 20%). In MEN1, ZES is the most common functional pNET syndrome (54%), although patients typically first develop renal stones related to hypercalcemia from hyperparathyroidism or have elevated prolactin levels resulting from pituitary tumors and only later develop ZES. However, studies show that 20 to 40% of patients with MEN1/ZES initially present with ZES symptoms.

In ZES patients, almost all the symptoms result from the effects of gastric acid hypersecretion, but late in the disease, patients can have tumor-related symptoms. Approximately one third of patients have metastatic liver disease at presentation, but less than 20% of other patients develop metastatic disease to the liver during a 10-year follow-up period.

Up to 5% of patients with ZES develop Cushing syndrome (Chapter 227) as a result of adrenocorticotropic hormone (ACTH) secretion by the gastrinoma. These patients usually have a metastatic gastrinoma in the liver, ZES without MEN 1, and a poor prognosis.

DIAGNOSIS

ZES should be suspected in any patient whose peptic ulcer disease is accompanied by diarrhea, is recurrent, does not heal with treatment, is not associated with *H. pylori* infection, is associated with a complication (bleeding, obstruction, esophageal stricture), is multiple or occurs in unusual locations, or is associated with a pancreatic tumor. ZES should also be suspected in patients with chronic secretory diarrhea (Chapter 140), peptic ulcer disease associated with large gastric folds, a family or personal history of renal stones or endocrinopathies, or the laboratory finding of hypercalcemia, hypergastrinemia, or gastric acid hypersecretion.

When suspected, the initial test is a fasting serum gastrin level, which is elevated in 99 to 100% of ZES patients. Recent studies report up to 60% of commercial gastrin assays are unreliable (over/underestimate true value), so a reliable assay should be used. Besides ZES, other causes of fasting hypergastrinemia include renal failure, *H. pylori* infections, and a physiologic response to achlorhydria or hypochlorhydria because of pernicious anemia, atrophic gastritis, or the use of PPIs. If the serum gastrin level is elevated, the fasting gastric pH should be determined. If the serum gastrin is more than 1000 pg/mL (normal, <100) and the gastric pH is less than 2.0, the patient almost certainly has ZES; approximately 40% of patients have this combination. If the gastrin is increased less than 10-fold and the gastric pH is higher than 2.0, basal acid output and a secretin test should be performed. Basal acid output is increased in patients with ZES, and more than 95% have a value greater than 15 mEq/hour if no previous gastric acid–reducing surgery has been performed. Because of their long duration of action, PPIs must be stopped for at least 1 week, if possible, to ensure that the cause of the hypergastrinemia is not the drug itself. Stopping a PPI in an undiagnosed ZES patient can lead to complications, so it needs to be done with care, and it is best to consult a group well versed in making the diagnosis.

Differential Diagnosis

A secretin test can exclude *H. pylori* infection, retained gastric antrum syndrome, antral G-cell hyperfunction or hyperplasia, chronic renal failure, and gastric outlet obstruction that may mimic ZES. Physiologically normal individuals show a less than 120 pg/mL increase in the gastrin level after intravenous secretin, whereas 94% of ZES patients with a fasting gastrin level that is elevated less than 10-fold above normal have a positive test. No false-positive results are reported except in patients with achlorhydria. In all patients with ZES, evaluation must exclude MEN 1 syndrome by searching for other endocrinopathies and assessing family history.

Imaging and Endoscopy

All patients should have imaging studies to localize the tumor. A cross-sectional imaging study such as triphasic computed tomography (CT) or magnetic resonance imaging (MRI) with contrast is usually the initial study because of their widespread availability.[13] Somatostatin receptor scintigraphy using single-photon emission CT (SPECT) after injection of indium-111–[diethylenetriamine pentaacetic acid-D-phenylalanine-1] octreotide is the most sensitive modality; it identifies 60% of primary gastrinomas and more than 90% of patients with metastatic liver disease, with a sensitivity equal to all conventional imaging studies (MRI, CT, ultrasound, angiography) combined.[14] For pancreatic gastrinomas, endoscopic ultrasound is particularly sensitive. Small duodenal gastrinomas (<1 cm) are frequently not detected by an imaging modality but can be found at surgery if routine duodenotomy is performed. Recent studies show that two new imaging techniques may be useful for small gastrinomas and other pNETs: the use of hybrid scanning with CT or MRI and somatostatin receptor scintigraphy (SRS) and the use of positron emission tomographic scanning, especially with gallium-68-labeled somatostatin analogues.

TREATMENT Rx

Medical Therapy

Patients need medical therapy directed at controlling the gastric acid hypersecretion and, if possible, surgical therapy to remove the gastrinoma. PPIs are now the drugs of choice. Because of their long duration of action, acid hypersecretion can be controlled in all patients with once- or twice-daily doses. The recommended starting dose for omeprazole is 60 mg once a day. In 30% of patients, higher doses are needed, particularly in patients with complicated disease (MEN 1), previous gastric surgery, or a history of severe esophageal reflux. With time the omeprazole dose can be reduced in most patients with uncomplicated disease to 20 to 40 mg/day. Patients must be treated indefinitely unless surgically cured. Long-term therapy is safe, and patients have been treated for up to 20 years with omeprazole without loss of efficacy, although reduced vitamin B_{12} levels may occur and require vitamin B_{12} supplementation (Chapter 164). Histamine-2 receptor antagonists are also effective, but frequent (every 4 to 6 hours) high doses are needed. Total gastrectomy, the historical treatment, is now performed only for patients who cannot or will not take oral antisecretory medications.[15] Selective vagotomy reduces acid secretion, but many patients continue to require a low dose of drug, and it is now rarely used. Parathyroidectomy should be performed in MEN 1 patients with hyperparathyroidism and ZES, because it reduces acid secretion and increases the sensitivity to antisecretory drugs.

Surgical Therapy

Surgical exploration for cure is recommended in all patients without unresectable liver metastases, MEN 1, or complicating medical conditions that limit life expectancy. Tumors are found by experienced endocrine surgeons in 95% of patients at surgery. Surgical resection decreases the metastatic rate, increases survival, and results in a 5-year cure rate of 30%. Patients with metastatic gastrinoma in the liver have a poor prognosis, with a 5-year survival rate of 30%.

Metastatic Disease

If the metastatic disease can be resected (>90%), surgery should be considered (5 to 15% of cases). If the metastatic disease is nonresectable and slowly increasing in size or is symptomatic, treatment with octreotide (100 to 450 µg two to three times daily) alone or in combination with interferon-α (1 to 5 million U, 3 to 7 days/week) is effective in inhibiting further tumor growth in 50 to 60% of patients. In a randomized multinational study, the somatostatin analog lanreotide was associated with significantly prolonged survival among patients with somatostatin-positive metastatic enteropancreatic neuroendocrine tumors of grade 1 or 2. If this treatment fails or if the tumor is rapidly growing, chemotherapeutic agents (streptozotocin, 5-fluorouracil, doxorubicin) or treatment with the mTOR inhibitor everolimus or the tyrosine kinase inhibitor sunitinib is recommended. Everolimus and sunitinib also have been shown in prospective randomized studies to more than double the progression-free survival time. For patients with extensive metastatic disease, somatostatin receptor–directed radiation therapy using analogues labeled with yttrium-90, lutetium-177, or indium-111 is increasingly used, but these therapies are still not approved.[16] Newer chemotherapy treatments using temozolomide show some promise in a small number of gastrinomas and other pNET patients. In advanced cases where metastases are confined to the liver, liver-directed therapies (embolization, chemoembolization, radioembolization) and local ablative methodologies such as radio frequency ablation, are increasingly used. Liver transplantation is occasionally performed in the rare patient with metastases limited to the liver.

PROGNOSIS

Approximately 25% of gastrinomas show aggressive growth. The most important prognostic predictor is the development of liver metastases. The presence of a large primary tumor, a pancreatic tumor, bone metastases, development of ectopic Cushing syndrome, or a high fasting gastrin level is associated with aggressive growth.

Glucagonomas

DEFINITION

Glucagonomas are endocrine tumors of the pancreas that ectopically secrete glucagon, causing a specific syndrome (see Table 195-1).

PATHOBIOLOGY

Glucagon hypersecretion explains the glucose intolerance. The exact origin of the rash is unclear; some studies report that prolonged glucagon infusions can cause the characteristic skin lesions. A role for possible zinc deficiency has been proposed because of the similarity of the rash to that seen with zinc deficiency (acrodermatitis enteropathica) and because the rash improves in some patients who are given zinc. The hypoaminoacidemia is thought to be secondary to the effect of glucagon on amino acid metabolism by altering gluconeogenesis. The wasting and weight loss are intrinsic parts of the glucagonoma syndrome, and recent studies suggest that a novel anorectic substance distinct from glucagon is responsible.

CLINICAL MANIFESTATIONS

The cardinal clinical features are a distinct dermatitis (necrolytic migratory erythema, seen in 70 to 90%) (Fig. 195-1), diabetes mellitus and glucose intolerance (40 to 90%), weight loss (70 to 96%), anemia (30 to 85%), hypoaminoacidemia (80 to 90%) with deficiencies of essential fatty acids, thromboembolism (10 to 25%), diarrhea (15 to 30%), and psychiatric disturbances (0 to 20%). The characteristic rash is usually found at intertriginous and periorificial sites, especially in the groin and buttocks (see Fig. 195-1). It is initially erythematous, becomes raised, and develops central bullae whose tops detach, with the eroded areas becoming crusty. Healing occurs with hyperpigmentation.

DIAGNOSIS

The diagnosis is established by demonstrating elevated plasma glucagon levels. Normal levels are 150 to 200 pg/mL; in patients with glucagonomas, levels usually (>90%) are higher than 1000 pg/mL. However, in some recent studies, up to 40% of patients had plasma glucagon values of 500 to 1000 pg/mL. Increased plasma glucagon levels also occur in renal insufficiency, acute pancreatitis, hypercorticism, hepatic diseases, celiac disease, severe stress and prolonged fasting, in patients treated with danazol, and in familial hyperglucagonemia. In these conditions, the level is usually less than 500 pg/mL except in patients with hepatic diseases or in those with familial hyperglucagonemia. Recently, two new glucagonoma-related syndromes have been described: Mahvash disease (characterized by mutations in the glucagon receptor, glucagon cell hyperplasia, hyperglucagonemia, but no symptoms of the glucagonoma syndrome) and glucagon cell adenomatosis (characterized by glucagon cell hyperplasia and occasional symptoms mimicking the glucagonoma syndrome).

Glucagonomas are generally large when discovered (mean, 5 to 10 cm), and they most frequently occur in the pancreatic tail (>50%). Liver metastases are commonly present at the time of diagnosis (45 to 80%).

FIGURE 195-1. **A patient with a glucagonoma with the characteristic rash (necrolytic migratory erythema). The rash is usually at intertriginous areas or periorificial sites and shows various stages of erythema, blistering, and crusting. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*. 3rd ed. London: Mosby; 2003.)**

TREATMENT Rx

Subcutaneous administration of the synthetic long-acting somatostatin analogue octreotide (100 to 400 µg two to three times daily) controls the rash in 80% of patients and improves weight loss, diarrhea, and hypoaminoacidemia,[17] but it usually does not improve the diabetes mellitus. Increasingly, long-acting depot formulations of octreotide (octreotide-LAR) or lanreotide autogel are being given by monthly injection. Zinc supplementation and infusions of amino acids or fatty acids, or both, can diminish the severity of the rash. After tumor localization, surgical resection is preferred; even debulking of metastatic tumor may be of benefit. For advanced disease, treatment is similar to outlined for advanced nonresectable gastrinomas.

PROGNOSIS

The prognosis is now largely determined by the growth of the tumor per se, because the symptoms of glucagon excess can be largely controlled by somatostatin analogues. This is particularly true with glucagonomas; in many series, more than 50 to 80% are metastatic at presentation, and patients usually present late with large primary tumors. The mean 5-year survival rate is 50%; however, extended survivals (>15 years) are reported in some patients with treatment with somatostatin analogues and other tumor-directed therapies.

VIPomas

DEFINITION

The VIPoma syndrome, also called the Verner-Morrison syndrome, pancreatic cholera, and the WDHA syndrome (for watery diarrhea, hypokalemia, and achlorhydria), results from an endocrine tumor, usually in the pancreas, that ectopically secretes vasoactive intestinal polypeptide (VIP).

EPIDEMIOLOGY AND PATHOBIOLOGY

VIPomas in adults are found in the pancreas in 80 to 90% of cases; rare cases result from intestinal carcinoids, ganglioneuromas, ganglioneuroblastomas, and pheochromocytomas. In children younger than 10 years and rarely in adults (<5%), the VIPoma syndrome is caused by ganglioneuromas or ganglioneuroblastomas at extrapancreatic sites. VIPomas are usually large and solitary; 50 to 75% of these tumors occur in the pancreatic tail, and 40 to 70% have metastasized at diagnosis. VIPomas frequently secrete both VIP and peptide histidine methionine, but VIP is responsible for the symptoms. VIP is a potent stimulant of secretion in the small and large intestine, which causes the cardinal clinical features of the VIPoma syndrome. VIP also causes relaxation of gastrointestinal smooth muscle, and this may contribute to the dilated loops of bowel that are common in this syndrome, as well as a dilated atonic gallbladder that is sometimes seen. Hypochlorhydria is thought to result from the inhibitory effect of VIP on acid secretion, the flushing is related to the vasodilatory effects of VIP, and the hyperglycemia is caused by the glycogenolytic effect of VIP. The mechanism of the hypercalcemia remains unclear.

CLINICAL MANIFESTATIONS

The cardinal clinical feature is severe, large-volume, watery diarrhea (>1 L/day) (100%), which is secretory and occurs during fasting. Hypokalemia (67 to 100%) and dehydration (83%) commonly occur because of the volume of the diarrhea. Achlorhydria is occasionally noted, but hypochlorhydria is usually found (34 to 72% of cases). Flushing occurs in 20% of patients, hyperglycemia in 25 to 50%, and hypercalcemia in 41 to 50%. Steatorrhea is uncommon (16%) despite the volume of diarrhea.

DIAGNOSIS

The diarrhea of VIPomas characteristically persists during fasting and is large in volume (>3 L/day in 70 to 80%); the diagnosis is excluded when fasting stool volume is less than 700 mL/day. To differentiate VIPomas from other causes of large-volume fasting diarrhea, fasting plasma VIP levels should be determined. The normal value in most laboratories is less than 190 pg/mL, and elevated levels are present in 90 to 100% of patients in various series. The differential diagnosis of large-volume fasting diarrhea (>700 mL/day) includes ZES, diffuse islet cell hyperplasia, surreptitious use of laxatives, the pseudopancreatic cholera syndrome, and rarely, HIV infection (Chapter 390). Serum gastrin levels identify patients with ZES, and plasma VIP levels are normal in most patients who abuse laxatives, in 82% of patients with pancreatic islet cell hyperplasia, and in patients with HIV-induced secretory diarrhea.

TREATMENT Rx

The symptoms caused by the VIP are controlled initially in more than 85% of patients by daily doses of octreotide (50 to 400 µg once to three times daily) or by monthly injections of the depot form, octreotide-LAR or lanreotide autogel, but increased doses may be needed over time. Before the availability of octreotide, small numbers of patients were reported to respond to a variety of agents, including high-dose prednisone (60 to 100 mg/day; 40 to 50%), clonidine, lithium carbonate, indomethacin, loperamide, metoclopramide, and phenothiazines. After tumor localization studies, surgical resection should be attempted if it is possible to remove all visible tumor; however, more than 50% of patients have generalized liver metastases at diagnosis, so complete resection may not be possible. For patients with unresectable advanced disease, treatment is similar to outlined for advanced nonresectable gastrinomas.[18]

PROGNOSIS

The prognosis is now largely determined by the growth of the tumor per se, because the symptoms of VIP excess can be largely controlled by somatostatin analogues. This is particularly true in patients with VIPomas, because they frequently (>50%) present with advanced metastatic disease. The mean 5-year survival is 50 to 70%.

Somatostatinomas

Definition and Pathobiology

Somatostatinomas are endocrine tumors that occur in the pancreas or upper small intestine and ectopically secrete somatostatin. In the gastrointestinal tract, somatostatin inhibits basal and stimulated acid secretion, pancreatic secretion, intestinal absorption of amino acids, gallbladder contractility, and release of numerous hormones, including cholecystokinin and gastrin.

CLINICAL MANIFESTATIONS

Most reported somatostatinomas are diagnosed histologically as an endocrine tumor containing somatostatin-like immunoreactivity and are not associated with a distinct clinical syndrome (the somatostatinoma syndrome). The somatostatinoma syndrome includes diabetes mellitus, gallbladder disease, diarrhea, steatorrhea, and weight loss. Sixty percent of somatostatinomas occur in the pancreas, and 40% are found in the duodenum or jejunum. Pancreatic somatostatinomas occur in the pancreatic head in 60 to 80% of cases; 70 to 92% will have metastasized at diagnosis, and they are usually large (mean, 5 cm) and solitary. In contrast, duodenal somatostatinomas are smaller (mean, 2.4 cm), frequently associated with psammoma bodies on histologic examination (11%), and less frequently have metastases at diagnosis (30 to 40%).

The somatostatinoma syndrome occurs much more commonly (80 to 95% of all cases) in patients with pancreatic than duodenal or intestinal somatostatinomas. Duodenal somatostatinomas occur in up to 10% of patients with von Recklinghausen disease and are usually asymptomatic.

DIAGNOSIS

Somatostatinomas are usually found by accident, particularly during exploratory laparotomy for cholecystectomy, during endoscopy, or on imaging studies. The presence of psammoma bodies on histologic examination of a duodenal endocrine tumor or any duodenal lesions in patients with von Recklinghausen disease should raise the suspicion of a duodenal somatostatinoma. The diagnosis of the somatostatinoma syndrome requires the demonstration of increased concentrations of somatostatin-like immunoreactivity in the plasma and the resected tumor. However, other tumors outside the pancreas or intestine, such as small-cell lung cancer, medullary thyroid carcinoma, pheochromocytomas, and paragangliomas, may also have elevated concentrations of somatostatin-like immunoreactivity. Somatostatinomas can be imaged using somatostatin receptor scintigraphy or, if needed, other conventional imaging studies to assess the tumor's location.

TREATMENT Rx

Treatment with octreotide or lanreotide can improve symptoms. Surgery, if possible, should be performed. For patients with unresectable advanced disease, treatment is similar to outlined for advanced nonresectable gastrinomas.[19]

PROGNOSIS

Patients with intestinal somatostatinomas, which uncommonly cause the somatostatinoma syndrome and are less malignant, have an excellent prognosis (5-year survival rate, >80%), whereas those with pancreatic somatostatinomas, which frequently cause the somatostatinoma syndrome and present with metastatic disease (>70%), have a much reduced 5-year survival rate (<50%).

GRFomas

DEFINITION

GRFomas are endocrine tumors that frequently originate in the pancreas but also occur in other extrapancreatic locations and ectopically release growth hormone–releasing factor (GRF). The GRF causes acromegaly that is clinically indistinguishable from that caused by a pituitary adenoma.

PATHOBIOLOGY

GRFomas most commonly occur in the lung (54%). Most of the remainder occur in the gastrointestinal tract, including 30% in the pancreas. Pancreatic GRFomas are usually large (mean, 6 cm), 39% are metastatic at diagnosis, 40% occur in combination with ZES, and 33% are in patients with MEN 1.

DIAGNOSIS

GRFomas are an uncommon cause of acromegaly. These tumors occurred in none of 177 unselected patients with acromegaly in one study. However, any patient with acromegaly and abdominal complaints, with acromegaly but no pituitary tumor (Chapter 224), or with acromegaly and hyperprolactinemia (which occurs in 70% of GRFomas) should be suspected of having a GRFoma. The intra-abdominal features of GRFomas result from its metastases and are typical of any malignant pNET. The diagnosis is confirmed by performing a plasma assay for GRF and growth hormone.

TREATMENT

The effects of the GRF can be controlled with octreotide or lanreotide in more than 90% of patients. Treatment should be directed at the GRFoma per se, as described for the other more common pNETs. For patients with unresectable advanced disease, treatment is similar to that outlined for advanced nonresectable gastrinomas.

Nonfunctional Pancreatic Neuroendocrine Tumors

DEFINITION

Nonfunctional pNETs are endocrine tumors that originate in the pancreas and either secrete no peptides or secrete products that do not cause clinical symptoms.

PATHOBIOLOGY

Frequently secreted nonfunctional peptides include chromogranin A (100%), pancreatic polypeptide (60%), and the α-subunit (40%) and β-subunit of human chorionic gonadotropin. Immunocytochemically, even higher percentages contain these peptides as well as insulin (50%), glucagons (30%), and somatostatin (13%).

CLINICAL MANIFESTATIONS

Nonfunctional pNETs are frequently diagnosed only late in the course of disease after the patient presents with symptoms or signs of metastatic disease and a liver biopsy reveals metastatic pNET. Any symptoms or signs result from the tumor per se and include abdominal pain (36 to 56%), abdominal mass or hepatosplenomegaly (8 to 40%), weight loss or cachexia (8 to 46%), and jaundice (27 to 40%). In 20% of asymptomatic patients, tumors are found incidentally at surgery.

DIAGNOSIS

Any patients with a long survival (>5 years) after a diagnosis of metastatic pancreatic adenocarcinoma should be suspected of having a nonfunctional pNET. Most primary tumors are large (70% are > 5 cm), and 70% occur in the pancreatic head. Liver metastases are frequent (38 to 62%) at presentation. An elevated plasma chromogranin A or pancreatic polypeptide level or a positive somatostatin receptor scintigraphic scan is strong evidence that a pancreatic mass is a pNET. Malignancy correlates with vascular or perineural invasion, a proliferative index of more than 2%, a mitotic rate of 2 or higher, a size of at least 4 cm, capsular penetration, nuclear atypia, lack of progesterone receptors, and the presence of calcitonin immunoreactivity in the tumor.

TREATMENT

Tumor localization is needed in all patients. Survival is better in patients with smaller tumors, patients who are asymptomatic at presentation, patients with no metastases, and patients in whom surgical resection can be performed.

Surgical resection should be performed whenever possible. For patients with unresectable advanced disease, treatment is similar to that outlined for advanced nonresectable gastrinomas.

PROGNOSIS

The overall 5-year survival rate varies in different series from 30 to 70%, but it is heavily dependent on the extent of the disease at diagnosis, with survival rates of 96% in patients without metastases at presentation, decreasing to 30 to 50% for those with metastatic disease.[20]

ACTHomas and Other Uncommon Tumors

pNETs that ectopically secrete ACTH cause 4 to 16% of the cases of ectopic Cushing syndrome. Cushing syndrome (Chapter 227) occurs in 5% of all cases of ZES, but in patients with sporadic ZES it is a late feature, occurring with metastatic liver disease. Its development is associated with a poor prognosis, and the response to chemotherapy is generally poor; however, occasional patients benefit from the use of long-acting somatostatin analogues (octreotide, lanreotide).

Paraneoplastic hypercalcemia (Chapter 245) can result from a pNET that releases parathormone-related peptide or an unknown hypercalcemic substance. Tumors are generally large, with metastatic liver disease at diagnosis. Somatostatin analogues may help control the hypercalcemia, but surgery, chemotherapy, hepatic embolization, and chemoembolization are the mainstays of treatment.

pNETs causing the carcinoid syndrome (Chapter 232) are usually large, and 68 to 88% are malignant. Octreotide may control the symptoms. Surgery, chemotherapy, hepatic embolization, chemoembolization, or molecular targeted therapy (everolimus, sunitinib) may be helpful.

A single case of a pNET that secreted renin manifested with severe hypertension; the tumor was localized with somatostatin receptor scintigraphy, and the patient's symptoms improved significantly after tumor resection. A single case of an erythropoietin-secreting pNET resulting in polycythemia, and a single case of a pNET secreting IGF-II or GLP-1 causing hypoglycemia have been described.

Two symptomatic cases of pNETs that secreted luteinizing hormone have been described; virilization occurred in the female patient, whereas the male patient had increased acne and a rash. In both cases, the tumors were resectable, and symptoms improved postoperatively. A single case of a pNET secreting cholecystokinin (CCKoma) has been recently described, with the patients demonstrating peptic ulcer disease, gallbladder disease, diarrhea, and weight loss.[21] A case of a pNET secreting enteroglucagon causing small intestinal hypertrophy has also been described.

REVIEW QUESTIONS

1. Which is not a typical pathologic feature of most pancreatic neuroendocrine tumors (pNETs)?

A. Stain for chromogranin
B. Stain for synaptophysin
C. Stain for neuron-specific enolase
D. Have features of APUDomas
E. Show moderate to increased mitoses

Answer: E Most pNETs show few mitoses, whereas most stain for all the other listed items, and they are historically classified as APUDomas owing to their staining characteristics.

2. Which molecular change is not generally involved in the pathogenesis of pNETs?

A. Mutations of oncogenes
B. Mutations in the *MEN1* gene
C. Mutations in the DAXX-ATRX complex genes
D. Mutations/alterations in the mTOR pathway
E. Alterations in the *p16* gene

Answer: A In contrast to adenocarcinomas of the pancreas, mutations in common oncogenes (*ras*, *c-Jun*, etc.) or in common tumor suppressor genes (*p53*, retinoblastoma) are uncommon in pNET. In contrast, each of the other changes occurs in pNETs.

3. A 49-year-old man with abdominal pain is referred to you, and on laboratory evaluation is found to have a serum gastrin level of 35,000 pg/mL (normal, <100). Which of the following is true?

A. Diagnosis of Zollinger-Ellison syndrome (ZES) is likely.
B. Diagnosis of ZES syndrome is certain.
C. Diagnosis of ZES is possible.
D. Imaging studies should be performed next.
E. Upper GI endoscopy should be the next study to establish ZES.

Answer: C No level of elevation of fasting gastrin alone establishes the diagnosis of ZES, no matter how high. Other diseases, particularly atrophic gastritis or pernicious anemia, which are much more frequent, can give fasting gastrin levels in this range. The next study to perform to rule out these latter possibilities is to measure the gastric pH and establish that it is 2 or less when the fasting serum gastrin is elevated.

4. Diarrhea is not a presenting symptom of which pNETs:

A. Zollinger-Ellison syndrome
B. VIPoma
C. Glucagonoma
D. Somatostatinoma
E. GRFoma

Answer: E GRFomas characteristically present with acromegaly due to ectopic secretion of GRF, and diarrhea is not a feature. Each of the other pNETs not infrequently present with diarrhea as a feature.

5. Which of the following treatments is not commonly used to treat metastatic progressive pNETs?

A. Streptozotocin ± 5-fluoruracil ± doxorubicin
B. Somatostatin analogues
C. Surgery if most (usually > 90%) of the metastatic tumor can be removed
D. High-dose radiation to the hepatic metastases
E. Liver-directed therapies such as embolization

Answer: D Radiation to the liver is not used, whereas each of the other modalities is used at different points to treat patients with progressive metastatic pNETs.

196

LIVER AND BILIARY TRACT CANCERS

ROBIN K. KELLEY AND ALAN P. VENOOK

Malignancies arising from the liver parenchyma and biliary ductal epithelium are a heterogeneous group of cancers with generally poor prognosis, whose treatment is complicated by underlying liver injury, cirrhosis, or biliary obstruction in the majority of cases. These cancers collectively represent the third leading cause of cancer death worldwide and are rising in incidence, requiring clinician awareness of their presentation, evaluation, and treatment.

DEFINITION

Cancers arising from the liver and biliary tract include hepatocellular carcinoma, cholangiocarcinoma, and gallbladder adenocarcinoma, as well as other less common malignant histologies (Table 196-1, Fig. 196-1). Cholangiocarcinomas are further subclassified by their anatomic location along the biliary tract: intrahepatic (also known as peripheral) or extrahepatic, which includes hilar (also known as Klatskin tumors) and distal locations. The liver is a frequent site of metastasis from other primary cancers, requiring consideration of metastatic disease in the differential diagnosis of liver tumors. This chapter focuses on primary malignant tumors of the liver and biliary tract; metastatic disease to the liver is presented in other chapters, according to primary tumor of origin.

EPIDEMIOLOGY

Hepatocellular Carcinoma

Hepatocellular carcinoma is the most common primary tumor of the liver and the second leading cause of cancer death worldwide, accounting for approximately 782,000 new cases and 746,000 deaths worldwide each year based on estimates from 2012.[1] Over 80% of hepatocellular carcinoma cases

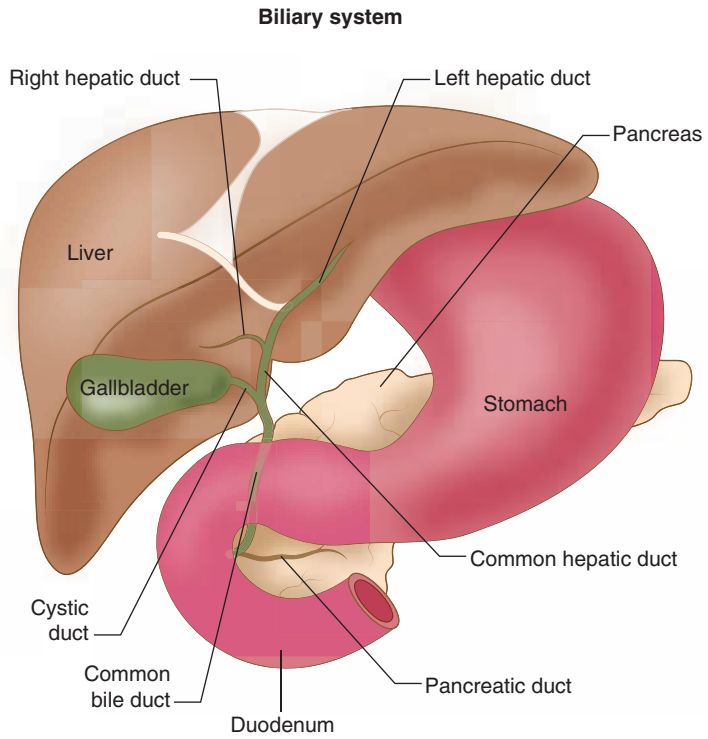

FIGURE 196-1. Anatomy of the liver and biliary tract. Hepatocellular carcinoma arises from liver parenchyma, and cholangiocarcinomas arise from the biliary ductal epithelium within (intrahapetic or peripheral) or outside of (extrahepatic) the liver. Tumors arising from the confluence of the right and left bile duct at the hepatic hilum are called hilar cholangiocarcinoma or Klatskin tumors.

TABLE 196-1 PRIMARY MALIGNANT TUMORS OF THE LIVER AND BILIARY TRACT

TUMOR TYPE	APPROXIMATE ANNUAL INCIDENCE
Hepatocellular carcinoma	782,000 cases/yr worldwide*
Gallbladder carcinoma	145,000 cases/yr worldwide
Cholangiocarcinoma	9,810 cases/yr in United States†
Mixed hepatocellular-cholangiocarcinoma	Rare
Fibrolamellar hepatocellular carcinoma	Rare
Cystadenocarcinoma	Rare
Hepatic endothelioid hemangioendothelioma	Rare
Angiosarcoma and other sarcomas	Rare

*Includes cases of intrahepatic cholangiocarcinoma.
†Includes cases of gallbladder cancer and excludes cases of intrahepatic cholangiocarcinoma.

occur in developing countries (Fig. 196-2), which is attributed to an increased prevalence of hepatocellular carcinoma risk factors, particularly hepatitis B virus (HBV) and hepatitis C virus (HCV) (Chapters 148 and 149, Table 196-2). HBV and HCV together account for over 80% of all hepatocellular carcinoma cases worldwide.[2,3] HBV is endemic in regions including Asia and sub-Saharan Africa and is vertically transmitted from mother to fetus in utero. HCV, which may be acquired by intravenous drug abuse or from blood transfusion, is another important risk factor for hepatocellular carcinoma, leading to an estimated hepatocellular carcinoma incidence of 2 to 8% per year among patients with cirrhosis caused by HCV. Obesity, diabetes, and the metabolic syndrome are risk factors for nonalcoholic fatty liver disease, a condition of rising incidence, particularly in Western populations, which can lead to steatohepatitis, cirrhosis, and hepatocellular carcinoma. Nonalcoholic fatty liver disease, alcohol-related disorders, and HCV are leading causes of hepatocellular carcinoma in the United States. Other risk factors for hepatocellular carcinoma include hepatitis D virus (which requires coinfection with HBV for pathogenicity), hereditary hemochromatosis, α_1-antitrypsin deficiency, primary biliary cirrhosis, autoimmune hepatitis, male gender, and dietary exposure to fungal aflatoxins.

Biliary Tract Cancers

Although classified as a rare cancer, cholangiocarcinoma is the most common primary biliary tract malignancy and the second most common primary cancer of the liver after hepatocellular carcinoma.[4] The incidence of intrahepatic cholangiocarcinoma appears to be increasing. Although most cases are sporadic, there is an increased risk for cholangiocarcinoma with the following conditions or exposures: primary sclerosing cholangitis, inflammatory bowel disease, viral hepatitis infection, congenital choledochal cysts or other structural abnormalities of the biliary tract, chronic pancreatitis, obesity, fluke infections and other causes of chronic cholangitis, bile duct adenomas, Caroli disease, and diabetes mellitus.

Gallbladder adenocarcinomas are a rare tumor type in the United States but account for 145,000 cases and 109,000 deaths per year worldwide based on estimates from 2008. There is significant regional variation in incidence, with higher incidence reported in India and areas of South America and Asia. Risk factors for gallbladder adenocarcinoma include female gender, chronic cholelithiasis, chronic cholecystitis, a history of gallbladder polyps, and abnormalities of the common bile duct. Calcification of the gallbladder ("porcelain gallbladder") is often considered a risk factor, but it is only weakly associated with development of cancer.

Other Primary Liver Cancers

Other primary tumors of the liver are much less common, with poorly understood risk factors. Chronic inflammatory conditions, including viral hepatitis, may be associated with the development of combined-histology liver tumors. Exposure to polyvinyl chloride has been implicated in the development of hepatic angiosarcomas. The fibrolamellar variant of hepatocellular carcinoma may occur more commonly in females. Hepatoblastoma tumors occur in infants and children, but almost never in adults.

PATHOBIOLOGY

Hepatocellular Carcinoma

Hepatocellular carcinoma is an epithelial neoplasm that arises from malignant transformation of liver hepatocytes (Fig. 196-3A and B). The pathogenesis of hepatocellular carcinoma is thought to be a multistep process triggered by underlying liver injury (such as from viral hepatitis, alcohol, iron overload, or aflatoxin exposure) in the majority of cases. Subsequent inflammation, necrosis, regeneration, cell turnover, and proliferation result in the progressive accumulation of genetic damage and somatic (acquired)

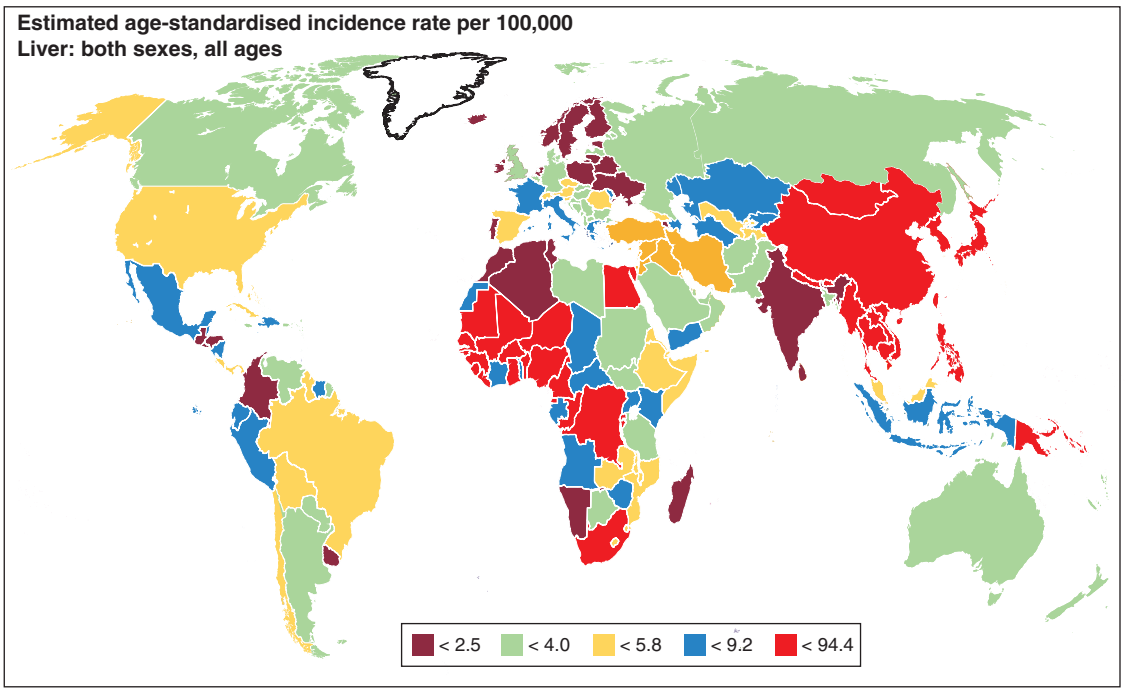

FIGURE 196-2. Global incidence of liver cancer. The incidence of liver cancer is highest in less developed regions, particularly Eastern and South-Eastern Asia and Middle and Western Africa.

TABLE 196-2 RISK FACTORS FOR HEPATOCELLULAR CARCINOMA

RISK FACTOR	INCIDENCE OF HEPATOCELLULAR CARCINOMA*
Asian male HBV carriers over age 40	0.4-0.6%/yr
Asian female HBV carriers over age 50	0.3-0.6%/yr
HBV carrier with family history of HCC	Higher incidence than without family history
African/North American Blacks with HBV	HCC occurs at younger age
HBV carriers with cirrhosis	3-8%/yr
HCV cirrhosis	3-5%/yr
Stage 4 primary biliary cirrhosis	3-5%/yr
Hereditary hemochromatosis with cirrhosis	Unknown
α_1-Antitrypsin deficiency with cirrhosis	Unknown
Other cause cirrhosis	Unknown

Modified from Bruix J, Sherman M. Management of hepatocellular carcinoma: an update. *Hepatology.* 2011;53:1020-1022.

HCC = hepatocellular carcinoma.

mutations.[5] Activation of oncogenes or inactivation of tumor suppressor genes, dysplasia, and subsequently carcinoma can arise. The most well-described mutations in hepatocellular carcinoma are point mutations or deletions resulting in inactivation of the tumor suppressor *TP53* in over 50% of cases and mutations in β-catenin *(CTNNB1)* in approximately 30% of cases. Alterations in Wnt, cell cycle, and chromatin-remodeling pathways have been described and may be associated with the etiology of underlying liver injury. In HBV-associated hepatocellular carcinoma, a unique mechanism of malignant transformation is direct viral DNA integration into the host genome, which appears to favor specific loci. A recurrent locus for HBV integration is the *TERT* gene which encodes telomerase reverse transcriptase. HBV integration can activate *TERT,* resulting in malignant transformation and immortalization in a subset of HBV-associated hepatocellular carcinomas.

Biliary Tract Cancers

Cholangiocarcinomas are a histologically diverse group of epithelial cancers that may arise from multiple different cell types within the liver, including biliary epithelial cells or hepatic progenitor cells, and are often surrounded by a dense stroma with cancer-associated fibroblasts (see Fig. 196-3C). Cholangiocarcinomas are associated with underlying inflammation and cholestasis, which activate growth factors and a proliferative response. Overexpression of Notch1 and AKT have been implicated in a process of hepatocyte conversion into cholangiocyte precursors of intrahepatic

cholangiocarcinoma. Molecular and genomic subtypes of biliary tract cancers can also be defined by mutational status (such as isocitrate dehydrogenase-1 mutation in approximately 15%) and gene expression profiles.

CLINICAL MANIFESTATIONS

General Considerations

Regardless of histologic subtype, primary tumors of the liver can manifest with right upper quadrant pain, mass effect causing early satiety or obstructive symptoms, nausea, bleeding, and biliary obstruction. All of these tumors have metastatic potential; thus presentation with constitutional symptoms (such as weight loss, fevers, or night sweats) and signs or symptoms of metastatic disease (such as bone pain or a pathologic fracture) are also possible, though less common. Paraneoplastic syndromes are rarely a manifesting symptom in hepatobiliary cancers but can include erythrocytosis from erythropoietin production by tumor and hypercalcemia of malignancy.

Hepatocellular Carcinoma

The clinical presentation of hepatocellular carcinoma can vary according to extent of tumor and underlying liver dysfunction. Some patients may be asymptomatic, particularly when diagnosed by surveillance imaging and/or α-fetoprotein (AFP) tumor marker elevation. In some cases, patients present with symptoms of worsening liver function and portal hypertension (Chapter 153), such as new ascites, encephalopathy, gastrointestinal bleeding, or jaundice, as a result of hepatic decompensation triggered by a growing tumor. This presentation is more common if there is associated portal vein thrombosis. In other cases, there may be chronic progressive upper abdominal pain because of tumor involvement of the sensitive liver capsule, sudden onset acute pain from tumor bleeding or rupture, or a palpable mass leading to the diagnosis of hepatocellular carcinoma. Constitutional symptoms such as cachexia, fatigue, and weight loss may be present with advanced stages. On physical examination, patients with hepatocellular carcinoma may have an enlarged liver with tenderness. Particularly in large and rapidly growing tumors, a bruit may be auscultated over the liver surface. Ascites, jaundice, signs of portal hypertension such as caput medusae and splenomegaly, and asterixis may be variably present if there is associated decompensation in hepatic function (Chapter 153). The tumor marker AFP is elevated in approximately 70% of cases but is not diagnostic (see later discussion).

Biliary Tract Cancers

Extrahepatic cholangiocarcinomas most often manifest with signs and symptoms of biliary obstruction, such as jaundice, pruritus, pale stools, dark urine, anorexia, nausea, and weight loss. Intrahepatic cholangiocarcinomas can also cause obstruction, but generally only when there is extensive disease present. Less commonly, complications such as biliary fistulae and hemobilia can occur. Gallbladder cancers are often diagnosed incidentally during cholecystectomy, but in some cases can be associated with right upper quadrant pain, biliary colic, or a tender, palpable mass. Infections of the biliary tract can produce symptoms including right upper quadrant pain, fever, chills, nausea, vomiting, and jaundice. Cholangitis can result from biliary obstruction by tumors throughout the biliary tract and can lead to complications such as abscess, bacteremia, or sepsis syndrome.

Diagnosis and Staging

General Considerations

The approach to patients with the finding of a liver mass requires assessment of risk factors and extent of underlying liver disease, if present. The diagnostic evaluation, staging, and treatment options are guided by whether underlying liver disease is present as well as by its extent. The differential diagnosis for hepatocellular carcinoma and biliary tract cancers includes benign liver lesions (such as hemangiomas, adenomas, abscesses, and regenerative nodules), malignant tumors of other primary liver histologies, mixed-histology tumors, and metastatic disease. It is recommended that diagnostic evaluation and procedures in patients with hepatobiliary tumors be performed in expert centers because the unique interplay of underlying liver disease, disease-specific imaging findings and staging, and risks for biopsy.

Hepatocellular Carcinoma

In patients with known cirrhosis or other risk factors for hepatocellular carcinoma (see Table 196-2), a liver mass may be identified during a program of surveillance by imaging and/or elevated serum AFP level, in the absence of other signs or symptoms of cancer. A randomized, controlled trial of surveillance by ultrasound and AFP every 6 months compared to no surveillance in a large, predominantly HBV-positive Chinese population showed a survival benefit from surveillance, although the benefit has not been proved in randomized trials in other populations.[■] In other patients, clinical manifestations as described earlier may prompt imaging that identifies a liver mass and leads to further diagnostic evaluation.

Hepatocellular carcinoma is unique in oncology in that a diagnosis can be made radiographically without tumor tissue sampling, in the appropriate clinical context. The requirements for a radiographic diagnosis of hepatocellular carcinoma without biopsy are that known underlying liver disease (see Table 196-2) is present as a risk factor and that imaging is performed using a hepatocellular carcinoma protocol that entails contrast-enhanced cross-sectional imaging during multiple phases of contrast administration (including arterial, portal venous, and delayed phases). In patients at risk for hepatocellular carcinoma, a nodule of at least 1 cm featuring arterial phase enhancement with decreased enhancement (known as "washout") during the portal venous phase of contrast is sufficient for a radiographic diagnosis of hepatocellular carcinoma (see diagnostic algorithm in Fig. 196-4). The bright arterial enhancement of hepatocellular carcinoma lesions on contrast-enhanced imaging studies is due to the propensity of this tumor to parasitize blood supply from the hepatic artery, while the normal hepatic parenchyma derives the majority of its blood supply from the portal vein. This results in hepatocellular carcinomas "washing out" as the background liver brightens during the later portal venous phase. Figure 196-5 depicts the classic arterial enhancement (part A) and portal venous washout (part B) of a hepatocellular carcinoma tumor within a cirrhotic liver. Of note, an elevated AFP level is not sufficiently sensitive or specific for diagnosis of hepatocellular carcinoma in cirrhotic patients with a liver mass. A biopsy is warranted to confirm the diagnosis of hepatocellular carcinoma if either arterial enhancement or portal venous washout is not present. In patients with small lesions who may be eligible for curative surgery or transplantation, consultation with a hepatologist and/or experienced liver surgeon, should be obtained before performing percutaneous biopsy, because of risk for tumor seeding (Fig. 196-4).

Once a patient has been radiographically and/or pathologically diagnosed with hepatocellular carcinoma, the staging for extent of disease requires cross-sectional imaging of the chest, abdomen, and pelvis, AFP measurement, and a bone scan, if symptoms or signs of bone metastases (such as bone pain or markedly elevated alkaline phosphatase value) are present. The staging of hepatocellular carcinoma also requires a thorough assessment of underlying liver function, which affects prognosis and treatment options independent of tumor extent. Several hepatocellular cancer–specific, joint tumor staging and liver disease scoring systems have been developed, including the Barcelona Clinic Liver Cancer (BCLC) staging system, the Okuda classification, and the Cancer of the Liver Italian Program (CLIP) scoring system, though there is no consensus regarding which is superior.[6]

Other Liver Tumors and Biliary Tract Cancers

For patients without known risk factors for hepatocellular carcinoma, or if diagnostic enhancement features of hepatocellular carcinoma are not met, pathologic confirmation by biopsy or cytologic examination is required for diagnosis of liver tumors. As is the case with suspected hepatocellular carcinomas, however, there is concern for tumor seeding of the needle track by percutaneous or endoluminal biopsy. Referral to an expert center is recommended to guide the diagnostic evaluation in potential surgical candidates.

Endoluminal approaches such as by endoscopic retrograde cholangiopancreaticogram (ERCP) cytologic brushing, or endoscopic ultrasound fine needle aspiration are preferred in patients with early stages of disease that may be amenable to curative surgery or transplantation. Staging of biliary tract and other rarer types of liver cancer generally includes cross-sectional imaging of the chest, abdomen, and pelvis. A mass in the gallbladder fossa suggests primary gallbladder cancer. Unlike hepatocellular carcinoma, cholangiocarcinomas characteristically display progressive enhancement during the portal venous phase of contrast imaging (Fig. 196-7). Biliary obstruction and ipsilateral hepatic lobe atrophy and contralateral hypertrophy may be present and can sometimes obscure identification of the actual tumor mass. For biliary tract cancers, CA-19-9 and carcinoembryonic antigen (CEA) tumor markers may be elevated and can help to monitor response to treatment, although levels can be confounded if biliary obstruction and hyperbilirubinemia are present. Upper and lower endoscopy are indicated to exclude metastatic disease in patients diagnosed with intrahepatic cholangiocarcinoma, which otherwise can be difficult to discriminate from metastatic disease radiographically and histologically. Cholangiography (by ERCP or magnetic resonance cholangiogram) may be indicated for both

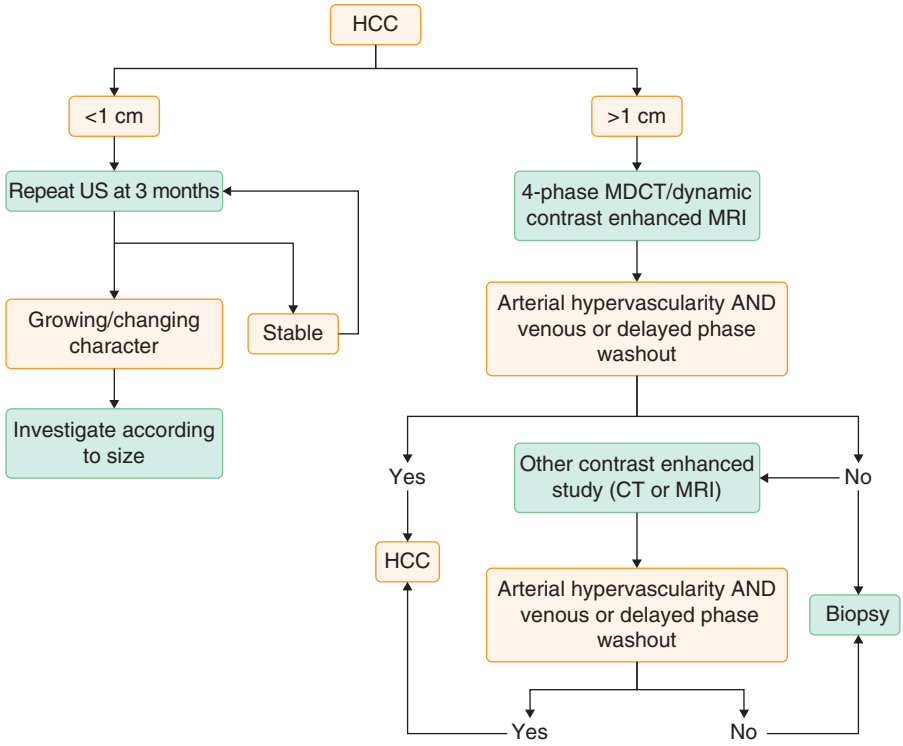

FIGURE 196-4. Hepatocellular carcinoma (*HCC*) diagnostic algorithm. American Association for the Study of Liver Diseases (AASLD) diagnostic algorithm for suspected hepatocellular carcinoma. CT = computed tomography; MDCT = multidetector CT; MRI = magnetic resonance imaging; US = ultrasound.

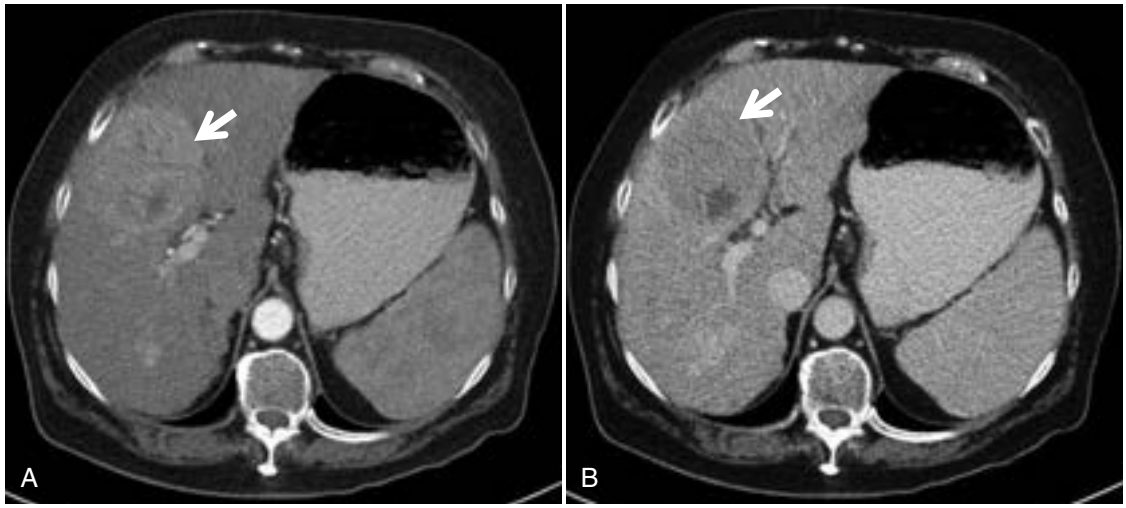

FIGURE 196-5. Imaging of hepatocellular carcinoma. In this contrast-enhanced computed tomography scan of the liver of a patient with hepatocellular carcinoma, a tumor in the right hepatic lobe demonstrates arterial phase enhancement (*white arrow,* panel A) followed by "wash-out" in the portal venous phase (white arrow, panel B).

diagnostic and therapeutic purposes (such as stent placement), particularly if biliary obstruction is present. A diagnostic laparoscopy to exclude peritoneal disease should be considered before undertaking a laparotomy for curative resection in patients with newly diagnosed gallbladder adenocarcinoma and cholangiocarcinoma, because of the propensity for radiographically occult peritoneal metastases, which would have an impact on surgical decision making. Staging of biliary tract cancers and other liver tumors follows the Tumor, Node, Metastasis (TNM) system of the American Joint Committee on Cancer.

TREATMENT

General Considerations

The treatment of patients with hepatobiliary cancers requires management of underlying liver disease as well as the tumor itself. In patients with active HBV infection or prior exposure, close monitoring of liver function and viral load is advisable; antiviral therapy may be required to prevent reactivation, which can occur with immunosuppressive therapy (Chapter 35).[7] Management of liver tumors in patients with cirrhosis may necessitate treatment for complications of portal hypertension or liver dysfunction (Chapter 153). In patients with biliary tract cancers, biliary obstruction is a common complication that often requires endoscopic stent placement, percutaneous drainage, or antibiotic therapy if cholangitis develops. Chemotherapy and supportive care medications may need dose adjustments depending on the degree of liver dysfunction.

Hepatocellular Carcinoma

The treatment of early stages of hepatocellular carcinoma depends on the degree of liver dysfunction. In patients with preserved liver function and without significant portal hypertension, surgical resection can be curative and is better than catheter-based options.[8] Among patients with increasing degrees of portal hypertension, however, surgical outcomes are significantly poorer than in patients without portal hypertension. For individuals with contraindications to surgery or inadequate projected future liver remnant

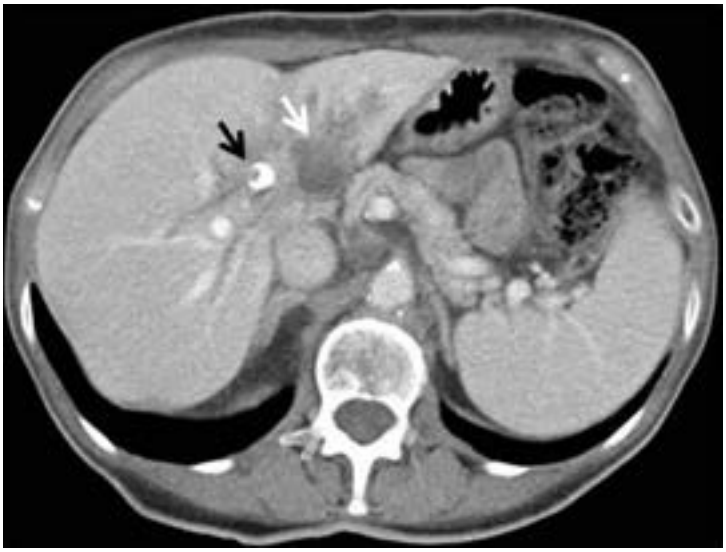

FIGURE 196-6. Imaging of cholangiocarcinoma. This computerized tomography image with contrast in portal venous phase depicts an infiltrative hilar cholangiocarcinoma (Klatskin tumor) extending into the left hepatic lobe (*white arrow*) with an endobiliary stent in place (*black arrow*).

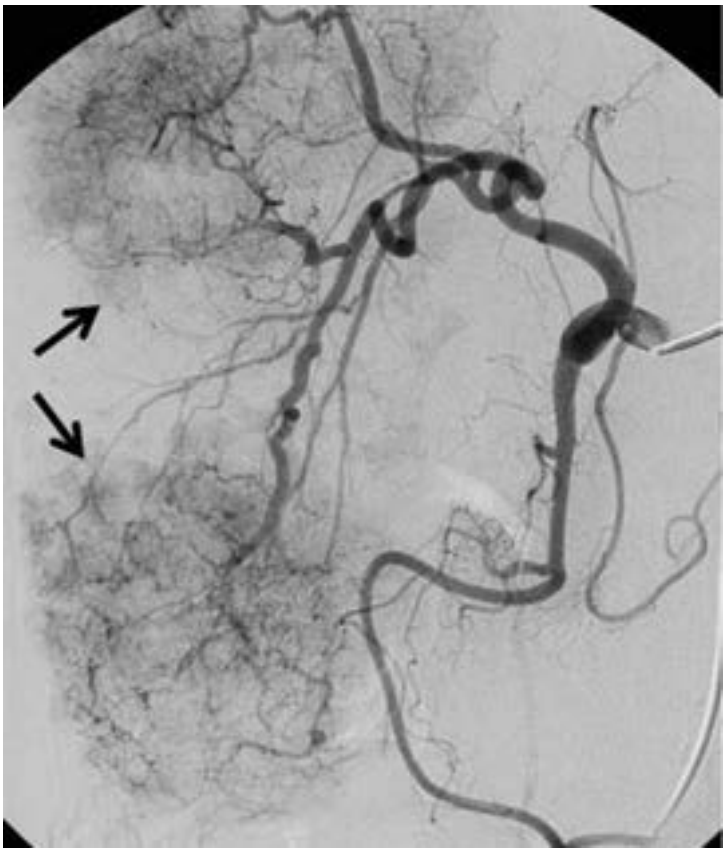

FIGURE 196-7. Trans-arterial chemoembolization (TACE) of hepatocellular carcinoma. This common hepatic artery angiogram from a 42-year-old woman with hepatitis B shows two distinct areas of "tumor blush" corresponding to underlying hepatocellular carcinoma lesions (*black arrows*) that were treated by TACE. (Courtesy Dr. Nicholas Fidelman, Department of Interventional Radiology, University of California, San Francisco.)

function, ablation of small tumors using probes that convey radiofrequency or microwaves, or by ethanol injection, can provide long-term control, and is sometimes curative.

For patients with early stages of hepatocellular carcinoma by the Milan Criteria (one lesion ≤ 5 cm or up to 3 lesions ≤ 3 cm each, without any evidence of vascular involvement or extrahepatic spread), orthotopic liver transplantation is an approved treatment with potential for long-term survival, achieving survival outcomes similar to patients undergoing transplantation for cirrhosis without cancer present. Extended criteria with parameters including larger tumor sizes may be accepted for transplantation at selected centers, often accompanied by liver-directed treatments such as embolization or ablation to control tumor burden during the period patients are waiting for transplant.[8]

When the hepatocellular carcinoma tumor burden exceeds criteria for transplantation or surgery but remains limited to the liver (BCLC intermediate stage), liver-directed therapies are commonly employed to delay progression and prolong survival, although these treatments are not likely to be curative. Transarterial chemoembolization (TACE) is the most common approach, which delivers embolic material, usually mixed with chemotherapeutic agents, via arterial catheters directly to vascular tumors within the liver. Randomized, clinical trials have demonstrated a survival benefit from TACE for intermediate-stage hepatocellular carcinoma. The optimal embolic material and chemotherapeutic agents for TACE have not yet been defined. Radioembolization using yttrium-90 bound to glass or resin microspheres is another arterially delivered therapy that may be employed in intermediate-stage hepatocellular carcinoma.[9]

For patients with advanced disease characterized by vascular involvement or extrahepatic spread, systemic therapy with sorafenib, a multikinase inhibitor whose targets include Raf kinase and vascular endothelial growth factor receptor isoforms, significantly prolonged survival compared to placebo in two randomized, phase III clinical trials. Conventional cytotoxic chemotherapy agents have not produced significant improvements in survival in hepatocellular carcinoma, unlike most other cancers, although a randomized trial of sorafenib combined with the anthracycline chemotherapeutic agent doxorubicin compared to doxorubicin alone suggested improved survival for the combination.[10] Sorafenib therapy is associated with greater absolute prolongation of survival in (1) patients with underlying HCV than in those with underlying HBV infection, (2) Western than in Asian populations, and (3) patients with Child-Pugh A than those with Child-Pugh B or poorer liver function, underscoring the clinical and biologic heterogeneity of hepatocellular carcinoma. In a recently reported phase III trial, sorafenib was found to be superior to sunitinib in overall survival, and also less toxic, in patients with hepatocellular carcinoma.

Biliary Tract Cancers

Surgical resection is the definitive therapy for patients with localized biliary tract cancers,[11] including gallbladder cancer. For patients with distal cholangiocarcinoma, a Whipple pancreaticoduodenectomy may be required. Liver transplantation for early-stage hilar cholangiocarcinoma after neoadjuvant chemotherapy and/or chemoradiation may be an option at selected centers.[12] In gallbladder cancer, cholecystectomy with en bloc hepatic resection and porta hepatis lymphadenectomy is recommended for patients with a gallbladder mass identified preoperatively on imaging or intraoperatively. A staging laparoscopy may be performed in advance to exclude occult peritoneal carcinomatosis. For patients with early-stage gallbladder cancer diagnosed incidentally on review of surgical pathologic findings after a cholecystectomy performed for benign causes, patients with tumors invading no deeper than the lamina propria (T1a) and negative surgical margins may be treated with observation only. Those found to have invasion to the muscular layer (T1b) or beyond may require additional hepatic resection and lymphadenectomy but should be referred to a center with expertise in the management of biliary tract cancers for evaluation and treatment.[13]

After surgical resection for patients with cholangiocarcinoma and gallbladder cancers, adjuvant therapy with chemotherapy and/or radiation, is often employed in fit patients, although randomized data are lacking. A large meta-analysis including 6710 patients from 20 studies suggested higher survival rates with the use of adjuvant chemotherapy, chemoradiation, or radiation.[14] In contrast, however, a randomized phase III trial comparing adjuvant treatment with gemcitabine or fluorouracil plus folinic acid versus observation in patients with periampullary cancers did not show a benefit for adjuvant therapy in a subset analysis of patients enrolled with a diagnosis of biliary tract cancers, although interpretation was limited by small sample size.

In patients with advanced biliary tract cancers not amenable to resection, combination chemotherapy with gemcitabine plus cisplatin improved survival compared to gemcitabine alone in a randomized phase III trial.

END-OF-LIFE CARE

The majority of patients diagnosed with primary hepatobiliary cancers will succumb to their cancer or complications thereof within a relatively short period of time; therefore, palliative care and end-of-life care play an integral role in management. As with most advanced cancers, pain control, treatment of nausea and constipation, and family and social support are essential. Bone metastases may require palliative radiation or stabilization procedures. Patients with advanced stages of hepatobiliary cancers, particularly hepatocellular carcinoma, are also at risk for developing complications of end-stage liver disease, such as intractable ascites, jaundice, pruritus, encephalopathy,

infections, and gastrointestinal bleeding (Chapter 135). Diuretic therapy, therapeutic paracentesis, and endoscopic management of gastrointestinal bleeding may be required. In biliary tract cancers, biliary obstruction and recurrent cholangitis also may require endoscopic or percutaneous biliary drainage and antibiotic therapy for palliation. Hospice referral may be appropriate when patients have progressed on standard anticancer therapies and/or are ineligible for further anticancer therapy because of extent of disease, liver dysfunction, poor performance status, or patient preferences.

In the United States, hepatocellular carcinoma is associated with a high incidence of health disparity, including immigrant status, racial or ethnic minority, and lower socioeconomic status. Providers must have an awareness of cross-cultural issues surrounding disclosure of diagnosis, pain control, use of alternative therapies, and end-of-life care. Pain management in patients with active substance abuse or a history of substance abuse (a risk factor for hepatocellular carcinoma) may be complicated by tolerance and/or dependency. In some cases, patients and caregivers may require providers' reassurance before using opiates or other analgesics for pain control because of concerns about addiction. Palliative care specialists and social workers provide important ancillary services in the end-of-life care for patients with hepatobiliary cancers.

PREVENTION

Screening and surveillance for hepatocellular carcinoma is associated with improved outcomes in selected populations, although a role for routine screening and surveillance has not been established across populations at risk and remains controversial. HBV vaccination programs have also been shown to reduce the incidence of hepatocellular carcinoma. Effective antiviral therapy for underlying HBV or HCV in patients with active viral hepatitis may be associated with a reduced risk for developing hepatocellular carcinoma.[15-17] Prevention and treatment of alcohol-related disorders, obesity, and other conditions associated with nonalcoholic fatty liver disease are appropriate measures to mitigate hepatocellular carcinoma risk factors and minimize ongoing liver injury, although prospective evidence for cancer risk reduction is limited.

There is limited evidence to support preventive measures or screening for biliary tract cancers. For patients with primary sclerosing cholangitis at increased risk for cholangiocarcinoma, periodic screening by noninvasive imaging and serum CA-19-9 marker measurements may be considered, although with limited supporting data.

PROGNOSIS

The prognosis of patients with hepatocellular carcinoma and biliary tract cancers is generally poor. For patients with hepatocellular carcinoma or intrahepatic cholangiocarcinoma, the overall 5-year survival across stages is approximately 20%. Among the minority of patients with hepatocellular carcinoma or intrahepatic cholangiocarcinoma diagnosed with localized stages of disease, the 5-year relative survival rate approaches 30%, although this figure is substantially higher in patients with early stages of disease who undergo curative ablation, surgery, or transplantation, among whom 5-year cause-specific survival rates generally approximate or exceed 60%.[18,19] For patients diagnosed with advanced stages of hepatocellular carcinoma or cholangiocarcinoma, the 5-year survival rate declines to approximately 3%, and the median overall survival remains less than a year with or without treatment.

For patients with gallbladder adenocarcinoma, the 5-year overall survival is approximately 15% across stages, with high rates of metastatic recurrence even among those with resectable disease. The prognosis of patients with rarer types of primary liver cancers such as fibrolamellar hepatocellular carcinoma, hepatic endothelioid hemangioendothelioma, or hepatic angiosarcoma is extremely heterogeneous and generally based on limited data from retrospective case series.

REVIEW QUESTIONS

1. Which of the following descriptions is sufficient for the diagnosis of HCC without biopsy?

A. There is no exception to the requirement for histologic diagnosis for HCC. A biopsy is always required to confirm malignant cells are present.
B. An Asian man with known hepatitis B virus (HBV) infection without cirrhosis who is found to have a 3-cm, space-occupying lesion in the liver and an α-fetoprotein (AFP) value of 400 ng/mL.
C. A patient with Child-Pugh C cirrhosis as a result of long-standing HCV infection who develops hepatic decompensation along with the finding of an infiltrative, ill-defined mass on a liver ultrasound and α-fetoprotein value of 43 ng/mL compared to baseline AFP of 18 ng/mL 1 year earlier.
D. The presence of a tumor at least 1 cm in size arterial phase enhancement and hypoenhancement ("wash-out") in portal venous phase on contrast-enhanced CT or MRI scan in a patient with known liver disease.

Answer: D A nodule greater than 1 cm in patients with risk factors for HCC may be diagnosed radiographically as HCC without biopsy if there is arterial phase enhancement with decreased enhancement during the portal venous phase. AFP is not sufficient or necessary for diagnosis. (Reference: Bruix J, Sherman M, Management of hepatocellular carcinoma: an update. *Hepatology.* 2011;53:1020-1022.)

2. A 54-year-old man has Child-Pugh B cirrhosis as a result of HCV infection and a recent history of esophageal variceal bleeding requiring transfusion. He is radiographically diagnosed with a 2-cm HCC in the right lobe of the liver that demonstrates arterial enhancement and portal venous phase "wash out" on a contrast-enhanced CT scan. There is no evidence of vascular invasion or extrahepatic spread on imaging. Which of the following is the most appropriate management?

A. Percutaneous liver biopsy to confirm the diagnosis of HCC followed by referral to the interventional radiology department for transarterial chemoembolization (TACE)
B. Ablation or resection of the tumor followed by whole liver adjuvant radiation therapy
C. Referral to an expert center to evaluate for liver transplant
D. Surgical resection followed by adjuvant sorafenib
E. Watchful waiting

Answer: C This patient with Child-Pugh B liver dysfunction has a history of variceal bleeding suggesting significant portal hypertension, which indicates he is not an appropriate candidate for liver resection because of inadequate remnant liver function. There is no proved role for adjuvant radiation after resection or ablation. Watchful waiting is not an appropriate option in this patient at high risk for complications of liver dysfunction and/or tumor progression. Outcomes of liver transplant for cirrhotic patients with small HCC lesions are equivalent to those of cirrhotic patients without HCC. (References: Mazzaferro V, Regalia E, Doci R, et al. Liver transplantation for the treatment of small hepatocellular carcinomas in patients with cirrhosis. *N Engl J Med.* 1996;334:693-699; Pelletier SJ, Fu S, Thyagarajan V, et al. An intention-to-treat analysis of liver transplantation for hepatocellular carcinoma using organ procurement transplant network data. *Liver Transplant.* 2009;15:859-868. Bruix J, Sherman M. Management of hepatocellular carcinoma: an update. *Hepatology.* 2011;53:1020-1022.)

3. Sorafenib is currently the standard of care for patients with advanced stages of hepatocellular carcinoma. Which of the following statements is true about this drug?

A. Sorafenib is a selective inhibitor of c-Met tyrosine kinase that achieves prolonged time to progression in patients with advanced HCC whose tumors are positive for overexpression of c-Met by immunohistochemistry.
B. Sorafenib is a multikinase inhibitor, whose targets include VEGFR2 and Raf kinases, that has been shown to prolong survival in patients with incurable HCC in randomized, double-blinded, placebo-controlled phase III trials.
C. Sorafenib is a multikinase inhibitor that inhibits viral replication and can reverse the progression of cirrhosis, with increased benefit in patients with Child-Pugh B and C cirrhosis compared to Child-Pugh A cirrhosis.
D. Sorafenib demonstrates improved outcomes in Asian patients with HBV-associated liver disease by comparison to non-Asian patients with underlying HCV infection as the cause of liver disease.
E. Sorafenib is an immune-modulatory drug that stimulates effector T-cell responses against tumor antigens.

Answer: B Sorafenib is not a c-Met inhibitor nor an immune-modulatory drug. Patients with worse hepatic dysfunction experience greater toxicity and shorter survival on sorafenib therapy. Absolute survival outcomes on sorafenib appear poorer in Asian patients with underlying HBV than in non-Asian patients with underlying HCV. (References: Llovet JM, Ricci S, Mazzaferro V, et al. Sorafenib in advanced hepatocellular carcinoma. *N Engl J Med.* 2008;359:378-390. Cheng AL, Kang YK, Chen Z, et al. Efficacy and safety of sorafenib in patients in the Asia-Pacific region with advanced hepatocellular carcinoma: a phase III randomised, double-blind, placebo-controlled trial. *Lancet Oncol.* 2009;10:25-34.)

4. A 47-year-old woman of South American descent undergoes laparoscopic cholecystectomy for a clinical diagnosis of cholelithiasis. After surgery, her pathology specimen is found incidentally to harbor adenocarcinoma of the gallbladder invading into the muscle layer (T1b) with negative margins. Staging imaging is negative for metastatic disease. Which of the following should be performed?

A. No further treatment or observation is required after laparoscopic cholecystectomy.
B. She should be followed with close observation including cross-sectional imaging and CA-19-9 tumor marker levels at approximately 6 month intervals for up to 5 years.
C. She should be referred to a center with expertise in biliary tract cancers for hepatic resection and lymphadenectomy.
D. She should be treated with adjuvant gemcitabine-based chemotherapy for 6 months.
E. She should receive adjuvant radiation to the surgical resection bed.

Answer: C (Reference: Fuks D, Regimbeau JM, Le Treut YP, et al. Incidental gallbladder cancer by the AFC-GBC-2009 Study Group. *World J Surg.* 2011;35:1887-1897.)

5. A 71-year-old man previously in good health and without any known liver disease is found to have mildly elevated AST, ALT, and alkaline phosphatase, but normal bilirubin. He is asymptomatic without jaundice. An ultrasound shows a 4-cm right lobe liver mass along with two smaller right lobe lesions and one left lobe lesion, without significant biliary dilatation. Contrast-enhanced CT scans of the chest, abdomen, and pelvis show the same four hypoenhancing liver lesions during arterial phase, with no other abnormalities noted. A percutaneous CT-guided biopsy shows adenocarcinoma. Which is the most appropriate next step in management?

A. Referral to a gastroenterologist for esophagogastroduoedenoscopy (EGD) and colonoscopy to complete diagnostic evaluation.
B. Referral to radiation oncology department for stereotactic beam radiation therapy for a diagnosis of unresectable, multifocal intrahepatic cholangiocarcinoma.
C. Referral to an expert center to evaluate for liver transplant for intrahepatic cholangiocarcinoma.
D. Referral to interventional radiology department for chemoembolization for a diagnosis of intermediate-stage bilobar hepatocellular carcinoma exceeding Milan criteria for transplantation.

Answer: A The clinical scenario describes multifocal adenocarcinoma lesions that could be due to intrahepatic cholangiocarcinoma with intrahepatic metastases, versus metastatic adenocarcinoma of another primary site, most commonly the gastrointestinal tract. Other primary adenocarcinoma tumors within the gastrointestinal tract that commonly metastasize to the liver (such as gastric and colon cancers) are not adequately evaluated by cross-sectional imaging and require EGD and colonoscopy to complete staging and guide treatment decision making. Although there may be a role for radiation for intrahepatic cholangiocarcinomas, the diagnosis must be confirmed before proceeding with radiation or chemotherapy. Liver transplantation is not an appropriate treatment for intrahepatic cholangiocarcinoma with multifocal liver lesions, nor for metastatic disease to the liver. Choice D is incorrect because the clinical vignette describes adenocarcinoma, not hepatocellular carcinoma, which has a histology different from that of adenocarcinoma.

197 TUMORS OF THE KIDNEY, BLADDER, URETERS, AND RENAL PELVIS

DEAN F. BAJORIN

RENAL CELL CARCINOMA

DEFINITION

Cancers of the kidney are a heterogeneous group of neoplasms, the majority of which are of epithelial origin and malignant. Renal cell carcinoma, classically referred to as clear cell carcinoma or hypernephroma, is not a single malignancy. Rather, renal cell carcinoma comprises a group of distinguishable entities, each with a strong relationship between its morphologic and genetic features.[1] The World Health Organization recognizes these biologic and histologic differences in its classification system of kidney cancers (Table 197-1). The metastatic potential depends on the histologic subtype and ranges from the most virulent conventional clear cell carcinomas (65% of total tumors but accounting for 90% of the metastases), to the more indolent papillary and chromophobe carcinomas (25% of the total but only 10% of the metastases), and to the benign oncocytomas (10% of all tumors).

EPIDEMIOLOGY

There will be over 63,000 new cases of kidney and renal pelvis tumors in the United States in 2014, resulting in approximately 13,000 deaths.[2] These cancers represent the sixth most common form of cancer in men and the eighth most common in women. The increase in incidence of renal cell cancers may be in part related to early detection as a consequence of computed tomography (CT) and magnetic resonance imaging (MRI) of the abdomen for other medical conditions. The ratio of males to females is approximately 2 : 1 to 3 : 1, and the incidence is highest in African Americans

TABLE 197-1 CLASSIFICATION OF RENAL CELL NEOPLASMS

BENIGN	MALIGNANT
Oncocytoma	Clear cell (conventional) renal cell carcinoma
Papillary (chromophil) adenoma	Papillary (chromophil) renal cell carcinoma
Metanephric adenoma	Chromophobe renal cell carcinoma
Nephrogenic adenofibroma	Collecting duct carcinoma
	Medullary carcinoma
	Mixed tubular and spindle cell carcinoma
	Renal cell carcinoma, unclassified

Modified from Storkel S, Eble JN, Adlakha K, et al. Classification of renal cell carcinoma: Workgroup No. 1. Union Internationale Contre le Cancer (UICC) and the American Joint Committee on Cancer (AJCC). *Cancer.* 1997;80:987-989.

TABLE 197-2 HISTOLOGIC SUBTYPES, GENETICS, AND SYNDROMES

HISTOLOGIC SUBTYPE	PERCENT	MAJOR GENETIC/ MOLECULAR DEFECTS	OTHER GENETIC/MOLECULAR DEFECTS	ASSOCIATED SYNDROMES
Conventional clear cell	75	LOH 3p Mutation of 3p25 (VHL)	+5q, −8p, −9p, −14q *TP53* mutation, *c-erB-1* oncogene expression	Von Hippel-Lindau Hereditary RCC
Papillary 1	5	*C-Met* gene mutation 7q31	Trisomy 7, −4q, −6q, −9p, −13q, +12, +16, +20	Hereditary papillary renal cell carcinoma (HPRCC)
Papillary 2	10	Fumarate hydratase 1q42	−9p, −11q, −14q, −17p, −21q *PRCC-TFE3* gene fusion	Hereditary leiomyomatosis renal cell carcinoma (HLRCC)
Chromophobe	5	Birt-Hogg Dubé 17p11	−1p, −2p, −6p, −13q, −21q, −Y *TP53* mutation	Birt-Hogg Dubé
Oncocytoma	9.7	Birt-Hogg Dubé 17p11	−1, −Y, 11q Rearrangement	Familial oncocytoma Birt-Hogg Dubé
Collecting duct	0.4	−18, −Y	−1q, −6p, −8p, −11, −13q, −21q *c-erB-1* oncogene expression	Renal medullary carcinoma

Modified from Zambrano N, Histopathology and molecular genetics of renal tumors. *J Urol.* 1999;162:1246-1258.

and lowest in Asians and Pacific Islanders. The mean age at diagnosis is in the sixth to seventh decade of life. Aside from genetic predisposition, risk factors associated with renal cell carcinoma include cigarette smoking, obesity, hypertension, and the use of diuretics. Cigarette smoking has been associated with greater risk in both men and women. The risk may decrease after smoking cessation but requires about 20 years. Obese persons have an increased risk for renal cell carcinoma, and the risk rises with increasing body mass index. Although there is an elevated risk associated with diuretic use, this association is hard to distinguish from the increased risk associated with hypertension. Renal cell carcinoma is more prevalent in patients with preexisting renal conditions such as polycystic kidney disease, horseshoe kidney, and chronic renal failure requiring hemodialysis.

PATHOBIOLOGY

The classification system for renal cell carcinomas permits a better understanding of the cell of origin for the various subtypes and their chromosomal abnormalities (Table 197-2). The classic clear cell carcinoma constitutes approximately 65% of tumors and is believed to be derived from the proximal convoluted tubule. It is generally solitary and well circumscribed, with a golden yellow color resulting from the abundant cytoplasmic lipid. Higher grade tumors contain less lipid and glycogen. Approximately half of the tumors exhibit either a solid or acinar growth pattern characterized by solid sheets of tumor cells accompanied by a rich capillary vascular network. Papillary renal cell carcinomas comprise from 7 to 14% of primary epithelial renal neoplasms. The majority of patients present with unilateral tumors. Multifocality, either bilateral or multifocal lesions in the same kidney, is present in approximately 45% of cases. The majority of these tumors exhibit a broad morphologic spectrum, including papillary, papillary-trabecular, and papillary-solid areas; associated necrosis is a common finding. The classic papillary pattern is characterized by discrete papillary fronds lined by neoplastic epithelial cells and containing a central fibrovascular core, easily recognized on low magnification. These tumors are divided into type 1 and type 2 lesions, based on cytologic features and genetic differences. Chromophobe renal cancers account for 6 to 11% of renal epithelial tumors. Characteristically, these tumors are solitary and discrete but not encapsulated. The typical histologic findings consist of large round-to-polygonal cells with well-defined cell borders and pale basophilic cytoplasm admixed with a smaller population of polygonal cells with eosinophilic cytoplasm. These tumors may be quite large at diagnosis, with resectable tumors reported as big as 23 cm.

Clear cell carcinoma is characterized by the loss of genetic material from the short arm of chromosome 3 (3p) and mutations in the von Hippel-Lindau *(VHL)* gene. In patients with von Hippel-Lindau (VHL) disease, these losses and mutations occur in virtually all cases. The more common sporadic tumors also have somatic mutations and hypermethylation in the same region in approximately 75 to 80% of cases. Conventional clear cell tumors have a mutation in the VHL gene, which is inactivated by a point mutation or by epigenetic gene silencing by promoter methylation. The loss of *VHL*, responsible for ubiquination and degradation of hypoxia-inducible factor (HIF), leads to upregulation of HIF-responsive genes responsible for angiogenesis and cell growth. Two of these upregulated genes are platelet derived growth factor (PDGF) and vascular endothelial growth factor (VEGF), which are pro-angiogenic proteins thought to induce the neovascularity in both primary and metastatic clear cell cancers. Patients with VHL more commonly develop tumors at an earlier age and frequently have multiple tumors. Other tumors associated with the syndrome include central nervous system hemangioblastomas, pancreatic neuroendocrine tumors, pheochromocytomas, retinal angiomas, and epididymal cystadenomas. More recent molecular characterization of renal cell carcinoma shows alterations in genes responsible for maintenance of chromatin states such as *PBRM1,* the SWI/SNF chromatin remodeling complex including *ARID1A* and *SMARCA4,* and members of the PI3K/AKT pathway.[3]

The majority of sporadic papillary renal cell carcinomas are characterized by trisomy of chromosomes 7 and 17 and loss of chromosome Y. Chromophobe renal cell cancers have genetic loss on chromosomes 1 and Y, as well as combined chromosomal losses affecting chromosomes 1, 6, 10, 13, 17, and 21. Hereditary papillary renal cell cancer is a result of germline mutations and activation of the *MET* proto-oncogene, which is located on chromosome 7p. These cells have aberrant hepatocyte growth factor receptors that are unable to deactivate after binding by the growth factor. Somatic *MET* gene amplifications also have been observed in approximately 10% of sporadic papillary renal cancer. Hereditary leiomyomatosis renal cell carcinoma, characterized by alteration of the gene fumarate hydratase, is associated with uterine leiomyomas (more common) or leiomyosarcoma (rare), cutaneous nodules (leiomyomas), and type 2 papillary renal cell carcinoma, which is often solitary and frequently develops metastases. Birt-Hogg Dubé syndrome is a rare disorder predominantly associated with chromophobe renal cancers but in which clear cell and chromophobe/oncocytic tumors can develop. Birt-Hogg-Dubé syndrome is characterized by fibrofolliculomas, pulmonary cysts, pneumothorax, and bilateral renal tumors. The gene associated with Birt-Hogg Dubé syndrome has been mapped to 17p and expresses a novel protein, folliculin, whose function is not yet characterized.

CLINICAL MANIFESTATIONS

Although renal cell carcinoma has a high propensity for metastases and is associated with paraneoplastic syndromes, the majority of patients are asymptomatic at presentation. Historically, renal cell carcinoma was characterized by the presenting triad of hematuria, a palpable mass, and pain in as many as 10% of patients. However, there has been a stage migration resulting in the detection of tumors at earlier stages with the increased use of abdominal imaging for unrelated medical conditions in modern series. Up to 48% of tumors may be discovered in this manner, and less than 5% of patients have a palpable mass at presentation. The more common manifesting symptoms are anemia, weight loss, malaise, and anorexia (Table 197-3). Patients presenting with renal cell carcinoma frequently have associated paraneoplastic syndromes. Hypercalcemia has been observed in approximately 20% of patients and can be due to the secretion of parathyroid hormone, parathyroid hormone–like peptide, and interleukin-6 (IL-6), which have been shown to stimulate osteoclastic bone resorption. Other associated syndromes include hypertension, erythrocytosis (from ectopic erythropoietin production), and the rare Stauffer's syndrome, which is the presence of liver dysfunction without the presence of hepatic metastases; the hepatic dysfunction resolves after surgical resection of the tumor.

TABLE 197-3 PRESENTING SYMPTOMS AND SIGNS OF RENAL CELL CARCINOMA (BOTH LOCALIZED AND METASTATIC DISEASE)

DIAGNOSIS

The complete evaluation for patients with suspected renal cell carcinoma should include a complete blood count, a chemistry profile, a bone scan, and a CT scan of the chest, abdomen, and pelvis. CT is the most reliable method for detecting and staging of renal cell carcinoma. The "ideal" CT scan for renal masses can be divided into four phases, including the pre-contrast images, the arterial phase (~25 seconds after injection), the nephrographic phase (~90 seconds into the injection), and the excretory phase. The most important phases for imaging renal tumors are the pre-contrast and nephrographic images because renal lesions appear low in density in contrast to the uniformly enhanced renal parenchyma. The arterial phase is helpful for identifying renal arteries and small hypervascular masses. The excretory phase aids in assessing the collecting system and the renal pelvis. The CT scan is also helpful in detecting regional metastases, and three dimensional CT imaging is now possible in cases in which nephron-sparing surgery or partial nephrectomy is planned. The additional use of ultrasonography and MRI can help distinguish benign from malignant lesions of the kidney and in treatment planning. Ultrasound is used when distinguishing cysts from solid lesions. MRI has the advantage of imaging tumors in patients with poor renal function in whom intravenous contrast may be contraindicated. MRI is also helpful for delineating any thrombi that may be extending into the renal vein or inferior vena cava, and magnetic resonance angiography can be used to determine the number and location of renal arteries in patients who are candidates for partial nephrectomy. Once the evaluation is complete, the clinical stage is assessed using the (Tumor, Node, Metastasis (TNM) system (Table 197-4).

TABLE 197-4 TNM STAGING OF RENAL CELL CARCINOMA

TUMOR, NODES, AND METASTASES CLINICAL CLASSIFICATION	
Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less in greatest dimension, limited to the kidney
T1a	Tumor 4.0 cm or less in greatest dimension limited to kidney
T1b	Tumor more than 4 cm but not more than 7 cm in greatest dimension; limited to kidney
T2	Tumor more than 7 cm in greatest dimension, limited to kidney
T2a	Tumor more than 7 cm but less than or equal to 10 cm in greatest dimension, limited to the kidney
T2b	Tumor more than 10 cm, limited to the kidney
T3	Tumor extends into major veins or the perinephric tissues but into the ipsilateral adrenal gland and not beyond Gerota's fascia
T3a	Tumor grossly extends into renal vein(or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into vena cava above diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)
N—Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
M—Distant Metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

TREATMENT

Rx

Localized Disease

The historical standard of care for patients with a renal cell carcinoma is a radical nephrectomy. Kidney cancers routinely selected for radical nephrectomy include large and centrally localized tumors that have effectively replaced the majority of the normal renal parenchyma, tumors associated with regional adenopathy (of benign or malignant etiology), those with inferior vena cava or right atrial extension, and even those in which metastatic disease is evident. Nephrectomy can be performed through a flank, transperitoneal, or transthoracic incision. The ipsilateral adrenal gland is also removed, but a regional lymph node dissection is optional and controversial. The increasing percentage of small tumors has resulted in a corresponding decrease in patients undergoing radical nephrectomy with excellent long-term survival.[4] Both open and laparoscopic approaches can be used for partial nephrectomy to control disease and preserve renal function. Laparoscopic nephrectomy offers a minimally invasive alternative to the classic radical nephrectomy. Partial nephrectomy for tumors of 7 cm or less, whether performed by open or minimally invasive laparoscopic technique, accomplishes rates of local tumor control and survival similar to radical nephrectomy. Partial nephrectomy reduces the risk for renal insufficiency over time.[5] Management with a partial nephrectomy is further supported by the fact that approximately 35% of renal cortical tumors are the indolent papillary or chromophobe carcinomas.

Renal cell carcinomas are resistant to both radiation therapy and cytotoxic chemotherapy; hence, those modalities of treatment have no role in the adjuvant setting after nephrectomy. Immunotherapy agents and approved drugs targeting VEGF or mammalian target of rapamycin (mTOR), beneficial in metastatic disease, have not been shown to affect survival favorably after nephrectomy.

Metastatic Disease

Approximately 30% of patients with renal cell carcinoma present with metastatic disease, and an additional 20 to 30% of patients with surgically resected primary tumors will relapse with metastases. Complications of metastatic disease include pain from either an unresectable primary tumor or skeletal metastases. Radiation therapy is frequently used for palliation of bone

metastases and for patients with multiple brain metastases. Palliative nephrectomy is sometimes used to provide symptomatic relief of pain. Surgical resection of the primary tumor is considered a mainstay of treatment even in the patient with metastatic disease and has been shown to extend survival in patients with metastatic disease. Surgical resection of metastatic sites of disease (metastasectomy) may also extend survival and even cure a subset of patients. The patients most likely to benefit from surgical resection of metastatic disease are those with a disease-free interval of greater than 1 year, those with a solitary site of metastasis, and those with lung metastases. Long-term survival has been observed when the solitary site of resection was the lung (up to 45%) and even the brain (up to 20%). Renal cell carcinoma is resistant to most conventional chemotherapy agents, with responses seen in less than 10% of patients.

Immunotherapy with either IL-2 or interferon-α (IFN-α) has been the historical standard treatment for patients with metastatic disease. High-dose intravenous IL-2, a potentially curative therapy, requires a dedicated inpatient setting because of its severe toxicities, including hypotension, pulmonary edema, renal failure, and central nervous system toxicity. However, most toxicities are reversible and complete or partial responses are seen in approximately 15 to 20% of patients; approximately 4% of patients achieve long-term, disease-free survival.[6] IFN-α therapy is less toxic than IL-2 and has an overall response rate of approximately 15%, but long-term survival is not observed. Reversible toxicities of IFN-α treatment include flulike symptoms, including fever, chills, myalgias, mild myelosuppression, and mild hepatic dysfunction.

Renal cell carcinoma has been an ideal candidate for the development of drugs targeting the downstream effects of *VHL* mutations.[7] Clinical trials have shown the benefit of tyrosine kinase inhibitors (TKIs), such as sunitinib,■ axitinib,■ pazopanib,■ and sorafenib,■ which block the actions of VEGF and PDGF; all are approved for the treatment of metastatic disease. Common side effects include fatigue, diarrhea, hypertension, and hand-foot syndrome, a condition in which blisters appear at areas of contact. The combination of IFN plus bevacizumab, an antibody that blocks the VEGF receptor, is superior to IFN alone and also has been approved for first-line treatment.■ Side effects include hypertension and an increased risk for bleeding. Two drugs targeting the mTOR pathway are also approved for the treatment of renal cell carcinoma both as first-line treatment and for patients whose disease has progressed despite TKI treatment. Temsirolimus, an intravenous mTOR inhibitor, improves survival of patients with untreated poor risk disease (those with more than three risk factors, see later).■ Everolimus, an oral mTOR inhibitor, improves the outcomes of patients who have been previously treated with sunitinib, sorafenib, or bevacizumab.■ Common side effects include fatigue, skin rash, and mouth sores.

PROGNOSIS

Progression-free survival and overall survival rates for resected nonmetastatic renal cortical tumors substantially differ according to multiple factors including age, size, grade and pathologic state (Figure 197-1, and also E-Figures 197-1, 197-2, and 197-3). The prognosis declines considerably for patients with more advanced disease, with long-term survival seen in only 20% of stage III patients and 5% or less in stage IV patients. Of the more common histologic subtypes of renal cell carcinoma, the prognosis of clear cell carcinoma is less favorable than that of papillary renal cell carcinoma; chromophobe renal cell carcinoma is the most favorable. For patients with metastatic disease, five clinical features associated with shorter survival are low performance status, high lactate dehydrogenase, low hemoglobin, high calcium, and absence of prior nephrectomy. Three strata groups have been defined using survival data from patients treated with immunotherapy: (1) favorable (zero risk factors) with a median survival of 20 months; (2) intermediate (1 or 2 risk factors), with a median survival of 10 months; and (3) poor (three or more risk factors) with a median survival of 4 months. IL-2 immunotherapy and surgical resection of solitary metastases can result in long-term survival of a small percentage of patients with renal cell cancer. Drugs targeting VEGF and the mTOR pathway are now the standard of care for patients with metastatic disease.

BLADDER CANCER

DEFINITION

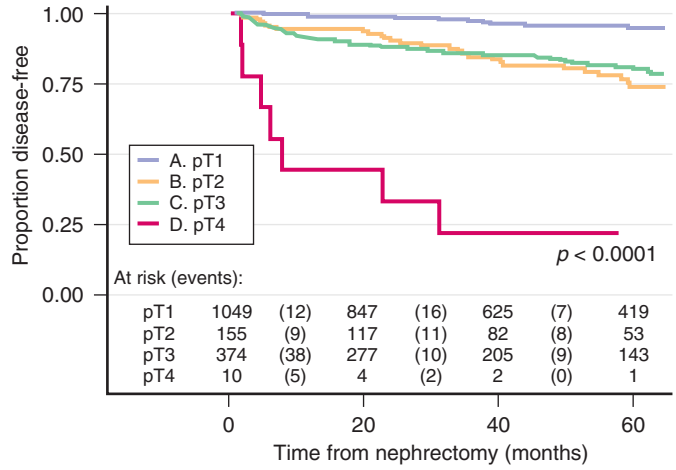
A spectrum of tumors arise from the urothelial lining of the bladder, renal pelvis, ureters, and urethra, of which transitional cell carcinoma is the most common. The vast majority of tumors arise from the bladder, with a minority arising from the upper tracts (renal pelvis and ureters) and even less frequently from the proximal urethra. Although transitional cell cancers possess a variable natural history, they have a proclivity for multifocality, high recurrence rates, and progression to higher pathologic stages. These tumors are generally grouped into the three broad categories of non–muscle invasive, muscle-invasive, and metastatic disease, each of which differs in clinical behavior, prognosis, and primary management. For non–muscle invasive tumors, the aim is to prevent recurrences and progression to a more advanced stage. In muscle-invasive disease, the medical challenge is to integrate the modalities of surgery, chemotherapy, and/or radiation to optimize cure and minimize morbidity. For metastatic disease, chemotherapy is used to palliate the symptoms of most patients, but there is a subset of patients in which combination chemotherapy may result in long-term cure. Long-term cure is directly related to stage and grade, ranging from 99% for low-grade Ta tumors to up to 15% for metastatic disease.

EPIDEMIOLOGY

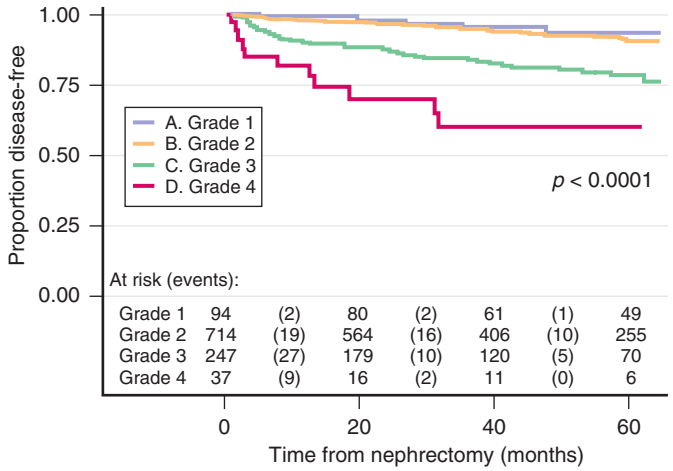
An estimated 74,000 new cases of bladder cancer will be diagnosed in the United States in 2014, of which approximately 15,000 patients are expected to succumb to their disease. The ratio of males to females is 3 : 1, similar in all racial groups; it is the fourth most common cancer in men. The 5-year survival for all stages is 78%, resulting in a high prevalence (>500,000 people in the United States living with bladder cancer); it is twice as prevalent in whites as in African Americans and is less frequently observed in Asians. The vast majority of patients (90%) are over 50 years of age at diagnosis, with a median age of 73 at diagnosis. There is a lifetime risk of 2.4% of men and women developing bladder cancer.

Carcinogens or their metabolites implicated in the carcinogenesis of bladder cancer are believed to be excreted in the urine, where they can act directly on the urothelial lining. The latency period from initial exposure to the development of cancer is almost 20 years, making it difficult to establish a definitive cause and effect relationship between a putative carcinogen and the development of disease. Cigarette smoking is the leading risk factor for bladder cancer, believed to contribute to half of the cancers in men and one quarter of the cancers in women. A longer duration of exposure is associated with a higher risk than a more intense exposure (in cigarettes/day) over a shorter time period. Overall, smokers have a two- to four-fold higher relative risk for bladder cancer than nonsmokers. Smoking is associated with cellular atypia of the urothelium; individuals who never smoked show atypia in only 4% of cases in contrast to a 50% incidence of atypia in smokers.

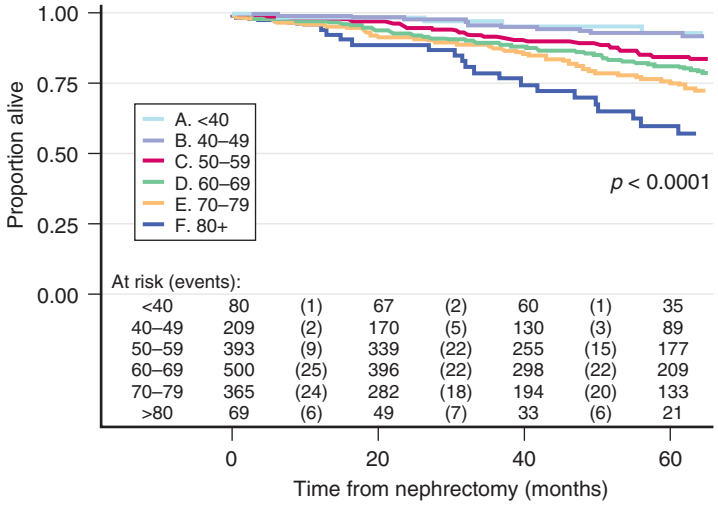
Polycyclic aromatic hydrocarbons such as 2-naphthylamine, 4-aminobiphenyl and benzidine, and benzene or exhausts from combustion gases are associated with an increased risk for bladder cancer. Occupations reported to be at higher risk include aluminum workers, dry cleaners, manufacturers of preservatives and polychlorinated biphenyls, and pesticide applicators. Arylamines, also implicated in carcinogenesis, are metabolically activated to electrophilic compounds by N-hydroxylation in the liver by cytochrome P-450 IA2 and detoxified by N-acetylation; studies suggest that individuals with a fast oxidizer and slow acetylator phenotype are at highest risk.



E-FIGURE 197-1. Progression-free survival according to pathologic tumor (pT) classification. Curve A indicates pT1 tumors; curve B, pT2 tumors; curve C, pT3 tumors; curve D, pT4 tumors. (The "pT" categories correspond to the "T" categories in TNM staging categories shown in Table 197-4.) (From Russo P, Jang TL, Pettus JA, et al. Survival rates after resection for localized kidney cancer: 1989-2004. *Cancer* 2008;113:84-96.)



E-FIGURE 197-2. Progression-free survival according tumor grade. Curve A indicates grade 1; curve B, grade 2; curve C, grade 3; curve D, grade 4.) (From Russo P, Jang TL, Pettus JA, et al. Survival rates after resection for localized kidney cancer: 1989-2004. *Cancer* 2008;113:84-96.)



E-FIGURE 197-3. Overall survival according to patient age. Curve A indicates <40 years; curve B, ages 40 to 49 years; curve C, ages 50-50 years; curve D, ages 60-69 years; curve E, ages 70-79 years; curve F, ages ≥ 80 years. (From Russo P, Jang TL, Pettus JA, et al. Survival rates after resection for localized kidney cancer: 1989-2004. *Cancer* 2008; 113:84-96.)

Occupations associated with a higher exposure to arylamines such as workers in the dye, rubber, or leather manufacturing industries are believed to be at higher risk for developing bladder cancer. *Schistosoma haematobium* infection enhances formation of carcinogenic N-nitroso compounds and results in an increased risk for both squamous and transitional cell carcinomas of the bladder. An association has been observed between squamous cell carcinoma (but not transitional cell tumors) and the presence of chronic urinary tract infections seen in paraplegics and patients with chronic bladder stones and indwelling Foley catheters. The chemotherapy agent cyclophosphamide can increase the risk for bladder cancer nine-fold when used chronically, and phenacetin-containing compounds have been implicated in the development of renal pelvis and ureteral tumors.

PATHOBIOLOGY

Urothelial tumors occur anywhere along the urinary tract, including the renal pelvis, ureters, bladder, and the urethra. Over 90% of tumors originate in the bladder, 8% in the renal pelvis, and the remaining 2% originate in the ureter and urethra. Transitional cell carcinomas comprise 90 to 95% of urothelial tumors; squamous cell (keratinizing) tumors (3%), adenocarcinomas (2%), and small cell tumors (1%) are the remainder. Mixed-histology tumors, consisting of predominantly transitional cell carcinoma with areas of squamous, adenocarcinomatous, or neuroendocrine elements are frequently observed. Squamous cell tumors are more frequent in the distal urethra, and adenocarcinomas occur in the embryonal remnant of the urachus on the dome of the bladder and in periurethral tissues. In endemic areas of *S. haematobium* infections (such as Egypt), 40% of tumors are squamous cell carcinomas. Rare tumors of the bladder include lymphoma, sarcoma, and melanoma.

The majority (70-80%) of newly detected bladder cancers are classified as non–muscle invasive tumors and include exophytic papillary tumors confined to the mucosa (Ta), tumors invading the lamina propria (T1), and carcinoma in situ (CIS). Non–muscle invasive bladder tumors are typically graded according to the World Health Organization/International Society of Urologic Pathology (WHO/ISUP) grading system as low-grade and high-grade. If the grading system is not specified, a numeric system can be used: well differentiated (G1), moderately differentiated (G2), poorly differentiated (G3), and undifferentiated (G4). Grading is more important for noninvasive Ta tumors because almost all invasive bladder tumors (T1 or greater) are high grade. Primary CIS, or Tis, without a concurrent Ta or T1 tumor, constitutes 1 to 2% of new bladder cancer cases. More frequently, Tis is found in the presence of multiple papillary tumors, either immediately adjacent to another lesion or involving remote mucosa in the bladder. Tis is, by definition, high-grade disease; it is regarded as a precursor to more invasive tumors because 60% of untreated tumors develop more invasive disease within 5 years. T1 tumors are an aggressive, invasive malignancy. Virtually all T1 tumors are high grade, and 50% have associated Tis. Disease in 50% of patients recurs by 1 year and in 90% within 5 years. A minority of primary tumors at diagnosis is found to invade the muscularis propria (T2), extend to perivesicular fat (T3), or extend into immediately adjacent organs (T4); all primary tumors stage T2 or higher are high grade.

The natural history of a urothelial tumor is to recur either at the same location or at a separate site in the urothelial tract and at the same or a more advanced stage. Several studies support the controversial concept that these recurrences are clonal in origin. The epidermal growth factor receptor (EGFR) is highly expressed (~80%) in bladder cancers; the Her2/Neu growth factor receptor is less frequently expressed (~50-70%). Studies suggest that higher expression of these receptors is associated with a more advanced and/or more aggressive phenotype of disease. Bladder cancer has a very high somatic mutation rate (7.7 per megabase) compared to that of other cancers, exceeded only by lung cancer and melanoma.[8] Epigenetic modifying genes *MLL2, ARID1A, KDM6A,* and *EP300* are significantly mutated in bladder cancer; approximately 75% have at least one inactivating mutation. Genes that regulate the cell cycle are also frequently mutated, including *TP53* in 49% and *RB1* in 13% of tumors. Amplifications of *ERBB2, MDM2,* and *EGFR* occur in a minority of tumors and represent potential therapeutic targets.

CLINICAL MANIFESTATIONS

Hematuria is the manifesting symptom in 80 to 90% of bladder cancer cases, but other patients may present with a urinary tract infection. Individuals over 40 years of age who develop hematuria should have an evaluation for the presence of urothelial cancer that includes urinary cytology, cystoscopy, and imaging of the urinary tract by either an ultrasound or CT scan. Screening of asymptomatic individuals for hematuria increases the probability of diagnosing bladder cancer at an earlier stage but does not improve survival; thus, it is not routinely recommended. Urinary frequency and nocturia may be present either as a consequence of irritative symptoms or a reduced bladder capacity. Pain, when present, typically reflects the location of the bladder tumor. Lower abdominal pain may occur as a result of a bladder mass, and rectal discomfort and perineal pain can result from tumors invading the prostate or pelvis. Tumors of the renal pelvis, ureter, or bladder in which the ureteral orifice is obstructed can cause hydronephrosis, reduced renal function, and flank pain. Patients with more advanced disease can present with anorexia, fatigue, weight loss, or pain from a metastatic bone lesion. The physical examination is frequently unremarkable in patients presenting with bladder tumors because the vast majority of patients have organ-confined tumors.

DIAGNOSIS

The mainstay of bladder cancer diagnosis and staging is the cystoscopic evaluation. The procedure includes examination under anesthesia to determine if a palpable mass (either mobile or not) is present. A nonmobile tumor mass is indicative of disease invading the pelvic sidewall that is unlikely to be resectable. Urine is obtained to evaluate for the presence of malignant cells. A cystoscope is inserted to visually inspect the bladder and detail the size, number, location, and growth pattern (papillary or solid) of all lesions. All visible disease undergoes transurethral resection of the bladder tumor to determine the histologic subtype and depth of invasion. Adequate evaluation, particularly in large tumors that may be invasive, requires that muscle is identified in the pathologic specimen. Repeat biopsy of the resected area is occasionally required to ensure that no muscle invasion is present, because invasion into muscle requires consideration of surgical removal of the bladder rather than endoscopic resection of the tumor. Biopsies from any areas of erythema are performed to assess for CIS. The urethra is inspected during withdrawal of the cystoscope, and biopsies are taken if clinically indicated. Patients with a positive cytologic findings but no apparent tumor within the bladder undergo selective retrograde catheterization of the ureters up to the renal pelvices to determine whether upper tract disease is present.

The decision whether to obtain images of the abdomen and pelvis is based on the cystoscopy results and the pathology of the tumor. Either a CT or magnetic resonance urogram can evaluate the upper urinary tracts, and a CT or MRI may distinguish whether a tumor extends to the perivesical fat (T3), prostate, or vagina (T4) and whether regional lymph nodes are involved (N+). In the case of larger, invasive tumors, the presence or absence of distal metastases can be documented with physical examination, CT of the abdomen and pelvis, a chest radiograph, and radionuclide bone scan.

All patients with carcinoma of the bladder or related sites are staged using the TNM system, advocated by the American Joint Committee on Cancer (AJCC) (Table 197-5). The TNM system categorizes the depth of invasion of the primary tumor, nodal metastases in the pelvis (or retroperitoneum for upper tract disease) on the basis of the number and size of regional nodal involvement, other nonregional lymph node sites, and any visceral sites of disease.

TREATMENT

Non–Muscle Invasive Disease

The standard treatment for non–muscle invasive tumors is a complete endoscopic resection. The majority of patients develop new tumors, 30% of which progress to a higher stage, mandating vigilant surveillance at 3-month intervals with cystoscopy, urine cytology, and repeat transurethral resection when indicated. Additional treatment in the form of adjuvant intravesical therapy depends on the number of lesions, the size, the depth of invasion, and the number of prior tumors in that individual. Prophylactic or adjuvant intravesical therapy is typically instituted in the setting when a patient has shown either a repeated tendency to develop new lesions in the bladder or is at high risk for recurrence or progression de novo. Intravesical therapy is not warranted for the first Ta tumor that is low grade. Instances of high recurrence and progression warranting intravesical therapy include multifocal or large lesions, high-grade papillary lesions, T1 tumors, CIS, or a combination of these. It is never advised for muscle-invasive tumors because agents instilled in the bladder do not penetrate beyond a few layers of cells. After allowing sufficient time for healing after the endoscopic resection, intravesical therapy is most frequently initiated with the immunologic agent bacillus Calmette-Guérin (BCG) weekly for 6 weeks, followed by a prolonged maintenance

TABLE 197-5 TNM DEFINITIONS FOR CANCERS OF THE BLADDER, URETER AND RENAL PELVIS

PRIMARY TUMORS OF THE BLADDER (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ (i.e., flat tumor)
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis propria
pT2a	Tumor invades non-muscle invasive muscularis propria (inner half)
pT2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumor invades the prostatic stroma, uterus, vagina
T4b	Tumor invades the pelvic wall, abdominal wall
REGIONAL LYMPH NODES FOR UROTHELIAL TUMORS OF THE BLADDER (N)	
NX	Regional lymph nodes cannot be assessed
N0	No lymph node metastasis
N1	Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral node)
N2	Multiple regional lymph node metastases in the true pelvis (hypogastric, obturator, external iliac, or presacral node)
N3	Lymph node metastasis to the common iliac lymph nodes
PRIMARY TUMORS OF THE URETER AND RENAL PELVIS (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma *in situ*
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades the muscularis
T3	(For renal pelvis only) Tumor invades beyond muscularis into peripelvic fat or the renal parenchyma
T3	(For ureter only) Tumor invades beyond muscularis into periureteric fat
T4	Tumor invades adjacent organs or through the kidney into perinephric fat

REGIONAL LYMPH NODES FOR UROTHELIAL TUMORS(N) OF URETER AND RENAL PELVIS	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, ≤2 cm in greatest dimension
N2	Metastasis in a single lymph node, >2 cm but ≤5 cm in greatest dimension; or multiple lymph nodes, ≤5 cm in greatest dimension
N3	Metastasis in a lymph node, >5 cm in greatest dimension
DISTANT METASTASIS FOR ALL UROTHELIAL TUMORS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

schedule.[9] Occasionally, other chemotherapeutic agents or cytokines are used when BCG is contraindicated. Treatment outcome is assessed at the 3- and 6-month evaluations following treatment to determine whether the bladder has been rendered tumor-free. If disease persists, either a repeat course of BCG treatment or even an immediate cystectomy may be recommended. Bladder toxicity caused by urothelial irritation can occur and includes bladder irritability or spasms, hematuria, and pain on urination. A rare complication of BCG is development of a systemic tuberculosis infection requiring treatment with systemic antituberculosis agents (Chapter 324). BCG is highly effective in eradicating Tis, with 70% of patients disease-free at 1 year and 40% at 10 years. Selected tumors in the ureter or renal pelvis can be managed by ureteroscopic resection, in some cases by instillation of BCG through the renal pelvis, or nephroureterectomy. Tumors of the prostatic urethra are frequently managed by cystoprostatectomy, particularly if a complete resection cannot be accomplished.

Muscle-Invasive Tumors

For patients with tumors infiltrating the muscularis propria, the standard of care in the United States is a radical cystectomy and pelvic lymphadenectomy because of the high incidence of cancer extending into the perivesicular fat or into regional lymph nodes. A prostatectomy is also performed in men; in women, the urethra, uterus, fallopian tubes, ovaries, and anterior vaginal wall are removed. Urinary flow can be directed through either a conduit diversion or a continent reservoir. With a conduit diversion, urine is drained directly from the ureters to a loop of small bowel that is anastomosed to the skin surface with no internal reservoir. Urine is collected in an external appliance. Alternatively, a low-pressure continent reservoir can be created from a detubularized segment of bowel attached to the abdominal wall with a continent stoma that can be self-catheterized at regular intervals. Low-pressure reservoirs also can be anastomosed to the urethra, creating an internal orthotopic neobladder that permits the patient to void via the normal urethra. The standard pelvic lymphadenectomy includes the distal common iliac, external iliac, obturator, and hypogastric nodes; improved survival and decreased local recurrence are associated with an increased number of lymph nodes removed. Complications of cystectomy include recurrent urinary infections, hyperchloremic acidosis, oxalate stones, incontinence, and impotence. Perioperative chemotherapy in addition to surgery is a standard of care for patients with muscle-invasive bladder cancer.[10] Neoadjuvant chemotherapy before cystectomy for muscle-invasive bladder cancer increases survival.[■] This survival benefit is achieved only with cisplatin-based combinations, which require that the patient has normal renal function and a good performance status. Some physicians prefer immediate cystectomy followed by adjuvant chemotherapy for tumors with a high risk for relapse. However, no evidence from prospective, randomized trials exists to support this approach in contrast to a proved survival benefit from neoadjuvant chemotherapy. Radical cystectomy is effective at providing long-term disease control in 75 to 80% of patients with organ-confined

disease; approximately 50% of those with tumors extending into the perivesical tissues; and up to a third of patients with regional lymph node involvement. Metastatic disease in the pelvic lymph nodes despite a normal preoperative CT scan is very frequent. Bilateral pelvic lymph node dissection in addition to cystectomy improves survival.[11] Some patients prefer a nonsurgical, bladder-sparing approach using radiation treatment rather than a cystectomy. Radiation with chemotherapy sensitization is preferred over radiation alone because of better tumor control. The best candidates for this approach are patients with a solitary early-stage lesion and no evidence of hydronephrosis. This tri-modality treatment for bladder preservation first requires a successful, near-complete transurethral resection of tumor followed by concurrent chemotherapy and radiation. External beam treatments are typically delivered in five daily fractions per week, ranging from 2.0 to 2.5 Gy, to a total treatment dose of approximately 65 Gy. Toxicities include inflammation of the skin, impotence, fatigue, and irritative symptoms from the bladder and bowel; persistent proctitis is rare. In this approach, cystectomy is reserved for patients whose disease failed to achieve complete response. The 5-year disease-free survival with this approach is 50%, with the majority of patients retaining a normally functioning bladder.

Metastatic Disease

Patients with metastatic disease are treated predominantly with chemotherapy. Cisplatin-based chemotherapy is the standard of care, and the two most commonly used regimens are gemcitabine plus cisplatin (GC) and the four-drug regimen of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC); six cycles of therapy are given over a 6-month period. The most frequently observed toxicities include anemia, thrombocytopenia, neutropenic fever, mucositis, and fatigue. The GC regimen is better tolerated and has less severe toxicities than MVAC. The median survival of patients treated with both regimens is approximately 14 months, and the 5-year survival is 15% or less. Patients with a good performance status and whose metastatic disease is limited to the lymph nodes (i.e., no visceral metastases) have the highest likelihood of response, and a 20 to 33% chance of 5-year disease-free survival.[12] The addition of paclitaxel to the GC doublet has not improved survival for all patients with metastatic bladder cancer but can be integrated with post-chemotherapy surgery in patients with local-regional metastases resulting in long-term cure.[13] Based on the high vascularity of bladder cancer and prior studies suggesting the benefit of bevacizumab which blocks the effects of VEGF, a national intergroup randomized trial is comparing the GC doublet plus either bevacizumab or placebo.[14] Multiple medical conditions preclude the use of cisplatin-based chemotherapy.[15] Patients with impaired renal function are treated with carboplatin-based therapy rather than cisplatin because it is less toxic to the kidneys. Carboplatin plus gemcitabine is the standard of care in patients ineligible for cisplatin.

PROGNOSIS

Cancer of the urinary bladder is a common but heterogeneous disease. Non–muscle invasive TaG1 lesions, easily treated with endoscopic resection alone, almost never progress. At the other end of the spectrum of non–muscle invasive disease, aggressive transitional cell carcinoma in situ requires intravesical immunotherapy with BCG in addition to endoscopic resection. This intravesical treatment can substantially reduce recurrence and progression, with 5-year disease-free survival rates of 60%. Muscle-invasive disease is most frequently cured with an integrated approach of systemic chemotherapy for micrometastases followed by cystectomy and pelvic lymphadenectomy; cure rates for T2 tumors can be as high as 80% with this multimodality approach. Bladder-sparing approaches associated with an improved quality of life are possible using external beam radiation. Metastatic urinary bladder cancer is a fast-growing and often lethal malignancy; despite aggressive chemotherapy only a small proportion (~15%) of patients are disease-free at 5 years.

CANCERS OF THE RENAL PELVIS AND URETERS

Approximately 10% of transitional cell carcinomas occur in the ureters and the renal pelvis. These tumors can arise either de novo or in the setting of prior tumors; the risk for developing an upper tract tumor in patients with multifocal carcinoma in situ of the bladder approaches 25% by 10 years. These tumors are morphologically similar to the tumors in the bladder and behave in a similar manner. Hematuria is the most common manifesting symptom, although patients with large tumors and/or ureteral obstruction can present with flank pain. A CT scan or MRI is used to stage the extent of primary disease and detect regional metastases. Low-grade tumors can be treated endoscopically, but high-grade tumors are most commonly treated with a nephroureterectomy. In contrast to cystectomy, a regional lymphadenectomy is not routinely performed. In renal pelvis tumors, the ureter is removed in addition to a nephrectomy because of the high risk for multifocal tumors along the entire upper tract and the inability to monitor the ureteral stump with accuracy. Systemic chemotherapy is used for unresectable primary tumors, patients with regional adenopathy, or recurrent tumors. Upper tract transitional cell carcinomas are staged according to the TNM system (see Table 197-5). Treatment for advanced, nonsurgical disease is with chemotherapy; these urothelial tumors have the same sensitivity to chemotherapy as bladder cancer, with similar response rates and 5-year survival rates. Cisplatin-based chemotherapy is used in patients with normal renal function, and carboplatin-based chemotherapy is considered if there is renal insufficiency from obstruction, a prior nephroureterectomy, or medical comorbidity.

REVIEW QUESTIONS

1. A patient with muscle-invasive urothelial cancer of the bladder wishes to have bladder-sparing treatment with chemotherapy plus radiation. Which of the following components is critical to the success of the therapy?

A. The radiation port includes the bladder, pelvic nodes, and a boost to the bladder.
B. Brachytherapy to the primary tumor, followed by a boost to the entire bladder.
C. Complete or near-complete transurethral resection of the bladder tumor (TURBT).
D. Adjuvant chemotherapy for three cycles of cisplatin-based chemotherapy.
E. Both A and C.

Answer: E A complete or near-complete TURBT is critical for success of this tri-modality approach (surgery, radiation, chemotherapy) to bladder-sparing treatment. Radiation is generally given to the bladder and pelvis, with a boost to the bladder cancer primary tumor.

2. A 56-year-old male patient with transitional cell carcinoma presents with carcinoma in situ involving the trigone of the bladder. The patient is treated with BCG therapy for two 6-week intervals without response. Repeat transurethral resection at 3 months shows persistent carcinoma in situ, along with new tumor invading the lamina propria but not the muscularis propria. The standard of care is:

A. Radical cystectomy with preservation of the prostate and neurovascular bundle to preserve sexual function.
B. Cystoprostatectomy and bilateral pelvic lymph node dissection.
C. Intravesical interferon or interleukin-2.
D. Systemic chemotherapy with a cisplatin-containing regimen.
E. External beam radiation with a chemotherapy radiosensitizer.

Answer: B The standard of care for refractory carcinoma in situ is cystoprostatectomy and bilateral pelvic lymph node dissection. Refractory disease is defined in this instance as progression to a greater stage within 6 months of therapy.

3. Interleukin-2 (IL-2) therapy for patients with renal cell carcinoma differs from drugs that target vascular endothelial growth factor (VEGF) in that:

A. IL-2 therapy can result in a 4% long-term cure in patients with metastatic disease.
B. IL-2 therapy has a greater response rate than VEGF inhibitors.
C. IL-2 therapy is given immediately after nephrectomy in contrast to VEGF inhibitors, which are given only for metastatic disease.
D. IL-2 can be given in patients with poor renal function.
E. IL-2 therapy is reserved for patients with brain metastases.

Answer: A The approval for IL-2 therapy by the U.S. Food and Drug Administration was, in part, based on this durability of complete responses in approximately 4% of patients, which is not seen with any other systemic treatments for metastatic renal cell carcinoma.

4. The preferred surgical management for a patient with a 7-cm renal cell carcinoma in one kidney and a simple cyst in the contralateral kidney includes:

A. Bilateral nephrectomy.
B. Open partial nephrectomy for the kidney with the 7-cm lesion.
C. Nephrectomy for the kidney with the 7-cm lesion and retroperitoneal lymph node dissection
D. Laparoscopic partial nephrectomy for the kidney with the 7-cm lesion.
E. Answers B and D.

Answer: E Partial nephrectomy to preserve renal function as much as possible is the preferred surgical management in patients with renal cell carcinoma. Simple cysts of the kidney are observed, and a retroperitoneal lymph node dissection is not the surgical standard of care for renal cell carcinoma.

5. A patient presenting with benign hair follicle tumors (fibrofolliculomas), pulmonary cysts with a history of pneumothorax in the past, and bilateral renal tumors has which of the following syndromes?

A. Hereditary papillary renal cell carcinoma (HPRCC)
B. Hereditary leiomyomatosis renal cell carcinoma (HLRCC)
C. Birt-Hogg-Dubé syndrome
D. Familial oncocytoma
E. Lynch syndrome

Answer: C Explanation: Birt-Hogg-Dubé syndrome is characterized by fibrofolliculomas, pulmonary cysts, pneumothorax, and bilateral of the renal tumors. Hereditary papillary renal cell carcinoma is associated with bilateral, multifocal tumors but not the other features. Hereditary leiomyomatosis renal cell carcinoma is associated with uterine leiomyomas (more common) or leiomyosarcoma (rare), cutaneous nodules (leiomyomas), and type 2 papillary renal cell carcinoma, which is frequently solitary and frequently develops metastases.

BREAST CANCER AND BENIGN BREAST DISORDERS

NANCY E. DAVIDSON

Invasive breast cancer, the most common nonskin cancer in women in the United States, will be diagnosed in approximately 232,000 women in 2014 and will result in approximately 40,000 deaths. Incidence and mortality from breast cancer appear to be dropping in the United States and parts of Western Europe. This decline is believed to reflect early detection by screening mammography and widespread use of adjuvant systemic therapy, as well as decreased use of hormone replacement therapy.

BREAST CANCER

EPIDEMIOLOGY AND PATHOBIOLOGY

Multiple risk factors for the development of breast cancer have been identified (Table 198-1). The principal risk factor is gender. Breast cancer is largely a disease of women, although it does occur in men at an incidence of approximately 1% that seen in women. A second critical risk factor is age. Approximately 75% of breast cancer cases in the United States are diagnosed in women older than 50 years of age.

Family history is a third critical risk factor. Approximately 20% of breast cancer occurs in women with a family history of breast cancer; increased risk

TABLE 198-1 RISK FACTORS FOR BREAST CANCER

RISK FACTOR	RELATIVE RISK
Any benign breast disease	1.5
Postmenopausal hormone replacement (estrogen with progestin)	1.5
Menarche at < 12 yr	1.1-1.9
Moderate alcohol intake (two to three drinks/day)	1.1-1.9
Menopause at > 55 yr	1.1-1.9
Increased bone density	1.1-1.9
Sedentary lifestyle and lack of exercise	1.1-1.9
Proliferative breast disease without atypia	2
Age at first birth > 30 yr or nulliparous	2-4
First-degree relative with breast cancer	2-4
Postmenopausal obesity	2-4
Upper socioeconomic class	2-4
Personal history of endometrial or ovarian cancer	2-4
Significant radiation to chest	2-4
Increased breast density on mammogram	2-4
Older age	>4
Personal history of breast cancer (in situ or invasive)	>4
Proliferative breast disease with atypia	>4
Two first-degree relatives with breast cancer	5
Atypical hyperplasia and first-degree relative with breast cancer	10

is associated with a diagnosis of breast cancer in first-degree relatives younger than 50 years. Of breast cancer cases, 5 to 8% occur in high-risk families. Several familial breast cancer syndromes with associated molecular abnormalities have been identified. Chief among them is the breast-ovarian cancer syndrome, which is linked to germline mutations in the breast cancer susceptibility genes, *BRCA1* and *BRCA2*. These mutations are inherited in an autosomal dominant fashion and can therefore be transmitted through the maternal or paternal line. Extensive studies suggest that a germline mutation in either of these genes is associated with a 50 to 85% lifetime risk for developing breast cancer. Testing for *BRCA1* and *BRCA2* mutations is now viewed as a standard option for women with clinical features suggestive of a hereditary breast cancer syndrome; these include multiple family members with early-onset breast or ovarian cancer, bilateral breast cancer, or Ashkenazi Jewish heritage. Careful counseling about the implications of a positive or negative test and about the limitations of testing is a prerequisite for testing.

Other hereditary cancer syndromes (Chapter 181) include germline loss-of-function mutations in *PALB2*,[1] the Li-Fraumeni syndrome (which is linked with germline mutations in the *p53* tumor suppressor gene), and Cowden syndrome (which is associated with inherited mutations in the *PTEN* gene). Finally, in addition to these high-penetrance genetic susceptibility syndromes, recent results from genome-wide association studies have identified a number of low-penetrance genetic associations, including single nucleotide polymorphisms in a variety of genes. If or how to incorporate these low-penetrance traits into clinical practice remains to be established. Whole-genome sequencing of breast cancers is exposing the scope of tumor diversity and helping to pinpoint avenues for precise diagnostics and targeted therapy.[2]

Reproductive risk factors include early menarche, late menopause, nulliparity, and late first pregnancy. In aggregate, these factors result in prolonged estrogen exposure of the breast. The emerging association between postmenopausal obesity and breast cancer likely reflects estrogen exposure as well. Certain types of breast pathology, including atypical hyperplasia and lobular carcinoma in situ, are also associated with increased risk. The possibility that increased breast density as assessed by mammography is a risk factor has also been raised. Finally, much interest has focused on the possibility that exogenous environmental factors predispose to breast cancer. Among the factors that appear to enhance breast cancer risk are ionizing radiation during adolescence, prolonged use of hormone replacement therapy, ongoing use of oral contraceptives, and alcohol consumption. Large studies have failed to show any convincing association between exposure to estrogenic pesticides or a high-fat diet and breast cancer.

CLINICAL MANIFESTATIONS

Breast cancer usually manifests as a mammographic abnormality or a physical change in the breast, including a mass or asymmetrical thickening, nipple discharge, or skin or nipple changes. Two unusual clinical manifestations include Paget disease of the nipple and inflammatory breast cancer. The former is a form of adenocarcinoma involving the skin and ducts and is manifested as nipple excoriation. The latter is recognized as a constellation of redness, warmth, and edema that often reflects tumor cell infiltration of dermal lymphatics of the breast; it should not be mistaken for simple mastitis.

Nipple discharge may be associated with breast malignancy. Although milky discharge is seldom associated with a malignant diagnosis, patients with a clear or bloody nipple discharge require breast examination and mammography and often excisional biopsy of any suspicious area. Ductography and sometimes ductoscopy may be used to identify the inciting lesion. A bloody discharge is frequently caused by an intraductal papilloma.

Breast pain is common, especially as a premenstrual symptom in premenopausal women. But it may also be associated with an underlying malignancy. Patients with localized noncyclic breast pain should undergo breast examination and bilateral mammography. If these are normal, ultrasound or magnetic resonance imaging (MRI) may be used to exclude the small possibility of a malignancy.

DIAGNOSIS

Diagnostic evaluation is generally triggered by suspicious findings on a screening mammogram or detection of a palpable breast abnormality by the patient or health care provider. For both clinically occult and clinically apparent lesions, pathologic evaluation is mandatory to establish a diagnosis. Today, fine-needle aspiration and core needle biopsy have replaced incisional or excisional biopsy as the standard diagnostic measures. These procedures can be performed in the office in patients with suspicious palpable lesions. For women with nonpalpable lesions, biopsy guided by mammography, ultrasonography, or MRI is now standard. Stereotactic- or ultrasound-guided core needle biopsies are almost as accurate as, and associated with lower complication rates than, open surgical biopsy. These technologies permit an accurate diagnosis that can be followed by definitive treatment planning. It is axiomatic, however, that further evaluation must be undertaken for suspicious lesions that give an equivocal diagnosis after needle aspiration or core biopsy. Finally, bilateral breast imaging is always recommended to identify any unsuspected lesions in the contralateral breast that may also require evaluation.

Staging and Prognostic and Predictive Markers

Although staging originally reflected the clinical assessment of tumor size, nodal status, and evidence of metastatic disease, pathologic staging is the most accurate estimate of tumor involvement and prognosis. The staging system for breast cancer was revised in 2010 (Tables 198-2 and 198-3).

Most patients with breast cancer present with stage I or II disease in the absence of symptoms. In these patients, laboratory studies can be limited to blood counts, chemistry panel, and chest radiograph, and more extensive radiologic evaluation is not warranted because of low yield. In contrast, women with clinical evidence of stage III or IV disease should undergo more intensive evaluation of common sites for metastases, including lung, liver, and bone, through computed tomography and radionuclide scanning.

The two most important determinants of prognosis for early-stage breast cancer are pathologic lymph node status and tumor size. Other factors that contribute to prognosis are the expression of the estrogen receptor-α (ER), progesterone receptor (PR), and HER2 proteins; these are conventionally measured by immunohistochemistry (IHC), although in situ hybridization (ISH) for *HER2* gene amplification is also employed. Poor prognosis is associated with high lymph node burden, poor histologic grade, large tumor size, absence of ER and PR expression, and overexpression of HER2.

Recently, the focus has been on the development of predictive markers to guide selection of therapy. The three established predictive markers for breast cancer are ER, PR, and HER2, and these should be routinely evaluated in every invasive cancer. Many tumors that express ER or PR, or both, are responsive to endocrine therapy, whereas those that lack ER and PR expression seldom respond to such therapy. Overexpression of the HER2 protein by IHC or *HER2* gene amplification by ISH is associated with response to the HER2-targeted therapies. Evidence that links expression of ER, PR, or HER2 to chemotherapy efficacy is equivocal.

TABLE 198-2 AMERICAN JOINT COMMITTEE ON CANCER TUMOR, NODE, METATASIS STAGING SYSTEM FOR BREAST CANCER

TNM STAGING

PRIMARY TUMOR (T)

Definitions for classifying the primary tumor (T) are the same for clinical and pathologic classification. If the measurement is made by the physical examination, the examiner uses the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis Tis (DCIS) Tis (LCIS) Tis (Paget)	Carcinoma in situ Ductal carcinoma in situ Lobular carcinoma in situ Paget disease of the nipple with no tumor
Note: Paget disease associated with a tumor is classified according to the size of the tumor.	
T1	Tumor 2 cm or less in greatest dimension
T1mic	Microinvasion 0.1 cm or less in greatest dimension
T1a	Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b	Tumor more than 0.5 cm but not more than 1 cm in greatest dimension
T1c	Tumor more than 1 cm but not more 2 cm in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

REGIONAL LYMPH NODES (N)

Clinical

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed to one another (matted) or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastases in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically apparent ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s), with or without axillary lymph node involvement, or in clinically apparent ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s), with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

Pathologic (pN)

pNX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
pN0	No regional lymph node metastasis histologically
pN0(i–)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) 0.2 mm or less (detected by IHC including isolated tumor cell(s)
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN0(mol+)	No regional lymph node metastasis by IHC or histology, positive molecular findings (RT-PCR)
pN1	Metastasis in 1 to 3 axillary lymph nodes, or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically detected
pN1mi	Micrometastasis (greater than 0.2 mm and/or more than 200 cells, none greater than 2.0 mm)
pN1a	Metastasis in 1 to 3 axillary lymph nodes with a least 1 metastasis greater than 2 mm
pN1b	Metastasis in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node dissection but not clinically detected
pN1c	Metastasis in 1 to 3 axillary lymph nodes and in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node dissection, but not clinically detected
pN2	Metastasis in 4 to 9 axillary lymph nodes or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN2a	Metastasis in 4 to 9 axillary lymph nodes (at least 1 tumor deposit greater than 2.0 mm)
pN2b	Metastasis in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN3	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically detected ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastasis in 10 or more axillary lymph nodes (at least 1 tumor deposit greater than 2.0 mm), or metastasis to the infraclavicular lymph nodes
pN3b	Metastasis in clinically detected ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometases detected by sentinel lymph node dissection, but not clinically detected
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes

DISTANT METASTASIS (M)

MX	Distant metastasis cannot be assessed
M0	No clinical or radiographic evidence of distant metastasis
cM0(+)	No clinical or radiographic evidence of distant metastases but deposits of molecularly or microscopically detected tumor cells in blood, bone marrow, or nonregional nodes without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiologic means and/or histologically proved greater than 0.2 mm

STAGE GROUPING

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T0 or T1	N1mi	M0
Stage IIA	T0	N1	M0
	T1	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

Note: Stage designation may be changed if postsurgical imaging studies show distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

IHC = immunohistochemistry; RT-PCR = reverse-transcriptase polymerase chain reaction; TNM = tumor, node, metastasis.

TABLE 198-3 TUMOR, NODE, METASTASIS (TNM) STAGE AND SURVIVAL

STAGE	TNM CATEGORY*	RECURRENCE FREE AT 10 YEARS (NO SYSTEMIC ADJUVANT THERAPY) (%)
0	TisN0M0	98
I	T1N0M0	80 (all stage I patients)
	T ≤ 1 cm	90%
	T > 1-2 cm	80-90
IIA	T0N1M0; T2N0M0	60-80
IIA	T1N1M0	50-60
IIB	T2 N1M0	5-10 worse than IIA and based on node status
IIB	T3N0M0	30-50
IIIA	T0 or T1 or T2N2M0; or T3N1 or N2M0	10-40
IIIB	T4N0 or N1 or N2M0	5-30
IIIC	Any T, N3M0	15-20
IV	Any T, any NM1	<5

TNM = tumor, node, metastasis.

TABLE 198-4 CARCINOMA IN SITU: DUCTAL VERSUS LOBULAR

FEATURE	LOBULAR CARCINOMA IN SITU	DUCTAL CARCINOMA IN SITU
Age	Younger	Older
Palpable mass	No	Uncommon
Mammographic appearance	Not detected on mammography	Microcalcifications, mass
Immunophenotype	E-cadherin negative	E-cadherin positive
Usual manifestation	Incidental finding on breast biopsy	Microcalcifications on mammography or breast mass
Bilateral involvement	Common	Uncertain
Risk and site of subsequent breast cancer	25% risk for invasive breast cancer in either breast over remaining lifespan	At site of initial lesion; 0.5% risk/yr of invasive breast cancer in opposite breast
Prevention	Consider tamoxifen or raloxifene or aromatase inhibitor	Consider tamoxifen or raloxifene if estrogen receptor positive
Treatment	Yearly mammography and breast examination	Lumpectomy ± radiation; mastectomy for large or multifocal lesions

Modern molecular techniques have provided further insight into molecular classification of breast cancer. Integrating data derived from analysis by genomic DNA copy number arrays, DNA methylation, exome sequencing, messenger RNA arrays, microRNA sequencing, and reverse-phase protein arrays, multiple genetically distinct types of breast cancer have been identified.[3,4] Transcriptional profiling has suggested that breast cancers can be divided into at least four molecular subsets: luminal A and B, HER2, and basal. The luminal subtypes frequently express ER, but luminal A appears to be associated with a better prognosis and higher likelihood of response to endocrine therapy than luminal B. The basal subtype is dominated by tumors that lack expression of ER, PR, and HER2—the so-called triple-negative breast cancer that lacks a readily identified molecular target. Multigene assays that evaluate these gene expression patterns are under investigation, and several multigene assays are available in clinical practice. One such assay, Oncotype Dx, may assist in the identification of women with early-stage steroid receptor–positive breast cancer who would benefit from the addition of chemotherapy to tamoxifen. A second assay, Mammaprint, may be useful to identify young women with breast cancer with poor prognosis. A number of other assays are under development, and both the Oncotype Dx and Mammaprint assays are the subject of large randomized trials to refine the conditions for their optimal use.

TREATMENT

Local Treatment of Early-Stage Breast Cancer

In Situ Carcinoma

Thanks to heightened breast cancer awareness and use of screening mammography, in situ carcinomas now account for 20 to 25% of newly diagnosed cases of breast cancer (Table 198-4). Most of these are ductal carcinoma in situ (DCIS). These lesions are associated with approximately a 30% risk for subsequent invasive breast cancer in the same breast. The risk for metastatic breast cancer with a diagnosis of DCIS is extremely small. As a consequence, management decisions are centered on the involved breast, and axillary lymph node evaluation is not routinely performed. Total mastectomy, the traditional therapy, has a high likelihood of cure, but studies suggest that breast conservation is appropriate for many women with DCIS. The major contraindications include poor cosmesis, extensive disease, or patient preference. Several models have suggested that size and grade of lesion and surgical margin status are important determinants of local outcome. Excision to obtain tumor-free margins is critical. Careful mammographic examination of the specimen and postexcision mammography of the breast are crucial to confirm that the DCIS has been adequately excised. A large randomized trial showed that radiotherapy plus lumpectomy decreased the likelihood of in situ or invasive recurrence compared with lumpectomy alone. Other data sets suggest that some women with favorable histologic findings who are willing to undergo close surveillance are candidates for local excision alone. In addition, the use of tamoxifen for 5 years can reduce ipsilateral breast cancer recurrence and contralateral breast cancer diagnosis by approximately 50%.

Controversy continues over whether lobular carcinoma in situ (LCIS) is truly a malignant lesion. LCIS is usually an incidental finding on a breast biopsy done for other indications, and it appears to be associated with a 25% risk for development of invasive breast cancer in either breast. Women with LCIS are generally managed expectantly with regular breast examination and mammography. Bilateral total mastectomy is sometimes considered for women with LCIS who have other risk factors or extreme anxiety. Finally, these women are candidates for tamoxifen or raloxifene or an aromatase inhibitor as a risk-reduction strategy based on the results of several large breast cancer chemoprevention trials.

Invasive Breast Cancer

Surgery

Although radical mastectomy (removal of the breast, axillary contents, and underlying chest musculature) was the mainstay for breast cancer treatment for many years, it is seldom performed today. Multiple randomized trials have consistently shown that breast conservation therapy (BCT) with lumpectomy plus radiotherapy provides identical survival rates to modified radical mastectomy (removal of the breast and lymph nodes) for women with stages I and II breast cancer. Medical contraindications to BCT include multifocal disease, previous radiotherapy, ongoing pregnancy that precludes the timely use of radiotherapy, poor cosmesis, and patient preference. Although the number of patients who receive BCT has increased substantially, there are wide geographic differences within the United States. Patients who undergo mastectomy should be counseled about the availability of a number of autologous tissue and implant options for reconstruction, either at the time of surgery or any time thereafter.

Because the likelihood of distant micrometastatic spread is highly correlated with the number of pathologically involved axillary lymph nodes, axillary dissection has traditionally been used to provide prognostic information. A drive toward limiting axillary surgery to minimize the incidence of postoperative lymphedema (see later) has led to the development of sentinel node techniques. A radioactive tracer, blue dye, or both are injected into the area around the primary breast tumor. The injected substance tracks rapidly to the dominant axillary lymph node—the sentinel node—which can be located and removed by the surgeon. If the sentinel node is tumor free, the remaining nodes are likely to be tumor free as well and no further axillary surgery is required. Currently, women with palpable axillary nodes and those with more extensively involved sentinel nodes are counseled to undergo axillary dissection. For women with small tumors and a clinically negative axilla, large randomized trials of sentinel node management and traditional axillary dissection suggest similar outcomes. Data suggest that it may also be possible to omit further axillary surgery for patients with a low burden of disease in sentinel nodes.

Adjuvant Radiotherapy

Radiotherapy has been a cornerstone in breast conservation therapy because women who undergo lumpectomy alone have a breast cancer recurrence rate of up to 40%, whereas the rate of recurrence is less than 10% with whole-breast radiotherapy. As a result, radiotherapy to the conserved breast reduces the breast cancer death rate by approximately 15%. Attempts to identify women whose tumors are so favorable that radiotherapy can be

withheld are ongoing. One large trial suggested that women older than 70 years with small ER-positive tumors who receive tamoxifen gain little with radiotherapy. Current research is also focused on the possibility that radiotherapy can be delivered safely and effectively to a smaller field (partial breast radiotherapy) or over a shorter period.

The role of postmastectomy radiotherapy continues to be a matter of debate. Based on the results of individual randomized trials and a meta-analysis suggesting a survival advantage, many radiation oncologists recommend postmastectomy radiation to women with more than three involved nodes and discuss its use for those with involvement of one to three nodes, in whom a smaller benefit is seen.

Adjuvant Systemic Therapy for Early-Stage Breast Cancer

Adjuvant systemic therapy is defined as the use of chemotherapy, endocrine therapy, or biologic therapy, or a combination of these, after definitive local therapy for early breast cancer. Its goal is to suppress or eradicate clinically occult micrometastases. Because current testing does not permit the definitive identification of the patient with micrometastases, recommendations for adjuvant systemic therapy are based on menopausal status, lymph node status, tumor size, and the extent of expression of the ER, PR, and HER2 proteins in breast cancer cells. The treatment algorithms that are currently used are the result of more than 50 years of clinical trials; the results of these trials have been compiled in sequential overview analyses that have evaluated the worldwide experience with use of endocrine therapy and chemotherapy. These analyses have shown that adjuvant therapy results in a proportional reduction in risk for recurrence across all patients regardless of risk for recurrence; this implies that the absolute benefit of adjuvant systemic therapy is greatest for individuals with the greatest risk for recurrence. Tools to assist the clinician and patient to make decisions about the use of adjuvant therapy include guidelines based on evidence and expert consensus such as the National Comprehensive Care Network (NCCN) and St. Gallen conference guidelines, as well as web-based algorithms such as Adjuvant Online (Table 198-5).[5]

Adjuvant Endocrine Therapy

Tamoxifen (20 mg/day for 5 years) has been the most widely used endocrine therapy. It improves outcomes in women of all ages with ER- or PR-positive breast cancer. Its side-effect profile includes an increased risk for thromboembolic events and uterine cancer, especially in postmenopausal women, because of its estrogen agonist properties. Potential benefits include promotion of bone density and lowering of cholesterol. An active area of research is the effects on outcome of altered activity of the tamoxifen metabolizing enzyme, CYP2D6, by either coadministration of pharmacologic inhibitors or by single-nucleotide polymorphism variants in the *CYP2D6* gene.

In recent years, the role of estrogen deprivation has been the subject of intense scrutiny—ovarian suppression or ablation for premenopausal women and aromatase inhibition for postmenopausal women. Ovarian ablation through surgery or radiotherapy is the oldest form of systemic therapy for breast cancer. More recent work has focused on the use of luteinizing hormone–releasing hormone (LHRH) agonists as a means of effecting a temporary and reversible ovarian suppression. Two large meta-analyses sought to define the role of these approaches. A meta-analysis of trials addressing the efficacy of LHRH agonists in women with early-stage ER-positive breast cancer suggested the following: (1) monotherapy with LHRH agonist has significant activity; (2) the efficacy of LHRH monotherapy is similar to that of certain chemotherapy regimens; and (3) LHRH agonists appear to add benefit to adjuvant chemotherapy, especially in women younger than 40 years, who are less likely than older women to become postmenopausal as a consequence of adjuvant chemotherapy. Unfortunately, these trials did not routinely include tamoxifen because its value in premenopausal breast cancer was recognized only after accrual for these ovarian suppression studies was completed. In sum, however, it appears that ovarian ablation or suppression is a viable strategy for premenopausal women with steroid receptor–positive breast cancer.

In premenopausal women, the combination of LHRH agonist plus aromatase inhibitor may be better than LHRH agonist plus tamoxifen. For example, in a recent randomized trial of hormone-receptor-positive early breast cancer in premenopausal women, adjuvant treatment with the aromatase inhibitor exemestane plus ovarian suppression, as compared with tamoxifen plus ovarian suppression, significantly reduced recurrence.

In postmenopausal women, the primary source of estrogen is the conversion of androgens synthesized by the adrenal glands to estrogen through the activity of CYP19 or aromatase in peripheral tissues such as mammary and adipose tissues. The aromatase inhibitors (anastrozole, letrozole, and exemestane) specifically inhibit this conversion, leading to further estrogen deprivation in older women. Randomized trials have shown that efficacy of aromatase inhibitors is similar or superior to that of tamoxifen and that these drugs have an acceptable side-effect profile. Multiple trials have compared monotherapy with tamoxifen, aromatase inhibitor, or sequential therapy; in aggregate, they suggest that the use of an aromatase inhibitor at some point should be considered for most postmenopausal women with steroid receptor–positive invasive breast cancer.[6] Side effects include postmenopausal symptoms, osteoporosis and fractures, and arthralgias. Aromatase inhibitors are not useful for receptor-negative breast cancer, nor should they be used as monotherapy in premenopausal women. The simultaneous administration of tamoxifen plus aromatase inhibitor does not improve outcome over aromatase inhibitor alone.

Duration of endocrine therapy appears to be quite important. Direct evidence suggests that at least 5 years of adjuvant endocrine therapy is associated with better outcomes than shorter periods. Two large, recently reported trials suggest that 10 years of tamoxifen is better than 5 years. Optimal duration of aromatase inhibitor therapy is under study.

Adjuvant Anti-HER2 Therapy

Increased understanding of growth and death pathways of breast cancer led to the identification of critical nonendocrine pathways that are potential targets for therapy. The transmembrane HER2/neu protein is overexpressed in approximately 20% of breast cancers, generally because of gene amplification. The efficacy and safety of the monoclonal antibody trastuzumab in the treatment of women with HER2-overexpressing metastatic breast cancer laid the foundation for several adjuvant trials that in aggregate showed that the addition of 1 year of trastuzumab to chemotherapy reduced the risk for recurrence by approximately 50% in women with high-risk HER2-positive early breast cancer. Thus, use of trastuzumab is considered for many women with

TABLE 198-5 ADJUVANT TREATMENT GUIDELINES FOR PATIENTS WITH EARLY-STAGE INVASIVE BREAST CANCER*

PATIENT GROUP*	TREATMENT
FAVORABLE HISTOLOGY (TUBULAR OR COLLOID)	
ER- and/or PR-Positive Breast Cancer	
<1 cm and pN0 or pN1mi	No adjuvant therapy
1-2.9 cm and pN0 or PN1mi	Consider adjuvant hormonal therapy†
≥3 cm or node-positive	Adjuvant hormonal therapy ± adjuvant chemotherapy†
ER- and PR-Negative Breast Cancer	
<1 cm and pN0	No adjuvant therapy
1-2.9 cm	Consider adjuvant chemotherapy
≥3 cm or node-positive	Adjuvant chemotherapy
HORMONE RECEPTOR–POSITIVE (ER- AND/OR PR-POSITIVE) BREAST CANCER	
Lymph Nodes Negative	
≤0.5 cm	Consider adjuvant hormonal therapy
0.6-1.0 cm well differentiated and no unfavorable features‡	Consider adjuvant hormonal therapy†
>1 cm	Adjuvant hormonal therapy ± adjuvant chemotherapy†
Lymph Nodes Positive	
	Adjuvant hormonal therapy + adjuvant chemotherapy
HORMONE RECEPTOR–NEGATIVE (ER- AND PR-NEGATIVE) BREAST CANCER	
≤0.5 cm and pN0	No adjuvant therapy
0.6-1.0 cm and pN0 or pNmi	Consider chemotherapy
>1 cm or lymph-node positive	Adjuvant chemotherapy
HER2 POSITIVE	
	Trastuzumab should be added to the suggested treatment above for all node-positive patients and considered for pN0 tumors that are > 5 mm

Modified from National Comprehensive Cancer Network Guidelines. Available at http://www.nccn.org.
*Data are insufficient to make chemotherapy recommendations for patients 70 years and older. Treatment should be individualized for these patients based on life expectancy and comorbidity.
†In ER-positive or PR-positive patients, decisions regarding the added value of chemotherapy in addition to hormonal therapy alone in N0 patients can be aided by the use of the Oncotype Dx assay to assess recurrence score.
‡Unfavorable characteristics include high-grade tumor, blood vessel or lymphatic invasion by tumor, and high tumor proliferation rate (high S phase by flow cytometry or high Ki-67 value by immunohistochemistry) or HER2-positive status or high recurrence score.
ER = estrogen receptor; PR = progesterone receptor.

HER2-positive tumors. More recent trials suggest that 1 year of therapy is better than 6 months and 2 years is no better than 1 year.[■] Important questions remain regarding long-term risks and benefits, the use of trastuzumab in the absence of chemotherapy, and the role of other anti-HER2 agents such as lapatinib, pertuzumab, or trastuzumab, and emtansine in addition to or in place of trastuzumab.

Adjuvant Chemotherapy

Individual trials and the Early Breast Cancer Trialists Collaborative Group meta-analysis have shown the benefit of adjuvant chemotherapy. Benefit varies by age and nodal status such that, in the meta-analysis, the absolute benefit is greatest in women younger than 50 years, in whom 15-year breast cancer mortality decreased from 42% to 32%, whereas it decreased from 50% to 47% for women aged 50 to 69 years.

These trials established several principles that guide chemotherapy use. Combination therapy appears to be more effective than single-agent chemotherapy. Effective agents include anthracyclines, taxanes, antimetabolites, and cyclophosphamide. Randomized trials demonstrated that 3 to 6 months of therapy is preferred over longer durations. Dose reduction below the standard level is associated with inferior outcome, but dose escalation through the use of colony-stimulating factors or autologous stem cells support leads to excess toxicity without improved outcome. Regimens that use colony-stimulating factors to accelerate the schedule of chemotherapy administration have been more successful.

Increased use of adjuvant chemotherapy and longer survival led to concerns about toxicity. Acute side effects of therapy are nausea and vomiting, bone marrow suppression, and hair loss; all are reversible, and the first may be mitigated by the use of modern antiemetics. Careful use of colony-stimulating agents can minimize complications of neutropenia, but current evidence argues against the use of erythroid-stimulating agents for chemotherapy-induced anemia. Induction of menopause is a common concern for premenopausal women. Its likelihood is related to the type and duration of chemotherapy and the age of the patient; most women older than 40 years will suffer drug-induced menopause. Doxorubicin-related cardiomyopathy is noted in approximately 1% of women who received doxorubicin-containing adjuvant chemotherapy. Use of standard adjuvant chemotherapy regimens results in a very small increase in the incidence of acute leukemia, but there is no evidence of increased incidence of other second tumors. Effect of chemotherapy on cognitive function is an area of study.

Sequencing of Adjuvant Therapy

Women frequently receive several adjuvant interventions, including chemotherapy, radiotherapy, endocrine therapy, and/or anti-HER2 therapy. A logical question is how best to sequence these therapies.

Because a large randomized trial showed that concurrent chemotherapy plus tamoxifen led to worse outcome than chemotherapy followed by tamoxifen, most practitioners delay the administration of endocrine therapy until after completion of chemotherapy. Conversely, the benefit of trastuzumab appears to be greater when it is coadministered with taxane chemotherapy rather than following completion of taxane. A randomized trial showed no clear difference between the sequence of chemotherapy followed by radiotherapy compared with radiotherapy followed by chemotherapy.

A number of trials have tested the concept that administration of systemic therapy before primary surgery would improve outcome over the standard sequence of surgery followed by systemic therapy. Together they suggest that, compared with adjuvant therapy, preoperative (also termed *neoadjuvant*) systemic therapy improves the rate of breast conservation but does not enhance disease-free or overall survival. The possibility that preoperative therapy can provide an in vivo assessment of tumor response to therapy is suggested by the correlation between the finding of a pathologic complete response (absence of invasive cancer in the surgical specimen) and long-term disease-free survival in some studies.

Follow-Up of Early-Stage Breast Cancer Survivors

A critical question is how longitudinal medical follow-up should be conducted in women who have received appropriate local and systemic therapy for early breast cancer. Randomized trials have addressed the question of the value of serial laboratory and radiology testing, as well as the role of primary care versus oncology specialist follow-up. On the basis of these and other studies, the American Society of Clinical Oncology has published evidence-based guidelines for follow-up of asymptomatic survivors of early-stage breast cancer. These guidelines are summarized in Table 198-6.

Stage III Breast Cancer

Locally advanced or inoperable stage III breast cancer accounts for approximately 10% of breast cancers. It is characterized by large primary tumor, fixed tumor or lymph nodes, or neoplastic invasion of the skin or chest wall. Inflammatory breast cancer falls into this category. It has a clinical presentation of breast swelling, warmth, and erythema and may or may not be associated with a mass. Because as many as one third of women with locally advanced breast cancer have distant metastases at the time of diagnosis, many oncologists perform an evaluation for distant disease even in asymptomatic patients.

TABLE 198-6 FOLLOW-UP GUIDELINES FOR PATIENTS WITH EARLY-STAGE BREAST CANCER: AMERICAN SOCIETY OF CLINICAL ONCOLOGY GUIDELINES

PROCEDURE OR TEST	FREQUENCY
History and physical examination* (eliciting of symptoms of breast cancer)	Every 3-6 mo for first 3 yr, every 6-12 mo for next yr, then yearly
MAMMOGRAPHY	
Mastectomy patients	Yearly
Lumpectomy patients	Yearly
Pelvic examination	Age appropriate
Breast self-examination	Monthly
Complete blood cell counts and chemistry studies	The literature does not support the use of these tests
Chest radiography, bone scans, PET scans, breast MRI, liver imaging, and tumor marker studies	Not recommended for routine follow-up in asymptomatic patients
Patient education regarding signs and symptoms of recurrence	Each visit

Modified from Khatcheressian JL, Hurley P, Bantug E, et al. Breast cancer follow-up and management after primary treatment: American Society of Clinical Oncology clinical practice guideline update. *J Clin Oncol.* 2013;31:961-965.
*Limited evaluation: assess for pain, dyspnea, weight loss, and other major changes in function. The limited examination should include an assessment of nodes, axillae, lumpectomy or mastectomy site, chest, and abdomen. Patients should be instructed regarding symptoms of recurrence.
MRI = magnetic resonance imaging; PET = positron emission tomography.

Diagnosis is usually established by fine-needle aspiration or core biopsy, and combined-modality therapy is used to maximize control of local disease and distant micrometastases. Several months of preoperative endocrine therapy or chemotherapy results in tumor regression in most patients, thereby allowing definitive breast surgery of some type to be performed. Postoperative radiotherapy is generally employed to enhance local control, and some studies suggest that administration of further chemotherapy, hormone therapy, anti-HER2 therapy, or a combination thereof (depending on the features of the cancer) is then desirable. Multimodality therapy results in a 5-year disease-free survival rate of approximately 50%.

Stage IV or Metastatic Breast Cancer

Although seldom curable, advanced breast cancer is a highly treatable illness. Palliation or prevention of symptoms without excess toxicity is the primary goal of treatment. The median survival after diagnosis of metastatic breast cancer is 2 to 3 years, although the range is great, and a small cadre of long-term survivors has been described. Several recent clinical trials have documented small improvements in survival with some of the newer therapies.

Most women with metastatic breast cancer present with symptoms or abnormalities on physical examination. Less than 10% of women present initially with metastatic disease; rather, advanced disease is normally diagnosed in women with a previous diagnosis of early breast cancer for which they received treatment. Common sites for metastases include bone, soft tissues, lung, liver, and brain. If metastatic disease is suspected, relevant hematologic, biochemical, and radiographic evaluation is indicated to assess location and severity of involvement. Because of the import of the diagnosis, pathologic confirmation is preferred. This permits verification of recurrent disease, exclusion of other diagnoses, and reassessment of biologic features such ER, PR, and HER2. Elevation of tumor markers (e.g., CA-27-29, carcinoembryonic antigen) or the presence of circulating tumor cells is not diagnostic of recurrent disease, although these markers may be useful adjuncts in the assessment of the effects of therapy.

The role of surgery in metastatic breast cancer is limited. It is useful in certain circumstances such as resection of a chest wall nodule or solitary brain metastasis or orthopedic stabilization to treat or prevent a long-bone fracture. Radiotherapy is a mainstay in the management of advanced disease. It may be used at any time during the patient's course to treat localized disease such as chest wall recurrence, brain metastases, or painful bony metastases. Systemic treatment is the primary mode for management of disseminated disease. Key principles for selection of therapy include maximal palliation of symptoms, minimization of treatment-related toxicity, and prevention of disease complications. An algorithm for treatment of stage IV breast cancer is shown in Figure 198-1.

Endocrine Therapy

Endocrine therapy is preferred as the first intervention for metastatic breast cancer whenever feasible because of its favorable therapeutic index. Factors that support the use of endocrine therapy include the expression of hormone

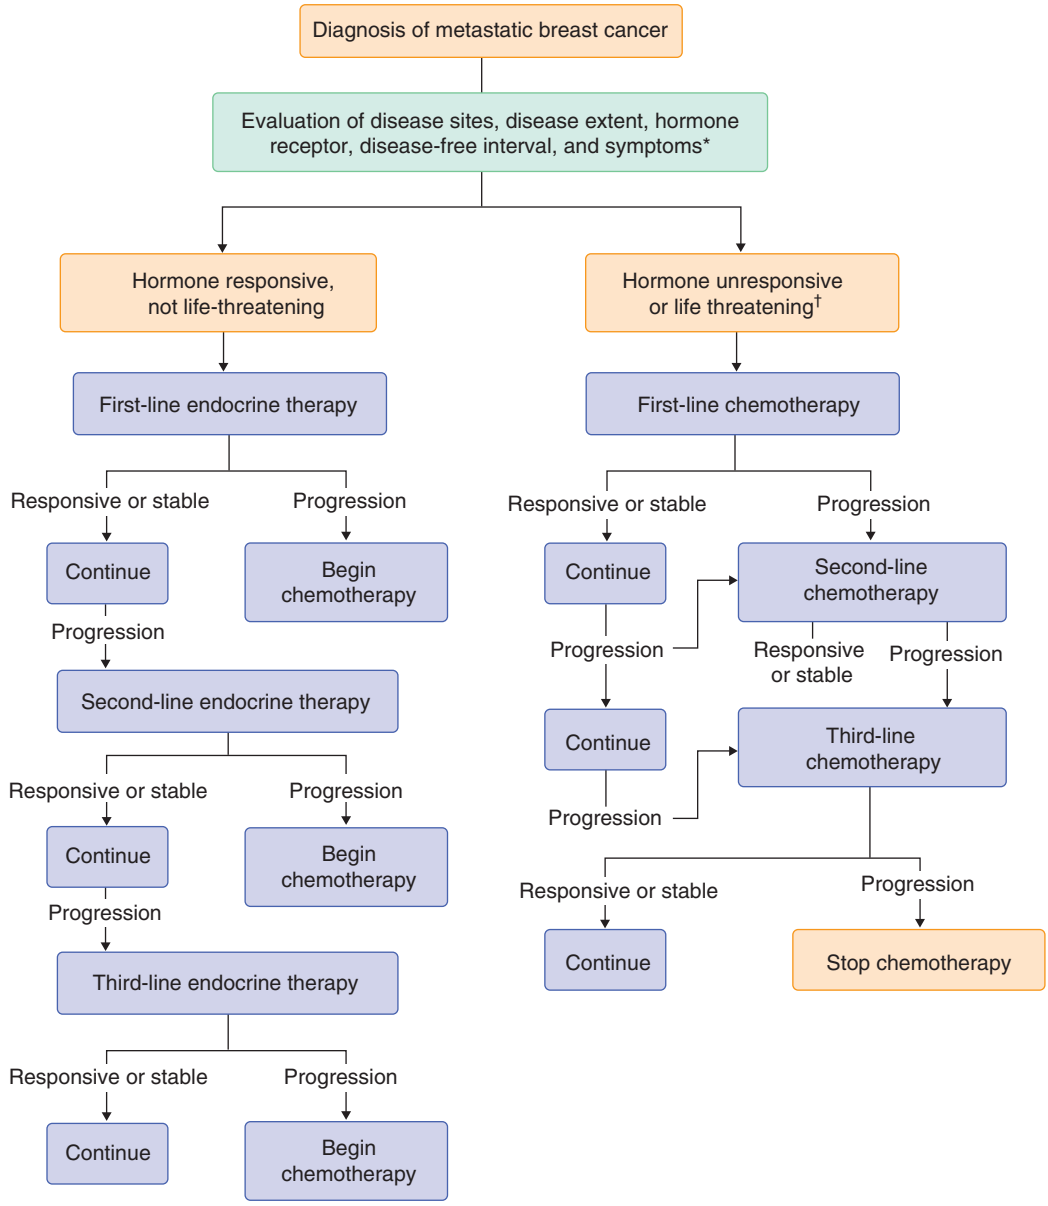

FIGURE 198-1. An algorithm used for the systemic treatment of stage IV breast cancer. *Consider use of bisphosphonate or denosumab if bone involvement. †Consider integration of anti-HER2 therapy if tumor is HER2 overexpressing.

receptors, a long disease-free interval, and absence of symptoms or visceral disease. More than half of the women who meet these criteria respond to an initial course of hormone therapy, with a median response duration of 9 to 12 months. Length of response is a good predictor for the likelihood of response to a second course of endocrine therapy when the first agent fails. A second course of endocrine therapy is less likely to be successful, and the duration of response is shorter; again, duration of response predicts for likelihood of success with third-line therapy. Successful application of this algorithm can result in good disease control with little toxicity for several years in some women.

A number of types of hormone therapy are now available. These include the selective estrogen receptor modulator (SERM) tamoxifen, the selective estrogen receptor–degrading agent fulvestrant, the aromatase inhibitors, and ovarian suppression by oophorectomy or LHRH agonists. Selection is usually made on the basis of efficacy, toxicity, and menopausal status. Serial administration of agents is the norm, although one study in estrogen receptor–positive postmenopausal metastatic breast cancer showed that the combination of the aromatase inhibitor anastrozole with fulvestrant was superior to anastrozole alone or sequential anastrozole and fulvestrant.[■] Other combination therapies (with the possible exception of ovarian suppression plus tamoxifen) do not improve outcomes. Recent work has also demonstrated the value of everolimus but not temsirolimus combined with an aromatase inhibitor to improve progression-free survival compared with an aromatase inhibitor alone in patients with hormone receptor–positive advanced breast cancer previously treated with nonsteroidal aromatase inhibitors.[■]

Several months of therapy are needed before the efficacy of a newly introduced endocrine therapy can be assessed. Patients and clinicians should be aware of the possibility of *treatment-related tumor flare*—a syndrome of worsening symptoms and increased circulating tumor markers—that can occur within the first few weeks of treatment. This response is usually of short duration and should not be confused with disease progression.

Chemotherapy

Most women with advanced breast cancer experience endocrine-unresponsive disease at some point and become candidates for palliative chemotherapy. Serial chemotherapy is the norm. Patients receive two to four cycles of therapy and then are evaluated for disease stabilization or improvement. Duration of therapy is variable for those who are responding to therapy. Several trials compared the approach of continuing therapy until time of disease progression with the approach of administering therapy, followed by a "drug holiday," with resumption of therapy at the time of disease progression. In sum, these studies suggest that survival is the same with these two approaches but that quality of life, as judged by the patients, is often better with continued therapy. Thus, decisions about continuation or cessation of a therapy are driven by perception of side effects and benefits by the patient and clinician.

Many active agents for breast cancer are now available. These include well-established drugs such as cyclophosphamide, doxorubicin, and methotrexate, as well as newer agents such as paclitaxel, docetaxel, vinorelbine, capecitabine, gemcitabine, carboplatin, ixabepilone, pegylated doxorubicin, and nanoalbumin–bound paclitaxel. All these agents are active individually and in combination. There is considerable debate about the value of combination therapy compared with sequential single-agent therapy for metastatic breast cancer. Current guidelines suggest the use of serial monotherapy unless the patient

has highly symptomatic disease or extensive visceral disease. In addition, much attention has been focused on schedule of administration. For example, weekly paclitaxel regimens appear to be more effective and better tolerated than regimens of every 3 weeks for many women. As with endocrine therapy, response rates and duration diminish with each successive change in therapy. As with early breast cancer, high-dose chemotherapy combined with autologous stem cell or bone marrow support has not shown benefit. A difficult question for patient and doctor is when to stop chemotherapy. No fixed rules exist, but many patients and physicians move to a program of supportive care if two successive chemotherapy regimens fail to produce a tumor response or disease stabilization.

Biologic Agents

Enhanced understanding of breast cancer biology has resulted in the identification of new targets for therapy beyond the estrogen receptor pathway. The first agent brought into clinical practice was the monoclonal antibody, trastuzumab (Herceptin), which is active against the transmembrane HER2/neu protein. Administration of trastuzumab monotherapy to women with metastatic HER2-overexpressing breast cancer led to partial or complete tumor regression in about 30% of women. Concurrent trastuzumab with paclitaxel increased response rate and duration and survival compared with paclitaxel alone for women with newly diagnosed HER2-overexpressing metastatic breast cancer. Similar results were seen with concurrent administration of trastuzumab and doxorubicin, but this combination was associated with a 20% incidence of congestive heart failure. This unexpected finding demonstrates the need for careful evaluation of new biologic agents as they enter the clinic. Dose and schedule of trastuzumab have been studied, and it appears that administration every 3 weeks is active with less patient inconvenience. Three other anti–HER2 agents are now available for treatment of advanced breast cancer in the United States, the oral small molecular inhibitor lapatinib; the monoclonal antibody pertuzumab, which inhibits HER dimerization; and the conjugate of a cytotoxic to trastuzumab, trastuzumab emtansine. How to combine and sequence these agents in the treatment of metastatic breast cancer is the subject of several clinical trials; in addition these agents are being tested in the neoadjuvant and adjuvant settings.

Strategies to block tumor angiogenesis have been explored. One such agent is bevacizumab, a monoclonal antibody that targets the VEGF. This agent has only modest activity as monotherapy in metastatic breast cancer. Its addition to taxane-based chemotherapy for women with newly diagnosed stage IV breast cancer appears to improve progression-free survival very modestly without a major impact on survival. Although two neoadjvuant studies have suggested that use of bevacizumab with chemotherapy can increase the rate of pathologic complete response in the surgical specimen compared with chemotherapy alone, trials of its use in the adjuvant setting are thus far negative.

Many other targeted agents are also under development. Of recent interest are the poly-ADP-ribose polymerase (PARP) inhibitors. These small molecule inhibitors of DNA repair show particular activity in women with *BRCA* mutant breast cancer in early studies; more definitive testing is in progress.

Supportive Care

Bone Health

Because palliation of symptoms and prevention of complications of metastatic disease are the primary goals of treatment for advanced breast cancer, careful attention to supportive care is vital. Bone is the most common site of metastasis in breast cancer, and bone disease can be a source of significant morbidity. Several studies have shown that regular administration of a bisphosphonate such as zoledronate or pamidronate or the anti-RANKL monoclonal antibody denosumab, in addition to endocrine therapy or chemotherapy, can reduce pain and lower the incidence of skeletal complications of disease. Although such therapy is now the norm, several issues remain unaddressed, including the optimal treatment interval and duration of therapy in metastatic breast cancer.

Given the propensity of breast cancer therapy to spread to bone and to lead to estrogen deprivation and osteopenia or osteoporosis (Chapter 243), the use of bisphosphonates in the adjuvant setting is under evaluation. Although individual trials have not shown improved outcomes with the use of bisphosphonates in the adjuvant setting, a recently presented meta-analysis suggests that these agents may be useful in the setting of estrogen deprivation such as in postmenopausal patients.

Postmenopausal Symptoms

Postmenopausal symptoms as a consequence of therapy or natural aging are common in breast cancer survivors. In general, hormone replacement therapy should be avoided in women with a history of breast cancer. A short course of treatment can be considered in patients with early-stage breast cancer who have truly disabling symptoms. Topical estrogens are considered for women with vaginal dryness that does not respond to lubricants. Vasomotor symptoms may be reduced with the use of certain antidepressants of the selective serotonin release inhibitor family. Multiple studies have failed to show consistent benefit from many alternative therapies.

Lymphedema

Lymphedema develops in the ipsilateral arm in up to 15% of women after treatment for early breast cancer. Its incidence is lower with sentinel lymph node procedures and meticulous radiotherapy planning. Prevention includes avoidance of trauma and possibly exercises. Early recognition of symptoms is key. Affected patients should be referred to specialists for consideration of treatment such as manual drainage or the use of compression stockings or pumps.

Special Circumstances

The risk for breast cancer is slightly increased during and just after pregnancy. Suspicious breast findings during pregnancy should be investigated vigorously. Surgical therapy for breast cancer can be safely performed after the first trimester of pregnancy, but radiotherapy should be delayed until after delivery. Current data suggest that certain adjuvant chemotherapy regimens can be safely administered in the second and third trimesters of pregnancy, and development is normal in children of mothers who receive this chemotherapy. Administration of antimetabolites should be avoided because of the potential for damage to the placenta. Initiation of endocrine therapy is generally delayed until after delivery. Pregnancy after a diagnosis of early breast cancer does not appear to increase the risk for metastatic disease in limited data sets. The major considerations for women contemplating pregnancy should be its timing with regard to endocrine therapy, which may require 5 or more years to complete, as well as the underlying risk for disease recurrence.

Men account for not more than 1% of breast cancer cases. Failure of the patient or health care provider to diagnose the disease means that it may be diagnosed at a later stage. Most breast cancers in men express ER, and treatment recommendations for these men are generally similar to those for postmenopausal women.

PREVENTION AND SCREENING

There is enormous interest in the development of breast cancer prevention strategies. Currently these include surgical, chemopreventive, and lifestyle modification approaches.

Prophylactic Mastectomy and Oophorectomy

Prophylactic mastectomy appears to reduce the risk for developing breast cancer by approximately 90% in individuals who are at high risk because of a strong family history or carriage of a germline *BRCA1* or *BRCA2* mutation. Prophylactic oophorectomy in *BRCA* mutation carriers has been shown to decrease breast cancer incidence by approximately 50%, presumably because of reduction in ovarian steroids.[7] It is critical that women who opt for prophylactic mastectomy be counseled about the possibility that cancer may develop in remnants of breast tissue that remain after prophylactic mastectomy.

Chemoprevention

The observation that adjuvant endocrine therapy with the SERM tamoxifen also decreased contralateral breast cancer led to evaluation of tamoxifen as a chemopreventive for well women who are at high risk for breast cancer. Meta-analysis of four randomized trials of tamoxifen versus placebo for high-risk women confirmed a 38% reduction in invasive breast cancer with tamoxifen. The largest trial, NSABP P01, randomized 13,388 high-risk women to receive either tamoxifen or placebo for 5 years. Risk factors used to determine eligibility were age 60 years or older, a diagnosis of lobular carcinoma in situ, or age 35 to 59 years with a constellation of risk factors that, when combined, resulted in a 1.67% or greater risk for breast cancer within 5 years. This study showed a 50% decrease in the diagnosis of breast cancer across all age groups at a cost of increased risk for endometrial cancer and thromboembolic events in women older than 50 years. These data led to the approval of tamoxifen to reduce the incidence of breast cancer in women at high risk as defined by the eligibility criteria for this prevention trial.

Other SERMs have been studied as chemopreventive agents.[8,9] Two trials have documented the utility of raloxifene as a breast cancer risk-reduction strategy. In one trial, raloxifene administration reduced the incidence of breast cancer in postmenopausal women of average breast cancer risk and elevated cardiovascular risk. A second trial showed that raloxifene was less effective than tamoxifen in preventing invasive breast cancer in postmenopausal women at high risk for breast cancer. Raloxifene use was associated with fewer uterine cancers than tamoxifen but carries the same risk for thromboembolic events. It is approved by the FDA for risk reduction

in high-risk postmenopausal women. Two large studies of an aromatase inhibitor (exemestane or anastrozole) show that either of these drugs lowers the incidence of breast cancer in moderate- to high-risk postmenopausal women by approximately 50%.[■■] A vitamin A derivative, fenretinide, showed some impact as a chemopreventive agent for secondary prevention in premenopausal breast cancer survivors but has not found a place in routine practice. Finally, large epidemiologic studies have raised the possibility that aspirin or certain statins might also decrease breast cancer risk, but these agents have not been prospectively tested.

Lifestyle Modification

Prevention strategies that involve lifestyle alterations have been suggested. The Women's Health Initiative did not show a clear role for a low-fat diet as a means of breast cancer prevention. Regular exercise, especially during adolescence, may be associated with reduced breast cancer risk. By extrapolation from the epidemiologic studies mentioned previously, abstinence from alcohol might slightly reduce the risk for breast cancer.

Screening

Screening strategies for breast cancer have traditionally included the triad of breast self-examination (BSE), clinical breast examination (CBE) by a health care professional, and screening mammography in well women. Although widely promulgated as an important component of early detection, two large randomized trials of conventional BSE versus observation failed to show any clinical advantage with BSE. As a result, many experts now promote breast awareness rather than regular BSE. The independent value of CBEs has not been rigorously assessed. Rather, it has been studied in conjunction with screening mammography, in which case the two interventions appear to decrease mortality from breast cancer by 25 to 30% in women older than 50 years. Considerable controversy continues over the value of screening mammography in women 40 to 50 years of age and those over 70 years of age as well, as the optimal interval between mammograms for women aged 50 to 70 years. Currently, the American Cancer Society recommends annual screening mammography for women older than 40 years of age who are at standard risk for breast cancer. In contrast, the U.S. Preventive Services Task Force recommends that women between 40 and 50 years of age be counseled about the risks and benefits of screening mammography and that screening mammography can be used at 2-year intervals for women aged 50 to 75 years (Table 198-7). However, women aged 40 to 49 years with a two-fold increased risk for breast cancer have similar benefit-to-harm ratios for biennial screening mammography, as do average-risk women aged 50 to 74 years. A study of digital versus conventional film screen mammography failed to show an overall advantage for digital mammography but suggests that digital mammography may be more useful for women with dense breasts. The survival benefits of mammography come at the cost of false positive results that lead to anxiety and further evaluation. According to various estimates, more than half of the women screened by mammography have false-positive results over 10 years of screening, and 7 to 9% get recommendations for breast biopsy.[10] Other studies have estimated an overdiagnosis rate of 3.3% for invasive cancer and from 18 to 32% for carcinoma in situ.[11] In general, screening is unlikely to be worthwhile for women with a life expectancy of less than ten years.[12]

The knowledge that screening mammography fails to diagnose approximately 10 to 15% of breast cancers has led to the evaluation of other imaging modalities. Of these, MRI is the most mature.[13] MRI has been promoted as a useful screening tool for women at high risk by virtue of the *BRCA* mutation; indeed, the American Cancer Society has recommended consideration of screening MRI for women whose predicted risk for breast cancer exceeds 20%. MRI has been shown to detect breast cancer in the contralateral breast in 3% of women with a newly diagnosed breast cancer whose contralateral mammogram showed no abnormality. Use of MRI in the general population is limited by the fact that it is highly sensitive but lacks specificity. As a result, MRI has not translated into improved selection of surgical treatments or a reduction in the number of operations. Insufficient information exists about other breast imaging modalities such as ultrasound and radionuclide imaging to support their use in screening asymptomatic women.

TABLE 198-7 BREAST CANCER SCREENING

TEST	ACS	USPSTF
Mammography		
40-<49 yr	Annual	Insufficient evidence to support
>49 yr	Annual if healthy	Every 2 yr, 50-75 yr
Clinical breast examination	Every 3 yr, 20-39 yr Annually, ≥40 yr	Insufficient evidence to support
Breast self-examination	Optional	Not recommended

ACS = American Cancer Society; USPSTF = U.S. Preventive Services Task Force.

BENIGN BREAST LESIONS

Benign breast disease includes mastalgia (pain and tenderness), mastitis (including infectious and noninfectious inflammatory conditions), trauma, and benign tumors. In addition, mastalgia can be caused by extramammary conditions, such as myocardial ischemia, pneumonia, pleural irritation, esophageal spasm, costochondritis, rib fracture, and varicella-zoster virus (preceding the skin eruption). After these conditions have been ruled out, mastalgia is considered to be a benign condition that is self-limited. It can be cyclical or noncyclical in timing (where it is thought to be related to hormonal activity), and it may occur in postmenopausal women, even in the absence of hormone replacement therapy.

Mastitis is due to breast inflammation or infection, and it can occur in either nonlactating or lactating women. The typical presentation in nonlactating women is occurrence in their 40s with the acute onset of severe breast pain and tenderness followed by erythema and swelling that tends to be localized in the nipple-areolar area. The cause in most cases is considered to be rupture of dilated subareolar ducts that leads to an inflammatory response to leakage of intraductal contents into periductal tissue. Infection is difficult to rule out, and, in practice, patients are often treated with empirical antibiotics; if symptoms do not resolve within 7 to 10 days on antibiotics, ultrasound is required to rule out abscess. If the latter is found, incision and drainage are required. The most important differential diagnosis with mastitis is inflammatory carcinoma, as noted previously. Therefore, failure to improve with antibiotics or to find an abscess should lead to evaluation by a breast surgeon. Mastitis in lactating women is often due to infection caused by a break in the skin of the nipple or milk stasis. *Staphylococcus aureus, Staphylococcus albus,* and sometimes *Escherichia coli* or streptococci are the most common pathogens. Treatment requires antibiotics and milk removal.

Nonproliferative and Proliferative Benign Breast Lesions

Nonproliferative benign breast lesions include (1) inflammatory fat necrosis, which follows surgical or blunt trauma, and generally resolves spontaneously; (2) lymphocytic mastitis, which may be seen in diabetic patients; and (3) granulomatous mastitis, associated with foreign body reactions (e.g., silicone and paraffin for breast augmentation and reconstruction after cancer surgery), sarcoid, or certain infections. Other nonproliferative benign breast lesions appear as tumor-like processes, including (4) fibroadenoma, a very common (~25% of women), usually solitary, sharply demarcated, smooth lesion in younger age groups; (5) phyllodes tumor (previously known as cystosarcoma phyllodes); (6) intraductal papilloma, solitary lesions that may be accompanied by bloody nipple discharge; (7) fibrocystic breast disease, which is now more appropriately called *fibrocystic changes* because it is observed clinically in up to 50% and histologically in 90% of women, composed of varying amounts of fibrosis and cysts sometimes associated with calcifications and inflammation; and (8) simple or complex cysts, which should be aspirated with ultrasound guidance and, when the fluid is not clear, sent for cytologic analysis.

Proliferative benign breast lesions include ductal or lobular hyperplasia; atypical hyperplasias are associated with increased risk for breast cancer.

Breast Cancer Risk

The increasing use of mammography has increased the frequency of breast biopsies, which, in turn, has increased the finding of benign breast lesions, the most common findings on biopsy. The benign breast lesions listed in the previous section encompass the general histologic spectrum of (1) nonproliferative lesions, (2) proliferative lesions without atypia, and (3) atypical hyperplasia, listed in ascending order of risk for breast cancer. A large number of retrospective and prospective studies have shown an overall relative risk for breast cancer of 1.5 to 1.6 for women with biopsy-proved benign breast disease compared with women in the general population. A study of 9087 women with all types of benign histologic findings, followed for a median of 15 years at the Mayo Clinic, found that 707 of them developed breast cancers. Increased risk for cancer persisted for at least 25 years after the original biopsy. Of the three broad histologic categories, the relative risk for cancer development was 4.24 associated with atypia, 1.88 with proliferative changes

without atypia, and 1.27 with nonproliferative lesions. It is not known whether the finding of a benign breast lesion with atypical histologic findings represents an actual precursor lesion for cancer or if it is only a marker for a general tendency to develop breast cancer. The observations that approximately half of breast cancers in these patients arise in the contralateral breast suggests the latter hypothesis.

REVIEW QUESTIONS

1. A 36-year-old woman presents with a palpable 2-cm right upper outer quadrant breast mass. There is no palpable axillary, cervical, or supraclavicular adenopathy, nor any skin or nipple changes. Bilateral mammography shows only the index 2-cm right breast lesion, and ultrasound-guided biopsy shows infiltrating ductal cancer with positive estrogen and progesterone receptor expression and absence of *HER2* expression. Options for local therapy could include breast conservation (lumpectomy, sentinel node removal, and radiotherapy) or mastectomy with or without reconstruction. Which factor would be an absolute contraindication to breast conservation therapy?

A. Patient is 35 weeks pregnant
B. Previous radiation therapy for a diagnosis of cervical cancer
C. *BRCA1* mutation carrier
D. Inability to obtain negative margins of the lumpectomy specimen even after re-excision
E. Family history of breast cancer in maternal grandmother

Answer: D Randomized clinical trials have demonstrated that breast conservation therapy and mastectomy are equally effective for most women with early-stage breast cancer. Thus, breast conservation therapy is the preferred approach for local therapy for most women. The primary reasons to favor mastectomy include the inability to excise all tumor in the breast (positive margins on re-excision or multifocal breast cancer) or inability to deliver radiotherapy (e.g., during an ongoing pregnancy or after previous mantle radiotherapy for treatment for Hodgkin's lymphoma). In this patient, radiation therapy could be safely delayed for several weeks to permit completion of the pregnancy. Because the breast does not fall in the treatment area for radiotherapy for cervical cancer, this patient could safely receive breast radiotherapy. Family history of breast cancer may contribute to breast cancer risk but does not have an impact on selection of therapy for breast cancer once diagnosed. Breast conservation therapy remains an option for women with a germline *BRCA1* or *BRCA2* mutation, although some patients will opt for bilateral mastectomy. Finally, patient preference should always take precedence after a detailed informed consent discussion has taken place.

2. The patient in Question 1 asks if she should consider genetic testing for a hereditary breast cancer syndrome because of the diagnosis of breast cancer at an early age. What additional element in her history would support the recommendation to proceed with testing?

A. Personal history of cervical cancer
B. Patient is of Irish Catholic extraction
C. Personal history of Hodgkin's lymphoma
D. Family history of breast cancer in paternal grandmother and ovarian cancer in paternal aunt
E. Family history of endometrial cancer in mother and postmenopausal breast cancer in maternal grandmother

Answer: D Germline mutations in the *BRCA1* or *BRCA2* gene leading to hereditary breast and ovarian cancer syndromes account for a few percent of breast cancer diagnoses in women. These mutations are autosomal dominant and can thus be inherited through the maternal or paternal line. Careful ascertainment of family history for cancer diagnosis on both sides of the family is critical. Clinical hallmarks of *BRCA1*- or *BRCA2*-related malignancies include the predisposition to breast and/or ovarian cancer (but not endometrial or cervical cancer), bilateral disease, and early onset of disease. Three founder mutations in *BRCA1* or *BRCA2* are found in 1 to 2% of Ashkenazi Jews but have not been described in Irish Catholics.

3. A 70-year-old postmenopausal woman underwent breast conservation surgery and radiotherapy for management of a 1.7-cm, grade 2 infiltrating ductal carcinoma with highly positive estrogen and progesterone receptor and absent *HER2* expression by immunohistochemistry. Sentinel lymph node biopsy was negative. Her general health is good. She takes no medications. Family history is negative for malignancy. A 5-year course of adjuvant treatment with the aromatase inhibitor, anastrozole, is recommended. She should be counseled that a potential side effect of anastrozole is:

A. Neutropenia.
B. Arthralgias.
C. Neuropathy.
D. Uterine cancer.
E. Risk of thromboembolic events.

Answer: B Two common types of adjuvant endocrine therapy, tamoxifen and the aromatase inhibitors such as anastrozole, are considered for postmenopausal women with hormone receptor–positive invasive breast cancer. Current guidelines suggest that use of an aromatase inhibitor is preferred for most postmenopausal women. These agents suppress aromatase, the enzyme that converts androgens synthesized in the adrenal glands to estrogens in adipose and breast tissues. Therefore, this patient should be counseled that letrozole could lead to signs and symptoms of estrogen deprivation such as vasomotor symptoms, bone loss, and elevated cholesterol. An increased incidence of arthralgias is also seen in placebo-controlled trials of aromatase inhibitors; the underlying mechanism is not well understood. Because of its estrogen suppressive action, anastrozole administration is not associated with the development of uterine cancer, a malignancy that is associated with unopposed estrogen, nor is it associated with increased risk for thromboembolic events that are seen with tamoxifen or hormone replacement therapy. Finally, unlike cytotoxics, endocrine therapy such as letrozole is not associated with neutropenia or neuropathy.

4. The patient in Question 3 asks what type of breast cancer–specific testing is required during her follow-up in the absence of symptoms. Which is the most appropriate strategy?

A. Regular history and physical examination without any testing in the absence of symptoms
B. Regular history and physical examination and annual mammography
C. Regular history and physical examination and annual mammography and breast MRI
D. Regular history and physical examination, annual mammography, and routine blood testing, including CBC, chemistry panel, and tumor markers
E. Regular history and physical examination; annual mammography; routine blood testing including CBC, chemistry panel and tumor markers, and annual PET/CAT

Answer: B Evidence-based guidelines for the follow-up of asymptomatic survivors of early breast cancer recommend regular physical examination and annual mammography. The goal of follow-up in such individuals is to facilitate the early diagnosis of a new breast cancer in the contralateral breast or a recurrence in the ipsilateral breast so that appropriate management can be undertaken. There is no information to support the use of MRI in addition to mammography for this purpose, and bilateral mammography is the preferred approach. A third potential goal is to assess patients for metastatic disease. The primary goal of therapy for metastatic breast cancer is palliation and prevention of symptoms. Randomized trials failed to show a benefit for routine blood tests or whole-body imaging to facilitate this goal or prolong survival. The preferred approach is regular history and physical examination and education of patients about symptoms that might suggest distant recurrence. Breast cancer survivors also should undertake a program of age-appropriate general health measures (e.g., pelvic examination, Pap smear, colon cancer screening, etc.). In addition, a diagnostic evaluation should be undertaken to investigate any suspicious symptoms or findings on physical examination in a survivor of early-stage breast cancer.

5. Multiple hereditary cancer syndromes and their associated genes have been identified. In addition to *BRCA1* and *BRCA2* germline mutations, germline mutations in which gene can predispose to breast cancer?

A. *p53*
B. *RET*
C. *APC*
D. *VHL*
E. *HER2*

Answer: A Germline mutations of the *p53* tumor suppressor gene define the Li-Fraumeni hereditary cancer syndrome, which is characterized by predisposition to multiple types of cancer, including breast cancer. Germline mutations of the *RET* gene are associated with multiple endocrine neoplasia (MEN) syndrome 2; its hallmarks are medullary thyroid cancer, pheochromocytoma, and hyperparathyroid gland abnormalities. Inherited mutations of the *APC* tumor suppressor gene characterize familial adenomatous polyposis of the colon and predispose to colon cancer but not breast cancer. Mutated *VHL* is seen in a variety of benign and malignant tumors, including clear cell renal cancers and breast cancer. The *HER2* gene is amplified in 15 to 20% of breast cancers; this somatic change is associated with sensitivity of the tumor to *HER2*-targted therapy; germline mutations of the *HER2* gene have not been described.

GYNECOLOGIC CANCERS

DAVID SPRIGGS

GENERAL CONSIDERATIONS

The role of the internist or primary care practitioner in the care of women with gynecologic cancers has three important components: awareness and prompt diagnosis of gynecologic cancers, primary care of the patient with active cancer, and care and surveillance of cancer survivors. Diagnosis of these cancers relies on both the collection of appropriate clinical history and routine gynecologic examination. None of these malignancies are common, but in every case, early detection and treatment leads to superior outcomes. Both demographic trends and the increased effectiveness of cancer treatment will contribute to a growing population of cancer survivors receiving care in the non-oncologist's practice.

CERVICAL CANCER

EPIDEMIOLOGY

Cervical cancer is an important worldwide health problem, often affecting younger women in the prime of life. Newly diagnosed cervical cancer will affect over 500,000 women annually and will lead to over 250,000 deaths, making it the third most common cancer in women around the world. Because of the long natural history of premalignant and early cervical cancer, annual cytologic screening (Pap smear) has dramatically reduced the incidence of advanced cervical cancer in the developed world and areas with good medical infrastructure. Cervical cancer remains an important cause of cancer death in the developing world, often striking young women in their most productive years. It is primarily a disease afflicting patients of lower socioeconomic status whose access to advanced medical care is limited. The overall 5-year survival rate for cervical cancer is approximately 67% in the United States (~12,000 new cases and roughly 4000 deaths in 2014) but depends on the group prevalence of annual screening to detect early-stage disease.[1] Younger women and white women have better outcomes than older women and black and Hispanic women based on many factors, including early diagnosis of localized cancers. Other factors linked to higher incidence of cervical cancer include age of first intercourse, parity (more live births linked to higher risk), current cigarette smoking, and male human papillomavirus (HPV)-related factors. Regions with a higher frequency of penile cancer and lower rates of male circumcision have a higher incidence of cervical cancer diagnoses. High prevalence of other sexually transmitted diseases is also a known risk factor, including *Chlamydia trachomatis* and herpes simplex virus infections. Finally, host immunity appears to play a major role. Both human immunodeficiency virus (HIV) infection and immune suppression related to transplantation are associated with dramatic increases in the incidence of cervical cancer.

PATHOBIOLOGY

Infection with specific, carcinogenic strains of HPV has been established as the necessary causal event for nearly all cervical cancer.[2] This includes both the most common squamous cell cancers (85%) and the less common, more difficult to detect, adenocarcinomas. Not all HPV strains are linked to cervical cancer, and the most common cancer-related subtypes include 16, 18, 32, 33, 35, 45, 52, and 58. Although the prevalence of the genotype will show substantial regional variation, over 70% of all cervical cancers can be linked to HPV 16, 18, and 45. Many other HPV strains can cause infection but will not lead to cervical cancer. HPV infection tends to occur soon after sexual initiation, and in most women will be cleared by the immune system within 24 months. In some cases the HPV DNA is incorporated into the host DNA and can continue to produce viral proteins (persistence). Often the HPV DNA is silenced and will go through a period of latency but can be reactivated later. The HPV protein E7 mediates immortalization through abrogation of the G1/S transition through interaction with the Rb protein. Other targets of E7 include a variety of cyclin-dependent kinases and cyclins that are critical for cell cycle regulation. The E6 protein binds to p53 and promotes its degradation, leading to decreased capacity for DNA damage repair. E6 also upregulates the cellular telomerase complex and contributes to immortalization of HPV-infected epithelial cells. As a consequence of inactivation of Rb and p53, there is loss of cell cycle regulation and a variety of subsequent mutations appear to accumulate. Mutational load appears to play a dominant role in the eventual development and progression of cervical cancer.

SCREENING

HPV infection of cervical epithelial cells leads to a failure of cellular differentiation and to cytologic abnormalities of the cervical epithelium referred to as cervical intraepithelial neoplasia (CIN). Whereas early, or low-grade, CIN often resolves, higher grades of CIN (CIN 2/3) appear to be linked to viral integration into host DNA and a failure to clear the infection. Persistent CIN can be detected by Pap cytologic testing during its long preinvasive phase, and this fact has led to the success of screening strategies in developed countries. Current recommendations mandate initiation of cytologic (Pap) testing at age 21 and every 2 years until age 30, when women with persistently negative screening tests can be screened every 3 years until age 65.[3,4] For women in the 30- to 65-year age group, a combined screening strategy of cytologic and HPV testing is preferred. The combination of HPV testing and

liquid-based cytology has a sensitivity of 96.7%; patients testing positive for HPV 16/18 should all be referred for colposcopy, regardless of their cytologic result. At age 65, women with multiple negative cytologic screening tests may discontinue screening. Any woman with a cytologic screen revealing CIN 2 or other abnormalities should be referred to a gynecologist for colposcopy and appropriate subsequent management. CIN 2/3 implies probable viral integration, so a woman with a history of CIN 2/3 should undergo more frequent and extended screening.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Early cervical cancer is generally asymptomatic, and thus detection is highly dependent on screening and routine gynecologic care. In advanced stages, patients may present with vaginal discharge or bleeding, pelvic pain, or abnormalities of bowel, bladder, or sexual function. The diagnosis of cervical cancer is usually based on positive cytologic status and direct inspection by vaginal speculum examination. Early cervical cancers are detected primarily by colposcopy and direct biopsy. The staging of cervical cancer is based on both expert clinical evaluation of resectability and imaging studies of both the pelvis and potential sites of distant metastases (lymph nodes, lungs, and abdominal sites).

TREATMENT

Rx

The primary treatment of localized cervical cancer is stage dependent. Staging of cervical cancer depends on the clinical evaluation of a skilled gynecologic oncologist; the International Federation of Gynecology and Obstetrics (FIGO) staging system is summarized in Table 199-1. In general, treatment of early-stage cervical cancer is exclusively surgical. The appropriate procedure will depend on patient age, comorbidities, stage, and tumor size. Radical hysterectomy with nodal dissection is the most common procedure, although younger patients with low risk for metastatic disease may undergo simple hysterectomy or even radical trachelectomy for highly selected patients who desire preservation of fertility. Patients with low-stage cervical cancer who have certain high-risk pathologic findings after surgery may benefit from radiation or chemotherapy.

There is some variability in treatment recommendations for patients with FIGO stage IB to IIA. Younger women with smaller tumors may be offered radical hysterectomy, whereas bulkier tumors and older patients may be better served by definitive chemoradiation. Patients with FIGO stage IIB to IV should all be treated with combinations of cisplatin and external beam radiation.[■] It is important to note that the combination of cisplatin and external beam radiation can provide an opportunity for cure and long-term survival, even in stage IV cancer of the cervix.

Patients with recurrent cancer of the cervix or patients with distant metastases at diagnosis are very rarely curable. Death is usually related to local recurrence, but distant metastatic spread to the lung, peritoneum, or bone is also common in cervical cancer. Platinum-based chemotherapy remains the mainstay of palliative treatment. The addition of bevacizumab, a humanized anti-vascular endothelial growth factor (VEGF) monoclonal antibody, to combination chemotherapy in patients with recurrent, persistent, or metastatic cervical cancer has been associated with an improvement of 3.7 months in median overall survival.[■] Recurrent or persistent tumors within the prior radiation field are particularly difficult to manage with chemotherapy. Local problems such as pain, bleeding, and fistulas between the bladder, vagina, and bowel are common in the advanced stages of this disease.

TABLE 199-1 APPROACH TO CERVIX CANCER BY STAGE*

STAGE	BRIEF DEFINITION	USUAL TREATMENT
0	Carcinoma in situ	Conization, hysterectomy
IA1	Microscopic stromal invasion < 3 mm	Conization, hysterectomy
IA2	Microscopic stromal invasion 3 to 5 mm	Radical hysterectomy
IB1	Visible lesion < 4 cm in greatest dimension	Radical hysterectomy
IB2	Visible lesion > 4 cm in greatest dimension	Chemoradiation
IIA	Tumor beyond the uterus, no parametrial involvement	Radical hysterectomy (selected)
IIB	Tumor beyond the uterus with parametrial extension	Chemoradiation
IIIA	Tumor involves lower third vagina but no pelvic wall extension	Chemoradiation
IIIB	Tumor extends to pelvic wall or hydronephrosis or regional lymph nodes	Chemoradiation
IVA	Involvement of mucosa of bowel or bladder	Chemo-radiation
IVB	Distant metastatic disease	Chemotherapy only

*Cervical cancer is staged clinically and not by either radiographic or pathologic findings. Chemoradiation generally includes weekly cisplatin treatment. Metastatic disease chemotherapy is generally based on cisplatin doublet treatment.

PROGNOSIS AND CARE OF SURVIVORS

Patients with a history of CIN 2/3 or other noninvasive disease require regular cytologic examinations, because the onset of cancer in patients with HPV 16/18 infection can occur years after primary infection. Early-stage cancer of the cervix is highly curable. Although perioperative complications can occur for any major operation, late complications of radical hysterectomy are not common but may include lymphedema and persistent bladder or rectal dysfunction. Patients with more advanced stage disease appropriately treated with chemoradiation combinations have long-term survival rates from 30 to over 80% percent, based on stage and underlying health. The late complications of chemoradiation are similar but probably more common, affecting 5 to 10% of survivors. Fistulas can occur between pelvic organs, including bladder, vagina, small bowel, and rectum. Other bladder problems may include urgency, incontinence, and chronic cystitis with loss of bladder capacity. Rectal problems include pain, diarrhea or constipation, urgency, and incontinence. Skeletal complications can include pelvic insufficiency fractures, associated with pain in as many as 10% of patients after radiation. Vaginal stenosis, dryness, and dyspareunia are common but usually can be managed with vaginal dilators and appropriate lubricants. Late complications of cisplatin-based chemotherapy include neuropathy, as well as renal insufficiency with chronic wasting of potassium and magnesium. Multimodality therapy regimens including radiation, surgery, and chemotherapy pose a higher risk for late complications and impaired patient quality of life decades after primary curative treatment.

PREVENTION

Our understanding of the pathobiology of HPV-derived cervical cancer supported the development of vaccines for the prevention of the most common oncogenic subtypes of HPV infection (Chapter 373). There are now licensed vaccines that immunize against HPV 16, 18, and selected other high-risk types. They are both safe and effective in substantially reducing the risk for cervical dysplasia and carcinoma.[■■] HPV vaccines require administration before sexual activity and can be highly effective in reducing the risk for cervical cancer. Both the approval trials and subsequent follow-up trials reveal a high level of safety and durable type-specific immunity that seems to persist for more than 5 years after a series of three initial vaccinations.[■] Additional HPV type coverage may eventually be available, but it is already clear from population-based studies that the vaccine can reduce the incidence of precursor lesions such as cervical dysplasia. Beyond immunization, prevention is absolutely linked to regular screening for early HPV-related lesions and appropriate management during the premalignant phase of the disease.

ENDOMETRIAL CANCER

EPIDEMIOLOGY

Endometrial cancer arises from the epithelium of the uterine lining, in distinction to uterine sarcomas that have their tissue of origin in the smooth muscle of the myometrium. Endometrial cancer is the most common gynecologic cancer in the United States, with over 52,000 new cases each year. Death from endometrial cancer occurs in approximately 8600 women each year. The risk factors for endometrial cancer include advancing age, estrogen exposure, obesity, and multiparity. As populations age across the world, the incidence of endometrial cancer is generally rising. The median age for the development of endometrial cancer is 60 years, and most endometrial cancers are diagnosed after age 50. Exposure to exogenous or endogenous estrogens appears to be a strong risk factor. Early menarche, late menopause, nulliparity, and unopposed estrogen in hormone replacement therapy are all implicated in higher endometrial cancer risk. Obesity is associated with higher levels circulating estrogens related to peripheral conversion of androstenedione to estrogen. Even the low rates of tamoxifen (a selective estrogen receptor modulator)-induced endometrial cancer are probably related to weak estrogenic effects on the endometrium.

PATHOBIOLOGY

Endometrial cancers can be divided into two large categories for understanding risk and biology. The more common tumors (type 1 cancers; 85%) are distinguished by endometrioid histology, a more differentiated grade, and a relationship to unopposed estrogen exposure. These type 1 malignancies tend to present as stage I or II cancers (confined to the uterus) and generally have a better prognosis than the type 2 cancers. They often retain expression of progesterone receptors.[5] On a molecular level, these tumors are more likely to be diploid, have wild-type *p53,* and be associated with loss of *PTEN* and microsatellite instability. In contrast, type 2 endometrial cancers are poorly differentiated, often have serous or clear cell histology, and often manifest at advanced stages with higher risk for dissemination. At the molecular level, type 2 endometrial cancers are aneuploid, carry mutations or loss of *p53* and lack *PTEN* deletion or other abnormalities of the PI3 kinase/AKT pathway.[6]

Most endometrial cancers are sporadic, but small percentages (3-5%) of type 1 cancers are associated with a cancer family history consistent with Lynch syndrome (hereditary nonpolyposis, colorectal cancer [HNPCC]). This familial cancer syndrome is associated with early-onset colon, ovary, renal, and endometrial cancers, related to germline mutations in one of the mismatch repair genes *MLH1, MSH2,* and *MSH6*. The development of endometrial cancer before 50 years of age with an appropriate family history or histologic appearance should prompt genetic testing of the patient, to guide both proband and family preventive management.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The 80% survivorship in endometrial cancer is predominantly related to the high likelihood of detection while the cancer is confined to the uterus. Abnormal uterine bleeding in postmenopausal women always should be regarded as suspicious. Abnormal vaginal discharge or nonspecific gastrointestinal symptoms also may be present at the time of diagnosis. It is important to recall that the routine Pap smear is not an appropriate diagnostic procedure to exclude endometrial cancer. The classic dilatation and curettage (D&C) has largely been replaced by an office endometrial biopsy. The D&C and hysteroscopy are now usually reserved for uterine bleeding problems that are difficult to diagnose. Common sites of spread for endometrial cancer at the time of diagnosis include pelvic or periaortic lymph nodes, ovary, and peritoneal implants. The recently revised FIGO staging system for endometrial cancer is shown in Table 199-2.

TABLE 199-2 APPROACH TO ENDOMETRIAL CANCER BY STAGE*

STAGE	BRIEF DEFINITION	USUAL TREATMENT
IA G1/2	Invasion to less than half the myometrial thickness	TAH and BSO, no XRT
IA G3	Invasion to less than half the myometrial thickness, poorly differentiated, serous cancer	TAH and BSO, consider chemotherapy, no XRT
IB G1/2	50% or more invasion of myometrial thickness	TAH and BSO, no XRT
IB G3	50% or more invasion of myometrial thickness, poorly differentiated	TAH and BSO, consider chemotherapy, no XRT
II	Uterine and cervical involvement	TAH and BSO, consider VBT
IIIA	Invades corpus serosa or adnexa	TAH and BSO, tumor-directed chemo-XRT and chemotherapy
IIIB	Vaginal or parametrial invasion	TAH and BSO, tumor-directed chemo-XRT and chemotherapy
IIIC1	Pelvic lymph node involvement	TAH and BSO, tumor-directed chemo-XRT and chemotherapy
IIIC2	Paraaortic lymph node involvement	TAH and BSO, tumor-directed chemo-XRT and chemotherapy
IVA	Invasion of bowel or bladder	TAH and BSO, tumor-directed chemo-XRT and chemotherapy
IVB	Distant metastatic disease	Chemotherapy only

*Endometrial cancer (FIGO 2009) staging is based on pathologic findings. Stages I and II endometrial cancer do not show a survival benefit from adjuvant radiation therapy. High-risk disease may benefit from adjuvant chemotherapy, but the studies are ongoing. For stage III and IV disease, complete debulking is preferred and platinum-based chemotherapy is generally needed. The use of volume-directed radiotherapy for gross residual disease is under investigation.
TAH and BSO = total abdominal hysterectomy and bilateral salpingo-oophorectomy ; XRT = radiation therapy; VBT = vaginal brachytherapy irradiation.

TREATMENT Rx

For the vast majority of patients with endometrial cancer, surgical resection represents the primary approach to management. In many cases, surgery resection (total hysterectomy with bilateral salpingo-oophorectomy, lymph node assessment) will be sufficient for both staging and treatment. Laparoscopic or robotic surgery has replaced open hysterectomy in many situations and appears to be a less morbid procedure. The role and extent of lymph node dissection and the use of sentinel node biopsy are areas of active surgical research. These advances continue to decrease the morbidity and length of hospitalization associated with primary surgical treatment. Following primary surgery, patients are staged by pathologic findings and stratified by risk factors to assign appropriate adjuvant therapy (see Table 199-2). Important risk factors for recurrence include stage (as determined by metastatic deposits, lymph node involvement, and depth of myometrial invasion), tumor histology, cytologic grade, and lymphovascular space involvement. General treatment approaches, by stage, are shown in Table 199-2. High-risk patients with stage 1 disease historically received adjunctive radiotherapy with significant reduction in local recurrence, but there is no evidence supporting a long-term survival impact of radiation. In type 2 endometrial cancers of serous histology, patients with even the lowest stage disease are at risk for distant recurrence and adjuvant chemotherapy is increasingly used.

For patients with higher stage (Stage III or IV) disease, complete surgical resection of gross disease appears to be the important determinant of survival. Platinum-based chemotherapy has been increasingly identified as effective and has replaced whole-abdominal radiation therapy as the mainstay of adjuvant therapy. Combinations of carboplatin and paclitaxel are generally well tolerated and will reduce recurrence in both high-risk and advanced stage disease groups. Even patients with substantial residual disease after surgery can sometimes achieve long remissions following platinum-based treatment. As with most solid tumors, recurrent cancer is difficult to cure. An exception appears to be local recurrence in patients who did not receive prior radiation. In that select group, radiation therapy should be given with curative intent. Otherwise, metastatic endometrial cancer can be managed with other systemic chemotherapies; the patterns of drug sensitivities are similar to those seen in recurrent ovarian cancer. Common sites of metastatic disease include the peritoneal cavity, liver, bone, lung, and occasionally brain. The comorbidities commonly associated with age and obesity can play an important role in the treatment choice for endometrial cancer. For patients whose overall health precludes a surgical procedure, curative radiation therapy can be offered. Although the long-term complications of definitive radiation treatment can be significant, it may be the best choice for patients with a compromised performance status.

PREVENTION

For sporadic endometrial cancers, the best prevention strategy appears to be a high degree of suspicion in the context of postmenopausal bleeding. Because of its location, these tumors are rarely asymptomatic late in their natural history and surgical extirpation is usually curative. In families with HNPCC, a total hysterectomy with bilateral salpingo-oophorectomy should be strongly considered in confirmed carriers who have completed their childbearing.

PROGNOSIS

Stage I and II endometrial cancers have an excellent cancer-specific prognosis. The common comorbidities of obesity and age (diabetes, hypertension, cardiovascular disease) complicate their overall management, but most of these patients will survive their cancers without recurrent disease. A substantial minority of patients with more advanced disease can still be cured at the time of primary therapy with combinations of surgery, chemotherapy, and sometimes radiation. Patients with persistent or recurrent disease will generally succumb to their illness within a 2- to 3-year period.

Late complications of surgical resection tend to be quite limited; some mild lymphedema is the most common late toxicity. Pelvic radiation has more reported late complications, including bowel, bladder, and sexual dysfunction, but recent advances in computer-based treatment plans may provide a better long-term risk-to-benefit ratio. The long-term adverse effects of adjuvant chemotherapy are rare but can include neuropathy and occasional renal injury.

UTERINE SARCOMAS

Gynecologic sarcomas most often arise in the uterus. The two most common malignant histologic types are carcinosarcoma of the uterus and leiomyosarcoma. Carcinosarcoma of the uterus is generally sporadic and is managed with a combination of complete surgical resection and adjuvant combination chemotherapy. Like endometrial cancer, even advanced stage carcinosar-

coma can be successfully treated by multimodality therapy, but recurrent disease is rapidly fatal. Leiomyosarcoma is a malignant smooth muscle tumor arising in the myometrium. Surgical resection is the mainstay of treatment, and the role of adjuvant chemotherapy or radiotherapy is unproved. Recurrent leiomyosarcoma can be treated with surgery (for localized disease) and chemotherapy.

CANCERS OF THE FALLOPIAN TUBE AND OVARY

EPIDEMIOLOGY

Ovarian cancer is a generic term for a family of diseases, including epithelial ovarian cancers, germ cell tumors of the ovary, and stromal cancers arising in the ovary. Cancer originating in the epithelium of the fallopian tube and ovarian surface is the fourth most common lethal cancer in American women. Approximately 22,000 new cases of ovarian cancers will be diagnosed each year, and because most are diagnosed at advanced stages, roughly 15,000 of these women will eventually die of their disease despite current therapy. Internationally, the incidence of ovarian cancer is highest in white women, and societies characterized by low parity, high-fat diets, and older populations. Ovarian cancer incidence is highest in North America and Europe, with lower incidence in Asia and Sub-Saharan Africa. In the United States, risk factors for ovarian cancer include family history of breast or ovarian cancer, early menarche, delayed menopause, and nulliparity, whereas oral contraceptives, aspirin, and breast-feeding are consistently shown to reduce risk. The median age of onset for ovarian cancer is approximately 60 years, although familial ovarian cancers occur roughly 10 years earlier than the sporadic form.

The indolent borderline tumors of the ovary (or tumors with low malignant potential) form a distinct group of epithelial ovarian cancers characterized by slow growth, rare metastatic spread, and a very different pattern of genetic alterations. These rare borderline tumors are primarily managed by surgical resection as necessary.

PATHOBIOLOGY

The histologic appearance (and accompanying genetic characteristics) allows epithelial ovarian cancers to be divided into serous, mucinous, clear cell, and endometrioid cancers. Although distinct on histologic and molecular grounds, the clinical management of these ovarian cancers has not yet diverged. High-grade serous ovarian cancer (HGSOC) comprises over 80% of the total number of patients and is the best characterized subset of ovarian tumors.[7]

At least 85% of ovarian cancers are sporadic and not associated with heritable abnormalities. However, approximately 10 to 15% of HGSOCs are linked to families carrying germline mutations that are inherited in an autosomal dominant fashion. The affected genes include *BRCA1* and *BRCA2,* which are critical cell cycle checkpoint regulators involved in the maintenance of DNA integrity, particularly in the homologous recombination pathway that is important for double-strand DNA repair. Certain ethnic populations founded from small ancestral populations such as the Ashkenazi Jews have a high frequency of mutations in these genes. In addition to these genes, other less common germline mutations in DNA repair–linked genes, including *CHEK2, ATM,* and *PALB2,* also can increase ovarian cancer risk. Affected members of these breast/ovarian cancer families have an increased risk for both early-onset breast and ovarian cancer and a high lifetime risk for these cancers. In sporadic ovarian cancers, these same genes may be lost through somatic mutation or gene silencing. It is now estimated that 50% or more of all ovarian cancers have a BRCA-like phenotype. Interestingly, *BRCA1/2* mutated ovarian cancer appears to have a superior survival compared to sporadic ovarian cancer.[8] Mutations in *BRCA1* or *BRCA2* confer a "collateral sensitivity" to cisplatin and other chemotherapy agents that induce double-stranded DNA damage. This collateral weakness has been targeted through the development of poly-ADP-ribose polymerase inhibitors. A smaller group of familial ovarian cancers is linked to families with Lynch syndrome (HNPCC) and impairment of DNA mismatch repair.

It is now accepted that most serous ovarian cancers arise through a well-defined series of mutations in the fallopian tube epithelium. Through sequential losses of the homologous DNA repair competence (via loss *of BRCA1, BRCA2, PALB2,* or other genes in the DNA repair pathway) and *p53* function, a defined sequence of events leads to serous carcinoma in situ and eventually carcinoma involving the ovary, lymph nodes, and peritoneal surfaces of the abdominal organs. The lifetime risk for women carrying an altered, high-risk allele for one of these genes may approach 70% or more, depending on environmental factors and modifying alleles when the second, nonpathogenic allele is lost.

CLINICAL MANIFESTATIONS

The diagnosis of ovarian cancer is complicated by the nonspecific nature of the initial symptoms.[9] Unfortunately, small adnexal masses are usually silent, but as a mass increases in size, symptoms include pelvic fullness, constipation, urinary frequency, and dyspareunia. In more advanced disease, the most common symptoms include fatigue, malaise, early satiety, bloating, and loss of appetite. Abdominal girth increase is often noted as malignant ascites accumulates.

DIAGNOSIS

Ultrasonography or computed tomography of the abdomen and pelvis will usually strongly support the diagnosis and lead to early surgical intervention. Although peritoneal fluid cytology can sometimes be diagnostic, percutaneous biopsy of adnexal masses should *not* be part of the initial workup, to avoid contamination of the peritoneal cavity by an otherwise confined tumor. CA-125 is a normal mucin antigen from MUC16 that is often found at abnormally high levels in the serum of patients with ovarian cancer (and sometimes in other cancers, including lung, pancreas, and uterus). However, serologic findings can be supportive but is not diagnostic in affirming or excluding the diagnosis of ovarian cancer because a variety of benign conditions also can elevate the CA-125 value.

TREATMENT

Rx

The treatment of ovarian cancer begins at the time of exploratory laparotomy, and adequate primary surgery remains the most important determinant of ovarian cancer survival. The surgery should be performed by a trained gynecologic oncologist in a highly experienced center to achieve the best outcome. Adequate initial surgery should include a total abdominal hysterectomy with bilateral salpingo-oophorectomy, omentectomy, and lymph node dissection. The upper abdomen and diaphragm should be inspected and biopsy samples obtained. Every effort should be made to remove any visible cancer. If complete resection is not achievable, cytoreduction to tumor bulk less than 1 cm is still useful and will permit intraperitoneal chemotherapy. If a successful complete resection is not possible, neoadjuvant chemotherapy and deferred surgery is an acceptable choice, although the projected survival is inferior to complete primary resection.

At the completion of primary surgery, a stage is assigned to the patient's tumor, based on extent of involvement as shown in Table 199-3. Using a combination of residual tumor bulk, tumor histology, grade and stage, one of four treatment plans is chosen, as illustrated in Figure 199-1. For stage IA or IB, grade 1 or 2 tumors, observation alone is the most acceptable treatment because these patients have a tumor recurrence rate below 5%. For all stage IC cancers, all grade 3 tumors, and the rare stage IIA tumors, the recommendation should be for three to six cycles of platinum-based chemotherapy. For stage IIB to IIIC tumors, with residual disease less than 1 cm in greatest dimension, six cycles of platinum-based intraperitoneal treatment is preferred, and bulkier disease or stage IV disease should receive intravenous platinum-based therapy.[10] These strategies are indicated in Table 199-3.

Following primary chemotherapy, reassessment of extent of residual disease by CA-125 and computed tomography is performed. For patients with persistent or resistant disease, other palliative chemotherapy can be offered but the outlook for such patients is quite poor. Patients in complete remission can be observed expectantly. Nearly all relapses will occur within a 3-year period, and regular quarterly follow-up is recommended in the United States. Over 75% of patients with advanced ovarian cancer will relapse in 12 to 30 months after diagnosis; although patients can be successfully treated for years, curative treatment is not yet available. Choice of chemotherapy at the time of recurrence depends on treatment-free interval, comorbidities, and residual toxicities. Active agents for retreatment include with carboplatin, gemcitabine, liposomal doxorubicin, pemetrexed, and bevacizumab.[11]

SCREENING AND PREVENTION

Although screening procedures have been aggressively sought for 25 years, there are no screening strategies that currently can be recommended, even for high-risk patients and definitely not for the general population of postmenopausal women. Combinations of serum CA-125 screening, transvaginal ultrasound testing, and panels of circulating serologic markers have all failed to achieve the requisite sensitivity and specificity in large-scale testing. Testing for germline and somatic mutations is increasingly important to

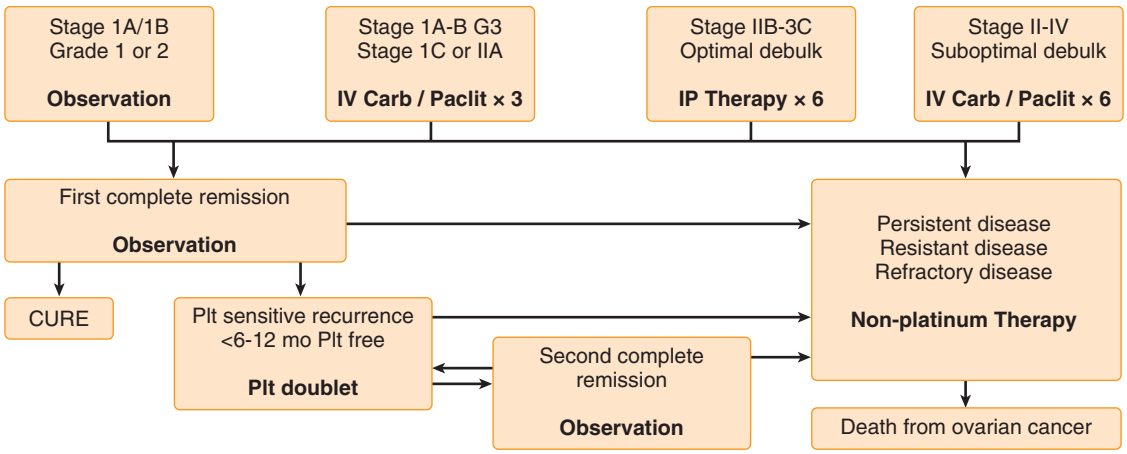

FIGURE 199-1. Ovarian cancer disease states model. The bulk of ovarian cancer management occurs after relapse. Primary therapy is allocated as indicated in the upper portion of the figure. The subsequent treatment depends on the elapsed time since the last exposure to a platinum complex drug. Patients with a platinum-free interval exceeding 6 to 12 months usually will receive a platinum-containing doublet and may attain a second (or greater) complete remision. Shorter intervals of platinum-free time will go on to nonplatinum single-agent treatment and have a median life expectancy of 1 to 2 years. Carb = carboplatin; Paclit = paclitexel; Plt = platinum.

TABLE 199-3 APPROACH TO OVARIAN CANCER BY STAGE*

FIGO STAGE	BRIEF DEFINITION	USUAL TREATMENT
IA G1/2	One ovary, no surface involvement	Staging laparotomy, observation only
IA G3	One ovary, no surface involvement; poorly differentiated	Staging laparotomy, chemotherapy for 3 cycles
IB G1/2	Both ovaries, no surface involvement	Staging laparotomy, observation only
IB G3	50% or more invasion of myometrial thickness, poorly differentiated	Staging laparotomy, chemotherapy for 3 cycles
IC	Surface involvement, positive cytology, or intraoperative spillage	Staging laparotomy, chemotherapy for 3 cycles
IIA	Extension to tubes or uterus	Staging laparotomy, chemotherapy for 3-6 cycles
IIB	Other pelvic organ extension	Staging laparotomy, chemotherapy for 3-6 cycles
IIC	Pelvic extension plus surface involvement, positive cytology, or intraoperative spillage	Staging laparotomy, chemotherapy with IP route preferred
IIIA	Microscopic tumor outside the true pelvis	Staging laparotomy, chemotherapy with IP route preferred
IIIB	Tumor < 2 cm in dimension outside the pelvis	Staging laparotomy, chemotherapy with IP route preferred
IIIC	Tumor > 2 cm outside the true pelvis or positive lymph nodes	Staging laparotomy, chemotherapy with IP route preferred
IV	Involvement of liver parenchyma, extension beyond the abdomen, cytology positive pleural effusion, inguinal lymph nodes	Chemotherapy

*Staging laparotomy includes total abdominal hysterectomy, bilateral salpingo-oophorectory and omentectomy. A pelvic lymph node dissection and upper abdominal exploration is also required. In well-staged, early-stage disease (IA/IB), the need for chemotherapy is based primarily on histologic grade. In advanced disease, optimal debulking to < 1 cm residual disease permits the use of intraperitoneal treatment (IP). All primary therapy should include a platinum drug and a second, non–cross-reactive drug such as paclitaxel or liposomal doxorubicin.

predict the response to therapy and prognosis.[12] The routine genetic testing of women with newly diagnosed ovarian cancer is recommended, in the appropriate circumstance, to discover families bearing *BRCA1/2* mutations who will require further monitoring.

Prevention strategies for ovarian cancer remain limited. Oral contraceptive use for 5 years or more can reduce ovarian cancer incidence by approximately 50%.[13] For high-risk women with mutations in *BRCA1* or *BRCA2*, a prophylactic salpingo-oophorectomy by age 40 can reduce ovarian cancer risk by more than 90% and will also reduce breast cancer incidence. Low-dose aspirin use has also been associated with reduced ovarian cancer risk.[14]

PROGNOSIS AND SURVIVOR MANAGEMENT

Women who remain disease-free for 3 years are likely to be cured of their ovarian cancer. Among patients with recurrence, median survival seems highly dependent on their initial stage and success of their primary debulking surgery. Patients with optimally debulked stage IIIC disease have a median survival in excess of 5 years, whereas patients with stage IV and patients with suboptimal debulking surgery have median survivals of 30 to 48 months. The terminal phase of ovarian cancer is generally characterized by progressive inanition and eventual intestinal obstruction. Ovarian cancer survivors may have intestinal adhesions from surgery and chronic neuropathy or electrolyte wasting from primary chemotherapy. Those ovarian cancer survivors living with chronic ovarian cancer are often able to continue to have productive work and family lives for several years after the diagnosis of ovarian cancer.

VULVAR CANCER

Cancer of the vulva is a relatively rare gynecologic malignancy that represents less than 5% of gynecologic cancer and is primarily seen in postmenopausal women. Like cervical cancer, the etiology of vulvar cancer is prior infection with HPV. Patients with vulvar cancer complain of itching, pain, and local discomfort, often arising in the presence of atrophic changes of the vulvar epithelium. The treatment of vulvar cancer is surgical excision with good margins and possible dissection of one or both inguinal lymph node regions in advanced disease. Recurrent or unresectable vulvar cancer also can be treated with external beam radiation, often in combination with cisplatin in radiation sensitizing doses.

UTERINE FIBROIDS

Uterine fibroids are the most common female pelvic tumor, with a prevalence as high as 40% during the reproductive years and as high as 70 to 80% by age 50. Fibroids, which are almost always benign monoclonal tumors, arise from disordered smooth-muscle cells in the uterine myometrium. A variety of somatic mutations, especially of the *MED12* gene on the X chromosome, have been described. Fibroids depend on estrogen and progesterone and usually shrink after menopause.[15] In early pregnancy and the postpartum period, however, they can grow rapidly.

The majority of fibroids are asymptomatic, but they can cause pelvic pressure, pain, and heavy uterine bleeding. Diagnosis is typically made by physical examination and confirmed by ultrasound. Although fibroids are not premalignant tumors, a uterine sarcoma can have similar symptoms at presentation.

Noninvasive, hormonally based anti-progesterone therapies such as oral ulipristal acetate (5 or 10 mg per day for 13 weeks) can reduce the size of fibroids, decrease dysfunctional uterine bleeding and pain, and improve overall quality of life. For persistent symptoms, surgical removal of the fibroid or of the uterus itself can be performed during laparotomy or by laparoscopic surgery. Power morcellation, a process by which the uterus is divided into smaller fragments that can be removed in stages laparoscopically, is no longer routinely recommended because of the small but finite risk of disseminating pieces of potentially malignant tissue found in a small percentage of fibroid uteruses.[16] Robotically assisted and laparoscopic hysterectomy have similar morbidity profiles, but the use of robotic technology results in

substantially higher costs. Other strategies for the treatment of symptomatic uterine fibroids include uterine artery embolization, transvaginal temporary uterine artery occlusion, and MRI-guided focused ultrasound.

OTHER GYNECOLOGIC CANCERS

Any structure of the müllerian tract can undergo malignant transformation. Other types of gynecologic cancer include germ cell tumors of the ovary (homologs of testicular cancer), stromal tumors of the ovary, and cancers of the vagina, vulva, and vulvar adnexa. These are all much less common than the tumors described earlier. Because of the rarity of these cancers, early referral to experts in gynecologic oncology is essential. Survivors of these rare forms of gynecologic cancer will share the residual side effects that affect survivors of cervical, endometrial, and ovarian cancers, such as potential alterations of bowel, bladder, and sexual function, as well as lymphedema and the consequences of early menopause.

REVIEW QUESTIONS

1. Which gynecologic cancer is responsible for the most deaths in the United States each year?

A. Cervical cancer
B. Endometrial cancer
C. Uterine sarcomas
D. Ovarian cancer
E. Vulvar cancer

Answer: D As noted in the chapter, endometrial cancer is more than twice as common as ovarian cancer, yet ovarian cancer is more likely to be discovered at an advanced stage. The number of deaths in the United States is roughly twice the number of endometrial cancer deaths. Cervix cancer is much more common in other parts of the world where vaccination and screening are less prevalent.

2. Which of the following women can stop routine cytologic screening for cervical cancer?

A. A 21-year-old woman immunized at age 19 against HPV
B. A 38-year-old woman who has completed her childbearing
C. A *BRCA1* carrier who underwent a risk-reducing salpingo-oophorectomy 5 years ago
D. A 48-year-old woman who underwent a total hysterectomy for benign uterine bleeding 3 years ago
E. A 26 year old graduate student with 3 prior negative Pap tests.

Answer: D The immunization for HPV needs to occur before sexual initiation and generally must occur in the early teens at the latest. HPV vaccination has no effect on patients previous infected with HPV. Neither pregnancy nor parity is a major risk factor for cervical cancer, and salpingo-oophorectomy has no benefit for this purpose. However, a woman who underwent a total hysterectomy has no cervical tissue and no risk.

3. Which endometrial cancer stage grouping includes patients most likely to receive a survival benefit from adjuvant whole-pelvic radiation therapy?

A. Stage IA, grade 1
B. Stage IB, grade 2
C. Stage IIIC1, grade 3
D. Stage IVB, grade 3
E. Stage IA, grade 3

Answer: C Patients with early-stage (stage I) disease will have decreased local recurrence rates, but no overall survival advantage has been demonstrated to date. A patient with stage III disease with positive pelvic nodes may benefit. Patients with stage IVB will not have disease that can be encompassed in a single field.

4. Which ovarian cancer patient can have postsurgical observation without chemotherapy?

A. Stage IA, grade 3 serous ovarian cancer
B. Stage IB, grade 1 serous ovarian cancer
C. Stage 1C, grade 2 cancer (based on positive peritoneal cytology)
D. Stage 2A, grade 1 optimally debulked ovarian cancer
E. Stage IIIA, endometrioid ovarian cancer

Answer: B Only stage IA or IB, grade 1 cancers are suitable for observation.

5. Which of the following is the most common complication of chemoradiation for cervical cancer?

A. Vascular insufficiency fracture of the pubic ramus
B. Transitional cell cancer of the bladder
C. Intermittent diarrhea
D. Chronic anemia
E. Rectovaginal fistula

Answer: C Diarrhea can be seen in 10% or more of patients following pelvic radiation. Insufficiency fractures occur less frequently, and radiation-induced tumors are quite rare.

TESTICULAR CANCER

LAWRENCE H. EINHORN

EPIDEMIOLOGY

Testicular tumors are relatively uncommon and account for only 1% of male malignancies in the United States. The incidence of testicular cancer is increasing globally, although mortality rates remain low.[1] The primary age group is 15 to 35 years for nonseminomatous tumors and a decade older for seminomas.

Male patients with a history of cryptorchidism have a 10- to 40-fold increased risk for the development of testicular cancer. The normally descended testis in these men is also at higher risk, suggesting a dysgenetic abnormality.

PATHOBIOLOGY

More than 95% of tumors of the testis originate from germ cells.[2] Germ cell tumors can be seminomas or nonseminomatous germ cell tumors. Seminomas are more likely to be confined to the testis (stage I) and small-volume metastases to the retroperitoneal lymph nodes are exquisitely sensitive to radiation therapy. Pure seminomas never have elevated serum α-fetoprotein (AFP) levels. Nonseminomatous germ cell tumors consist of embryonal cell carcinomas, choriocarcinomas, yolk sac tumors, or teratomas, alone or mixed with other elements. Teratomas do not secrete human chorionic gonadotropin (hCG) or AFP and do not usually metastasize; they grow by local extension and are completely resistant to radiation therapy and chemotherapy.

Most germ cell testicular cancers in adults are associated with the cytogenetic abnormality i12p—an isochromosome of the short arm of chromosome 12—which is a highly specific finding in germ cell tumors. Genome-wide associated studies (GWAS) have identified association with variants in several genes, most strongly with *KITLG*.[3] Sertoli cell tumors, Leydig cell tumors, and lymphomas are the most common non–germ cell tumors. In men older than 60 years, most tumors are non-Hodgkin lymphoma (Chapter 185), with a predilection for bilateral involvement.

CLINICAL MANIFESTATIONS

Most patients with testicular cancer are initially evaluated because of testicular pain or because of a mass in or enlargement of one testis. Others are asymptomatic, and the cancer is first detected during a routine physical examination. Less commonly, the diagnosis is made during an evaluation for infertility, in part because testicular cancer can cause oligospermia.

Metastatic spread is either lymphatic or hematogenous. Lymphatic metastases usually go initially to the ipsilateral retroperitoneal lymph nodes, where they may be associated with flank pain. Lymphatic metastases may continue in a superior direction to the posterior mediastinum and eventually to the left supraclavicular lymph nodes. A large retroperitoneal mass or a supraclavicular lymph node may be palpable on physical examination. Hematogenous spread usually occurs first to the pulmonary parenchyma bilaterally. Pulmonary symptoms such as chest pain, shortness of breath, dyspnea on exertion, coughing, or hemoptysis are seen only with extensive pulmonary metastases. Other sites of hematogenous spread include the liver, bone, or brain. Significant elevation of the serum hCG level may produce gynecomastia.

DIAGNOSIS

Patients with a palpable mass in the testis should be suspected of having testicular cancer, especially if there is a history of cryptorchidism. Other causes of testicular and scrotal abnormalities may be included in the differential diagnosis. Acute pain in the testis suggests torsion. Painful enlargement

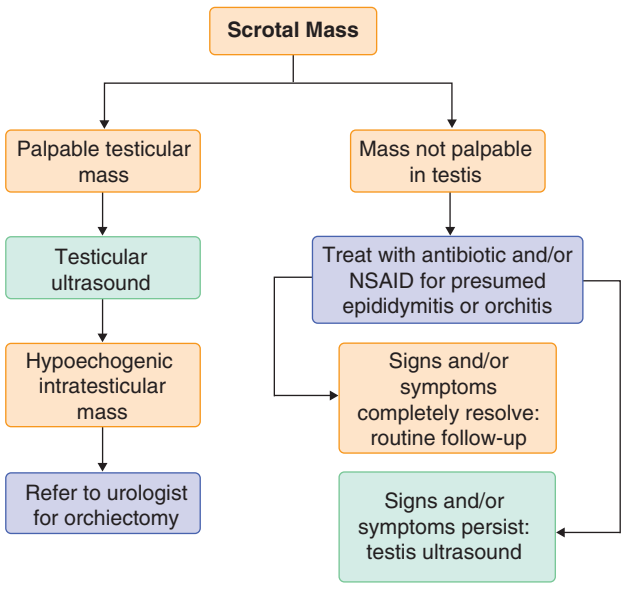

FIGURE 200-1. Management of a scrotal mass. NSAID = nonsteroidal anti-inflammatory drug.

may be due to a hydrocele, which may be caused by an underlying primary testicular malignancy. Pain and tenderness adjacent to the testis may be due to epididymitis or a varicocele. Tenderness of the testis itself on physical examination may reflect orchitis. However, an underlying neoplasm should always be considered.

Any testicular symptoms, including pain or a suspected mass, require evaluation. Testicular ultrasound is the test of choice in all suspicious cases. A hypoechogenic mass within the testis must be presumed to be testicular cancer and requires referral to a urologist (Fig. 200-1).

When orchiectomy reveals the diagnosis of testicular cancer, a staging evaluation is performed to determine the extent of disease and appropriate therapy. Clinical stage I disease is confined to the testis; stage II disease reflects spread to the retroperitoneal lymph nodes; and stage III is supradiaphragmatic disease, with either nodal metastases to the posterior mediastinum or supraclavicular region or hematogenous spread, especially to the lungs.

In addition to a full history and physical examination, serum hCG and AFP levels should be determined. Because the serum half-life is 1 day for hCG and 5 days for AFP, an AFP level of 1000 may take more than a month to normalize after orchiectomy, even if the tumor has been completely removed and there are no metastases. Imaging studies to define the extent of disease include abdominal and pelvic computed tomography (CT) and a chest radiograph. If the chest radiograph does not show pulmonary metastases, a chest CT scan should be performed. Bone scans and head CT scans can be reserved for patients with symptoms suggestive of osseous and central nervous system metastases, respectively.

PREVENTION AND TREATMENT

Rx

A careful testicular examination is a mandatory part of the physical examination in men, especially young men (Chapter 15), and is the key means of detecting tumors at an early stage.[4] With the patient lying supine or standing up, the testis is gently palpated with the thumb and second and third fingers; the entire anterior, posterior, and lateral surfaces of the testis should be examined. Men ages 15 to 34 years should be taught to perform the examination on themselves.[5]

Local and Regional Disease

Seminomas

Approximately 70% of seminomas are initially diagnosed at clinical stage I.[6] Although the cure rate with orchiectomy alone is 85%, treatment also can include 2000 cGy para-aortic irradiation or adjuvant carboplatin. The preferred option, however, is surveillance, which avoids unnecessary therapy in 85% of patients as well as potential late consequences of therapy.

Twenty percent of patients with seminoma are initially found to have stage II disease (positive abdominal CT scan). For these patients, radiation therapy has a 90% cure rate; in patients who are not cured by radiation therapy, subsequent combination chemotherapy (cisplatin combined with etoposide, with or without bleomycin) is usually curative. If the transverse diameter of the tumor is greater than 3 cm, if there are multiple anatomic levels of nodal metastases, or if stage III disease is present, the preferred initial treatment is cisplatin combination chemotherapy without irradiation; the cure rate is 90 to 100% unless there are non-pulmonary visceral metastases.[7]

Nonseminomatous Germ Cell Tumors

Management of clinical stage I nonseminomatous germ cell tumors begins with orchiectomy, which has a 70% cure rate. This is followed by either retroperitoneal lymph node dissection; one course of bleomycin, etoposide, and cisplatin (BEP); or close surveillance (which can detect metastases early and guide curative chemotherapy). Most relapses occur in the first year, during which meticulous surveillance should include history and physical examination, serum markers, and chest radiograph every 2 months and abdominal CT scans every 4 months. All studies are performed every 4 months during the second year, every 6 months during the third to fifth years of surveillance, and annually thereafter. However, abdominal CT scans are performed just every 6 months during the second year of surveillance, but annually in years 3-5, and then are discontinued. The physical examination should include palpation of the remaining testis, because patients have a 1 to 2% chance of developing a contralateral primary tumor. The major complication of retroperitoneal lymph node dissection is inadvertent severing of the sympathetic plexus, with resultant retrograde ejaculation or failure of ejaculation. Nerve-sparing retroperitoneal lymph node dissection can retain antegrade ejaculation in more than 95% of patients. Some centers advocate primary chemotherapy for high-risk clinical stage I disease (embryonal predominant with vascular invasion) with cisplatin combination chemotherapy, but surveillance is still an option in these patients.

For clinical stage II disease with persistently elevated serum markers or a transverse tumor diameter greater than 3 cm, chemotherapy is preferred. Other patients with stage II disease are treated with retroperitoneal lymph node dissection, often followed by close surveillance (as described earlier, but without abdominal CT scans) or adjuvant chemotherapy. Testicular cancer has a higher cure rate with surgery alone, despite nodal metastases, than any other cancer.

TABLE 200-1 DEFINITION OF POOR RISK DISEASE (ALL NONSEMINOMATOUS GERM CELL TUMOR)

Presence of any of the following:
- Human chorionic gonadotropin (hCG) > 50,000 mIU/mL
- α-Fetoprotein (AFP) > 10,000 ng/mL
- Non-pulmonary visceral metastases (e.g., bone liver, brain)
- Primary mediastinal nonseminomatous germ cell tumor

Chemotherapy for Disseminated or Persistent Disease

The combination of bleomycin, etoposide, and cisplatin (BEP) repeated every 3 weeks for three or four courses cures 70% of patients with metastatic disease and is the standard chemotherapy for disseminated testicular cancer. Poor-risk disease (Table 200-1) has a 50 to 60% cure rate with standard three-drug therapy, intermediate-risk disease (hCG 5000 to 50,000 IU/mL or AFP 1000 to 10,000 ng/mL) has a 75% cure rate, and all other forms of metastatic disease (good risk) have a 90 to 100% cure rate. Approximately 60% of patients receiving chemotherapy have good-risk disease, and just three courses of BEP is an adequate duration of therapy.

In the 30% of metastatic germ cell tumors that are not cured by initial combination chemotherapy, the use of standard-dose salvage therapy (ifosfamide, cisplatin, and either vinblastine or paclitaxel)[8] or high-dose carboplatin and etoposide therapy, followed by peripheral blood stem cell transplantation, can cure 25 to 70% of refractory cases, depending on patient characteristics. Late relapse beyond 2 years from completion of chemotherapy occurs in 2 to 3% of patients with metastatic disease. This usually is manifested by a rise in serum AFP. Optimal approach is evaluation for site(s) of metastases and surgical resection if feasible.

PROGNOSIS

Sequelae in Long-Term Survivors

Testicular cancer is the most curable solid tumor, with a 10-year survival rate of more than 95%. However, the typically normal life expectancy of individuals with the disease who were treated at a young age has led to the emergence of significant morbidities.

Testicular cancer survivors, particularly those who were initially treated with a combination of chemotherapy and irradiation, are at increased risk for developing second malignancies. These may include a wide variety of solid tumors and hematologic malignancies. Etoposide and cisplatin are associated with cumulative dose-dependent development of myelodysplastic syndrome (Chapter 182) and secondary leukemia.[9] Patients are also at increased risk for developing metachronous contralateral testicular cancer.

Increased cardiovascular risk in long-term survivors manifests most prominently as hyperlipidemia (Chapter 206) and metabolic syndrome (Chapter 229). The risk for metabolic syndrome is especially increased in survivors with testosterone levels in the lowest quadrille.[10] The clinical significance of low-grade hypogonadism among testicular cancer survivors has not been well studied. Although 10-year paternity rate in testicular cancer survivors is reduced by 30% compared with that in the general population, the majority of individuals who attempt paternity after treatment will become biologic fathers without medical assistance. Other long-term complications in survivors may include peripheral neuropathy, ototoxicity, and chronic renal insufficiency.

REVIEW QUESTIONS

1. A 25-year-old man presents with a mass in his left testis, elevated hCG and α-fetoprotein, 10-cm retroperitoneal mass, and multiple bilateral pulmonary metastases. An orchiectomy revealed embryonal cell carcinoma + teratoma. He is treated with bleomycin + etoposide + cisplatin (BEP) and achieves a complete remission except for a persistent 3-cm retroperitoneal mass. This is subsequently resected and revealed mature teratoma. Seven years later, routine follow-up revealed an elevated serum α-fetoprotein of 150 ng/mL, normal hCG, and normal history and physical examination. His chest CT is normal, but abdominal CT revealed a left-sided pelvic mass measuring 5 cm in size. You now recommend:

A. Fine-needle aspiration of pelvic mass.
B. Chemotherapy with paclitaxel + ifosfamide + cisplatin (TIP).
C. Chemotherapy with vinblastine + ifosfamide + cisplatin (VeIP).
D. High-dose chemotherapy with peripheral blood stem cell support.
E. Surgical resection of pelvic mass.

Answer: E This patient has experienced a late relapse. This happens in approximately 2% of patients seemingly cured with initial chemotherapy. Typically, this is first diagnosed during annual follow-up after 5 years from initial chemotherapy and is manifested by an elevated serum AFP and nodal metastasis. The optimal curative strategy is surgery, not salvage chemotherapy.

2. Using the International Staging System for non-seminomatous germ cell tumors, all of the following constitute advanced disease (poor risk) *except:*

A. Histology of pure choriocarcinoma.
B. Serum α-fetoprotein greater than 10,000 ng/mL.
C. Presence of osseous metastases.
D. Primary mediastinal yolk sac tumor with 8-cm anterior mediastinal mass as only evidence of disease.

Answer: A Histology is not an independent prognostic variable. Any non-pulmonary visceral metastasis, AFP > 10,000 or any primary mediastinal non-seminomatous germ cell tumor constitutes poor-risk disease.

3. A 27-year-old man underwent a left orchiectomy with pathologic findings revealing embryonal cell carcinoma. His pre-orchiectomy serum hCG was 90 MIU/mL and AFP 130 ng/mL. Chest CT was normal, as was physical examination post-orchiectomy. Abdominal CT revealed a 3-cm left para-aortic node. One week later, hCG normalized, but AFP rose to 180 ng/mL. The correct recommendation would be:

A. Repeat serum AFP 2 weeks later
B. Fine-needle biopsy of left retroperitoneal lymph node
C. Three courses of bleomycin + etoposide + cisplatin (BEP)
D. Four courses of bleomycin + etoposide + cisplatin (BEP)

Answer: C He has a rising serum AFP and requires appropriate chemotherapy for his good-risk metastatic disease with three courses of BEP.

4. Which statement about testicular seminoma is incorrect?

A. Slight elevation of AFP may be present
B. Slight elevation of hCG may be present
C. Most patients present with clinical stage I disease
D. Radiation therapy is an option for clinical stage II disease with abdominal nodes < 3 cm

Answer: A Most seminomas are clinical stage I. Slight elevations in serum hCG may be observed, but seminomas are never associated with elevated AFP. Radiation therapy remains an option for clinical stage II seminoma.

5. A 35-year-old patient presents with an enlarged left supraclavicular lymph node. An excisional biopsy and complete resection reveals pure seminoma. A testis ultrasound is abnormal, disclosing a small tumor in the right testis. Orchiectomy pathology is also determined to be pure seminoma. Abdominal and pelvic CT scans abnormal with a 2- × 2-cm inter-aortocaval node. Chest CT is normal. What is the preferred treatment for this patient?

A. Radiotherapy to abdominal nodes and left supraclavicular fossa
B. Radiotherapy to abdominal nodes
C. Retroperitoneal lymph node dissection (RPLND)
D. Chemotherapy with BEP × 3

Answer: D He has stage III seminoma. The left supraclavicular metastasis was removed, but this is still stage III disease and radiotherapy is inappropriate. RPLND is never an option for initial therapy of any stage of seminoma.

201 PROSTATE CANCER

ERIC J. SMALL

DEFINITION

Prostate cancer is the most common noncutaneous malignant neoplasm in men in the United States, where it results in about 32,000 deaths each year, making it the second most common cause of cancer death in men. Prostate cancer is a single histologic disease with marked clinical heterogeneity ranging from indolent, clinically unimportant disease to a virulent, rapidly lethal phenotype.

EPIDEMIOLOGY

The incidence of clinically diagnosed prostate cancer reflects the effects of screening by the prostate-specific antigen (PSA) assay. Before PSA testing was available, about 19,000 new cases of prostate cancer were reported each year in the United States; this number reached 84,000 by 1993 and peaked at about 300,000 new cases in 1996. Since 1996, the reported annual incidence of prostate cancer in the United States has declined to about 190,000, a number that may more closely estimate the true incidence of clinically detectable disease. The death rate from prostate cancer has declined by about 1% per year since 1990. The age-specific decrease in the mortality rate has been greatest in men younger than 75 years. Men older than 75 years still account for two thirds of all prostate cancer deaths. Whether this decline is due to early detection (screening) or to improved therapy has not been established.

Risk factors for prostate cancer[1] include increasing age, family history, African American ethnicity, obesity, and dietary factors. Epidemiologic studies have suggested that nutritional factors such as reduced fat intake and increased soy protein may have a protective effect against the development of prostate cancer. The incidence of prostate cancer among African Americans is nearly twice that observed among white Americans. Prostate cancer is diagnosed in African Americans at a more advanced stage, and disease-specific survival is lower in African Americans. The relative contributions of biologic, genetic, and environmental differences, as well as differences in health care access, are not well established. Prior vasectomy and benign prostatic hypertrophy (BPH) (Chapter 129) do not increase the risk. Prostatic intraepithelial neoplasia, particularly when it is high grade, is recognized as a premalignant lesion, so its presence on biopsy increases the likelihood of subsequent malignancy.

PATHOBIOLOGY

Prostate cancer is more common among relatives of men with early-onset prostate cancer. However, although many genetic abnormalities with both loss and gain of function have been identified, none occur in more than 10% of patients with prostate cancer. For example, germline mutation (G84E) of $H0XB_{13}$, a homeobox transcription factor gene that is important in prostate development, has been associated with significantly increased risk of hereditary prostate cancer.[2] Consistent patterns of changes associated with an increased likelihood for the development of prostate cancer have not been identified.

Approximately half of prostate cancers demonstrate genetic rearrangements,[3,4] including fusion of promoters or enhancers of androgen-responsive genes such as *TMPRSS2* (transmembrane protease, serine 2) with oncogenic *ETS (E-26)* transcription factors such as *ERG (ETS-related gene)*. Gene fusions lead to overexpression of these oncogenic transcription factors.

Testosterone is required for maintenance of a normal, healthy prostatic epithelium, but it is also a prerequisite for the development of prostate cancer. Prostate cancers express robust levels of androgen receptor (AR), and signaling through the AR results in growth, progression, and invasion of prostate cancer. Inhibition of signaling, typically by the surgical or pharmacologic reduction of testosterone levels, results in prostate cancer apoptosis and involution. Ultimately, however, androgen-deprivation therapy (ADT) loses clinical efficacy. The biologic events surrounding the clinical development of "androgen-deprivation–resistant prostate cancer," also called castration-resistant prostate cancer (CRPC), are not well delineated, but amplification of the AR, which is a common event in these patients, presumably makes the cancer sensitive to minute levels of androgen or other ligands of the AR. Androgens produced through accessory pathways by the adrenal gland and upregulation of enzymatic regulators of androgen synthesis pathways within CRPC cells provide additional sources of ligand. The identification of AR splice variants that are constitutively active and ligand independent raises this as a potential mechanism by which true hormone resistance develops. The development of resistance to potent androgen signaling inhibition may be associated with the emergence of aggressive, lethal CRPC with neuroendocrine differentiation. Whether this reflects a process of transdifferentiation or clonal selection is not known.

CLINICAL MANIFESTATIONS

Most patients with early-stage, organ-confined disease are asymptomatic. Obstructive voiding symptoms (hesitancy, intermittent urinary stream, decreased force of stream) generally reflect locally advanced disease with growth into the urethra or bladder neck, although these symptoms can be indistinguishable from BPH (Chapter 129). Locally advanced tumors can also result in hematuria and hematospermia. Prostate cancer that has spread to the regional pelvic lymph nodes occasionally causes edema of the lower extremities or discomfort in the pelvic and perineal areas. Metastasis occurs most commonly to bone, where it is frequently asymptomatic, but it can also cause severe and unremitting pain. Bone metastasis can result in pathologic fractures or spinal cord compression. Although visceral metastases are rare as presenting features of prostate cancer, there is an increasing incidence of pulmonary, hepatic, pleural, peritoneal, and central nervous system metastases that appear to be treatment emergent.

DIAGNOSIS

More than 60% of patients with prostate cancer are asymptomatic, and the diagnosis is made solely because of an elevated screening PSA level. A palpable nodule on digital rectal examination (DRE), which is the next most common clinical presentation, generally prompts biopsy. Much less commonly, prostate cancer is diagnosed because of advanced disease that causes obstructive voiding symptoms, pelvic or perineal discomfort, lower extremity edema, or symptomatic bone lesions.

Although the DRE has a low sensitivity and specificity for the diagnosis of prostate cancer, biopsy of a nodule or area of induration reveals cancer 50% of the time, suggesting that prostate biopsy should be undertaken in all men with palpable nodules. The PSA level has a far better sensitivity but a low specificity because conditions such as BPH and prostatitis can cause false-positive PSA elevations (Chapter 129). By use of a PSA threshold of 4 ng/mL, 70% to 80% of tumors are detected. Far greater accuracy is achieved with age-specific PSA thresholds. Thus, for men age 40 to 49 years, a PSA greater than 2.5 is considered abnormal; for men 50 to 59 years, a PSA greater than 3.5 is abnormal; for men 60 to 69 years, a PSA greater than 4.5 should prompt further evaluation; and patients age 70 to 79 years should have a PSA of 6.5 or less. The positive predictive value for a single PSA level above 10 ng/mL is greater than 60% for cancer, but the positive predictive value for a PSA level between 4 and 10 ng/mL is only about 30%. Assays of the PSA fraction that circulates unbound (percentage of free PSA) may help distinguish prostate cancer from benign processes; in patients with PSA levels of 4 to 10 ng/mL, the percentage of free PSA appears to be an independent predictor of prostate cancer, and a cutoff value of free PSA less than 25% can detect 95% of cancers while avoiding 20% of unnecessary biopsies.

Transrectal ultrasonography with biopsies is indicated when the PSA level is elevated, when the percentage of free PSA is less than 25%, or when an abnormality is noted on DRE. Extended field specimens (preferably up to six biopsies on each side) are generally obtained. Seminal vesicles are sampled in high-risk patients. A bone scan is warranted only in patients with PSA levels above 10 ng/mL, and abdominal and pelvic computed tomography or magnetic resonance imaging is usually unrevealing in patients with PSA levels below 10 to 20 ng/mL.

The prognosis of patients with prostate cancer correlates with histologic grade and extent (stage) of disease. More than 95% of prostate cancers are adenocarcinomas, and multifocality is common. Although uncommon, a neuroendocrine variant is increasingly being identified, because of increased awareness but also as a manifestation of the development of resistance to potent androgen signaling inhibition. The histologic (Gleason) grade of adenocarcinomas range from 3 to 5. The Gleason score, which refers to the sum of the two most common histologic patterns seen on each tissue specimen, ranges from 6 (3 + 3) to 10 (5 + 5). In general, tumors are classified as

well differentiated (Gleason score of 6), of intermediate differentiation (Gleason score of 7), or poorly differentiated (Gleason score of 8-10). Neuroendocrine differentiation is a histologic diagnosis that is confirmed by staining for chromogranin A or synaptophysin.

Clinical stage is defined by the extent of disease based on the physical examination, imaging studies, and pathology. Stage T1 is nonpalpable prostate cancer detected only on pathologic examination, noted either incidentally after transurethral resection for benign hypertrophy (T1a and T1b) or on a biopsy specimen obtained because of an elevated PSA level (T1c, the most common clinical stage at diagnosis). Stage T2 is a palpable tumor that appears to be confined to the prostate gland (T2a in one lobe or T2b in two lobes), and stage T3 is tumor with extension through the prostatic capsule (T3a if it is focal or T3b if seminal vesicles are involved). T4 tumors are those with invasion of adjacent structures, such as the bladder neck, external urinary sphincter, rectum, levator muscles, or pelvic sidewall. Nodal metastases can be microscopic and detectable only by biopsy or lymphadenectomy, or they can be visible on imaging studies. Distant metastases are predominantly to bone, but occasional visceral metastases occur.

PREVENTION

The precise role for screening remains controversial.[5-7] Currently, many organizations recommend screening with PSA, but the U.S. Preventive Services Task Force recommends against screening.[8] Of two large randomized screening trials using PSA levels, one reported a reduction in prostate cancer–specific mortality,[■] but neither found an overall reduction in mortality rate.[■■] Overall, PSA screening reduces prostate cancer death at 11 years by 21% (absolute reduction, 0.10 deaths per 1000 persons-years or 1.07 deaths per 1000 men) but not all-cause mortality.[■] Although overall mortality from prostate cancer has fallen during the screening era, there is no direct evidence that there is a causal relationship.[■] Screening of men at high risk for developing prostate cancer (family history and African Americans) has not been specifically tested. Randomized trials have shown that vitamins C and selenium are not effective in preventing prostate cancer,[9] and vitamin E supplementation increases prostate cancer by 17%.[10] The use of 5α-reductase inhibitors (both finasteride and dutasteride) unambiguously reduces the risk for development of prostate cancer.[■■] However, this approach has not been widely adopted, primarily because of attendant side effects, most notably sexual dysfunction.

TREATMENT Rx

Localized Prostate Cancer

Principles of Therapy

The principal therapeutic options for men with localized prostate cancer include (1) active surveillance[11]; (2) retropubic or perineal radical prostatectomy, with or without postoperative radiation therapy to the prostate margins and pelvis; (3) external-beam radiation therapy; and (4) brachytherapy (either permanent or temporary radioactive seed implants), with or without external-beam radiation therapy to the prostate margins and pelvis.

Treatment options require individualization, taking into account the patient's comorbidity, life expectancy, likelihood of cure, and personal preferences based on an understanding of the potential morbidity associated with each treatment. A multidisciplinary approach to integrate surgery, radiation therapy, and androgen deprivation is increasingly recommended. For higher risk patients with a greater likelihood of nodal micrometastases, androgen deprivation is often combined with radiation therapy encompassing both the prostate and the pelvis. In patients at extremely high risk of micrometastatic disease or with comorbidities, systemic therapy alone without concurrent local therapy may be appropriate.

Prostate-specific antigen screening has led to the early detection of a large number of nonpalpable tumors, for which conventional clinical means of staging are inadequate. Thus, less emphasis is being placed on clinical stage, and more emphasis is being placed on Gleason score, PSA values, and other predictors of outcome. Careful risk assessment is required to identify patients who are appropriate candidates for definitive local treatment.

Several studies have confirmed that serum PSA level, clinical stage, and biopsy Gleason score can be used to predict the final pathologic stage after prostatectomy and that these are independent predictors of clinical outcome. For example, in a radiation therapy series, clinical stage T3 or higher, PSA level above 10 ng/mL, and biopsy Gleason score of 7 or higher were risk factors for poor outcome (death or PSA elevation); the 5-year survival rate without PSA elevation was 85% for patients with none of these adverse features (good risk), 65% for patients with one adverse feature (intermediate risk), and 35% for patients with two or three adverse features (poor risk). Similar statistics are cited in radical prostatectomy series. The percentage of biopsy specimens that are positive and the rate of increase in the PSA value are each independent predictors of outcome after radical prostatectomy and can be used to counsel patients about their therapeutic options. A number of multivariable prognostic models have been developed and validated and have been used to develop simple nomograms or online risk calculators.

Low- to Intermediate-Risk Disease

In one randomized trial of patients younger than 75 years with clinical stage T1b, T1c, or T2 prostate cancer, radical prostatectomy compared with no therapy significantly reduced the relative risk of death caused by prostate cancer by about 40% (an 11% absolute risk reduction) and the overall mortality rate by a similar absolute amount at 18 years.[■] Reductions in progressive disease and metastases were also significant. The adverse effects on quality of life differed between the two strategies—more sexual dysfunction and urinary leakage after radical prostatectomy and more urinary obstruction with active surveillance—but were of similar magnitude.[■] Nerve-sparing radical prostatectomy was not routinely performed in this study, and many patients already had palpable disease, so the implications for less advanced disease with newer surgical techniques are not known. In another randomized trial of men with localized prostate cancer, radical prostatectomy did not significantly reduce all-cause or prostate-cancer mortality compared with observation through at least 12 years of follow-up, although patients with a PSA greater than 10 ng/mL and possibly patients with intermediate-risk or high-risk tumors may benefit.[■]

Active surveillance is an increasingly important option for men with low-risk disease. Careful observation of PSA and serial biopsies identifies patients who will never need local therapy. In large active surveillance series, anywhere from 50% to 75% of patients never require local therapy.

Nerve-sparing procedures and careful dissection techniques have decreased the risk of postoperative urinary incontinence and impotence. Postoperative urinary incontinence is reported to occur in fewer than 10% of cases. Postoperative impotence depends on a variety of factors, including the patient's age, preoperative erectile function, extent of cancer, and whether a nerve-sparing procedure was performed. In general, impotence rates of 10% to 50% are cited. Robotic-assisted laparoscopic prostatectomies have gained popularity but have not been shown to result in better outcomes. After a radical prostatectomy, the PSA should become undetectable; a detectable PSA implies the presence of cancer cells, either locally or at a metastatic site. Immediate (adjuvant) postoperative radiation therapy improves biochemical progression-free survival and local control in patients with one or more pathologic risk factors (capsule penetration, positive surgical margins, invasion of a seminal vesicle) after radical prostatectomy.

Conventional external-beam radiation therapy is being replaced by three-dimensional conformal radiation therapy or intensity-modulated radiation therapy, which permits higher doses to the target tissue with less toxicity. Randomized trials suggest a benefit with higher doses of radiation. Brachytherapy, which is the placement of permanent or temporary radioactive seeds directly into the prostate, is adequate for intracapsular disease with no more than minimal transcapular extension; otherwise, it should be combined with external-beam radiation therapy.

High-Risk Disease

Patients with adverse risk features (Gleason score of 8 to 10, PSA >10, stage T3) are at high risk of nodal and micrometastatic disease and are generally treated with aggressive local therapy in combination with androgen deprivation, which is synergistic with radiation therapy.[■■] Taken in the aggregate, trials suggest that 4 months of androgen deprivation with radiation therapy can improve local control and prolong progression-free survival in patients with intermediate-risk features, and long-term androgen deprivation (up to 3 years) prolongs local control, progression-free survival, and overall survival in patients with high-risk features compared with radiation therapy alone.[■■] Patients with stage T3 disease and Gleason scores of 7 have intermediate outcomes, with 8-year survival rates of about 70%; patients with stage T3 disease and Gleason scores of 8 to 10 have 8-year survival rates after radiation therapy of about 50%. Compared with ADT alone, the addition of radiation therapy to ADT improved the overall survival rate at 7 years from 66% to 74% in patients with locally advanced prostate cancer.[■] Several randomized controlled trials suggest that patients with high-risk disease who are treated surgically and have capsule penetration, positive margins, or seminal vesicle involvement should receive immediate adjuvant radiation therapy.

Recurrent Disease

Between 30% and 50% of men treated with radiation therapy or prostatectomy have evidence of disease recurrence, as defined by a climbing PSA level. PSA doubling time is predictive of survival, and a short PSA doubling time (<3-6 months) is associated with a higher likelihood of systemic disease. For selected patients with clear local recurrences, low PSA levels, and prolonged PSA doubling times, local salvage therapy (surgery for patients previously treated with radiation therapy, radiation therapy for patients previously treated with surgery, and androgen deprivation) can be considered. Although

ADT readily controls PSA levels, it is unknown whether it prolongs life in patients with PSA-only recurrent disease.

Advanced Disease

In patients whose radical prostatectomy surgery reveals microscopic involvement of lymph nodes, immediate androgen deprivation prolongs survival compared with deferment of androgen deprivation until osseous metastases are detected.[12] Similarly, patients who are at high risk of nodal invasion and who undergo external-beam radiation benefit from concurrent short-term hormonal therapy.

In patients with newly diagnosed metastatic prostate cancer, ADT is the mainstay of treatment and results in symptomatic improvement and disease regression in approximately 80% to 90% of patients. ADT can also be achieved by orchiectomy or by medical castration with a luteinizing hormone–releasing hormone (LHRH) agonist (leuprolide acetate, goserelin acetate). Intermittent ADT, typically consisting of 12 months of therapy followed by time off therapy before resuming ADT is an option in patients with nonmetastatic disease and is potentially useful in patients with metastatic prostate cancer.

Some LHRH agonists cause a transient worsening of signs and symptoms during the first week of therapy as a result of a surge in luteinizing hormone and testosterone, which peaks within 72 hours; an antiandrogen (flutamide, bicalutamide, or nilutamide) should be given with the first LHRH injection to prevent a tumor flare. Medical castration occurs within 4 weeks. The duration of hormone sensitivity is 5 to 10 years for node-positive or high-risk localized (or recurrent) prostate cancer, but it is closer to 24 months in patients with overt metastatic disease. The most common side effects of androgen ablation are loss of libido, impotence, hot flashes, weight gain, fatigue, anemia, and osteoporosis. Bisphosphonates and denosumab reduce bone mineral loss associated with androgen deprivation.

Castration-Resistant Prostate Cancer

Typically, the first manifestation of resistance to androgen deprivation is a climbing PSA level in the setting of anorchid levels of testosterone.[13] In about 15% of patients, discontinuation of antiandrogen therapy (flutamide, bicalutamide, nilutamide) while continuing treatment with LHRH agonists results in a PSA decline that can be associated with symptomatic improvement and can persist for 4 months or more. If antiandrogen withdrawal fails, treatment with secondary hormonal manipulations, such as ketoconazole or estrogens, is appropriate. Sipuleucel-T is an autologous dendritic cell product that has been shown to prolong life and is appropriate for patients with castration-resistant metastatic prostate cancer who do not have cancer-associated pain, visceral metastases, rapidly progressive disease, or the need for systemic steroids.

As noted earlier, AR amplification is a common event in castration-resistant prostate cancer. Consequently, novel agents that target the AR axis have demonstrated dramatic improvements in response proportion, progression-free survival, and overall survival. Agents that target either the ligand (e.g., the androgen biosynthesis inhibitor abiraterone acetate), as well as agents that target the receptor (e.g., enzalutamide, a direct AR antagonist) in this pathway have been shown to increase survival in metastatic castration-resistant prostate cancer patients, have been approved for use by the Food and Drug Administration, and have dramatically changed the therapeutic landscape. The optimal sequencing or combination of these agents is under investigation, as is the treatment of metastatic castration-resistant prostate cancer resistant to these agents, including treatment-emergent neuroendocrine variants.

Radium 223 is an α-emitting agent that localizes to metastatic prostate cancer lesions in bone and has been shown to provide a survival advantage in patients with bone-predominant disease and no visceral metastases. The optimal sequencing and combination of this agent with others is under investigation.

Thereafter, treatment with chemotherapeutic regimens, such as docetaxel plus corticosteroids or mitoxantrone plus corticosteroids, may be effective. Randomized phase III trials have demonstrated a survival advantage of approximately 25% in patients receiving taxol-based therapy compared with mitoxantrone, and docetaxel-prednisone is now considered a standard therapeutic approach in patients with metastatic, androgen deprivation–resistant prostate cancer. After therapy with docetaxel, patients who remain candidates for further chemotherapy can be treated with cabazitaxel, an agent shown to prolong life in this group of patients. In general, serial PSA levels are the best (albeit imperfect) way to follow up with patients, and a decline of 30% to 50% is associated with improved survival. Zoledronic acid or denosumab is indicated in castration-resistant prostate cancer patients with bone metastases because each reduces the incidence of skeletal-related events.

Palliative Care

Many patients with advanced prostate cancer have bone pain or functional impairments that adversely affect quality of life, and the provision of appropriate palliative care is an integral component of their management. In addition to the usual analgesics, glucocorticoids serve as anti-inflammatory agents and can alleviate bone pain. For patients with widespread bone metastases and pain not easily controlled with analgesics or local irradiation, samarium-153 or radium-223 can be administered intravenously; they are selectively concentrated in bone metastases and are effective in alleviating pain in many patients.

The approach to the treatment of patients with prostate cancer is detailed in Table 201-1.

TABLE 201-1 APPROACH TO THE TREATMENT OF PROSTATE CANCER

EXTENT OF CANCER	THERAPEUTIC OPTIONS
Organ confined: low risk (usually T1 or T2, GS = 7, PSA <10 ng/mL)	Active surveillance Radical prostatectomy External-beam radiation therapy to prostate Brachytherapy
Organ confined: intermediate risk (usually T2, GS = 7, PSA = 10-20 ng/mL)	Active surveillance Radical prostatectomy External-beam radiation therapy to prostate, possibly to pelvis, with or without ADT Brachytherapy
Organ confined: high risk (usually T3, GS >7, PSA >20 ng/mL)	Radical prostatectomy (with adjuvant radiation therapy, if needed) External-beam radiation therapy to prostate and pelvis (usually with ADT) Brachytherapy plus radiation therapy (usually with ADT)
Climbing PSA level after local therapy	ADT: antiandrogen monotherapy or combined ADT Salvage radiation therapy (for patients with prior prostatectomy) Salvage radical prostatectomy (for patients with prior radiation therapy) Surveillance Investigational therapy
Node positive	ADT Pelvic or prostate radiation therapy + ADT Investigational therapy
Metastatic: untreated hormone-refractory prostate cancer	ADT Second-line hormones Sipuleucel-T immunotherapy Chemotherapy Investigational therapy

ADT = androgen-deprivation therapy; GS = Gleason score; PSA = prostate-specific antigen.

PROGNOSIS

In general, the 10-year PSA progression-free survival rate is 70% to 80% with well-differentiated tumors, whether treatment is with radiation therapy or surgery; 50% to 70% for intermediate risk tumors; and 30% for high risk tumors. For patients with a climbing PSA level after radical prostatectomy, time to detectable PSA, Gleason score at the time of prostatectomy, and PSA doubling time are important prognostic variables. The likelihood of bone metastases at 7 years ranges from 20% for good-prognosis patients to 80% for poor-prognosis patients. Patients require periodic surveillance and careful comprehensive medical care.[14]

For patients with microscopic nodal disease, the 10-year survival rate approaches 80% in men treated with androgen deprivation. The median survival period in men treated with androgen deprivation for established metastatic disease ranges from 2 to 6 years. The median survival period for men with metastatic castration-resistant prostate cancer approaches 3 years, a dramatic improvement from the survival reported even 5 years ago.

FUTURE DIRECTIONS

Molecular markers can not only identify patients at risk for the development of progressive disease but also act as therapeutic targets. In addition, the genomic characterization of prostate cancer subtypes will lead to risk-adapted therapy. Enhanced understanding of AR biology may permit the development of specific hormonal therapies and guide the more rational use of existing agents.

REVIEW QUESTIONS

1. Which of the following is not a risk factor for prostate cancer?

A. African American race
B. Benign prostatic hypertrophy
C. Obesity
D. Family history
E. Dietary factors

Answer: B Neither benign prostatic hypertrophy (BPH) nor a prior history of vasectomy is associated with an increased risk of prostate cancer. The incidence of prostate cancer among African Americans is nearly twice that observed among white Americans. Obesity is associated with several malignancies, and prostate cancer is among the prominent (along with breast cancer, gynecologic malignancies, esophageal adenocarcinoma, colorectal, and renal cell carcinoma). Family history is a significant risk, especially involving relatives of men with early age of onset of prostate cancer. Some dietary factors are likewise considered to enhance or reduce the risk of prostate cancer; the protective nutritional factors include reduced fat intake and increased soy protein (see the Epidemiology section).

2. A 65-year-old man in previously good health generally is found to have an area of induration on the prostate palpable on routine digital rectal examination. The next step should be

A. prostate biopsy.
B. PSA level.
C. imaging for visceral metastases.
D. cystoscopy.
E. sigmoidoscopy.

Answer: A Although the digital rectal examination has a low sensitivity and specificity for the diagnosis of prostate cancer, biopsy of a nodule or an area of induration reveals cancer 50% of the time, suggesting that prostate biopsy should be done in all such cases. The PSA (if it has not been already done) will be useful as a parameter of disease to follow if prostate cancer is pathologically diagnosed, but whatever its level is at this time it would not obviate the need for a biopsy. Imaging or procedures to evaluate the local extent of disease or metastases is premature before a pathological diagnosis is made (see the Diagnosis section).

3. Which of the following is effective in preventing prostate cancer?

A. Vitamin C
B. Selenium
C. Nonsteroidal anti-inflammatory drugs (NSAIDs)
D. Vitamin E
E. Finasteride

Answer: E Androgen inhibition by the 5α-reductase inhibitors finasteride and dutasteride has been shown to unambiguously reduce the risk of development of overall prostate cancers, although there was a subsequently disputed finding of an increase in the number of cases with specifically higher grade disease with these drugs. Randomized trials have shown that vitamin C and selenium are not effective in preventing prostate cancer. Vitamin E has not been demonstrated to be effective. NSAIDs have demonstrated effectiveness in prevention of some cancers, such as colorectal cancer, but there is no convincing evidence that its actions likewise apply to the prevention of prostate cancer (see the Prevention section).

MALIGNANT TUMORS OF BONE, SARCOMAS, AND OTHER SOFT TISSUE NEOPLASMS

JAMES H. DOROSHOW

PRIMARY BONE TUMORS

DEFINITION

Primary bone tumors arise from cells that are normal components of bone tissues and that have the potential to metastasize. They are relatively uncommon malignancies (accounting for 0.2% of all neoplasms in the Surveillance, Epidemiology, and End Results [SEER] database, with 1.8 new cases per 100,000 population per year). Malignant bone tumors must be distinguished from a variety of more common benign bone lesions, such as osteochondromas and enchondromas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with primary malignant and benign bone tumors present with pain, swelling, and occasionally pathologic fracture of the involved bone. If radiologic studies suggest a malignant primary bone tumor (see characteristics of each subtype described later), an orthopedic oncologist should be consulted before carrying out a biopsy because improper biopsy technique may compromise subsequent surgical care, particularly limb-sparing surgery. Staging of patients with bone tumors generally requires computed tomography (CT) scans of the chest, abdomen, and pelvis to evaluate whether metastatic disease is present. Characterization of the primary bone tumor may benefit from magnetic resonance imaging (MRI) assessment of soft tissue extension or CT scan assessment of cortical bone involvement, or both.

MAJOR PRIMARY MALIGNANT BONE TUMORS

Myeloma, the most common primary bone malignancy, is covered in Chapter 187.

Osteosarcoma

Osteosarcoma is the most common malignant sarcoma of bone, representing about 35% of cases. It has a bimodal age distribution with the highest incidence in patients younger than 20 years of age, most likely related to the normal rapid bone growth that occurs during adolescence. In this age group, most tumors arise in the metaphyseal areas of the long bones of the extremities, particularly around the knee. Males are affected more commonly than females at a ratio of 3 : 2. A second peak of incidence occurs in adults older than 60 years. The sites of origin in these older patients are somewhat more heterogeneous, with craniofacial and pelvic bones each accounting for 20% of tumors. Osteosarcomas are classified based on location, cell type, and tumor grade. All osteosarcomas contain varying amounts of osteoid, with most also containing some cartilage and fibrous tissue.[1,2] Radiographically, osteosarcomas usually present as mixed osteoblastic and osteolytic lesions, although pure forms of either appearance can occur. Periosteal elevation (Codman's triangle), cortical destruction, and tumor extension into soft tissue are common on plain radiographs or MRI.

The incidence of osteosarcoma is increased in families that carry germline deletions of retinoblastoma (*RB*), *TP53* (Li-Fraumeni), or *RecQ* DNA helicase (Rothman-Thompson, Werner, or Bloom syndrome) genes. Consistent with these observations, although most younger patients with osteosarcomas have no apparent predisposing factor or family history of bone tumors, alterations in the *TP53* and *RB* genes of such sporadic tumors occur in 40% and 60% of patients, respectively. In older patients, a variety of conditions may predispose to osteosarcoma, most convincingly antecedent Paget disease or prior radiation therapy.

TREATMENT

Rx

Osteosarcoma is a highly proliferative neoplasm that metastasizes rapidly, most often by hematogenous spread; the most common site of metastasis is the lung. Despite aggressive surgical resection of the primary bone tumor, the incidence of recurrence with metastatic disease is high in the absence of systemic treatment, consistent with the concept that most patients present with clinically inapparent micrometastatic disease. The development of effective systemic chemotherapy with doxorubicin and cisplatin, with or without methotrexate, has had a profoundly positive effect on treatment outcome, with 5-year disease-free survival rates exceeding 65% in patients younger than 40 years with nonmetastatic extremity tumors. However, subsequent progress has been less striking.[3] Most patients are managed with initial neoadjuvant chemotherapy, delayed resection of the primary tumor, and then further postoperative chemotherapy. Serum alkaline phosphatase levels, often elevated in patients with osteosarcoma, can be used to monitor disease status.

Modern surgical techniques have allowed resection of most extremity osteosarcomas without amputation. Although resection of lung metastases can be curative in about 20% of selected patients, detection of radiographically-apparent metastatic disease at presentation significantly worsens prognosis. Long-term disease control in older adults with osteosarcoma is substantially lower than in younger patients, with a 5-year overall survival rate of 22% in one series of patients older than 65 years, most likely because of fundamental differences in the underlying molecular pathophysiology of tumors in older adults. Although osteosarcoma is generally considered to be relatively radiation resistant, radiation can play a palliative role in selected patients.

Chondrosarcoma

Chondrosarcoma is a malignant tumor characterized by hyaline cartilage differentiation; it is the second most common sarcoma of bone, representing 25% of bone sarcomas. The peak incidence is in the fifth to seventh decades of life. The most common primary sites are in the pelvis, proximal femur, and proximal humerus. Patients present with long-standing complaints of swelling, pain, or both. Radiographically, chondrosarcoma usually appears as a mixed lytic and sclerotic lesion.[4] MRI provides the optimal modality for determining the extent of marrow replacement by conventional intramedullary chondrosarcoma. Distinguishing low-grade chondrosarcomas from benign central enchondromas can be difficult; location in the axial skeleton and size larger than 5 cm favors malignancy.

Up to 15% of chondrosarcomas arise from preexisting peripheral osteochondromas and, similar to their benign counterparts, harbor mutations in the exostosin *(EXT)* gene. The remaining 85% of chondrosarcomas arise in a central location, some in preexisting enchondromas. Chondrosarcomas are divided into three grades, with higher grade tumors characterized by greater cellularity and cellular atypia. In one series, 61% of patients had grade 1 tumors; only 4% of such patients developed metastases. In contrast, 36% of patients had grade 2, and 3% grade 3 tumors; among this combined group, 29% developed metastases.

TREATMENT

Unlike osteosarcoma and Ewing sarcoma, chondrosarcomas generally grow slowly, metastasize less commonly, and have an excellent prognosis after adequate surgical resection. Although chondrosarcomas are considered relatively radiation resistant, radiation therapy may provide palliation for patients with large or recurrent, unresectable central chondrosarcomas.

Ewing Sarcoma

Ewing sarcoma and primitive neuroectodermal tumors (PNET) are a family of small round cell sarcomas that represent 16% of primary bone sarcomas. The molecular hallmark of Ewing sarcoma is the translocation between the Ewing sarcoma protein (EWS) and an ETS (E26 transformation-specific or E-twenty-six) family transcription factor. In 85% of cases, the t(11;22)(q24;q12) translocation between *EWSR1* and *FLI1* is detected, although other fusion genes have also been described.[5,6]

As with osteosarcoma, the peak incidence occurs during the second decade of life, but unlike osteosarcoma, the incidence of Ewing sarcoma is unimodal, being distinctly unusual in older adults and in nonwhites. Ewing sarcoma tends to arise in the diaphyseal region of long bones, in the pelvis, or in the ribs. Ewing tumors are characterized radiologically by a permeative or "moth-eaten" appearance of the affected bone, with a multilayered "onion-skin" periosteal reaction. MRI studies frequently document a significant soft tissue mass associated with the bone lesion. Unlike other sarcomas of bone, Ewing sarcoma may present with symptoms of an inflammatory systemic illness, with intermittent fevers, anemia, leukocytosis, and an increased sedimentation rate.

Eighty-five percent of Ewing's family sarcomas contain a t(11;22)(9q24;q12) chromosomal translocation that juxtaposes the EWS gene on chromosome 22 with FLI1, an ETS family transcription factor. Another 15% contain a variant in which EWS is juxtaposed to ERG, another ETS family member on chromosome band 21q22. Because Ewing sarcoma resembles other small round cell tumors microscopically, reverse transcription–polymerase chain reaction and fluorescent in situ hybridization studies that document such translocations play a critical role in confirming the diagnosis. Ewing sarcoma/PNET cells characteristically express the CD99/MIC2 cell membrane glycoprotein.

TREATMENT

Patients with localized disease treated with multimodality therapy can achieve a 5-year event-free survival rate of 70%, but the 5-year overall survival rate of patients who present with overt bone or bone marrow metastatic disease at diagnosis is less than 20%.[5] The development of effective systemic chemotherapy regimens has substantially improved long-term control of Ewing sarcoma.[7] After completion of staging procedures, patients are treated with neoadjuvant chemotherapy. One highly active regimen alternates cycles of vincristine, doxorubicin, and cyclophosphamide with ifosfamide and etoposide. After 3 months of chemotherapy, the primary tumor is resected, radiated, or both, depending on the location and extent of the primary tumor. Chemotherapy is then resumed for a total of up to 1 year of treatment. Using such an approach, the mean 5-year event-free survival rate for patients who present with nonmetastatic disease is 73%.[8] Insulin-like growth factor-1 receptor antagonists have demonstrated clinical activity in recent clinical trials for chemotherapy-refractory disease.

METASTATIC TUMORS TO BONE

Tumors metastatic to bone are important causes of cancer-related morbidity. Effective prevention and treatment of skeleton-related metastases are important parts of clinical care for many cancer patients. The most common tumors that metastasize to bone are breast cancer in women and prostate cancer in men followed by cancers of the lung, kidney, gastrointestinal tract, and thyroid.

Bone metastases typically present with localized or referred pain and less commonly as a new bone fracture. Plain radiographs may demonstrate blastic or lytic lesions. Although bone metastases from prostate cancer are often blastic and multiple myeloma usually lytic, most other tumors have a mixed appearance. In patients with one documented bone metastasis or in patients with widely metastatic disease and bone pain, a radiologic survey can identify bone metastases that may ultimately place the patient at risk for a pathologic fracture. Radionuclide bone scans are useful to delineate the extent of bone metastases and in following response to therapy. However, a negative study result must be interpreted cautiously because tumors that are potentially purely lytic (particularly multiple myeloma) may not be detectable by bone scan. In such tumors, a plain skeletal survey or CT or MRI scan is preferable. Routine screening for bone metastases is not indicated for cancer patients with no symptoms or signs of bone involvement.

TREATMENT Rx

In the absence of fracture or impending fracture, painful bone metastases are treated with external-beam radiation therapy. In patients with numerous bone metastases, systemic chemotherapy or endocrine therapy can play an important palliative role. Pathologic fractures or imminent fractures are generally managed by operative internal fixation.

PREVENTION

In patients with breast cancer, prostate cancer, and multiple myeloma, bisphosphonate therapy increases the time to a first skeletal event.[8] Bisphosphonate therapy also appears to prolong survival in patients with metastatic breast cancer. The optimal schedule and duration of administration of bisphosphonates to maximize benefit and minimize potential complications remain to be established.

SARCOMAS AND OTHER CONNECTIVE TISSUE NEOPLASMS

DEFINITION

Sarcomas are tumors of mesenchymal origin that make up approximately 1% of human cancers.[9] They are a heterogeneous group of malignant neoplasms of connective tissues, including bone and soft tissue, comprising more than 50 histologic subtypes. Mesenchymal cells (derived from mesoderm), as well as neural crest cells (from ectoderm), give rise to connective tissues and provide critical functions such as support and nourishment to neural tissues. When growth, differentiation, or survival of these cells is aberrant, tumors arise, and this is the family of neoplasms to which sarcomas belong. Sarcomas include a vast array of tumor types related to muscle, stromal tissue, adipose tissue, blood and lymphatic vessels, nerves and nerve sheaths, cartilage, bone, and other fibrous tissues.

EPIDEMIOLOGY

Although very rare in adults, true sarcomas represent a disproportionately large number of cancers in the pediatric population (≈15% of pediatric cancers). The overall incidence of sarcomas of soft tissue and bone is approximately 15,000 cases per year in the United States. The prevalence of sarcomas significantly exceeds the incidence because sarcomas can be cured with expert multidisciplinary care. Hence, the initial evaluation and management of patients suspected of having sarcomas should be performed by an experienced team with relevant expertise and interdisciplinary capabilities (including expertise in sarcoma pathology, surgical specialization, and radiotherapeutic

experience and judgment, as well as access to the latest systemic therapeutic agents).[10]

Certain patients are at high risk of developing sarcomas, most notably individuals in families with Li-Fraumeni syndrome and those with neurofibromatosis (at risk for malignant peripheral nerve sheath tumors and gastrointestinal stromal tumors [GISTs]) or familial polyposis (at risk for intra-abdominal desmoid tumors). Other risk factors include exposure to radiation (including radiation therapy for other cancers, such as patients with prior irradiated breast cancer or survivors of retinoblastoma). Chemical carcinogens can also increase the risk of sarcoma development, such as the increased incidence of sarcomas in Vietnam veterans exposed to Agent Orange or the greatly increased risk of hepatic angiosarcomas associated with occupational exposure to polyvinyl chloride. However, the vast majority of sarcomas appear to be sporadic, with no evident inciting risk factors.

PATHOBIOLOGY

Sarcomas and other connective tissue neoplasms are a heterogeneous mixture of diseases with a wide range of clinical behaviors and outcomes. Some soft tissue neoplasms, such as localized tenosynovial giant cell tumors, can be cured by expert resection, but more advanced tumors of this type (referred to as pigmented villonodular tenosynovitis) often lead to debilitating amputations or even death because of metastatic disease. Expert pathological review is necessary for the diagnosis of specific sarcoma subtypes; unfortunately, interobserver variability can impair even the most elegant diagnostic categories, such as those promulgated by the World Health Organization. Increasingly, knowledge of the molecular pathways that drive sarcomas has provided more objective diagnostic tools, including novel immunohistochemical staining patterns and genetic markers. In general, sarcomas may exhibit differentiation patterns consistent with defined connective tissues (e.g., well-differentiated liposarcoma may appear as only slightly bizarre fat cells under the microscope), or they may be unclassifiable. In any case, as diagnostic tools have evolved, it has become possible to place poorly differentiated tumors more accurately into certain histopathologic categories based on the expression of lineage-related proteins (e.g., smooth muscle actin expression may help categorize tumors as leiomyosarcomas) or on the basis of genomic markers (e.g., overexpression of chromosome 12 material or the *MDM2* gene locus is most consistent with a dedifferentiated liposarcoma). Recent studies have revealed that mesenchymal-to-epithelial transition (MET) may be operative in sarcomas, and MET may be an important basic biological and clinical process in tumors of mesenchymal original in general.[11]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Given the variety of sarcoma subtypes, it is understandable that the clinical course of these diseases can range from rapidly evolving and immediately life-threatening to indolent lesions that can take decades to evolve (e.g., atypical lipomatous tumors, also known as well-differentiated liposarcomas). Most patients with sarcomas present with a mass, often nontender, with a history of abnormal growth over time. For extremity tumors of soft tissues, it is important to note that many benign tumors (e.g., lipomas) cannot be easily distinguished from more worrisome neoplasms or even from frankly malignant sarcomas. Therefore, it is important to include sarcoma in the differential diagnosis of any mass.

The initial biopsy or surgical approach to a sarcomatous lesion is often the most important, and a poorly oriented biopsy or a suboptimal surgical procedure can make the difference between cure with full limb function and disease recurrence with the need for amputation or mutilating surgical re-resection. The National Comprehensive Cancer Network has developed expert consensus guidelines for clinical practice that emphasize the importance of expert management from the moment a suspected sarcoma presents. The initial diagnosis includes appropriate imaging studies of relevant anatomic areas, including plain radiographs, CT, or MRI to define the anatomic area of the mass and surrounding tissue, as well as systemic staging because sarcomas can spread in well-defined patterns to distal sites such as the lung or liver. The decision to proceed to diagnostic biopsy, with optimal orientation, is an important one, and for certain lesions, forgoing incisional biopsy and proceeding directly to expert surgical excision may be justified. The most important consideration is to make the correct diagnosis, and there must be sufficient amounts of properly prepared and expertly oriented tissues for optimal diagnostic analysis. In certain tumors with pathognomonic molecular markers (e.g., the translocation between chromosomes X and 18 that characterizes synovial sarcoma or the balanced translocation between chromosomes 12 and 16 that defines myxoid and round cell liposarcoma), molecular analyses such as fluorescence in situ hybridization may help make the diagnosis. New molecular subtypes of sarcoma enter the pathology literature frequently; these new diagnostic categories may lead to the use of novel, molecularly targeted therapies. Nowhere has this been more evident than in the rapid evolution of effective therapy against the major pathobiologic cause of GISTs (see below).

The diagnosis of a soft tissue sarcoma is made by evaluating biopsy material in a clinical context, which includes understanding the tumor's anatomic location and imaging characteristics. Such contextual diagnostics are critical to understanding whether a lesion may represent a primary sarcoma or whether it may be the first presentation of metastases from an occult primary tumor located elsewhere. Given the broad spectrum of sarcomas, the diagnostic considerations are quite far reaching, especially because many benign pathophysiologic conditions can mimic sarcomas.

TREATMENT

Rx

The most important element of treatment is expert multidisciplinary care. The range of options is too broad to categorize simply, and the specific details of each patient's anatomy, comorbidities, functional status, and personal preferences must be taken into account when defining treatment options and management plans. Therefore, the care of virtually all sarcoma patients should be managed by an expert multidisciplinary team with expertise in advanced surgical or orthopedic oncology techniques, radiation therapy, reconstructive surgery, physical therapy and rehabilitation medicine, systemic therapies such as conventional cytotoxic chemotherapy, hormonal therapy, and modern molecularly targeted therapy with agents such as kinase inhibitors, and psychosocial support and specialized nursing care. Therefore, appropriate referral to obtain expert opinion and to define the diagnostic and treatment options for patients with suspected sarcomas is recommended.

For most localized masses for which sarcoma is in the differential diagnosis, the first step is to obtain the correct diagnosis in a manner that does not compromise patient outcome or function. The need for biopsy must be considered first because some small, localized sarcomas are best approached through definitive surgical excision following careful staging and expert review of imaging studies. For suspected sarcomas in deeper locations, such as within muscle compartments, or for large visceral lesions, biopsy may be necessary to ascertain that the process is in fact a sarcoma, as well as to fully characterize the histopathologic subtype. This may make the difference between initial management with chemotherapy, as might be appropriate for a highly chemosensitive disease, versus surgery, which might be appropriate for a less chemosensitive disease such as dedifferentiated liposarcoma. Expert opinion varies regarding the utility and timing of adjuncts to surgical resection, such as radiation therapy or systemic cytotoxic chemotherapy.

In general, expert surgical resection is the first-line of therapy for localized sarcomas. Preoperative systemic chemotherapy may be appropriate for some rhabdomyosarcomas. Many expert teams favor preoperative radiation therapy for certain sarcomas; irradiation of a large primary tumor can deliver smaller doses to surrounding normal tissues preoperatively compared with postoperatively, but this is a matter of personal preference. A randomized trial of preoperative versus postoperative radiation therapy for large sarcomas of the extremity was performed in Canada, and outcomes were similar, with subtle differences: patients who received preoperative radiation had a higher incidence of serious postoperative wound complications, but the long-term functional outcomes were slightly more favorable.

Many sarcoma centers disagree about the relative value of cytotoxic chemotherapy, although there is no doubt that chemotherapy has greatly improved disease control rates and cure rates of certain subtypes of aggressive sarcomas such as rhabdomyosarcoma. For other forms of sarcoma originating in bone (e.g., chondrosarcoma) or soft tissue (e.g., leiomyosarcoma, synovial sarcoma), there is no strong evidence that systemic chemotherapy increases cure rates or long-term clinical outcomes, although there may be some improvement in local disease control and recurrence-free survival. This has led to discordant expert opinion: many experts believe that the risks and toxicities of aggressive chemotherapy justify the benefit of longer disease-free survival, but others believe that such toxicities are not reasonable without a major improvement in overall survival. Limited series of postoperative adjuvant therapy are often contradictory owing to the relatively small patient groups under study, as well as divergent patient selection factors, such as the inclusion of those with a lower risk of recurrence or death from metastatic disease. Inclusion of a sizable percentage of sarcoma patients with low-risk disease no doubt dilutes the results of even a reasonably effective therapy and runs the risk of making the study result negative.

It is also critical to recognize that treatment may differ radically depending on the histologic diagnosis. The best example of this is GIST (also see Chapters 192 and 193), a form of sarcoma that, in more than 95% of cases, is driven by aberrant tyrosine kinase signaling.[12] Routine systemic chemotherapy is completely ineffectual against this disease; however, tyrosine kinase inhibitor

therapy (e.g., with imatinib mesylate or sunitinib malate) produces dramatic tumor regressions and tumor control in more than 85% of patients. Fortunately, pathologists are increasingly able to recognize this disease histopathologically, and immunohistochemistry to detect CD117 (the Kit receptor tyrosine kinase) and DOG1 (a membrane antigen that is reasonably specific for GIST), as well as tumor genotyping via molecular genetics have significantly increased the accuracy of GIST diagnosis in the past decade. Imatinib has been approved by the Food and Drug Administration to decrease the risk of disease recurrence following resection of GISTs with significant potential for relapse. However, patients with a low risk of relapse have not derived substantive benefits from adjuvant imatinib because they have a very good chance of being cured by surgery alone. GIST is an excellent example of a sarcoma in which critical therapy decisions must be made in the context of the proper molecular diagnosis.[13]

For soft tissue sarcomas other than GIST, radiation therapy can play a meaningful role in preventing disease recurrence, especially for lesions that arise in the extremities. Radiation therapy can also provide significant palliation of unresectable disease, and it can be surprisingly effective in certain tumors such as desmoid tumor. However, radiation-associated sarcomas are increasingly common after therapeutic radiation therapy (e.g., in patients cured of breast cancer with radiation therapy), and an increasing incidence of poorly differentiated sarcomas or vascular sarcomas has been reported in patients after irradiation for other diseases.

As noted earlier, traditional cytotoxic chemotherapy is effective at increasing disease control and cure rates for certain sarcomas (especially those most prevalent in pediatric patients, such as rhabdomyosarcoma). It is less effective in improving long-term cure rates for patients with most other forms of soft tissue and bone sarcomas, such as liposarcoma, leiomyosarcoma, synovial sarcoma, and other subtypes. Nonetheless, appropriate use of chemotherapy can lead to objective responses in certain patients and can palliate those with metastatic disease with disease control and prolongation of progression-free survival. Targeted therapies hold potential promise for some sarcomas. For example, pazopanib, a multitargeted tyrosine kinase inhibitor at 800 mg once daily, improves the overall survival period from 10.7 to 12.5 months in patients who have metastatic nonadipocytic soft tissue sarcoma and who have had previous chemotherapy. Furthermore, a recent study demonstrated the first effective treatment for an uncommon, vasculogenic sarcoma of young adults, alveolar soft part sarcoma, with a multikinase inhibitor (cediranib) that primarily targets the vascular endothelial growth factor.

Sarcoma experts often disagree about the relative value and toxicity of combination chemotherapy as opposed to sequential single-agent chemotherapy. In patients with very aggressive and highly symptomatic sarcomas, clinicians may choose a combination chemotherapy regimen, even if there is a greater risk of toxicity, to ensure some measure of rapid disease control or even a greater chance of disease regression. In contrast, in patients with asymptomatic metastatic disease (e.g., a sarcoma patient with indolent pulmonary metastases and no symptoms), the optimal choice might be single-agent chemotherapy to avoid toxicity and to maximize the choice of subsequent chemotherapeutic agents after the benefit of the first agent is fully realized. There are no definitive data from properly powered randomized trials demonstrating that any chemotherapy for metastatic sarcoma of soft tissue (other than GIST) improves overall survival. All experts agree that owing to the complexity of the trials, the diseases, and the clinical settings, one must allow for variations in interpretations for individual patients. This explains the greatly discordant practice patterns observed across the country based on referrals, provider experience, and patient characteristics and preferences.

PROGNOSIS

Discussing prognosis for sarcomas overall is difficult because they represent such a variety of diseases with widely divergent natural histories. It is estimated that approximately 50% of patients with localized sarcomas can be cured, and the risk of recurrence is related to variables such as tumor grade (low-grade tumors have a lower risk of recurrence or metastasis compared with intermediate- or high-grade tumors), tumor size, and tumor location or depth. For patients with recurrent or metastatic sarcoma, outcome depends on many factors, including the time from initial diagnosis to the first appearance of metastatic disease; a longer disease-free interval is associated with longer survival, probably indicating a slower rate of tumor proliferation. Another factor that may determine outcome is the number of metastatic lesions; it is possible that oligoclonal metastases, with few lesions, can be surgically resected, which itself may be associated with improved survival.

Advances in targeted therapies have also affected survival, as documented by the dramatic improvements in survival and disease control for GIST and other kinase-driven sarcomas, such as dermatofibrosarcoma protuberans, giant cell tumor of bone, perivascular epithelioid cell–oma (PEComa), tenosynovial giant cell tumor, and alveolar soft part sarcoma. The natural history of these diseases will almost certainly be changed by a more mechanistic understanding of the underlying neoplasia-promoting signals that cause the transformation and maintenance of the sarcoma. Expert multidisciplinary management of sarcomas is critical to improving outcomes, and ongoing translational and therapeutic research will provide dividends far beyond the relatively low incidence and prevalence of these mesenchymal cell neoplastic disorders.

REVIEW QUESTIONS

1. A 72-year-old woman with metastatic breast cancer to multiple sites who has been treated with an aromatase inhibitor complains of severe left hip pain. Plain radiographs of the pelvis and left femur demonstrate greater than 90% lytic destruction of the femoral neck. Her performance status except for the pain is excellent. The most appropriate therapy, in addition to adequate pain control, to consider at this time is

A. initiation of combination chemotherapy with doxorubicin and paclitaxel.
B. intravenous bisphosphonate therapy.
C. immediate palliative radiation therapy to the left hip.
D. operative procedure to stabilize the hip.
E. bed rest followed by reassessment in 6 weeks.

Answer: D Patients with breast cancer at risk of immediate hip fracture should be referred for an orthopedic procedure to stabilize the hip; radiation therapy will follow the surgery, as will consideration of a change in systemic treatment.

2. Which of the following malignancies is associated with germline abnormalities of the *TP53* gene?

A. Chondrosarcoma
B. Ewing's sarcoma
C. Angiosarcoma
D. Osteogenic sarcoma
E. Gastrointestinal stromal tumor (GIST)

Answer: D Li-Fraumeni families are characterized by hereditary osteogenic sarcomas that are associated with germline mutations in *TP53*.

3. Gastrointestinal stromal tumors (GISTs) are highly responsive to tyrosine kinase inhibitors that target which of the following proteins?

A. c-Kit
B. Epidermal growth factor receptor (EGFR)
C. BCL-2
D. Focal adhesion kinase
E. PDGFRA (platelet-derived growth factor receptor-alpha)

Answer: A Imatinib, which targets both the c-Kit and bcr-abl kinase, is highly active in the treatment of GISTs (as well as chronic myelogenous leukemia).

4. Which of the following statements concerning soft tissue sarcomas is **incorrect**?

A. Soft tissue sarcomas are a relatively homogeneous group of malignancies at the molecular level because they all originate from primordial mesenchyme.
B. Classification of soft tissue sarcoma subtypes is difficult at the level of light microscopy.
C. Traditional cytotoxic chemotherapy is only useful for specific types of soft tissue sarcoma.
D. Radiation to the chest wall as part of a combined modality approach to patients with breast cancer can lead to secondary sarcomas in the radiated field.
E. Many benign tumors (e.g., lipomas) cannot be easily distinguished clinically from frankly malignant sarcomas.

Answer: A Soft tissue sarcomas are among the most heterogeneous groups of malignancies currently known.

5. Which of the following sarcomas has the best prognosis after definitive surgery?

A. Ewing's sarcoma
B. Liposarcoma
C. Chondrosarcoma
D. Leiomyosarcoma
E. Osteosarcoma

Answer: C Definitive surgery is curative in many patients with chondrosarcoma; the recurrence rate after surgery with each of the other diseases is considerably higher.

MELANOMA AND NONMELANOMA SKIN CANCERS

LYNN M. SCHUCHTER

MELANOMA

EPIDEMIOLOGY

Current estimates are that one of 37 men and one of 56 women will be diagnosed with melanoma during their lifetimes. Each year in the United States, approximately 76,690 new cases of invasive melanoma are detected, and 9480 patients die of melanoma. The explanation for the rising incidence is thought to be increasing sun exposure, especially early in life. Melanoma is the leading cause of death from cutaneous malignant disease, and it accounts for 1% to 2% of all cancer deaths in the United States. Melanoma affects all age groups; the median age at diagnosis is 50 years. Melanoma is largely a disease of whites, with a very low incidence in African Americans, Asians, and Hispanics.

PATHOBIOLOGY

Exposure to sunlight, especially ultraviolet (UV) radiation (Chapter 20), has been strongly implicated as a causative factor in the development of melanoma. Melanomas originate from melanocytes, which are located predominantly in the basal cell layer of the epidermis and use the enzyme tyrosinase to synthesize melanin pigment, which serves to protect against UV damage (Chapter 435). Worldwide, the incidence of melanoma in whites generally correlates inversely with latitude; that is, rates are generally higher closer to the equator and become progressively lower near the poles.

Risk Factors

Risk factors for melanoma include family history of melanoma, prior melanoma or nonmelanoma skin cancer, inherited genetic susceptibility, and sun

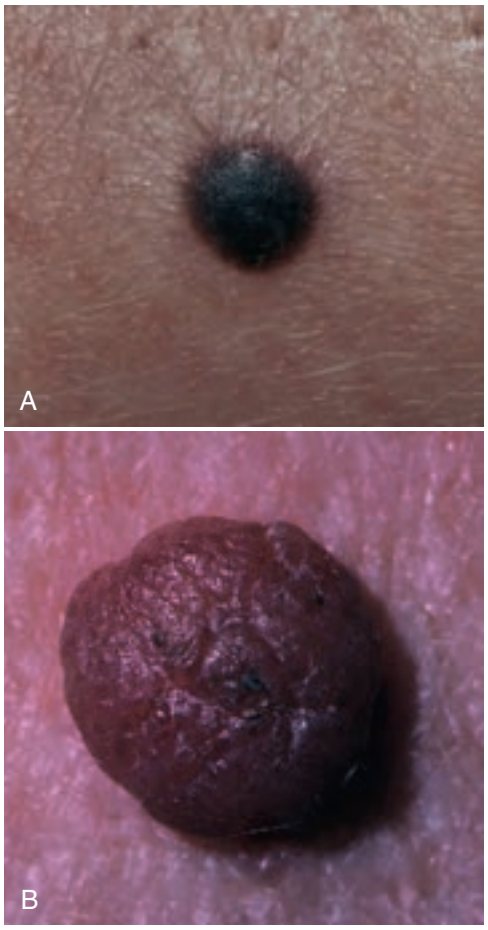

FIGURE 203-1. Nevi. A, Common benign nevus. B, Dermal nevus.

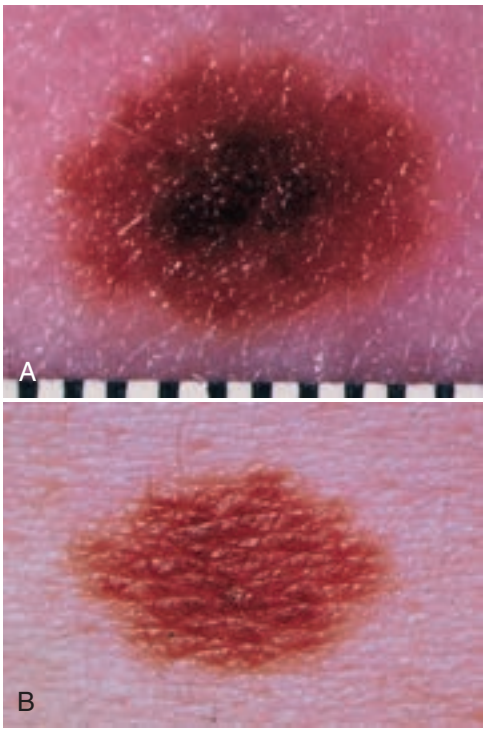

FIGURE 203-2. Dysplastic nevi. A and B, Examples of dysplastic nevi.

exposure. Artificial exposure to UV radiation by indoor tanning is likewise a risk factor for melanoma. Individuals with fair complexions, blond or red hair, blue eye color, and freckles, who have a tendency to burn rather than tan, have higher rates of melanoma. The pattern of sun exposure may also be important; intermittent intense exposure, rather than long-term exposure, may carry a higher risk of melanoma.

Individuals with an increased number of typical or benign moles, atypical moles, or dysplastic nevi (Figs. 203-1 and 203-2) also have an increased risk for melanoma. Atypical moles or dysplastic nevi are important precursor lesions of melanoma and serve as markers for increasing risk. For example, individuals with dysplastic nevi have a 6% lifetime chance of developing melanoma, and this risk increases to as high as 80% in individuals who have dysplastic nevi and a strong family history of melanoma.

Genetics

Approximately 10% of patients with melanoma have a family history of melanoma.[1] Several chromosomal loci determine susceptibility to melanoma, the most important of which is *p16/CDKN2A*, a gene located on chromosome 9p21. This gene is a member of a class of molecules that play a central role in cell cycle regulation. Of the members of melanoma-prone families, 25% to 40% have mutations in this gene. The risk of developing cutaneous melanoma in an individual who is a *CDKN2A* carrier is between 30% and 90% by age 80 years and varies by geographic location. Testing for mutations in the *p16/CDKN2A* locus is commercially available, but its clinical utility is unclear at this time. Genetic variability in melancortin-1 receptor (MC1R) plays a key role in pigmentation of skin and hair and more recently has been implicated in melanoma predisposition.

Somatic mutations in primary and metastatic melanoma primarily involve the mitogen activated protein kinase pathway. Activating mutations in *B-RAF* can be found in approximately 50% of melanomas, and 20% of melanomas are associated with a mutation in *N-RAS*. Recent studies have found that melanoma on mucous membranes, acral skin (soles, palms), and skin with chronic sun damage (i.e., lentigo maligna melanoma) have frequent mutations in *c-kit*. Thus, distinct patterns of genetic alterations are found in primary melanomas based on anatomic location and extent of sun exposure. Uveal melanoma is associated with mutations in *GNAQ/GNA11*. Monosomy of chromosome 3 and somatic mutations in the gene encoding BRCA-1 associated protein (BAP) on chromosome 3 have been associated with worse outcome and the development of metastatic melanoma. The discovery of somatic mutations in melanoma and associated aberrant signal transduction pathways has provided leads for the development of molecularly targeted therapy for patients with advanced melanoma.

CLINICAL MANIFESTATIONS

Early detection and recognition of melanoma are key to improving survival. The signs of early melanoma are based on the clinical appearance of the pigmented lesion and a change in the shape, color, or surface of an existing mole. Most patients report a preexisting mole at the site of the melanoma. Itching, burning, or pain in a pigmented lesion should increase suspicion, although melanomas often are not associated with local discomfort. Bleeding and ulceration are signs of a more advanced melanoma. Most melanomas are varying shades of brown, but they may be black, blue, or pink. The ABCDEs for the recognition of melanoma are asymmetry, border irregularity, color variation, diameter greater than 6 mm, and evolution or a change in a skin lesion. The "ugly duckling" sign is recognizing a pigmented lesion that looks different from other skin lesions and is therefore suspicious.

Cutaneous melanoma has been divided into four subtypes. Superficial spreading melanoma, which accounts for 70% of all melanomas, can be located on any anatomic site (Fig. 203-3). Lentigo maligna melanoma, which represents 4 to 10% of all melanomas, tends to occur more commonly in chronically sun-exposed skin in older patients, frequently on the head and neck (Fig. 203-4); clinically, it appears as a macular (flat) lesion, arising in a lentigo maligna. Nodular melanoma (Fig. 203-5) accounts for 15% to 30% of melanomas and manifests as a rapidly enlarging elevated or polypoid lesion, often blue or black. The ABCDE rule does not always apply as well to nodular melanomas. Acral lentiginous melanoma manifests as a darkly pigmented, flat to nodular lesion on the palm, on the sole, or subungually; sunlight is not thought to play a causative role in this form of melanoma. Histologic subtype does not directly correlate with clinical behavior. However, recent data suggest that histologic subtype may correlate with specific genetic abnormalities.

Ocular melanomas arise from the pigmented layer of the eye. Uveal melanoma is the most common intraocular malignancy of adults. Melanomas

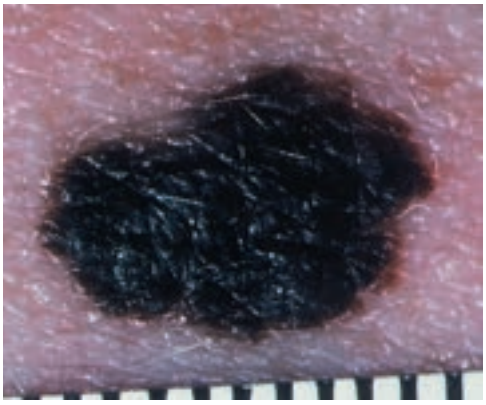

FIGURE 203-3. Superficial spreading melanoma.

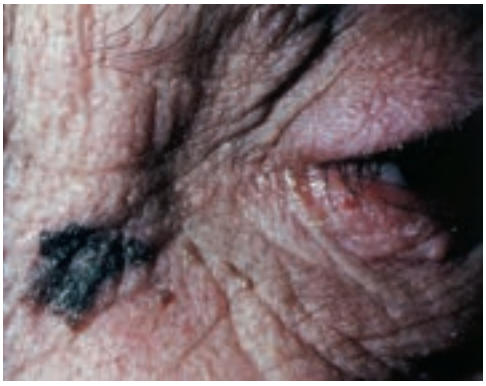

FIGURE 203-4. Lentigo maligna melanoma.

FIGURE 203-5. Nodular melanoma.

can also arise from noncutaneous sites, including mucosal epithelium in the gastrointestinal tract, anorectal area, genitourinary tract, and nasal and nasopharyngeal mucosa. Melanomas of the vulva and vagina are relatively rare. In general, mucosal melanomas are diagnosed at a more advanced stage of disease. The mainstay of treatment is surgical.

DIAGNOSIS

Any skin lesion suggestive of melanoma should be sampled using biopsy with complete excision, including a 1- to 2-mm margin of normal skin and some subcutaneous fat. An incisional biopsy may be necessary for lesions too large for complete excision. The role of sentinel lymph node biopsy (SLNB) is explained in detail in the Treatment section. Shallow shave biopsies, curettage, cryosurgery, laser, and electrodessication are contraindicated in lesions suggestive of melanoma. Other lesions that can be confused with melanoma include blue nevi, pigmented basal cell carcinoma (BCC), seborrheic keratosis, and hemangiomas (Table 203-1).

TABLE 203-1 CLINICAL FEATURES OF COMMON NEVI, DYSPLASTIC NEVI, AND MELANOMAS

DISEASE	CHARACTERISTICS
Common acquired nevi (moles)	These tend to be small, flat, and round; the border is regular, smooth, and well defined; the color is homogeneous, usually no more than two shades of brown; any site is affected; lesions are usually <6 mm.
Dysplastic nevi (atypical moles)	These occur predominantly on the trunk; they tend to be large, usually >5 mm, with a flat component; the border is characteristically fuzzy and ill defined. The shape can be round, oval, or misshapen. The color is usually brown but can be mottled with dark brown, pink, and tan. Some individuals have only one to five moles; others have more than 100.
Melanoma	The border is more irregular; lesions tend to be larger, often >6 mm; substantial heterogeneity of color is noted, ranging from tan-brown, dark brown, black, pink, red, gray, blue, or white.

Prognostic Factors

As with most malignancies, the outcome of melanoma depends on the stage and extent of disease at presentation. For localized melanoma, the most important prognostic factor is involvement of regional lymph nodes. The most important prognostic factor related to the primary tumor is the depth of invasion (Breslow's thickness) of the melanoma, which is measured in millimeters from the top of the epidermis to the underlying dermis. Increasing thickness is associated with an increased risk for recurrence, regional lymph node involvement, and death from melanoma. Whereas patients whose melanomas are smaller than 1 mm thick have about an 80% to 90% 10-year survival rate, patients whose melanomas are greater than 4 mm thick have only a 40% to 50% 10-year survival rate. Other poor prognostic factors related to the primary melanoma include the presence of ulceration, an increasing level of invasion (Clark's level), a high mitotic rate, and the presence of microscopic satellites. Regional lymph node involvement (stage III) has a major impact on survival, with 5-year survival rates ranging from 20% to 70%, depending on the number of involved lymph nodes. Melanomas that arise on the extremity tend to have a better prognosis, and women tend to do better than men.

Staging System for Melanoma

Staging and prognosis for melanoma are based on the TNM system, in which T refers to tumor, N to nodes, and M to metastasis, which was updated in 2009 (E-Table 203-1). Stages I and II indicate clinically localized primary melanoma, stage III indicates regional involvement (lymph nodes or in-transit metastases), and stage IV is metastatic disease beyond the regional lymph nodes (i.e., lung, liver, brain).

Patient Evaluation

The initial evaluation of a patient with melanoma includes a personal history, a family history, a total skin examination, and palpation of regional (draining) lymph nodes. The focus is to identify risk factors, signs or symptoms of metastases, dysplastic nevi, and additional melanomas. A chest radiograph and liver enzyme tests may be performed at the discretion of the physician. Most patients who present with melanoma do not have distant metastatic disease at presentation; therefore, extensive evaluations with computed tomography (CT) to search for distant metastases have an extremely low yield and are not indicated in asymptomatic patients. More extensive staging evaluation with CT or positron emission tomography (PET) can be considered in patients with high-risk disease (primary melanoma >4 mm thick or node-positive disease), in whom the risk of distant metastatic disease is higher.

E-TABLE 203-1 TUMOR, NODE, METASTASIS STAGING CATEGORIES FOR CUTANEOUS MELANOMA

CLASSIFICATION	THICKNESS (MM)	ULCERATION STATUS OR MITOSES
T		
Tis	NA	NA
T1	≤1.00	a: Without ulceration and mitosis <1/mm^2 b: With ulceration or mitoses ≥1/mm^2
T2	1.01-2.00	a: Without ulceration b: With ulceration
T3	2.01-4.00	a: Without ulceration b: With ulceration
T4	>4.00	a: Without ulceration b: With ulceration
	NO. METASTATIC NODES	**NODAL METASTATIC BURDEN**
N		
N0	0	NA
N1	1	a: Micrometastasis* b: Macrometastasis†
N2	2-3	a: Micrometastasis* b: Macrometastasis† c: In transit metastases or satellites without metastatic nodes
	SITE	**SERUM LDH**
M		
M0	No distant metastases	NA
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

LDH = lactate dehydrogenase; NA = not applicable.
*Micrometastases are diagnosed after sentinel lymph node biopsy.
†Macrometastases are defined as clinically detectable nodal metastases confirmed pathologically.

TREATMENT

Primary Melanoma

After melanoma is diagnosed, the standard treatment is surgical excision. Several prospective randomized trials have been conducted to define the optimal surgery for primary melanoma. The extent of the surgery depends on the thickness of the primary melanoma. Large surgical excisions are no longer required, and most wide excisions can be performed with primary closure. For melanoma in situ, excision with a 0.5-cm border of clinically normal skin is sufficient. For melanomas less than 1 mm thick, a 1-cm margin is recommended. If the thickness is between 1 and 4 mm, a 1- to 2-cm margin is recommended. For melanomas thicker than 2 mm, 2-cm resection margin also is sufficient and safe. In cosmetically sensitive areas (face) or anatomically difficult areas (ear, hands), it may be difficult to achieve the desired margin, but at least a 1-cm margin should be obtained whenever possible.

Management of Regional Lymph Nodes

Clinically Normal Regional Lymph Nodes

In approximately 10% to 20% of patients who do not have clinically apparent lymph node involvement, lymph nodes contain occult micrometastases. The risk for occult lymph node involvement rises with increasing tumor thickness. Results from randomized trials fail to show a survival benefit from elective or prophylactic lymph node dissections in patients with clinically negative lymph nodes.

Sentinel lymph node biopsy is a technique that accurately evaluates whether microscopic melanoma cells involve regional lymph nodes. The technique relies on the concept that specific regions of the skin drain specifically to an initial lymph node within the regional nodal basin through an organized pathway of afferent lymphatic channels. This technique is performed by injecting the primary melanoma site with blue dye (isosulfan blue), radiolabeled colloid, or both. When both modalities are used in combination, a sentinel node can be identified in 98% of patients; biopsy of the node accurately determines whether melanoma cells have metastasized to that specific lymph node basin. The sentinel node technique also promotes a more comprehensive histologic examination of lymph nodes because limited amounts of pathologic material are submitted.

Sentinel lymph node biopsy allows earlier identification of metastases and is an important staging tool. The likelihood of detecting melanoma in SLNB increases with thickness of the primary lesion. SLNB is recommended to patients with melanoma 1 mm thick or thicker. The use of this technique for patients with thinner melanomas, that is, less than 1 mm thick can be considered if the primary has high risk features, is controversial. The SLNB is generally performed at the same time as the wide excision of the primary tumor. If the SLNB result is negative for melanoma, no further lymph node surgery is required. If melanoma is detected by the SLNB, complete lymph node dissection remains the standard of care. A recently reported randomized trial showed that the use of SLNB in patients with intermediate-thickness of thick primary melanomas provides accurate and important staging information; enhances regional disease control; and among patients with nodal metastases, improved melanoma-specific survival.

Clinically Apparent Regional Lymph Nodes

Surgical (therapeutic) lymphadenectomy is the preferred treatment of cytologically (fine-needle aspiration) positive or pathologically proven regional lymph node involvement with melanoma. The goal is to provide long-term, disease-free survival and reduce local morbidity of enlarged lymph nodes.

Adjuvant Therapy

Postsurgical adjuvant therapy can be considered for patients at high risk for recurrence (melanomas ≥4 mm thick or node-positive disease). These patients have at least a 25% to 75% chance of dying of melanoma. Adjuvant treatment options include interferon-α (IFN-α), enrollment in a clinical trial, or observation. High-dose IFN-α is the only U.S. Food and Drug Administration (FDA)—approved adjuvant therapy for patients with melanoma. Randomized clinical trials have shown that therapy with IFN-α can prolong disease-free survival but has not consistently demonstrated improvement in overall survival. The treatment is given for 1 year and is associated with considerable side effects, which require close monitoring. Intermediate and low doses of IFN-α as well as pegylated IFN-α have also been evaluated in a series of clinical trials. Pegylated IFN-α was recently approved by the FDA for treatment of patients with stage III melanoma. Numerous vaccine studies are ongoing but are considered experimental at present. Ipilimumab, a monoclonal antibody targeting CTLA-4, has been shown to prolong survival in patients with metastatic melanoma. Currently, ipilimumab is being studied in multiple phase III trials as an adjuvant therapy in patients with high risk melanoma.

Treatment and Course of Advanced Melanoma (Stage IV)

Melanoma can metastasize to virtually any organ, especially the lung, skin, liver, and brain. Until recently, the overall survival period for patients with metastatic melanoma has ranged from 5 to 11 months, with a median survival period of 9 months. However, new approaches with immunotherapy and molecularly targeted therapy based on somatic mutation profile have led to several recent FDA approvals of new agents that have redefined the standard of care for patients with metastatic melanoma.[2]

New immunotherapy approaches include ipilimumab, which blocks cytotoxic T-lymphocyte antigen 4 (CTLA-4).[3] Immunotherapy with ipilimumab has been shown to be better than dacarbazine alone (3-year survival rate, 21% vs. 12%) for previously untreated metastatic melanoma. Ipilimumab, 3 mg/kg intravenously every 3 weeks for a total of four doses, is FDA approved for patients with unresectable stage III or stage IV melanoma. Treatment with ipilimumab results in immune-mediated adverse reactions, including enterocolitis, hepatitis, dermatitis, and endocrinopathies such as hypopituitarism and hypothyroidism. Dose interruption of ipilimumab and corticosteroids are the main stays of treatment for this side effect mediated by T-cell activation and proliferation.

A second investigational approach to inhibit regulation of T-cell activation is to block the PD-1/PD-L1 (programmed cell death) pathway. Monoclonal antibodies targeting both PD-1 and PD-L1 are now in clinical trials. The first-in-class anti PD-1 antibody nivolumab, a fully human IgG4 monoclonal PD-1 antibody, has shown impressive clinical activity in patients with advanced melanoma. Another PD-1 inhibitor recently FDA approved is lambrolizumab, which also has significant clinical activity (response rate >40%) with fewer immune adverse events than traditionally seen with ipilimumab. Combining anti-CTLA-4 with anti-PD-1 immunotherapy has been encouraging in early non-randomized studies.[4]

The discovery of somatic genetic mutations in melanoma has provided leads for the development of molecularly targeted therapies. The MAP (mitogen-activated protein) kinase pathway, which is activated in most melanomas because of mutations in *BRAF*, *NRAS*, and *c-kit*, has been the focus of most clinical investigations of signal transduction (kinase) inhibitors. In patients with metastatic melanoma whose tumors harbor the *V600E BRAF* mutation, vemurafenib (960 mg orally twice daily), trametinib (2 mg orally twice daily), and dabrafenib (150 mg orally twice daily) each can increase 6-month survival rate significantly compared with dacarbazine. Squamous cell carcinoma (SCC) and keratoacanthomas develop in approximately 20% of patients with melanoma treated with vemurafenib because of paradoxical activation of MAPK signaling. Nevertheless, vemurafenib provides a median overall survival time of about 16 months in treated patients with *BRAF V600*–mutant metastatic melanoma. Recently, combination targeted therapy with dabrafenib (BRAF inhibitor) and trametinib (MEK inhibitor)[5] has been FDA approved based on results showing a 70% response rate and an acceptable safety profile. Combination therapy with several different regimens has now been shown to provide better progression free survival, better overall survival, and no increase in side effects in patients with metastatic melanoma. Preliminary results also show that imatinib can induce regression in patients whose melanomas are driven by *KIT* mutations.

Surveillance and Follow-up

Patients should be educated on the clinical characteristics of melanoma, the importance of safe sun exposure strategies, and the performance of monthly self-examinations of the skin. Patients should be followed regularly for evidence of local or regional recurrence, distant metastatic disease, and a second primary melanoma. The intensity of the surveillance and the extent of the investigation are influenced by risk for recurrence with more frequent follow-up visits in patients who have thicker tumors or node-positive disease because these patients are at greater risk for recurrence.

For patients with low-risk melanoma (≤1 mm), visits are recommended every 6 months for 2 years and then annually. The surveillance guidelines for patients with high-risk melanoma include evaluation every 3 to 4 months for 2 years and then every 6 months for 3 years. After 5 years, patients are seen once a year. Patients are generally followed for 10 years. However, lifelong dermatologic examination is recommended, particularly for patients with dysplastic nevi or a family history of melanoma. In general, a history and physical examination are performed at each visit. Periodic chest radiographs, laboratory studies, and other imaging studies are performed at the discretion of the treating physician. The physical examination should include a thorough skin examination because at least 3% of patients develop an additional primary cutaneous melanoma within 3 years. Regional lymph nodes should be thoroughly examined, especially in patients without prior nodal surgery. For the remainder of the examination, one should keep in mind the frequency of metastases to lung, liver, and brain. Follow-up studies may include a complete blood cell count and chemistry studies, including liver enzyme tests. An elevated lactate dehydrogenase level suggests metastatic melanoma.

PREVENTION

The most important measures to prevent melanoma are to reduce excessive sun exposure, particularly to the midday sun, and to avoid sunburns. Sunscreen products with a sun protection factor (SPF) of 15 or greater and protective clothing are recommended, and one randomized trial found

that regular sunscreen use reduced incident melanoma by 50% and invasive melanoma by 75%.[6] Sunscreens block primarily UVB rays, which are considered to be the major causative agent of cutaneous cancers. Newer sunscreen products also block UVA rays, which may contribute to the risk of melanoma.

Screening for skin cancer, whether by self-examination or by a health care provider, is controversial (Chapter 15). Many public health experts do not recommend screening for adults in the general population, but some organizations do. On the basis of the type and number of nevi, family history of melanoma, prior melanoma, and history of severe sunburns, clinicians can identify patients who are at high risk for melanoma and who may benefit from screening programs. In several population studies, screening has detected melanomas at an earlier, curable stage. Physicians, other health care providers, and the public should be educated regarding the early signs of melanoma and the need for prompt biopsy of a suspicious pigmented lesion.

Patients with clinically atypical nevi (see Fig. 203-2), particularly if they have a family history of melanoma, require a regular dermatologic surveillance program. Regular skin examinations should be performed every 6 to 12 months, preferably assisted by the use of serial photography.

Recent studies have focused on the impact of vitamin D levels on the risk for melanoma, and results have been conflicting. The potential health benefits of vitamin D continue to be evaluated, both in terms of melanoma prevention and risk.

BASAL AND SQUAMOUS CELL SKIN CANCER

Nonmelanoma skin cancer (BCC and SCC) is the most common malignant disease in the United States.[7] Although national statistics are imprecise, an estimated 900,000 to 1,200,000 of nonmelanoma skin cancers are diagnosed annually in the United States. SCC accounts for 20%, and most of the remainder are BCC. SCC is associated with a higher absolute mortality rate; most of the 2300 annual deaths from nonmelanoma skin cancer in the United States arise from this tumor.

EPIDEMIOLOGY

Overall, skin cancer incidence rates are rising because of increased recreational sun exposure, longer life expectancy, and depletion of the ozone layer. More than 99% of nonmelanoma skin cancers occur in whites. These skin cancers are most commonly seen in elderly persons, especially those with fair skin and long-standing sun exposure. However, nonmelanoma skin cancers are increasingly being seen in people in their 30s and 40s. The lifetime risk of developing BCC is 30%.

PATHOBIOLOGY

Basal cell carcinoma arises from a pluripotential stem cell within the skin. Acquired mutations in the patched gene 1 *(PTCH1)*, a tumor suppressor gene in the hedgehog signaling pathway, have been identified in cases of sporadic BCC. Sporadic BCC are also associated with mutations in the genes encoding p53 and ras.

Squamous cell carcinoma of the skin is a malignant disease of epidermal keratinocytes. Many such carcinomas are derived from actinic keratosis, a precursor that appears as a rough, scaly, often erythematous papule, which often is more apparent on palpation than on visual examination. Estimates of the likelihood of progression of actinic keratosis to SCC range from 0.025% to as high as 20%. Mutations in the gene encoding the p53 protein and in the *RAS* oncogene have been found in both actinic keratosis and SCCs. Mutations in *p16* have also been reported in SCCs.

Risk Factors

The most important risk factor is exposure to UV radiation from sunlight. The most clearly established association is with UVB radiation, but increasing evidence suggests that UVA is probably carcinogenic as well (Chapter 20). The timing and pattern of sun exposure are associated with different types of skin cancer. In general, SCC is associated with cumulative sun exposure and occurs most frequently in areas maximally exposed to the sun (e.g., the face, back of hands, and forearms). Intermittent, intense exposure to the sun, particularly in childhood, is associated with an increased risk for BCC. There is evidence for a dose-response relationship between artificial UV radiation exposure by use of tanning beds and the risk of skin cancers, especially BCC, and the association is stronger for individuals with a younger age at exposure.[8] Individuals who have fair skin, light-colored eyes, red hair, a tendency to burn rather than tan, and a history of severe sunburns are at increased risk for nonmelanoma skin cancers. Other risk factors, primarily for SCC, include chronic arsenic exposure, therapeutic radiation, chronic inflammatory skin conditions, psoralen plus UVA (PUVA) treatment for psoriasis and other diseases, and immunosuppression. Most cases in African American patients are associated with scarring or burns rather than UV exposure. Human papillomavirus infection (Chapter 373) has also been implicated in some SCCs, particularly in the autosomal dominant disorder epidermodysplasia verruciformis.

Basal cell carcinoma can be seen in association with several conditions, including the basal cell nevus syndrome (also called nevoid basal cell carcinoma syndrome or Gorlin syndrome), albinism, and xeroderma pigmentosum. The basal cell nevus syndrome is a rare autosomal dominant disorder caused by germline mutations in the patched gene *(PTCH)*.

CLINICAL MANIFESTATIONS

Basal Cell Carcinoma

Approximately 90% of BCCs occur on sun-exposed areas such as the face, neck, ears, scalp, and arms. The nose is the most common site. Typical BCC appears as slowly growing, shiny, skin-colored to pink translucent papules with telangiectasia and a "pearly," rolled border (Fig. 203-6). As the tumor grows, the center may become ulcerated and bleed, although there is usually no associated pain or tenderness. BCC rarely metastasizes and is usually curable with a variety of treatments. Although the mortality rate is low, these cancers may result in significant morbidity owing to invasive local growth with potential disfigurement and destruction of skin, bone, and cartilage. Clinical trials with inhibitors of the hedgehog pathway for patients with advanced BCC have demonstrated very encouraging clinical activity.

Squamous Cell Carcinoma

This type of skin cancer usually appears on areas of skin that are heavily damaged by sun exposure. The most common sites include the head or neck, back, forearms, and dorsum of the hand. Clinically, SCC occurs as a discrete scaly erythematous papule on an indurated base that can develop on normal-appearing skin or on an actinic keratosis (Fig. 203-7). The lesion may grow

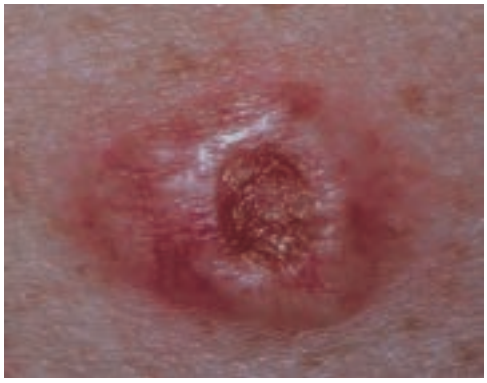

FIGURE 203-6. Basal cell carcinoma.

FIGURE 203-7. Squamous cell carcinoma of the skin.

over time and may become ulcerated, itchy, or painful and may bleed. Keratoacanthoma is a variant that is characterized by rapid growth and a crateriform appearance with a central plug. Bowen disease, or SCC in situ, manifests as an erythematous, scaly, sharply defined plaque.

Untreated SCC may cause significant local destruction. However, unlike BCC, SCC carries a 0.5% to 5% risk for metastasis. Higher risk lesions are those that are larger than 2 cm, are moderately or poorly differentiated, have perineural involvement, are located on the ear or the lip, arise in scars, or occur in immunosuppressed patients. Most metastases develop in regional lymph nodes, although metastases may also occur in lung, liver, brain, skin, or bone. For patients with lymph node metastases, the 5-year survival rate is less than 50%.

DIAGNOSIS

The diagnosis of BCC and SCC is frequently suspected by inspection alone, but histologic confirmation is usually indicated. Either a shave or a punch biopsy technique is acceptable (Chapter 436). Care should be taken to include the base of the lesion if a shave biopsy technique is used.

TREATMENT

Rx

Basal Cell Carcinoma

Basal cell carcinomas are classified as low or high risk based on their clinical features, location, and histology. Treatment options includes cryotherapy (liquid nitrogen), electrosurgery (i.e., curettage and electrodessication), topical treatment (i.e., 5-fluorouracil, photodynamic therapy, or imiquimod), surgical excision, Mohs' surgery, or radiation therapy. Mohs' microsurgery involves serial excisions of a skin cancer with subsequent microscopic examinations for residual tumor, providing histologic control of the surgical margins to achieve the lowest recurrence rate while maximally preserving uninvolving tissue.[9] The procedure should be considered when treating recurrent cases; microscopically aggressive forms, such as the morpheaform subtype; lesions greater than 2 cm in greatest diameter; and tumors of the ears, eyelids, nose, nasolabial folds, and lips. Cure rates for BCC range between 90% and 99%.

Treatment of advanced BCC and metastatic BCC can now be approached using targeted therapy. Vismodegib, an inhibitor of the hedgehog signaling pathway, has recently been FDA approved.[10] In a nonrandomized study, treatment with vismodegib provided objective tumor responses in 30% to 43% of patients and a complete response in 20% of patients with locally advanced or metastatic basal-cell carcinoma. Side effects associated with therapy include muscle spasms, taste abnormalities, diarrhea, and fatigue.

Squamous Cell Carcinoma

As with BCC, SCC can also be cured by traditional surgical excision or Mohs' surgery, cryotherapy, topical therapies, and radiation therapy. Topical 5-fluorouracil, photodynamic therapy, and imiquimod have roles in the management of in situ SCC. The optimal approach for a specific patient requires consideration of likelihood of the lesion recurring or metastatic potential, cosmetic factors, and the expertise of the treating physicians.

Mohs' micrographic surgery provides the lowest recurrence rate, with cure rates greater than 90%. Mohs' microsurgery is especially useful for recurrent tumors or lesions that have an increased risk of metastasis. Cetuximab, a monoclonal antibody that targets epidermal growth factor receptor (EGFR), has some antitumor activity in patients with advanced SCC of the skin.

Follow-up

Patients with BCC and SCC require ongoing follow-up to detect local recurrences and to recognize new skin cancers. The likelihood of developing a second BCC or SCC has been estimated to be 15% over 3 years. In addition, these patients have an increased risk of developing cutaneous melanoma. Patient education regarding modification of risk factors (i.e., sun exposure) is an important component of follow-up.

PREVENTION

Primary prevention strategies are aimed at reducing long-term sun exposure.[11] Public education and patient education should encourage the regular use of sunscreens with a SPF of 15 or greater, especially in childhood, and sun-protective clothing (e.g., a broad-brimmed hat). Avoidance of tanning parlors and minimizing of total sun exposure, especially to the midday sun, is recommended. The thinning of the ozone layer has been linked to increased UV radiation and increases in the incidence of nonmelanoma skin cancers. Currently, no evidence indicates that total-body skin examination is effective at reducing mortality or morbidity from nonmelanoma skin cancer.

REVIEW QUESTIONS

1. A 62-year-old woman was recently diagnosed with a 0.77-mm-thick melanoma. There was no ulceration, it was a Clark's level III, and the mitotic count was 1.0/mm^2. The melanoma arose from her left posterior arm. The patient had blood work performed, which included a CBC, chemistry panel, and LDH, which were normal. Which of the following imaging studies is appropriate for this patient?

A. No imaging studies
B. CT scan of the chest, abdomen, and pelvis and MRI of the brain
C. PET/CT scan and MRI of the brain
D. Bone scan; CT scan of the chest, abdomen, and pelvis; and brain MRI
E. CT scan of the chest, abdomen, and pelvis

Answer: A The staging evaluation of a patient with a low risk melanoma should include a physical examination, including a skin examination. Routine blood work and imaging is not routinely recommended. The majority of patients who present with melanoma do not have distant metastatic disease at presentation; therefore, extensive evaluations with computed tomography (CT) scans to search for distant metastases have an extremely low yield and consequently are not indicated in asymptomatic patients. More extensive staging evaluation with CT scans of the chest, abdomen, and pelvis can be considered in patients with high-risk disease (thick primary melanoma >4 mm thick or node-positive disease) in whom the risk of distant metastatic disease is higher.

National Comprehensive Cancer Network (NCCN) guidelines. Available at http://www.nccn.org.

2. A 55-year-old man presents to your office with a right axillary lump. Two years ago, he was treated for a malignant melanoma on his right upper arm. The melanoma was 1.3 mm thick, and there was no ulceration present. The melanoma was treated with wide excision, which showed no residual melanoma, and the patient was then monitored. He now presents to your office with an enlarged right axillary lymph node, which measures 2.5 × 2.0 cm. The patient has no symptoms, no fever, and the remainder of the physical examination findings are unremarkable. Which of following would you recommend to this patient now?

A. Arrange for fine-needle aspiration (FNA) of the lymph node
B. Surgical excision of the lymph node
C. Prescribe of a 10-day course of antibiotics
D. Referral to radiation therapy to begin radiation therapy to right axillary region
E. Continue monitoring and have the patient return to the office in 3 months because this likely represents a postoperative seroma

Answer: A In this patient with a history of melanoma, an enlarged regional lymph node is highly suspicious for disease recurrence. Obtaining an FNA, often with ultrasound guidance, is the most appropriate next step to confirm diagnosis. The physical examination does not suggest this represents an infection, and postoperative seroma would be highly unusual this far out from surgery. After melanoma is confirmed, then staging evaluation should be completed with CT scans of the chest, abdomen, and pelvis or PET scan. Additional surgery with complete lymph node dissection and plans for adjuvant systemic therapy would follow providing no distant metastatic disease was identified.

3. A 35-year-old woman presents with a mild cough, fatigue, and some weight loss. She was treated for melanoma on her left lower leg 3 years ago. Imaging studies reveal multiple pulmonary nodules. A CT-guided biopsy confirms diagnosis of metastatic melanoma. Analysis of the tumor for which of the following mutations would be most useful in determining treatment options?

A. *KIT*
B. *BRAF*
C. *EGFR*
D. *ALK*
E. *KRAS*

Answer: B *BRAF* V600 is the most common somatic mutation in melanoma, occurring in 50% of patients. It also tends to occur in younger patients with melanoma, so this is the most likely mutation in this patient. Importantly, BRAF inhibitors (vemurafenib, dabrafenib) are effective therapies for patients with *BRAF* mutant melanoma and are now approved by the Food and Drug Administration based on survival benefit demonstrated in randomized phase III clinical trials. *KIT* is uncommonly mutated in melanoma (<3% of melanomas). *KIT* mutations are most frequent in acral (arising on palms and soles or subungual), mucosal melanoma or cutaneous melanomas associated with chronic sun exposure. In this patient, testing for *BRAF* mutation first is most appropriate. *EGFR* mutation is not associated with melanoma; it is mutated in lung cancer. *ALK* and *KRAS* are not somatic mutations that occur in melanoma.

4. Which of the following patients has the highest risk for developing melanoma?

A. A 35-year-old woman with red hair and blue eyes who has had more than five blistering sunburns
B. A72-year-old farmer who has had chronic sun exposure for more than 60 years
C. A68-year-old woman who has had several basal cell and squamous cell skin cancers
D. A29-year-old woman with multiple dysplastic nevi and an uncle and cousin who had melanoma

Answer: D All of these patients are at increased for melanoma. Individuals with red hair, blue eyes, history of blistering sun burns, chronic sun exposure, and history of nonmelanoma skin cancers (basal cell and squamous cell) are at increased risk. However, the highest risk patient is the woman with dysplastic nevi and a family history of melanoma. In this patient, a careful family history should be obtained to determine if additional relatives have melanoma or other cancers, and all should be referred for dermatology evaluation. This patient could be part of familial melanoma/dysplastic nevus syndrome, which is associated with very high risk of developing melanoma and associated with germline mutation in p16.

5. A 44-year-old man was recently diagnosed with stage IV melanoma. Staging workup showed multiple liver metastases, lung metastases, and bone metastases. Symptoms at this time include mild shortness of breath, cough, significant bone pain, and an 8-lb weight loss. Mutation testing for *BRAF* confirmed *V600E BRAF* mutation. What treatment would you recommend now?

A. Dabrafenib
B. Trametinib
C. Imatinib
D. Sorafenib

Answer: A In this patient with symptomatic metastatic melanoma, the most appropriate choice would be a highly potent and selective *BRAF* inhibitor. Dabrafenib treatment is associated with an approximately 60% response rate. Clinical benefit has been seen within 72 hours of administration. Trametinib is a recently approved MEK inhibitor; however, clinical activity is less than that reported for dabrafenib. Similarly, sorafenib, although it targets BRAF, has little activity in melanoma. Imatinib targets *c-kit*, so its selection is not appropriate.

Ascierto P, Minor D, Ribas A, et al. Phase II trial (BREAK-2) of the BRAF inhibitor dabrafenib (GSK118436) in patients with metastatic melanoma. *J Clin Oncol.* 2013;31:3205-3211.

6. A 63-year-old woman was recently diagnosed with stage IV melanoma. Staging workup showed lung and bone metastases. She has no symptoms at this time. Her oncologist has recommended treated with ipilimumab. Which of the following statement best describes the mechanism of action of ipilimumab?

A. Blocks cytotoxic T-lymphocyte antigen 4 (CTLA-4)
B. Inhibits DNA replication
C. Inhibits the MAP kinase pathway
D. Directly stimulates T cells activity
E. Interferes with CD 20 on B cells

Answer: A Ipilimumab is a negative regulator of T-cell activation. It interferes with the ability of CTLA-4 to interact with its ligand, which is an inhibitory signal. Thus, CTLA-4 blockade with ipilimumab results in T-cell activation and proliferation. Ipilimumab, a type of immunotherapy, is approved by the Food and Drug Administration (FDA) for the treatment of unresectable stage III and IV melanoma. Chemotherapy agents such as cyclophosphamide interfere with DNA replication. Molecularly targeted agents such as BRAF inhibitors work through inhibiting the MAP kinase pathway. Interleukin-2, FDA approved for the treatment of metastatic melanoma, directly stimulates T cells. Monoclonal antibodies, such as rituximab, induces destruction of B cells, which express CD 20. This therapy is used to treat patients with chronic lymphocytic leukemia and non-Hodgkin's lymphoma.

204

CANCER OF UNKNOWN PRIMARY ORIGIN

JOHN D. HAINSWORTH AND F. ANTHONY GRECO

DEFINITION

The first signs or symptoms of cancer are frequently the result of metastases to visceral or nodal sites. In most such patients, the clinical diagnosis of metastatic cancer is evident and is confirmed by biopsy of a metastatic lesion. Subsequent clinical evaluation with a comprehensive history, physical examination, complete blood cell count, screening chemistries, chest and abdominal computed tomography (CT) scans, and directed radiologic studies based on specific symptoms or signs identifies the primary tumor site as well as the extent of metastatic disease. Patients who have no primary tumor located after this clinical evaluation are defined as having *cancer of unknown primary origin*. Further clinical and pathologic evaluation identifies the primary site in only a few patients, and approximately 80% never have a primary site identified during their subsequent clinical course.

EPIDEMIOLOGY

In patients whose primary site of cancer remains undetectable, the primary site has presumably remained small or, less likely, regressed spontaneously. Before the routine use of CT or magnetic resonance imaging (MRI) for diagnosis, large autopsy series identified primary sites (usually <2 cm in diameter) in 85% of patients with cancer of unknown primary origin, usually in the pancreas, lung, and various other gastrointestinal (GI) sites. With the use of CT and MRI for diagnosis, however, primary sites are identified at autopsy in only 50% to 70% of patients.[1]

Approximately 4% of all patients with cancer have metastatic disease without a known primary site; the annual incidence is approximately 80,000 cases in the United States. Cancer of unknown primary site occurs with approximately equal frequency in men and women, and it increases in incidence with advancing age.

DIAGNOSIS

The initial clinical and pathologic evaluations should focus on identifying a primary site, when possible, and on identifying patients for whom specific treatment is indicated.

Biopsy and Pathologic Evaluation

The diagnosis of metastatic cancer should be confirmed by biopsy of the most accessible metastatic lesion. A fine-needle aspiration is usually sufficient to confirm the diagnosis of metastatic cancer but does not provide adequate material for optimum pathologic evaluation. Therefore, a larger biopsy (surgical or core needle) should be performed if technically feasible.

TABLE 204-1 RECOMMENDED EVALUATION AFTER INITIAL LIGHT MICROSCOPIC DIAGNOSIS

DIAGNOSIS	CLINICAL EVALUATION*	SPECIAL PATHOLOGIC STUDIES
Adenocarcinoma (or poorly differentiated adenocarcinoma)	PET CT of the chest and abdomen Men: serum PSA Women: mammography, breast MRI Colonoscopy (patients with colon cancer "profile") Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, laboratory values	Men: PSA stain Women: estrogen and progesterone receptor stains (if clinical features suggest metastatic breast cancer) Molecular tumor profiling
Poorly differentiated carcinoma	PET CT of the chest and abdomen Serum hCG and AFP Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, and laboratory values	Immunoperoxidase staining Molecular tumor profiling Electron microscopy (if other studies are indeterminate or conflicting)
SCC, cervical nodes	PET Direct laryngoscopy with visualization; biopsy of the nasopharynx, pharynx, hypopharynx, and larynx Fiberoptic bronchoscopy (if laryngoscopy results are negative)	—
SCC, inguinal nodes	PET Complete examination of perineal area (including pelvic examination) Anoscopy Cystoscopy	—

*In addition to a history, physical examination, complete blood cell counts, chemistry profile, and chest radiograph.
AFP = α-fetoprotein; CT = computed tomography; hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging; PET = positron emission tomography; PSA = prostate-specific antigen; SCC = squamous cell carcinoma.

The initial light microscopic evaluation identifies adenocarcinoma in approximately 60% of patients with cancer of unknown primary site. Other diagnoses obtained by initial light microscopy include poorly differentiated carcinoma (25%), squamous carcinoma (10%), and poorly differentiated neoplasm (inability to distinguish among carcinoma, lymphoma, melanoma, and sarcoma; 5%).[3]

Additional pathologic evaluation is essential in all poorly differentiated tumors. Immunochemical (IHC) stains can usually identify the tumor lineage (e.g., carcinoma vs. lymphoma vs. sarcoma) when the histologic diagnosis is "poorly differentiated neoplasm." Because more than 50% of these patients have lymphoma, this distinction is important. When the histologic diagnosis is "poorly differentiated carcinoma," IHC staining sometimes identifies germ cell tumors or neuroendocrine carcinoma.

In patients with adenocarcinoma, it is seldom possible for the pathologist to determine a primary site by light microscopic examination of histology. IHC stains can narrow the diagnostic spectrum, particularly when interpreted in conjunction with clinical features. In several situations, IHC stains are quite specific, including prostate-specific antigen (PSA) for prostate cancer (Chapter 201), estrogen and progesterone receptors for breast cancer (Chapter 198), and leukocyte common antigen for non-Hodgkin lymphoma (Chapter 185). Other diagnoses suggested by immunoperoxidase staining include neuroendocrine carcinomas, melanomas (Chapter 203), and sarcomas (Chapter 202).

Occasionally, electron microscopy or analysis for tumor-specific chromosomal abnormalities (i12p in germ cell tumors, Chapter 200; t11:22 in Ewing tumor; immunoglobulin gene rearrangements in non-Hodgkin lymphoma, Chapter 185) are useful in the evaluation of poorly differentiated tumors if results of other pathologic studies are inconclusive.

Molecular tumor profiling is a new diagnostic method that is in the process of changing the management of patients with cancer of unknown primary origin. Gene expression profiles differ in various normal body tissues, and most cancers retain expression profiles specific to their tissue of origin. Molecular profiling assays can correctly predict the tissue of origin in 85% to 90% of metastatic cancers by detecting tissue-specific gene expression patterns.[4,5] Although the accuracy of the profiling predictions is more difficult to quantitate in patients with cancer of unknown primary origin (because most primaries never become manifest), current evidence indicates a similar high accuracy rate.[6,7] Therefore, molecular tumor profiling is a valuable addition to the pathologic evaluation, and is indicated when histologic examination and IHC do not identify a tissue of origin.

Search for the Primary Site

After completion of the brief, directed initial evaluation necessary to make the diagnosis of cancer of unknown primary origin (see the Definition section), further diagnostic studies should be limited (Table 204-1). The value of positron emission tomography (PET) in identifying a primary site is debated; in the only prospective study to date, PET results did not augment results of CT scanning.[8] Other routine radiologic and endoscopic evaluations of asymptomatic areas are rarely useful in identifying a primary site and therefore are not recommended. Levels of serum tumor markers, including carcinoembryonic antigen, CA-125, CA-19-9, and CA-15-3, are frequently increased in patients with carcinoma of unknown primary site; however, these elevations are nonspecific and should not be used to infer a primary site even though they can be useful in monitoring response to treatment.

Specific clinical presentations should trigger additional diagnostic evaluation. In all men with metastatic adenocarcinoma, serum PSA should be measured. Mammography and breast MRI should be considered in women with metastatic adenocarcinoma, particularly if clinical features are consistent with metastatic breast cancer (e.g., axillary node involvement, pleural effusion, lytic or blastic bone metastases). In patients younger than 50 years of age with poorly differentiated carcinoma, serum human chorionic gonadotropin and α-fetoprotein (AFP) levels should be measured to screen for germ cell tumors. Patients with metastatic squamous carcinoma involving cervical lymph nodes should have a thorough endoscopic evaluation of the head and neck, including visualization of the structures from the nasopharynx to the larynx and biopsy of any suspicious areas (Chapter 190). Fiberoptic bronchoscopy should also be considered in patients who have low cervical adenopathy and in whom no head or neck primary site is established by endoscopic examination. In patients with metastatic squamous carcinoma involving inguinal lymph nodes, all perineal structures should be carefully inspected, including by anoscopy, a urologic evaluation, and a pelvic examination in women.

TREATMENT

Management of Specific Treatable Subsets

Because patients with cancer of unknown primary site have advanced disease, therapeutic nihilism has been common. However, several subsets of patients can benefit from specific treatment, and they can be identified on the basis of clinical and pathologic features (Table 204-2). These patients are important to recognize and treat appropriately because some individuals in each group have the potential for long-term survival.

Adenocarcinoma

Women with Axillary Lymph Node Metastases

Metastatic breast cancer should be suspected in women who have axillary lymph node involvement with adenocarcinoma, particularly when other metastatic sites are not evident. In these patients, pathologic evaluation of the

TABLE 204-2 SPECIFIC PATIENT SUBSETS AND RECOMMENDED TREATMENT

SUBSET-IDENTIFYING FEATURES		
HISTOLOGIC	**CLINICAL**	**TREATMENT RECOMMENDATIONS**
Adenocarcinoma	Women, isolated axillary adenopathy	Treat as stage II breast cancer
Adenocarcinoma, poorly differentiated carcinoma	Women, peritoneal carcinomatosis (Occasionally men?)	Treat as stage III ovarian cancer
Adenocarcinoma	Men, elevated PSA or blastic bone metastases	Treat as advanced prostate cancer
Adenocarcinoma, poorly differentiated carcinoma	Single metastatic lesion	Definitive local therapy (resection or radiation therapy [or both]) with or without chemotherapy
Adenocarcinoma	Colon cancer profile	Treat as metastatic colorectal cancer
Squamous	Cervical adenopathy	Treat as locally advanced head or neck cancer
Squamous	Inguinal adenopathy	Definitive local therapy (node dissection with or without radiation therapy) with or without chemotherapy
Poorly differentiated carcinoma	Young men with midline tumor or elevated hCG or AFP	Treat as extragonadal germ cell tumor
Neuroendocrine carcinoma, poorly differentiated	Diverse clinical presentations	Treat as advanced stage small cell lung cancer
Neuroendocrine carcinoma, well differentiated	Usually liver metastases	Treat as metastatic carcinoid tumor

AFP = α-fetoprotein; hCG = human chorionic gonadotropin; PSA = prostate-specific antigen.

initial lymph node biopsy should include staining for estrogen and progesterone receptors and for *HER-2* expression; elevated levels provide strong evidence for the diagnosis of breast cancer.

When no other metastases are identified, these women should be treated as if they had stage II breast cancer, which is potentially curable with appropriate therapy (Chapter 198). Modified radical mastectomy identifies a breast primary site in 44% to 82% of women even when the breast examination and mammographic findings are normal. Axillary lymph node dissection followed by radiation therapy to the breast appears to give results similar to those of mastectomy, although these two options for primary therapy have not been compared directly. Adjuvant systemic therapy should follow standard guidelines for the treatment of women with stage II breast cancer.

Women with Peritoneal Carcinomatosis

Adenocarcinoma involving the peritoneum in women usually originates from the ovary (Chapter 199), although carcinomas arising in the GI tract or breast can occasionally produce this syndrome. However, diffuse peritoneal carcinomatosis occasionally occurs in women who have histologically normal ovaries or who have had previous bilateral oophorectomy. The peritoneum is frequently the only site of tumor involvement, and serum CA-125 levels are usually elevated. When histologic features suggest ovarian cancer, this syndrome has been called *peritoneal papillary serous carcinoma* or *primary extraovarian serous carcinoma*.

Even when the histologic features are not typical, women with adenocarcinoma of unknown primary site involving the peritoneum often have cancers with biologic characteristics similar to those of ovarian cancer (Chapter 199). Treatment of these patients should follow guidelines for stage III ovarian cancer. When feasible, a full laparotomy with maximal surgical cytoreduction should be performed followed by combination chemotherapy with a taxane/platinum–containing regimen. Measurement of serial serum CA-125 levels provides an accurate assessment of the efficacy of treatment. A few of these patients may have complete responses and long-term survival, particularly when initial surgical cytoreduction leaves minimal residual disease. A similar syndrome of peritoneal carcinomatosis that is responsive to chemotherapy for ovarian cancer has rarely been reported in men.

Men with Skeletal Metastases or Elevated Serum Prostate-Specific Antigen Levels

Metastatic prostate cancer (Chapter 201) should be suspected in men with adenocarcinoma predominantly involving bone, particularly if the metastases are blastic. An elevated serum PSA level or tumor immunostaining for PSA confirms the diagnosis of prostate cancer. Occasionally, men with adenocarcinoma of unknown primary site and patterns of metastasis unusual for prostate cancer (e.g., lung metastases, mediastinal lymph node metastases) are found to have elevated serum PSA levels. These patients should be treated according to guidelines for advanced prostate cancer. Androgen ablation produces excellent responses and substantial palliation in most patients.

Single Metastatic Lesion

Occasionally, a single metastatic lesion containing adenocarcinoma or poorly differentiated carcinoma is identified, and a complete evaluation reveals no other evidence of disease. Such presentations can include a single lymph node or subcutaneous site or single lesions in various visceral sites, including bone, liver, lung, brain, and adrenal gland. The possibility of an unusual primary site mimicking a metastatic lesion should be considered (e.g., a subcutaneous nodule from a primary apocrine or sebaceous carcinoma rather than a metastasis), but this possibility can usually be excluded on the basis of clinical or pathologic features. PET is useful in excluding other metastatic lesions.

For patients with only a single identifiable lesion, definitive local therapy is recommended, guided by the site of tumor involvement. Such therapy may include surgical resection, radiation therapy, or a combination of these modalities. Although most of these patients eventually develop other metastatic sites, a significant disease-free interval is often experienced, and local treatment provides substantial palliation. The role of systemic chemotherapy in addition to definitive local therapy is not well defined; younger patients with poorly differentiated carcinoma or poorly differentiated adenocarcinoma are often treated with a short course of a taxane/platinum–based regimen.

Colon Cancer Profile

The accurate recognition of patients likely to respond to treatment for advanced colon cancer has become increasingly important because the efficacy of colon cancer treatment has improved substantially. In patients with cancer of unknown primary origin, a "colon cancer profile" includes (1) metastases predominantly in the liver, peritoneum, or both; (2) adenocarcinoma with histologic features typical of GI origin; and (3) typical immunohistochemical staining (CK20 positive, CK7 negative, and CDX-2 positive).[9] Patients with this profile should be treated according to guidelines for metastatic colorectal cancer (Chapter 193).

Squamous Cell Carcinoma

Cervical Adenopathy

Squamous cell carcinoma (SCC) of unknown primary site is relatively uncommon. Most patients with this syndrome have involvement of cervical lymph nodes, usually in the upper or midcervical area. Often, patients with this syndrome are middle aged or elderly and have a history of substantial tobacco or alcohol use or both. A primary site in the head and neck region should be suspected (Chapter 190); however, complete endoscopic evaluation fails to identify a primary site in approximately 15% of these patients. Even if other test results are negative, PET identifies a primary site in the head and neck region in approximately 25% of such patients and should be part of the initial evaluation.

Even when no primary site is identified, these patients should receive treatment with concurrent chemotherapy and radiation therapy,[10] as is currently recommended for locally advanced SCC arising in the head and neck. Combined modality therapy produces 5-year disease-free survival rates of 50% to 60%; multiple involved lymph nodes or nodes larger than 2 cm are adverse prognostic features (Chapter 190).

Inguinal Adenopathy

Occasionally, metastatic squamous cell cancer is found in inguinal lymph nodes. In most of these patients, a primary site can be located in the perineal or anorectal area. For the occasional patient in whom no primary site is identified, long-term survival can result from local therapy with inguinal lymph node dissection, with or without radiation therapy. Recently, combined-modality treatment with concurrent chemotherapy and radiation therapy has improved

cure rates in patients with several SCCs arising in this region (e.g., cervix, anus, bladder). Although data are incomplete, a reasonable approach is the addition of chemotherapy with a platinum–5-fluorouracil regimen, as described for locally advanced carcinoma of the cervix.

Poorly Differentiated Carcinoma

Extragonadal Germ Cell Cancer Syndrome

Young men with clinical features of extragonadal germ cell tumors, including tumors in the mediastinum or retroperitoneum or those associated with elevated serum levels of human chorionic gonadotropin or AFP, should be treated according to guidelines for extragonadal germ cell tumors (Chapter 200). Some of these patients can be proven to have germ cell tumors by identifying an i12p chromosomal abnormality even when the diagnosis is not possible with other standard pathologic techniques. Approximately 30% to 40% of such patients achieve complete responses and long-term survival after chemotherapy with cisplatin, etoposide, and bleomycin as used for advanced germ cell tumors.

Anaplastic Lymphoma

An appropriate initial pathologic evaluation should identify most histologically atypical lymphomas. Occasionally, IHC staining for leukocyte common antigen is negative or cannot be adequately performed in patients with anaplastic lymphoma. The disease in some of these patients can be recognized using other IHC stains (e.g., Ki-1, CD-30), molecular genetic analysis (detection of immunoglobulin gene rearrangements), or molecular tumor profiling. All patients with lymphomas identified by special pathologic studies should be treated using standard guidelines for aggressive non-Hodgkin lymphoma (Chapter 185).

Neuroendocrine Carcinoma

In approximately 10% of poorly differentiated carcinomas, neuroendocrine features are identified by either IHC staining or electron microscopy. Treatment of these patients is discussed later (see Neuroendocrine Carcinoma).

Other Poorly Differentiated Carcinomas

In most patients with poorly differentiated carcinoma, there are no clinical or pathologic features that allow their assignment to any of the treatable subsets. These patients have a prognosis similar to patients with adenocarcinoma of unknown primary site, and treatment should follow similar guidelines.

Neuroendocrine Carcinoma

Poorly Differentiated Neuroendocrine Carcinoma or Small Cell Anaplastic Carcinoma

These high-grade neuroendocrine tumors are now reliably identified using widely available IHC stains. Although the origin of these tumors remains obscure, they are often highly sensitive to combination chemotherapy; platinum–etoposide chemotherapy as used in the treatment of small cell lung cancer, produces an overall response rate of approximately 60%, and 15% to 20% of patients have complete responses. In patients with locoregional disease, the addition of radiation therapy after chemotherapy is reasonable.

Low-Grade (Carcinoid-Type) Neuroendocrine Tumors

Occasionally, low-grade neuroendocrine tumors are found at a metastatic site. In almost all cases, the liver is the site of involvement, and the histologic features suggest a carcinoid (Chapter 232) or islet cell tumor of GI origin (Chapter 195). Various clinical syndromes caused by the secretion of vasoactive peptides (e.g., serotonin, vasoactive intestinal peptide, gastrin) have been described. Similar to other carcinoid tumors, these tumors often have indolent biologic characteristics, and patients can frequently survive for several years despite multiple liver metastases. Unlike poorly differentiated neuroendocrine tumors, these tumors are relatively resistant to chemotherapy, and intensive combination regimens should usually be avoided. Management of these patients should follow guidelines for metastatic carcinoid tumors (Chapter 232) and may include the use of somatostatin analogues, local ablative procedures (e.g., surgical resection, radiofrequency ablation, chemoembolization), targeted agents (e.g., sunitinib, everolimus), or fluorouracil-based chemotherapy regimens.

Empiric Chemotherapy

Approximately 70% to 80% of patients with adenocarcinoma or poorly differentiated carcinoma of unknown primary site do not fit into any of these defined clinical subsets. In these patients, treatment with empiric chemotherapy (usually taxane–platinum or gemcitabine–platinum combinations) has been of modest benefit, producing response rates of 30% to 45% and a median survival time of 9 to 11 months. However, empiric chemotherapy regimens, designed at a time when there was substantial overlap in the systemic therapy of different tumor types, are no longer able to provide adequate "coverage" as therapy for different cancers becomes more specific. At present, the standard of care is shifting from empiric chemotherapy to site-specific treatment, directed by the molecular tumor profiling prediction of the site of tumor origin.

Site-Specific Therapy Directed by Molecular Tumor Profiling

Molecular tumor profiling results in a prediction of the primary site in more than 90% of patients with cancer of unknown origin. Site-specific therapy has several potential advantages over empiric therapy, including the ability to appropriately incorporate tumor-specific targeted agents and to avoid unnecessary treatment in patients with unresponsive tumor types. In a group of 194 patients with cancer of unknown primary, assay-directed site-specific treatment produced a median survival period of 12.5 months.[11] Patients predicted to have more responsive tumor types (and therefore likely to derive the most benefit from site-specific treatment) had a median survival period of 13.4 months compared with 7.6 months for less treatment-responsive tumor types. In general, treatment responses and survival were consistent with the cancer type predicted; patients predicted to have breast or ovarian tumors had median survival periods of more than 24 months with site-specific treatment.[12] As additional treatment results become available, it is likely that molecular assay-directed, site-specific therapy will become the new treatment standard, with empiric chemotherapy reserved for patients whose tumors are unclassifiable by molecular profiling.

REVIEW QUESTIONS

1. A 65-year-old man, former cigarette smoker, presents with an asymptomatic right neck mass. He feels well otherwise. Physical examination is normal except for a firm, nontender, movable 2 cm lymph node in the right jugulodigastric area. CT scan of the neck shows the palpable right cervical node and two adjacent nodes, each measuring 1.5 cm, deeper in the right anterior cervical area. CT scans of the chest and abdomen are normal. Needle biopsy of the palpable node shows squamous carcinoma. The most likely diagnosis is

A. metastatic lung cancer.
B. metastatic gastric cancer.
C. locally advanced base of tongue cancer.
D. metastatic esophageal cancer.
E. metastatic squamous skin cancer.

Answer: C Squamous cell carcinomas (SCCs) arising from various sites in the head and neck (nasopharynx, oropharynx, hypopharynx, larynx) frequently metastasize to ipsilateral upper cervical lymph nodes. In 85% of patients who present with metastatic SCC in the upper cervical nodes, appropriate evaluation identifies the head or neck primary site. SCCs of the lung or esophagus occasionally present with a palpable neck node but almost always in the lower cervical or supraclavicular area. Metastatic gastric cancer sometimes spreads to the left supraclavicular nodes (Virchow's nodes) but has adenocarcinoma histology. Metastases from SCC skin cancers are rare.

2. In the patient described in question 1, the procedure most likely to identify the primary site is

A. PET scan.
B. ENT endoscopy (nasopharynx, oropharynx, hypopharynx, larynx).
C. fiberoptic bronchoscopy.
D. upper GI endoscopy.
E. right radical neck dissection.

Answer: B Endoscopy with visualization of the mucosal surfaces of the nasopharynx, oropharynx, hypopharynx, and larynx identifies a primary site in a large majority of such patients. PET scan can also identify an occult head or neck primary site but much less consistently. Bronchoscopy and upper GI endoscopy are not usually productive because most often the primary site is in the head or neck. Radical neck dissection before further evaluation is inappropriate.

3. A previously healthy 30-year-old man presents with fatigue, a 10-lb weight loss, and severe abdominal and back pain that has steadily increased during the past month. Abdominal CT scan shows a 15 × 10 × 8 retroperitoneal mass, with the superior aspect adjacent to the pancreas but not clearly invading the pancreas or other organs. A CT-guided core needle biopsy shows poorly differentiated carcinoma. A chest CT scan shows a single 0.5-cm noncalcified right lung nodule of questionable significance. Further evaluation should include all of the following except

A. immunohistochemical staining of the biopsy specimen (by pathologist) to better characterize the cancer type.
B. GU history, particularly any history of cryptorchidism.
C. testicular ultrasonography.
D. serum hCG and AFP levels.
E. endoscopic retrograde cholangiopancreatography (ERCP).

Answer: E Because of this patient's age, tumor location in the retroperitoneum, and biopsy showing poorly differentiated carcinoma, an extragonadal germ cell tumor (EGCT) is a likely diagnosis and is definitely the most treatable carcinoma in this setting. Additional pathologic evaluation with immunohistochemical stains (OCT4, PLAP, hCG) may support a germ cell tumor diagnosis, and high-grade non-Hodgkin's lymphoma (occasionally mistaken for a poorly differentiated carcinoma) should be ruled out with an LCA stain. Elevated serum hCG or AFP in this clinical setting would provide strong evidence for an EGCT. The risk of germ cell tumor is increased in patient with cryptorchidism even after surgical correction. Pancreatic cancer is an unlikely diagnosis in this situation (size and location of mass, age of patient, histology), and ERCP would prolong the evaluation and delay initiation of treatment.

4. A 60-year-old woman presents with a 2-month history of anorexia, 15-lb weight loss, and mild RUQ abdominal discomfort. Physical examination results are normal. Blood counts are normal; the chemistry profile reveals levels of AST and ALT three times the upper limit of normal. Abdominal CT scan shows six liver lesions consistent with metastases (the largest is 4 cm). Chest CT scan is normal. Colonoscopy is normal. Liver biopsy (core needle) shows metastatic adenocarcinoma compatible with a GI primary tumor; immunohistochemical staining shows CK20 positive, CK7 negative, and CDX2 positive. Molecular tumor profile predicts a colorectal site of tumor origin. Best management includes

A. treat with chemotherapy for metastatic colon cancer.
B. repeat the colonoscopy.
C. laparotomy to search for primary site and resect liver metastases if possible.
D. treat with empiric chemotherapy for cancer of unknown primary site.
E. advise the patient that treatment in this situation will probably be ineffective and discuss hospice referral.

Answer: A This patient has a carcinoma of unknown primary site with a colon cancer "profile": metastases to liver, typical adenocarcinoma histology, and suggestive immunohistochemical staining. In addition, the molecular tumor profiling prediction is colon cancer. Site-specific treatment of metastatic colon cancer is currently associated with median survival time of 20 to 24 months, which is substantially better than the expected 9- to 11-month median survival time with empiric CUP chemotherapy and long enough that hospice referral is not appropriate. A negative colonoscopy is frequent in patients with this syndrome; repeat colonoscopy will not change treatment, even if a small primary colon cancer is found. Resection of six liver metastases is very unlikely to be beneficial even if technically feasible. However, resection of residual hepatic metastases may have a role in patients who have an excellent response to first-line chemotherapy.

5. A 45-year-old premenopausal woman presents with a new mass in her right groin. She feels well and denies any recent urinary or gynecologic symptoms. Physical examination reveals a firm, nontender 2.5-cm right inguinal lymph node, with an adjacent 1.5-cm node, also firm and nontender. CT scans of the chest, abdomen, and pelvis reveal no additional findings. A needle biopsy of the largest inguinal lymph node shows metastatic squamous cell cancer. In this patient, procedures indicated in a search for the primary site may include all except

A. pelvic examination with colposcopy and biopsy of suspicious lesions.
B. cystoscopy.
C. PET scan.
D. breast MRI.
E. anoscopy.

Answer: D Female patients who present with squamous cell cancer metastatic to inguinal nodes usually have a primary site that is detectable in the vagina, cervix, bladder, or anorectal area. Evaluation should search for these primary sites. If metastases from any of these primary sites are limited to ipsilateral inguinal lymph nodes, appropriate treatment is sometimes curative. This presentation (location of metastases, squamous histology) is not suggestive of breast cancer, and a breast MRI is an unnecessary procedure in this situation.

APPROACH TO INBORN ERRORS OF METABOLISM

OLAF A. BODAMER

DEFINITION

The term *metabolism* (Greek: *metabolé*, "change") refers to the network of chemical reactions that sustain the human organism through the digestion, absorption, transport, and utilization of nutrients. Inborn errors of metabolism are genetic disorders that affect these intrinsic metabolic pathways through deficiencies of enzymes, membrane transporter proteins, signaling peptides, or structural proteins. The resulting clinical phenotype follows a spectrum of different organ manifestations that may be progressive, fluctuating, or stationary in nature and may be manifested at any age. Any inborn error of metabolism can principally be manifested during adolescence or adulthood, although severe presentations are typically recognized during infancy and childhood.

HISTORY

Archibald Garrod pioneered the field of inborn errors of metabolism after recognizing alkaptonuria as one of the first metabolic conditions due to homozygosity of mutant alleles in 1902. He had the foresight to recognize the autosomal recessive inheritance of additional inborn errors of metabolism, including cystinuria, pentosuria, and albinism, and to speculate about "chemical individuality" as one of the driving forces of selection and evolution. However, it was not until the early 1950s that the deficiency of homogentisate 1,2-dioxygenase (HGD) was recognized as the underlying cause of alkaptonuria, and it took many more years to identify pathogenic mutations in the *HGD* gene.

The advent of novel analytical techniques led to the molecular and biochemical characterization of known inborn errors of metabolism and the delineation and recognition of new clinical phenotypes, some of which were previously not presumed to be due to inborn errors of metabolism. The completion of the first human genome in 2001 and the following "genomics" revolution laid the foundation for the successive identification of many additional inborn errors of metabolism through next-generation sequencing, bringing the total number of catalogued inborn errors of metabolism to more than 1500 (March 2014).

The initiation of population-based newborn screening in 1964 through Robert Guthrie resulted in its recognition as an important public health measure to prevent morbidity and mortality of inborn errors of metabolism. More than 4 million newborn infants are screened annually in the United States for 31 core conditions, including mostly inborn errors of metabolism. As a consequence, approximately 12,500 newborn infants are diagnosed each year through newborn screening. Rarely, mothers with an inborn error of metabolism are diagnosed through newborn screening of their infants subsequent to placental transfer of pathognomonic metabolites.

EPIDEMIOLOGY

Inborn errors of metabolism occur in all populations, although their incidence and prevalence rates may vary considerably because of differences in carrier rates. These variations are readily explained by the presence of founder mutations, for example, in individuals of Ashkenazi Jewish or Amish ancestry, or by an increased rate of parental consanguinity that leads to a relative increase in mutant allele frequency (Table 205-1). Knowledge of the increased carrier frequencies is instrumental for preconception genetic counseling and targeted carrier screening.

PATHOBIOLOGY

The complexity of human metabolism and its spatial relationship with the human proteome, genome, and methylome are poorly understood. Naturally occurring variants in human nucleotide sequences may or may not result in variation of amino acid sequences in peptides and proteins. It is now well established from whole exome and genome sequencing that individuals may carry in excess of 10,000 nucleotide variants; most variants are silent, *single-nucleotide polymorphic variants*. Up to 4% of variants may be pathogenic in either recessive or dominant genes. These variants in particular will lead to functional changes in proteins that may render the affected individual susceptible to disease, increase the risk for undesired side effects on treatment with certain drugs, or increase the risk for genetic conditions in future generations.

Variation of human peptides and proteins is not merely explained through genomic sequence variation. Post-transcriptional alternative splicing will generate tissue-specific isoforms of proteins that are adapted to their functional needs through post-translational modification and conformational plasticity.

Genetics

Inborn errors of metabolism are monogenic conditions that follow autosomal recessive or dominant, X-linked recessive or dominant, or mitochondrial inheritance patterns. Of note is the existence of genetic or environmental modifiers that contribute to the interindividual and intrafamilial variability of phenotypic expression, although for most inborn errors of metabolism, these modifiers remain elusive. In case of mitochondrial inheritance, heteroplasmy (the random distribution and expression of mitochondrial mutations in different organs) may explain by itself the striking variability of clinical symptoms in mitochondrial conditions. The concept of synergistic heterozygosity (i.e., heterozygosity for pathogenic mutations affecting different enzymes simultaneously within the same pathway) may explain why some individuals with symptoms reminiscent of inborn errors of metabolism are not formally diagnosed.

Pathophysiology

The severity of any given inborn error of metabolism depends on the degree of enzyme deficiency and the complex interaction of the underlying pathogenic mutations, genetic modifiers, and environment. Hypomorphic mutations may not lead to overt disease until adulthood, whereas severe mutations in the same gene may lead to infantile-onset disease associated with significant morbidity and mortality. The underlying pathophysiologic mechanisms may contribute individually or in combination to the disease state (Table 205-2). Complete blockage of a catabolic pathway may result in accumulation of toxic substrates, activation of secondary minor pathways, or a relative shortage of downstream products. As a consequence, different organs may be affected by the same metabolic defect. An example is homocystinuria due to mutations in the gene for cystathionine β-synthase, which causes lens dislocation and intellectual disabilities and increases the risk for cardiovascular disease. Accumulation of homocysteine contributes to the vascular risk, whereas lack of the downstream product cysteine is an important factor in the dislocation of the lens through loosening of the zonular fibers (Table 205-3).

Clinical Phenotype

Inborn errors of metabolism typically affect multiple organs and, in more than 50% of cases, the central and peripheral nervous systems and muscles. One or more organ manifestations may dominate the clinical phenotype, although oligosymptomatic cases may occur. The clinical phenotype represents a continuous clinical spectrum ranging from the severe end, presenting during infancy, to the mild end of the spectrum, presenting during adolescence or adulthood. Some affected individuals may never come to medical attention because of almost complete absence of symptoms or atypical presentation. Recent data from newborn screening programs suggest much higher incidence rates for some inborn errors of metabolism due to the detection of a high rate of mild cases in which disease-related signs or symptoms may never develop. Some clinical signs are pathognomonic for an inborn error of metabolism, whereas others should raise the suspicion for the presence of an inborn error of metabolism (Table 205-4).

Classification

Inborn errors of metabolism can be classified on the basis of the underlying pathomechanism (see Table 205-2), the nature or localization of the protein involved (see Table 205-3), or the clinical phenotype (see Table 205-4). The most logical classification is based on the nature or localization of the affected protein and pathway.

INBORN ERRORS OF METABOLISM

Disorders of Protein Metabolism

These conditions are due to cytosolic or mitochondrial enzyme deficiencies affecting mostly catabolic pathways (Table 205-5). Disorders of protein

TABLE 205-2 PATHOPHYSIOLOGIC MECHANISMS IN INBORN ERRORS OF METABOLISM

MECHANISM	DISORDER
Accumulation of toxic substrates through primary blockage of catabolic pathway	Organic acidopathies (MMA, PA) MSUD, tyrosinemia type I
Accumulation of nontoxic macromolecules through blockage of catabolic pathway	Lysosomal storage disorders (MPS)
Energy failure through primary blockage of pathway relevant for ATP synthesis	Fatty acid oxidation defects Glycogen storage disorder types I and III Respiratory chain enzyme deficiencies
Impairment of post-translational glycosylation	Congenital disorders of glycosylation
Deficiency of end product through primary blockage of anabolic pathway	Albinism, orotic aciduria, scurvy, disorders of creatine metabolism
Lack of detoxification through primary blockage of catabolic pathway	Urea cycle defects

ATP = adenosine triphosphate; MMA = methylmalonic aciduria; MPS = mucopolysaccharidoses; MSUD = maple syrup urine disease; PA = propionic aciduria.

TABLE 205-3 SELECTED PROTEINS AND INBORN ERRORS OF METABOLISM

PROTEIN	LOCALIZATION	FUNCTION	DISORDER
Enzyme	Cytosolic	Urea production	Urea cycle defects
Enzyme	Mitochondrial	Fatty acid oxidation	Disorders of fatty acid oxidation
		ATP synthesis	Respiratory chain enzyme deficiencies
Transporter	Cellular membrane	Creatine transport	Creatine deficiency
		Folic acid transport	Folic acid deficiency
	Mitochondrial membrane	Carnitine transport	CACT deficiency
Transporter	Blood	Transport of cobalamin	Cobalamin deficiency

ATP = adenosine triphosphate; CACT = carnitine acylcarnitine translocase.

TABLE 205-4 CHARACTERISTIC SIGNS OF INBORN ERRORS OF METABOLISM

ORGAN	CLINICAL SIGN	DISORDER
Eye (cornea)	Cornea verticillata	Fabry's disease
Skeletal system	Ochronosis, black urine	Alkaptonuria
Connective tissue	Carpal tunnel syndrome	MPS I, II, VI, and VII
Central nervous system	Ataxia	Respiratory chain enzyme deficiency
Muscle	Hypotonia	Pompe's disease, GSD V Disorders of creatine metabolism
Liver	Hepato(-spleno)megaly Fibrosis, cirrhosis	MPS I, II, VI, and VII GSD I, III GSD IV, IXb/c, LAL deficiency
Kidney	Renal insufficiency	Cystinosis, Fabry's disease
Skin	Angiokeratomas	Fabry's disease

GSD = glycogen storage disease; LAL = lysosomal acid lipase; MPS = mucopolysaccharidosis.

metabolism may also be due to defects of plasma membrane protein transport (Table 205-6).

PHENYLKETONURIA

Phenylalanine is an essential amino acid important for growth and production of thyroid hormone, neurotransmitters, and melanin. Phenylketonuria (PKU) is caused by deficiency of tetrahydrobiopterin (BH4)–dependent phenylalanine hydroxylase that catalyzes the conversion of phenylalanine to tyrosine. PKU may also be caused by deficiency of enzymes that are required for BH4 synthesis. PKU is one of the "traditional" inborn errors of metabolism and the first to be included in newborn screening programs, demonstrating that early diagnosis and continued therapy consistently result in normal intellectual development.[1]

TYROSINEMIA

There are three types of tyrosinemia due to different enzyme deficiencies within the catabolic pathway of tyrosine. Deficiency of fumarylacetoacetase in tyrosinemia type I leads to production of toxic byproducts of a minor pathway. These byproducts are primarily toxic to the liver, resulting in acute liver failure and renal Fanconi's tubulopathy if it is left untreated. Succinylacetone, one of the toxic byproducts, serves as a diagnostic metabolite. Tyrosinemia type II results in significant elevations of tyrosine concentration in all tissues, leading to painful corneal lesions, hyperkeratosis of the palms and soles, and mild intellectual disability.

MAPLE SYRUP URINE DISEASE

The clinical phenotype in maple syrup urine disease (MSUD) is due to accumulation of toxic compounds including oxoisocaproic acid resulting from deficiency of the branched-chain α-keto acid dehydrogenase complex. This multienzyme complex, similar to the pyruvate dehydrogenase complex, consists of four different subunits, E_{1a}, E_{1b}, E_2, and E_3. Deficiency of any subunit or a combination of subunits will cause MSUD. Mild forms of MSUD may

TABLE 205-5 DISORDERS OF PROTEIN METABOLISM

DISORDER	ENZYME DEFECT	METABOLITES	CLINICAL PHENOTYPE
Argininemia	Arginase	Arginine	Hyperammonemia, neurologic disease
Argininosuccinic aciduria	Argininosuccinate lyase	Argininosuccinate*	Hyperammonemia, liver cirrhosis
Citrullinemia	Argininosuccinate synthetase	Citrulline, orotic acid*	Hyperammonemia, liver cirrhosis
Homocystinuria	Cystathionine β-synthase	Homocysteine, methionine	Marfanoid habitus, intellectual disability, lens dislocation
Maple syrup urine disease	Branched-chain α-keto acid dehydrogenase complex	Alloisoleucine,* leucine, valine, isoleucine	Encephalopathy, ataxia, metabolic decompensation
Ornithine transcarbamylase deficiency	Ornithine transcarbamylase	Orotic acid,* ornithine, arginine	Severe hyperammonemia, X-linked inheritance
Phenylketonuria	Phenylalanine hydroxylase	Phenylalanine	Intellectual disability,† seizures†
Tyrosinemia type I	Fumarylacetoacetase	Succinylacetone,* tyrosine	Acute liver failure, tubulopathy
Tyrosinemia type II	Tyrosine aminotransferase	Tyrosine, phenylalanine	Corneal lesions, hyperkeratosis of the skin, mild intellectual disability

*Diagnostic compound.
†If untreated.

TABLE 205-6 INBORN ERRORS OF METABOLISM CAUSED BY DEFECTS IN PLASMA MEMBRANE TRANSPORTER PROTEINS

DISORDER	TISSUE AFFECTED	SUBSTRATE	MODE OF INHERITANCE	CLINICAL PHENOTYPE
Cobalamin malabsorption	Ileum	Cobalamin	Autosomal recessive	Pernicious anemia
Carnitine uptake deficiency	Kidney, small intestine	Carnitine	Autosomal recessive	Hypoglycemia, hypotonia
Cystic fibrosis	Apical epithelia	Chloride	Autosomal recessive	Pneumonia, ileus
Cystinuria	Kidney, small intestine	Cystine, lysine, arginine, ornithine	Autosomal recessive	Urolithiasis
Familial hypophosphatemic rickets	Kidney, small intestine	Phosphate	X-linked dominant	Rickets
Folate deficiency	Lymphocyte, erythrocyte	Methyltetrahydrofolate	Autosomal recessive	Aplastic anemia
GLUT1 deficiency	Blood-brain barrier, erythrocyte	Glucose	Autosomal recessive	Seizures, microcephaly
Hartnup's disease	Kidney, small intestine	Neutral amino acids	Autosomal recessive	Nicotinic acid deficiency
Hereditary renal hypouricemia	Kidney	Uric acid	Autosomal recessive	Urolithiasis
Hereditary spherocytosis	Erythrocyte	Sodium	Autosomal dominant or recessive	Hemolytic anemia
Iminoglycinuria	Kidney, small intestine	Glycine, proline, hydroxyproline	Autosomal recessive	Benign, pancreatitis?
Isolated lysinuria	Kidney, small intestine	Lysine	Autosomal recessive	Growth failure, seizures
Lysinuric protein intolerance	Kidney, liver, intestine	Lysine, arginine, ornithine	Autosomal recessive	Growth failure, intellectual disability, hyperammonemia
Renal glycosuria	Kidney	Glucose	Autosomal recessive	Benign
Renal tubular acidosis type 1	Distal renal tubule	H^+ secretion, citrate, calcium	Autosomal dominant	Hypokalemia, growth failure, nephrocalcinosis
Renal tubular acidosis type 2	Proximal renal tubule	Bicarbonate	Autosomal recessive	Hyperchloremic metabolic acidosis

Modified from Elsas L II: Approach to inborn errors of metabolism. In: Goldman L, Schafer AI: Goldman's Cecil Medicine. 24th ed. Philadelphia: Elsevier Saunders; 2012:1340-1346.

present with fluctuating neurologic symptoms as well as episodes of ketoacidosis.

Disorders of the Urea Cycle

The role of the urea cycle is to convert ammonium as a byproduct of amino acid metabolism to nontoxic urea that is readily excreted in urine and to synthesize arginine and ornithine. Arginine is an important precursor for the nitric oxide pathway, and it is substrate for creatine/creatine phosphate synthesis. Several mitochondrial and cytosolic enzymes as well as transporters are required for the function of the urea cycle. Individuals with any of the disorders of the urea cycle are at risk for hyperammonemia during catabolic episodes when there is an increased rate of protein breakdown.[2] All conditions are inherited as an autosomal recessive trait with the exception of ornithine transcarbamylase deficiency, which is inherited as an X-linked recessive trait (see Table 205-5).

Disorders of Membrane Transport

Many inborn errors are due to mutations in genes encoding plasma membrane transporter proteins (see Table 205-6). These transporter proteins are responsible for the active transport of small molecules including vitamins, carnitine, glucose, amino acids, and electrolytes across different membranes. The blood-brain barrier plays a particular role in the protection and transport of nutrients to and from the central nervous system. GLUT1 facilitates the transport of glucose across many cellular membranes, including the blood-brain barrier. Deficiency of GLUT1 results in low cerebrospinal fluid glucose concentrations despite normal glucose levels in the blood, a circumstance that is used diagnostically. Affected individuals develop seizures that may be treated with ketone bodies. Other glucose transporters GLUT 2, 3, and 4 are expressed in the liver, kidneys, neurons, and skeletal and heart muscles, with more than one glucose transporter expressed by most cells.

Organic Acidurias

Organic acidurias are disorders due to mitochondrial enzyme deficiencies and accumulation of potentially toxic substrates, activation of alternative pathways, and lack of downstream products. Although the typical clinical presentation is during infancy or childhood, adult cases with mild or atypical symptoms have been reported in the medical literature. Although individuals with organic acidurias are at risk for metabolic decompensation during catabolic episodes, this risk is somewhat lower during adulthood (Table 205-7).

TABLE 205-7 ORGANIC ACIDURIAS

DISORDER	ENZYME DEFECT	INHERITANCE	URINE METABOLITES
Glutaric aciduria type I	Glutaryl-CoA dehydrogenase	Autosomal recessive	3-Hydroxyglutaric acid, glutaric acid
Holocarboxylase synthetase deficiency	Holocarboxylase synthetase	Autosomal recessive	β-Hydroxyisovaleric acid, β-methylcrotonylglycine, β-hydroxypropionic acid, 3-methylcitrate
Isobutyric aciduria	Isobutyryl-CoA dehydrogenase	Autosomal recessive	Isobutyric acid
Isovaleric aciduria	Isovaleryl-CoA dehydrogenase	Autosomal recessive	Isovaleric acid
Methylmalonic aciduria	Methylmalonyl-CoA dehydrogenase	Autosomal recessive	Methylmalonic acid
Mevalonic aciduria	Mevalonate kinase	Autosomal recessive	Mevalonic acid
Propionic aciduria	Propionyl-CoA carboxylase	Autosomal recessive	3-Methylcitrate, propionic acid, 3-hydroxypropionic acid

TABLE 205-8 INBORN ERRORS OF PEROXISOMES

DISORDER	GENE DEFECT	METABOLITES
Zellweger's spectrum	*PEX 1,2,3,5,6,10,12,13,14,16,19,26; DLP1*	Very long chain fatty acids, bile acids, phytanic and pipecolic acids, erythrocyte plasmalogen
Rhizomelic chondrodysplasia punctate type I	*PEX 7*	Phytanic acid, erythrocyte plasmalogen
X-linked adrenoleukodystrophy	*ABCD1*	Very long chain fatty acids
Acyl-CoA oxidase deficiency	*ACOX1*	Very long chain fatty acids
Methylacyl-CoA racemase deficiency	*AMACR*	Bile acid intermediates, phytanic and pristanic acids
Dihydroxyacetone phosphate acyltransferase deficiency	*GNPAT*	Erythrocyte plasmalogen
Refsum's disease	*PHYH*	Phytanic acid
Hyperoxaluria type I	*AGXT*	Oxalic acid

Lysosomal Storage Disorders

The lysosomal storage disorders comprise a heterogeneous group of more than 50 distinct disorders due to genetic defects in lysosomal enzymes and membrane proteins or transporters, resulting in lysosomal accumulation of specific substrates. The accumulation in tissues and organs is progressive, ultimately causing deterioration of cellular and tissue function. Many lysosomal disorders affect the central nervous system, and most patients have a decreased lifespan and significant morbidity. Lysosomal storage disorders may be categorized on the basis of the type of substrate stored. Disorders of glycosaminoglycan metabolism include the mucopolysaccharidoses (MPS): MPS I, Hurler's syndrome, Scheie's syndrome; MPS II, Hunter's syndrome; MPS IIIA-D, Sanfilippo's syndrome A-D; MPS IVA, IVB, Morquio's syndrome A and B; MPS VI, Maroteaux-Lamy syndrome; MPS VII, Sly's syndrome.[3] Disorders of ganglioside metabolism include Fabry's disease, Gaucher's disease, Niemann-Pick disease, Tay-Sachs disease, I-cell disease, fucosidosis, mannosidosis, sialidosis, and aspartylglycosaminuria. Danon's and Pompe's diseases are two lysosomal storage disorders resulting in storage of glycogen in different types of muscle cells.

Peroxisomal Disorders

Peroxisomes are cell organelles that are metabolically very active. They are the site of plasmalogen, cholesterol, and bile acid synthesis. Additional pathways include gluconeogenesis from amino acids, the formation of oxalic acid, and the breakdown of hydrogen peroxide, purines, polyamines, phytanic acid, pipecolic acid, and very long chain fatty acids. Disorders of peroxisomal metabolism may result in elevated very long chain fatty acids and phytanic and pipecolic acids but low plasmalogen concentrations (Table 205-8).

Disorders of Respiratory Chain Complexes

Thirteen proteins of the five different mitochondrial respiratory chain enzyme complexes are encoded in the mitochondrial gene, with the remainder being nuclear encoded. Complex II is entirely encoded by the nuclear genome. Disorders that affect any or a combination of the mitochondrial complexes will result in a broad clinical phenotype affecting multiple organs with marked intrafamilial and interfamilial variability due to heteroplasmy in case of mitochondrial inheritance.

Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDG) are due to defects in proteins that are involved in post-translational glycosylation of peptides and proteins. More than 30 different forms of CDG with a broad clinical spectrum affecting multiple organs are recognized. The traditional classification of CDG disorders is based on pathophysiologic considerations, whereas the newer classification uses the underlying molecular defects. Secondary changes in glycosylation pattern may be observed in galactosemia and hereditary fructose intolerance. The most common form of CDG, CDG type Ia, is due to deficiency in the *PMM2* gene encoding phosphomannomutase. Most of the patients with CDG Ia present during infancy and childhood with developmental delay, severe infections, bleeding diathesis, and liver impairment, although older patients with milder phenotypes have been described.[4]

DIAGNOSIS

Biochemical and Molecular Testing

The path to a diagnosis of an inborn error of metabolism begins with ascertainment of the medical and family history as well as an in-depth clinical evaluation. The majority of inborn errors of metabolism can be diagnosed through analysis of small molecules (metabolites, peptides, and hormones) in appropriate body fluids (serum, whole blood, urine, and cerebrospinal fluid), followed by enzyme testing in tissues (dried whole blood, lymphocytes, leukocytes, fibroblasts, and muscle tissue). Tissue biopsies for histology and histochemistry are still of value in some cases. Selected metabolic tests for diagnosis of inborn errors of metabolism include analysis of amino acids in plasma, dried blood spots, urine, and cerebrospinal fluid; analysis of acylcarnitine species in plasma and dried blood spots; analysis of total and free carnitine in plasma and urine; analysis of succinylacetone in dried blood spots and urine; and analysis of orotic acid in plasma and urine.

Molecular confirmation is warranted for prediction of phenotype and is a prerequisite for family planning, including preimplantation diagnosis, prenatal testing, and carrier testing for the partner (Table 205-9).

Next-Generation Sequencing

The completion of the first draft sequence of the human genome in 2001 laid the foundation for a new era that came to fruition after the advent of next-generation sequencing technologies. Next-generation sequencing enables the rapid and accurate sequencing of whole human genomes and exomes that represent the 1 to 2% of the genome that is translated into proteins. The continuous refinement of next-generation sequencing technologies has led to a rapid decline of sequencing cost, thereby facilitating the sequencing of tens of thousands of individuals in both research and clinical settings.

Clinical whole exome or genome sequencing in CLIA- and CAP-accredited laboratories may aid in the diagnosis of rare mendelian disorders including

TABLE 205-9 DIAGNOSTIC TESTS FOR INBORN ERRORS OF METABOLISM

METABOLITE	BIOLOGIC MATRIX	METHOD	DISORDER
Amino acids	Plasma, urine, CSF	HPLC, MS-MS	Disorders of amino acid metabolism including PKU, MSUD, tyrosinemia, urea cycle defects, lysinuric protein intolerance
Organic acids	Urine, CSF	GC-MS	Organic acidopathies including MMA, PA, IVA Lactic acidosis, mitochondrial disorders including disorders of the Krebs cycle, respiratory chain enzymes, fatty acid oxidation defects
Acylcarnitine species	Plasma, DBS	MS-MS	Fatty acid oxidation defects, organic acidopathies
Total/free carnitine	Plasma, DBS, urine	MS-MS	Carnitine transporter deficiency, CPT I/II deficiencies (in conjunction with acylcarnitine species), secondary carnitine deficiency
Orotic acid	Plasma, urine	GC-MS, MS-MS	Orotic aciduria, OTC deficiency, citrullinemia type I
Succinylacetone	Plasma, DBS, urine	GC-MS	Tyrosinemia type I
Glycosaminoglycans	Urine	TLC, MS-MS	Mucopolysaccharidoses

CPT I/II = carnitine palmitoyltransferase I/II; CSF = cerebrospinal fluid; DBS = dried blood spots; GC-MS = gas chromatography–mass spectrometry; HPLC = high-pressure liquid chromatography; IVA = isovaleric aciduria; MMA = methylmalonic aciduria; MS-MS = tandem mass spectrometry; MSUD = maple syrup urine disease; OTC = ornithine transcarbamylase; PA = propionic aciduria; PKU = phenylketonuria; TLC = thin-layer chromatography.

TABLE 205-10 THERAPEUTIC STRATEGIES FOR INBORN ERRORS OF METABOLISM

LEVEL	THERAPEUTIC APPROACH	DISORDER
Gene	Solid organ transplantation	Urea cycle defects, tyrosinemia type I
	Stem cell transplantation	Adrenoleukodystrophy, MPS I, GSD IA (experimental)
	Gene therapy	Pompe's disease (phase I/II trial)
	Read-through therapy	Duchenne's muscular dystrophy (phase III), cystic fibrosis (phase III)
Enzyme	Recombinant enzyme infusion	Gaucher's, Pompe's, and Fabry's diseases; MPS I, II, IVA, VI Phenylketonuria (phase III)
	Chaperone	Fabry's and Pompe's diseases (phase III)
Substrate	Substrate reduction	Phenylketonuria, maple syrup urine disease
	Substrate inhibition	Gaucher's disease, Tay-Sachs disease

GSD IA = glycogen storage disease type IA; MPS I = mucopolysaccharidosis type I.

inborn errors of metabolism, provided all other diagnostic avenues are exhausted. Although sequencing may be relatively straightforward and inexpensive, analytical challenges remain. An individual may carry a large number of gene variants requiring a dedicated analytical pipeline to identify the pathogenic variants of interest. The diagnostic yield may be as high as 25% in preselected cases.[5]

TREATMENT

The individual treatment strategy follows these general principles: enhancement of enzyme activity through cofactor administration; stabilization of enzyme structure through chaperone therapy; enzyme replacement therapy; reduction of substrate through dietary intervention; substrate inhibition through blockage of the reverse enzyme reaction; replacement of the affected organ (e.g., liver); and stem cell transplantation or therapy.[6,7] Other therapeutic approaches including "read-through" and gene therapies are in clinical trials. Read-through therapy refers to a small molecule (ataluren) that renders ribosomes less sensitive to premature stop codons and allows read-through. Ataluren has been tested in individuals with Duchenne's muscular dystrophy and cystic fibrosis due to nonsense mutations (Table 205-10).

The choice of therapy is guided by the underlying diagnosis, but additional factors warrant consideration. A curative approach may be preferred whenever possible, although this may be rarely an option in adults with inborn errors of metabolism, as in the case of bone marrow or stem cell transplantation in metachromatic leukodystrophy or X-linked adrenoleukodystrophy. Therapeutic agents that address central nervous system manifestations have to cross the blood-brain barrier to be effective, thereby limiting the use of larger molecules, including enzymes, for treatment of neurologic manifestations.

Individuals with inborn errors of metabolism should always be managed by a multidisciplinary team of biochemical geneticists, internists, and genetic counselors at a tertiary center with significant expertise in the management of these disorders. Ideally, a biochemical genetics laboratory to facilitate immediate sample testing should be on site.

Genetic Counseling

Genetic counseling through board-certified genetic counselors is an integral part of the evaluation and management of patients with any familial condition including complex inborn errors of metabolism. A three-generation family history and thorough medical history are the prerequisites for a focused clinical and diagnostic evaluation. Genetic counseling communicates the limitations and implications of genetic testing and associated test results to the patient and the family at large.

Enzyme Therapy

The therapeutic goal of enzyme therapy is to increase endogenous enzyme activity. Individuals with cofactor (vitamin)–responsive enzyme deficiencies may benefit from supraphysiologic doses of the respective vitamin. An example is BH4-responsive PKU due to mutations in the *PAH* gene affecting the binding site of phenylalanine hydroxylase (PAH); 20 mg/kg of BH4 will result in stabilization of the PAH through a chaperone-like effect and, as a consequence, increased PAH activity. Patients with BH4-responsive PKU will experience improved phenylalanine tolerance and metabolic control when taking BH4 supplementation.

Enzyme replacement therapy has been available for treatment of Gaucher's disease for more than 15 years. Initially, glucocerebrosidase, the enzyme deficient in Gaucher's disease, had been purified from human placentas and administered intravenously to affected patients. More recently, glucocerebrosidase has been overexpressed in Chinese hamster ovary cells and produced in large quantities in bioreactors. Recombinant enzyme replacement therapies are now available for Pompe's disease (α-glucosidase), Fabry's disease (α-galactosidase), mucopolysaccharidosis type I (α-iduronidase), mucopolysaccharidosis type II (α-iduronate sulfatase), mucopolysaccharidosis type IVA (galactosamine-6-sulfatase), and mucopolysaccharidosis type VI (arylsulfatase B). Additional enzyme therapies are currently in different phases of clinical trials (see Table 205-10).

Nutritional Therapy

The therapeutic goal of nutritional therapy is the correction of the metabolic imbalance through reduced substrate accumulation, promoting protein synthesis through anabolism and the prevention of episodes of metabolic decompensation. In addition, supplementation of a reduced product may be needed. An example is the therapy for PKU. The mainstay of its therapy is the reduction of phenylalanine intake through low-protein food and the simultaneous supplementation of phenylalanine-free amino acids for sustained growth and development. This regimen will reduce the phenylalanine levels in plasma and, most important, in the brain to nontoxic, nearly normal levels that facilitate age-appropriate intellectual development. On occasion, tyrosine supplementation is needed when tyrosine levels are low. Similar dietary strategies apply to other disorders of amino acid metabolism and organic acidopathies, although natural protein restriction may be more pronounced to reduce the risk for metabolic decompensation during a catabolic episode (intercurrent illness).

Another approach to reduce substrate accumulation is through inhibition of the reverse enzyme reaction that leads to substrate synthesis. This concept has been shown to be effective in reducing glucosylceramide in mild to moderate Gaucher's disease type I. Miglustat is an inhibitor of the enzyme glucosylceramide synthase that catalyzes the reverse direction of glucocerebrosidase, the enzyme that is deficient in Gaucher's disease type I.

Individuals with inborn errors of metabolism at risk for metabolic decompensation, such as urea cycle disorders, organic acidopathies, and disorders of fatty acid oxidation, should always carry an "emergency letter" detailing the diagnosis, symptoms of decompensation, emergency treatment, and contact information of the tertiary metabolic center.

Vitamin Therapy

There are a number of inborn errors of metabolism that affect transport or metabolism of vitamins. These conditions typically benefit from supraphysiologic doses of vitamins. An example is thiamine-responsive megaloblastic anemia, which is due to mutations in the thiamine transporter gene *SLC19A2*. Affected individuals develop sensorineural deafness, vision loss, diabetes mellitus, and megaloblastic anemia. Diabetes and anemia respond to high doses of thiamine. Other examples include disorders of vitamin B_{12} (cobalamin) absorption, transport, and metabolism and disorders of biotin and folic acid metabolism.

Organ, Bone Marrow, and Stem Cell Transplantation

Liver transplantation has been done in patients with tyrosinemia type I, urea cycle defects, methylmalonic aciduria, propionic aciduria, lysosomal lipase deficiency, and glycogen storage diseases affecting the liver. The effect of liver transplantation in these conditions is two-fold. First, metabolic control will be improved in those conditions in which the diseased liver is the main contributor to the overall lack of sufficient metabolic control. However, the intrinsic defect will not be corrected elsewhere after liver transplantation, and an affected individual may continue to have significant neurologic disease in methylmalonic aciduria, for example. Second, liver function will be restored in those conditions that lead to chronic liver disease, including liver fibrosis and cirrhosis, or in which there is a significant risk for malignant transformation. Kidney transplantation may be required in conditions that affect kidney function, as is the case in methylmalonic aciduria or cystinosis.

Bone marrow or stem cell transplantation has limited benefits in patients with inborn errors of metabolism. Examples include presymptomatic bone marrow or stem cell transplantation in severe mucopolysaccharidosis type I, metachromatic leukodystrophy, and X-linked adrenoleukodystrophy. Stem cell therapy is currently under investigation for glycogen storage disease type I.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding disorders caused by inborn errors of metabolism?

A. They present clinically in neonates and early childhood because the metabolic pathways disrupted in these disorders affect vital organ functions.
B. They are typically autosomal recessive diseases caused by founder mutations and parental consanguinity.
C. They can affect multiple organs with the exception of the central and peripheral nervous systems.
D. They may present with pathognomonic clinical signs.
E. They are characterized by mitochondrial inheritance.

Answer: D Inborn errors of metabolism may exhibit clinical signs that are diagnostically pathognomonic, such as ochronosis and black urine in alkaptonuria or angiokeratomas and cornea verticillata in Fabry's disease (see Table 205-4). The clinical phenotypes of inborn errors of metabolism range widely from severe disease presenting in infancy to mild symptoms and signs recognized only in adulthood as well as many cases that are asymptomatic and consistent with normal life expectancy. They are monogenic conditions that follow autosomal recessive or dominant, X-linked recessive or dominant, or mitochondrial inheritance patterns. More than 50% of clinical overt cases affect the central or peripheral nervous system. (See section on pathobiology.)

2. Which of the following therapeutic modalities is *not* currently in use for the clinical management of patients with inborn errors of metabolism?

A. Intravenous enzyme replacement therapy
B. Stem cell therapy
C. Liver transplantation
D. Nutritional therapy
E. None of the above has been shown to be effective in any inborn errors of metabolism.

Answer: B Examples of effective treatments include intravenous enzyme (glucocerebrosidase) replacement therapy (A) for Gaucher's disease; liver transplantation (C) for tyrosinemia type I, urea cycle defects, methylmalonic aciduria, propionic aciduria, lysosomal lipase deficiency, and glycogen storage diseases; and nutritional therapy (D) for phenylketonuria by reduction in phenylalanine intake through low-protein food along with simultaneous supplementation with phenylalanine-free amino acids. Stem cell therapy is currently under investigation for glycogen storage disease type I. (See section on treatment.)

3. Which of the following is *not* currently considered first-line diagnostic testing for inborn errors of metabolism?

A. Whole exome sequencing
B. Biochemical analysis of metabolites in body fluids
C. Enzyme testing in tissues
D. Tissue biopsies for histology and histochemistry
E. Prenatal and carrier testing

Answer: A Most inborn errors of metabolism can be diagnosed by analysis of small-molecule metabolites in appropriate body fluids like whole blood, serum, urine, and cerebrospinal fluid (B). This is usually followed by appropriate enzyme testing in tissues like dried whole blood, leukocytes, fibroblasts, and muscle tissue (C). Tissue biopsies for histology and histochemistry (D) are still of value in some cases. Molecular confirmation is available for prediction of phenotype and is a prerequisite for family planning, including preimplantation diagnosis, prenatal testing, and carrier testing for the partner (E). Clinical whole genome or exome sequencing in CLIA- and CAP-accredited laboratories may aid in the diagnosis of rare mendelian disorders like inborn errors of metabolism, but analytical challenges remain and should be considered at this time only if all other diagnostic avenues are exhausted. (See section on diagnosis.)

4. A 35-year-old woman is brought to the emergency department with a history of acute-onset nausea, headaches, and stupor after a protein-rich meal. She has a history of similar events in the past. Her brother died as an infant of an encephalopathic crisis. The plasma ammonium level on admission is 400 μmol/L (reference: <40 μmol/L). What is the most appropriate initial treatment?

A. Enzyme replacement therapy
B. Liver transplantation
C. Intravenous fluids only
D. Alternative pathway therapy with intravenous sodium benzoate or sodium phenylbutyrate
E. Hydroxycobalamin IM

Answer: D The 35-year-old woman suffers from ornithine transcarbamylase (OTC) deficiency. OTC is a urea cycle enzyme that is part of the urea cycle responsible for conversion of nitrogen to urea. Deficiency of any of the five urea cycle enzymes and three transporter proteins will lead to variable elevations of plasma ammonium during episodes of intercurrent illnesses, catabolism, or high-protein meals. OTC deficiency is inherited as an X-linked recessive trait, explaining why the affected brother died as an infant during a hyperammonemic crisis. Female carriers of OTC deficiency may show symptoms only when they are exposed to a high-protein meal. The goal of therapy is to normalize ammonium levels quickly through alternative pathway therapy, hemofiltration, or hemodialysis. Outcome is poor if ammonium levels are not corrected in a timely manner.

5. A 32-year-old man from Pakistan with a seizure disorder has been recently diagnosed with an inborn error of metabolism. His family history is remarkable for an affected sister and consanguinity of the healthy parents. There is a distant male cousin with the same condition. Given this family history, what is the most likely mode of inheritance for this condition?

A. Mitochondrial inheritance
B. X-linked recessive inheritance
C. Autosomal recessive inheritance
D. Autosomal dominant inheritance with complete penetrance
E. Complex inheritance including different genetic and environmental factors

Answer: C Due to consanguinity of the healthy parents and absence of affected family members in other generations, autosomal recessive inheritance is the most likely mode of inheritance for the condition in question. Mitochondrial (maternal) inheritance of mutations in mitochondrial genes may be observed in respiratory chain disorders, with variable expressivity of disease due to heteroplasmy. X-linked recessive inheritance as in OTC deficiency results in severely affected males and mildly or unaffected carrier females. Disorders with an autosomal dominant inheritance with complete penetrance affect multiple family members at each generation. The recurrence risk is 50% for future offspring of affected individuals. Complex inheritance may be observed in cancer, glaucoma, and Alzheimer's disease because of different contributions from genetic and environmental factors.

6. A 23-year-old woman and her 25-year-old husband, both of Ashkenazi Jewish ancestry, are seen for genetic counseling regarding their risk of having a child with Gaucher's disease or other conditions. What is the most appropriate response regarding their risk?

A. Their risk of having a child with Gaucher's disease is negligible.
B. Carrier screening of both parents for Gaucher's disease through analysis of common mutations in the *GBA* gene is indicated.
C. Prenatal diagnosis is recommended during early pregnancy through analysis of glucocerebrosidase activity in amniocytes.
D. Carrier screening of both parents should be comprehensive and include an Ashkenazi Jewish disease panel and SMA (spinal muscular atrophy) for both parents and fragile X for the mother.
E. Only karyotyping for the mother is indicated.

Answer: D The carrier frequency for a number of genetic conditions including Gaucher's disease is markedly increased in individuals of Ashkenazi Jewish ancestry. Carrier screening should therefore not be restricted to Gaucher's disease but also include Tay-Sachs disease, Canavan's disease, spinal muscular atrophy, and many others for both parents as well as fragile X for the mother.

7. A 19-year-old man has been diagnosed with a disorder of fatty acid oxidation. He is at increased risk for complications due to which pathophysiologic mechanism?

A. Accumulation of toxic substrates due to blockage of pathway
B. Energy failure due to primary blockage of a pathway that is important for ATP synthesis
C. Progressive accumulation of nontoxic substrates due to a defect in a catabolic pathway
D. Defect in post-translational glycosylation
E. Blockage of an anabolic pathway

Answer: B Disorders of fatty acid oxidation lead to reduced β-oxidation of fatty acids of various chain lengths, depending on the exact enzyme deficiency. As a consequence, fewer acetyl-CoA equivalents are produced that would be available for ATP or ketone body synthesis. Clinically, patients with disorders of fatty acid oxidation have a reduced fasting tolerance and are at risk for hypoglycemia and energy failure in skeletal and cardiac muscles.

8. The diagnosis of a mucopolysaccharidosis type I is suspected in a 21-year-old woman with hepatosplenomegaly, corneal clouding, and carpal tunnel syndrome. What is the first-line diagnostic test to confirm the diagnosis?

A. Urine glycosaminoglycans
B. Urine organic acids
C. Plasma acylcarnitine profile
D. Plasma amino acids
E. Whole exome sequencing

Answer: A Mucopolysaccharidosis type I is characterized through increased excretion of dermatan and heparan sulfates (glycosaminoglycans).

DISORDERS OF LIPID METABOLISM

CLAY F. SEMENKOVICH

As Western lifestyles become more pervasive, disorders of lipid metabolism remain among the most common problems faced by clinicians. Ischemic heart disease, the most common cause of global disability, is caused in part by abnormal lipids. Stroke, a common cause of death in the United States, is also related to disorders of lipid metabolism. Both are likely to dominate the clinical landscape of a world where obesity and diabetes are ubiquitous. Appropriate management of common lipid disorders should be a part of the skill set for everyone who provides clinical care to adults.

COMPONENTS OF LIPID TRANSPORT

Cholesterol and Triglycerides

Cholesterol is a critical constituent of eukaryotic cell membranes and the precursor for the synthesis of steroid hormones such as cortisol, vitamin D, progestins, estradiol, and testosterone. Triglycerides carry fatty acids, nutrients that are used preferentially by muscle tissue and are especially important as an energy source in the fasting state. Because both cholesterol and triglycerides are essentially insoluble in water, the lipid transport system evolved to transport fats from one site to another through an aqueous environment.

Lipoproteins

Cholesterol and triglycerides are transported in lipoproteins (Table 206-1), spherical particles that differ in size and composition, depending on their site of origin. Each particle is composed of a central core consisting of cholesteryl esters (the product of an esterification reaction between the polar cholesterol molecule and a fatty acid) and triglycerides, both nonpolar compounds. Free cholesterol, phospholipids, and apolipoproteins are found on the particle surface.

Chylomicrons and their remnants are the largest lipoproteins. Produced by the intestine, these particles carry fats that are absorbed from the diet. Their residence time in the circulation after a meal is short, on the order of minutes in healthy people. Chylomicrons are large and light; that is, their density is low. Because fat floats on water, particles with high fat and low protein content have lower density. Very low density lipoprotein (VLDL) is a triglyceride-rich particle produced by the liver. The removal of triglycerides from VLDL converts this particle to intermediate-density lipoprotein (IDL), which is subsequently metabolized to yield low-density lipoprotein (LDL, known as bad cholesterol). A covalent modification of the apolipoprotein (apo) in LDL, apo B100, results in the formation of lipoprotein (a). High-density lipoprotein (HDL, or good cholesterol) is formed in the blood as a byproduct of the metabolism of triglyceride-rich lipoproteins and the acquisition of esterified cholesterol from peripheral tissues.

Apolipoproteins

Apolipoproteins are amphipathic molecules capable of interacting with both the lipids of the lipoprotein core and the aqueous environment of the plasma. They function as biochemical keys, allowing lipoprotein particles access to specific sites for the delivery, acceptance, or modification of lipids. Major apolipoproteins, their chromosomal locations with sequence accession numbers, and functions are shown in Table 206-2. Serum measurements of apolipoproteins may have clinical utility. For example, increased levels of apo B and decreased levels of apo AI are associated with vascular disease. Apo B48, specific for gut-derived particles, derives its name from the fact that it is about 48% of the size of apo B100. Apo B100 and apo B48 are products of the same gene, with B48 resulting from the post-transcriptional introduction of a premature stop codon in the apo B messenger RNA by apobec1, a cytidine deaminase. Apolipoproteins can be associated with well-defined disorders. For example, genetic variation at the lipoprotein (a) locus is associated with aortic valve calcification and clinical aortic stenosis.[1]

Receptors and Proteins

Several receptors and proteins required for normal lipid transport are listed in Table 206-3.

TABLE 206-1 LIPOPROTEIN CHARACTERISTICS

LIPOPROTEIN	APOLIPOPROTEIN CONTENT	MAJOR LIPIDS	SIZE (DIAMETER, nm)	DENSITY (g/mL)
Chylomicrons, chylomicron remnants	Apo B48, apo E, apo AI, apo AII, apo AIV, apo CII, apo CIII	Triglycerides from diet	80-500	≪1.006
VLDL	Apo B100, apo E, apo CII, apo CIII	Triglycerides from liver	30-80	<1.006
IDL	Apo B100, apo E	Cholesteryl esters, triglycerides	25-35	1.006-1.019
LDL	Apo B100	Cholesteryl esters	18-25	1.019-1.063
HDL	Apo AI, apo AII, apo AV	Cholesteryl esters, phospholipids	5-12	1.063-1.210
Lp(a)	Apo B100, apo(a)	Cholesteryl esters	~30	1.055-1.085

Apo = apolipoprotein; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); VLDL = very low density lipoprotein.

TABLE 206-2 MAJOR APOLIPOPROTEINS

APOLIPOPROTEIN	CHROMOSOMAL LOCATION, GENBANK SEQUENCE IDENTIFICATION	FUNCTIONS
Apo B100	2p24-p23, M14162	Structural component of atherogenic lipoproteins (VLDL, IDL, LDL); VLDL secretion; ligand for LDL receptor; elevated levels associated with vascular disease
Apo B48	Same as apo B100	Chylomicron secretion from intestine
Apo E	19q13.31, K00396	Ligand for binding of triglyceride-rich particles to LDL receptor and LRP; potential roles in Alzheimer's disease and neuronal injury
Apo AI	11q23-q24, X02162	Structural component of HDL; activates LCAT; elevated levels associated with protection from vascular disease
Apo AII	1q21-Q23, NM_001643	Genetically and biochemically associated with familial combined hyperlipidemia
Apo AIV	11q23-qter, NM_000482	Potential role in regulating food intake
Apo AV	11q23, AF202889	Required for normal lipolysis of triglyceride-rich lipoproteins
Apo CII	19q13.2, X00568	Activator of LPL
Apo CIII	11q23-qter, X01388	Inhibitor of LPL
Apo (a)	6q26-q27, X06290	Covalent bond with apo B100 forms Lp(a) and renders particle resistant to uptake by LDL receptor; genetically and biochemically associated with valvular calcification and aortic stenosis

Apo = apolipoprotein; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LCAT = lecithin–cholesterol acyltransferase; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); LPL = lipoprotein lipase; LRP = LDL receptor–related protein; VLDL = very low density lipoprotein.

TABLE 206-3 IMPORTANT RECEPTORS AND PROTEINS IN LIPID TRANSPORT

PROTEIN	CHROMOSOMAL LOCATION, GENBANK SEQUENCE IDENTIFICATION	FUNCTIONS
LDL receptor	19p13.3, AY114155	Clearance of apo B100 and apo E–containing lipoproteins; activity increased by statin drugs; deficiency causes familial hypercholesterolemia
PCSK9	1p32.3, NC_000001.10	Degrades LDL receptor; deficiency decreases LDL levels
LDL receptor–related protein (LRP)	12Q13-Q14, NM_000014	Clearance of apo E–containing lipoproteins
Scavenger receptor B1 (SR-B1)	12q24.32, Z22555	HDL receptor
Lipoprotein lipase (LPL)	8p22, NM_000237	Rate limiting for triglyceride metabolism; deficiency causes chylomicronemia syndrome
Lecithin–cholesterol acyltransferase (LCAT)	16q22.1, NM_000229	Esterifies cholesterol in HDL to increase HDL cholesterol levels; deficiency decreases HDL levels
Cholesteryl ester transfer protein (CETP)	16q13, NM_000078	Exchanges cholesteryl ester in HDL for triglycerides in apo B–containing lipoproteins; deficiency increases HDL levels
ABCA1	9q31, AJ12376	Transfers cholesterol in tissues to nascent HDL particles; deficiency causes Tangier disease

ABCA1 = ATP-binding cassette A1; apo = apolipoprotein; HDL = high-density lipoprotein; LDL = low-density lipoprotein; PCSK9 = proprotein convertase subtilisin-like/kexin type 9.

Low-Density Lipoprotein Receptor

The LDL receptor mediates the removal of LDL as well as some VLDL and IDL particles by binding to apo B100 and apo E. The most important site of LDL receptor expression is the liver, where its regulation is controlled by sterol regulatory element–binding proteins (SREBPs). SREBPs are found in inactive forms in the endoplasmic reticulum. Cholesterol levels in the cell are sensed by SCAP (SREBP cleavage-activating protein), which interacts with SREBPs. SCAP is capable of transporting SREBPs to the Golgi and subsequently to a compartment where they are cleaved by proteases. These proteases result in the release of the SREBP N terminus, allowing this molecule to migrate to the nucleus to stimulate the expression of genes involved in cholesterol synthesis. When intracellular cholesterol levels are high, the SCAP/SREBP complex does not move to the Golgi, SREBPs are not processed, and cholesterol synthesis stops. When cholesterol levels are low, the SCAP/SREBP complex moves to the Golgi, SREBPs are converted to active forms, and genes important for cholesterol synthesis and acquisition (such as the LDL receptor) are transcribed. Statin drugs effectively lower cholesterol. They inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in cholesterol synthesis. When statins inhibit HMG-CoA reductase, intracellular cholesterol levels fall, SCAP shepherds SREBPs to the Golgi for activation, an active SREBP stimulates transcription of the LDL receptor gene, and increased levels of the LDL receptor protein on the surface of the hepatocyte bind and remove LDL particles from the circulation.

Proprotein Convertase Subtilisin-like/Kexin Type 9

Proprotein convertase subtilisin-like/kexin type 9 (PCSK9) is a secreted enzyme that binds to the LDL receptor and increases its degradation, resulting in elevated levels of LDL cholesterol. PCSK9 deficiency in humans is associated with low LDL levels and less atherosclerosis. Pharmacologic antagonism of PCSK9 strikingly lowers LDL cholesterol levels in humans treated with a statin.[2] Potential therapies targeting PCSK9 to affect clinical outcomes are being actively pursued.

Low-Density Lipoprotein Receptor–Related Protein

The LDL receptor–related protein (LRP), also called the chylomicron remnant receptor, participates in the removal of intestine-derived lipoproteins by interacting with apo E. Chylomicron remnants carry apo B48, which is missing the LDL receptor–binding domain, but these particles are also cleared by the LDL receptor through apo E binding.

Scavenger Receptor B1

Scavenger receptor B1 (SR-B1) is a protein expressed in liver that binds HDL. Unlike the LDL receptor that endocytoses LDL particles, the SR-B1 protein does not internalize HDL particles but instead facilitates the transfer of cholesteryl ester from HDL to the liver. Its genetic manipulation in mice has raised clinically relevant questions about the significance of elevated HDL levels. Inactivation of SR-B1 elevates HDL cholesterol levels but promotes atherosclerosis, presumably because of disruption of the transport of cholesterol from peripheral cells, where it can cause disease to the liver, where it is excreted. These results suggest that it is not the level of HDL but the flux of cholesterol through HDL that affords protection from vascular disease.

Lipoprotein Lipase

Lipoprotein lipase (LPL) is rate limiting for the metabolism of triglyceride-rich lipoproteins and is required for the generation of HDL particles because

HDL is absent from LPL-deficient mice. Deficient LPL activity thus provides a physiologic explanation for the common association between high triglyceride levels and low HDL cholesterol.

Niemann-Pick C1-like Protein

The Niemann-Pick C1-like protein (NPC1L1) in the small intestine and liver helps transport dietary cholesterol from the intestinal lumen to intestinal enterocytes. Heterozygous inactivating mutations of the *NPC1L1* gene are associated with 12-mg/dL lower LDL levels and a 50% lower risk of coronary disease.[3] Ezetimibe inhibits the NPC1L1 protein.

Lecithin–Cholesterol Acyltransferase

Lecithin–cholesterol acyltransferase (LCAT) is associated with HDL in the circulation, where it esterifies free cholesterol to form cholesteryl esters that are easily stored in the nonpolar core of the lipoprotein. LCAT deficiency, a rare disorder, is characterized by low HDL as well as by anemia and renal failure, clinical features probably related to disruption of normal membrane function by the accumulation of excess unesterified cholesterol.

Cholesteryl Ester Transfer Protein

Cholesteryl ester transfer protein (CETP) exchanges one molecule of cholesteryl ester in HDL for one molecule of triglyceride in apo B–containing particles such as VLDL. The resulting HDL particle is triglyceride enriched, enhancing its clearance (especially by an enzyme related to LPL, hepatic lipase) and lowering HDL. Inhibition of CETP activity increases HDL levels.

ATP-Binding Cassette A1

ATP-binding cassette A1 (ABCA1) is a cell membrane protein that mediates the transfer of cholesterol and phospholipids from cells to lipid-poor apo AI, a process that promotes HDL formation. ABCA1 in the liver contributes to the genesis of HDL, and overexpression of ABCA1 in macrophages may diminish atherosclerosis. Heterozygous ABCA1 deficiency is responsible for isolated low HDL cholesterol levels that occur in some families. Rare homozygotes for ABCA1 mutations have Tangier disease, characterized by the accumulation of cholesteryl esters in macrophages and resulting in distinctive features, including orange-yellow tonsils, neuropathy, and hepatosplenomegaly. HDL is very low to absent. Atherosclerosis is probably increased in these patients, but its extent may be moderated by concomitantly low LDL levels.

EXOGENOUS LIPID METABOLISM

Animal products containing cholesterol and triglycerides are eaten regularly by most people. Dietary fats broken down in the gut into individual components are transported across cell membranes into the enterocyte, where they are re-esterified into cholesteryl ester and triglycerides, then packaged onto apo B48. These particles gain access to the plasma through the thoracic duct and acquire other apolipoproteins in part by transfer from HDL. These mature chylomicrons circulate to peripheral tissues. LPL, bound to the capillary endothelium in tissues such as adipose tissue and muscle, is activated by apo CII on chylomicrons, and fatty acids hydrolyzed from triglycerides by LPL are released and transported into adipose tissue for storage or into muscle for energy. This process also requires apo AV, an apolipoprotein transported in HDL that appears to facilitate the interaction between LPL and triglyceride-rich lipoproteins, as well as glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1 (GPIHBP1), a recently discovered protein that forms a platform for triglyceride metabolism at the endothelium.

Progressive hydrolysis of triglyceride converts chylomicrons into chylomicron remnants, which are enriched in cholesteryl esters. Chylomicron remnants are removed in the liver by species that bind apo E: LRP, the LDL receptor, and cell surface glycosaminoglycans. Chylomicrons are large, and it is unlikely that they contribute to atherosclerosis. Chylomicron remnants are small enough to enter the subendothelial space, where they are taken up by macrophages. Remnants are atherogenic and may promote atherosclerosis after meals. This process is missed by the standard practice of measuring fasting lipoproteins.

Chylomicrons are not soluble. Their presence causes the "tomato soup" appearance of blood drawn after a fatty meal. Because they are mostly triglycerides, they float to the top of serum that is refrigerated overnight, leaving a layer of "cream" on top of the sample. The detection of chylomicrons in fasting serum has clinical relevance because it indicates a risk for pancreatitis and other elements of the chylomicronemia syndrome.

ENDOGENOUS LIPID METABOLISM

Fats deposited in the liver are metabolized into component lipid species, re-esterified as cholesteryl ester and triglycerides, and stored in hepatocytes or exported as lipoproteins (Fig. 206-1). The liver produces the triglyceride-rich VLDL. Its rate of production depends on the availability of triglycerides. Apo B100 is the major apolipoprotein of VLDL, but regulation of the apo B gene does not appear to control VLDL synthesis. Production of the apo B100 protein depends on its cotranslational stabilization. As the message is translated into protein, the presence of triglyceride stabilizes the peptide and allows the continued addition of amino acids. In the absence of triglycerides, the apo B molecule is degraded. The transfer of triglycerides to the growing apo B peptide is mediated by microsomal transfer protein (MTP). Mutations in MTP cause abetalipoproteinemia, a rare disease characterized by the absence of circulating apo B. In the absence of apo B, the metabolism of fat-soluble vitamins (normally carried in lipoproteins) is disrupted, and patients with abetalipoproteinemia suffer from multisystem defects, including severe neurologic dysfunction and retinopathy that are presumably caused by deficiency of vitamins E and A. Drugs that interfere with MTP function lower lipids but, not surprisingly, cause the accumulation of triglyceride in the liver. The apo B gene is normal in patients with abetalipoproteinemia. Mutations in the apo B gene cause another condition known as hypobetalipoproteinemia, caused by shortened forms of the apo B protein. Subjects with hypobetalipoproteinemia have very low but not absent levels of circulating lipids and appear to be healthy.

Nascent VLDL containing one apo B100 molecule per particle is secreted into the plasma, where it acquires apo E, apo CII, and apo CIII. In a process analogous to that occurring with chylomicrons, apo CII on VLDL activates LPL, and fatty acids hydrolyzed from triglycerides by LPL are released in capillary beds and transported into tissues. With continued hydrolysis, VLDL

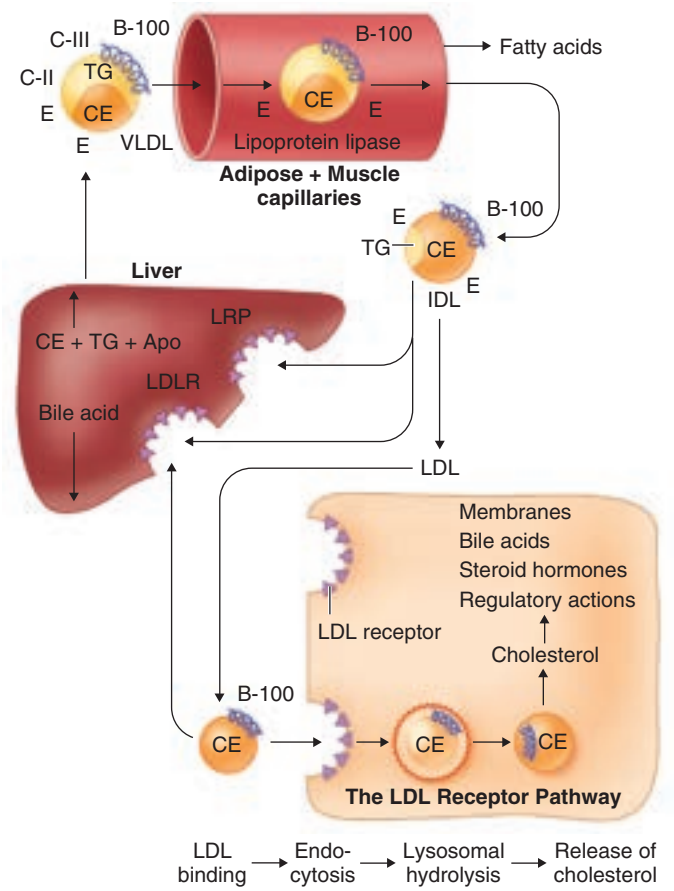

FIGURE 206-1. Endogenous lipid metabolism. In the liver, triglycerides (TG), cholesteryl esters (CE), and apolipoprotein B100 are packaged as very low density lipoprotein (VLDL) particles. TG is hydrolyzed by lipoprotein lipase to generate intermediate-density lipoprotein (IDL), which is further metabolized to generate low-density lipoprotein (LDL). This particle can be removed by the liver or by peripheral cells. Cholesterol derived from LDL regulates several processes and can be used for the synthesis of bile acids, steroid hormones, and cell membranes. LDLR = low-density lipoprotein receptor.

is converted to IDL, a cholesteryl ester–rich particle with an apolipoprotein complement of only apo B and apo E. These particles, like chylomicron remnants, are atherogenic. Unlike chylomicron remnants, IDLs are included in current management schemes because reporting of LDL cholesterol levels by most clinical laboratories includes IDL. IDL can be taken up by either the LRP or the LDL receptor in the liver. In the presence of a normal apo E molecule, IDLs are converted to LDL, consisting of one molecule of apo B100 per particle and cholesteryl esters with essentially no triglycerides. The majority of LDL is removed from the plasma by the LDL receptor pathway in the liver. LDL uptake is followed by migration of LDL particles to lysosomes, where cholesterol is released for (depending on the cell type) plasma membrane localization, bile acid synthesis, steroid hormone synthesis, and interaction with SCAP for the control of SREBP activation. Some LDL enters the subendothelial space of the vascular wall, where its modification by oxidation or other processes promotes its uptake by macrophages in atherosclerotic lesions.

Most VLDL particles are large and are not thought to promote vascular disease. Some small VLDL particles as well as IDL and LDL are atherogenic. Because VLDL is mostly triglyceride, patients with elevated fasting triglyceride levels have either increased numbers of VLDL particles or an increased triglyceride content in VLDL. LDL has a plasma half-life of 2 to 5 days. The detection of elevated fasting cholesterol levels usually reflects the presence of either increased numbers of LDL particles or increased cholesteryl ester in LDL. LDL also exists in a range of sizes. Small, dense LDL tends to occur in the setting of concomitant hypertriglyceridemia. This type of lipoprotein is thought to have greater atherogenic potential than larger LDL species, perhaps because of easy access to the vascular wall and greater susceptibility to oxidative modification. Lipoprotein particle size and number can be quantified by nuclear magnetic resonance techniques, but it is not clear that these data provide diagnostic advantages beyond the determination of total cholesterol, triglycerides, LDL cholesterol, and HDL cholesterol.

REVERSE CHOLESTEROL TRANSPORT AND HIGH-DENSITY LIPOPROTEIN METABOLISM

Lipid metabolism is dynamic. Lipoprotein particles interact with the vasculature and with one another, exchanging surface materials, apolipoproteins, and nonpolar lipids. HDL is an important reservoir for components cast off during the metabolism of other lipoproteins as well as lipids discarded by cells. Nascent HDL is generated by the liver and intestine as a phospholipid disc containing apo AI and apo AII. It accepts unesterified (free) cholesterol and phospholipids shed from cells. This unesterified cholesterol is converted to cholesteryl ester by the action of LCAT and stored in the center of the disc, allowing it to become spherical. As the core triglycerides of VLDL are metabolized by LPL, the VLDL particle collapses, leaving redundant surface lipids (phospholipid in the form of lecithin and unesterified cholesterol) and excess apolipoproteins such as apo CII, apo CIII, and apo E, which are transferred to HDL.

Reverse cholesterol transport is the beneficial process by which cholesterol in peripheral cells, such as foam cells in an atherosclerotic lesion, is transported back to the liver for excretion. There are at least two well-defined pathways mediating this transfer (Fig. 206-2). First, after accepting cholesterol from peripheral cells and esterifying it through the action of LCAT, HDL can interact directly with the liver by binding to SR-B1 and transferring cholesteryl ester to the hepatocyte. Second, HDL can transfer cholesteryl ester to apo B100–containing lipoproteins such as VLDL through the action of CETP. This cholesteryl ester can ultimately be transported to the liver after conversion of VLDL to IDL to LDL and uptake by the LDL receptor. This pathway is not direct because the transfer of cholesteryl ester to apo B–containing lipoproteins results in cholesterol-enriched particles that may be taken up by foam cells in atherosclerotic plaques before being cleared by the liver. Humans with genetic defects in CETP have high HDL levels and appear to be healthy. The benefits of raising HDL with medications are uncertain. Increasing HDL cholesterol and apo AI through the use of the CETP inhibitor dalcetrapib did not improve outcomes in patients after an acute coronary syndrome.[4] Increasing HDL cholesterol through the use of niacin does not provide clinical benefit to patients with atherosclerotic vascular disease intensively treated with a statin.

LIPID-ACTIVATED NUCLEAR RECEPTORS AND LIPID METABOLISM

Nuclear receptors are transcription factors that are activated by ligand binding to increase the expression of specific sets of genes. Several nuclear receptors

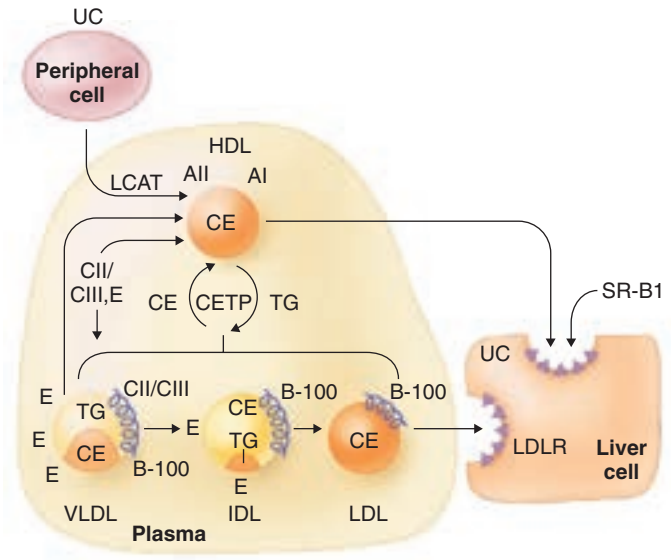

FIGURE 206-2. Reverse cholesterol transport and high-density lipoprotein (HDL) metabolism. Unesterified cholesterol (UC) in peripheral cells can be transferred to HDL and esterified by lecithin-cholesterol acyltransferase (LCAT). This cholesterol ester (CE) in HDL can be transferred to the liver directly through scavenger receptor B1 (SR-B1). Alternatively, it can be transferred to apolipoprotein B100–containing lipoproteins in exchange for triglycerides (TG) through the action of cholesteryl ester transfer protein (CETP). IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; VLDL = very low density lipoprotein.

are activated by lipids, play important roles in systemic lipid metabolism, and are current or potential targets of medications for altering lipids in patients.

Peroxisome proliferator-activated receptors (PPARs) are thought to be activated by fatty acids or their derivatives, such as phospholipids. There are at least three types: PPARα, PPARγ, and PPARδ. PPARα stimulates the expression of genes mediating fatty acid oxidation and those promoting the formation of HDL. Fibrate drugs such as gemfibrozil and fenofibrate work by activating PPARα. They lower triglycerides by accelerating the oxidation of fatty acids in the liver, so that less lipid is available for stabilizing apo B100 in VLDL secretion, and they elevate HDL by increasing the expression of apo AI, LPL, and other genes. PPARγ is expressed mostly in adipose tissue and macrophages. It increases the expression of genes promoting the development of fat tissue and appears to suppress chronic inflammation. Thiazolidinedione drugs such as pioglitazone work by activating PPARγ. They lower blood glucose concentration in people with diabetes by decreasing insulin resistance, a complex process that also results in multiple lipid effects, including lower triglycerides and higher HDL (expected to be beneficial) and higher LDL (expected to be detrimental). Their use is complicated by volume expansion and an increased risk of heart failure. PPARδ is expressed widely and has multiple effects, including increased fatty acid oxidation.

Two other nuclear receptors are activated by lipids and modulate lipid physiology. Liver X receptors (LXRα and LXRβ) are activated by oxidized derivatives of cholesterol. In the liver, they promote the synthesis of fatty acids and triglycerides in addition to stimulating both the conversion of cholesterol into bile acids and the excretion of bile acids into the gut. In the intestine, they suppress the absorption of cholesterol. The farnesoid X receptor (FXR) is activated by bile acids. FXR stimulates the secretion of bile acids into bile as well as the reabsorption of bile acids from the intestine.

Together, these receptors help orchestrate two important, futile cycles in lipid metabolism. In one, fatty acids exported from the liver (in the form of triglycerides within VLDL) and from the intestine (in chylomicron triglycerides) are released to peripheral tissues by the action of LPL. Some are taken up by muscle, where their activation of PPARα accelerates their oxidation in mitochondria, yielding adenosine triphosphate. Others enter adipose tissue, where they are re-esterified into triglycerides. From there, fatty acids are released in a process stimulated by catecholamines and glucagon. This process is complicated, involving hormone-sensitive lipase, adipose triglyceride lipase, and the remodeling of proteins that coat lipid droplets to alter their accessibility to lipases. After lipolysis, fatty acids bind to albumin and return to the liver, where they can fuel the production of more VLDL particles. Nicotinic acid improves lipids in part by blocking the release of fatty acids from adipose tissue through a process that is incompletely understood.

In another futile cycle, bile acids (formed from cholesterol and constituting the major pathway for the excretion of cholesterol from the body) are secreted into the intestine through events stimulated by LXR and FXR. Bile acids are reabsorbed in the terminal ileum. Treatment with bile acid sequestrants such as colesevelam interrupts this enterohepatic circulation, and the increased excretion of cholesterol (in the form of bile acids) depletes cholesterol content in the liver, leading to the induction of LDL receptors and thereby lowering circulating levels of LDL. This treatment also tends to elevate triglyceride levels, the result of de-repression of several processes mediated by FXR that decrease fatty acids and triglycerides. Through effects likely involving both LXR and FXR, colesevelam lowers blood glucose concentration in people with type 2 diabetes.

IMPORTANT CLINICAL DISORDERS OF LIPID METABOLISM

Familial Hypercholesterolemia

EPIDEMIOLOGY

Familial hypercholesterolemia (FH) is an autosomal dominant form of hypercholesterolemia caused by defects in LDL receptor activity. The majority of affected patients have mutations in the LDL receptor gene. Heterozygotes for LDL receptor mutations occur at a frequency of perhaps 1 in 500 in the population, but they account for up to 5% of premature myocardial infarctions (those occurring in men younger than 55 years and women younger than 65 years).

PATHOBIOLOGY

In addition to defects in the LDL receptor gene, other mutations can cause autosomal dominant hypercholesterolemia that is clinically indistinguishable from FH. These include familial defective apo B, caused by mutations that interfere with the ability of LDL to bind the LDL receptor, and variants in PCSK9.

CLINICAL MANIFESTATIONS

Total cholesterol levels are usually higher than 300 mg/dL, with LDL cholesterol levels higher than 200 mg/dL. Triglyceride levels are generally normal. Clinical features include thickening of the Achilles tendon as well as xanthomas at the extensor tendons of the knees and hands, reflecting the infiltration of lipid-laden macrophages at these sites. Clinically apparent tendon xanthomas may occur in a minority of patients with FH. Arthralgias are common, perhaps because of the presence of macrophage-mediated inflammation; these tend to improve with cholesterol lowering. Other features include xanthelasmas and corneal arcus, although the latter is also seen in elderly people and certain ethnic populations independent of cholesterol levels. Homozygotes (about 1 in 1 million) have total cholesterol levels in the range of 800 to 1000 mg/dL and usually do not survive to adulthood without liver transplantation to provide LDL receptors. Children and adolescents with this disease may develop aortic valve disease because of macrophage infiltration at the aortic origin.

The penetrance of cardiovascular events in heterozygous FH is variable. Some subjects present with sudden death or accelerated disease in their 20s, and others (generally women without other risk factors) survive beyond menopause without clinically evident disease.

TREATMENT

Rx

Treatment should address any associated risk factors for vascular disease, such as smoking, hypertension, and diabetes. Patients should be instructed in maintaining a diet low in saturated fat and cholesterol, and most require more than one cholesterol-lowering medication to achieve goals. It is not uncommon for FH patients to be treated with a statin drug, a bile acid sequestrant such as colesevelam, and nicotinic acid. Some with aggressive disease require LDL apheresis, which involves perfusing blood through a column that extracts apo B–containing lipoproteins. Lomitapide, an MTP inhibitor, was recently approved to treat homozygous FH. This agent prevents the assembly of apo B–containing lipoproteins, which allows improvement in circulating lipids in those who have LDL receptor deficiency and thus are unable to increase LDL receptor expression through the use of statins. A serious side effect of lomitapide is fatty liver. Mipomersen, an antisense oligonucleotide targeting apo B, was also recently approved to treat homozygous FH. Hepatic toxicity is also a concern with this agent. The exact role for these therapies is uncertain, and both require careful monitoring to ensure safe use.

Familial Combined Hyperlipidemia

EPIDEMIOLOGY

Familial combined hyperlipidemia is an autosomal dominant form of hyperlipidemia that is present in up to 2% of the general population. It accounts for as many as 20% of cases of premature coronary artery disease.

PATHOBIOLOGY

The specific molecular defect is uncertain. Familial combined hyperlipidemia also appears to be associated with the metabolic syndrome (Chapter 229). The disorder is characterized by the primary overproduction of apo B. VLDLs secreted by the liver are small. Small, dense LDLs, thought to be particularly atherogenic, accumulate. For a given concentration of LDL cholesterol, patients with familial combined hyperlipidemia have greater numbers of LDL particles and an increased apo B concentration.

DIAGNOSIS

The diagnosis is made in the setting of a family history of premature coronary disease with different lipid phenotypes combined in the same family. Affected family members may have elevated triglycerides, elevated LDL cholesterol, or both, or they may have hypertriglyceridemia with low HDL cholesterol. Lipid phenotypes commonly change over time.

Familial Hypertriglyceridemia

Familial hypertriglyceridemia is also a common autosomal dominant disorder, occurring in 1 to 2% of the general population. Affected family members have isolated elevated triglycerides. A unifying molecular mechanism is lacking. The phenotype is stable, with affected family members consistently showing isolated hypertriglyceridemia on repeated analyses. The disorder is characterized by primary overproduction of triglyceride. Lipoprotein particles tend to be large, consisting of increased amounts of triglyceride relative to apo B. For a given level of cholesterol, these patients have lower numbers of lipoprotein particles and a decreased apo B concentration. The relationship between this disorder and cardiovascular risk is uncertain. Affected kindreds do not appear to have a propensity for premature vascular disease, but these individuals are at risk for the chylomicronemia syndrome when an additional stimulus for hypertriglyceridemia, such as uncontrolled diabetes, is present.

Chylomicronemia Syndrome

PATHOBIOLOGY

This syndrome occurs when triglycerides are extremely elevated, usually higher than 2000 mg/dL. Individuals with homozygous defects in the *LPL* gene can present with the syndrome in infancy, although the penetrance of clinical sequelae is extremely variable. Some individuals suffer repeated episodes of the syndrome throughout life, whereas others with triglyceride levels consistently above 2000 mg/dL remain completely asymptomatic. The basis for the wide spectrum of symptoms despite similar degrees of severe hypertriglyceridemia is unknown. *LPL* gene therapy in the form of alipogene tiparvovec (the human *LPL* gene in an adeno-associated virus vector) was recently approved by the European Commission to treat patients with LPL deficiency. This represents the first gene therapy approved for use in the Western world. Other molecular defects responsible for the chylomicronemia syndrome include mutations in apo CII and apo AV.

Although defects in LPL, apo CII, and apo AV can cause the syndrome, the disorder is most likely to occur when patients with a common predisposition to hypertriglyceridemia (familial combined hyperlipidemia or familial hypertriglyceridemia) develop another defect associated with elevated triglycerides (such as uncontrolled diabetes, obesity, and treatment with glucocorticoids, estrogens, or other drugs).

CLINICAL MANIFESTATIONS

Clinical features include eruptive xanthomas (see Fig. 51-12) on the back, buttocks, knees, and elbows; lipemia retinalis (a white appearance of retinal blood vessels, usually seen with triglyceride levels >4000 mg/dL); severe abdominal pain and pancreatitis (which can be life-threatening); hepatosplenomegaly; dyspnea; lymphadenopathy; and neurologic dysfunction, such as memory loss and peripheral neuropathy.

DIAGNOSIS

Evaluation can be complicated by the presence of extreme hypertriglyceridemia, which interferes with the determination of amylase (pancreatic lipase

should be measured when pancreatitis is suspected) and artifactually lowers serum glucose, sodium, and other analytes.

TREATMENT Rx

Treatment consists of intravenous hydration and other supportive care for pancreatitis, complete elimination of dietary fat (which usually causes striking decreases in lipids within 24 to 48 hours), and appropriate blood glucose control with insulin in the setting of diabetes.

Dysbetalipoproteinemia

This rare disorder is caused by a mutation in apo E. There are three common variants of the apo E protein: E2, E3 (considered normal), and E4. Subjects with one or more E4 alleles are at risk for Alzheimer's disease. Subjects with two E2 alleles are at risk for dysbetalipoproteinemia. The frequency of this genotype is about 1% in the general population, but dysbetalipoproteinemia is rare, requiring an additional poorly defined factor. Hypothyroidism is known to precipitate the disorder. Subjects classically present with equal elevations of triglycerides and cholesterol in the range of about 300 to 600 mg/dL and xanthomas, especially in the palmar creases of the hands. They are at substantial risk for coronary artery disease. Unlike patients with FH, patients with dysbetalipoproteinemia are also at risk for severe peripheral vascular disease. Atherosclerosis occurs in part because of the presence of elevated concentrations of chylomicron remnants, which are not removed normally because of the presence of apo E2, and IDL particles, which are not converted normally to LDL in the presence of apo E2. It is unknown why the remnants that accumulate in dysbetalipoproteinemia cause both peripheral vascular disease and coronary disease, whereas the LDL particles that accumulate in FH tend to cause only coronary disease.

Diabetic Dyslipidemia

PATHOBIOLOGY

Insulin is a critical regulator of lipid metabolism, and because diabetes represents impaired insulin signaling, lipid disorders are common in both type 1 and type 2 diabetes (Chapter 229). Hypertriglyceridemia is the hallmark of diabetic dyslipidemia. This is driven by two mechanisms. First, LPL is insulin dependent. In the absence of insulin or in the presence of insulin resistance, LPL enzyme activity is deficient, and triglyceride-rich lipoproteins cannot be metabolized appropriately. Second, insulin suppresses the release of free fatty acids from adipose tissue stores. Insulin deficiency or resistance results in unabated release of free fatty acids, and these return to the liver, where they stabilize apo B synthesis and increase VLDL production.

TREATMENT Rx

The lack of insulin in patients with type 1 diabetes causes diabetic ketoacidosis, in which elevated triglycerides can be severe and are corrected by reinstitution of insulin therapy (Chapter 229). Intensive insulin therapy in type 1 diabetes decreases triglycerides, LDL, and often lipoprotein (a). Patients gain weight with intensive insulin therapy, and increased adiposity tends to lower HDL levels, which may explain why HDL does not always increase in intensively treated type 1 patients. Patients with type 2 diabetes usually have increased triglycerides and decreased HDL. These abnormalities improve but seldom normalize with better glycemic control. Most of the improvement occurs with initial pharmacologic glucose-lowering therapy, regardless of its mechanism of action.

Diabetes is frequently classified as a secondary cause of lipid disorders. However, lipid abnormalities are intrinsic to diabetes, and people with diabetes who lack clinical evidence of vascular disease have the same risk for cardiovascular events as those with established coronary disease. Therefore, every person with diabetes should be evaluated for lipid disorders, and adequate control of lipid levels often requires treatment with a statin drug. In patients with diabetes, cholesterol-lowering therapy with a statin reduces major cardiovascular events on the basis of primary prevention trials as well as secondary prevention trials. Statin treatment should not be delayed while glycemic control is optimized.

EVALUATION AND THERAPY OF LIPID DISORDERS

DIAGNOSIS

The initial evaluation should include a complete history and physical examination, with careful attention to potential secondary causes of lipid disorders (Table 206-4). Diabetes, obesity, hypothyroidism, and excess alcohol intake are probably the most common secondary contributors to abnormal lipid metabolism.

Among prescription medications, β-adrenergic blocking agents are frequent contributors to abnormal lipid profiles. These agents have proven beneficial effects after myocardial infarction but also tend to promote weight gain, to elevate triglycerides, and to decrease HDL. Many clinicians are using lower doses of these agents and relying on more lipid-neutral drugs (angiotensin-converting enzyme inhibitors and angiotensin receptor blockers) for blood pressure control.

It is now common for internists to encounter patients with human immunodeficiency virus (HIV) infection with hyperlipidemia. Some series estimate that more than half of HIV-infected patients treated with protease inhibitors for 2 years develop dyslipidemia, frequently with a redistribution of fat resembling that in genetic lipodystrophy syndromes (Chapter 389). Newer protease inhibitors appear to have fewer metabolic sequelae than older agents such as ritonavir. In addition to appropriate management of other risk factors, lipid-lowering therapy should be tailored to the ongoing HIV drug regimen. Pravastatin is least likely to interact with protease inhibitors but is less effective at lowering LDL cholesterol. Agents such as simvastatin that are substantially metabolized by the cytochrome P-450 3A4 system should not be used in patients treated with protease inhibitors because of delayed

TABLE 206-4 SECONDARY CAUSES OF LIPID DISORDERS

CONDITION OR MEDICATION	COMMENTS
Diabetes	Common contributor to dyslipidemia; abnormal lipids are seldom normalized by glycemic control alone
Obesity	Increased triglycerides and decreased HDL are common; LDL may be elevated in some and decrease with weight loss
Hypothyroidism	Thyroid hormone regulates multiple steps in lipid metabolism, including LDL receptor expression and LPL activity
Alcohol	Can cause hypertriglyceridemia in susceptible patients, but mild intake is linked to decreased risk of vascular disease
Renal disease	Increased LDL in nephrotic syndrome, hypertriglyceridemia in end-stage renal disease
Obstructive liver disease	Can be associated with very high cholesterol levels; some evidence that diseases such as primary biliary cirrhosis are not associated with increased vascular events despite dyslipidemia
Diuretics	Increased LDL with high doses; current practice of using low doses of thiazides decreases vascular events and has minimal effect on lipids
β-Adrenergic receptor blockers	Increased triglycerides and decreased HDL, probably by inhibiting LPL
Anabolic steroids	Can result in very low HDL (<10 mg/dL)
Estrogens	Exacerbate hypertriglyceridemia when given orally; this effect is not seen with topical estrogen therapy
Protease inhibitors	Increased triglycerides and decreased HDL, especially in the setting of HIV-associated lipodystrophy
Glucocorticoid excess	Increased triglycerides and decreased HDL, probably related to exacerbation of insulin resistance
Antipsychotics	Increased triglycerides and decreased HDL, probably related to increased adiposity and insulin resistance
Retinoids	Increased triglycerides
Systemic lupus erythematosus	Chronic inflammation may increase risk of vascular disease independent of effects on lipid metabolism
Acute intermittent porphyria	Many agents used to treat lipid disorders reported to provoke episodes of abdominal pain

HDL = high-density lipoprotein; HIV = human immunodeficiency virus; LDL = low-density lipoprotein; LPL = lipoprotein lipase.

clearance of the statin. PPARα agonists such as fenofibrate can be used to lower triglycerides, but the effects are limited because their clearance is accelerated by protease inhibitor treatment.

Antipsychotics have complex effects on metabolism. Some of the newer agents used to treat schizophrenia promote hyperlipidemia, obesity, and insulin resistance. Although therapeutic decisions should be based on psychiatric responses, substituting for agents with prominent metabolic side effects, such as olanzapine, can improve lipid profiles.

Laboratory Evaluation

After an 8- to 12-hour fast (tell patients that drinking water and other calorie-free beverages during this period is acceptable), total triglycerides, total cholesterol, HDL cholesterol, and LDL cholesterol should be measured. In most clinical laboratories, LDL cholesterol is still calculated by this formula: LDL = total cholesterol − HDL cholesterol − (triglycerides/5). This formula is not valid when triglyceride levels are higher than 400 mg/dL, however. It is also possible to measure LDL directly, which is sometimes useful for monitoring the therapeutic effects on LDL alone, and this determination does not require patients to fast. Excessive lipid determinations may not be helpful. Biologic and random variability in cholesterol levels is considerable, and for patients with levels that are 19 mg/dL or more below their goal, serial monitoring is more likely to detect false-positive than true-positive increases during a period of 3 years.

What constitutes "normal" lipid levels is unknown. Prior expert consensus panels have identified a normal triglyceride level as lower than 150 mg/dL. Values from 150 to 199 mg/dL are borderline high, 200 to 499 mg/dL is considered high, and above 500 mg/dL is very high. In patients with fasting triglyceride levels higher than 500 mg/dL, triglycerides are a primary target of therapy to decrease the risk of pancreatitis and chylomicronemia syndrome. These individuals should be managed in consultation with specialists in lipid disorders. Treatment usually involves a very low fat diet, an exercise program, a weight loss regimen in the setting of obesity, glycemic control in the setting of diabetes, and either nicotinic acid or a fibrate drug alone or in combination with fish oils.

Risk Assessment

In 2013, the American College of Cardiology and the American Heart Association released new guidelines for the treatment of cholesterol.[5,6] These recommendations differ from the recommendations of the National Cholesterol Education Program Adult Treatment Panel III report from 2002 in several important ways. Previously, the number of risk factors present was determined and used in conjunction with calculated risk to identify specific therapeutic goals for LDL cholesterol levels. Risk factors for coronary heart disease include smoking, hypertension (or treatment for hypertension), family history of premature coronary heart disease (younger than 55 years in men, 65 years in women), low HDL (<40 mg/dL), and age (older than 45 years in men, 55 years in women). These risk factors can still be useful in the evaluation and management of patients, but their use is de-emphasized in the most recent guidelines. Also de-emphasized is the notion of specific LDL targets. Previously, the LDL goal was lower than 100 mg/dL (or optionally lower than 70 mg/dL) in high-risk patients with known atherosclerotic cardiovascular disease. An alternative metric was non-HDL cholesterol. Goals for non-HDL cholesterol (calculated as total cholesterol minus HDL cholesterol) were 30 mg/dL higher than those for LDL. For example, in a high-risk patient with an LDL goal of less than 100 mg/dL, the corresponding non-HDL cholesterol goal was less than 130 mg/dL. These targets may still be useful in certain clinical settings, but they were not recommended in the most recent guidelines because their utility was not validated in randomized clinical trials.

The latest guidelines have not been uniformly endorsed by professional organizations representing those involved in the care of patients with lipid disorders. However, they are likely to influence clinical practice.[7] They are also subject to modifications as new data become available.

In short, the current American College of Cardiology/American Heart Association guidelines identify groups of individuals for which statin therapy is recommended and other groups for which statin therapy is not recommended. These are summarized in Table 206-5. High-intensity statin therapy to decrease LDL by 50% or more than with the use of higher doses of atorvastatin or rosuvastatin is recommended. Moderate-intensity therapy to decrease LDL by 30% to less than 50% with the use of lower doses of atorvastatin, rosuvastatin, or other statins is an option for patients who cannot tolerate high-intensity therapy or for patients with diabetes and a 10-year risk of atherosclerotic cardiovascular disease of less than 7.5%.

TABLE 206-5 TREATMENT RECOMMENDATIONS BASED ON 2013 ACC/AHA CHOLESTEROL TREATMENT GUIDELINES

STATIN THERAPY RECOMMENDED	STATIN THERAPY NOT RECOMMENDED
Patients with clinically evident atherosclerotic cardiovascular disease	Adults with end-stage renal disease
Adults with LDL cholesterol > 190 mg/dL	Patients with NYHA class II, III, or IV heart failure
Patients with type 1 or type 2 diabetes and LDL cholesterol ≥ 70 mg/dL	Adults > 75 years of age without clinical evidence of atherosclerotic cardiovascular disease
Adults with LDL cholesterol ≥ 70 mg/dL and 10-year risk of atherosclerotic cardiovascular disease ≥ 7.5%*	

*Determined by risk calculator found at *http://my.americanheart.org/cvriskcalculator*.
ACC/AHA = American College of Cardiology/American Heart Association; LDL = low-density lipoprotein; NYHA = New York Heart Association.

A risk calculator for estimating 10-year risk of atherosclerotic cardiovascular disease is found at *http://my.americanheart.org/cvriskcalculator*. This can be downloaded to devices such as smart phones, allowing the provision of individualized information to patients at the point of care.

TREATMENT Rx

General Measures

Intensive Lowering of Low-Density Lipoproteins

Many randomized clinical trials support the concept that intensive LDL lowering decreases cardiovascular event rates in patients with coronary heart disease and its equivalents. In the Heart Protection Study, those with an LDL level of less than 100 mg/dL benefited from further lowering of LDL with simvastatin. In the Pravastatin or Atorvastatin Evaluation and Infection Therapy trial, patients with acute coronary syndrome derived greater benefit with an LDL level of 62 mg/dL reached with atorvastatin than with an LDL level of 95 mg/dL reached with pravastatin. In the Treating to New Targets study, patients with stable coronary heart disease had fewer clinical events with an LDL level of 77 mg/dL on 80 mg of atorvastatin than with an LDL level of 101 mg/dL on 10 mg of atorvastatin. In the Incremental Decrease in End Points through Aggressive Lipid-Lowering study, patients with stable coronary heart disease with an LDL level of 81 mg/dL on 80 mg of atorvastatin had fewer events than those with an LDL level of 104 mg/dL on 20 mg of simvastatin. In healthy individuals with an LDL level less than 130 mg/dL and C-reactive protein level higher than 2 mg/dL, rosuvastatin (20 mg/day) reduced major cardiovascular events by 44% and all-cause mortality by 20%. Moderate-dose statin therapy increases the risk of diabetes by 2 persons per 1000 person-years, but it reduces the risk of cardiovascular events by 6.5 persons per 1000 person-years. The benefits of statin therapy exceed the diabetes hazard, even in patients at high risk for development of diabetes.[8]

Lifestyle Changes

Therapeutic lifestyle changes should be recommended as part of the treatment regimen. These include smoking cessation, weight reduction, exercise on most days of the week, reduced intake of dietary cholesterol to less than 200 mg/day, reduction of saturated fat to less than 7% of total calories, increased soluble fiber intake (to at least 10 g/day), and consumption of plant stanols or sterols (2 g/day). However, the role of these changes alone in reducing the risk of cardiovascular disease is unclear. In overweight or obese people with diabetes, an intensive lifestyle intervention did not decrease cardiovascular events.[9]

Medical Therapy

Medications commonly used to treat lipid disorders are listed in Table 206-6.

Statins

Statins are effective. An analysis of results from 90,000 participants in statin trials suggested that the 5-year incidence of cardiovascular events decreases by about 1% for each decrease of 2 mg/dL in LDL. The benefit appears to be independent of a patient's baseline lipid values.

Statins are safe, a notion confirmed in numerous studies during two decades. When statins were introduced, concerns were raised about the possibility of increased mortality with these agents due to noncardiovascular causes such as cancer. Eleven-year total follow-up of patients in the Heart Protection Study, a trial that compared simvastatin with placebo, confirmed long-term benefits with statin use without effects on noncardiovascular mortality or cancer incidence. In the entire Danish population, those using statins had reduced cancer mortality compared with those who never used statins for each of 13 different cancer types.[10]

TABLE 206-6 MEDICATIONS USED TO TREAT LIPID DISORDERS

CLASS	SIDE EFFECTS	LIPID EFFECTS	SPECIFIC AGENTS (DOSE)
Statins (HMG-CoA reductase inhibitors)	Mildly increased liver enzymes, myalgias without evidence of muscle disease, constipation, insomnia, rhabdomyolysis (rare)	↓↓LDL, 18-55% ↑HDL, 5-15% ↓TG, 7-30%	Simvastatin (20-40 mg/day) Atorvastatin (10-80 mg/day) Pravastatin (20-80 mg/day) Fluvastatin (20-80 mg/day) Lovastatin (20-80 mg/day) Rosuvastatin (10-40 mg/day) Pitavastatin (1-4 mg/day)
Nicotinic acid	Flushing, nausea, diarrhea, hyperglycemia, hyperuricemia, hepatotoxicity (rare)	↑↑HDL, 15-35% ↓↓TG, 20-50% ↓LDL, 5-25% ↓Lp(a), variable	Extended-release or crystalline niacin (1-2 g/day)
Fibrates	Mildly increased liver enzymes, dyspepsia, gallstones, hepatotoxicity (rare), rhabdomyolysis (rare)	↓↓TG, 20-90% ↑HDL, 10-20%	Gemfibrozil (1.2 g/day) Fenofibrate (34-200 mg/day)
Cholesterol absorption inhibitor	Hepatitis, abdominal pain, back pain, arthralgias	↓LDL, 18%	Ezetimibe (10 mg/day)
Bile acid sequestrants	Constipation, decreased absorption of some drugs	↓LDL, 15-30% ↑TG, variable ↑HDL, 3-5%	Colesevelam (2.5-3.75 g/day); this agent also approved for lowering glucose in type 2 diabetes Cholestyramine (4-16 g/day) Colestipol (2-16 g/day)
Fish oils	Eructation, dyspepsia	↓TG, variable ↑ LDL, variable	Omega-3-acid ethyl esters (variable)

HDL = high-density lipoprotein; HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); TG = triglyceride.

Statins are well tolerated. Up to 5% of patients have mildly elevated serum transaminases with therapy, which is usually asymptomatic and resolves spontaneously. Statins cause important liver injury in 1.2 per 100,000 users, usually 3 to 4 months after therapy is started. Atorvastatin is mostly associated with cholestatic liver injury, whereas hepatocellular injury is more common with simvastatin. Therapy should be discontinued if elevations exceed three times the upper limit of normal or if patients have symptoms of liver dysfunction (especially fatigue and weight loss). Rhabdomyolysis is rare and more likely in the setting of concurrent treatment with azole antifungals, erythromycin, cyclosporine, and several other agents. Common but generally mild side effects include constipation, abdominal pain, and difficulty sleeping. Some patients report cognitive difficulties with statins, but it is difficult to appreciate the exact role of statin use in the development of these symptoms.

A substantial minority of patients treated with statins develop myalgias without physical findings or laboratory evidence of muscle dysfunction. The cause of this side effect is unknown. Rarely, statins cause clinical myopathy, which may be related to genetic variations in the capacity to synthesize creatine.[11] Curiously, clinical trials have not documented a difference in muscle symptoms in statin-treated compared with placebo-treated subjects. Clinicians should not minimize the impact of statin intolerance on quality of life for people with lipid disorders. However, muscle aches and joint pain are experienced by all patients at some time, and these common symptoms are often incorrectly attributed to statins. It may be appropriate to consider hypothyroidism, vitamin D deficiency, rheumatologic disorders such as polymyalgia rheumatica, or depression in these patients. The problem may be resolved by stopping the medication, allowing symptoms to resolve, restarting at a much lower dose with gradual increases during weeks, and using a different statin. In one health care system, more than half of patients discontinued statins at least temporarily, 17% had statin-related events documented, and more than 90% of those who were rechallenged with a statin were still taking the medication 1 year later.[12]

Combinations of statins with other agents such as amlodipine and extended-release niacin can enhance compliance and decrease copayment costs.

Nicotinic Acid

Nicotinic acid is a B complex vitamin that in high doses lowers triglycerides, elevates HDL, and modestly lowers LDL. The most common side effect is flushing, which can be diminished with aspirin, by taking the medication with a small snack, and by avoiding hot beverages. It may be useful in patients with very high triglyceride levels who are at risk for pancreatitis. In those already achieving low levels of LDL with a statin, adding niacin does not improve clinical outcomes even though it lowers LDL and raises HDL, and it increases serious adverse events.

Fibrates

Fibrates lower triglycerides in patients with very high levels who are at risk for pancreatitis, especially those who cannot tolerate niacin. These drugs increase HDL but also tend to increase LDL in patients with high triglyceride levels. Fibrates in combination with a statin increase risk of rhabdomyolysis. In patients with type 2 diabetes, the addition of fenofibrate to simvastatin did not reduce cardiovascular end points compared with simvastatin alone.[13]

Other Agents

Ezetimibe lowers both LDL and triglycerides, with minimal effects on HDL. It is effective at achieving additional LDL lowering when it is used in combination with a statin. In a large randomized trial, the addition of 10 mg ezetimibe to high-dose statin therapy further reduced LDL from 70 mg/dL to 53 mg/dL and reduced adverse cardiovascular outcomes by an absolute 2% without adverse effects in patients who were stable after an acute coronary syndrome.

Proprotein convertase subtilisin/kexin type 9 (PCSK9), a serine protease that is produced primarily in the liver, controls levels of LDL cholesterol by binding to hepatic LDL receptors and promoting their degradation. PCSK9 antagonists lower LDL cholesterol levels by about 50% or more, regardless of whether they are added to diet therapy, statin therapy, or combined statin plus ezetimibe.[14] Ongoing clinical trials will assess whether they have an equivalent effect on cardiovascular outcomes.

Bile acid sequestrants lower LDL and decrease cardiovascular event rates. They are especially effective in combination with statins. Acceptance by patients is limited because of gastrointestinal side effects. These agents also tend to elevate triglycerides and decrease the absorption of some drugs. The sequestrant colesevelam may have less of an effect on the absorption of other drugs and has been demonstrated to lower glucose concentration in patients with type 2 diabetes.

Fish oils may be used as an adjunct in the therapy of patients with very high triglyceride levels. These omega-3 fatty acids, which occur naturally in cold-water fish, may work by activating PPARα. They may have beneficial effects on cardiovascular risk, but low-dose fish oil treatment of patients with diabetes or at risk for diabetes, most of whom were receiving statins, did not decrease cardiovascular events.[15]

PRIMARY PREVENTION

The results of clinical trials strongly support lipid lowering for secondary prevention, which is decreasing events in those with known disease. Data are less compelling for primary prevention, which is decreasing events in those without known disease. Use of a statin to lower lipids is clearly effective for primary prevention in at least three groups: patients with multiple risk factors, individuals with type 2 diabetes, and middle-aged and older people with relatively low LDL levels in the setting of elevated C-reactive protein. In the Anglo-Scandinavian Cardiac Outcomes Trial–Lipid-Lowering Arm, subjects with hypertension and at least three other risk factors had fewer events with an LDL level of 90 mg/dL achieved with atorvastatin than with an LDL level of about 130 mg/dL in control subjects. In the Collaborative Atorvastatin Diabetes Study, people with type 2 diabetes had fewer events with an LDL level of about 75 mg/dL achieved with atorvastatin compared with placebo-treated subjects with an LDL level of about 119 mg/dL. In the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin, men older than 50 years and women older than 60 years had fewer events and were less likely to die with an LDL level of about 55 mg/

dL achieved with rosuvastatin compared with placebo-treated subjects with an LDL level of about 108 mg/dL. An analysis of 18 primary trials involving more than 56,000 participants concluded that treatment of subjects with no evidence of cardiovascular disease with statins reduced all-cause mortality and vascular events with no evidence of excess adverse events.

The 2013 guidelines recommend statin therapy for primary prevention in individuals with an LDL cholesterol level above 190 mg/dl, those with diabetes, and those with a 10-year risk of atherosclerotic cardiovascular disease of at least 7.5% (see Table 206-5).

There does not appear to be a threshold effect of LDL on atherogenesis. In people with established coronary heart disease and those with diabetes, reaching very low LDL cholesterol levels is desirable. The absolute value at which maximal benefit is reached is unknown, and higher doses of statins are associated with more side effects (especially increased serum transaminases), but some analyses suggest that an LDL level of 40 mg/dL represents no increased risk of vascular disease.

REVIEW QUESTIONS

1. A 46-year-old man presents with hypercholesterolemia. He underwent coronary artery bypass grafting at the age of 43 years. He has a 20 pack-year history of smoking but quit tobacco after his bypass surgery. His father died suddenly of unknown causes at the age of 45 years, and an older brother had a myocardial infarction in his 50s. The patient is currently taking amlodipine, metoprolol, and aspirin. He took some type of statin in the past but did not like the way it made him feel. His examination is notable for a body mass index of 25, blood pressure of 150/92 mm Hg, arcus corneae, a fourth heart sound on cardiac examination, no evidence of heart failure, and thickened Achilles tendons. His laboratory results are notable for normal renal and liver function, normal fasting glucose concentration, total cholesterol level of 290 mg/dL, low-density lipoprotein (LDL) level of 232 mg/dL, high-density lipoprotein (HDL) level of 44 mg/dL, and triglyceride level of 135 mg/dL. Which course of action might be appropriate?

A. Noninvasive imaging to assess the status of his bypass grafts before deciding on a medical regimen.
B. Referral to a dietitian (with a goal of decreasing dietary cholesterol and saturated fat) and initiation of statin therapy with rapid escalation to maximum recommended doses.
C. Initiation of fibrate therapy, given his apparent intolerance of a statin.
D. Referral to a dietitian, optimization of blood pressure control, and gradual introduction of a statin in combination with one or more additional agents for LDL lowering.

Answer: D This patient has heterozygous familial hypercholesterolemia, caused by the presence of a single copy of a deficient allele for the LDL receptor. Whereas the development of atherosclerosis can vary in familial hypercholesterolemia, this individual is known to have vascular disease, and imaging will be unlikely to affect his lipid management. Dietary advice is warranted, but a statin alone or a fibrate alone will be inadequate for LDL lowering. Therapeutic lifestyle changes, management of other risk factors for atherosclerosis (such as hypertension), and initiation of lipid therapy that includes a statin as well as agents with complementary mechanisms of action (such as a bile acid sequestrant and niacin) are most appropriate.

2. A 39-year-old man is referred for management of high cholesterol. He was recently hospitalized for uncontrolled diabetes and severe abdominal pain. Review of the electronic medical record from that admission revealed no previous history of diabetes, peak glucose concentration of 390 mg/dL, no evidence of diabetic ketoacidosis, pancreatitis detected on abdominal computed tomography scanning, initial total cholesterol level of 945 mg/dL, triglyceride level of 4732 mg/dL, and hemoglobin A_{1c} level of 10.5%. He was made NPO, was treated with insulin, and improved during several days. He was discharged with a total cholesterol level of 371 mg/dL and triglyceride level of 947 mg/dL, with a laboratory notation that the sample was lipemic. His discharge medications included a high dose of rosuvastatin, long-acting insulin, and metformin. Which of the following statement(s) about this presentation is (are) true?

A. The elevated total cholesterol level in this patient indicates a very high risk of cardiovascular disease.
B. Skin lesions, transient hepatosplenomegaly, mild cognitive impairment, and abnormal eye findings are associated with this condition.
C. Elevated triglycerides in this condition should be treated with plasmapheresis.
D. Appropriate therapy may result in nearly normal lipid levels in this patient.

Answers: B and D This patient has the chylomicronemia syndrome, usually due to a genetic predisposition to hypertriglyceridemia in combination with uncontrolled diabetes. These patients may have xanthomas (especially on the trunk), organomegaly, confusion, and lipemia retinalis on funduscopic examination. The presence of chylomicrons is suggested by the laboratory detection of lipemia. The very high levels of cholesterol probably do not indicate a high risk of vascular disease because they reflect the presence of chylomicrons that are thought to be too large to enter the vascular wall. Pheresis is not usually indicated. Potent statins such as rosuvastatin are not appropriate initial therapy. Optimized glycemic control and some combination of a fibrate, niacin, and fish oils are indicated to maintain fasting triglyceride levels below 500 mg/dL, a value thought to be associated with less risk of lipid-induced pancreatitis. Many of these patients are obese, and significant weight loss can result in near-normalization of lipid levels.

3. A 44-year-old woman presents with elevated triglycerides. Except for childbirth, she has never been hospitalized. She admits to being sedentary but wants to lose weight. She denies chest pain or other symptoms. She has had abnormal lipids for several years and previously tried niacin but could not tolerate the side effect of flushing. She does not drink alcohol or use tobacco and takes no medications except for ibuprofen for menstrual cramps. He father died at the age of 58 years, around the time of an elective surgical procedure. She has three sisters, and all have elevated triglycerides, although none is known to have heart disease. There is no family history of pancreatitis. Her examination findings are normal except for a body mass index of 34. Her fasting lipids are notable for triglyceride level of 318 mg/dL, total cholesterol level of 243 mg/dL, LDL cholesterol level of 126 mg/dL, and HDL cholesterol level of 34 mg/dL. Appropriate management could include which of the following?

A. Noninvasive imaging to assess the possibility of coronary artery disease.
B. Therapeutic lifestyle changes for 6 months followed by fibrate therapy, given her intolerance of niacin by history.
C. Therapeutic lifestyle changes for 6 months followed by initiation of prescription fish oil therapy at low doses with gradual escalation to the maximum recommended dose.
D. Therapeutic lifestyle changes and initiation of statin therapy at this visit.

Answer: D This patient has familial combined hyperlipidemia, perhaps the most common inherited lipid disorder. It is associated with premature coronary disease. She has no symptoms, so noninvasive cardiac imaging may not be useful, but a treadmill stress test might be helpful as she considers starting an exercise program as part of therapeutic lifestyle changes. Statin therapy should be recommended. Whereas her LDL level is not particularly high, her non-HDL cholesterol level is 209 mg/dL. An appropriate goal might be a non-HDL cholesterol level of less than 130 mg/dL.

4. A 67-year-old man presents to you with statin intolerance. He underwent coronary artery bypass grafting at the age of 55 years and has taken simvastatin followed by atorvastatin for many years with no symptoms. Recent angiography demonstrated patent grafts. Several months ago, he developed vague aching and cramping in his lower extremities that was attributed to his statin. His atorvastatin was discontinued and the symptoms improved, but they did not resolve. Other statins were prescribed, and all were associated with increased muscle cramping, especially noticed at night. He has now been off statins for a month and currently complains of muscle pain, constipation, and recent weight gain of about 10 pounds that he attributes to physical inactivity due to muscle pain. His examination is notable for a blood pressure of 142/94 mm Hg with two antihypertensives, pulse of 58, periorbital edema, no evidence of heart failure, mild diffuse muscle tenderness without fasciculations, and trace lower extremity edema. His laboratory results reveal an LDL cholesterol level of 157 mg/dL and a creatine kinase level of 351 μg/L (normal, <120 μg/L). What is the best next step for this patient?

A. Admission to the hospital for management of rhabdomyolysis
B. Muscle biopsy
C. Initiation of ezetimibe to lower LDL cholesterol
D. Assessment of renal and thyroid function

Answer: D This patient has hypothyroidism. He does not have rhabdomyolysis, which is associated with extreme elevations of muscle enzymes, severe muscle pain, dark urine, and renal dysfunction. A muscle biopsy is not indicated at this point. Ezetimibe might be a useful adjunct, but its use does not address his muscle symptoms. The current level of creatine kinase elevation is modest, but it is prudent to assess renal function because this patient may have had greater degrees of muscle dysfunction while taking statins. In this patient, thyroid-stimulating hormone was elevated and free thyroxine was decreased, consistent with primary hypothyroidism. This condition is common, increases the risk for statin-induced myopathy, and causes myopathy independent of statins. Once thyroid status is corrected with thyroid hormone, statin therapy, reintroduced cautiously, can be well tolerated.

5. A 56-year-old woman with type 2 diabetes presents to your office for routine care. She is postmenopausal and has intermittent vasomotor symptoms but does not wish to take estrogens because of concerns about side effects. She smoked less than a pack of cigarettes a day in her 20s but quit more than 20 years ago. Her most recent hemoglobin A_{1c} level is 7.4%, she does not have microalbuminuria, and there is no personal history of heart disease, but both of her parents died of cardiovascular causes after the age of 65 years. She has no complaints except for knee pain due to osteoarthritis. Her current medications include losartan, exenatide, and metformin. Except for a body mass index of 29, her examination findings are normal. Her most recent lipid panel is notable for triglyceride level of 145 mg/dL, HDL level of 50 mg/dL, and LDL level of 96 mg/dL. She realizes that cardiovascular disease is the most common cause of death in diabetes but does not wish to take statins because her LDL is already below 100 mg/dL and she is wary of statins, especially since they are reported to cause diabetes. Which of the following represents appropriate advice for this patient?

A. Begin statin therapy with a goal of decreasing LDL by 30 to 40% from the current level of 96.
B. Begin insulin therapy with a goal of lowering the hemoglobin A_{1c} to a nearly normal level.
C. Institute an aggressive program of weight loss through diet and exercise to decrease the risk of cardiovascular disease.
D. Begin nutritional supplements including chromium, antioxidant vitamins, and low-dose fish oils.

Answer: A Even if lipid levels are initially fairly low, patients at risk for coronary disease, like this woman with diabetes, benefit from statin treatment. Aggressive attempts to improve glycemia in this population of patients do not clearly provide benefit and may cause harm. A controlled trial of weight loss did not decrease cardiovascular events in subjects similar to this patient. Supplements including minerals, vitamins, and fish oils have not been shown to provide cardiovascular benefit in individuals like this patient.

GLYCOGEN STORAGE DISEASES

DAVID A. WEINSTEIN

DEFINITION

Glycogen, a highly branched polymer of glucose, is the storage form of glucose in mammals. The major sites of glycogen deposition are skeletal muscle and liver. Several other tissues and organs, including the heart, smooth muscle, kidney, and intestine, are sites of glycogen synthesis that can be impaired in the glycogen storage diseases (GSDs).

EPIDEMIOLOGY

The overall frequency of the GSDs is approximately 1 case per 20,000 to 25,000 births. Sixteen distinct types have been identified, which are referred to either by the deficient enzyme or by a numbering system that reflects the historical sequence of their description. They are all uncommon and some are extremely rare. Six types account for approximately 97% of GSD cases: GSD I (25%), GSD II (15%), GSD III (24%), GSD IV (3%), and GSD VI and IX (30%). It is likely, however, that the mild forms of GSD are under-recognized.

PATHOBIOLOGY

Glucose transporter type 2 (GLUT2) predominates in the liver (and pancreatic beta cells) and has a high K_m (≈15 to 20 mmol/L); consequently, the free glucose concentration in hepatocytes increases in direct proportion to the increase in plasma glucose concentration. Glucose is rapidly phosphorylated by glucokinase to form glucose 6-phosphate, which is converted to glucose 1-phosphate, the starting point for glycogen synthesis (Fig. 207-1). Hepatic glycogen synthase catalyzes the formation of α-1,4 linkages that elongate the chains of glucose molecules. A branching enzyme leads to formation of α-1,6 linkages at branch points along the chain. The concentration of GLUT4 in the plasma membrane of skeletal muscle increases markedly after exposure

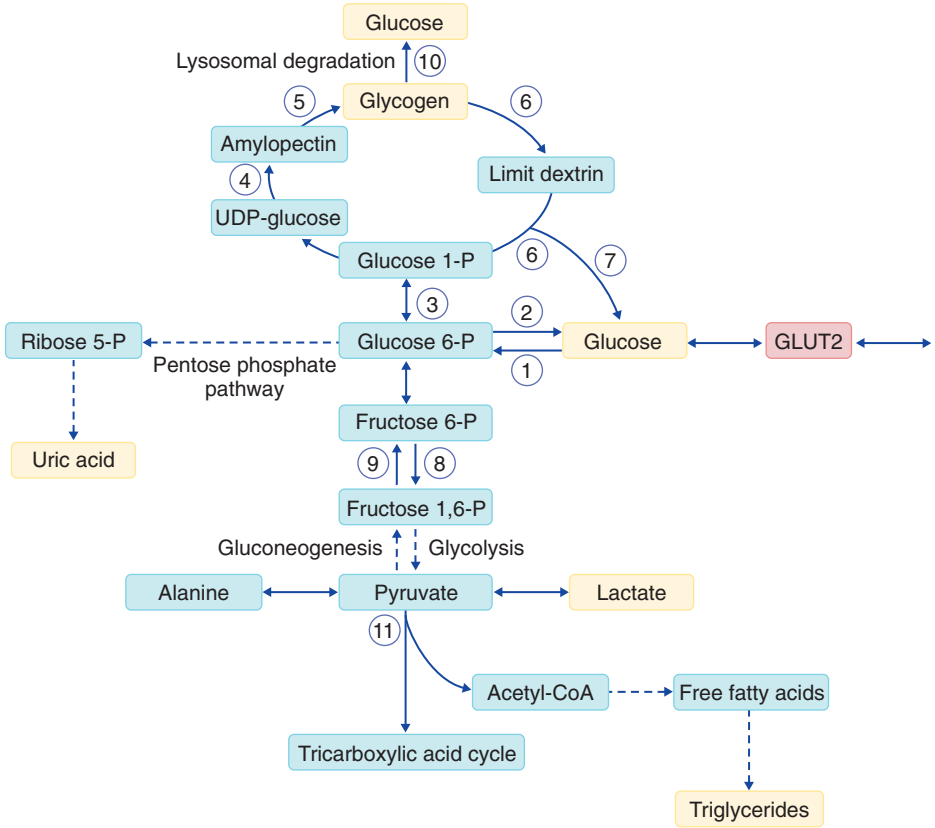

FIGURE 207-1. Simplified scheme of glycogen synthesis and degradation in the liver. Note that in skeletal muscle, GLUT4 transports glucose across the cell membrane and glucose-6-phosphatase is absent. UDP-glucose = uridine diphosphoglucose; 1, hexokinase/glucokinase; 2, glucose-6-phosphatase; 3, phosphoglucomutase; 4, glycogen synthase; 5, branching enzyme; 6, glycogen phosphorylase; 7, debranching enzyme; 8, phosphofructokinase; 9, fructose-1,6-bisphosphatase; 10, acid maltase; 11, pyruvate dehydrogenase.

to insulin and in response to exercise, resulting in increased glucose transport into skeletal muscle, where it is either oxidized to provide energy for contracting muscle or converted to glycogen.

In the intervals between meals and during the overnight fast, a cascade of enzymatic reactions (including adenylate cyclase, phosphorylase *b* kinase, and cyclic adenosine monophosphate–dependent protein kinase) activate hepatic glycogen phosphorylase, the rate-limiting enzyme in glycogenolysis, leading to the formation of glucose 6-phosphate. Glucose-6-phosphatase catalyzes the terminal reaction of both glycogenolysis and gluconeogenesis, the hydrolysis of glucose 6-phosphate, thereby allowing glucose to be released from the liver into the systemic circulation. This process is critically important for the maintenance of glucose homeostasis. Because muscle lacks glucose-6-phosphatase, it cannot release glucose for systemic use. Muscle glycogen is used to meet the energy requirement of contracting muscle and is a source of lactate, pyruvate, and alanine for gluconeogenesis early in starvation. The rate of glycogenolysis in muscle is most rapid during the first 5 to 10 minutes of exercise. As exercise continues and blood flow to muscle increases, blood-borne substrates (glucose and free fatty acids) become increasingly important sources of energy.

The GSDs or glycogenoses comprise several inherited disorders of glycogen synthesis or degradation. All are autosomal recessive with the exception of a subtype of GSD IX that is X-linked. The GSDs are caused by mutations in the genes that code for enzymes involved in the synthesis or degradation of glycogen and may involve the liver, skeletal muscle, and kidney. They are all characterized by an abnormal tissue concentration or structure (or both) of the glycogen molecule.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hepatomegaly and hypoglycemia[1] are the principal clinical manifestations of the hepatic glycogenoses; muscle cramps, exercise intolerance, easy fatigability, and progressive weakness are the major manifestations of the muscle glycogenoses. Features of the most common GSDs are shown in Table 207-1. Molecular genetic testing performed on DNA extracted from blood or saliva is used to diagnose all the common forms of GSD.

TREATMENT

Rx

The goal of treatment of the hepatic forms of GSD is to prevent hypoglycemia and glucose counter-regulation. The specific details of therapy principally depend on whether normal gluconeogenesis can occur. In GSD I, abnormal glucose-6-phosphatase activity impairs both glycogenolysis and gluconeogenesis. In contrast, gluconeogenesis is intact in the other liver forms of GSD, allowing protein to be used as a substrate for endogenous glucose production. Fatty acid oxidation is also intact in all types of GSD except for GSD I, resulting in ketone formation during periods of hypoglycemia.[2]

TABLE 207-1 PRINCIPAL FEATURES OF THE COMMON GLYCOGEN STORAGE DISEASES

TYPE AND DEFECTIVE ENZYME	CHARACTERISTIC CLINICAL FEATURES	HIGH-RISK POPULATIONS	THERAPY
0 *Hepatic glycogen synthase*	Liver small or normal in size, fasting ketotic hypoglycemia, postprandial hyperglycemia and hyperlactatemia	French Canadian Italians	UCS, especially at bedtime, with high-protein diet
Ia *Glucose-6-phosphatase* *von Gierke's disease*	Hepatomegaly, failure to thrive, growth retardation, severe hypoglycemia, lactic acidosis, hyperuricemia, hyperlipidemia	Ashkenazi Jews Mexicans Chinese Japanese	UCS during the day and night or continuous overnight intragastric feeding
Ib *Glucose 6-phosphate transporter*	Same as type Ia; also neutropenia, recurrent bacterial infections, and inflammatory bowel disease	Native Americans Iranian Jews Italians	UCS as for Glycogen Storage Disease Ia; granulocyte colony-stimulating factor
II *Lysosomal acid maltase (α-glucosidase)* *Pompe's disease*	Infantile form is characterized by severe generalized hypotonia, muscle weakness, and hypertrophic cardiomyopathy leading to cardiorespiratory failure usually by 1 year of age. Skeletal myopathy with slowly progressing muscle weakness is the primary clinical manifestation of the juvenile- and adult-onset forms. Serum creatine kinase is markedly increased.	None	Intravenous enzyme replacement with recombinant human α-glucosidase
III *Debranching enzyme* *Cori's or Forbes' disease*	Hepatomegaly, moderate to severe ketotic hypoglycemia, muscle weakness and wasting, hypertrophic cardiomyopathy (IIIa), increased transaminases; without muscle involvement (IIIb)	Faroe Islanders First Nation (Canada) Indian subcontinent	High-protein diet with low-dose UCS supplementation
IV *Glycogen branching enzyme* *Andersen's disease*	A clinically heterogeneous disorder The typical presentation is liver disease in early childhood progressing to lethal cirrhosis. The less common neuromuscular presentation is distinguished by age at onset into 4 groups: perinatal, congenital, childhood, and adult.	None	No specific treatment Liver transplantation has resulted in decreased glycogen storage in heart and skeletal muscle.
V *Muscle glycogen phosphorylase* *McArdle's disease*	Symptoms usually begin in adolescence or early adulthood with exercise intolerance, fatigue, myalgia, muscle cramps, and muscle swelling. Transient myoglobinuria due to rhabdomyolysis may occur after exercise. Severe myoglobinuria may lead to acute renal failure. Later in adult life, persistent and progressive muscle weakness and atrophy with fatty replacement occur. Serum creatine kinase is increased.	None	High-protein diet (50% carbohydrate and 25-30% protein) Oral sucrose before sustained aerobic exercise may be beneficial.
VI *Hepatic glycogen phosphorylase* *Hers' disease*	Hepatomegaly; growth retardation; moderate ketotic hypoglycemia; increased serum transaminases, cholesterol, and triglycerides	Mennonites	UCS dosed to prevent hypoglycemia and ketosis
VII *Muscle phosphofructokinase* *Tarui's disease*	Manifested in childhood with fatigue, muscle cramps, exercise intolerance; rhabdomyolysis and myoglobinuria with strenuous exertion; increased serum creatine kinase; may have mild hemolytic anemia and mild hyperbilirubinemia; hyperuricemia	None	No specific treatment; avoid strenuous exercise
IX *Phosphorylase b kinase*	Hepatomegaly, mild ketotic hypoglycemia, growth retardation, increased serum transaminases, hypercholesterolemia, hypertriglyceridemia May be X-linked or autosomal recessive	None	UCS dosed to prevent hypoglycemia and ketosis; high-protein diet to normalize prealbumin

UCS = uncooked cornstarch.

Treatment of GSD I consists of providing a continuous dietary source of glucose to maintain blood glucose levels at 75 to 90 mg/dL before meals and overnight. Glucose concentrations must be maintained above 70 mg/dL to prevent counter-regulation, which causes shunting of glucose 6-phosphate into alternative pathways, resulting in hyperlactacidemia, hyperuricemia, and hypertriglyceridemia. In infants, continuous glucose can be provided by frequent feeds during the day and continuous intragastric feeds at night through a nasogastric or gastrostomy tube. Beginning at 6 to 12 months of age, uncooked cornstarch (UCS), which is slowly digested and absorbed into the circulation as glucose, can be used as an alternative method of continuously providing glucose. Initially, UCS is given every 3 hours. As children age and guided by the results of periodic blood glucose and lactate monitoring, the interval between feeds eventually is increased to 4 to 6 hours. An extended-release cornstarch preparation allows many older patients to sleep through the night without awakening.[3] Galactose and fructose must be restricted because they cannot be converted to glucose, and consumption of large quantities may exacerbate the biochemical derangements. Optimal care usually ameliorates all biochemical abnormalities; however, if optimal dietary management does not lower serum uric acid and triglycerides to acceptable levels, treatment with allopurinol and gemfibrozil, respectively, is indicated. Neutropenia (Chapter 167) in type Ib responds well to low-dose granulocyte colony-stimulating factor (G-CSF) therapy; however, untoward effects of G-CSF may include splenomegaly and very rare cases of leukemia.[4] The recommended starting dose (2.5 µg/kg/day) is therefore lower than in other conditions, and the lowest possible dose that prevents infections is used. An enterocolitis that resembles Crohn's disease (Chapter 141) occurs almost universally in GSD type Ib, and mesalamine (Pentasa) is the first-line therapy because small intestinal disease predominates.

Patients with the other forms of GSD use a high-protein diet (2 or 3 g/kg) supplemented with complex carbohydrates and UCS, which, typically, is administered every 6 to 8 hours to maintain glucose concentrations above 75 mg/dL. Because β-oxidation of fatty acids can occur in these forms of GSD, ketosis can develop rapidly and UCS doses are titrated to maintain a normal blood ketone concentration (<0.3 mmol/L). Protein dosing is aimed at normalization of total protein and prealbumin concentrations. Strict avoidance of fructose and sucrose is unnecessary; however, intake of simple sugars is still discouraged to avoid excessive storage of glycogen. This is particularly important in GSD III because excessive glycogen storage has been associated with worsening of the associated hypertrophic cardiomyopathy.[5]

Treatment of the muscle glycogenoses is shown in Table 207-1.

Prevention of Complications

Despite improvements in care, long-term complications are common in GSD I and III. There is increasing evidence, however, that complications can be delayed or even prevented with optimal metabolic control.[6] Hepatic adenomas can develop in patients with GSD I during adolescence or early adulthood and may gradually enlarge, undergo malignant transformation, or hemorrhage into the peritoneal cavity. Nephrocalcinosis and nephrolithiasis, caused by hypocitraturia, are also common and can be prevented by oral citrate supplementation. Maintenance of optimal metabolic control can prevent renal tubular dysfunction, focal segmental glomerulosclerosis, anemia, gout, and osteoporosis.[7,8]

In type III GSD, a hypertrophic cardiomyopathy can develop. The cardiac disease appears to be caused by overstorage of glycogen, and restriction of simple sugars and carbohydrates has resulted in normalization of cardiac function. Hepatic adenomas develop in 10% of patients, and hepatocellular cancer is rare. Most patients with type III do not have myopathic symptoms during childhood and early adulthood. Progressive myopathy can develop beginning in the teenage years, and it can become debilitating. A very high protein diet (3 or 4 g/kg) may slow the progression of the muscle disease.[2]

Short stature and osteoporosis are the only common complications in GSD O, VI, and IX, but these can be prevented by maintenance of optimal metabolic control and avoidance of ketosis.[9] Cirrhosis has been described as a complication in untreated patients with GSD IX, but scarring may be prevented with treatment.[10]

PROGNOSIS

The prognosis for all of the hepatic GSDs is now excellent. Almost all complications can be delayed or prevented with optimal metabolic control. Patients are doing well into adulthood, and pregnancies have now become routine.[11] Liver transplantation should be viewed as a treatment of last resort,[12] especially because gene therapy may be available for treatment of these disorders in the future.

The Association for Glycogen Storage Disease website (*http://www.agsdus.org*) provides basic information about the GSDs intended to be of use to people affected by one of the GSDs, their families, and other interested parties. Similar organizations exist in the United Kingdom, France, Spain, the Netherlands, Germany, Italy, Sweden, the Faroe Islands, Poland, and Russia.

REVIEW QUESTION

1. Which of the following symptoms and signs would *not* be a likely presenting manifestation of glycogen storage disease in an adult?

A. Unexplained hepatomegaly
B. Limb-girdle muscle weakness
C. Transient ischemic attacks
D. Symptoms of hypoglycemia
E. Muscle cramps

Answer: C Most cases of glycogen storage disease seen by internists will have been already diagnosed in childhood. However, individuals with much milder disease (presumably associated with less severe enzyme activity as determined by genotype) may present with symptoms and signs in adulthood. Hepatomegaly (A) and hypoglycemia (D) are the principal clinical manifestations of the hepatic glycogenoses; muscle cramps (E), exercise intolerance, and progressive fatigue and weakness are the major manifestations of the muscle glycogenoses (see Table 207-1). For example, whereas infants with Pompe's disease (type II glycogen storage disease) present at birth (floppy infant syndrome) or shortly thereafter and progress to respiratory failure, cardiomyopathy, and death by the age of 1 year unless treated, adult-onset disease commonly is manifested as limb-girdle muscle weakness (B), which can mimic that of other musculoskeletal disorders, especially muscular dystrophies. (Vissing J, Lukacs Z, Straub V. Diagnosis of Pompe disease. JAMA Neurol. 2013;70:923-927.) Cerebrovascular disease (C) may be seen in homocystinuria but is not known to be associated with glycogen storage diseases.

208

LYSOSOMAL STORAGE DISEASES

DONNA M. KRASNEWICH AND ELLEN SIDRANSKY

The lysosomal storage diseases encompass a group of more than 45 different inherited disorders, all sharing a defect in lysosomal function. Lysosomes are acidic, membrane-bound organelles present in the cytoplasm containing enzymes that degrade macromolecules. These disorders ensue when one or more of the hydrolytic enzymes are deficient or when essential lysosomal transporters, receptors, cofactors, or protective proteins are defective or lacking. Typically, complex macromolecules, including glycolipids, mucopolysaccharides, and glycoproteins are delivered to the lysosome, where they undergo sequential modification by a series of hydrolases. An enzymatic deficiency becomes clinically important when macromolecules accumulate owing to inadequate degradation. Different categories of defects resulting in lysosomal dysfunction are encountered in the lysosomal storage disorders; examples of each type are listed in Table 208-1.

Although most lysosomal storage disorders are rare, as a group their frequency is estimated to be 1 per 7000 to 8000 live births. This is an underestimate because milder or attenuated forms of these disorders are often not identified. All of the disorders have an autosomal recessive pattern of inheritance, with the exception of Fabry disease and Hunter's syndrome (mucopolysaccharidosis II), which are X-linked recessive, and Danon's disease, caused by mutations in the lysosome-associated membrane protein 2 (LAMP-2), which is inherited in an X-linked dominant manner. As a whole, these disorders are characterized by a vast spectrum of manifestations, often causing them to evade diagnosis. Many were traditionally classified into infantile, juvenile, and adult types on the basis of the patient's age at the onset of manifestations, but atypical presentations complicate these distinctions. Among the factors contributing to this phenotypic diversity are the amount of residual enzyme activity, the cellular localization of the enzyme, the genotype, and the genetic background of the affected individual as well as other genetic, environmental, and epigenetic influences.[1]

With the advent of new therapies for some of the lysosomal storage disorders, early establishment of the diagnosis is paramount. Suggestive clinical findings include coarse facial features; organomegaly; specific eye findings, including corneal clouding or a cherry red spot (of the macula); cytopenia; and skeletal abnormalities, notably dysostosis multiplex. Disorders associated with each of these findings are listed in Table 208-2. There should be a greater index of suspicion whenever these features occur in concert, the findings are progressive, there is developmental regression, or the patient appears dissimilar to other family members.

The diagnostic work-up includes a careful history, with analysis of the family pedigree and assessment of developmental milestones in childhood and adolescence. A family history of consanguinity, other affected siblings, multiple miscarriages, or early deaths can aid in making the diagnosis. Ethnicity can be a helpful clue because some of the lysosomal disorders occur with increased incidence in specific populations, such as Ashkenazi Jews (Gaucher disease type 1, Tay-Sachs' disease, mucolipidosis type IV) and Scandinavians (mannosidosis, aspartylglucosaminuria, Salla's disease, Gaucher disease type 3). On physical examination, special attention should be paid to head circumference, facial appearance, enlargement of the tongue, hepatosplenomegaly, skeletal manifestations (including kyphosis), broadening of the long bones, and stiffness of the joints. Skin evaluation may reveal angiokeratoma, especially around the umbilicus and in skin creases. The eye evaluation should include a funduscopic and slit-lamp examination as well as an assessment for atypical eye movements, which may be pathognomonic for disorders such as

TABLE 208-1 CLASSIFICATION OF LYSOSOMAL STORAGE DISORDERS BASED ON THE TYPE OF DEFECT*

SPHINGOLIPIDOSES
Fabry disease (α-galactosidase)
Farber disease (ceramidase)
GM_1 gangliosidosis/Landing's disease (β-galactosidase)
GM_2 gangliosidosis/Tay-Sachs' disease
Sandhoff's disease (α-hexosaminidases A and B)
Gaucher disease (glucocerebrosidase)
Niemann-Pick disease, types A and B (sphingomyelinase)
Metachromatic leukodystrophy (arylsulfatase A)
Krabbe's disease (β-galactocerebrosidase)
LIPID STORAGE DISORDERS
Wolman's disease (acid lipase)
Ceroid-lipofuscinosis, adult type, Kufs'/Parry's (CLN4, heterogeneous)
MUCOPOLYSACCHARIDOSES
Type I/Hurler's disease (α-L-iduronidase)
Type II/Hunter's disease (iduronate-2-sulfatase)
Type III/Sanfilippo's disease (four different enzymes in the degradation of heparan sulfate defining types A-D)
Type VI/Maroteaux-Lamy's disease (*N*-acetylgalactosamine-4-sulfatase)
Type VII/Sly's disease (α-glucuronidase)
OLIGOSACCHARIDOSES
Aspartylglucosaminuria (aspartylglucosaminidase)
Fucosidosis (α-fucosidase)
α-Mannosidosis (α-mannosidase)
Schindler's disease (α-*N*-acetylgalactosaminidase)
Sialidosis I (sialidase)
Sialidosis II/mucolipidosis I (sialidase)
MUCOLIPIDOSES
Mucolipidosis II/I-cell disease (*N*-acetylglucosaminylphosphotransferase)
Mucolipidosis III/pseudo-Hurler (*N*-acetylglucosaminylphosphotransferase)
Mucolipidosis IV (*MCOLN1* mutation)
LYSOSOMAL GLYCOGEN STORAGE
Glycogenosis type II/Pompe's disease (α-1,4-glucosidase)
LYSOSOMAL TRANSPORT DISORDERS
Sialic acid storage disease/Salla's disease (sialin/SLC17A5)
Cystinosis (cystine transporter)
Niemann-Pick disease, type C (intracellular cholesterol transport)
MULTIPLE ENZYME DEFICIENCY
Galactosialidosis (β-galactosidase and sialidase)
Multiple sulfatase deficiency/Austin's disease (sulfatases)

*Full chapters describing each of these disorders are available in Valle D, Beaudet AL, Vogelstein B, et al, eds. The Online Metabolic and Molecular Bases of Inherited Disease. http://www.ommbid.com/OMMBID.

neuronopathic Gaucher disease and Niemann-Pick disease type C. Unexplained cardiomyopathy and cryptogenic stroke may be the initial presentation of Fabry's disease. A careful neurologic and cognitive evaluation can be fruitful because some of the later presentations include dementia and psychiatric manifestations.[2] Moreover, regression of milestones can provide an early diagnostic clue. Preliminary diagnostic studies include urine for thin-layer chromatography, blood count with smear for vacuolated white blood cells, skeletal radiography, and ophthalmologic examination.

For the most part, the diagnosis of a specific lysosomal storage disorder is made by assaying enzymatic activity in a blood sample or fibroblast cell line. A lysosomal panel, evaluating the activity of multiple lysosomal enzymes from the same sample, should be the first-tier test. If a lysosomal storage disorder is still suspected, a tissue biopsy, most often of the bone marrow or liver, can be considered, although this is rarely indicated. Most of the genes encoding the lysosomal enzymes have been identified, and mutation analysis is available. However, in most cases, there is vast genotypic heterogeneity, and mutation screening is useful only when a mutation has already been identified in a specific family or when specific mutations are known to be common in a specific ethnic group.

Improved care and new therapeutic modalities have transformed the natural history of several of these disorders. With patients' increased longevity, diseases that were once encountered only by pediatricians have now made their way to the offices of internists. Moreover, many of the classic complications are now avoided by early therapeutic interventions, such as enzyme replacement therapy.[3] However, in some instances, prolonged longevity has unmasked unanticipated clinical manifestations. Physicians' increased awareness of the range of manifestations and presentations of lysosomal disorders may lessen the long delays in diagnosis that patients frequently describe. Lysosomal disorders encountered in adult patients are discussed here, with a focus on Gaucher disease and Fabry disease.[4] A brief discussion of specific disorders frequently diagnosed during adulthood as well as of childhood-onset lysosomal disorders that persist through adulthood is included.

GAUCHER DISEASE

PATHOBIOLOGY

Gaucher disease, the *autosomal* recessively inherited deficiency of the lysosomal enzyme glucocerebrosidase, is a disorder primarily of the reticuloendothelial system.[5] Lysosomes within macrophages become engorged with the substrate glucocerebroside, giving rise to the characteristic Gaucher cells, with a wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. The accumulated glycolipid glucosylceramide is derived from the degradation of senescent leukocytes or erythrocyte membranes.

CLINICAL MANIFESTATIONS

Clinically, Gaucher disease has been divided into three types on the basis of the absence or presence and the rate of progression of neurologic involvement. Type 1, the non-neuronopathic form, is the most common type and can be manifested at any age. Type 2, the acute neuronopathic form, manifests before or shortly after birth and has a rapid and progressive course. Type 3 is the subacute neuronopathic form. The spectrum of manifestations encountered in this disorder ranges from asymptomatic octogenarians to infants who succumb in utero. Some patients defy classification into one of the three types. It is a pan-ethnic disorder, although type 1 Gaucher disease is more frequent among Ashkenazi Jews, in whom the carrier frequency is about 1 in 16; in contrast, the approximate carrier frequency in the general population is 1 in 100.

The gene encoding glucocerebrosidase (*GBA1*) is located on chromosome 1q21, and more than 300 different mutations have been found in patients. Several mutations are encountered with increased frequency in type 1 Gaucher disease; for example, among Ashkenazi Jews, mutation N370S is the most common allele. However, the mutations identified do not adequately account for the range of manifestations encountered.

In recent years, an association between Gaucher disease and parkinsonism (Chapter 409) has been reported.[6,7] Both patients with Gaucher disease and carriers of mutations in *GBA1* have a higher incidence of Parkinson's disease and Lewy body disorders.[8] Studies in cohorts of patients with Parkinson's disease around the world demonstrate that they have a more than five-fold increased frequency of *GBA1* mutations, rendering this the most common genetic risk factor for parkinsonism identified to date.

Commonly encountered symptoms in all types of Gaucher disease include easy bruisability, hepatomegaly, splenomegaly, chronic fatigue, and bone pain or pathologic fractures. Laboratory findings include anemia, thrombocytopenia, and elevations of ferritin, acid phosphatase, angiotensin-converting enzyme, and, at times, liver enzymes. Painless splenomegaly is the most common presentation in patients with type 1 Gaucher disease, and the spleen can be massively enlarged. Occasional patients have pulmonary involvement or pulmonary hypertension. Bone involvement is a significant cause of morbidity and can be manifested with extreme bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including the classic Erlenmeyer flask deformity of the distal end of the femur and osteopenia (Fig. 208-1A). Pathologic fractures (especially of the hip, ribs, or spine), lytic bone lesions, and osteoporosis may occur. Painful bone crises, episodes of bone infarcts, can last for weeks and may require aggressive pain management.

Type 2 disease, which is rare, is characterized by a rapid neurodegenerative course with extensive visceral involvement; death usually occurs within the first 2 years of life. The disease is diagnosed prenatally or in infancy and is associated with increased tone, strabismus, and organomegaly. Failure to thrive and compromised airway from laryngospasm are typical. Progressive psychomotor degeneration leads to death, usually secondary to an intercurrent respiratory infection and respiratory compromise.

Type 3 disease is clinically variable and is often noted in infancy or childhood. In addition to organomegaly and bone involvement, patients have abnormal horizontal eye movements, and some develop myoclonic epilepsy or neurodegenerative manifestations. A subgroup of patients has cardiac

TABLE 208-2 MANIFESTATIONS ENCOUNTERED IN DIFFERENT LYSOSOMAL STORAGE DISORDERS

FINDING	DISORDERS
Hepatosplenomegaly	GM_1 gangliosidosis, Niemann-Pick disease, Gaucher disease, Wolman's disease, fucosidosis, Pompe's disease, mannosidosis, multiple sulfatase deficiency, sialidosis, galactosialidosis, several mucopolysaccharidoses, cystinosis
Coarse facies	GM_1 gangliosidosis, fucosidosis, Pompe's disease, mannosidosis, multiple sulfatase deficiency, I-cell disease, several mucopolysaccharidoses, mucolipidosis II, sialic acid storage disease, aspartylglucosaminuria
Skeletal findings	GM_1 gangliosidosis, Gaucher disease, fucosidosis, mannosidosis, sialidosis, galactosialidosis, several mucopolysaccharidoses, I-cell disease, mucolipidosis III
Cherry red spot	Infantile forms of GM_1 gangliosidosis, Sandhoff's disease, Tay-Sachs' disease, Niemann-Pick disease, sialidosis, galactosialidosis, I-cell disease
Corneal clouding	GM_1 gangliosidosis, several mucopolysaccharidoses, mannosidosis, I-cell disease, mucolipidosis III and IV, multiple sulfatase deficiency, galactosialidosis
Cognitive impairment	GM_1 gangliosidosis, Sandhoff's disease, Tay-Sachs' disease, Niemann-Pick disease, Gaucher disease type 2, Wolman's disease, fucosidosis, mannosidosis, multiple sulfatase deficiency, sialidosis, galactosialidosis, several mucopolysaccharidoses, sialic acid storage disease, aspartylglucosaminuria, I-cell disease, mucolipidosis III and IV, Krabbe's disease, metachromatic leukodystrophy, neuronal ceroid lipofuscinosis
Hematologic	
Foam cells	GM_1 gangliosidosis, Niemann-Pick disease, Gaucher disease, acid lipase deficiency, fucosidosis
Granulated or vacuolated white blood cells	Several mucopolysaccharidoses, sialidosis, galactosialidosis. neuronal ceroid-lipofuscinosis, Niemann-Pick disease, Wolman's disease, fucosidosis, mannosidosis, aspartylglucosaminuria, I-cell disease, mucolipidosis III, multiple sulfatase deficiency
Psychiatric or behavioral manifestations	Several mucopolysaccharidoses (especially Sanfilippo's), sialidosis, galactosialidosis, Fabry disease, mannosidosis, neuronal ceroid-lipofuscinosis, metachromatic leukodystrophy, Tay-Sachs' disease, Niemann-Pick disease, type C
Newborn presentations	Gaucher disease, type 2; GM_1 gangliosidosis; Krabbe's disease; Niemann-Pick disease, types A and C; mucopolysaccharidosis I, IVA, VII; Pompe's disease; sialidosis, types I and II; mucolipidosis, types I and II; Schindler's disease; Wolman's disease; infantile sialic acid storage disease; sialuria; Salla's disease; galactosialidosis; multiple sulfatase deficiency; prosaposin deficiency

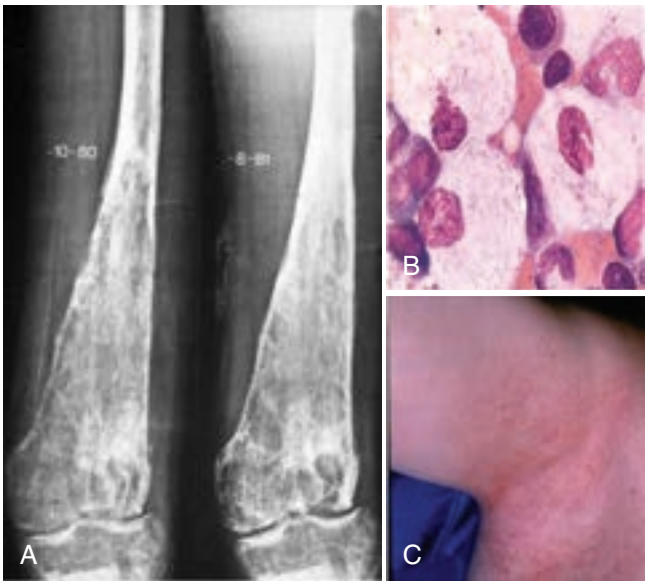

FIGURE 208-1. **A, Radiographic image showing the Erlenmeyer flask deformity in Gaucher disease. C, Angiokeratomas, the nonblanching punctate skin lesion in Fabry disease.**

calcifications, hydrocephalus, and other atypical manifestations, and all carry the mutation D409H in the *GBA1* gene.

DIAGNOSIS

Gaucher disease should be considered in the differential diagnosis of patients of all ages with unexplained organomegaly, easy bruisability, or bone pain (Table 208-3). The diagnosis can be made by demonstration of deficient glucocerebrosidase activity in leukocytes or cultured cells. In some populations, particularly Ashkenazi Jews, mutation analysis can be diagnostic as mutation N370S accounts for about 70% of mutant alleles. However, the presence of a highly homologous pseudogene sequence nearby can complicate molecular analyses. Bone marrow and liver biopsies show pathologic changes (Fig. 208-1B) but are not indicated for diagnosis. Carrier identification is best achieved by DNA testing when the mutant allele is known. Prenatal diagnosis is possible by determining the enzymatic activity or specific mutations in chorionic villi or cultured amniotic fluid cells.

TABLE 208-3 SUGGESTIVE DIAGNOSTIC FEATURES IN ADULTHOOD FOR GAUCHER DISEASE AND FABRY DISEASE

GAUCHER DISEASE	FABRY DISEASE
Family member with Gaucher disease	Family history of Fabry disease
Hepatomegaly, splenomegaly (sometimes massive)	Cutaneous lesions of capillaries (angiokeratoma)
Frequent epistaxis	Hypohidrosis or heat intolerance
Easy bruising	Intermittent episodes of severe pain in the extremities (acroparesthesias)
Abnormal saccadic eye movements	Left ventricular hypertrophy of unknown etiology in young adulthood
Thrombocytopenia or anemia	Stroke of unknown etiology in young adulthood
Painful bone crisis	Chronic kidney disease of unknown etiology in young adulthood
Erlenmeyer flask deformity of the distal femur, aseptic necrosis of the femoral heads	Multiple renal sinus cysts discovered incidentally
Pathologic fractures, unexplained rib fracture	Female carriers may have more variable and less severe symptoms with later onset
Multiple myeloma	
Parkinsonism	
Elevated serum ferritin, angiotensin-converting enzyme, or tartrate-resistant acid phosphatase	

TREATMENT

Rx

Enzyme replacement with recombinant glucocerebrosidase is available for the treatment of symptomatic patients with type 1 disease (Table 208-4). Studies show that anemia, thrombocytopenia, and organomegaly are reversed within 12 to 36 months with enzyme doses between 30 and 120 IU/kg given monthly. The treatment is ongoing, administered intravenously, and extremely expensive. Asymptomatic and mildly symptomatic adults do not always require treatment. Several companies are now marketing different forms of recombinantly produced enzyme. The enzyme does not cross the blood-brain barrier and does not alter the neurologic progression of patients with neuronopathic forms of Gaucher disease, but it can still be useful in alleviating visceral manifestations. It does not prevent the development of parkinsonism. Efforts are also under way to develop alternative therapies, including substrate reduction therapy, chemical chaperones, and gene therapy. One oral form of substrate reduction therapy, an iminosugar derivative, has been approved and is efficacious for some of the systemic manifestations of type 1 Gaucher disease. Useful supportive therapies include bisphosphonates for osteoporosis, orthopedic surgery for bone fractures, and palliative therapy and hydration for bone crises. Total or partial splenectomy, once commonly performed in patients with Gaucher disease, is now rarely indicated. Bone marrow transplantation (Chapter 178) has improved systemic but not neurologic manifestations.

TABLE 208-4 ENZYME REPLACEMENT THERAPY (ERT) FOR GAUCHER DISEASE AND FABRY DISEASE

GAUCHER DISEASE	FABRY DISEASE
ERT is a costly but effective intravenous therapy generally administered every other week for life.	ERT is costly, and there are not uniform recommendations for its use.
Decreased splenic and hepatic volumes and increases in hemoglobin levels and platelet counts should be expected in the first year of treatment.	On the basis of some current trials, hemizygous males with a low or undetectable level of α-galactosidase A should be treated with ERT, whether or not clinical features are present.
Asymptomatic and mildly symptomatic adults do not always require treatment.	On the basis of current trials, female carriers and atypically affected males with clinical features of Fabry disease should be treated with ERT.
ERT does not cross the blood-brain barrier and does not correct neurologic features of neuronopathic forms of Gaucher disease.	Other trials suggest that ERT should not be started in patients with proteinuria or reduced glomerular filtration rate unless there are other findings of Fabry disease.
ERT will not prevent the development of parkinsonism.	

FABRY DISEASE

PATHOBIOLOGY

Fabry disease, an X-linked inherited deficiency of the lysosomal enzyme α-galactosidase A, has intermediate penetrance in females and is considered a systemic vascular disorder. The disease incidence is about 1 in 117,000 live male births. Evidence suggests that 50% of females with Fabry disease are either asymptomatic or are not identified. This defect in the hydrolytic cleavage of the terminal molecule of galactose from glycolipids causes lysosomal accumulation of globotriaosylceramide and galabiosylceramide in many cell types. Lysosomal inclusions or lipid deposits can be seen in vascular cells, including both endothelial and smooth muscle cells; cardiac cells, such as endocardial cells, cardiomyocytes, and cardiac valves; kidney epithelial cells, including tubular and glomerular cells and podocytes; and nerve cells, including dorsal root ganglia and some central nervous system neurons.

The gene encoding α-galactosidase A, *GLA*, is located on Xq22.1. More than 431 mutations have been described, including missense/nonsense mutations, small deletions, large deletions, splice defects, and complex rearrangements. Most affected individuals have 2 to 25% residual activity, but the most severe form of Fabry disease has been correlated with complete absence of α-galactosidase A activity.

CLINICAL MANIFESTATIONS

Clinically, angiokeratomas (nonblanching, punctate, blue-black skin lesions), debilitating pain, and corneal opacities can occur in early childhood and may lead to the diagnosis. If the diagnosis is missed, the disease can result in progressive renal and cardiac deterioration. Patients have a propensity for ischemic stroke, sometimes in their 20s but more commonly in the fourth and fifth decades of life. As with many metabolic disorders, there is a spectrum of presentations that can mimic more common disorders, and many patients are undiagnosed.

Fabry disease typically manifests in childhood in classically affected males with episodes of extremity pain. Angiokeratomas develop in adolescence, followed by advancing renal disease during adulthood. The progressive cardiac and cerebrovascular involvement accounts for a majority of the deaths in adulthood associated with Fabry disease. X-linked inactivation and the penetrance of this X-linked disorder are reflected in the fact that approximately 90% of females carrying the mutation have symptoms,[9] although affected males show more significant clinical manifestations at an earlier age than heterozygous females do.

The majority of patients experience acroparesthesia, or a "Fabry crisis," characterized by excruciating, burning pain that may be either continuous or episodic. The pain typically affects the feet first, followed by the hands, and may be triggered by exercise, stress, and extremes in environmental temperatures. Abdominal or flank pain, simulating renal colic, may occur.

Angiokeratomas (Fig. 208-1C) are often the first sign of Fabry disease and may be accompanied by hypohidrosis. These classic skin lesions increase in number and size over time and are typically most dense between the umbilicus and the knees; however, they may occur anywhere, including the buccal mucosa. Ophthalmologic findings include conjunctival and retinal tortuosity and corneal opacities (cornea verticillata). Characteristic lenticular lesions are observed during slit-lamp examination and are present in affected males and female heterozygotes. Progressive hearing loss may also occur.

Renal involvement is common and is first manifested as proteinuria, followed by progressive renal insufficiency, with birefringent "Maltese crosses" sometimes seen in the urinary sediment. Chronic kidney disease is part of the natural history, and end-stage renal disease may develop in the second to fourth decades. Fabry disease should be considered when multiple renal sinus cysts are seen on an imaging study. As affected men and women age, cardiovascular findings may include ventricular hypertrophy, conduction defects, coronary artery disease, aortic and mitral valve insufficiency, and aortic root dilation. Furthermore, atypical Fabry disease can be manifested with concentric left ventricular hypertrophy and no other disease findings.[10] Cerebrovascular involvement, leading to transient ischemic attacks and stroke, occur in approximately 25% of patients, with a mean age at onset of 40 years.

Female carriers of this X-linked disorder tend to have more variable and less severe symptoms, with a later age at onset. Affected women may not have proteinuria, even with pronounced renal impairment, and in almost 40%, stroke is the initial presentation. Whereas angiokeratomas are not typically seen in affected women, half have hypohidrosis and heat intolerance. The initial stages of cardiomyopathy in affected women is generally 10 years later than the classic presentation in men and may be the only manifestation of Fabry disease.

DIAGNOSIS

Fabry disease should be considered in individuals with angiokeratoma, acroparesthesia, and corneal lesions as well as in individuals with cryptogenic strokes, idiopathic cardiomyopathy, or renal disease (Table 208-3). Men and women with left ventricular hypertrophy without any other explanation or with a family history of renal, cardiovascular, cerebrovascular, or skin issues should be screened for Fabry disease. Angiokeratoma should be differentiated from Fordyce's disease, benign angiokeratomas of the scrotum, and angiokeratoma circumscriptum. Angiokeratomas are also seen in other lysosomal disorders including mannosidosis, fucosidosis, sialidosis, and β-galactosidase and β-hexosaminidase deficiency. Corneal abnormalities are similar to those seen secondary to the use of chloroquine or amiodarone; exposure to silicone dust can result in similar renal findings.

A presumed diagnosis can be confirmed by low α-galactosidase activity in peripheral white blood cells or cultured skin fibroblasts. Levels below 20% of normal are considered diagnostic, and levels up to 35% of normal should be considered suggestive. *GLA* mutation analysis is available and is critical for confirmation in atypically presenting males and heterozygote females because random X chromosome inactivation may lead to only slightly reduced or normal enzyme activity.

TREATMENT

Rx

Symptomatic treatment of the clinical manifestations of Fabry disease should follow standard medical care. Antiplatelet agents such as clopidogrel and aspirin or long-acting dipyridamole should be used for the prevention of strokes. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are appropriate to manage hypertension and to preserve renal function. Kidney transplantation is effective in individuals with end-stage renal disease. Neuropathic pain can be treated with relatively low doses of antiepileptic medications, antidepressants, topical anesthetics, or pain relievers. Nonsteroidal anti-inflammatory agents should be avoided because of potential renal toxicity.

Enzyme replacement therapy has been available since 2001, and clinical trials suggest a modest benefit in modifying the natural course of the disease. Whereas there are no uniform recommendations, it is generally agreed that this therapy is appropriate for classically affected males, symptomatic females, and males with atypical disease (Table 208-4).[11]

OTHER LYSOSOMAL DISORDERS SEEN IN ADULTS

Metachromatic leukodystrophy, the deficiency of arylsulfatase A, results in the accumulation of sulfatides in the central and peripheral nervous systems, leading to demyelination of axons and peripheral nerves. It has a spectrum of manifestations, divided into childhood and adult variants. In both, gait disturbance and cognitive regression are seen. The adult form is associated with behavioral disturbances and dementia, often mistakenly resulting in a

diagnosis of psychosis. Metachromatic leukodystrophy is a recognized underlying cause of psychiatric illness in adults, and prominent features include auditory hallucinations, bizarre delusions, behavioral changes, personality changes, disinhibition and disorganization in daily life, and catatonic posturing. The diagnosis can be especially difficult in these individuals. Other neurologic signs, such as dysarthria and spasticity, manifest later as the disease progresses. The diagnosis is made initially by demonstration of low arylsulfatase A activity. However, because there can be a pseudodeficiency, it must be confirmed by molecular diagnosis or the demonstration of the excretion of sulfatides in urine.

Tay-Sachs' disease, caused by β-hexosaminidase A deficiency, is characterized by an excessive accumulation of the fatty acid derivative ganglioside GM_2 in neurons. There are three clinical variants based on the age at onset: type 1, infantile acute; type 2, subacute (2 to 18 years); and type 3, late onset. The main features of the disease are neurologic and cognitive deterioration as well as blindness, the macular cherry red spot, and deafness. In patients with late-onset GM_2 gangliosidosis, psychiatric signs may manifest years before the appearance of motor findings. The most common psychiatric signs include acute psychosis, mania, and depression without psychosis. Either recurrent progressive psychosis, consistent with schizophrenia-hebephrenia, or major depression followed by psychotic features may occur. Dysarthria and progressive speech loss are also common. The disorder is diagnosed by measurement of β-hexosaminidase A activity in the serum or white blood cells in the presence of normal or elevated activity of the β-hexosaminidase B isoenzyme. In pregnant women or those taking oral contraceptives, the test should be performed only in leukocytes.

Niemann-Pick disease type C has a spectrum of features ranging from a rapidly progressive, fatal neonatal phenotype to an adult-onset chronic, neurodegenerative course. Progressive ataxia, vertical supranuclear ophthalmoplegia, dystonia, and dementia are variable. Hepatosplenomegaly is frequently encountered. The disorder results from an error in cellular trafficking of exogenous cholesterol, leading to lysosomal accumulation of unesterified cholesterol, and has been linked to mutations in the *NPC1* (95% of cases) and *NPC2* (5% of cases) genes. The diagnosis is made by demonstration of impaired cholesterol esterification in cultured fibroblasts, termed the Filipin test, or by molecular genetic testing for mutations. Glycosphingolipids and cholesterol accumulate in different tissues such as the liver, spleen, bone marrow, and brain. In adults, psychiatric manifestations are observed that are consistent with acute psychosis, paranoid delusions or schizophrenia with delusions, hallucinations, disorganized behavior, and aggressiveness. Miglustat (*N*-butyldeoxynojirimycin) has been shown in clinical trials to stabilize but not to prevent or reverse key neurologic findings.[12] Decisions about starting this therapy typically involve the team of physicians, parents, and caregivers of the affected individual.

Aspartylglucosaminuria, a disorder more common in Finland than elsewhere in the world, is an autosomal recessive defect in glycoprotein degradation characterized by a slow or progressive delay in psychomotor development. Delayed speech and motor defects are often accompanied by repeated upper respiratory infections. Patients typically achieve the developmental competency of a 5- to 6-year-old child at around puberty; subsequently, they may experience progressive deterioration, resulting in the severe cognitive impairment seen in adulthood. The characteristic coarse facial features, thick calvaria, and osteoporosis result from mild connective tissue transformation. About 20% of patients experience seizures during the later stages of the disease, resulting primarily from abnormalities in the differentiation between gray and white matter and delayed myelination. The diagnosis is made by the detection of elevated urine oligosaccharides and deficient aspartylglucosaminidase activity in leukocytes.

The *neuronal ceroid-lipofuscinoses* are divided into four major groups—infantile, classic late infantile, juvenile, and adult—reflecting the age at symptom onset and the appearance of storage material on electron microscopy. Although generally inherited in an autosomal recessive fashion, the adult type can be inherited as a dominant allele. These diseases are characterized clinically by visual impairment leading to blindness, gait abnormalities, seizures, dementia, and early death. They are a genetically heterogeneous group of progressive, hereditary neurodegenerative diseases with variable onset of clinical manifestations. To date, approximately 160 mutations causing neuronal ceroid-lipofuscinoses have been found in eight human genes, complicating genetic analysis. Symptoms result from deficiencies in palmitoyl-protein thioesterase 1 and tripeptidyl-peptidase 1. The diagnosis is based on diminished enzyme activity and molecular genetic testing and, in some cases, clinical findings and electron microscopy of biopsied tissues. Accumulation of autofluorescent ceroid lipopigments is seen in the brain and other tissues. Adult patients may exhibit behavioral disturbances and cognitive decline, and parkinsonian features may be prominent.

Pompe's disease is discussed in Chapters 207 and 421.

The *mucopolysaccharidoses* (MPS) are a group of disorders resulting from defective lysosomal degradation of glycosaminoglycans. These chronic, progressive storage disorders show clinical manifestations that vary by type. Findings include coarse facial features, dysostosis multiplex, organomegaly, and neurologic manifestations with regression. All types are inherited in an autosomal recessive pattern except for MPS II/Hunter, which is X-linked. The mucopolysaccharidoses were once typically thought of as pediatric disorders, but with the advent of enzyme replacement therapy and the recognition of milder forms, more patients are reaching adulthood. Classically, patients with MPS type IS/Scheie, II/Hunter, III/Sanfilippo, IV/Morquio, and VI/Maroteaux-Lamy may have life expectancies beyond the pediatric years. Patients with MPS type IS may present with normal to short stature, normal intelligence, degenerative joint disease, corneal opacities, and cardiac valve lesions. Patients with MPS II/Hunter share the symptoms of MPS I/Hurler, except that airway involvement may be more significant in individuals with Hunter's syndrome, and the corneas are clear. Patients with MPS III/Sanfilippo have primarily central nervous system manifestations, with mild somatic involvement. They have progressive speech impairment, with the development of severe behavioral and sleep disturbances. Later they have an unrelenting loss of skills and deterioration into a vegetative state, with death in the third decade. Individuals with MPS IV have severe skeletal dysplasia, with normal intelligence in type A and a degenerative course in type B. Treatment is available in the form of enzyme replacement therapy for MPS IS, MPS II, and MPS IV, and enzyme therapies for other forms are in development. Medical management is type specific. In general, attention should focus on airway involvement resulting from progressive storage in the soft tissue of the upper airway and the need to optimize joint mobility and function by physical therapy. Patients with MPS I, II, and VI should be monitored for the development of cervical myelopathy due to dural thickening, which may lead to loss of endurance before ascending paralysis becomes apparent.[13]

Cystinosis is a lysosomal storage disorder with three clinical phenotypes: the most common infantile or nephropathic form, an intermediate or juvenile-onset form, and a benign form typically seen in adults and affecting primarily the eyes. Lysosomal cystine accumulation results from mutations in the gene *CTNS*, which codes for cystinosin, a lysosomal carrier protein. Individuals with the nephropathic form have lysosomal cystine accumulation leading to multiorgan system involvement, including progressive renal disease, corneal crystals, and effects on the thyroid, gonads, pancreas, muscle, and central nervous system. The adult form has only corneal crystals. Treatment is supportive and should include cysteamine, which is an oral medication that decreases cystine accumulation.[14] Cysteamine hydrochloride eyedrops dissolve corneal crystals and relieve photophobia.

REVIEW QUESTIONS

1. All except which of the following are different defects that can result in lysosomal storage disorders?

A. Sphingolipidosis
B. Lysosomal transport disorders
C. Phenylketonuria
D. Oligosaccharidoses
E. Lipid storage disorders

Answer: C Lysosomal storage disorders are a group of more than 45 different inherited disorders, all sharing a defect in lysosomal function. Lysosomes, acidic, membrane-bound organelles present in the cytoplasm, contain enzymes that degrade cellular macromolecules. These disorders occur when one or more of the hydrolytic enzymes are deficient or when essential lysosomal transporters, receptors, cofactors, or protective proteins are defective or lacking. Sphingolipidosis, the oligosaccharidoses, lipid storage disorders, and lysosomal transport disorders are all considered lysosomal storage disorders. Phenylketonuria is a disorder of amino acid metabolism, and abnormal lysosomal storage does not occur.

2. To make the diagnosis of a lysosomal storage disorder:

A. A tissue biopsy is often necessary.
B. DNA analyses are required.
C. Enzymatic assays can be performed on a blood or fibroblast sample.
D. Urine tests are the standard of care.
E. Clinical criteria alone are adequate.

Answer: C The diagnosis of most lysosomal storage disorders can be made by assaying the enzyme activity in a blood sample or fibroblasts pellet from a skin biopsy specimen. The first tier of diagnostics should be a lysosomal disease diagnostic panel, evaluating the enzyme activity of multiple lysosomal enzymes. Whereas the genes encoding the lysosomal enzymes have been identified and mutation analysis is available, there is vast genotypic heterogeneity. Thus, mutation screening is most useful when a mutation has already been identified in a specific family or when specific mutations are known to be common in an ethnic group.

3. A 24-year-old woman with no prior health issues presents with sudden onset of dysarthria and right hemiparesis. She also mentions that she "sweats less than her peers during exercise." She had a paternal grandmother and uncle who both died of renal disease in their fourth decade. Her work-up should include testing for:

A. Gaucher disease
B. Fabry disease
C. Glycogen storage disease
D. Wolman's disease
E. All of the above

Answer: B Female carriers of Fabry disease, which is an X-linked disorder, have less severe symptoms with a later age at onset. About 40% of affected women have stroke as the initial symptom. Whereas the typical skin finding in Fabry disease of angiokeratoma is not seen in women, about half complain of hypohidrosis and heat intolerance. Renal involvement is common, with progressive renal insufficiency and end-stage renal disease in the second to fourth decades. Affected men have proteinuria, which is less frequently seen in affected women, even those affected with renal disease. Gaucher disease, glycogen storage disease, and Wolman's disease are not manifested with stroke symptoms in men or women.

4. A 22-year-old Ashkenazi Jewish college student presents with thrombocytopenia and painless splenomegaly. He is otherwise healthy with no relevant family history. His work-up should include diagnostic testing for

A. Hurler's disease
B. Fucosidosis
C. Cystinosis
D. Gaucher disease
E. Hereditary hemorrhagic telangiectasia

Answer: D Type 1 Gaucher disease should be considered in an otherwise healthy young adult with thrombocytopenia and painless splenomegaly. The carrier frequency of mutations in the gene encoding glucocerebrosidase (*GBA1*), which underlies Gaucher disease, is about 1 in 16 in Ashkenazi Jews, in contrast to the carrier frequency in the general population of about 1 in 100. Hurler's disease is a mucopolysaccharidosis that manifests with hepatosplenomegaly, typically in childhood, although patients may live to adulthood. Cystinosis manifests in adults with corneal crystals. Hereditary hemorrhagic telangiectasia is an autosomal dominant disease that is manifested with abnormal blood vessel formations (telangiectasias) of the skin, mucous membranes, lungs, and gut. Fucosidosis manifests in childhood with developmental delay and a neurodegenerative course.

5. The following is true about the association between Gaucher disease and parkinsonism:

A. All patients with Gaucher disease ultimately develop parkinsonism.
B. The increased risk of Parkinson's disease is observed only in Ashkenazi Jews.
C. Mutations in *GBA*, the gene encoding glucocerebrosidase, are extremely rare in subjects with parkinsonism.
D. An increased frequency of parkinsonism is seen in both patients with Gaucher disease and Gaucher disease carriers.
E. Lewy body disorders other than Parkinson's disease are not associated with mutations in *GBA1*.

Answer: D Mutations in the glucocerebrosidase gene are one of the most common genetic risk factors for the development of parkinsonism. Both patients with Gaucher disease and Gaucher disease carriers have an increased risk of both Parkinson's disease and related synucleinopathies, such as dementia with Lewy bodies. The increased frequency of *GBA1* mutations is observed in both Jewish and non-Jewish patients with parkinsonism. However, the majority of patients with Gaucher disease never develop Parkinson's disease.

HOMOCYSTINURIA AND HYPERHOMOCYSTEINEMIA

MANUEL SCHIFF AND HENK BLOM

DEFINITION

Homocysteine is a nonprotein amino acid and is a key metabolic branch point metabolite between the trans-sulfuration and remethylation pathways of methionine metabolism. The many conditions associated with high

homocysteine levels encompass a wide range of clinical manifestations. The normal level of plasma total homocysteine (tHcy) is below 15 µM. However, the threshold of tHcy above which a disorder of homocysteine metabolism should be suspected and a specific therapy should be initiated is around 50 µM.

Homocystinuria and hyperhomocysteinemia primarily include inherited disorders of homocysteine metabolism but can also involve acquired nutritional cobalamin (Cbl, vitamin B_{12}) or folate deficiencies. Severely elevated plasma levels of homocysteine are accompanied by homocystinuria as rare autosomal recessively inherited disorders that are associated with vascular, neurologic, ocular, and skeletal abnormalities. Lesser elevations of plasma homocysteine, without homocystinuria, occur in about 5 to 7% of the population; these individuals with hyperhomocysteinemia only do not have the clinical stigmata of homocystinuria but are at increased risk of atherosclerotic cardiovascular disease (Chapter 52) and venous thromboembolism (Chapter 176).

Inherited disorders of homocysteine metabolism (Figs. 209-1 and 209-2) comprise *disorders of the trans-sulfuration pathway* with cystathionine β-synthase (CBS) deficiency (or classic homocystinuria) and *disorders of remethylation* of homocysteine to methionine. The latter include 5,10-methylenetetrahydrofolate reductase [MTHFR] deficiency and inherited disorders of cobalamin absorption, transport, and intracellular metabolism and the very rare congenital folate malabsorption disorder. Intracellular remethylation defects include disorders that all have defective methionine synthesis in common: MTHFR deficiency impairs methyltetrahydrofolate synthesis; defective lysosomal release of cobalamin (CblF and CblJ) and defects in cytosolic reduction and transport of hydroxocobalamin (CblC and CblD) impair the synthesis of both methylcobalamin and

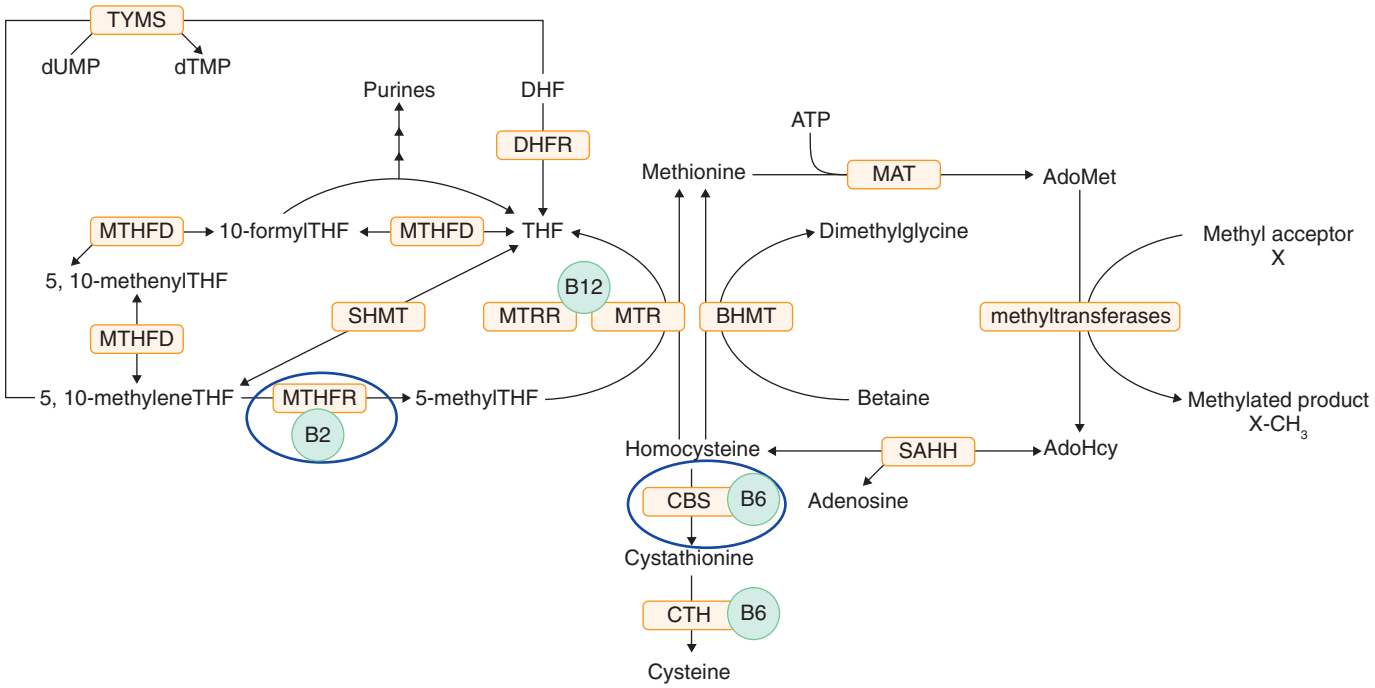

FIGURE 209-1. Homocysteine metabolism and the folate cycle. The two conditions leading to accumulation of homocysteine (CBS and MTHFR) are surrounded by a circle. AdoHcy = *S*-adenosylhomocysteine; AdoMet = *S*-adenosylmethionine; ATP = adenosine triphosphate; BHMT = betaine-homocysteine methyltransferase; CBS = cystathionine β-synthase; CTH = cystathionine γ-lyase; DHF = dihydrofolate; DHFR = dihydrofolate reductase; dTMP = deoxythymidine monophosphate; dUMP = deoxyuridine monophosphate; MAT = methionine-adenosyltransferase; MTHFD = methylenetetrahydrofolate dehydrogenase/methenyltetrahydrofolate cyclohydrolase/formyltetrahydrofolate synthetase; MTHFR = methylenetetrahydrofolate reductase; MTR = methionine synthase; MTRR = methionine synthase reductase; SAHH = *S*-adenosylhomocysteine hydrolase; SHMT = serine-hydroxymethyltransferase; THF = tetrahydrofolate; TYMS = thymidylate synthase.

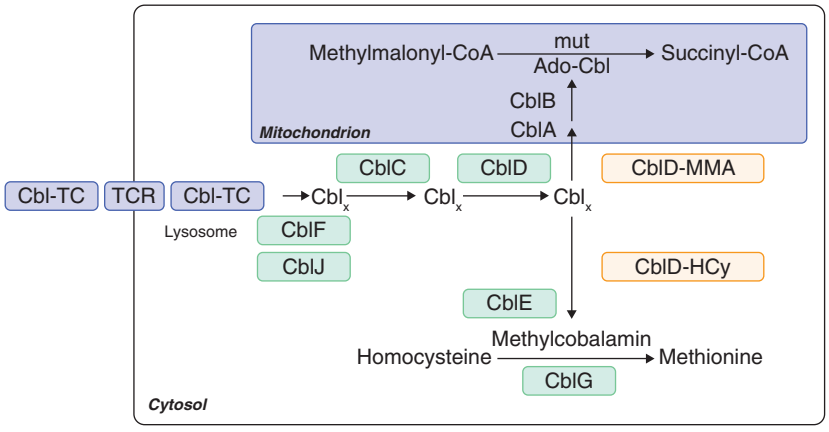

FIGURE 209-2. Intracellular cobalamin metabolism pathway and its defect. To date, 10 complementation group defects of the cobalamin pathway have been described. After binding to the transcobalamin receptor (TCR), cobalamin bound to TC enters the cell through lysosome-mediated endocytosis and is released through proteolysis. Export from the lysosome into the cytoplasm is defective in patients with the CblF and recently described CblJ defects. The steps in the cytosol after lysosomal release are defined by the complementation groups CblC and CblD. The exact form of cobalamin at this stage is unclear (as indicated by Cbl_x). In the cytosol, cobalamin is reductively methylated by methionine synthase reductase (CblE) to methylcobalamin, the cofactor for methionine synthase (CblG). After its transport into the mitochondrion, cobalamin is converted to adenosylcobalamin (Ado-Cbl), the cofactor for methylmalonyl–coenzyme A (CoA) mutase (mut), by cobalamin adenosyltransferase (CblB). The CblD defect can cause isolated methylmalonic aciduria (CblD-MMA complementation group), isolated homocystinuria (CblD-HCy), or both (CblD). In all these conditions with defective remethylation (TC and TC receptor deficiency, CblF, CblJ, CblC, CblD, CblD-HCy, CblE, and CblG defects), there is homocysteine accumulation due to dysfunction in methionine synthesis.

TABLE 209-1 GENETIC DEFECTS ASSOCIATED WITH HOMOCYSTINURIA

FUNCTIONAL DEFECT	COMMON NAME	ENZYME DEFECT	GENE	CHROMOSOME LOCUS
Trans-sulfuration	"Classic" homocystinuria	Cystathionine β-synthase	*CBS*	21q22.3
Remethylation	Folate-dependent homocystinuria	Methylenetetrahydrofolate reductase	*MTHFR*	1p36.3
	CblE	Methyltransferase reductase	*MTRR*	5p15.2-p15.3
	CblG	Methionine synthase	*MTR*	1q43
Cobalamin transport	TC-II	Transcobalamin	*TCN2*	22q11.2-qter
	CblF	Lysosomal B_{12} translocase	*LMBRD1*	6q13
Cobalamin processing	CblC	Intracellular cobalamin chaperone?	*MMACHC*	1p34.1
	CblD	Cobalamin reductase?	*MMADHC*	2q23.2
	CblJ	Cobalamin processing?	*ABCD4*	14q24.3

adenosylcobalamin; and isolated deficiencies of methionine synthase (CblE and CblG) are associated with defective methylcobalamin synthesis as well as the CblD-Hcy variant.

In CBS deficiency, in addition to severe elevations of plasma tHcy, plasma methionine level is also increased. In contrast, in remethylation disorders, the increased tHcy is accompanied by a low (or low-normal) level of methionine in plasma because of the ineffective conversion (remethylation) of homocysteine to methionine. Among the remethylation disorders, the cobalamin-processing (CblC) defect (the most frequent inherited disorder of intracellular cobalamin metabolism) and MTHFR deficiency are by far the most frequent, although in absolute numbers these disorders are still rare. Accordingly, this chapter focuses on CBS deficiency, CblC defect, and MTHFR deficiency.

EPIDEMIOLOGY

Prevalence and Incidence

The worldwide prevalence of CBS deficiency has been reported at 1 in 344,000. Minimum estimates of the incidence of CBS deficiency by newborn screening programs have ranged from 1 in 60,000 to 1 in 300,000 live births, varying with the population and the screening method. Estimates of its incidence in Europe have been in the area of 1 in 40,000, which corresponds to a carrier (heterozygote) frequency of about 1%, but studies screening for known mutations suggest that the prevalence may be more than twice that rate. Studies from the Middle Eastern countries have shown incidence rates as high as 1 in 1800. The incidence of severe homocysteine remethylation defects is probably less than 1 in 500,000 live births.

PATHOBIOLOGY

The homocysteine that accumulates (in both CBS deficiency and remethylation defects) is a multisystem toxic agent that exerts its effects either directly or indirectly through conversion to *S*-adenosylhomocysteine (see Fig. 209-1), which potentially inhibits many essential methyltransferases. Direct cellular homocysteine toxicity involves endothelial injury and neuronal cell death. The effects of homocysteine on vascular endothelium predispose to thrombosis that may occur at any age and affect arteries or veins of any size. Specifically in CBS deficiency, accumulation of homocysteine or cysteine deficiency induces modification of connective tissue proteins, possibly being the origin of the skeletal and ocular manifestations. These effects are probably related to fibrillin, which is a component of the matrix of periosteum and perichondrium, the major component of the zonular fibers of the ocular lens, and a protein singularly rich in cysteine. Fibrillin structure is affected by the linking of homocysteine to cysteine; as a result, some clinical features of homocystinuria overlap with fibrillin mutations (Marfan syndrome; Chapter 260).

Remethylation defects (CblC and MTHFR) result not only in severe elevations of homocysteine but also in a shortage of methionine, required for protein synthesis and *S*-adenosylmethionine generation. The latter causes, through this route, a further reduction of cellular methylation capacity in addition to the accumulation of *S*-adenosylhomocysteine, especially in the central nervous system. CblC defect is an inborn error of intracellular cobalamin metabolism due to a defect of the methylmalonic aciduria and homocystinuria type C protein (*MMACHC*). After normal dietary intake, intestinal absorption, blood transport, and cellular uptake, cobalamin is delivered in the cytosol, where it becomes bound to MMACHC. This protein has been shown to catalyze dealkylation of alkylcobalamins, such as adenosylcobalamin and methylcobalamin, and the decyanation of cyanocobalamin.[1] In the absence of normal MMACHC, neither methylcobalamin (the cofactor of methionine synthase) nor adenosylcobalamin (the cofactor of methylmalonyl-CoA mutase) is functional, leading to defects of the methionine synthase (remethylation defect) and methylmalonyl-CoA mutase (methylmalonic acid accumulation), respectively (see Fig. 209-2). In MTHFR deficiency, the methyl donor 5-methyltetrahydrofolate (5-methylTHF) cannot be produced, which secondarily impairs methionine synthase function and subsequent remethylation (see Fig. 209-2). The pathogenesis of MTHFR deficiency can be ascribed to homocysteine toxicity together with methionine cellular depletion. However, the pathophysiologic mechanism of the other remethylation defect, the CblC defect, remains incompletely understood. Toxic accumulation of methylmalonic acid in the CblC defect might play an additional role.

All these genetic disorders associated with homocystinuria are inherited in an autosomal recessive manner and are summarized in Table 209-1.

CLINICAL MANIFESTATIONS

CYSTATHIONINE β-SYNTHASE DEFICIENCY Affected individuals are normal at birth after an uneventful pregnancy and delivery. If untreated, they progressively develop the core clinical symptoms of CBS deficiency,[2] which involve four major organ systems.

CENTRAL NERVOUS SYSTEM Developmental delay and mental retardation affect about 60% of the patients to a variable degree of severity. Seizures, electroencephalographic abnormalities, and psychiatric disturbances have also been reported in approximately half of the cases. Focal neurologic signs may be a consequence of cerebrovascular accidents.

EYE Dislocation of the ocular lens (ectopia lentis), myopia, and glaucoma are frequent, severe, and characteristic complications. Retinal detachment and degeneration, optical atrophy, and cataracts may eventually appear. Myopia often precedes lens dislocation. Ectopia lentis is detected in most untreated patients from 5 to 10 years of age and in nearly all untreated patients by the end of the fourth decade. In children as well as in adults, it is often the clue to diagnosis. The dislocation is generally downward, whereas it is usually upward in Marfan syndrome. Once ectopia lentis has occurred, a peculiar trembling of the iris (iridodonesis) after eye or head movement may be evident.

SKELETON Osteoporosis is almost invariably detected, at least after childhood. Frequent consequences are scoliosis and a tendency toward pathologic fractures and vertebral collapse. Homocystinuric patients tend to be tall, with thinning and elongation (dolichostenomelia) of long bones near puberty, enlarged metaphyses and epiphyses (especially at the knees), and arachnodactyly, present in about half of the patients. Other bone deformities include genu valgum, pes cavus, and pectus carinatum or excavatum. Restricted joint mobility, particularly at the extremities, contrasts with the joint laxity observed in Marfan syndrome.

VASCULAR SYSTEM Thromboembolic complications, occurring in arteries and veins of all parts of the body, constitute the major cause of morbidity and mortality at any age. Because of the very low prevalence of arteriosclerosis and thrombosis in children or adolescents, homocystinurias should be excluded in any such case presenting with arterial or venous occlusive disease.

Two phenotypic variants are recognized, B_6-responsive homocystinuria and B_6-nonresponsive homocystinuria. B_6-responsive homocystinuria is usually milder than the nonresponsive variant.

Adult-Onset Clinical Presentation

The expression of all clinical symptoms is extremely variable and may be manifested during childhood but also during adulthood, even up to 60 years of age. Individuals are often tall and slender with a marfanoid habitus and are prone to osteoporosis. The main acute manifestation in adulthood is

cardiovascular disease. In all forms of inherited homocystinurias, isolated arterial and venous occlusive disease may be manifested at any age. Thromboembolism is the major cause of early death and morbidity. Adults can also present with isolated quick loss of diopter (refractive capacity), which is the most common symptom before diagnosis.

The IQ in individuals with untreated homocystinuria varies widely, from 10 to 138. In B_6-responsive untreated individuals, the mean IQ is 79 versus 57 for those who are B_6 nonresponsive. The neuropsychiatric symptoms (like schizophrenia or autism-like features) may remain apparently isolated, but a thorough clinical history and examination will often reveal associated features like marfanoid habitus, skeletal abnormalities, and lens dislocation.

Remethylation Disorders: CblC Defect and MTHFR Deficiency

Clinical signs of remethylation defects are mainly neurologic. Neonatal and early-onset patients exhibit acute neurologic distress. In childhood, patients exhibit nonspecific mental retardation often associated with acquired microcephaly. Without appropriate therapy, remethylation-defective patients may develop acute or rapidly progressive neurologic deterioration, sometimes leading to death. Adolescents and adults exhibit, after a period of normal development or mild developmental delay, a rapid mental or psychiatric deterioration. These patients may typically have signs of subacute combined degeneration of the cord. In addition, adults can be asymptomatic or present with isolated stroke.

In the CblC defect,[3-5] 5-methylTHF accumulates because of the block at methionine synthase (the 5-methylTHF trap), causing a functional cellular folate deficiency. This explains the hematologic manifestations (megaloblastic bone marrow leading to macrocytic anemia or pancytopenia) that are not present in MTHFR deficiency. In the CblC defect, severe (occasionally fatal) multisystem deterioration may occur. This includes hemolytic-uremic syndrome, cardiomyopathy, and interstitial pneumonia, which all share an identical pathologic hallmark (i.e., thrombotic microangiopathy). In addition, a peculiar and poorly understood retinopathy with nystagmus is often present.

Adult-Onset Clinical Presentation

Adult-onset CblC disease is less frequent than childhood onset and is dominated by neuropsychiatric manifestations such as ataxia, cognitive impairment, and psychosis. Hemolytic-uremic syndrome (even isolated) can also be present.

In MTHFR deficiency, the neuropsychiatric presentation is similar and can be subtle. Patients may remain asymptomatic or exhibit isolated arterial stroke.

In both remethylation defects, the neurologic disorder results in many signs similar to the late stage observed in childhood. Previously, most of these patients had either a normal or a mild developmental delay, and a striking feature is the rapid mental deterioration occurring in the second decade of life accompanied by bouts of unexplained lethargy and a progressive cerebral, myelopathic, and neuropathic disorder with variable results on neurophysiologic investigations.

In both groups of inherited homocystinurias, isolated arterial and venous occlusive disease may be manifested at any age. Because of the very low incidence of arteriosclerosis and thrombosis in children or adolescents, homocystinurias should be excluded in any case in this age presenting with these clinical manifestations.

DIAGNOSIS

If homocystinuria is suspected clinically, plasma tHcy should be determined. If tHcy (normal values, 5-15 µM) is higher than 50 µM, determination of serum vitamin B_{12} and folate levels in both serum and red blood cells, plasma amino acids, and urinary organic acids (or plasma methylmalonic acid) is warranted. If tHcy is below 50 µM, the probability of a homocystinuria is minute. If plasma methionine is elevated or high-normal with low plasma cysteine, the plasma abnormalities point to CBS deficiency, whereas decreased or low-normal methionine and elevated tHcy point to remethylation defects. In the CblC defect, hematologic abnormalities with megaloblastic bone marrow maturation are observed along with normal vitamin B_{12} and folate blood levels. Nutritional vitamin B_{12} or folate deficiencies and other genetic causes of cobalamin and folate metabolism should also be considered in the differential diagnosis of remethylation defects.[6] It has to be kept in mind that CBS deficiency can cause secondary vitamin B_{12} and folate deficiency and remethylation defects can cause secondary folate deficiency. In MTHFR deficiency, folate levels (red blood cells or plasma) are usually low. Blood cell count with blood smear (looking for characteristics of vitamin B_{12} and folate deficiency), blood vitamin status, and metabolic biomarkers (tHcy, methionine, and methylmalonic acid) are usually enough to differentiate between the different forms of homocystinurias (Table 209-2). Definitive diagnosis can be confirmed at the molecular level by sequence analysis of the putative gene (see Table 209-1); if the molecular studies are not conclusive, functional studies can be performed in fibroblasts or lymphocytes.

TREATMENT

Rx

In 2015, general treatment guidelines will be available through the European Network and Registry for Homocystinurias and Methylation Defects website (*http://www.e-hod.org*). None of the treatment options are evidence based because of the rarity of these disorders.

Therapeutic Goals

The general therapeutic goal is to reduce tHcy accumulation and, for remethylation disorders, to bypass the remethylation defect, thereby

TABLE 209-2 CLINICAL FEATURES OF HOMOCYSTINURIAS

	BIOCHEMICAL FEATURES			CLINICAL FEATURES	
CLASS	***tHcy***	***Meth***	***MMA***	***System***	***Signs***
CBS deficiency	↑	↑	–	Ocular	Ectopia lentis, myopia, glaucoma, optic atrophy, retinal detachment
				Skeletal	Elongated and thinned bones, arachnodactyly, genu valgum, pectus malformation, scoliosis
				Vascular	Thromboembolic events (arterial or venous)
				Neurologic	Mental retardation in untreated cases, cerebrovascular thromboses, seizures
					Psychiatric disorders, personality disorder
MTHFR deficiency	↑	↓	–	Ocular	Ectopia lentis
				Vascular	Thromboses
				Neurologic	Variable: psychiatric to severe neurologic
Transcobalamin	↑	–/↓	+	Hematologic	Early-onset pancytopenia, macrocytosis
CblF, CblJ	↑	–/↓	+	Pansystemic	MMA, macrocytosis, stomatitis, congenital heart defects
CblC, CblD	↑	↓	+	Hematologic	Pancytopenia
				Neuropsychiatric	
				Systemic (CblC)	Hemolytic-uremic syndrome
CblE, CblG	↑	↓	–	Vascular	Thromboses
				Hematologic	Pancytopenia
				Neurologic	

Cbl = cobalamin; CBS = cystathionine β-synthase; Meth = plasma methionine; MMA = methylmalonic acid (urine or plasma); MTHFR = methylenetetrahydrofolate reductase; tHcy = total plasma homocysteine.

maintaining normal methionine and folate concentrations.[7] This should correct the hematologic abnormalities and ensure normal neurologic development or prevent further neurologic deterioration. Normalization of plasma tHcy levels would be ideal, but in practice, it is difficult if not impossible to achieve. However, the experience with CBS deficiency patients has shown that treatment can prevent further thromboembolic events even when the tHcy levels remain clearly above the normal range. Decreasing tHcy to 50 to 70 µM would therefore be a more reasonable goal in many patients with CBS deficiency as well as in those with remethylation disorders.

Available Treatment Options

To date, all the remethylation disorders are similarly treated with the combined supplementation of vitamin B_{12}, vitamin B_9 (folate), vitamin B_6 (pyridoxine), betaine, and methionine, although the dosage and route of administration may vary with the type of defect.

In CBS deficiency, therapy is more standardized with a longer experience available. It is based on (1) increasing residual CBS activity with the use of vitamin B_6 (in B_6-responsive patients); (2) decreasing the load on the affected pathway and replacing the deficient products by a low-methionine diet, limitation of natural proteins, amino acid mixture, special low-protein foods, and supplementation of cystine to increase cysteine; and (3) increasing remethylation to methionine with folate, vitamin B_{12}, and betaine to reduce tHcy accumulation.

Vitamin B_{12}

Vitamin B_{12} is the cofactor of methionine synthase. Its natural form, hydroxocobalamin, is more effective than the synthetic form cyanocobalamin. In CBS deficiency, hydroxocobalamin may be given orally (1 mg/day to 1 mg/week) according to the serum B_{12} level to prevent cobalamin deficiency.

In remethylation disorders, initial treatment includes daily parenteral administration of hydroxocobalamin (1 mg/day). If MTHFR deficiency is confirmed, switching to oral hydroxocobalamin (1 mg/day to 1 mg/week) or even stopping hydroxocobalamin supplementation may deserve discussion. Conversely, in CblC defect, lifelong high-dose intramuscular hydroxocobalamin injections are needed. The optimal interval between intramuscular injections remains to be determined, but recent data support the need for long-term daily doses.

Folate (Vitamin B_9)

Folate (vitamin B_9) is available in three different forms: folic acid, a stable synthetic form of the vitamin used, for example, in food fortification; folinic acid (5-formylTHF), the most stable form of the reduced and active vitamin; and 5-methylTHF (CH3-THF), the main natural and circulating form of the vitamin. A folinic acid formulation for parenteral administration is available for emergency treatment, whereas the other forms are available only for oral use. Whatever the disorder, folinic acid is more appropriate because it is the most stable reduced form, and folic acid may exacerbate cerebral CH3-THF deficiency, especially in MTHFR deficiency. In CBS deficiency, folinic acid should be given orally (1 to 5 mg/day) to avoid folate depletion. Moreover, folate repletion may be necessary to permit a pyridoxine response, which means that pyridoxine responsiveness should always be tested after potential folate depletion correction. In the CblC defect, long-term high-dose oral folinic supplementation is added to compensate for the methyl folate trap and to correct the hematologic abnormalities. The daily dose varies from 5 to 30 mg. The same folinic acid doses should be used in MTHFR deficiency.

Vitamin B_6 (Pyridoxine)

Vitamin B_6 (pyridoxine), through its action as the cofactor for CBS, is given orally in pharmaceutical doses in CBS-deficient patients to treat possible B_6-responsive individuals. There is no consensus on the dose and duration of B_6, which is usually given from 100 to 500 to 1000 mg/day during a period of several weeks, after which tHcy is determined to evaluate whether B_6 has been effective in normalizing (or even lowering) tHcy. As discussed before, B_6 should always be combined with folinic acid. In B_6-responsive patients, long-term therapy with pyridoxine and folate prevents further deterioration. In remethylation disorders, B_6 might theoretically enhance homocysteine removal and may be given at a low dose (50 to 100 mg/day).

For pyridoxine-responsive CBS-deficient patients, pyridoxine should be kept at the lowest dosage able to achieve adequate metabolic control. Because of reported high-dose pyridoxine toxicity on the nervous system, daily dosages higher than 400 to 500 mg/day in children and adults should probably be avoided for a long-term treatment. In pyridoxine-nonresponsive patients, a daily dosage of 50 to 100 mg of pyridoxine can be added to the treatment.

Betaine

Betaine is derived from choline and is a substrate for the enzyme betaine-homocysteine methyltransferase and therefore acts as a methyl donor (see Fig. 209-1). Oral betaine supplementation decreases homocysteine levels. Despite widespread use, there is little consensus on betaine dosage and frequency of administration. Case studies and early literature have used doses of 150 to 250 mg/kg/day in children and 5 to 10 g/day in adults, usually given two or three times daily. These early data were confirmed by pharmacokinetic studies (performed in CBS-deficient patients), which showed that above 200 mg/kg/day in two to three divided doses, there was no obvious benefit in lowering tHcy.

In CBS deficiency, the use of betaine is usually followed by an increase in plasma methionine and a fall in plasma tHcy. No harmful effects from raised methionine have been documented in patients receiving betaine therapy except one case of cerebral edema in a CBS patient with a plasma methionine level above 1000 µM. In B_6-nonresponsive early-treated patients, a low-methionine diet alone can be highly successful with good long-term outcomes, provided lifelong compliance is good. The clinical benefits of betaine are therefore questionable in compliant patients on a low-methionine diet. However, in some patients (especially when dietary compliance is a problem), betaine has been of benefit and may allow an increase in natural protein intake, thus improving the nutritional status.

In remethylation disorders, betaine increases systemic methionine levels and probably also methionine availability to the central nervous system, especially in patients with MTHFR deficiency. Early betaine treatment prevents mortality and allows normal psychomotor development in patients with severe MTHFR deficiency, highlighting the importance of timely recognition.[8] In the CblC defect, there are data reporting a synergistic action of hydroxocobalamin with betaine, lowering the tHcy level.

Oral Methionine

Oral methionine may also hold promise as an additional therapeutic measure in remethylation defects for several reasons. Cerebral methionine depletion is a key pathogenic factor. Added methionine might act synergistically with betaine by supplying intracellular methionine, and acute methionine loading does not lead to further homocysteine accumulation (with the attendant risk of thromboembolism). As a whole, whatever the remethylation defect, methionine depletion is rarely corrected by betaine therapy alone, whereas the association of methionine and betaine usually corrects methionine depletion.

PREVENTION

It is prudent to adopt measures to prevent additional risk of thrombosis, such as using long-term, low-dose aspirin and avoiding smoking and oral contraceptives. Nitrous oxide may also be relatively contraindicated because it can inhibit methionine synthase. Surgery poses serious risks but can be performed safely as long as attention is paid to the patient's hydration and coagulation status.

PROGNOSIS

In CBS deficiency, pyridoxine responsiveness generally correlates with higher residual enzyme activity, and the prognosis is significantly better than that for unresponsive cases, with or without treatment. Skeletal, ocular, vascular, and neurologic complications are all reduced with successful treatment. Without the early institution of treatment, the median IQ in a large outcome study was 57 for unresponsive patients and 78 for responsive patients. With early treatment, pyridoxine-unresponsive patients have a nearly normal median IQ. For patients who are responsive to and compliant with treatment, the prognosis for intellectual development is good, especially with diet alone. However, in case of poor adherence, significant elevations in tHcy generally persist, and some increased risk for vascular complications probably remains.

In the few MTHFR-deficient patients treated promptly in their neonatal period, the outcome is good with respect to the first years of neurologic development despite suboptimal metabolic control. If undiagnosed or untreated or late treated, these patients have a very poor outcome with severe impairments. In spite of some pathogenic similarity (intracellular methionine depletion due to impaired remethylation), CblC-defective patients have in general a particularly poor long-term outcome with multisystem involvement, thrombotic microangiopathy, and retinopathy.

REVIEW QUESTIONS

1. A 56-year-old man presents with ectopia lentis and venous thrombosis. What would be the first step in ruling out homocystinuria due to cystathionine β-synthase deficiency?

A. Rule out Marfan syndrome
B. Measure cystathionine β-synthase in cultured fibroblasts
C. Measure total homocysteine and methionine in plasma
D. Try oral vitamin B_6
E. Sequence the cystathionine β-synthase gene

Answer: C Given the clinical picture, if plasma methionine and total homocysteine levels are elevated, the diagnosis of cystathionine β-synthase deficiency is certain and therapy is urgently needed.

2. A patient is diagnosed with cystathionine β-synthase deficiency. The mutation is not known. What is the best way to start therapy?

A. Oral aspirin
B. Oral vitamin B_6 along with oral folinic acid
C. Vitamin B_{12} injections
D. Oral vitamin B_6 alone
E. Cocktail of all the vitamins B_2, B_6, B_{12}, and folinic acid

Answer: B Determination of B_6 responsiveness is key as vitamin B_6 can be the sole and effective lifelong treatment. Folate repletion with folinic acid supplementation is necessary to permit a pyridoxine response.

3. A 27-year-old woman presents with renal failure, malignant hypertension, and microangiopathic hemolysis. She has early-onset nystagmus and had an unexplained stroke a few years earlier. What do you do?

A. Start immunosuppressive therapy
B. Start plasmapheresis
C. Measure plasma total homocysteine, methionine, and methylmalonic acid and start hydroxocobalamin parenteral injection
D. Give high-dose folinic acid and betaine
E. Give vitamin B_6

Answer: C Atypical hemolytic-uremic syndrome associated with stroke and nystagmus points toward CblC deficiency. Hydroxocobalamin IM is urgent to correct hemolytic-uremic syndrome.

4. If a cystathionine β-synthase–deficient patient does not respond to B vitamin therapy, what other therapeutic option remains?

A. Enzyme replacement
B. Adding cysteine as *N*-acetylcysteine
C. Dietary methionine restriction
D. Aspirin administration
E. Stem cell therapy

Answer: C Dietary methionine restriction is the first line of treatment in pyridoxine-unresponsive CBS deficiency.

5. One should determine plasma total homocysteine if a patient presents with

A. Neural tube defect
B. Hypotonia
C. Stroke before the age of 18 years
D. Brittle hair
E. Liver dysfunction

Answer: C Stroke or thrombosis, especially in adolescents and younger adults, should prompt measurement of total homocysteine in plasma because treatments aimed at lowering of total homocysteine levels and reducing (if not abolishing) the vascular risk are available.

210 THE PORPHYRIAS

RICHARD J. HIFT

DEFINITION

The porphyrias are a group of eight disorders arising from disturbances in heme biosynthesis. Each disorder corresponds to abnormal activity of one of the enzymes that catalyze the heme biosynthetic pathway. Most porphyrias are genetic and heritable, with the exception of the sporadic form of porphyria cutanea tarda and rare instances of porphyria arising from acquired somatic mutations.

CLASSIFICATION

Approximately 90% of heme biosynthesis occurs within the erythron (specifically within erythroid precursors), leading to the production of heme for incorporation into hemoglobin. The remainder is synthesized in all other nucleated cells of the body, producing heme for incorporation into a number of vital hemoproteins. The liver is the predominant site of nonerythroid heme synthesis, with much of the product being incorporated into enzymes of the cytochrome P-450 (CYP) system.

Thus, the porphyrias may be classified into two categories, the erythropoietic and hepatic porphyrias. Disturbances in erythroid heme biosynthesis give rise to three forms of erythropoietic porphyria: congenital erythropoietic porphyria (CEP), erythropoietic protoporphyria (EPP), and X-linked protoporphyria (XLPP). Disturbances in nonerythroid heme biosynthesis give rise to five forms of hepatic porphyria: acute intermittent porphyria (AIP), variegate porphyria (VP), porphyria cutanea tarda (PCT), hereditary coproporphyria (HCP), and ALA dehydratase porphyria (ALADP).

A clinically applicable classification divides the porphyrias into another two cross-cutting groups (Table 210-1). The acute porphyrias are those characterized by the potential to develop the potentially fatal acute attack (AIP, VP, HCP, and ALADP). The nonacute porphyrias are accompanied predominantly by cutaneous manifestations (PCT, CEP, EPP, and XLPP).

EPIDEMIOLOGY

Each porphyria has a prevalence that may vary between populations, depending on local gene frequencies for the mutations that give rise to it. Assessment of prevalence is complicated by incomplete penetrance, difficulties in case ascertainment, and unevenness in the accuracy of biochemical diagnosis performed by different laboratories. The most accurate figures have recently been reported from Europe, where diagnostic laboratories in each country are centralized and linked into an international network. The network has reported a prevalence of 9.2 per million for EPP, 5.9 per million for AIP, and 3.2 per million for VP.[1] It is likely that the figures for North America will be broadly similar. PCT, which is environmentally induced and treatable, has an annual incidence exceeding 6 per million in Norway and nearly 4 per million in Sweden; its prevalence in the United States has been estimated at 4 per 100,000. HCP has a lower prevalence; the two autosomal recessive disorders, CEP and ALADP, are very rare, and experience is restricted to small case series and case reports.

AIP and VP may become prevalent in specific populations as a result of a founder effect, whereby a particular mutation spreads widely in an isolated population and becomes locally common. In northern Sweden, AIP has a prevalence estimated at 23 per million. In South Africa, VP has become the most common monogenetic disorder among the Dutch-descended immigrant population of South Africa, with a prevalence estimated at 1.2 per thousand of the white population.

PATHOBIOLOGY

The pathobiology of the porphyrias is easily understood by reference to the heme biosynthetic pathway (Fig. 210-1). There are slight differences between erythroid and nonerythroid heme synthesis. The initial step in the pathway is the synthesis of 5-aminolevulinate (ALA), catalyzed by the enzyme 5-aminolevulinate synthase (ALAS). The ubiquitous or housekeeping enzyme ALAS1 is strongly expressed in the liver and is encoded by the *ALAS1* gene on chromosome 3. The erythroid form, ALAS2, is encoded by the *ALAS2* gene on the X chromosome. The two genes share 73% homology.

TABLE 210-1 SUMMARY OF THE PORPHYRIAS

PORPHYRIA	KEY CLINICAL FEATURES AND LONG-TERM COMPLICATIONS	INHERITANCE
ACUTE PORPHYRIAS		
More Common		
Acute intermittent porphyria	Acute attacks Hypertension Renal failure Hepatocellular carcinoma	Autosomal dominant
Variegate porphyria	Vesiculo-erosive skin disease Acute attacks Hepatocellular carcinoma	Autosomal dominant
Less Common		
Hereditary coproporphyria	Vesiculo-erosive skin disease Acute attacks	Autosomal dominant
Rare		
ALA dehydratase porphyria	Acute attacks Neuropathy	Autosomal recessive
NONACUTE PORPHYRIAS		
More Common		
Porphyria cutanea tarda	Vesiculo-erosive skin disease Associated with iron loading, alcoholic liver disease, hepatitis C, HIV infection, renal failure, and other disorders	Acquired, sometimes on a background of an inherited mutation
*Erythropoietic protoporphyria	Immediate photosensitivity Cholelithiasis, liver disease	Autosomal recessive; frequently in association with a common polymorphism in the ferrochelatase gene
Rare		
*X-linked protoporphyria	Immediate photosensitivity Cholelithiasis, liver disease	X-linked
*Congenital erythropoietic porphyria	Vesiculo-erosive skin disease Severe photomutilation	Autosomal recessive

*The three forms of erythropoietic porphyria. The remainder are classified as hepatic porphyrias.

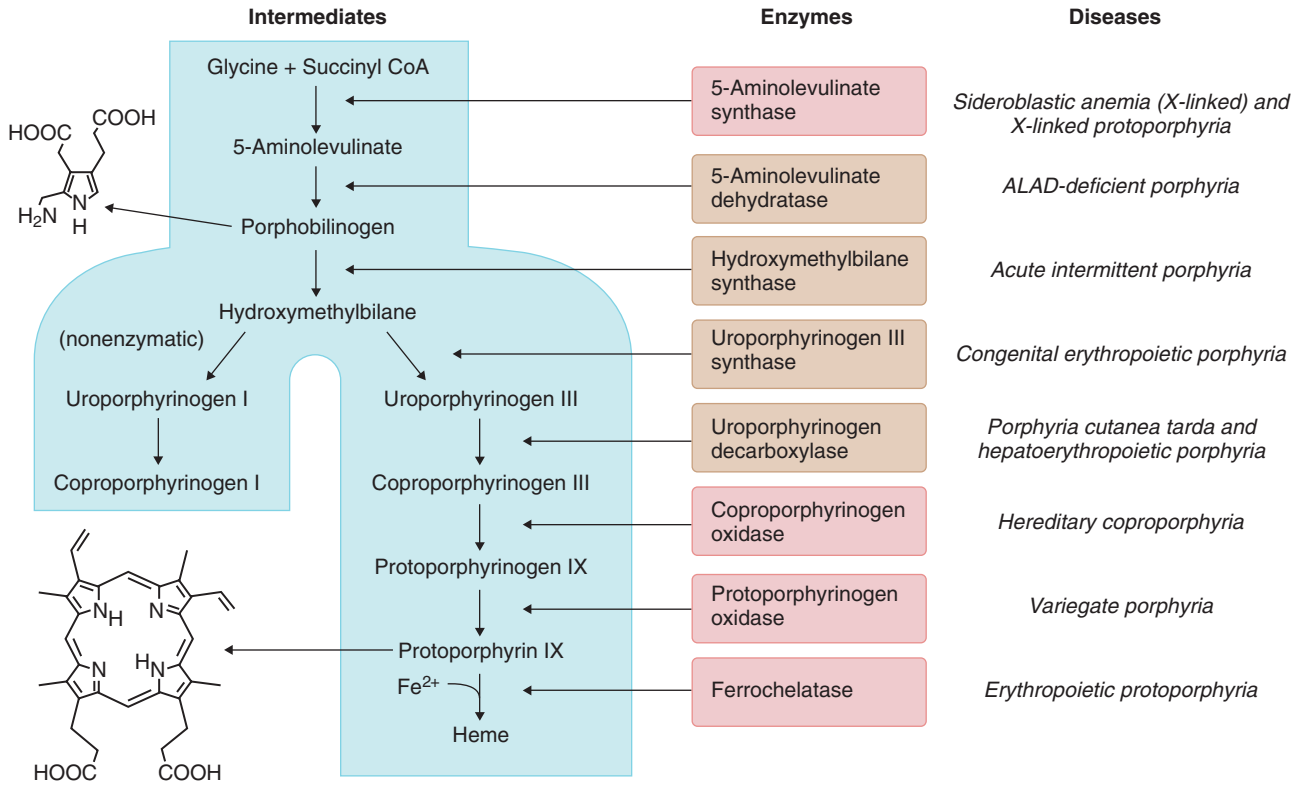

FIGURE 210-1. The heme biosynthetic pathway. Heme is synthesized through a series of porphyrin precursors and porphyrin intermediates, catalyzed by specific enzymes as indicated. The form of porphyria associated with abnormal enzyme function is shown on the right.

The remaining genes are common to both systems, although transcriptional variations lead to minor differences in size between the erythropoietic and hepatic forms of porphobilinogen synthase (previously known as ALA dehydratase), hydroxymethylbilane synthase, and uroporphyrinogen-III synthase.

Heme production is tightly coupled to heme requirement, and the flux of metabolites through the pathway is regulated by a process of negative feedback inhibition. The synthesis of ALA is the rate-limiting step in the pathway. In the liver, as heme use is increased (e.g., for incorporation into CYP), there is a reduction in a postulated hepatic regulatory free heme pool, the transcription of *ALAS1* is initiated, and ALAS1 activity increases. Conversely, when the requirement for heme drops, ALAS1 is repressed, leading to a reduction in porphyrin synthesis. Regulation in the erythropoietic system is somewhat different. Control is exercised through the binding of iron regulatory proteins to an iron response element in the 5′ region of the *ALAS2* mRNA. The extent of downregulation or upregulation of translation is controlled by the availability of iron.

The structure of the biochemical intermediates of heme biosynthesis as well as of the heme catabolic products biliverdin and bilirubin is shown in E-Figure 210-1. After ALAS-mediated synthesis, ALA is converted into porphobilinogen (PBG), which has a monopyrrolic ring structure. These two compounds, ALA and PBG, are classified as porphyrin precursors. Four PBG molecules are then combined to form the linear tetrapyrrole hydroxymethylbilane, which is then enzymatically cyclized by the enzyme uroporphyrinogen-III synthase, resulting in the tetrapyrrolic macrocycle uroporphyrinogen III. This is the first of a series of porphyrinogens. Spontaneous cyclization is possible but produces the series I isomer, which is not physiologic and is not further metabolized. Sequential modification of the porphyrinogen side chains results in the production of a sequence of porphyrinogens and their oxidized counterparts, the porphyrins. In the final step, iron is incorporated into the macrocycle, resulting in the functional heme molecule. The distinction between porphyrin precursors and porphyrins is important in diagnosis and in predicting the clinical presentation of each form of porphyria. The enzymes ALAS, coproporphyrinogen oxidase, protoporphyrinogen oxidase, and ferrochelatase are all mitochondrial, whereas the remaining enzymes are cytosolic. Heme synthesis therefore begins and ends in the mitochondrion, with intermediate metabolism occurring in the cytoplasm.

The porphyrin precursors and the initial porphyrins in the pathway are water soluble, circulate freely in the plasma, and are largely excreted in urine. The later porphyrins are hydrophobic, may be protein bound in the plasma, and undergo biliary excretion, eventually being excreted in the stool. The pattern of accumulation and excretion of precursors and porphyrins is exploited for the biochemical diagnosis of porphyrias and ultimately underlies the varying presentations of the acute and nonacute porphyrias. The acute attack is always associated with elevations in the precursors, and the acute porphyrias are therefore those in which such an accumulation occurs. Porphyrins are photosensitive molecules, and those forms of porphyria in which large amounts of porphyrin accumulate in plasma and skin have photosensitive skin disease as their major clinical presentation. In the nonacute porphyrias, the levels of precursors remain unchanged, accounting for the lack of acute attacks. Because porphyrins are typically elevated, they are manifested with skin disease alone. Two forms of porphyria, HCP and VP, may demonstrate both porphyrin elevation and a propensity to periodic elevation in the precursors; these porphyrias are therefore characterized by both skin disease and the risk of an acute attack.

Etiology

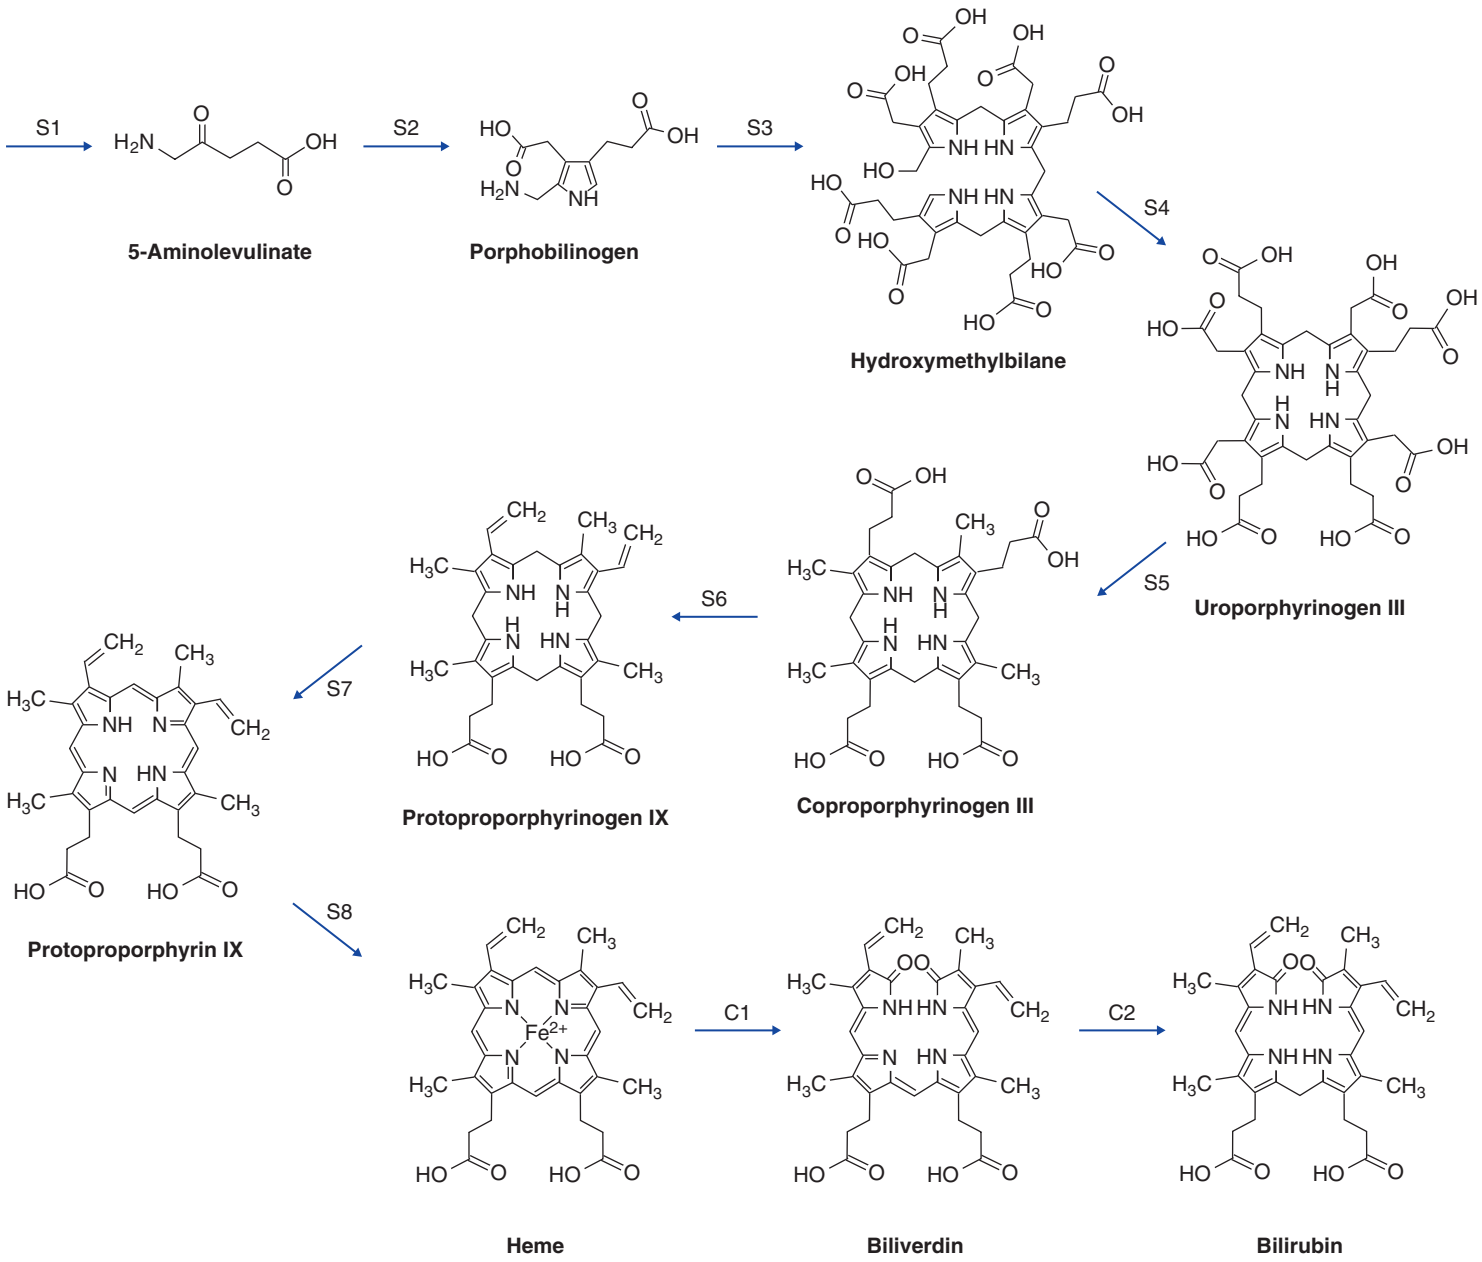
Acute Porphyrias

Acute Intermittent Porphyria

AIP is inherited as an autosomal dominant disorder. Because the enzyme block is early in the pathway, elevation of the precursors is characteristic and leads to a potential for development of the acute attack but not skin disease. Although an excess of nonphysiologic series I porphyrin isomers is typically observed in urine, this results from spontaneous cyclization of accumulated PBG, particularly in the bladder. Rare cases of homozygous AIP have been described.

Variegate Porphyria

VP is inherited as an autosomal dominant disorder. The *PPOX* gene is carried on chromosome 1. The number of known mutations approaches 200. Penetrance is estimated at approximately 37%. VP is associated with elevations in porphyrins, leading to photosensitivity, and also with acute attacks, during which phase of the illness the levels of precursors become markedly elevated. This has been ascribed to an allosteric inhibition of hydroxymethylbilane synthase by coproporphyrinogen and protoporphyrinogen, which accumulate in VP. Occasional cases of homozygous VP have been described. Such cases are either homozygous for mutations associated with some residual enzymatic activity or are compound heterozygotes, in which a mutation on one allele that results in complete loss of catalytic activity is accompanied on the other by a mutation associated with some residual catalytic activity. The homozygous state for mutations associated with complete loss of enzymatic activity is lethal.



E-FIGURE 210-1. Heme biosynthesis and catabolism. S1-S3. Synthesis of the porphyrin precursors and the first tetrapyrrole. S1. 5-Aminolevulinate is synthesized from glycine and succinyl coenzyme A, catalyzed by the mitochondrial enzyme ALA synthase. S2. Two molecules of 5-aminolevulinate condense to form a cyclic pyrrole, porphobilinogen, catalyzed by the cytosolic enzyme ALA dehydratase. S3. Four molecules of porphobilinogen are combined to form an open tetrapyrrole, hydroxymethylbilane, catalyzed by the cytosolic enzyme hydroxymethylbilane synthase. **S4-S7. Sequential modification of tetrapyrrolic porphyrinogens, porphyrins, and heme.** S4. The cytosolic enzyme uroporphyrinogen-III synthase catalyzes ring closure and brings about a specific isomerization, forming a closed macrocycle. This is uroporphyrinogen III. In the absence of the enzyme, spontaneous cyclization occurs, giving rise to uroporphyrinogen I. This nonphysiologic isomer is not available for further enzymatic conversion. S5. Uroporphyrinogen III undergoes four sequential decarboxylation reactions all catalyzed by the cytosolic enzyme uroporphyrinogen decarboxylase, producing sequentially heptacarboxylic porphyrinogen, hexacarboxylic porphyrinogen, pentacarboxylic porphyrinogen (not shown), and coproporphyrinogen. S6. Coproporphyrinogen III re-enters the mitochondrion and is oxidized by coproporphyrinogen oxidase to protoporphyrinogen IX. S7. Protoporphyrinogen IX is oxidized to protoporphyrin IX by the mitochondrial enzyme protoporphyrinogen oxidase. S8. Elemental iron is inserted into the macrocycle by the mitochondrial enzyme ferrochelatase, forming heme. **Heme catabolism.** C1. Catalyzed by heme oxygenase, the tetrapyrrolic macrocycle is opened, releasing iron and carbon monoxide and forming biliverdin. C2. A reduction step catalyzed by biliverdin reductase results in bilirubin, which is bound to albumin and other plasma proteins and excreted.

Hereditary Coproporphyria

HCP is an autosomal dominant disorder. The *CPOX* gene is carried on chromosome 7, and more than 50 disease-associated mutations have been described. Both acute attacks and skin disease are encountered; the mechanism for the acute attack is similar to that of VP, with hydroxymethylbilane synthase being allosterically inhibited by accumulated coproporphyrinogen. Rare cases of homozygous HCP have been described.

ALA Dehydratase Porphyria

This is a rare autosomal recessive disorder, described in fewer than 10 cases. The *ALAD* gene is carried on chromosome 9.

Nonacute Porphyrias

Porphyria Cutanea Tarda

This disorder results from reduced activity of the enzyme uroporphyrinogen decarboxylase (UROD). PCT is unique among the porphyrias in that it is in most cases not inherited. Approximately 75% of patients present with sporadic PCT. In these cases, the *UROD* gene is normal, but patients will demonstrate a reduction in UROD activity. This is due to a chemically mediated inhibition of the enzyme. The inhibitor has been identified as uroporphomethene, an aberrant oxidative product of the normal substrate of the enzyme uroporphyrinogen. Sporadic PCT has a number of specific associations. First, nearly all cases are associated with some degree of hepatic iron loading. It is thought that the iron functions as an oxidant, facilitating the formation of the uroporphomethene inhibitor. Second, many cases will show evidence of liver dysfunction, commonly due to alcohol or hepatitis C viral infection. A number of other miscellaneous factors may also precipitate PCT, including HIV infection, estrogen exposure, renal failure, lymphoma, systemic lupus erythematosus, and toxins such as hexachlorobenzene. The relationship of viral infection and liver disease to PCT predisposition is not understood. It has been suggested that common factors may be downregulation of hepcidin, leading to iron overload, and increased oxidative stress, with these two factors potentiating the inhibitory mechanism.[2] An association with diabetes has also become evident. Reversal of the UROD inhibition results in biochemical and clinical remission.

In some cases, iron loading has been shown to relate directly to the inheritance of mutations in genes responsible for iron regulation. For example, the C282Y mutation in the *HFE* gene commonly found in white patients with hereditary hemochromatosis (Chapter 212) is over-represented in PCT. In other cases, the reason for the iron loading is less clear.

Approximately 25% of cases of PCT are classified as familial PCT. In these patients, an inherited mutation in a *UROD* allele can be shown. The resulting 50% reduction in UROD activity is not in itself sufficient to precipitate clinical expression. When disease does become clinically manifested, these patients commonly show evidence of the same precipitating factors described in sporadic PCT, but they may present at a younger age. Disease therefore results from a combination of an inherited mutation and environmental factors that result in inhibition of the remaining functional enzyme.

Rare cases of homozygous PCT have been described. These are known as hepatoerythropoietic porphyria and are manifested with severe photomutilation resembling that seen in CEP.

Erythropoietic Protoporphyria

EPP is inherited in a complex fashion. The *FECH* gene is carried on chromosome 18, and more than 100 disease-associated mutations have been reported. Molecular analysis demonstrates the presence of an inherited mutation on one allele resulting in reduced enzymatic activity. However, this is insufficient in its own right to result in clinical symptoms. A small proportion will be found to be homozygous, resulting in sufficiently reduced ferrochelatase activity for the disease to become clinically manifested. Approximately 94%, however, can be shown to have coinherited a *FECH* polymorphism, prevalent in white populations, that is associated with moderately reduced ferrochelatase activity. This *FECH**IVS3-48C low-expression allele is subject to aberrant splicing and decreased stability of the transcript, resulting in low expression. The gene frequency may reach 11% in European populations. The summative effect of the family-specific mutation and low-expression allele is sufficient to reduce ferrochelatase activities to a level below approximately 35%, at which stage the clinical syndrome may develop. In the strict sense, EPP is a recessive disorder, but the high prevalence of the low-expression allele in the population means that the compound heterozygous state occurs commonly in families carrying an EPP mutation. Thus, the prevalence is much higher than would typically be expected of an autosomal recessive disorder; its inheritance has been described as pseudodominant. A recent study in North America of 155 unrelated patients reported that 136 carried the combination of a loss-of-function *FECH* mutation and the low-expression allele, whereas only three carried two loss-of-function mutations. The remaining 15 patients were shown to have XLPP.[3]

X-Linked Protoporphyria

This is the most recent form of porphyria to be identified. The clinical presentation is nearly identical to that of EPP, and its existence as an independent entity was not suspected until a subgroup of families with EPP were found not to carry ferrochelatase mutations. XLPP is associated with a number of mutations occurring in a sharply restricted region at the C terminus of the *ALAS2* gene. These mutations appear to modify an important control region leading to stabilization of the mRNA transcript or, possibly, enhanced access of succinyl coenzyme A to ALAS, either of which will result in abnormally elevated ALAS2 activity. These are therefore gain-of-function mutations that result in an increased flux of porphyrins through the erythroid heme biosynthetic pathway. Both ferrochelatase and iron availability become rate limiting, such that large amounts of protoporphyrin cannot be further metabolized to heme but are diverted to the plasma. Because the pathophysiologic mechanism for EPP is also dependent on the overproduction of protoporphyrin, the two disorders are nearly identical clinically. The *ALAS2* gene is carried on the X chromosome, making XLPP an X-linked disorder. Loss-of-function mutations in the *ALAS2* gene are responsible for X-linked sideroblastic anemia (Chapter 159), a condition unrelated to XLPP, that is associated with gain-of-function mutations. Erythrocyte protoporphyrin levels tend to be higher in patients with XLPP than in those with EPP, with a higher proportion being zinc chelated. Penetrance appears to be near 100%, and liver complications are more prevalent. Transmission is as expected of an X-linked disorder, one manifestation of which is the absence of father to son transmission.

Somatic Mutations

Very rarely, non-germline tissue-specific mutations may result in manifest porphyria. Cases of CEP, EPP, and VP have been described in neoplastic and paraneoplastic settings, such as myelodysplasia, myeloproliferative disorders, and hepatocellular carcinoma.

Pathogenesis

Photosensitivity

In those porphyrias associated with skin disease, porphyrins are found in high concentrations in plasma, skin, and blister fluid. Porphyrins are fluorescent. Stimulation by light results in an excitation of the porphyrin molecules, the promotion of electrons to a higher energy state, and the production of singlet oxygen. Relaxation to the ground state is accompanied by loss of energy manifesting as a radiation of red light. In the skin, this energy may be transferred to biologic molecules, resulting in oxidation of membrane lipids, polypeptides, and nucleic acids, thus accounting for the skin disease. The most potent wavelengths for porphyrin excitation lie within the ultraviolet spectrum, in the Soret band between 400 and 410 nm. Four additional absorption bands are present in the range of 500 to 700 nm; thus even visible light, against which most sunscreens are ineffective, is harmful to the skin in subjects with a cutaneous porphyria.

Pathologic examination will reveal epidermal bullae, duplication of basement membranes, and deposition of hyaline material, which appears to be associated with fibrin, immunoglobulins, and complement in and around the blood vessels of the dermis, suggesting that these vessels may be the principal target for light-induced injury.

Acute Attack

Elevated concentrations of the heme precursors ALA and PBG are always present in patients during the acute attack, and remission is commonly accompanied by a reduction in these concentrations. A causal role for either or both of these molecules has therefore long been suspected but never unequivocally proven. ALA is structurally similar to known neurotransmitters such as glutamine and γ-aminobutyric acid. Given the central role of nervous system dysfunction in the acute attack, it is suspected that ALA may be directly involved. Alternatively, it may serve as a proxy marker for some other as yet unidentified neurotoxin. An earlier contrasting hypothesis, that the neuropathy associated with an acute attack is mediated by intraneuronal heme deficiency, appears less likely because recent clinical experience has shown that liver transplantation cures AIP and VP and has induced acute

attacks of porphyria in previously nonporphyric recipients who received an explanted porphyric liver as part of a domino transplant.

On histologic examination, nerve damage is characterized by axonal loss, although some degree of segmental demyelination may be present. There may be a reduction in intradermal nerve fiber density on skin biopsy. Skeletal muscle may show neurogenic atrophy. Nerve conduction studies, although not pathognomonic, tend to show a fairly characteristic pattern suggesting axonal neuropathy with relatively little evidence of demyelination. Upper limbs may be affected more than the lower limbs. Sensory nerves may be variably affected; electromyography initially shows a pattern of denervation, with widespread fibrillation, later replaced by a pattern of reinnervation marked by polyphasic motor unit potentials with increased amplitude and duration.

Induction of Porphyria

The block in porphyrin synthesis with consequent heme deficiency that characterizes all forms of porphyria does not appear to result in any direct clinical adverse effect. Although patients with CEP, EPP, and XLPP may be mildly anemic, this is in part secondary to hemolysis in CEP and iron deficiency in XLPP. In the acute porphyrias, hemoproteins such as CYP and tryptophan pyrrolase will reveal evidence of heme desaturation, again without obvious clinical consequences. The principal effect of the heme deficiency is the derepression of ALAS1, thus substantially increasing the flux of porphyrins through the pathway, accentuating the rate-limiting effect of the enzyme block and resulting in a significant overproduction of porphyrins and, possibly, precursors, which then result in the characteristic clinical syndromes. This mechanism is key to the understanding of the porphyrias.

The development of the acute attack is strongly associated with hyperinduction of ALAS1, typically by increased gene transcription in response to a reduction in free heme concentrations. Whereas the resultant increased activity of the heme biosynthetic pathway leads to an appropriate increase in heme levels in normal individuals, after which ALAS1 is suppressed, in patients with an acute porphyria, the defective enzyme is rate limiting; adequate heme concentrations are not reached, thereby leaving the pathway in a state of hyperinduction, and ALA and PBG accumulate in quantities sufficient to induce clinical symptoms. The most common precipitant of the acute attack is exposure to a number of drugs that share the ability to induce ALAS1. Such drugs are termed porphyrogenic.

This synthesis of CYP apoenzyme and heme is tightly correlated. The most powerfully porphyrogenic compounds include multifunctional inducers that induce multiple hepatic microsomal enzymes, those that induce the CYP3A and CYP2C9 subclasses, and those that are associated with irreversible mechanism-based inhibition of CYP. Such inhibition results in destruction of the enzyme, release of heme (which is then catabolized by heme oxygenase, leading to a reduction in the free heme pool), and consequently ALAS1 induction. These processes are mediated by nuclear receptors, particularly the constitutively active receptor and the pregnane xenobiotic receptor. Now that these mechanisms are understood, it is possible with high accuracy to predict which drugs are most likely to be porphyrogenic.

Calorie deprivation is known to induce porphyrin synthesis and even the acute attack, whereas glucose administration has a suppressive effect. This so-called glucose effect has been shown to be mediated by the transcriptional coactivator PGC-1α, which is induced when the liver shifts from the use of glucose as an energy substrate to β-fatty acid oxidation, activating the ALAS1 promoter and increasing heme synthesis.

Patients carrying a gene for an acute porphyria do not respond uniformly or predictably to drug exposure. Some patients will not respond at all, others may show some biochemical evidence of increased porphyrin production, and others will develop severe clinical symptoms. The reason for this variation in response or for the observation that acute attacks are extremely rare before puberty is not well understood. It is thought that the variability may result from the inheritance of polymorphisms in other genes responsible for drug metabolism, including cytochrome P-450, and possibly by metabolome-level variations, in other words, a complex interaction of genetic, biochemical, and hormonal interactions at a particular point in time. Similarly, the reason for the incomplete penetrance of many of the porphyrias is not yet understood; some 60% of patients carrying a gene for VP, for instance, fail to manifest biochemical or clinical evidence of disturbed porphyrin synthesis.

Women with AIP may show a pattern of regularly recurring attacks associated with the luteal phase of the menstrual cycle, although this is fortunately uncommon. It appears that endogenous hormone production is sufficient to stimulate ALAS and to cause an acute attack. Acute attacks have also been ascribed to calorie deprivation. Both stress and infection have been listed as possible inducers of the acute attack, although the evidence for this is weak.

CLINICAL MANIFESTATIONS

Patients with CEP, EPP, and the homozygous forms of the acute porphyrias usually present in childhood. This is an extremely rare occurrence in the three dominantly inherited acute porphyrias, in which both biochemical and clinical evidence of disease expression is typically delayed until after puberty. Although adult patients may present at any age, the first presentation is typically in the third decade.

Acute Porphyrias

The cardinal manifestation of the acute porphyrias is the acute attack. This metabolic crisis is characteristically manifested as severe, generalized abdominal pain, felt throughout the abdomen and sometimes in the lower back, buttocks, and thighs. The pain is severe and requires opioids for relief. It is not associated with peritonitis, and abdominal examination is typically unremarkable. There is autonomic overactivity manifested as hypertension, tachycardia, and gastrointestinal dysfunction, typically vomiting, constipation, and occasionally ileus.

Severe acute attacks are associated with a number of other features. Hyponatremia is common and when severe may lead to seizures and altered consciousness, particularly when hypotonic intravenous fluids are administered. Although often ascribed to the syndrome of inappropriate antidiuretic hormone (Chapter 116), the pattern of electrolyte excretion frequently suggests renal salt wasting, sometimes associated with marked urinary losses of potassium, calcium, and magnesium.

A severe, untreated acute attack may be complicated by a rapid-onset motor neuropathy, usually developing 24 hours or more after the onset of the abdominal pain. Very occasionally, a patient will present with neuropathy with a history of minimal or no abdominal pain; this may lead to a delay in suspecting porphyria as the cause. The neuropathy is typically symmetrical and may affect proximal muscles predominantly. Although motor signs predominate, there may be some sensory involvement in a central, so-called bathing suit distribution. The neuropathy may result in quadriparesis. Weakness of the respiratory muscles is common and may result in respiratory failure requiring ventilation. Once established, motor neuropathy typically requires months for recovery. Occasional patients may develop a prominent small-fiber neuropathy after attacks that is manifested with a generalized dysesthesia and hyperalgesia.

Cranial nerve or cerebellar involvement is occasionally noted, with facial and vagus nerve involvement in particular, although involvement of the trigeminal, hypoglossal, accessory, and oculomotor nerves has also been observed. The most extreme cases may develop the posterior reversible encephalopathy syndrome with radiologic evidence of reversible cerebral ischemia. On occasion, autonomic overactivity is so severe as to resemble a pheochromocytoma crisis (Chapter 228).

There is a widespread and unjustified misperception that psychiatric manifestations are a prominent part of the symptoms of the acute porphyrias. Claims that historical figures such as King George III of England and his relatives and Vincent van Gogh had porphyria all perpetuate the myth that AIP is associated with chronic insanity but are not supported by convincing evidence.[4] During the acute phase, the acute attack frequently is manifested with anxiety and sometimes with a short-lived psychotic episode, which reverses completely with remission of the attack. A statistical association with chronic anxiety and depression in patients with AIP has been shown. There is no association with chronic psychosis or a need for institutionalization.

The acute attack is more common in females than in males, is extremely rare before puberty, and becomes uncommon from the sixth decade onward. Pregnancy may precipitate acute attacks, but this is infrequent. Large studies suggest that there may be a slight increase in risk of perinatal death in women with the acute porphyrias; in a study of 136 deliveries, this did not reach statistical significance, but significance was shown when restricted to first pregnancies alone.[5]

The acute attack has become less common in recent decades as a result of earlier diagnosis and careful attention to its prevention. It is uncommon for a patient who has had an attack to suffer a recurrence once preventive measures have been instituted. Patients repeatedly exposed to porphyrogenic medication, including recreational drugs, may suffer recurrent acute attacks. A very small number of patients may show a course characterized by recurrent acute attacks of unknown etiology; this is particularly a feature of some young women with AIP. In some of these women, there is a clear relationship

to the menstrual cycle. In the remainder, such an association is not obvious, and a vicious circle of recurrent attacks and hospitalizations becomes established. Such patients become severely debilitated and cachectic, show evidence of accumulating neuronal damage, experience a poor quality of life, and may ultimately die.

Other Manifestations

Patients with AIP are prone to develop chronic hypertension and renal dysfunction, probably due to chronic activation of the sympathetic nervous system. A strong and unexplained association between both AIP and VP and noncirrhotic hepatocellular carcinoma (Chapter 196) has been reported from several centers. Swedish patients with AIP older than 50 years have been shown to be at 86-fold increased risk of hepatocellular carcinoma.[6] The risk is significantly higher in women. There is evidence of an increased risk in VP as well, but surprisingly, such an association has not been seen in South Africa despite the frequency of VP in that population.

Homozygous Acute Porphyrias

Homozygous AIP is a serious disorder that may be associated with severe neurodevelopmental abnormalities, including porencephaly, psychomotor and developmental retardation, ataxia, epilepsy, cataracts, and a number of other neurologic manifestations. It is usually fatal in childhood. Homozygous VP is associated with skeletal dysmorphism, severe skin disease, nystagmus, seizures, a sensory neuropathy, and cognitive impairment. An association with cerebral demyelination, detectable on magnetic resonance imaging, has recently been described. Despite the severity of the symptoms, there is no appreciable early mortality, and for reasons as yet unknown, acute attacks are not a feature of homozygous VP. Homozygous HCP takes two forms: the first resembles homozygous VP with small stature, photosensitivity, psychomotor retardation, and neurologic defects; the second is manifested at birth with hemolytic anemia and severe jaundice. This variety is associated with specific mutations in the *CPOX* gene that specifically block an intermediate stage in the oxidation of coproporphyrinogen and protoporphyrinogen, resulting in the accumulation of a harderoporphyrinogen intermediate, and is known as harderoporphyria.

ALA Dehydratase Deficiency Porphyria

This is an extremely rare recessive disorder that may be manifested in either childhood or adulthood, depending on the severity of the phenotype, typically with chronic neuropathy, other neurologic symptoms, and acute attacks.

Vesiculo-erosive Skin Disease

The characteristic skin disease of VP, HCP, PCT, and CEP is described as vesiculo-erosive. Patients present with blistering and erosions, typically in response to minor skin trauma, in sun-exposed areas, particularly the dorsal surface of the hands and forearms, the face, and, if sun exposed, the nape of the neck and the dorsal surfaces of the feet. There is no immediate photosensitivity, and the changes develop insidiously. Therefore, patients frequently fail to make the association between sun exposure and skin damage. The lesions heal slowly, leaving a residuum of scarring and small, localized areas of hypopigmentation or hyperpigmentation (Fig. 210-2). Milia may be present, particularly on the dorsal surfaces of the hands and in the digital clefts.

It is unusual for the skin disease of VP and HCP to develop beyond this. Patients with PCT, however, may show marked facial hypertrichosis, hyperpigmentation, and sometimes alopecia. They may also develop thickening of the skin of the fingers and hands; these pseudosclerodermoid changes may occasionally lead to a misdiagnosis of localized scleroderma.

The most severe skin disease is characterized by marked photomutilation, including loss of skin appendages such as the nose, ears, and lips. This is seen in CEP and in hepatoerythropoietic porphyria. The skin disease of homozygous VP is marked by an accentuation of the features characteristic of heterozygous VP, alopecia and resorption of digits, which may be due to photo-osteolysis (Fig. 210-3) or, alternatively, may represent part of the skeletal dysmorphism characteristic of the disorder.

Porphyria Cutanea Tarda

PCT typically presents in middle-aged and older subjects who develop characteristic skin lesions in sun-exposed areas. Acute attacks are not a feature. Given the strong association with iron loading and liver disease, clinical and biochemical assessment commonly reveals evidence of increased iron storage, liver dysfunction, alcohol abuse, or renal dysfunction. In the less common setting of HIV infection, systemic lupus erythematosus, or lymphoma, clinical evidence for these disorders will be present.

FIGURE 210-2. The hands in variegate porphyria. The characteristic lesions are bullae, shallow erosions that develop scabs and heal slowly, leaving areas of hypopigmentation and hyperpigmentation. The skin disease of porphyria cutanea tarda and hereditary coproporphyria is similar.

FIGURE 210-3. The hands of a patient with a homozygous form of variegate porphyria. In addition to the characteristic vesiculo-erosive skin lesions, there is marked brachydactyly, representing both photo-osteolysis and a skeletal developmental defect.

Congenital Erythropoietic Porphyria

This rare autosomal recessive disorder is associated with a spectrum of disease severity. Severely afflicted patients demonstrate photomutilation, with scarring, loss of skin appendages (such as ears, nose, lips, fingernails, and digits), ulcerative keratitis, and corneal scarring. A form of immediate photosensitivity after sunlight exposure and characteristic pink erythematous facial papules have been described.[7] Patients may show erythrodontia, osteodystrophy, hypercellular bone marrow, hemolytic anemia, and splenomegaly. Other patients are more mildly affected and may present later in life. The skin damage deteriorates progressively with increasing age. Impact on quality of life and psychosocial consequences may be severe. Prenatal cases presenting in utero with severe anemia associated with hydrops fetalis have been described. There is a variable genotype-phenotype correlation. Although some mutations tend to be associated with more severe disease, the severity may vary between patients even though they carry the same mutation. The most predictive features of a severe course are early age at onset and the presence of hematologic complications, particularly severe anemia and

FIGURE 210-4. The hands in erythropoietic protoporphyria. There is thickening and grooving of the skin over the knuckles.

thrombocytopenia. One study has suggested that *ALAS2* acts as a modifier gene, with severity of phenotype being modulated by mutations in that gene.[8]

Skin Disease Associated with Immediate Photosensitivity

Erythropoietic Protoporphyria

Patients with EPP and XLPP do not manifest the typical vesiculo-erosive pattern of skin disease described before but develop a characteristic pattern of immediate photosensitivity. Patients will report that after a period of sun exposure, they develop severe discomfort and pain in sun-exposed areas. This may be associated with erythema and edema. The discomfort may take 24 to 48 hours to settle after cessation of sun exposure. The onset of the illness is often in childhood but diagnosis is frequently delayed, and the reason for a child's reluctance to remain outdoors is often not recognized immediately. Chronic skin changes are minimal and are usually limited to the development of a waxy thickening and grooving of the skin, typically over the bridge of the nose and over the knuckles (Fig. 210-4). A mild microcytic hypochromic anemia may be present. A subset of patients develop a condition known as seasonal palmar keratoderma; it has been shown that these patients carry homozygous or compound heterozygous ferrochelatase mutations.

Approximately 10% of patients with EPP will develop hepatobiliary disease secondary to the massive accumulation of protoporphyrin within the hepatocytes and biliary porphyrin excretion, typically with cholelithiasis secondary to elevated biliary porphyrin concentrations. Approximately 2% may present with severe and potentially life-threatening liver disease, including cirrhosis and liver failure.

X-Linked Protoporphyria

XLPP and EPP cannot for practical purposes be distinguished clinically. XLPP is likely to have a higher penetrance as well as a typical X-linked pattern of inheritance. Patients are more prone to liver disease than are those with EPP. Some patients will report a correlation between iron deficiency and severity of symptoms.

Other Settings

A transient immediate acute photosensitivity is occasionally observed in patients with VP as they emerge from an acute attack. This is sometimes associated with acute loss of fingernails. Some patients with CEP may manifest immediate photosensitivity in addition to the characteristic vesiculo-erosive skin response. Immediate photosensitivity is observed in some patients in whom the synthetic metalloporphyrin tin protoporphyrin was administered as a heme oxygenase inhibitor to prolong remission with repeated acute attacks of AIP. It is also noted in patients treated with ALA or synthetic porphyrin analogues as part of photodynamic therapy for cancer.

DIAGNOSIS

An accurate diagnosis is essential in the management of porphyria. Although the pattern of symptoms and skin manifestations may suggest the diagnosis, a clinical diagnosis alone is notably inaccurate, given the varying and often nonspecific manifestations of the disorders as well as the inexperience of most physicians in dealing with them. A failure to diagnose the porphyrias may have serious consequences, with unnecessarily impaired quality of life and, in some, the potential for a possibly fatal acute attack. Conversely, it is not unusual for patients, typically with a history of frequent, unexplained abdominal pain, to be erroneously labeled as having an acute porphyria.

Biochemical Diagnosis

Biochemical analysis is central to the diagnosis and evaluation of the porphyrias. For AIP, hydroxymethylbilane synthase assays have been widely used but are now discouraged owing to their inaccuracy. Recent reports have highlighted the gain in diagnostic accuracy that results from restricting diagnostic testing for porphyria to a small number of national reference laboratories that analyze sufficient cases to develop expertise and that cooperate in a quality enhancement network.

The pattern of porphyrin accumulation in urine, stool, plasma, and erythrocytes that characterizes a specific porphyria forms the basis of diagnosis. In practice, this is complicated by the varying water solubility of the precursors and porphyrins, leading to differential patterns of accumulation in urine, stool, and plasma. It must be stressed that examination of urine alone may lead to both misdiagnosis and misclassification of the porphyria. Given the differential excretion of porphyrins, it is essential that testing include urine, stool, and plasma. Where an erythropoietic porphyria is suspected, an erythrocyte porphyrin analysis must be performed as well.

Porphyrin analysis is typically performed with a high-performance liquid chromatographic separation technique with fluorometric detection of the porphyrins. The series I and III isomers can be distinguished and the concentration of each individual porphyrin species quantitated by reference to standard specimens. Differentiation of isomers is particularly important in the identification of HCP. The erythropoietic porphyrias are easily confirmed by assessing the biochemical profile of porphyrins in erythrocytes.

A useful screening assessment is plasma fluorescence scanning. The fluorescence emission maximum varies between different porphyrins and with the extent of their protein binding. When it is subjected to ultraviolet light, a plasma sample will typically demonstrate an emission peak at approximately 630 nm in EPP, 625 nm in VP, and 619 nm in AIP, HCP, and PCT.

The acute attack is always associated with an elevation of the porphyrin precursors ALA and PBG. The first step in the assessment of the confirmation of an acute attack is therefore to submit urine for determination of these levels, specifically PBG. In the appropriate clinical setting, elevated levels are highly confirmatory; and conversely, when these are normal, the diagnosis must be reconsidered. Some laboratories are able to measure ALA and PBG in plasma, which may have a slight advantage in accuracy. For immediate use in the emergency setting, semiquantitative test kits that allow the identification of elevated urinary PBG concentrations without the use of specialized equipment have been developed. It is recommended that every emergency department have ready access to such a kit.

Genetic Testing

Given that the various porphyrias result from mutations in different genes and that within each porphyria, numerous family-specific mutations may give rise to the characteristic phenotype, molecular diagnosis is not well suited to the primary evaluation of a patient. No mutation-specific diagnostic test will exclude any form of porphyria other than the one specifically associated with that gene and that mutation. It is for this reason that biochemical analysis is recommended as the first step. Furthermore, whereas biochemical testing, by quantitating precursor and porphyrin levels, provides information on the degree of activity of the porphyria at a particular moment, molecular techniques do not. Once a biochemical diagnosis of porphyria has been made, the underlying mutation should be identified. Screening of family members for this mutation will then determine carrier status. This is particularly important in the case of the acute porphyrias, such that as-yet unaffected family members can practice risk avoidance, particularly in terms of their exposure to potentially porphyrogenic medication. Where there is a very high prevalence as a result of a founder effect, screening for that mutation may prove useful in preliminary assessment. This is the case in South Africa, where a single *PPOX* mutation, the R59W mutation, accounts for more than 95% of all cases of VP.

Differential Diagnosis

The differential diagnosis of an acute porphyria will include any cause of severe abdominal pain, including surgical emergencies. Forty percent of

children with hereditary tyrosinemia type I may develop a syndrome closely resembling the acute attack; this is mediated by the accumulation of succinylacetone, which is a potent inhibitor of 5-aminolevulinate dehydratase.

When patients present with a motor neuropathy or quadriparesis, other causes of neuropathy may be considered. The initial diagnosis in such cases is often the Guillain-Barré syndrome. A careful history may reveal a history of abdominal pain (although very occasionally this is absent), and neurophysiologic testing will show a pattern of axonal necrosis rather than demyelination. A biochemical analysis for porphyria will confirm the correct diagnosis.

The differential diagnosis of a typical vesiculo-erosive porphyria is limited. Other chronic bullous diseases will require exclusion. Epidermolysis bullosa is similar but is not restricted to sun-exposed areas. A common differential is pseudoporphyria, which may be found in association with end-stage renal or liver disease, with tanning bed use, or as a class of drug-induced skin reactions, particularly in response to nonsteroidal anti-inflammatory drugs, nalidixic acid or tetracycline, sulfur-containing diuretics, systemic retinoids, cyclosporine, and dapsone. The skin manifestations closely resemble a cutaneous porphyria. Despite the clinical similarity, there is no underlying enzymatic or genetic defect, and plasma porphyrin profiles are normal.

It is not uncommon for patients with liver disease to excrete elevated amounts of coproporphyrin in the urine. This is termed coproporphyrinuria. It represents a slight diversion of coproporphyrin excretion from bile to urine, is not related to any disturbance in heme biosynthesis, and is essentially irrelevant.

TREATMENT

Rx

Given the rarity of the porphyrias, the evidence for efficacy of therapy seldom reaches grade A status. In most instances, treatment recommendations are based on experience in small case series or on expert opinion.

Acute Porphyrias

It is essential that the physician treating the acute attack of porphyria have a clear concept of the disorder, what treatment is appropriate, and when and how it should be applied. It is therefore important for patients to be referred to a physician with experience in porphyria or to be managed in close cooperation with such an expert.

Supportive therapy includes opioid analgesia in doses sufficient to relieve the abdominal pain. This is severe, and physicians with little experience in porphyria will frequently underdose and may even disbelieve the patient's complaints, being misled by the lack of physical signs in the abdomen, even though this is typical of the acute attack. Morphine and newer opioids should be selected in preference to meperidine, given its addictive potential. It is essential that all porphyrogenic drugs or other potential precipitants be stopped or corrected, and no medication may be administered to the patient unless its safety in porphyria has been checked.

Patients may require antiemetics. Although β-blockers may assist in slowing the pulse and reducing blood pressure, these are rarely sufficiently elevated to require treatment in their own right. Furthermore, they settle rapidly once specific therapy is administered.

Electrolyte balance requires careful monitoring. Hyponatremia may be a problem, and hypotonic fluids, such as glucose, should not be administered in large volumes. Although carbohydrate loading has been shown to have a suppressive effect on porphyrin synthesis, its effect is minimal in comparison with heme therapy.

Specific Therapy

Administration of exogenous heme results in negative feedback inhibition of ALAS, resulting in a rapid reduction in porphyrin synthesis. Such therapy is effective, has been confirmed in a controlled trial,[■] and is now the standard of care for the acute attack. The practical advantages have been three-fold: to shorten the period of symptoms for the patient; to shorten the course of the acute attack, allowing earlier discharge; and to prevent severe complications, such as encephalopathy and motor neuropathy. Although lyophilized hematin is effective, current practice is to administer heme arginate, a more stable compound. It is administered intravenously in a dose of 3 mg/kg daily for 4 days. The manufacturer recommends that the dose be reconstituted in 100 mL of a 0.9 % sodium chloride solution and infused into a large vein during at least 30 minutes. Some authorities suggest administration in human serum albumin as albumin has a buffering effect that may reduce the incidence of phlebitis at the site of infusion. There is also some evidence that administration in albumin may facilitate hepatic uptake. Typically, administration of heme arginate is followed within 24 hours by a reduction in symptoms, and after 72 hours the patient is usually symptom-free and may be discharged. Treatment during pregnancy has been shown to be safe.

It is essential that heme arginate be administered at an early stage of the acute attack. It will prevent but not reverse motor neuropathy. Once this has developed, the patient is committed to a lengthy period of hospitalization and rehabilitation.

Very rarely, patients present with a syndrome of severe, accelerated hypertension, tachycardia, and cerebral complications that may include coma, seizures, and the posterior reversible encephalopathy syndrome. This may resemble an uncontrolled pheochromocytoma. Administration of magnesium sulfate in association with combined α- and β-blockade is useful in controlling the autonomic overactivity while the attack is brought into remission with heme arginate. Recovery is usually complete.

Recurrent Attacks

Recurrent acute attacks are an uncommon manifestation of the acute porphyrias. A careful drug history is important in excluding exposure to porphyrogenic medication. Where a relationship between the attacks and the menstrual cycle is suspected, gonadal suppression with gonadotropin-releasing hormone agonists such as goserelin and buserelin may be attempted. In some patients, this is efficacious in aborting the pattern of recurrent attacks. In a small trial in 16 women, four responded with a complete cessation of symptoms, and 11 had some improvement. Because patients are at risk of osteoporosis after gonadal suppression, add-back hormonal therapy was attempted; estradiol and progesterone precipitated attacks in two and five of nine women, respectively.[9]

Some patients with a history of recurrent acute attacks have received prophylactic heme arginate at scheduled intervals, apparently with benefit in some. A permanent indwelling central venous catheter is often required for this. Currently, there is concern that frequent administration of heme arginate may induce heme oxygenase, leading to rapid catabolism of heme, thus initiating a vicious circle of reduction in hepatocyte free regulatory heme levels, ALAS1 induction, and increased porphyrin synthesis, promoting the development of another attack. Theoretically, this vicious circle might be ameliorated by the administration of heme oxygenase inhibitors, such as the metalloporphyrins like tin protoporphyrin, tin mesoporphyrin, and zinc mesoporphyrin. This has been attempted in a few patients and appeared to be of some short-term benefit, although it did not affect the overall outcome. Furthermore, exogenous hematin and heme arginate are iron rich, and patients receiving frequent courses of therapy may become iron overloaded. For these reasons, repetitive administration of heme arginate should be undertaken with extreme caution.

Orthotopic liver transplantation has now proved its value in the management of patients with recurrent acute attacks.[10] It is effectively curative in both AIP and VP, preventing further acute attacks. Transplantation should therefore be considered in any patient who develops a pattern of severe repetitive acute attacks, particularly when there is incomplete recovery between attacks, progressive disability, or severely impaired quality of life, and in patients for whom no causal factor amenable to removal or amelioration is identified.

Skin Disease

There is no specific therapy for vesiculo-erosive skin disease. Sun avoidance is central in management. This may require behavioral modification as well as careful attention to dress, wearing nontranslucent clothing to reduce the skin's ultraviolet exposure. Trauma to exposed areas should be minimized. Sunscreens may have a role but must prevent the transmission of both UVA and UVB wavelengths and preferably light at visible wavelengths as well. Zinc oxide is more effective than titanium dioxide. Although sunscreens containing micronized zinc oxide or titanium are translucent and cosmetically more acceptable, they reflect less light and therefore provide only partial protection. Nonmicronized pastes are more effective.

A number of photostable UVA filters are under development and may prove beneficial. Where skin disease is severe, as in CEP, consideration may be given to replacement of fluorescent lighting with other forms of illumination with lower short-wavelength light emission and the application of transparent film to windows, spectacles, and windshields to exclude the relevant wavelengths.

Established lesions should be carefully cleaned with nonastringent antiseptics. In our experience, aseptic lancing of bullae may hasten resolution. Where secondary infection is noted, topical or systemic antibiotics are indicated.

Porphyria Cutanea Tarda

PCT may be expected to remit once the precipitating factors have been removed. Therefore, alcohol use should be severely restricted. Hepatitis C, if present, should be treated. The reduction of hepatic iron stores is highly effective in the treatment of PCT. A common regimen is to carry out a 500-mL venesection (phlebotomy) fortnightly until iron parameters are in the low-normal range; this typically requires about 8 to 12 sessions. Intravenous and oral iron chelators are effective but are associated with more serious adverse effects than venesection. Patients with renal failure or conditions such as the myelodysplastic syndrome present a special problem as they are typically anemic. The drop in hemoglobin may be counteracted by administration of erythropoietin (erythropoiesis-stimulating agents), with the additional benefit

of its effect in mobilizing iron from the liver. However, in our experience, careful venesection without erythropoietin has proved safe and effective, the hemoglobin level returning to its usual set point after each session.

Chloroquine has been shown in a trial to be as effective as venesection in inducing remission in PCT, with an efficacy similar to that of venesection.[11] By disrupting lysosomal structure, it allows the release of porphyrins stored in the liver into the plasma, from which they are cleared by the kidneys. Thus, it is common to see a transient increase in plasma porphyrins and worsening of skin disease in the first few weeks of therapy. Chloroquine must be used in low doses, typically 125 mg twice weekly, because larger, daily doses may result in a severe transaminitis. Units with experience in treating PCT tend to have their own preference for chloroquine therapy or venesection. Our practice has been to combine phlebotomy with chloroquine, and this has proved extremely satisfactory. Remission of PCT, once attained, is usually maintained for many years, although re-treatment may occasionally be necessary. There is some evidence that α-tocopherol may provide additional benefit when it is prescribed in association with standard therapy for PCT.

Reports have suggested that direct treatment of hepatitis C and HIV with antiviral agents has resulted in an improvement in PCT even in the absence of venesection or chloroquine therapy. Given the deleterious effects of iron overload, however, it would appear prudent to combine such treatment with iron-lowering therapy.

Erythropoietic Protoporphyria

A reduction in sun exposure is central to the management of EPP and requires behavioral change, attention to dress, and use of broad-spectrum sunscreens. A small proportion of patients appear to respond positively to the administration of β-carotene in doses sufficiently large to induce carotenodermia; however, despite a number of trials of varying quality, efficacy has not been convincingly proved.[12] If it is effective at all, it is not known whether the benefit is due to the light-reflecting effect of the increased skin pigmentation, to its antioxidant effects, or to a combination. Narrow-band UVB phototherapy has in some cases resulted in increased phototolerance. Treatment with slow-release subcutaneous implants of afamelanotide, a synthetic melanocyte-stimulating hormone analogue, has yielded encouraging results in preliminary clinical studies.[13] Such analogues induce the synthesis of both melanin and eumelanin, which absorbs and reflects radiation over a wider light spectrum. In addition to inducing hyperpigmentation, afamelanotide also has antioxidant properties that may be of some benefit.

Claims have been made for a number of interventions in terms of their utility in reducing the acute pain of EPP, including lotions, steroids, local anesthetics, antihistamines, water immersion, and ice packs. Although individual patients may feel that they are helped by one or another, a study has not shown a consistent benefit for any single intervention.

The liver disease found in association with EPP in a small proportion of patients constitutes a serious problem. Such patients require the care of an experienced hepatologist, and there are no clear guidelines in treatment. Administration of oral sorbents such as activated charcoal and cholestyramine, which interrupt hepatic porphyrin recycling, have yielded inconsistent results. Hypertransfusion and administration of heme arginate may suppress porphyrin synthesis but are not suitable for long-term use. Severely affected patients are candidates for orthotopic liver transplantation. Given that the viscera are porphyrin laden and prone to severe light-induced necrosis, careful preparation of the patient is necessary, and surgery has to be carried out with appropriately filtered operating lights. Severe motor neuropathy has proved to be an unexpected but not unusual complication of liver transplantation in EPP. After transplantation, protoporphyrin will reaccumulate in the liver. Consideration may therefore be given to performing combined bone marrow and liver transplantation.

Congenital Erythropoietic Porphyria

Light avoidance, with protection for both skin and eye, is essential. Afamelanotide has shown benefit in a single case. Given the hemolysis and resultant jaundice, neonates with CEP may be subjected to phototherapy, which may seriously damage the skin. Some patients require chronic transfusion for anemia and may benefit from splenectomy. CEP is often a severe disease, and successful autologous stem cell transplantation will prevent further disfigurement and inevitable psychosocial consequences. There is emerging consensus that young subjects with severe CEP should be offered stem cell transplantation.[14] It should be borne in mind that the phenotype of CEP is extremely variable. Currently, stem cell transplantation is reserved for patients with a mutation known to be associated with a severe phenotype and for those presenting at a younger age or with progressive severe hemolytic anemia or thrombocytopenia because these factors are predictive of a poor outcome. This will require an expert decision.

Investigational Therapies for the Porphyrias

Intravenous administration of recombinant hydroxymethylbilane synthase to patients with AIP was studied in a small series. Although it reduced plasma ALA and PBG levels, it was ineffective in treating symptoms; this was presumably due to limited access to the hepatocyte. Gene replacement, with a variety of vectors, is under active development and has shown promise in laboratory studies, particularly for the management of CEP and AIP. Gene silencing by RNA interference directed at *ALAS1* mRNA to block ALAS1 induction in the acute porphyrias appears encouraging. Where the effect of a mutation is to reduce protein stability, interventions to improve stability may lead to improvement in enzyme concentration and activity. In CEP, laboratory studies suggest that administration of a proteosome inhibitor may improve UROS function where the enzyme deficiency is due to an unstable and rapidly degraded protein.[15]

Given the success of autologous stem cell transplantation in CEP and EPP and of liver transplantation in AIP and VP, experimental work on transplantation continues. A laboratory study suggesting that induced pluripotent stem cells are capable of correcting CEP was encouraging.[16] Hepatocyte transplantation has shown promise experimentally in the treatment of AIP and would have advantages over orthotopic liver transplantation.[17]

PREVENTION

Primary Prevention

Given that most of the porphyrias are genetically determined, there is currently no practical way in which these illnesses may be prevented. Diagnosis in utero by molecular methods for the identification of family-specific mutations is possible, and theoretically selective abortion would prevent transmission of the disease. In practice, however, this is not indicated. Only in a tiny minority of patients are the common acute porphyrias of sufficient severity to seriously impair the quality of the patient's life. Penetrance is incomplete, and even when the disease is clinically expressed, symptoms are not expected to develop until the end of the second decade. Termination of pregnancy is therefore inappropriate. Although patients with EPP may experience an impaired quality of life, few would argue that this is of a severity that would justify termination. The only situation in which it might be justified could be in CEP and in the homozygous acute porphyrias. However, these being recessive disorders, the incidence is extremely low, and these disorders are for practical purposes unforeseeable. The exception may be in cases of known consanguinity, in which the possibility of recessive inheritance is increased. Given that both familial and sporadic PCT tend to occur in association with disorders such as iron loading, hepatitis C, and alcoholic liver disease, treatment or avoidance of these conditions would be expected to reduce incidence.

Secondary Prevention

The most important aspect of prevention is anticipating and preventing or ameliorating the potential clinical effects and complications in the patient with known porphyria. In the acute porphyrias, interventions are directed at preventing the onset of the acute attacks. It is essential that the patient avoid exposure to any drug that might potentially be porphyrogenic. It is thus necessary that all gene carriers and the health professionals who care for them understand the absolute importance of consulting a drug safety database before taking or prescribing any medicinal agent. We recommend use of the European web-based database The Drug Database for Porphyria (*http://www.drugs-porphyria.org*) maintained by the Norwegian Porphyria Centre. Traditional drug safety lists are incomplete because the information on which they are based is typically obtained from clinical experience in porphyria and animal or tissue culture experiments and may therefore not be available for many drugs, particularly those that have come into use more recently. Second, the information derived from these sources is frequently poorly generalizable to the porphyric population at large, given the unreliability of some of the sources from which the information is derived, the extreme variability in response between individual patients, and the major differences in drug metabolism between species. The Drug Database for Porphyria, by contrast, is based on the prediction of porphyrogenicity on the grounds of metabolism and information is therefore available even before clinical experience has accumulated; preliminary analysis suggests that the predictions are highly reliable, and where a drug has been predicted to be safe, there have not as yet been any instances of clinical use resulting in an adverse effect.[18] The patient should wear a medical bracelet. Given the association of acute attacks with calorie deprivation, subjects with the acute porphyrias should avoid periods of low calorie intake.

Children with cutaneous porphyrias or those known to be a gene carrier for one of the adult-onset porphyrias with photocutaneous sensitivity, such as VP, should be encouraged to develop healthy habits of sun avoidance and

sun protection before the onset of symptoms. Patients with established disease need to modify their behaviors and attend to their dress to limit sun exposure. In cases of extreme photosensitivity, filtering of natural and artificial light may be beneficial.

Patients with PCT should be screened for hemochromatosis-associated mutations. These may be of prognostic significance in family members in detecting and therefore treating hemochromatosis early.

PROGNOSIS

With few exceptions, the prognosis of all the porphyrias is good. PCT is treatable, and remission is expected once the precipitating factors, including iron overload, have been corrected. Patients with the acute porphyrias may expect a normal lifespan, provided the appropriate precautions are taken to prevent the acute attack or, should such an attack develop, it is appropriately treated at an early stage. The skin disease of porphyria is not life-threatening.

The prognosis is poor in those patients who present with a pattern of frequent, repeated attacks and do not respond to interventions intended to break the cycle. The course is frequently one of slow deterioration during several years and may ultimately be fatal. Such patients should be assessed for orthotopic liver transplantation. Patients with CEP are subject to severe photomutilation with serious psychosocial consequences and should be assessed for allogeneic stem cell transplantation. Patients with homozygous AIP are prone to severe developmental abnormalities and may die in childhood. By contrast, there appears to be no early mortality in patients with homozygous VP, although the photomutilation and neurodevelopmental effects will have psychosocial and educational consequences.

The prognosis for the individual acute attack is excellent, provided the condition is recognized, confirmed, and appropriately treated at an early stage before neuropathy has developed. Where the patient has developed quadriparesis, the prognosis for ultimate recovery is good with excellent supportive care, including assisted ventilation. Recovery to the point of independence and nearly full power may require a year of support and rehabilitation and is not always complete. Experience has shown that it is important to avoid further acute attacks during the period of convalescence and to treat them immediately and effectively should they develop to prevent a relapse in neuropathy.

REVIEW QUESTIONS

1. Which is the most common form of acute hepatic porphyria?

A. Acute intermittent porphyria
B. ALA dehydratase deficiency
C. Hereditary coproporphyria
D. Porphyria cutanea tarda
E. Variegate porphyria

Answer: A All forms of acute porphyria are hepatic porphyrias, and acute intermittent porphyria is the most common everywhere except in the South African white population, in which variegate porphyria is locally prevalent as a result of a founder effect. Hereditary coproporphyria is considerably less common than both these forms of porphyria, and ALA dehydratase porphyria is excessively rare, having been described in fewer than 10 patients. Although porphyria cutanea tarda is a hepatic porphyria, it is not an acute porphyria because it presents clinically with skin disease alone and never with acute attacks.

2. The enzyme 5-aminolevulinate synthase 1 (ALAS1) is regulated by

A. Cytochrome P-450 concentration
B. Erythrocyte hemoglobin concentration
C. Free heme pool within the hepatocyte
D. Iron availability
E. Substrate availability

Answer: C ALAS1 is the hepatic isoenzyme. When the regulatory free heme pool in the hepatocyte is reduced, ALAS1 is induced, heme biosynthesis is upregulated, and heme levels rise. Conversely, when it is replete, heme synthesis stops. The erythroid isoenzyme ALAS2, by contrast, is principally regulated by iron availability. The availability of the substrates glycine and succinyl coenzyme A is not a limiting factor in heme synthesis. Hemoglobin concentrations are of no relevance to the regulation of hepatic heme synthesis.

3. What is the characteristic clinical presentation of erythropoietic protoporphyria?

A. Erosions and blisters
B. Hyperpigmentation
C. Hypertrichosis
D. Immediate photosensitivity
E. Photomutilation

Answer: D Patients with erythropoietic protoporphyria and X-linked protoporphyria complain of immediate photosensitivity, which is manifested as burning, itching, and pain in the skin after a short period of exposure to sunlight. This may be accompanied by erythema and edema. The other options on this list are not characteristic of this form of photosensitivity. Blisters and erosions are typical of the vesiculo-erosive form of cutaneous porphyria noted in variegate porphyria, porphyria cutanea tarda, hereditary coproporphyria, and congenital erythropoietic porphyria. Hypertrichosis may be noted in chronic cases, particularly in porphyria cutanea tarda, and photomutilation is encountered only in the most severe forms of vesiculo-erosive porphyria, such as congenital erythropoietic porphyria, hepatoerythropoietic porphyria, and the homozygous forms of variegate porphyria and hereditary coproporphyria.

4. Which of the following statements best characterizes the solubility and route of excretion of protoporphyrin?

A. It is of intermediate water solubility and may be identified in both urine and stool.
B. It is water insoluble and may be identified in urine.
C. It is water insoluble and may be identified in stool.
D. It is water soluble and may be identified in stool.
E. It is water soluble and may be identified in urine.

Answer: C The different porphyrins vary in their water solubility. The earlier porphyrins, such as uroporphyrin and the porphyrin precursors, are water soluble or hydrophilic and are readily detectable in urine, whereas very little emerges in the stool. Water solubility decreases with each step in the heme biosynthetic pathway. Protoporphyrin is hydrophobic and for practical purposes is undetectable in urine. It is excreted in bile and is therefore identified in stool. Some of the intermediate porphyrins, including coproporphyrin, are of intermediate solubility and detectable in both urine and stool. These properties are important because it is necessary to analyze both urine and stool (as well as plasma and, in the case of erythropoietic porphyrias, in erythrocytes) for an accurate diagnosis.

5. Which of the following treatment modalities is of most importance in modifying the course of the acute attack of porphyria?

A. Assisted ventilation
B. β-Blockade
C. Heme arginate
D. Liver transplantation
E. Meperidine

Answer: C Heme arginate is safe and highly effective in terminating the acute attack. When administered early, it will prevent serious complications such as quadriparesis and will reduce the hospital stay. Analgesia is an essential part of management but does not affect the natural history of the attack. β-Blockade may counteract the autonomic activity but is usually not necessary and will not alter the natural course. Assisted ventilation is relevant only in the patient who has had a serious attack with motor neuropathy, quadriparesis, and respiratory failure. Orthotopic liver transplantation is reserved for patients with a severe progressive course marked by recurrent acute attacks.

211

WILSON DISEASE

STEPHEN G. KALER AND MICHAEL L. SCHILSKY

DEFINITION

Wilson disease is an autosomal recessive disorder of copper transport. Affected individuals accumulate abnormal levels of copper in the liver and later in the brain as a consequence of mutations in both alleles of the Wilson disease gene (*ATP7B*). The gene encodes a copper-transporting ATPase expressed primarily in the liver, where its major function is excretion of hepatic copper into the biliary tract. The clinical condition of hepatolenticular degeneration with associated cirrhosis was first described in 1912 by S.A.K. Wilson. There are wide differences between patients in the age at onset and the spectrum of symptoms.

EPIDEMIOLOGY

The incidence of Wilson disease, defined as the occurrence of new cases, is approximately 1 in 30,000 to 40,000 live births. For special populations in which consanguinity is common, the risk of autosomal recessive traits such as Wilson disease is higher. In the general population, the prevalence of heterozygous gene carriers (defined as the ratio of all individuals with one mutant *ATP7B* allele to the population at risk of harboring one) is estimated to be 1 in 90. Some consider this figure an underestimate, however, on the basis of recent population data of the frequency of *ATP7B* mutation in the United Kingdom.[1]

PATHOBIOLOGY

Individuals normally consume 1 to 3 mg of dietary copper daily, of which approximately 50% is absorbed through the gastrointestinal tract. Most diets contain adequate amounts of copper, and certain foods (e.g., shellfish, liver, mushrooms, chocolate, nuts) contain higher quantities. In normal homeostasis, copper is absorbed from the stomach and duodenum, where absorption at the apical surface of the enterocyte is mediated by a specific copper transporter, hCTR1. The Menkes disease gene (*ATP7A*), which encodes a copper-transporting ATPase with high homology to *ATP7B*, transports copper from intestinal epithelial cells into the blood stream, where it is bound by albumin or amino acids, carried to the liver and other organs and tissues, or excreted by the kidney. This last pathway represents a minor pathway for copper excretion, and adults excrete up to 40 μg of copper per day in the urine.

Within the liver, copper may be (1) incorporated into ceruloplasmin, a multifunctional 132-kD α_2-glycoprotein enzyme containing six or seven copper atoms per molecule; (2) used in the synthesis of other copper-requiring enzymes; (3) bound by metallothionein, a low-molecular-weight, cysteine-rich protein that provides a storage and detoxification depot for copper and other trace metal elements; or (4) excreted into the bile. Copper excreted into bile does not undergo enterohepatic recirculation and thus represents a pathway for copper excretion.

In Wilson disease, metallation of ceruloplasmin is usually reduced, reflecting impaired transport of copper into the trans-Golgi compartment, where glycoprotein processing and the copper acquisition by apoceruloplasmin occurs. This results in low circulating levels of holoceruloplasmin (the protein with its full complement of copper). Because ceruloplasmin accounts for 90% of circulating copper, total serum copper is also low in most Wilson disease patients. However, free copper (non–ceruloplasmin-bound) is abnormally elevated in untreated Wilson disease patients. The flaw in copper incorporation into ceruloplasmin does not cause hepatic copper accumulation in Wilson disease, as evidenced by patients with aceruloplasminemia, in whom complete absence of this protein is associated with normal hepatic copper content. Rather, it is the effect of mutant ATP7B to reduce biliary copper excretion that produces massive hepatic copper overload when the condition is unrecognized. If the diagnosis goes unrecognized, copper overload subsequently involves other tissues, including the brain, which is particularly sensitive to perturbations in trace metal homeostasis.

The brain concentrates copper and other heavy metals for metabolic use. Copper is important for brain development and function, and copper excess (as well as deficiency) can seriously affect brain function.[2] In brain, astrocytes are considered important regulators of copper homeostasis, and in Wilson disease, the occurrence of abnormal astrocytes is a typical neuropathologic feature.

CLINICAL MANIFESTATIONS

Presenting clinical features of Wilson disease include nonspecific liver disease (Fig. 211-1), neurologic abnormalities, psychiatric illness, hemolytic anemia, renal tubular Fanconi syndrome, and various skeletal abnormalities.

There is considerable variation in clinical presentation and phenotype in Wilson disease.[3,4] Age influences the specific presentation. Most individuals who present with liver disease are younger than 30 years, sometimes in the first decade of life, whereas those presenting with neurologic or psychiatric signs range in age from the first to the eighth decade of life. This reflects the sequence of events in the pathogenesis of this disease (see earlier discussion). However, regardless of clinical presentation, some degree of liver disease is invariably present.[5] In one series of 400 adult patients with Wilson disease, approximately 50% presented with neurologic and psychiatric symptoms, 20% with neurologic and hepatic symptoms, and 20% with purely hepatic symptoms.

In patients with neurologic presentations, abnormalities include speech difficulty (dysarthria), dystonia, rigidity, tremor or choreiform movements, abnormal gait, uncoordinated handwriting, and (rarely) a combined motor

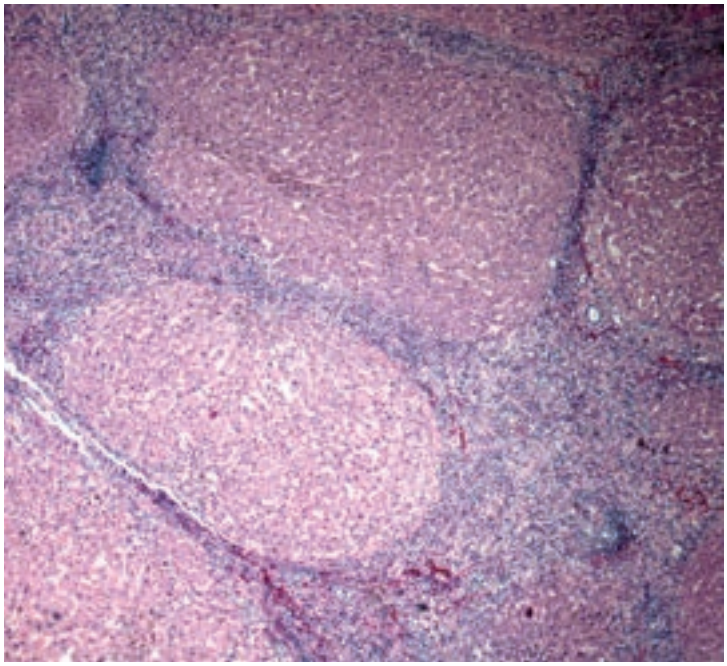

FIGURE 211-1. Hepatic cirrhosis in Wilson disease. (Image courtesy Kisha A. Mitchell, MD.)

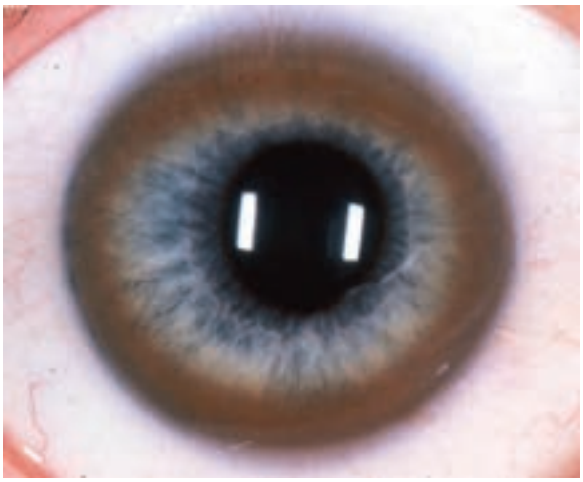

FIGURE 211-2. Kayser-Fleischer ring in a newly diagnosed patient with Wilson disease.

and sensory peripheral neuropathy.[6] Wilson disease may properly be classified as a movement disorder. The neurologic signs and symptoms reflect a predilection for involvement of the basal ganglia (e.g., caudate, putamen) in the brains of these individuals. Parkinson disease or other movement disorders may be mistakenly diagnosed.

In psychiatric presentations, changes in personality (irritability, anger, poor self-control), depression, and anxiety are common symptoms. Psychosis or bipolar disorder may also occur. Patients presenting with psychiatric symptoms are typically in their late teens or early 20s, a period during which substance abuse and schizophrenia are also prime diagnostic considerations. Wilson disease should be formally excluded in all teenagers and young adults with new-onset psychiatric signs, especially if results of liver function tests are abnormal or a family history of Wilson disease is noted.

In hepatic presentations, signs and symptoms include jaundice, hepatomegaly, edema, and ascites. Secondary endocrine effects of liver disease may include delayed puberty or amenorrhea. Viral hepatitis, autoimmune hepatitis, and cirrhosis are often initial diagnostic considerations in individuals with Wilson disease. Rare patients have Wilson disease concurrent with another liver disorder, and the diagnosis of Wilson disease is often delayed in these individuals as a consequence.

In addition to brain and liver, the eye is a primary site of copper deposition in Wilson disease, producing a benign but pathognomonic sign, the Kayser-Fleischer ring (Fig. 211-2). The Kayser-Fleischer ring is a golden to green-brown annular deposition of copper in the periphery of the cornea. This important diagnostic sign first appears as a superior crescent, then develops inferiorly and ultimately becomes circumferential. Slit-lamp examinations are required to detect rings in their early stage of formation. Copper can also accumulate in the lens and produce "sunflower" cataracts.

Approximately 95% of patients with neurologic signs manifest the Kayser-Fleischer ring, compared with approximately 50 to 65% of those with hepatic presentations. Copper chelation therapy, zinc treatment, and liver transplantation cause fading and even disappearance of corneal copper over time.

Hemolytic anemia resulting from the direct toxic effects of copper on red blood cell membranes has been observed in Wilson disease. This is usually associated with the release of massive quantities of hepatic copper into the circulation, a phenomenon that can be sudden and catastrophic due to the development of acute (fulminant) liver failure. On occasion, there may be bouts of hemolytic anemia unassociated with liver failure, but these individuals eventually develop progressive liver disease.

Renal dysfunction in Wilson disease is tubular in nature and leads to abnormal losses of amino acids, electrolytes, calcium, phosphorus, uric acid, and glucose. This effect is presumably related to direct copper toxicity or toxicity of copper complexes with metallothionein. High copper levels have been noted previously in the kidneys of patients with Wilson disease. Treatment with copper chelation often improves the renal disturbances.

There can be skeletal effects of Wilson disease, including osteoporosis and rickets; these may be attributable to renal losses of calcium and phosphorus. Osteoarthritis primarily affecting the knees and wrists also occurs in Wilson disease patients and may involve excess copper deposition in the bone and cartilage.

DIAGNOSIS

Wilson disease should be considered in patients with liver disease without a clear etiology; in patients presenting with acute liver failure with associated hemolysis; in patients with neurologic and psychiatric disease, especially if there is concomitant liver disease; and in first-degree relatives of identified patients.

Laboratory findings that support the diagnosis include low levels of serum copper and serum ceruloplasmin, elevated urine copper excretion (>100 μg/24 hours), elevated hepatic transaminase levels, low serum albumin, elevated prothrombin time (international normalized ratio), aminoaciduria, low uric acid levels, and direct antiglobulin test (Coombs)–negative hemolytic anemia. Analysis of liver biopsy specimens for histologic features and copper content also can assist diagnosis; most patients have copper contents above 250 μg/g dry weight liver, although some may have values as low as 75 μg (normal, <40 μg). Clinical signs of the disease include the stigmata of chronic liver disease, neurologic signs and symptoms, and Kayser-Fleischer rings (possibly requiring slit-lamp examination for detection). A scoring system was developed by experts who attended an international meeting on Wilson disease in Leipzig that was designed to help determine if the diagnosis should be pursued further. This scoring system was the first to use biochemical, clinical, and molecular genetic data to give a cumulative score that would suggest further evaluation is needed or achievement of the diagnosis is accomplished; it has been used in a diagnostic algorithm developed by the European Association for the Study of the Liver.[7]

Molecular diagnostics for *ATP7B* mutations has been extremely helpful, especially for difficult to diagnose cases and for family screening, in which it may be used as first-line testing if the mutations in the proband have been identified.[8] Cost and the large numbers of mutations for *ATP7B* (now more than 500) have hampered use of genetic testing for all patients being considered for Wilson disease; however, technical advances will likely increase future use of this test.

Incorporation of a stable radioisotope, ^{64}Cu, into serum ceruloplasmin is a highly specific diagnostic test; patients with Wilson disease incorporate very little ^{64}Cu into ceruloplasmin. This test is particularly useful in patients thought to have Wilson disease despite normal ceruloplasmin levels, and it distinguishes affected individuals from heterozygotes. Clinical availability of this test, however, is limited.

Increased urinary excretion of copper (>100 μg/24 hours) is another easily performed and important diagnostic test for this disorder. Copper-free collection containers should be used. A variation involving serial urine copper measurements is the penicillamine "challenge," in which 500 mg of

penicillamine is administered orally after collection of a baseline 24-hour urine specimen and repeated after 12 hours during the second 24-hour urine collection. A more than 10-fold increase in copper excretion is highly suggestive of Wilson disease.

Percutaneous needle liver biopsy for quantitative measurement of hepatic copper remains a useful test for the diagnosis of Wilson disease. As noted before, hepatic copper values higher than 250 μg/g of dry weight (normal, 20 to 50 μg/g dry weight) are characteristic of Wilson disease, although individuals with Wilson disease may have levels as low as 75 μg/g dry weight liver. Copper quantitation by inductively coupled plasma mass spectrometry or by atomic absorption spectrometry on dried and digested specimens is preferred to paraffin-embedded specimens, although paraffin-embedded specimens may be used when the diagnosis is considered retrospectively and adequate tissue was obtained. Histochemical staining of a liver biopsy specimen for copper by rhodanine may suggest Wilson disease but is less reliable.

In summary, in the absence of formal molecular evidence, the diagnosis of Wilson disease should be considered when at least two of the following are present: a positive family history, Kayser-Fleischer rings, Coombs-negative hemolytic anemia, low serum copper and ceruloplasmin levels, elevated hepatic copper content, increased 24-hour urine copper excretion, and positive penicillamine challenge result.[9,10]

TREATMENT

Penicillamine contains a free thiol that binds copper and greatly enhances urinary excretion, thereby preventing copper overload and its effects. Faithful compliance with oral penicillamine treatment has enabled the good health of thousands of patients with Wilson disease worldwide during the past 50 years.[11,12] Pyridoxine (vitamin B_6) should be prescribed concomitantly to counter the vitamin B_6 deficiency that tends to develop with long-term penicillamine administration.

Certain individuals, about 20%, are intolerant of penicillamine. Significant side effects include hypersensitivity; nephrotoxicity; hematologic abnormalities; and a distinctive rash, elastosis perforans serpiginosa, that often involves the neck and axilla. Furthermore, in some patients with neurologic presentations, penicillamine treatment induces paradoxical worsening of the neurologic disease.

Even though penicillamine is the therapy with the longest experience, other pharmaceutical agents are available and may be considered for use as first-line drugs. For example, zinc acetate and triethylene tetramine dihydrochloride (trientine) are suitable alternative agents with somewhat less significant side effect profiles.

Oral zinc acetate also has proved highly effective in Wilson disease.[13] The mechanism involves decreased copper absorption by the intestine into the blood stream by induction of the copper storage protein metallothionein in intestinal epithelial cells. Zinc monotherapy has particular value in young, presymptomatic patients; in patients who are pregnant, given the possible fetal teratogenic effects of other compounds; and as maintenance therapy for patients. Whereas most patients do well with zinc therapy, 10 to 20% of users note dyspepsia, and a higher incidence of hepatic decompensation has been observed with long-term zinc therapy compared with chelation therapy. Another drawback to zinc is the relatively long time (4 to 6 months) needed to restore proper copper balance if zinc monotherapy is used in the initial stage of treatment.

Tetrathiomolybdate forms stable tripartite complexes with proteins and copper. This drug both decreases copper absorption and reduces circulating free copper. It is fast-acting and can restore normal copper balance within several weeks, compared with the several months required with other copper chelators or with zinc. Tetrathiomolybdate is especially appropriate for the initial treatment of patients with neurologic presentations on the basis of a completed clinical trial.

Regardless of the specific regimen chosen, treatment of Wilson disease is lifelong because noncompliance eventually leads to symptomatic disease or liver failure.[14]

Liver transplantation is a rare consideration in Wilson disease because the condition is typically responsive to medical therapy. It should be considered for patients presenting with acute liver failure due to Wilson disease or those presenting with end-stage liver disease with irreversible hepatic damage who are unlikely to respond to medical therapy. Long-term outcomes after transplantation for Wilson disease are excellent, and the disease does not recur in the transplanted organ.[15]

Apart from pharmacologic treatment, there are several other important considerations in the treatment of Wilson disease. These include dietary restriction of copper-containing foods, especially shellfish and liver, both of which are copper rich. The major sources of patients' drinking water should be tested for copper concentration and avoided if levels approach 1.3 mg/L, which is the current maximum contaminant level goal (MCLG) established by the U.S. Environmental Protection Agency. The MCLG for copper in drinking water is set at a concentration at which no known or expected adverse health effects occur and for which there is an adequate margin of safety.

In newly diagnosed patients with neurologic manifestations, there is frequently a need for speech therapy and physical or occupational therapy and, for many others, psychological and genetic counseling.

Wilson Disease Heterozygotes

There is some debate about the risk of copper overload among individuals who are heterozygous carriers for Wilson disease. Even though Wilson disease is a classic autosomal recessive trait—that is, requiring two mutant alleles at the *ATP7B* locus for expression of the disease—a report from the U.S. National Academy of Sciences suggested that heterozygous carriers of Wilson disease may be a relatively sensitive population in terms of copper overload, particularly when dietary or drinking water copper exposure is higher than usual. Abnormally increased urinary copper excretion has been documented among some siblings of patients with Wilson disease, although genetic confirmation of the carrier or noncarrier status of these individuals was not available. Further patient and family studies are needed to formally address these questions.

PROGNOSIS

The prognosis in Wilson disease is generally favorable. Current therapeutic approaches can prevent, stabilize, or reverse most of the significant clinical signs and symptoms, including Kayser-Fleischer rings. However, if treatment is stopped, recurrence of symptoms and potentially fatal liver damage inevitably occurs.

FUTURE DIRECTIONS

Gene therapy for Wilson disease is a possibility. Because the Wilson copper transporter is expressed most prominently and functions most critically in the liver, this organ could be specifically targeted by the use of adenoviral or adeno-associated viral vectors (e.g., AAV8). Hepatocyte transplantation, an alternative to gene therapy, may also be applicable to the treatment of liver-specific metabolic disorders through therapeutic liver repopulation.

REVIEW QUESTIONS

1. The diagnosis of Wilson disease can be excluded in a patient

A. If the individual is younger than 21 years
B. If a Kayser-Fleischer ring is detected on slit-lamp examination
C. If the individual's penmanship is neat
D. If results of repeated 24-hour urine copper collections are normal
E. If serum ceruloplasmin and serum copper levels are normal

Answer: D Wilson disease may be manifested at any age, although appearance of symptoms before the age of 5 years is rare. The Kayser-Fleischer ring representing copper accumulation in the periphery of the cornea is a diagnostic hallmark of Wilson disease. Dysgraphia is sometimes reported by affected patients, but if it is not present, it should not exclude the diagnosis. The 24-hour urine copper excretion is reliably elevated in Wilson disease, and normal results exclude the diagnosis.

2. All except which of the following are true concerning the diagnosis of Wilson disease?

A. Schizophrenia in a 20-year-old can be a presenting manifestation.
B. Hepatic manifestations usually precede neurologic symptoms.
C. Serum copper and serum ceruloplasmin levels are invariably low.
D. *ATP7B* mutation analysis is useful for detection of presymptomatic affected individuals.
E. Neurologic symptoms often occur later than hepatic signs.

Answer: C An estimated 10% of individuals with Wilson disease have normal serum copper and ceruloplasmin levels, for reasons that remain unclear.

3. ATP7B is a copper-transporting molecule that

A. Mediates copper transport to the brain
B. Enables biliary excretion of copper
C. Is mutated in Menkes disease
D. Has its gene located on the X chromosome
E. Is responsible for intestinal copper absorption

Answer: B The Wilson disease gene product, ATP7B, normally mediates excretion of copper from the liver into the bile. The gene is located on chromosome 13. *ATP7A* is the gene mutated in X-linked recessive Menkes disease.

4. Low serum copper and ceruloplasmin levels may be found in all except which of the following?

A. ATP7A-related distal motor neuropathy
B. Wilson disease
C. Aceruloplasminemia
D. Menkes disease
E. Post–bariatric surgery

Answer: A Serum copper and ceruloplasmin levels are normal in patients with ATP7A-related isolated distal motor neuropathy. These can be low in all the other conditions listed.

5. Neurologic presentations of Wilson disease

A. Never coincide with hepatic symptoms
B. Do not include dysarthria, dystonia, rigidity, tremor, or choreiform movements
C. Usually involve stroke events affecting the basal ganglia
D. Never feature a sensory neuropathy
E. Are nearly always (95% of the time) associated with presence of Kayser-Fleischer rings

Answer: E Kayser-Fleischer rings are typically associated with neurologic presentation of Wilson disease. Basal ganglia copper deposition is a pathologic feature in Wilson disease; however, stroke is not.

IRON OVERLOAD (HEMOCHROMATOSIS)

BRUCE R. BACON

DEFINITION AND EPIDEMIOLOGY

Hereditary hemochromatosis (HH) is a common inherited disorder of iron metabolism. The genetic abnormality responsible in most patients with typical HH is found in homozygous form in about 1 in 250 persons of northern European descent. It is characterized by an increase in iron absorption from the upper gastrointestinal tract, with subsequent tissue iron deposition in parenchymal cells of the liver, heart, pancreas, joints, and endocrine organs. The autosomal recessive inheritance pattern of HH was clearly shown in the 1970s, and the gene responsible for most cases of HH was identified in 1996 by investigators using a positional cloning technique.[1] The gene is called *HFE*

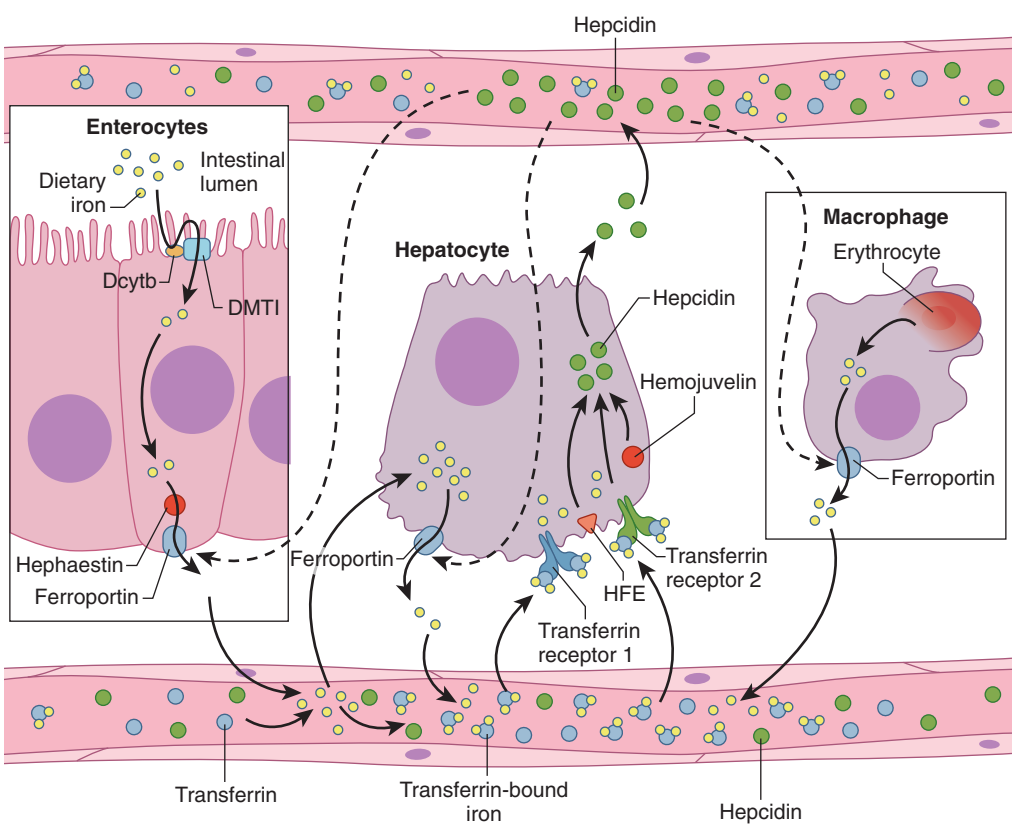

FIGURE 212-1. Orchestration of iron homeostasis. In the duodenal enterocyte, dietary iron is reduced to the ferrous state by duodenal ferric reductase (Dcytb), transported into the cell by divalent metal transporter 1 (DMT1), and released by way of ferroportin into the circulation. Hephaestin facilitates enterocyte iron release. Hepatocytes take up iron from the circulation either as free iron or as transferrin-bound iron (through transferrin receptors 1 and 2). Transferrin receptor 2 may serve as a sensor of circulating transferrin-bound iron, thereby influencing expression of the iron regulatory hormone hepcidin. The hepcidin response is also modulated by HFE and hemojuvelin. Hepcidin is secreted into the circulation, where it downregulates the ferroportin-mediated release of iron from enterocytes, macrophages, and hepatocytes (*dashed lines*). (From Fleming RE, Bacon BR. Orchestration of iron homeostasis. *N Engl J Med.* 2005;352:1741-1744.)

and encodes a novel major histocompatibility complex (MHC) class I–like molecule that binds with transferrin receptor (TfR) and affects hepcidin homeostasis (Fig. 212-1). Prospective population studies have demonstrated that only about 50 to 60% of patients who are homozygous for the major mutation found in *HFE* (called C282Y) have evidence of phenotypic expression of iron overload, and only a small percentage (<10%) go on to develop tissue damage from excess iron deposition. These findings of the highly variable penetrance of C282Y homozygosity have changed modern thinking about HH and must be considered when patients are evaluated for this disease in a physician's office and when national health policy for screening of this genetic disorder is developed.

The discovery of *HFE* has had a tremendous impact in a number of areas. The ability to accurately diagnose disorders of iron overload has been strengthened, family screening is improved, and the evaluation of patients with other forms of liver disease complicated by moderate to severe iron overload is possible. Furthermore, with the discovery of *HFE*, a considerable new body of knowledge about the mechanisms and regulation of iron absorption has been identified, both in the normal situation and in the pathologic condition seen when *HFE* mutations are present.

PATHOBIOLOGY

Classification of Iron Overload Syndromes

The term *hereditary hemochromatosis* should be reserved for inherited disorders of iron metabolism (see Fig. 212-1) that lead to tissue iron loading (Table 212-1). The most common form of this disease, *HFE*-related HH, is caused primarily by homozygosity for the C282Y mutation in the *HFE* gene. Other heritable forms of iron overload have also been recognized (non–*HFE*-related HH).[2,3] These include autosomal recessive forms of HH characterized by rapid iron accumulation and caused by mutations in the genes for hemojuvelin (*HJV*) and hepcidin (*HAMP*) (also called juvenile hemochromatosis); an autosomal dominant form of HH caused by mutations in the ferroportin gene; an autosomal recessive form of HH resulting from mutations in the gene for *TFR2* (*SLC40A1*); and rare forms of HH resulting from mutations in the *DMT1* gene or mutations in the portion of the ferritin gene encoding the iron-responsive regulatory element. Some other types of iron overload may have a familial or inherited component, but the genes involved have not yet been identified. For example, African iron overload is a familial disorder of iron loading prevalent in sub-Saharan Africa that is exacerbated by the ingestion of an iron-rich home-brewed beer. However, iron overload can also occur in individuals who do not drink this beverage. A similar form of iron overload has been suggested in African Americans, and further study is necessary to clarify this condition. The degree of iron loading can be similar to that seen in *HFE*-related HH, but the cellular and lobular distribution of iron is different. In addition, a rare disorder termed congenital alloimmune hepatitis is responsible for most cases of neonatal iron overload and is characterized by a modest increase in hepatic iron accompanied by severe liver injury present at birth.

It has been recognized during the last several years that many patients who have *HFE*-linked hemochromatosis have no evidence of iron overload. With this in mind, four stages of HH have been described[4]:

1. Genetic predisposition with no phenotypic abnormality
2. Iron overload (approximately 2 to 5 g total body iron) without symptoms
3. Iron overload with mild or early symptoms
4. Iron overload with organ damage, such as cirrhosis

The ability to establish a genetic diagnosis has led to a much greater understanding of genotype-phenotype correlations.

Genetics and Pathophysiology of Hemochromatosis

Since the classic linkage studies of Simon and colleagues in the mid-1970s, it has been known that the gene for hemochromatosis is located in the human leukocyte antigen (HLA) region on chromosome 6. In 1996, a team of molecular geneticists using a positional cloning technique identified a candidate gene for HH, which is now called *HFE*. *HFE* codes for a novel MHC class I–like molecule, which, like all MHC proteins, requires interaction with β_2-microglobulin for normal presentation on the cell surface. Three principal missense mutations have been identified in *HFE:* one results in a change of cysteine at position 282 to tyrosine (Cys282 → Tyr, C282Y), the second

TABLE 212-1 CLASSIFICATION OF IRON OVERLOAD SYNDROMES

HEREDITARY HEMOCHROMATOSIS

results in a change of histidine at position 63 to aspartate (His63 → Asp, H63D), and the third results in a change of serine at position 65 to cysteine (Ser65 → Cys, S65C). A few other mutations have been identified in *HFE*, but their frequency is low and their clinical impact is limited. In the original studies, 83% of typical phenotypic HH patients were found to be homozygous for the C282Y mutation. Several other studies from around the world in predominantly white populations demonstrated that among patients with typical hemochromatosis, about 85 to 90% were homozygous for C282Y. Thus, about 10 to 15% of patients with typical phenotypic HH have some reason other than C282Y homozygosity for their iron overload.

Nearly all absorption of dietary iron occurs in the duodenum, where iron may be taken up either as ionic iron or as heme. Ionic iron requires reduction to the ferrous state, which is accomplished by the ferric reductases (e.g., duodenal ferric reductase), which are expressed on the luminal surface of duodenal enterocytes (see Fig. 212-1). This ferrous iron crosses the apical membrane through divalent metal transporter 1, and iron taken up by the enterocyte is either stored as ferritin or transferred across the basolateral membrane to the plasma. This latter process occurs by the iron transporter ferroportin and requires oxidation of iron to the ferric state by the ferroxidase hephaestin.[5] Hypoxia-inducible factor-2 (HIF-2α) regulates the expression of key genes involved in iron absorption and may be involved in the hyperabsorption of iron in the context of hepcidin deficiency in HH.[6]

Hepcidin is a 25–amino acid, liver-derived peptide that influences systemic iron status such that it is now considered to be the principal iron regulatory hormone (see Fig. 212-1). Dysregulation of hepcidin expression is thought to play a role in the pathogenesis of HH. Patients with *HFE*-related HH have low hepatic expression of hepcidin, as do *HFE* knockout mice, despite excess hepatic iron stores. Conversely, overexpression of hepcidin in *HFE* knockout mice prevents the HH phenotype. Iron-induced regulation of hepcidin expression involves a bone morphogenetic protein (BMP)–dependent signaling pathway. BMPs bind to specific receptors on hepatocytes, thereby triggering SMAD protein–dependent activation of hepcidin expression. Selective inhibition of BMP signaling abrogates iron-induced upregulation of hepcidin. Hemojuvelin is a BMP coreceptor and facilitates the binding of BMP to its receptor; knockout of the hemojuvelin gene markedly decreases BMP signaling and hepcidin expression and causes iron overload. It has been hypothesized that *TFR2* in hepatocytes may act as an iron sensor. Mutations in *TFR2* cause a rare form of HH in humans, and *Tfr2* mutant mice have an HH phenotype. In HH, excess iron (both transferrin bound and non–transferrin bound) is avidly taken up by hepatocytes and stored. Iron stores increase to the point at which iron-induced oxidative damage occurs, resulting in cell injury and cell necrosis with phagocytosis by Kupffer cells. Iron-laden Kupffer cells become activated and produce profibrogenic cytokines (transforming growth factor-β, platelet-derived growth factor), which stimulate hepatic stellate cells to synthesize excess collagen and other matrix proteins. Increased fibrosis and then cirrhosis result.

CLINICAL MANIFESTATIONS

Several symptoms and clinical findings have been identified in patients with fully established HH, and all physicians should be aware of these symptoms and findings, which are summarized in Tables 212-2 and 212-3. Table 212-4

summarizes the typical laboratory findings in symptomatic and asymptomatic patients with HH. Recent series have revealed that many asymptomatic patients who are C282Y homozygotes are now coming to medical attention because they are identified by family screening studies or population surveys or after abnormalities of iron studies are discovered on routine blood chemistry testing. It is ideal to identify patients who have some phenotypic expression with abnormal results of iron studies but no evidence of organ damage. Several large population screening studies have shown evidence of phenotypic expression with abnormal findings of iron studies in about 40 to 50% of C282Y homozygotes, but less than 10% of these individuals actually have signs and symptoms of the disease.

DIAGNOSIS

Because patients with genetic abnormalities can be identified before there is evidence of phenotypic expression, the method of diagnosing HH has undergone a change. The role of liver biopsy has lessened considerably with the advent of genetic testing. Nonetheless, some general principles should be acknowledged. If the diagnosis of HH is being considered, blood tests, including transferrin saturation (serum iron ÷ transferrin or total iron-binding capacity × 100%) and ferritin levels, should be obtained. Transferrin saturation does not need to be measured in the fasting state for reliable results to be obtained. In patients with symptoms (see Table 212-2), both these values are elevated; however, transferrin saturation is typically the earliest phenotypic marker of HH and may be elevated in young C282Y homozygotes with normal ferritin levels. Serum ferritin is sometimes elevated in other conditions in which there is no evidence of iron overload.[7] Confounding causes of high serum ferritin include alcohol consumption, metabolic syndrome, liver damage (acute or chronic), and more unusual disorders, such as Gaucher's disease and macrophage activation syndrome (hemophagocytic lymphohistiocytosis). Overall, about 90% of patients with hyperferritinemia do not have iron overload, which often remains unexplained. Thus, ferritin is relatively sensitive but not specific for iron overload.[8]

Magnetic resonance imaging is a fast and efficient noninvasive technique to assess and to monitor liver iron concentration. It is based on the accumulation of iron leading to signal loss in the liver, particularly with T2*-weighted sequences. Magnetic resonance sequences do lose accuracy, however, when the hepatic iron concentration is very high.

In the past, if an elevated transferrin saturation or ferritin level was identified, a liver biopsy would be performed to establish a diagnosis by histochemical iron stains and biochemical determination of the hepatic iron concentration with calculation of the hepatic iron index (HII). The HII is the patient's hepatic iron concentration (in μmol/g dry weight) divided by the patient's age in years. Previously, when the HII was higher than 1.9, the diagnosis of HH was established. Recent studies with genetic testing have shown that many (>50%) HH patients may have an HII of less than 1.9. Thus, the HII is no longer important in the diagnosis of HH.

Currently, when abnormalities of iron studies are identified, it is reasonable to proceed to genetic testing. Among individuals who are C282Y homozygotes or compound heterozygotes (C282Y/H63D), liver biopsy is reserved for those with elevated liver enzymes or ferritin levels above 1000 ng/mL (Fig. 212-2). Several studies have shown that advanced fibrosis or cirrhosis is not seen in HH patients when ferritin levels are below 1000 ng/mL or when liver enzymes are normal. Accordingly, as genetic testing has become more widely available, liver biopsy is less necessary.

When liver biopsy is performed, iron deposition is found preferentially in a periportal (acinar zone 1) region of the hepatic lobule, with a decrease in gradient in acinar zones 2 and 3. With significant iron loading, sinusoidal lining cell (Kupffer cell) iron deposition can be identified, and iron can be found in bile duct cells and in fibrous tissue in portal tracts or septa. In patients with secondary iron overload related to alcoholic liver disease or chronic viral hepatitis, iron deposition is typically in Kupffer cells as well as in hepatocytes, and it occurs in a panlobular (as opposed to a periportal) distribution. Histologic evaluation of iron-staining patterns provides information complementary to that obtained by traditional biochemical testing for iron overload along with genetic testing.

TREATMENT

Even though there have been advances in the molecular and cellular biologic understanding of HH, and although the impact of *HFE* mutation analysis on diagnosis has been significant, the treatment of HH remains simple, inexpensive, and safe. Patients should have therapeutic phlebotomy of 500 mL of whole blood (approximately 200 to 250 mg of iron, depending on the hemoglobin concentration) on a weekly basis, if tolerated. Therapeutic phlebotomy should be performed until iron-limited erythropoiesis develops, identified by failure of the hemoglobin level and hematocrit to recover before the next phlebotomy.[9] It is reasonable to monitor transferrin saturation and ferritin levels periodically (every 3 months) to predict the return of iron stores to normal and to provide encouragement to patients who are undergoing phlebotomy. Therapeutic phlebotomy should be continued until the ferritin level is into the normal range of 50 to 100 ng/mL. Transferrin saturation may still be elevated (> 50%) but should not dictate further phlebotomy.[10] It is not necessary for patients to become anemic or iron deficient—just depleted of excess iron stores. Some patients may require weekly phlebotomy for 1 year or longer. Others may be able to tolerate phlebotomy of only a half-unit of blood (250 mL) every other week. Once the initial *therapeutic* phlebotomy has been completed, most patients require *maintenance* phlebotomy, with 1 unit of blood removed every 2 to 3 months. This requirement is derived empirically, with the intent being to maintain a ferritin level between 50 and 100 ng/mL. Recognizing that HH subjects could constitute a safe source of blood for transfusion, the U.S. Food and Drug Administration now allows blood phlebotomized from HH donors to be used for transfusion as long as the phlebotomies are performed in authorized blood centers that comply with specific provisions for safeguard.[11]

With successful iron depletion, patients have an improved sense of well-being, right upper quadrant abdominal pain dissipates, liver test results improve, and diabetes may be easier to manage. Established cirrhosis, arthropathy, and testicular atrophy generally do not improve (Table 212-5).

Iron chelation therapy may be necessary for patients who are anemic and cannot tolerate phlebotomy. Parenteral infusions (administered either subcutaneously by an infusion pump or intravenously overnight through a port) of deferoxamine can be used. Ototoxicity and ocular toxicity are possible with deferoxamine, and appropriate monitoring should be performed. An orally administered iron chelator, deferasirox (Exjade), has been approved and is available for treatment of iron overload in patients with iron-loading anemias and HH.[12] This therapy is expensive and has potential for toxicity, but it is more convenient than phlebotomy. Minihepcidins that mimic hepcidin activity are being tested in laboratory animals as a possible future treatment of iron overload.[13]

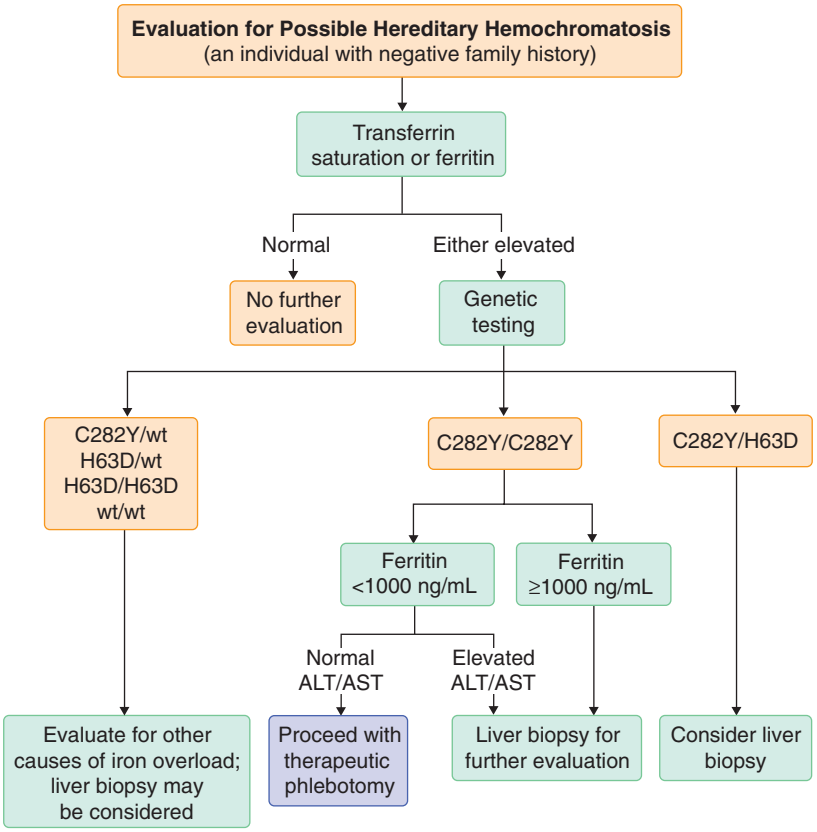

FIGURE 212-2. **Algorithm for evaluation of possible hereditary hemochromatosis in a person with a negative family history.** ALT = alanine transaminase; AST = aspartate transaminase.

TABLE 212-5 RESPONSE TO PHLEBOTOMY TREATMENT IN PATIENTS WITH HEREDITARY HEMOCHROMATOSIS

Reduction of tissue iron stores to normal
Improvement in survival if diagnosis is made and treatment is instituted before the development of cirrhosis and diabetes
Improvement in sense of well-being and energy level
Improvement in cardiac function
Improvement in controlling diabetes
Reduction in abdominal pain
Reduction in skin pigmentation
Normalization of elevated liver enzymes
Reversal of hepatic fibrosis
No reversal of established cirrhosis
Eliminates the risk of HH-related HCC if iron removal happens before the development of cirrhosis
Reduction in portal hypertension in patients with cirrhosis
No improvement in arthropathy
No reversal of testicular atrophy

HCC = hepatocellular cancer; HH = hereditary hemochromatosis.

PREVENTION

Family Screening

Once an HH proband is recognized, all first-degree relatives should be offered testing. In the past, HLA haplotyping was performed, but now *HFE* mutation analysis is recommended, along with the determination of transferrin saturation and ferritin levels. In probands with children, *HFE* mutation analysis is performed in the spouse to accurately predict the genotype in the child. If the spouse has either mutation, testing of the child is necessary, although the value and availability of genetic testing in children are debated. If an adult relative of a C282Y homozygote is identified and is either a C282Y homozygote or a compound heterozygote, and if results of blood iron studies are abnormal, a presumptive diagnosis can be made, and therapeutic phlebotomy can be initiated with the guidelines already discussed.

Population Screening

Because HH is a common disorder with a well-described treatment and a long latent period (i.e., time before disease occurs), some have suggested that it is an ideal candidate for population screening by genetic testing. However, studies have shown a less than expected phenotypic expression and a decreased number of patients with clinical manifestations of iron-mediated disease, raising questions about this recommendation. Initial results from a large National Institutes of Health–sponsored screening study in North America demonstrated a prevalence of C282Y homozygosity of 1 in 227 (Table 212-6). The C282Y homozygotes had higher ferritin levels than the general population, but 25% had normal ferritin levels. In screening for iron overload as opposed to screening for *HFE*-linked HH, transferrin saturation should be measured. In this situation, when abnormalities of iron studies are identified and the patient does not have a mutation in *HFE*, liver biopsy should be considered to clarify the situation relative to iron stores.

PROGNOSIS

If patients are identified, diagnosed, and treated[14] before the development of cirrhosis, their life expectancy is the same as that for an age- and sex-matched control population. If patients are not identified and treated before the development of cirrhosis, they are at risk for premature death from complications of diabetes, chronic liver disease, or hepatocellular cancer.[15] Treated cirrhotic patients are still at risk for hepatocellular cancer and should undergo surveillance abdominal imaging every 6 to 12 months.

Mutation Analysis in Patients with Liver Disease

Many patients with liver disease have abnormalities in serum parameters of iron metabolism. These abnormalities are more commonly seen in patients with hepatocellular liver diseases than in those with cholestatic liver diseases. Several clinical studies have shown that approximately 50% of patients with alcoholic liver disease, chronic viral hepatitis C, and nonalcoholic steatohepatitis (NASH) have abnormalities of serum iron studies. This abnormality is usually an elevation in serum ferritin, but elevated transferrin saturation is occasionally seen as well. When liver biopsy is performed, increased iron deposits can be seen, usually in a panlobular distribution, with iron in both hepatocytes and sinusoidal lining cells (Kupffer cells)

TABLE 212-6 PREVALENCE OF C282Y HOMOZYGOTES WITHOUT IRON OVERLOAD IN SCREENING STUDIES

POPULATION SAMPLE	COUNTRY	*n*	PREVALENCE OF HOMOZYGOTES	C282Y HOMOZYGOTES WITH A NORMAL FERRITIN LEVEL (%)

Total		124,636	1 in 240	41

(E-Figs. 212-1 to 212-5). Hepatic iron concentrations may be slightly increased or normal. When *HFE* mutations have been evaluated in patients with alcoholic liver disease, there has been no increased incidence of either C282Y or H63D (either heterozygote or homozygote) compared with control populations. Furthermore, there was no increase in *HFE* mutations in patients with alcoholic liver disease who had an increased amount of fibrosis. Thus, the abnormal iron studies frequently seen in patients with alcoholic liver disease are most likely due to mechanisms other than mutations in *HFE*.

In chronic hepatitis C, the relationship of abnormalities of iron studies and elevated hepatic iron concentration with a response to interferon monotherapy has been known for several years. Numerous studies have shown that patients who fail to respond to interferon monotherapy have a higher hepatic iron concentration than those who do respond. A corollary to this observation involves therapeutic phlebotomy to deplete iron stores in the hope of improving response to therapy. Reduction in iron stores by therapeutic phlebotomy does reduce elevated liver enzymes and has had some marginal beneficial effect on liver histologic features, but it does not have any virologic effects. When *HFE* mutation analysis has been investigated in patients with chronic hepatitis C, the frequency of C282Y and H63D has been equivalent to that in control populations. Most studies have shown that when *HFE* mutations are present, they correlate with increased iron stores seen histologically. Some studies have shown a synergistic effect with the development of fibrosis. At present, it is recommended that *HFE* mutation analysis be done when abnormalities of iron studies are seen in patients with chronic hepatitis C. Also, iron stains are typically performed on liver biopsy samples when biopsies are done to grade and to stage chronic hepatitis C. If iron stores are increased, it is reasonable to perform therapeutic phlebotomy to deplete excess iron stores before antiviral therapy is initiated.

In patients with NASH, several studies have provided conflicting results.[16] Some have shown an increase in *HFE* mutations in patients with NASH, and others have shown no difference from control populations. When there has been an increased prevalence of *HFE* mutations in NASH, there has been good correlation between abnormal serum parameters of iron and a correlation with hepatic iron concentration. Furthermore, some studies have shown an increase in fibrosis in NASH patients with *HFE* mutations. Finally, one study showed a reduction in elevated liver enzymes and improvement in parameters of insulin resistance in patients with NASH treated by phlebotomy to produce near iron deficiency. These observations suggest an interaction between the expression of fatty liver disease and iron metabolism.

Finally, in porphyria cutanea tarda (PCT), the relationship between abnormalities of iron metabolism and the role of therapeutic phlebotomy has been known for many years.[17] Also, it has recently been shown that as many as 70% of patients with PCT are infected with hepatitis C virus, and many patients with PCT drink excessive amounts of alcohol. An increased prevalence of *HFE* mutations has been shown in both European and American studies of PCT patients, and the use of phlebotomy to deplete excess iron stores is still recommended. Thus, *HFE* mutation analysis is of value in patients with PCT and may be of value in patients with chronic hepatitis C and NASH. It is probably not of value in patients with alcoholic liver disease.

REVIEW QUESTIONS

1. How common is the C282Y/C282Y genotype in the United States?

A. 1 in 70
B. 1 in 250
C. 1 in 500
D. 1 in 1000

Answer: B Numerous large-scale prospective population surveys from North America, Australia, and Europe have determined that the prevalence of the C282Y/C282Y genotype is about 1 in 250 individuals (see Table 212-6).

2. Of individuals who are C282Y homozygotes, what percentage go on to develop phenotypic expression?

A. 100%
B. 75%
C. 50%
D. 25%

Answer: C Before the discovery of *HFE* in 1996, it was thought by experts in hereditary hemochromatosis (HH) that all patients with genotypic susceptibility would have phenotypic expression. After the discovery of *HFE*, several large population surveys from North America, Europe, and Australia have shown that about half of C282Y homozygotes do not have phenotypic expression. There is highly variable penetrance of C282Y homozygosity (see Definition and Epidemiology).

3. In patients with hemochromatosis who have symptoms, what is the most common presenting complaint?

A. Arthralgias
B. Heart failure
C. Impotence
D. Complications of cirrhosis

Answer: A Surveys of HH patients who present with symptoms show that arthralgias, usually in the hands and fingers, are the most common. Impotence, heart failure, and cirrhosis with complication are much less commonly seen.

4. Compared with the general population, what is the likelihood for development of hepatocellular cancer in cirrhotic patients with hemochromatosis?

A. 10-fold increase
B. 50-fold increase
C. 200-fold increase
D. 500-fold increase

Answer: C Cirrhosis from HH results in a major increase in risk for hepatocellular cancer above that in the general population. At one time, there was a concern that extrahepatic malignant disease was also increased, but this has not been confirmed.

5. What is the level of hepcidin in inherited syndromes of iron overload?

A. Increased
B. Same as normal
C. Decreased

Answer: C Inherited syndromes of iron overload should be remembered as hepcidin deficiency conditions. The mechanisms whereby hepcidin regulation results in reduced levels are still to be determined.

213 NUTRITION'S INTERFACE WITH HEALTH AND DISEASE

DOUGLAS C. HEIMBURGER

OLD AND NEW PARADIGMS IN THE SCIENCE OF NUTRITION

Nutrition science was characterized by two major phases in the 20th century. During the first phase, nutrition scientists discovered, characterized, and synthesized the essential nutrients and described their deficiency syndromes in detail. The dietary requirements for these nutrients were estimated and periodically updated as recommended dietary allowances (RDAs). Beginning in 1997, the RDAs were reformulated in a series of volumes containing dietary reference intakes (DRIs); in addition to the recommended intakes judged to be sufficient to meet the nutrient requirements of nearly all healthy individuals, the DRIs include estimates of tolerable upper intake levels—that is, the highest intake levels likely not to pose any adverse health risks.

More fundamentally, the DRIs focus on accumulating evidence related to the relationships of diet and nutritional status to the diseases that plague Western societies, such as coronary heart disease (CHD), cancer, diabetes, and the other leading causes of death. DRIs recommend intake levels that not only prevent deficiencies but also may promote long-term health and disease prevention.

NUTRITION'S INFLUENCE ON MORTALITY AND MORBIDITY

Evidence of a Connection between Diet and Disease

It has been estimated that between 300,000 and 800,000 deaths per year could be prevented in the United States if Americans followed evidence-based dietary recommendations. Substantial additional benefits from reduced morbidity and enhanced functional status would also accrue. However, the causal connections between diet and chronic diseases are difficult to tease out of the complex network of other risk factors, including social and behavioral variables, so a wide variety of studies must be relied on to establish these connections with reasonable certainty.

Epidemiologic studies are unable to infer causal relationships and may be confounded by variables that have not been examined. They are also challenged by the difficulty of accurately assessing the diets of free-living individuals.

Animal and in vitro studies can overcome some of these drawbacks but may be confounded by experimental conditions that differ from those encountered by humans. A large number of prospective, randomized human intervention trials have been undertaken to test the effects of dietary change on risk for disease. However, even these trials are not always conclusive because of pitfalls associated with selecting study populations and isolating individual dietary factors.

Taken together, epidemiologic, animal, in vitro, and intervention studies are proving that human dietary habits contribute importantly to the pathogenesis of most of the major causes of death in developed countries.[1] In the recently published Global Burden of Disease Study 2010, 15 dietary risk factors and physical inactivity collectively accounted for 10% of global deaths and disability-adjusted life years.[2]

Diseases Influenced by Nutrition

Table 213-1 lists 8 of the top 15 causes of death in the United States that are influenced by nutrition. Five are strongly linked to dietary habits, and three are associated with alcohol abuse. The table also outlines dietary contributions to obesity, atherosclerosis, osteoporosis, diverticular disease, and neural tube defects. A meta-analysis indicates that vitamin D_3 supplementation reduces mortality in adults.■ Table 213-2 summarizes the 2010 Dietary Guidelines for Americans, and Table 213-3 compares dietary recommendations promulgated by professional societies for risk reduction and/or management of the major chronic diseases. The close agreement among these recommendations enhances their credibility.

Coronary Heart Disease

Nutritional influences on the leading cause of death in the United States, CHD, have been the subject of a great deal of research. The overall U.S. mortality rate from CHD peaked in the 1960s and, in a trend that initially surprised medical science, has declined steadily since then. Changes in lifestyle, including diet, are responsible for a substantial proportion of this decline. Elevated plasma low-density lipoprotein (LDL) cholesterol levels are a major risk factor for CHD and peripheral atherosclerosis, and they correlate strongly with dietary saturated fat intake and less strongly with cholesterol intake. Intake of both these substances in the United States is derived largely from foods of animal origin, such as meats, dairy products, and eggs. Attempts to produce less atherogenic substitutes for some of these foods have not always proved beneficial. For instance, hydrogenation of vegetable oils to create margarine and shortening results in the formation of *trans*-fatty acids, which affect serum cholesterol levels in a manner similar to—and are perhaps even worse than—the saturated fatty acids found in butter and lard. LDL cholesterol levels can be lowered modestly by increasing the intake of soluble fiber from legumes, fruits, vegetables, and flax seed, as well as by consuming proteins and isoflavones from soy foods. LDL must be oxidized before it induces injury to the arterial wall. Although adequate dietary levels of the antioxidant vitamins C and E and β-carotene have been shown to inhibit LDL oxidation, pharmacologic doses of these vitamins have not reduced CHD events when tested in randomized trials.■ In fact, pharmacologic doses of vitamin E (>400 IU/day) and other antioxidants have no benefit and may increase all-cause mortality.

Epidemiologic evidence suggests that fish consumption may reduce CHD risk, perhaps through the action of omega-3 fatty acids, but randomized trials have found no benefit from omega-3 supplementation.■ Evidence also indicates that moderate consumption of alcohol, especially wine, is associated with a decreased risk for CHD, possibly by increasing high-density lipoprotein (HDL) cholesterol levels, preventing the oxidation of LDL, or both. The polyphenols in red wine are also apparently beneficial. Traditional Mediterranean lifestyle patterns—with diets high in vegetables, fruits, olive oil, fish, nuts, complex grains and carbohydrates, and red wine, along with physical activity—are associated with reduced risks for cardiovascular disease.■[3] A conservative estimate suggests that moderate dietary modification by the U.S. population, consisting mainly of replacing saturated fats with complex carbohydrates, fiber, monounsaturated fats, and fish, could easily lead to a 10% reduction in serum cholesterol levels and a 20% or greater reduction in CHD.[4] The actual risk reduction could be much greater.

Cancer

Nutrients, non-nutritive dietary constituents, and nutritional status can influence the risk for cancer in a variety of ways. Nutrition interacts with each step of carcinogenesis (carcinogen activation and tumor initiation, promotion, and progression). Excess energy intake may favor the generation of free radicals and reduce the body's ability to detoxify carcinogens. By contrast, antioxidant nutrients scavenge free radicals and other (pre)carcinogens and may thereby inhibit their activation, their ability to initiate mutations, or both. Folic acid may improve a cell's ability to preserve, repair, and methylate its DNA, either preventing or reversing the tendency toward mutation. Folic acid supplementation, however, may increase the cancer risk in some individuals, so supplementation beyond the levels present in multivitamins is not advised.■ Obesity has emerged as a major risk factor for many cancers, perhaps by inducing insulin resistance and elevating serum levels of insulin, insulin-like growth factor, and related tumor-promoting hormones. Excessive alcohol intake also promotes tumor growth.

Lung Cancer

Evidence indicates that the number-one cancer killer, lung cancer (Chapter 191), is influenced by diet. Although the most important causal factor is cigarette smoking, consumption of fruits and vegetables is inversely associated with lung cancer risk in both smokers and nonsmokers. It is probable that both nutrients and the non-nutritive phytochemicals in fruits and vegetables are responsible for the protective effects. However, in view of the disappointing results of randomized trials of supplementation with β-carotene, which increased mortality from lung cancer and other causes, antioxidant supplements should not be used to reduce disease risk, especially in tobacco smokers.

Breast Cancer

The number-two cause of cancer deaths in women, breast cancer (Chapter 198), is positively associated with obesity, especially when excess adiposity is located predominantly in the abdomen, and with physical inactivity. The

TABLE 213-1 DIETARY INFLUENCES ON MAJOR CAUSES OF DEATH AND MORBIDITY IN THE UNITED STATES

CAUSE OF DEATH OR MORBIDITY	FACTORS ASSOCIATED WITH DECREASED RISK	FACTORS ASSOCIATED WITH INCREASED RISK
DEATH		
Heart disease	Intake of complex carbohydrates, particular fatty acids (e.g., monounsaturated, polyunsaturated, and omega-3 fatty acids from fish), soluble fiber, polyphenols, soy proteins, antioxidants (vitamins E and C, β-carotene, selenium), folic acid, moderate alcohol	Intake of saturated fat, cholesterol, excess calories, sodium; abdominal distribution of body fat
Cancer	Intake of fruits and vegetables (for β-carotene; vitamins A, C, D, and E; folic acid; calcium; selenium; phytochemicals), fiber	Intake of excess calories, fat, alcohol, red meat, salt- and nitrite-preserved meats, possibly grilled meats; abdominal distribution of body fat
Cerebrovascular disease	Intake of potassium, calcium, omega-3 fatty acids	Intake of sodium, alcohol (as with hypertension)
Accidents		Excess alcohol consumption
Diabetes mellitus	Intake of fiber	Intake of excess calories, fat, alcohol; abdominal distribution of body fat
Suicide		Excess alcohol consumption
Chronic liver disease and cirrhosis		Excess alcohol consumption
Hypertension and hypertensive renal disease	Intake of fruits and vegetables, potassium, calcium, magnesium, omega-3 fatty acids	Intake of sodium, alcohol, excess calories, total and saturated fat; abdominal distribution of body fat
MORBIDITY		
Obesity		Intake of excess calories and fat
Osteoporosis	Intake of calcium, vitamin D, vitamin K	Intake of excess vitamin A, sodium, protein
Diverticular disease, constipation	Intake of fiber	
Neural tube defects	Intake of folic acid	

TABLE 213-2 DIETARY GUIDELINES FOR AMERICANS, 2010: KEY RECOMMENDATIONS

BALANCING CALORIES TO MANAGE WEIGHT

Prevent and/or reduce overweight and obesity through improved eating and physical activity behaviors.
Control total calorie intake to manage body weight. For people who are overweight or obese, this will mean consuming fewer calories from foods and beverages.
Increase physical activity and reduce time spent in sedentary behaviors.
Maintain appropriate calorie balance during each stage of life—childhood, adolescence, adulthood, pregnancy and breast-feeding, and older age.

FOODS AND FOOD COMPONENTS TO REDUCE

Reduce daily sodium intake to less than 2300 milligrams (mg) and further reduce intake to 1500 mg among persons who are 51 years and older and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease. The 1500-mg recommendation applies to about half of the U.S. population, including children and most adults.
Consume less than 10% of calories from saturated fatty acids by replacing them with monounsaturated and polyunsaturated fatty acids.
Consume less than 300 mg per day of dietary cholesterol.
Keep *trans*-fatty acid consumption as low as possible by limiting foods that contain synthetic sources of *trans* fats, such as partially hydrogenated oils, and by limiting other solid fats.
Reduce the intake of calories from solid fats and added sugars.
Limit the consumption of foods that contain refined grains, especially refined grain foods that contain solid fats, added sugars, and sodium.
If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age.
Individuals should meet the following recommendations as part of a healthy eating pattern while staying within their calorie needs:
- Increase vegetable and fruit intake.
- Eat a variety of vegetables, especially dark-green and red and orange vegetables and beans and peas.
- Consume at least half of all grains as whole grains. Increase whole-grain intake by replacing refined grains with whole grains.
- Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy beverages.
- Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds.
- Increase the amount and variety of seafood consumed by choosing seafood in place of some meat and poultry.
- Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories and/or are sources of oils.
- Use oils to replace solid fats where possible.
- Choose foods that provide more potassium, dietary fiber, calcium, and vitamin D, which are nutrients of concern in American diets. These foods include vegetables, fruits, whole grains, and milk and milk products.

BUILDING HEALTHY EATING PATTERNS

Select an eating pattern that meets nutrient needs over time at an appropriate calorie level.
Account for all foods and beverages consumed and assess how they fit within a total healthy eating pattern.
Follow food safety recommendations when preparing and eating foods to reduce the risk for food-borne illnesses.

RECOMMENDATIONS FOR SPECIFIC POPULATION GROUPS

Women Capable of Becoming Pregnant

Choose foods that supply heme iron, which is more readily absorbed by the body, additional iron sources, and enhancers of iron absorption such as vitamin C–rich foods.
Consume 400 μg per day of synthetic folic acid (from fortified foods and/or supplements) in addition to food forms of folate from a varied diet.

Women Who Are Pregnant or Breast-Feeding

Consume 8 to 12 ounces of seafood per week from a variety of seafood types.
Because of their high methyl mercury content, limit white (albacore) tuna to 6 ounces per week and do not eat the following four types of fish: tilefish, shark, swordfish, and king mackerel.
If pregnant, take an iron supplement, as recommended by an obstetrician or other health care provider.

Individuals Aged 50 Years and Older

Consume foods fortified with vitamin B_{12}, such as fortified cereals, or dietary supplements.

TABLE 213-3 DIETARY GUIDELINES PROMULGATED BY NATIONAL ORGANIZATIONS*

	U.S. DEPARTMENT OF AGRICULTURE AND DEPARTMENT OF HEALTH AND HUMAN SERVICES: DIETARY GUIDELINES FOR AMERICANS (2010)	NATIONAL CHOLESTEROL EDUCATION PROGRAM ADULT TREATMENT PANEL III: THERAPEUTIC LIFESTYLE CHANGE DIET (2002)	NATIONAL HIGH BLOOD PRESSURE EDUCATION PROGRAM/JOINT NATIONAL COMMITTEE: 7 DIETARY APPROACHES TO STOP HYPERTENSION (DASH; 2006)	AMERICAN DIABETES ASSOCIATION (2004 AND 2012)	AMERICAN CANCER SOCIETY (2012)
Indication or Objective	***General Health Promotion and Disease Prevention***	***Elevated Cholesterol, Heart Disease Prevention***	***Prehypertension and Hypertension***	***Diabetes Prevention and Treatment***	***Cancer prevention***
NUTRIENT/FOOD GROUP					
Total energy	Prevent and/or reduce overweight and obesity through improved eating and physical activity behaviors	Manage weight, increase physical activity	Reduce energy intake to lose weight if overweight	Reduced energy intake and modest weight loss can improve glycemia and insulin resistance and reduce risk for type 2 diabetes	Achieve and maintain a healthy weight throughout life. Choose foods and beverages in amounts that help achieve and maintain a healthy weight
Fruits and vegetables	Increase vegetable and fruit intake. Eat a variety of vegetables, especially dark-green and red and orange vegetables and beans and peas		8-10 servings/day		Consume a healthy diet, with an emphasis on plant foods. Eat at least 2.5 cups of vegetables and fruits each day
Meat	Choose a variety of protein foods, which include seafood, lean meat, and poultry (for more, see Protein). Choose seafood in place of some meat and poultry		≤6 servings/day		Limit consumption of processed and red meats
Dairy	Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy beverages		2-3 servings/day of low-fat dairy		
Grains, fiber	Consume at least half of all grains as whole grains. Replace refined grains with whole grains	Consider increased viscous (soluble) fiber (10-25 g/day) and plant stanols/sterols (2 g/day) to enhance LDL lowering	6-8 servings of whole grains and whole-grain products	Achieve U.S. Dietary Guidelines recommendation	Choose whole grains instead of refined grain products
Fat	Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories and/or are sources of oils. Use oils to replace solid fats where possible	25-35% of daily energy intake	<27% of daily energy intake		The totality of the evidence does not support a relationship between total fat intake and cancer risk
Saturated fats	<10% of daily calories, by replacing them with MUFA and PUFA	<7% of daily energy intake	6% of daily energy intake	<7% of daily energy intake	
Polyunsaturated fats	Replace solid fats with PUFA	Up to 10% of daily energy intake		Up to 10% of daily energy intake	
Monounsaturated fats	Replace solid fats with MUFA	Up to 20% of daily energy intake		15-20% of daily energy intake; combination of MUFA and carbohydrates should equal 60-70% of total energy intake	
Trans-fats	Keep as low as possible	Intake should be kept low		Intake should be minimized	
Cholesterol	<300 mg/day	<200 mg/day	150 mg/day	<300 mg/day; those with LDL cholesterol ≥100 may benefit from lowering cholesterol intake to 200 mg/day	
Carbohydrates		50-60% of daily energy intake	55% of daily energy intake	Total amount of carbohydrate is more important than the source or type. Individualize the mix of carbohydrate, protein, and fat	
Sugar	Reduce added sugars			Sucrose and sucrose-containing foods do not need specific restriction by diabetic persons. Persons at risk for type 2 diabetes should limit sugar-sweetened beverages	

TABLE 213-3 DIETARY GUIDELINES PROMULGATED BY NATIONAL ORGANIZATIONS—cont'd

	U.S. DEPARTMENT OF AGRICULTURE AND DEPARTMENT OF HEALTH AND HUMAN SERVICES: DIETARY GUIDELINES FOR AMERICANS (2010)	NATIONAL CHOLESTEROL EDUCATION PROGRAM ADULT TREATMENT PANEL III: THERAPEUTIC LIFESTYLE CHANGE DIET (2002)	NATIONAL HIGH BLOOD PRESSURE EDUCATION PROGRAM/JOINT NATIONAL COMMITTEE: 7 DIETARY APPROACHES TO STOP HYPERTENSION (DASH; 2006)	AMERICAN DIABETES ASSOCIATION (2004 AND 2012)	AMERICAN CANCER SOCIETY (2012)
Indication or Objective	***General Health Promotion and Disease Prevention***	***Elevated Cholesterol, Heart Disease Prevention***	***Prehypertension and Hypertension***	***Diabetes Prevention and Treatment***	***Cancer prevention***
Protein	Choose a variety of protein foods, which include eggs, beans and peas, soy products, and unsalted nuts and seeds (for more, see Meat)	Approximately 15% of daily energy intake	18% of daily energy intake	10-20% of daily energy intake if renal function is normal	
Alcohol	Up to 2 drinks/day for men and up to 1 drink/day for women; persons in special circumstances (e.g., pregnancy, history of alcoholism) should abstain		<2 drinks/day for men and <1 drink/day for women	If individuals choose to drink, limit to 2 drinks/day for men and 1 drink/day for women, and take extra precautions to prevent hypoglycemia	Drink no more than 1 drink/day for women or 2 drinks/day for men
Sodium	Reduce daily sodium intake to less than 2300 mg, and further reduce intake to 1500 mg among persons who are 51 years and older or are members of special groups		<2400 mg/day	<2400 mg/day	
Potassium			4700 mg/day		
Calcium			1250 mg/day	1000-1500 mg/day	1000-1200 mg/day
Magnesium			500 mg/day		

*For further details, see the websites listed in this chapter.
LDL = low-density lipoprotein; MUFA = monounsaturated fatty acid; PUFA = polyunsaturated fatty acid.
Adapted from Heimburger DC, Ard JD, eds. *Handbook of Clinical Nutrition*, 4th ed. Philadelphia: Elsevier; 2006.

positive association between obesity and postmenopausal breast cancer has been attributed in part to the synthesis of estrogen (a risk factor for breast cancer) in adipose tissue. Epidemiologic evidence suggests that alcohol intake may also be a risk factor for this disease, particularly in women with lower intakes of folic acid.

Colorectal Cancer

Colorectal cancer (Chapter 193) is the third leading cause of cancer mortality in men and women. The risk for colorectal cancer correlates positively with the intake of red meat (especially when it is overcooked) and dietary fat and with obesity, and the risk correlates inversely with the intake of calcium and folic acid. Evidence regarding the effect of dietary fiber is somewhat equivocal, but the preponderance of evidence points to a protective effect; there is no evidence of harm. Higher physical activity is associated with a 30 to 50% lower risk for colon cancer.

Summary

The interaction of all these influences is powerful enough to suggest that diet and physical inactivity contribute to well over 35% of cancer deaths in Western countries. Even though no independent benefit has been found from dietary supplementation with potentially protective nutrients such as carotenoids, vitamins C and E,[■■] folic acid, selenium,[■] and fiber, they are all present in vegetables and fruits, and a liberal intake of fruits and vegetables is strongly recommended. A very large randomized trial indicated that lowering dietary fat intake did not reduce rates of breast cancer[■] or colon cancer, but it is very likely that maintaining an appropriate body weight and being physically active can reduce cancer risks.

Hypertension

Elevated blood pressure (Chapter 67) is a major risk factor for stroke, CHD, heart failure, peripheral vascular disease, and renal disease. It is often associated with obesity, especially abdominal obesity, and weight reduction in obese hypertensive people generally leads to an improvement in blood pressure. Sodium restriction also usually reduces blood pressure levels. The Dietary Approaches to Stop Hypertension (DASH) diet, which is rich in fruits, vegetables, and low-fat dairy products and advocates a reduced saturated and total fat content, can also decrease blood pressure levels; reducing one's sodium intake provides an additional benefit when included as part of the DASH diet.[5] Because alcohol intake elevates blood pressure, its use should be limited in hypertensive patients.

Diabetes Mellitus

Type 2 diabetes mellitus (Chapter 229) is strongly associated with obesity, especially abdominal obesity, so maintenance of a desirable body weight throughout life is of major importance in both preventing and treating type 2 diabetes. Sugar consumption does not lead to diabetes, except to the extent that it may promote weight gain. A focus on dietary carbohydrate restriction is no longer recommended for persons with type 2 diabetes; rather, a variety of dietary patterns, including low-carbohydrate, low-glycemic index, and Mediterranean diets, are effective in improving glycemic control and markers of cardiovascular disease risk.[■] Because higher-fat diets tend to promote both obesity and CHD, for which diabetic patients are at high risk, dietary fat intake should be kept low. Alcohol can cause hypoglycemia, hyperglycemia, and increased triglyceride levels in diabetic patients, and its use should be limited. In both diabetic and nondiabetic people, excess alcohol intake is responsible for many deaths, particularly from accidents and liver disease, and it is a factor in some suicides.

Osteoporosis

Osteoporosis (Chapter 243) is influenced by several dietary factors. Inadequate calcium intake during adolescence can result in suboptimal peak bone mass in early adulthood, and during later life it can lead to accelerated bone loss, thereby increasing the risk for osteoporosis. Sodium and protein, which are consumed by Americans in greater quantities than required, may promote excess bone loss. Excessive supplementation with vitamin A reduces bone mass and increases fracture risk. Vitamin D, vitamin K, and magnesium assist in maintaining optimal bone mass.

Other Conditions

Obesity

The causes and health effects of obesity, the most prevalent nutritional disorder in the United States, are reviewed in Chapter 220. The metabolic

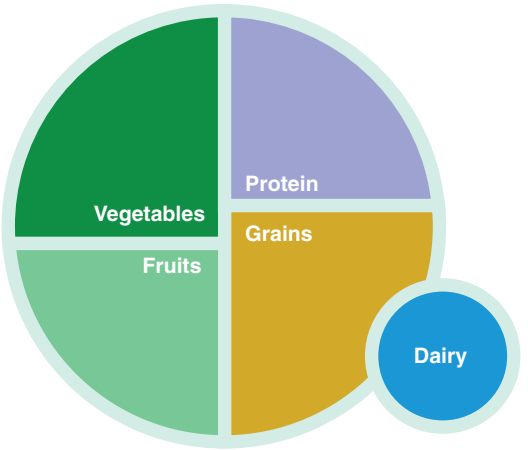

FIGURE 213-1. U.S. Department of Agriculture's MyPlate. MyPlate illustrates that a substantial proportion of dietary intake should be derived from vegetables, fruits, and grains, as contrasted with many Americans' expectation that protein sources should dominate. For more information, see www.ChooseMyPlate.gov.

syndrome, a constellation that includes obesity with an enlarged waist circumference; increased serum glucose, triglycerides, and blood pressure; and reduced HDL cholesterol, is strikingly prevalent in the United States and is a major risk factor for CHD, cancer, type 2 diabetes, and hypertension (Chapter 67).

Intestinal Diverticular Disease

Low dietary fiber intake causes constipation, and it is thought to be a cause of intestinal diverticular disease.

Congenital Neural Tube Defects

Inadequate maternal folic acid intake has been definitively proved to be a major risk factor for congenital neural tube defects such as spina bifida and myelomeningocele. For this reason, cereal and grain products have been fortified in the United States with folic acid since 1998.[6]

TRANSLATING EVIDENCE INTO DIETARY CHANGE

Thus, the evidence is strong that dietary habits can influence the incidence and severity of many incapacitating or lethal diseases in the United States. No justification exists for the belief that modification of the "usual" American diet is unnecessary or futile. The only questions are whether change is feasible and what is required to effect it. Various health agencies and the U.S. government have used public education, particularly the publication of dietary goals, as their primary means (see Table 213-3). The Department of Agriculture and the Department of Health and Human Services have developed and periodically revised the Dietary Guidelines for Americans (see Table 213-2) and a food guidance system, now called MyPlate (Fig. 213-1). MyPlate is part of a larger communications initiative based on the 2010 Dietary Guidelines for Americans to help consumers make better food choices. Although the practical application of nutritional genomics is not yet ready for routine clinical practice, it is an important, emerging science that may in the future be applied to nutrigenetic testing to provide dietary advice.[7]

Physicians can influence their patients' health by encouraging them to optimize their dietary habits and providing them with instructional materials and assistance from dietitians in making needed changes. A significant barrier to practical nutritional interventions could be removed if health insurers would reimburse dietitians' services.

REVIEW QUESTIONS

1. Which of the following, when included in the diet, is most likely to increase a person's risk for cardiovascular disease?

A. Monounsaturated fatty acids
B. *Trans*-fatty acids
C. Soy protein
D. Alcohol

Answer: B As noted in the Coronary Heart Disease section of the chapter, hydrogenation of vegetable oils to create margarine and shortening results in the formation of *trans*-fatty acids, which affect serum cholesterol levels in a manner similar to—and are perhaps even worse than—the saturated fatty acids found in butter and lard. The other three choices are all noted in the same section to have potentially protective effects against coronary heart disease.

2. The risk for hypertension is reduced by relatively high intakes of which of the following dietary sources?

A. Alcohol
B. Fat
C. Fruits and vegetables
D. Sodium

Answer: C As noted in the Hypertension section of the chapter, the Dietary Approaches to Stop Hypertension (DASH) diet, which is rich in fruits, vegetables, and low-fat dairy products and advocates a reduced saturated and total fat content, can decrease blood pressure levels; reducing one's sodium intake provides an additional benefit both alone and when included as part of the DASH diet.

3. Which of the following lifestyle habits is most likely to reduce the risk for chronic diseases?

A. Multivitamin supplementation
B. Vitamin A supplementation
C. Dietary fat restriction
D. General adherence to dietary recommendations

Answer: D There is no clear evidence that supplementation with multivitamins or vitamin A, or restriction of dietary fat alone, will reduce the risk for chronic diseases. As noted in the Osteoporosis section of the chapter, excessive supplementation with vitamin A reduces bone mass and increases fracture risk. Evidence supports general adherence to dietary recommendations as the best nutritional means to reduce the risk for chronic diseases.

4. Long-term control of the blood glucose level in an obese type 2 diabetic patient is likely to be improved most by which of the following?

A. Moderate caloric restriction
B. Fat restriction
C. Protein restriction
D. Carbohydrate restriction

Answer: A As noted in the Diabetes Mellitus section of the chapter, dietary carbohydrate restriction is no longer the focus of management of type 2 diabetes, and persons with obesity and type 2 diabetes are best served by weight reduction. This is best accomplished by moderate caloric restriction, not by focusing on restriction of carbohydrates, fats, or protein.

5. A 54-year-old white woman has a bone mineral density that indicates osteopenia in both the spine and hip. Which of the following nutrients may enhance the efficacy of calcium in preserving her bone mineral density?

A. Vitamin A
B. Vitamin K
C. Protein
D. Sodium

Answer: B As noted in the Osteoporosis section of the chapter, vitamin K assists in maintaining optimal bone mass, whereas excess intakes of vitamin A, protein, and sodium promote bone loss.

214

NUTRITIONAL ASSESSMENT

BRUCE R. BISTRIAN

GOALS AND IMPORTANCE OF NUTRITIONAL ASSESSMENT

Nutritional assessment in clinical medicine has three primary goals: to identify the presence and type of malnutrition, to define health-threatening obesity, and to devise suitable diets as prophylaxis against disease later in life. The focus of this chapter is on the diagnosis of protein-energy malnutrition because of its wide prevalence and major impact on disease outcome.[1,2] Other deficiency diseases are of much less relevance in that most occur in conjunction with protein-energy malnutrition or in specific disease states, such as thiamine deficiency in alcoholic liver disease and fat-soluble vitamin deficiency in malabsorptive states. The classic deficiency diseases, whether primary or secondary, are considered elsewhere in those chapters specifically dealing with the diseases mentioned here. The widespread availability of parenteral and enteral therapeutic measures since the mid-1980s that can provide adequate feeding regimens for virtually any disease condition makes a rudimentary knowledge of the pathophysiology of protein-energy malnutrition and its nutritional assessment essential for all primary care practitioners (Chapter 213).

CLINICAL NUTRITIONAL ASSESSMENT

Clinical assessment of protein nutritional status is based principally on the clinical history, physical examination including simple anthropometry, and measurement of the levels of several secretory proteins.

Clinical History

Although detailed dietary assessment can at times be helpful, in most circumstances physicians can safely limit their diet questions to whether patients have been following a prescribed diet, how much alcohol they drink, and whether they habitually take dietary supplements, including vitamins, minerals, and herbs. In ambulatory patients, the ability to maintain usual and adequate weight generally indicates that serious micronutrient deficiency is probably not the result of dietary inadequacy. Isolated vitamin deficiencies in the absence of weight loss or symptoms are rare, except perhaps for folate and vitamin B_{12} (Chapter 164). Although nutritional anemias do exist, as a consequence of strict vegetarian or vegan diets for vitamin B_{12}, or uncommonly today for folate except with extreme diets (as a result of widespread fortification of folate in food in developed countries), the role of dietary deficiency in anemias is limited in the absence of underlying disease, altered physiology (e.g., achlorhydria with aging), or weight loss. Only iron deficiency is a common cause of dietary anemia (Chapter 159). By contrast, full dietary assessment and diet prescriptions are likely to help patients with conditions such as fat malabsorption accompanied by weight loss, cramps, or diarrhea. Such evaluations are most effectively carried out by dietitians. Thus, detailed nutritional assessment of protein-energy malnutrition with secondary assessment of vitamin and mineral deficiencies is usually needed only when

protein-energy malnutrition or a specific disorder known to interfere with nutrient metabolism coexists, such as celiac disease, pernicious anemia, or nutrient-drug interactions. Even then, the assessment should emphasize the likely deficiencies. For fat malabsorption (Chapter 140), one should check levels of the fat-soluble vitamins A, D, E, and K; important divalent and trivalent cations (calcium [Ca^{2+}], zinc [Zn^{2+}], magnesium [Mg^{2+}], and iron [Fe^{3+}]); and phosphorus and alkaline phosphatase. When ileal resection has occurred, serum vitamin B_{12} levels should be measured, and the potential for bile salt depletion should be considered. Weight loss resulting from short-gut syndrome should prompt assessment of the fat-soluble vitamins, folic acid, vitamin B_{12}, calcium, magnesium, phosphorus, zinc, and iron. At least initially, levels of the water-soluble vitamins likely to have clinical impact such as thiamine and ascorbic acid should be checked, but provision of the full complement of vitamins should be routine in the management of this condition. Measurements of body water status (weight, blood urea nitrogen, serum creatinine, serum sodium) and acid-base balance (serum carbon dioxide combining power, chloride and potassium, and urine and arterial pH) should be obtained if the diarrhea is profuse (Chapter 140).

Protein-energy malnutrition, as defined by significant weight loss of more than 5% or hypoalbuminemia, affects at least 25% of patients hospitalized for acute care and are secondary to the underlying disease in most instances. Many of these patients can benefit from nutritional support and require a thorough clinical nutritional assessment, including a dietary history, physical examination, and laboratory tests that serve to confirm clinical impressions. The history should list information about the timing and amount of weight loss, medical illnesses, medications, gastrointestinal symptoms (abdominal pain, diarrhea, dysphagia), diet habits (eating fewer than two meals per day, alcohol consumption, dietary supplement intake, dental status), social habits (eating alone, needing assistance in self-care), economic status (having enough money for food), and mental status, particularly the presence of depressive symptoms. A special focus should be reserved for elderly people, in whom protein-energy malnutrition secondary to these last factors is more common (Chapter 24).

Nutritional Support

Four factors principally determine the timing, need, and appropriateness of nutritional support: (1) the presence and severity of protein-energy malnutrition, defined primarily by degree of weight loss and weight-to-height ratio as a percentage of standard or body mass index (BMI); (2) the presence and severity of the systemic inflammatory response, defined principally by the serum albumin level but also by the presence of fever, leukocytosis, and increased band forms; (3) the actual or expected duration of inadequate nutritional intake; and (4) the prognosis of the underlying condition. Well-nourished individuals have a 7- to 10-day reserve of energy and protein to withstand a moderate systemic inflammatory response without adverse nutritional consequences. Greater degrees of systemic inflammatory response and preexisting protein-energy malnutrition dramatically shorten the period that semistarvation, defined as consuming less than 50% of the energy and protein needs, can be tolerated. An important corollary is that when energy intake is limited, protein requirements for optimal outcomes are increased such that a reduction in energy intake to 50% of needs nearly doubles the desirable intake for protein.

Weight Loss

A recent unintended weight loss of 10 lb, or more than 5% of usual weight, should prompt efforts to diagnose the underlying disorder or social circumstance. Weight loss alone does not distinguish the composition of tissue loss, which can range from 25 to 30% lean tissue in semistarvation alone to 50% lean tissue loss following semistarvation plus injury and as much as 75% of the weight loss with the severest forms of injury, severe sepsis, major body burns, severe closed head injury, and multiple trauma. Therefore, unintentional weight loss of more than 10 lb or more than 5% of usual weight indicates a need for thorough nutritional assessment. Weight loss in excess of 10% of usual weight should be considered to represent protein-energy malnutrition that will impair physiologic function, particularly muscle strength and endurance. Weight loss in excess of 20% should be considered severe protein-energy malnutrition that will substantially impair the function of most organ systems. If major elective surgery is planned (Chapter 431), such individuals would benefit from adequate feeding preoperatively for up to 7 days or at least early nutritional intervention postoperatively. If palliative or curative radiation therapy or systemic chemotherapy is planned, adequate feeding during therapy with the use of supplemental formulas, tube feeding, or parenteral nutrition (in that order) is indicated, with enteral feeding preferred. However, if the weight loss represents end-stage systemic illness, commonly seen as a cachexia syndrome of loss of weight and muscle mass with symptoms of weakness (e.g., cancer; end-stage liver, renal, or lung disease; acquired immunodeficiency syndrome) for which no primary therapy is planned or is effective, invasive nutritional support is rarely indicated.

Physical Examination

Although the patient's external appearance and a check of the skin, eyes, mouth, hair, and nails often provide clues to the presence of nutritional abnormalities (Table 214-1), the physical findings of deficiency syndromes of vitamins, essential fatty acids, and trace metals are relatively insensitive and nonspecific. With respect to protein-energy malnutrition, only the marasmic form in which semistarvation is the principal mechanism and cachexia syndromes resulting from semistarvation and a mild systemic inflammatory response are evident at examination. Adult marasmus and cachexia, the more severe forms, can be defined as 15% or more of recent weight loss, a weight-to-height ratio lower than 85% of desirable weight, or a BMI of less than 17. Loss of subcutaneous fat and skeletal muscle is manifested by sunken temples, thin extremities, wasting of the muscles of the hand, and, rarely, edema. Although kwashiorkor in children is characterized by severe edema and a potbelly appearance from hepatomegaly and ascites, one rarely encounters these clinical signs in cases of hypoalbuminemic malnutrition that develops in the setting of systemic inflammation resulting from disease in industrialized societies. Significant hypoalbuminemia of less than 3.5 g/dL results from a systemic inflammatory response, often without the accompanying anthropometric changes for which nutritional support can help to improve outcome if the response is prolonged beyond a week. With severe injury and greater depression of serum albumin to the 2.4 g/dL level or lower, early feeding within the first 24 to 48 hours can improve outcome. A mixed picture of protein-energy malnutrition with weight loss and lean tissue loss with mild hypoalbuminemia (cachexia) is found with many chronic inflammatory conditions with end-stage systemic illness or the sarcopenia of aging.

Body Weight

The most useful element in the physical examination is body weight, which is expressed as a relative value to evaluate the patient in relation to the healthy population. Weight and height are easily obtained, and standards for comparison have been established (Table 214-2). Although newer standards are available, they reflect the increasing prevalence of obesity in the U.S. population. Use of the 1959 standards allows the same tables to be used to diagnose significant protein-energy malnutrition (<85% of desirable weight, which approximates the fifth percentile) and significant obesity, defined as obesity predisposing to excessive mortality risk (>130% of desirable weight or BMI of ≥30). Although severe protein-energy malnutrition often occurs at levels greater than 85% of desirable weight because of the greater likelihood of preexisting obesity, this condition is generally detected by percentage of weight loss or by upper arm anthropometry. Height can be measured in a reclining patient with a tape measure, and in certain situations the clinician may rely on the patient's history. The major confounding variable that limits the value of weight and height as an index of protein-energy malnutrition is the tendency for water retention with disease, and thus weight gain may not reflect an increase in lean body mass or protein content. Fluid retention is particularly a problem in patients with hypoalbuminemic malnutrition because of the effects of aldosterone, antidiuretic hormone, and insulin stimulated by the stress response, which causes sodium and fluid retention. Fluid retention, however, does not usually confound initial weight assessment in patients who are first seen at the physician's office, except in those patients with diseases such as cardiac failure, end-stage liver disease, and severe renal disease in whom the disturbance in water metabolism results from the underlying disease and not principally from the hormonal response to systemic inflammation.

Body Mass Index

The BMI, which is the weight in kilograms divided by the height in meters squared, has gained favor as a nutritional measure because of two valuable attributes. The measure is relatively independent of height, and the same standards apply to male and female patients. The following BMI values are used: normal nutrition, BMI of 20 to less than 30; significant protein-energy malnutrition, less than 18.5; overweight, from 25 to less than 30; and obesity, 30 or greater, with severe obesity defined as a BMI of 35 to less than 40, and morbid obesity as 40 and greater. Evidence from developing countries

TABLE 214-1 CLINICAL SIGNS AND SYMPTOMS OF NUTRITIONAL INADEQUACY IN ADULT PATIENTS

	CLINICAL SIGN OR SYMPTOM	NUTRIENT
General	Wasted, skinny appearance	Calorie
	Loss of appetite	Protein-energy, zinc
Skin	Psoriasiform rash, eczematous scaling	Zinc, vitamin A, essential fatty acids
	Pallor	Folate, iron, vitamin B_{12}, copper
	Follicular hyperkeratosis	Vitamin A, vitamin C
	Perifollicular petechiae	Vitamin C
	Flaking dermatitis	Protein-energy, niacin, riboflavin, zinc
	Bruising	Vitamin C, vitamin K
	Pigmentation changes	Niacin, protein-energy
	Scrotal dermatosis	Riboflavin
	Thickening and dryness of skin	Linoleic acid
Head	Temporal muscle wasting	Protein-energy
Hair	Sparse and thin, dyspigmented	Protein
	Easy to pull out	Protein
	Corkscrew hairs	Vitamin C
Eyes	History of night blindness (also impaired visual recovery after glare)	Vitamin A, zinc
	Photophobia, blurring, conjunctival inflammation	Riboflavin, vitamin A
	Corneal vascularization	Riboflavin
	Xerosis, Bitot's spots, keratomalacia	Vitamin A
Mouth	Glossitis	Riboflavin, niacin, folic acid, vitamin B_{12}, pyridoxine
	Bleeding gums	Vitamin C, riboflavin
	Cheilosis	Riboflavin, pyridoxine, niacin
	Angular stomatitis	Riboflavin, pyridoxine, niacin
	Hypogeusia	Zinc
	Tongue fissuring	Niacin
	Tongue atrophy	Riboflavin, niacin, iron
	Nasolabial seborrhea	Pyridoxine
Neck	Goiter	Iodine
	Parotid enlargement	Protein
Thorax	Thoracic rosary	Vitamin D
Abdomen	Diarrhea	Niacin, folate, vitamin B_{12}
	Distention	Protein-energy
	Hepatomegaly	Protein-energy
Extremities	Edema	Protein, thiamine
	Softening of bone	Vitamin D, calcium, phosphorus
	Bone tenderness	Vitamin D
	Bone ache, joint pain	Vitamin C
	Muscle wasting and weakness	Protein, calorie, vitamin D, selenium, sodium chloride
	Muscle tenderness, muscle pain	Thiamine
Nails	Spooning	Iron
	Transverse lines	Protein
Neurologic	Tetany	Calcium, magnesium
	Paresthesias	Thiamine, vitamin B_{12}
	Loss of reflexes, wristdrop, footdrop	Thiamine
	Loss of vibratory and position sense	Vitamin B_{12}
	Ataxia	Vitamin B_{12}
	Dementia, disorientation	Niacin
Blood	Anemia	Vitamin B_{12}, folate, iron, pyridoxine
	Hemolysis	Phosphorus, vitamin E

*Corrected to nude weights and heights by assuming 1-inch heel for men, 2-inch heel for women, and indoor clothing weight of 5 and 3 lb for men and women, respectively.
Adapted from the *Metropolitan Life Insurance Company Statistical Bulletin,* 1959;4:1.

suggests that the BMI is better correlated with outcome than are weight and height.

Upper Arm Anthropometry

Approximately 50% of body fat is subcutaneous. The use of skinfold calipers to define the triceps skinfold thickness (TSF) is the most practical technique to estimate body fat. Standards for skinfold measurement are available from the National Health and Nutrition Examination Surveys I and II and were derived from a probability sample of the U.S. population. Generally, a value lower than the fifth percentile is used to define abnormality (Table 214-3).

The principal value of the TSF measurement is to determine the arm muscle circumference (AMC) or arm muscle area.

$$\text{AMC (cm)} = \text{arm circumference} - (\pi)(\text{TSF})[\text{mm}])/10$$

The AMC is a specific measure of protein-energy malnutrition if the fifth or tenth percentile is chosen as the cutoff point, and it is particularly valuable in patients with edematous states and in amputees, in whom weights are inaccurate or insensitive. The TSF and AMC measurements[3] are most useful in initially defining marasmic-type malnutrition or the mixed disorder. Many dietitians are skilled in upper arm anthropometry.

Serum Proteins

Despite many concerns, the serum albumin level remains the traditional standard for nutritional assessment by virtue of its extensive history and its continued use to separate the principal forms of protein-energy malnutrition. Hypoalbuminemia is a strong predictor of risk for morbidity and mortality[4] in both hospitalized and ambulatory patients. In almost all cases, except perhaps for hereditary analbuminemia, excessive loss secondary to nephrotic syndrome (Chapter 121), and, occasionally, protein-losing enteropathy, hypoalbuminemia identifies the recent or ongoing presence of a systemic inflammatory response. A value for serum albumin of less than 3.5 g/dL is considered to indicate a mild systemic inflammatory response, whereas a value of less than 2.4 g/dL represents a severe systemic inflammatory response, reflecting systemic inflammation that produces anorexia (limiting food intake) and increases protein catabolism and thus accelerates the development of protein-calorie malnutrition. With a half-life for albumin of 18 to 20 days and the fractional replacement rate of about 10% per day, the return of serum albumin to normal takes about 2 weeks of feeding when the stress response remits. Adequate feeding in the presence of systemic inflammation will not increase the serum albumin concentration, even though substantial nutritional benefit will occur in terms of wound healing and immune function. Levels of other proteins, such as transferrin, prealbumin, and retinol-binding protein, with respective half-lives of 7 days, 2 days, and half a day, also fall acutely with injury and respond more quickly when systemic inflammation remits. Serum transferrin also varies with iron status, however, and prealbumin and retinol-binding protein vary with dietary carbohydrate

and renal function. As a result, these proteins do not reliably identify the presence and severity of the systemic inflammatory response any better than does albumin, but they reflect the nutritional response more quickly when inflammation lessens.

Composite Screening Tools

Investigators have made numerous attempts to combine the various components of nutritional assessment, including clinical history, physical examination, anthropometry, and serum proteins, into a single score.[5] Some of the more widely used tools include the following: the Subjective Global Assessment,[6] which classifies patients as A, B, or C or as having normal, mild, or moderate malnutrition; the Nutritional Risk Index, which is based on weight loss and serum albumin only; and the more extensive evaluations with the Mini-Nutritional Assessment and Malnutrition Universal Screening Tool. A clear advantage of one technique over another has not been established.

NUTRITIONAL THERAPY AND ITS ASSESSMENT

The same indices that are used in the baseline nutritional assessment can be used to assess response to therapy, provided certain points are kept in mind.

Assessing Lean Body Mass and Total Body Water

In a stressed, hospitalized patient receiving nutritional support, day-to-day weight changes generally reflect changes in fluid balance rather than energy balance. In an ambulatory setting, weight increases or decreases are most likely to reflect changes in protein nutritional status and body fat because the underlying illness is usually less severe. Even the most sensitive research methods for assessing changes in lean body mass, however, do not offer major improvements in diagnosis in the more seriously ill patients. Techniques that measure total body water, such as isotope dilution and underwater weighing, from which lean tissue is extrapolated, fail to account for the distortion in hydration of lean tissue with illness. Surrogate measures of total body protein to estimate lean tissues such as total body potassium measurement and dual x-ray absorptiometry do not adjust for differing body composition with disease. A newer method, single-frequency or multifrequency body impedance analysis, does show promise as a simple, accurate, noninvasive method[7] that may allow distinction between intracellular and extracellular water, with the former used to estimate lean tissue for an initial assessment. However, the inherent difficulties resulting from the greater disturbance of total body water in critically ill patients have not been overcome with this technique. Magnetic resonance imaging and total body nitrogen analysis are the most reliable tools for assessing the amount of lean tissue but are primarily useful for research purposes. The gold standard for assessing lean tissue is in vivo neutron activation analysis for nitrogen, but this is and will remain a research procedure. Combining clinically available, rapid techniques like dual x-ray absorptiometry scanning to assess body fat content with body impedance analysis[8] to measure total body water has shown some promise in estimating true lean tissue in critically ill patients.

Restoration of Lean Tissue

In an unstressed patient with the marasmic form of protein-calorie malnutrition, providing adequate energy and 1.2 to 1.5 g/kg protein should cause a positive nitrogen balance of 2 to 6 g/day (60 to 180 g lean tissue) and slow weight gain, depending on the extent of positive energy balance. For instance, a 300-kcal excess of intake over expenditure would provide approximately 120 g of lean tissue (100-kcal equivalent) in addition to 200 kcal (22 g) as fat, for a total of approximately 140 g, or approximately ⅓ pound of weight per day. Weight gains in excess of this number usually reflect sodium and thus water retention from the insulin stimulated by dietary carbohydrate. Such overhydration can be improved by reducing salt and limiting fluid intake. In patients with hypoalbuminemic malnutrition who are no longer stressed, a similar nutritional regimen will lead to a comparable gain of tissue, but weight change is often less as edema becomes mobilized, with normalization of serum albumin in 2 to 4 weeks and of retinol-binding protein, prealbumin, and transferrin more quickly. In stressed patients with hypoalbuminemic malnutrition, appropriate nutritional support often does not restore lean tissue but does improve other important functions, such as wound healing and immunocompetence. These are important treatment goals because they can improve the ultimate clinical outcome. Both the systemic inflammatory response and the limited activity level reduce the efficiency of skeletal muscle repletion, which represents 30% of body weight and 75% of actively metabolizing lean tissue. Functional testing of muscle strength and endurance, such as hand dynamometry, can be useful as a means of assessing this response but has not found wide clinical acceptance. Similarly, any reduction in other physiologic functions or impairment in the patient's ability to perform the usual activities of daily living will accentuate the consequences of protein-energy malnutrition. Cachexia syndromes reflect the loss of lean tissue with mild to moderate persistent inflammation due to an underlying chronic disease. Response to nutritional therapy is generally poor unless there is improvement or correction of the basic disease process.

Measures of Energy Expenditure and Caloric Need

Although caloric expenditure can now be reliably and easily measured with portable indirect calorimeters, estimated energy expenditure is sufficient in most clinical situations. The three components of total energy expenditure are basal energy expenditure (~55 to 65% of total energy expenditure), thermal effect of feeding (~10% of total energy expenditure), and activity energy expenditure (25 to 33%). An energy intake of 30 to 35 kcal/kg of body weight will maintain weight in most sedentary ambulatory patients, with adjustments upward or downward in 200- to 300-kcal increments as prompted by biweekly changes in weight. Although young, severely burned, or traumatized patients may require 35 to 40 kcal/kg in the acute phase to meet total energy expenditure, providing energy intakes principally as carbohydrates that exceed 35 kcal/kg substantially increases the likelihood of hyperglycemia. Evidence strongly implicates hyperglycemia in excess of 180 mg/dL as a major risk factor for nosocomial infection, thus emphasizing the importance of better glycemic control by the use of insulin infusions or by reducing the level of energy intake, or both. Most postoperative patients who require invasive nutritional support for mechanical or infectious complications usually require approximately 25 kcal/kg to meet energy needs and not more than 30 kcal/kg because of their older age and reduced activity and energy expenditure. Overfeeding should be avoided in such patients, and modest underfeeding for the first several weeks of acute illness may actually improve outcome in seriously ill patients.

The nutritional monitoring of the most critically ill patients[9] is primarily to assess how closely estimated nutritional needs are delivered on a daily basis, rather than any other presently defined nutritional marker beyond weight as an estimate of fluid status. Early parenteral feeding is no better than enteral feeding. Moreover, it is yet to be determined how early the full feeding should begin (immediately or within 7 days) and what constitutes best feeding practice (hypocaloric feeding at 50 to 70% of estimated energy expenditure with higher protein of at least 1.5 g/kg, versus 100% of both energy and protein needs at least for the first several weeks of critical illness). The disadvantage of full feeding in critically ill patients is the greater risk for hyperglycemia and its increased infectious complications and greater fluid

administration with its adverse consequences. Hypocaloric feeding appears to be as effective as full feeding for at least the first several weeks of critical illness. Measurement of energy expenditure by indirect calorimetry is generally reserved for the most severely marasmic patients, in whom estimates are often inaccurate, and for critically ill patients on prolonged mechanical ventilation or invasive nutritional support beyond several weeks, in whom provision of full energy needs may be beneficial.

REVIEW QUESTIONS

1. Which of the following statements is correct regarding clinical nutritional assessment?

A. Normal values of body mass index (BMI) are higher in women than men in the second through fifth decades of life.
B. BMI values are useful to grade different levels of obesity or overweight, but not as an indicator of malnutrition.
C. The use of calipers to measure triceps skinfold is the easiest way to estimate body fat.
D. The level of hypoalbuminemia cannot be used to predict risk for morbidity and mortality in ambulatory patients.
E. Adequate feeding in the presence of systemic inflammation increases the serum albumin in malnourished patients.

Answer: C Approximately 50% of body fat is subcutaneous, so the use of skinfold calipers to define the triceps skinfold thickness (TSF) is the most practical technique to estimate body fat. (see Upper Arm Anthropometry section). The same standards of BMI (weight in kilograms divided by the height in meters squared) apply to males and females; and there are BMI standards to define malnutrition (see Body Mass Index section). Hypoalbuminemia is a strong predictor of risk for morbidity and mortality in both hospitalized and ambulatory patients (Van Stijn MF, Korkic-Halilovic I, Makker MS, et al. Preoperative nutrition status and postoperative outcome in elderly general surgery patients: a systematic review. *JPEN J Parenter Enteral Nutr.* 2013;37:37-43). Even though adequate feeding of malnourished patients who have coexisting inflammatory states benefits them in wound healing and immune function, it will not increase serum albumin levels under these conditions (see Serum Proteins section).

2. Which of the following clinical measures provides the most accurate indicator of changes in energy balance and lean body mass in seriously ill hospitalized patients?

A. Day-to-day weight changes
B. Isotope dilution
C. Dual x-ray absorptiometry
D. Total body nitrogen analysis
E. None of the above

Answer: E The gold standard for assessing lean tissue is in vivo neutron activation analysis for nitrogen, but this is and will remain a research procedure. Day-to-day weight changes in hospitalized patients generally reflect fluid balance rather than energy balance. Total body nitrogen analysis is likewise primarily a research tool. The other tests listed provide flawed estimates in acute illness (see Assessing Lean Body Mass and Total Body Water section).

3. Which of the following is *not* a risk of full feeding or overfeeding (as opposed to hypocaloric feeding) of critically ill patients?

A. Hyperviscosity
B. Hyperglycemia
C. Fluid overload
D. Nosocomial infections
E. Worse postoperative outcomes

Answer: A Hyperviscosity is not known to be associated with full feeding or overfeeding. Hyperglycemia and its attendant increase in risk for nosocomial infections are significant risks, as is fluid overload. Overfeeding should be avoided in postoperative patients who require invasive nutritional support, and modest underfeeding for the first several weeks of acute illness may actually improve outcomes in seriously ill patients (see Measures of Energy Expenditure and Caloric Need).

PROTEIN-ENERGY MALNUTRITION

MARK J. MANARY AND INDI TREHAN

DEFINITION

The term *protein-energy malnutrition* encompasses at least three distinct clinical syndromes. The first and most common, *stunting*, occurs throughout the developing world. It is a consequence of chronic macronutrient and micronutrient deficiency prenatally and during early childhood and is manifested as low birth weight and irreversible cognitive and physical stunting, including below normal weight and short stature in the first few years of life. In contrast to this chronic form of protein-energy malnutrition, a second manifestation takes the form of *acute malnutrition*, a primarily macronutrient deficiency. In its most severe forms, it includes kwashiorkor, marasmus (wasting), and marasmic kwashiorkor. The third syndrome is the wasting that occurs secondary to acute or chronic underlying illnesses such as renal or hepatic insufficiency, inflammatory bowel disease, malignancy, or a systemic infection such as HIV or tuberculosis.

EPIDEMIOLOGY

Global rates of stunting and acute malnutrition are difficult to quantify accurately, given the primarily rural populations where they mostly occur. Approximately 25% of children younger than 5 years are stunted worldwide, and another 8% suffer from marasmus. The number with kwashiorkor is unknown and underreported because of minimal high-quality surveillance data[1]; therapeutic feeding programs in southern Africa (the area with the highest prevalence) often report that 50 to 70% of cases of severe acute malnutrition have kwashiorkor rather than marasmus. It is estimated that some 15% of the total mortality for children younger than 5 years worldwide is attributable to stunting and that another 12% is attributable to wasting.[2]

Rates of secondary protein-energy malnutrition among those with medical and surgical illnesses vary widely and are a function of underlying disease processes, comorbidities, nutritional status before illness, and level of financial resources and social support. It is not unusual for malnutrition rates of 25 to 60% among hospitalized patients to be reported in the literature.

PATHOBIOLOGY

Most stunting in children occurs during the critical "1000 days" window between conception and 2 years of age, although there is some evidence that partial catch-up growth can occur in later childhood.[3] Maternal undernutrition contributes to low birth weight, which persists as underweight, short stature, and cognitive stunting. Stunting also places children at elevated risk for acute malnutrition when challenged by food shortages or acute infections. Even children without prenatal stunting are at high risk for stunting and acute malnutrition when raised in impoverished environments. HIV infection and exposure, diarrhea, pneumonia, measles, and malaria are common in the developing world and can lead to anorexia with decreased dietary intake, increased energy expenditure, and poor nutrient absorption, placing the child at risk for stunting and acute malnutrition. The end of exclusive breastfeeding (whether prematurely or at the recommended 6 months of age) and the introduction of complementary feeding is also a high-risk period as the child ingests a variety of environmental pathogens and often suffers a relative loss of high-quality protein, lipids, and micronutrients.

Two major pathobiologic factors have been recently appreciated to contribute significantly to the development of protein-energy malnutrition in children.[4] The first is environmental enteric dysfunction (abbreviated EED, formerly "environmental enteropathy" or "tropical enteropathy"), endemic in children and adults throughout the developing world. It is characterized by blunted and atrophied intestinal villi, hyperplasia of the crypts, and lymphocytic infiltration of the lamina propria, histologically similar in many ways to celiac disease. EED appears to be a T-cell-mediated response to repeated environmental insults, such as gastrointestinal infections with a fecal-oral transmission pattern. The net effect of EED is an increase in intestinal permeability with bacterial and toxin translocation due to loss of tight junction integrity, impaired immune functioning, and malabsorption. EED is generally subclinical, predisposing children to growth faltering, and leaves them more susceptible to developing acute malnutrition. A second, related, risk factor for the development of acute malnutrition is a disturbed configuration of the intestinal microbiome, which fails to develop in an age-appropriate manner compared with unaffected children.[5,6] The ability to clinically identify these abnormalities in the microbiome and provide specific therapy is not yet available.

Secondary protein-energy malnutrition that occurs in the context of an underlying illness often results from a triad of decreased energy intake, malabsorption, and catabolic stressors. Virtually any chronic and/or critical illness can precipitate protein-energy malnutrition, but among the most common are cancer, HIV/AIDS, tuberculosis, inflammatory bowel disease, chronic kidney disease, chronic liver disease, and rheumatologic illnesses. The patient is in a state of net negative energy balance manifested by decreased weight and metabolic rate, accompanied to varying degrees by muscle wasting, depletion of fat stores, reduced cardiorespiratory capacity, skin thinning with easy breakdown and ulceration, hypothermia, immunodeficiency with impaired wound healing, and apathy.

The specific pathobiologic etiologies and risk factors for the development of this secondary protein-energy malnutrition are numerous. Primary among them is poor dietary intake as a result of nausea, anorexia, depression, poor dentition, and oral-motor weakness accompanying the underlying illness. Even nutrients that are ingested may not be absorbed, for example, because of reduced bile salt secretion leading to steatorrhea, pancreatic insufficiency, and damage to the intestinal mucosa in Crohn's disease. Systemic inflammation and oxidative stress are common in critical illness, cirrhosis, patients with HIV/AIDS and other infections, and hemodialysis patients, contributing to a catabolic state. In patients with chronic renal disease, altered amino acid homeostasis by the kidney, resistance to growth hormone and insulin-like growth factor-1, low testosterone levels, insulin resistance, and altered insulin signaling are all important factors in protein-energy wasting.[7] Patients with chronic liver disease often suffer from protein-energy malnutrition due to a combination of altered gut motility, dyspepsia, cholestasis with poor absorption of fat-soluble vitamins, small intestine bacterial overgrowth, a hypermetabolic state, inadequate hepatic protein synthesis, lack of glycogen reserves, and blood loss from varices and the intestinal lumen.

CLINICAL MANIFESTATIONS

Stunting manifests quite simply as short stature and underweight for age. Brain development, and thus head circumference, may also be small for age, although this is relatively proportional for overall body size.

Acute malnutrition manifests in at least three different forms. Children with wasting are emaciated and weak, having suffered significant weight loss in a relatively short period. The wasting often first manifests in the axilla and groin, progressing to the thighs and buttocks, and eventually visible in the face, which may take on an "old man" appearance. These children may appear apathetic but in fact may be quite inconsolable when approached. Wasting may be mild, moderate, or severe ("marasmus") (Fig. 215-1).

FIGURE 215-1. Kwashiorkor and marasmus in brothers. The younger brother, on the left, has kwashiorkor with generalized edema, skin changes, pale reddish yellow hair, and an unhappy expression. The older child, on the right, has marasmus, with generalized wasting, spindly arms and legs, and an apathetic expression. (From Peters W, Pasvol G, eds. *Tropical Medicine and Parasitology*, 5th ed. London: Mosby; 2002, Fig. 986.)

FIGURE 215-2. Edematous malnutrition or kwashiorkor.

The second form of acute malnutrition, edematous malnutrition or kwashiorkor, was classically described to occur when a child was weaned rapidly from the high-quality protein source that is breast milk, although this is not universal. Children with kwashiorkor have a weight that is generally low-to-average for their age. They present with bilateral peripheral edema that begins in the feet and progresses cephalad as it worsens. Despite what can be a relatively profound edema, they generally do not have ascites, nor is their illness a result of hepatic insufficiency or hypoalbuminemia. The skin may have patchy areas of "flaky paint" depigmentation, commonly with areas of breakdown and resultant infection (Fig. 215-2). The hair is often sparse, dry, brittle, and depigmented, appearing brown-yellow in children whose hair is normally black and thick.

Why some children in nearly identical living conditions develop marasmus while others develop kwashiorkor and most remain without acute malnutrition is not understood but does not appear to be a result of disparate protein intake; recent evidence suggests that alterations in the commensal intestinal microbiome may be responsible. Finally, children with marasmic kwashiorkor have both the severe weight loss of marasmus and the edema of kwashiorkor. Compared with children with either syndrome alone, these children are generally the most ill with the poorest prognosis.

Protein-energy malnutrition in patients with severe or chronic underlying disease generally presents as low body-mass index (BMI) or with progressive weight loss.

Virtually every organ system and tissue type is starved of energy in all forms of protein-energy malnutrition, resulting in a homeostatic drive to adapt to the decreased energy available. Fat is increasingly used as the body's primary fuel source within the first few days, having replaced glucose, and ketosis quickly develops. Overall glucose production and protein breakdown decrease markedly, decreasing urea production and urinary fluid losses. The basal metabolic rate decreases, accompanied by hypothermia and easy fatiguing. As starvation continues, nearly all of the body's fat stores are depleted, and lean muscle tissue may be cut in half. In addition to decreased muscle mass, hypokalemia leads to rapid muscle fatigue. Cardiac muscle is not spared, potentially leading to bradycardia, decreased stroke volume, hypotension, and poor tissue perfusion. Intravascular volume may be diminished at the same time that cellular and capillary leakage increases, leading to generalized edema, particularly in kwashiorkor.

Pulmonary capacity is adversely affected because of decreased respiratory muscle mass and electrolyte disturbances. The skin and hair often atrophy, depigment, and break down, leaving the patient susceptible to cutaneous infections. Insulin and thyroid hormone levels decrease, and cortisol concentrations increase. A state of immunodeficiency develops as lymphoid tissues atrophy and cell-mediated immunity is diminished, placing the malnourished patient at high risk for opportunistic infections. Pancytopenia can occur as a result of bone marrow suppression. Prolonged malnutrition leads to deterioration of all portions of the gastrointestinal system, including atrophy and blunting of the intestinal villi (thereby complicating therapeutic feeding), impaired exocrine pancreatic function, and decreased gastric and biliary secretions. Hepatomegaly and fatty liver infiltration are seen. Except in cases in which renal pathology is the inciting pathway, kidney function is relatively well preserved until late in the course. Although the brain is preserved longer than other organs, cerebral atrophy is seen in acute malnutrition, and (often permanently) delayed cognitive development is a profound complication with lifelong consequences among survivors.

DIAGNOSIS

Careful anthropometry must be conducted to accurately evaluate any individual for protein-energy malnutrition. In the case of children, it can be particularly challenging to gain their cooperation for anthropometry. Precise measurements of height (to the nearest 0.5 cm or less), weight (to the nearest 100 g or less), mid-upper arm circumference (MUAC; to the nearest 2 mm or less), and an assessment of peripheral pitting edema should be performed. Standardized World Health Organization growth charts should be used for diagnosis and classification.[8]

A child is considered to have *moderate stunting* when the height-for-age Z-score (HAZ) lies between 2 and 3 standard deviations (SD) below the mean. *Severe stunting* is diagnosed when the HAZ is more than 3 SD below the mean. Familial short stature, hypothyroidism, growth hormone deficiency, and micronutrient deficiency are all on the differential diagnosis for a stunted child, although these will be relatively rare compared with stunting in the relevant epidemiologic context.

Moderate wasting is based on having a weight-for-height Z-score (WHZ) between 2 and 3 SD below the mean. *Severe wasting*, or marasmus, is based on a WHZ more than 3 SD below the mean. For children aged 6 to 59 months, the MUAC can also be used to diagnose wasting because a healthy minimum MUAC remains relatively constant throughout this age. In these children, MUAC cutoffs of 115 to 125 mm and of less than 115 mm are generally considered diagnostic for moderate and severe wasting, respectively. Most children diagnosed as wasted by WHZ and MUAC criteria will be the same, but there is a sizeable population that will only be diagnosed by one or the other criterion. Given that the population identified by MUAC is generally younger and at higher risk for death than the population identified by WHZ,[9] MUAC is preferred for identifying severely malnourished children. Nevertheless, if resources exist to screen children by WHZ in addition to MUAC, that strategy is most likely to identify all acutely wasted children. Congenital heart disease, severe diarrhea and dehydration, malabsorptive syndromes due to intestinal parasites, malaria, HIV/AIDS, and tuberculosis should be considered in the differential diagnosis of a child presenting with wasting. Still, if a child has wasting based on anthropometric criteria,

nutritional rehabilitation needs to be provided while their underlying illness is addressed simultaneously.

The presence of edema in the appropriate clinical context, regardless of other anthropometric parameters, should prompt serious consideration of the diagnosis of kwashiorkor. Edema is most easily detected on the dorsum of the feet. The degree of edema is graded as 1+ if confined to the lower extremities, 2+ if additionally present on the upper extremities, and 3+ if extending to the face. The usual physiologic causes of edema, including underlying cardiac, hepatic, and renal diseases, should be considered in the differential diagnosis. In the rural impoverished populations where kwashiorkor is found, routine health care is also generally limited; thus, the possibilities of congenital or rheumatic heart disease, acute proliferative glomerulonephritis (postinfectious or post-streptococcal), profound anemia (from primary iron deficiency, severe malaria, or hookworm, among other causes), and tuberculosis should be considered. Nevertheless, for the overwhelming majority of children with edema presenting for care in these populations, kwashiorkor remains the leading diagnosis (E-Fig. 215-1).

Secondary malnutrition due to underlying illness also requires careful anthropometry, with a BMI of less than 18.5 kg/m^2 representing moderate malnutrition and a BMI of less than 15 kg/m^2 representing severe protein-energy malnutrition. Even without a BMI this low, any significant weight loss, especially if associated with lean muscle loss in addition to depletion of fat stores, should prompt consideration of protein-energy malnutrition and necessitates an investigation into an underlying illness if one had not been previously identified. No reliable diagnostic tests are available to identify those with protein-energy malnutrition because serum markers such as albumin, prealbumin, and C-reactive protein are themselves acute phase reactants and nonspecific for this purpose.

TREATMENT

Rx

Studies of probiotics and antibiotics to treat environmental enteric dysfunction have not shown benefit. However, albendazole, zinc, and micronutrient supplementation have shown some benefit.

There is relatively little that can be done for a child with stunting because the physical and cognitive growth faltering suffered in the first "1000 days" is not likely to be amenable to therapy. These children remain at high risk for further stunting during childhood, although some degree of catch-up growth is possible in later childhood and adolescence, even without specific nutritional interventions. Attention should be directed to an overall improvement in their dietary quality and diversity, particularly with respect to increased protein intake. Exclusive breast-feeding until 6 months of age and continued breast-feeding with appropriate supplementary foods until at least 2 years of age should be encouraged whenever possible, except in the case of an HIV-infected mother. Routine health care, including immunizations, vitamin A supplementation, and periodic deworming, should be ensured. In high-prevalence settings, HIV testing and treatment should be sought. Improvements in sanitary living conditions are likely to be the most beneficial.

Children with severe acute malnutrition have traditionally been managed as inpatients with fortified milk-based formulas as the key nutritional component of their overall care. A coordinated 10-step plan for the inpatient management of severe acute malnutrition has led to tremendous improvements in recovery and mortality rates (Fig. 215-3). Children are initially started on F-75 formula every 2 to 4 hours and then progress to F-100 as their appetite increases and they demonstrate that they are able to tolerate the solute load without severe diarrhea (Table 215-1).
